The pharmacokinetics and pharmacodynamics of a single 15-mg oral dose of **midazolam** was studied in 6 epileptic patients taking either carbamazepine, phenytoin or both drugs together, and in 7 control subjects not taking either of these antiepileptics. The AUC of **midazolam** in the epileptic patients was reduced to 5.7%, and the peak serum levels to 7.4% of their value in the control subjects. The pharmacodynamic effects (subjective drowsiness, body sway with eyes closed and open, as well as more formal tests) were also reduced. Most of the epileptic patients did not notice any effects of the **midazolam**, while the control subjects were clearly sedated for 2 to 4 hours after taking the **midazolam**, and also experienced amnesia.²³

Mechanism

The inconsistency of these reports is not understood. Benzodiazepine-induced changes in the metabolism of phenytoin^{2,8,10,14} as well as alterations in the apparent volume of distribution have been suggested as possible mechanisms. Enzyme induction by phenytoin may possibly account for the reduction in serum benzodiazepine levels.

Importance and management

A confusing picture. Concurrent use certainly need not be avoided (it has proved to be valuable in many cases) but monitor the outcome of concurrent use and consider monitoring serum phenytoin levels so that undesirable changes can be detected. Only diazepam, chlorthalidone and clonazepam have been implicated, but it seems possible that other benzodiazepines could also interact.

Benzodiazepines + Antiepileptics; Valproate

Valproate appears to increase the serum levels of diazepam lorazepam and possibly midazolam, while clobazam appears to raise valproate levels. Clonazepam clearance may increase and valproate clearance decrease during concurrent use, and increased adverse effects have been seen. An isolated case describes sleepwalking in a patient taking valproate and zolpidem.

Clinical evidence

A. Benzodiazepines

(a) Clobazam

In one study sodium valproate was reported to have no marked effect on clobazam,¹ but a study in children found that clobazam caused an 11% increase in the serum levels of valproate, despite a reduction of at least 10% in the valproate dosage.²

(b) Clonazepam

The addition of clonazepam to sodium valproate increased the unwanted effects (drowsiness, absence status) in 9 out of 12 paediatric and adolescent patients.³ An analysis of the clonazepam-valproate interaction in 317 epileptic patients found that concurrent use increased clonazepam clearance by 14% and decreased valproate clearance by 17.9%.⁴

(c) Diazepam

Sodium valproate increased the serum levels of free diazepam twofold in 6 healthy subjects.⁵

(d) Lorazepam

In healthy subjects, lorazepam 1 mg every 12 hours for 3 days had no effect on the pharmacokinetics of valproate semisodium 500 mg every 12 hours. However, valproate semisodium increased the AUC and maximum serum levels of lorazepam by 20% and 8%, respectively. Sedation scores were not affected by concurrent treatment, suggesting that the interaction is not clinically significant.⁶

A 40% decrease in the clearance of a 2-mg intravenous bolus dose of lorazepam was seen in 6 out of 8 healthy subjects while they were taking valproate 250 mg twice daily.⁷ A woman taking valproate, phenytoin, and carbamazepine went into a coma after she received a total of 6 mg of intravenous lorazepam. She promptly recovered on stopping the valproate.⁸

(e) Midazolam

An *in vitro* study in which midazolam was added to serum found that the free fraction of midazolam in the serum from valproate-treated epileptic patients was almost double that found in serum from untreated healthy subjects. It was suggested that displacement of midazolam by valproate could result in an increase in midazolam effects.⁹ *Animal* studies suggest that pre-treatment with valproate may increase the levels of midazolam in the brain.⁹

B. Non-benzodiazepine hypnotic

A report describes sleepwalking in a patient when valproate 250 mg twice daily was added to treatment with **zolpidem** 5 mg at night and citalopram 30 mg daily. The patient stopped the valproate and the sleepwalking episodes resolved. Later, the valproate was restarted causing the sleepwalking to recur. This time the symptoms resolved when the **zolpidem** was stopped.¹⁰

Mechanism

It seems that valproate reduces the glucuronidation of lorazepam,^{6,7} and therefore benzodiazepines that are mainly metabolised by glucuronide conjugation, such as **oxazepam** and **temazepam** are also likely to be affected. It is also thought that valproate may displace midazolam from its

plasma binding sites.⁹ However, this mechanism alone rarely results in clinically significant interactions.

Importance and management

Evidence of an adverse interaction between valproate and the benzodiazepines and related hypnotics is sparse, and concurrent use is generally beneficial. However, on rare occasions potentially clinically significant effects have been seen. It has been suggested that the combination of clonazepam and sodium valproate should be avoided.³ However, a very brief letter points out that neither drug affects the serum concentrations of the other and that clonazepam and valproate can be given together in patients with absence seizures since some patients have an excellent response to the combination.¹¹

It has been recommended that if clobazam is added to valproate it would be prudent to monitor for any increases in valproate serum levels.²

Enhanced sedation has been briefly described during the concurrent use of valproate and unnamed benzodiazepines.¹²

Benzodiazepines and related drugs + Antimuscarinics

Atropine and hyoscine do not affect the absorption or the sedative effects of diazepam but atropine may slow the absorption of zopiclone.

Clinical evidence, mechanism, importance and management

(a) Diazepam

A study in 8 healthy subjects given a single 10-mg oral dose of diazepam showed that serum diazepam levels were not significantly changed by the concurrent use of **atropine** 1 mg or **hyoscine hydrobromide** 1 mg, nor were the sedative effects of diazepam altered.¹

(b) Zopiclone

In 12 healthy subjects the absorption of a single 7.5-mg dose of zopiclone was reduced by intravenous **atropine** 600 micrograms. Mean plasma zopiclone levels at 1 hour were reduced from 22.7 nanograms/mL to 6.5 nanograms/mL and at 2 hours from 49.3 nanograms/mL to 31.9 nanograms/mL by **atropine**. This was presumably due to altered gut motility.² The clinical importance of these findings is not known.

Benzodiazepines + Antipsychotics

Marked respiratory depression has been reported in three patients when they were given lorazepam with loxapine, and neuroleptic malignant syndrome has been reported in another three

patients taking benzodiazepines and antipsychotics. The effects of lorazepam on psychomotor tests and memory was not affected by concurrent amisulpride. Airways obstruction has been reported in patients given intramuscular levomepromazine with intravenous benzodiazepines. Additive sedative effects appear to occur with zaleplon, zolpidem or zopiclone and some antipsychotics.

Clinical evidence, mechanism, importance and management

A. Benzodiazepines

(a) Lorazepam

1. *Loxapine*. A woman with a manic bipolar affective disorder was admitted to hospital and given lorazepam 2 mg with loxapine 25 mg. After 2 hours she was found to be lethargic with sonorous respirations, occasional episodes of apnoea and an irregular respiration as low as 4 breaths per minute. She was given oxygen and recovered spontaneously within 12 hours. She had experienced no previous problems with lorazepam, and had none when it was later given while she was taking perphenazine.¹ Two other cases have been reported where patients given intramuscular lorazepam 1 to 2 mg and oral loxapine 50 mg developed prolonged stupor, a significantly lowered respiration rate (8 breaths per minute), and in one case hypotension. Both showed signs of recovery within 3 to 5 hours and both had taken each of these drugs alone without problems.²

2. *Amisulpride*. A single-dose study in 18 healthy subjects found that amisulpride 50 mg or 200 mg did not potentiate or antagonise the effects of a single 2-mg dose of lorazepam on psychomotor performance or memory.³

(b) Other benzodiazepines

1. *Neuroleptic malignant syndrome*. Three cases of neuroleptic malignant syndrome have been reported following the use of **diazepam** with **risperidone**, **clorazepate** with **zuclopenthixol** and **tiapride** with **clonazepam**. In 2 cases this followed the abrupt withdrawal of long-term benzodiazepines. All 3 patients recovered, one without any treatment.⁴ These reports are isolated and unexplained. There appears to be no clear reason for avoiding concurrent use, but it should be well monitored.

2. *Obstruction of airways*. A patient with catatonic schizophrenia was given intravenous **diazepam** 20 mg followed by intramuscular haloperidol 10 mg and **levomepromazine** 50 mg. Because of combative behaviour about 50 minutes later, he was given intravenous **flunitrazepam** 2 mg, and about 2 hours later another dose of both intravenous haloperidol 12 mg and **flunitrazepam** 5 mg. An hour after the last injection he became mildly cyanotic due to collapse of glossopharyngeal structures and excessive oral and nasal secretions, causing airways obstruction. Four other cases of airways obstruction associated with the combination of intramuscular **levomepromazine** in doses of 0.52 mg/kg or more and intravenous **flunitrazepam** or **diazepam** are also described. A subsequent review of all cases found that there were no cases of airways obstruction in patients who received haloperidol with either **levomepromazine** or a benzodiazepine. The interaction occurred immediately after the last intravenous injection in one patient and about 25 minutes after intramuscular **levomepromazine** but onset may be delayed up to 2 hours or more.⁵

B. Non-benzodiazepine hypnotics

(a) Zaleplon

A single 50-mg dose of **thioridazine**⁶ had no effect on the pharmacokinetics of zaleplon 20 mg, and the psychomotor tests showed only short term additive effects lasting 1 to 4 hours. These short-term CNS additive effects are small and unlikely to be clinically relevant, and so there would seem to be no reason for avoiding concurrent use.

(b) Zolpidem

Single-dose studies found that the pharmacokinetics of 20-mg doses of zolpidem were unaffected by 50 mg of **chlorpromazine**^{7,8} or 2 mg of **haloperidol**.⁷ The pharmacokinetics of both of these antipsychotics were unaffected by zolpidem, except that in one study the elimination half-life of **chlorpromazine** was increased from about 5 to 8 hours.⁸ **Chlorpromazine** increased the sedative effects of zolpidem (as indicated by impaired performances of manual dexterity and Stroop's tests).^{7,8} It seems likely that additive sedation will be seen with other sedative drugs.

(c) Zopiclone

No pharmacokinetic interaction was found when 12 healthy subjects were given a single 7.5-mg oral dose of zopiclone with **chlorpromazine** 50 mg. However, the overall performance in a number of psychomotor tests

(including digit symbol substitution and simulated driving) was definitely impaired more by the combination of the drugs than by **chlorpromazine** alone. Zopiclone with **chlorpromazine** impaired memory and learning, and caused a marked impairment of the performance of the tests.⁹ In practical terms this means that patients given **chlorpromazine** with either of these drugs should be warned that they will almost certainly feel drowsy and be less able to drive or handle potentially hazardous machinery safely.

Benzodiazepines + Aprepitant

Aprepitant inhibits the metabolism of oral midazolam resulting in increased plasma levels. It appears to have less effect on intravenous midazolam. A few days after aprepitant treatment is stopped a transient slight reduction in midazolam plasma levels may occur due to induction of its metabolism. Alprazolam and triazolam are expected to be affected similarly.

Clinical evidence

In a randomised study 16 healthy subjects took either aprepitant 125 mg on day 1 followed by 80 mg daily for 4 days, or 40 mg on day 1 followed by 25 mg daily for 4 days, with a single 2-mg oral dose of midazolam on days 1 and 5. The aprepitant 40/25 mg dosing schedule had no significant effect on the pharmacokinetics of midazolam. However, the aprepitant 125/80 mg dosing schedule increased the AUC of oral midazolam by 126% and 229% on days 1 and 5, respectively, and increased the maximum plasma levels of midazolam by 46% and 94% on days 1 and 5, respectively.¹

In a randomised, placebo-controlled study, 24 healthy subjects were given aprepitant 125 mg on day one then 80 mg daily for a further 2 days. A single 2-mg intravenous dose of midazolam was given on days 4, 8 and 15. The 3-day aprepitant regimen increased midazolam levels slightly on day 4 (AUC increased by 25% and clearance reduced by 20%), decreased midazolam levels slightly on day 8 (AUC decreased by 19% and clearance increased by 24%) and had almost no effect by day 15, when compared to placebo.²

Mechanism

Aprepitant inhibits the cytochrome P450 isoenzyme CYP3A4 by which midazolam is metabolised, resulting in increased midazolam levels. The pharmacokinetic effect on intravenous midazolam indicate the effects of aprepitant on systemic rather than on intestinal CYP3A4 activity. Aprepitant is also a mild inducer of CYP3A4,^{2,3} however the induction is transient, with maximal effect 3 to 5 days after the end of treatment.

Importance and management

Based on the way midazolam interacts with similarly potent inhibitors of CYP3A4, aprepitant may be expected to increase the drowsiness and length of sedation and amnesia in patients given midazolam. Consider reducing the midazolam dose in patients given aprepitant and monitor the outcome of concurrent use carefully. The manufacturer notes that the potential effects of increased levels of other benzodiazepines metabolised via CYP3A4, such as **alprazolam** and **triazolam**, should be considered if

they are given with aprepitant. They also state that the effects of aprepitant on plasma levels of intravenously administered CYP3A4 substrates are expected to be less than the effects on orally administered substrates.³

Benzodiazepines + Aspirin

The induction of anaesthesia with midazolam is more rapid in patients who have been pretreated with aspirin.

Clinical evidence

A study in patients about to undergo surgery found that pretreatment with aspirin 1 g (given as intravenous **lysine acetylsalicylate**) one minute before induction shortened the induction time with intravenous midazolam 300 micrograms/kg. Only 60% were 'asleep' within 3 minutes of receiving midazolam alone, but 80 to 81% were 'asleep' within 3 minutes of receiving midazolam given after the aspirin pretreatment.¹

Mechanism

Not understood. It has been suggested that aspirin increases the amount of free (and active) midazolam in the plasma since they compete for the binding sites on the plasma albumins.^{1,2}

Importance and management

Information is limited but what is known shows that the effects of midazolam are increased by aspirin. Be alert for the need to reduce the dosage. However, note also that regular aspirin use may increase the risk of bleeding during surgery, and in some situations this may justify avoidance of aspirin in the week before surgery.³

Benzodiazepines and related drugs + Azoles

Fluconazole, itraconazole and ketoconazole very markedly increase the serum levels of midazolam and triazolam, thereby increasing and prolonging their sedative and amnesic effects. Similar but smaller effects are seen with itraconazole or ketoconazole and alprazolam and with itraconazole and brotizolam. Even less effect is seen with etizolam and itraconazole and no important interaction occurs between estazolam and itraconazole. Small effects are found with the non-benzodiazepine hypnotic, zolpidem, with ketoconazole and even less effects with zopiclone and itraconazole. No important interaction occurs between bromazepam and fluconazole, temazepam and itraconazole, zolpidem and fluconazole and probably chlordiazepoxide and ketoconazole.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

1. *Itraconazole*. A single 800-microgram dose of alprazolam was given to 10 healthy subjects before and after a 6-day course of itraconazole 200 mg daily. The itraconazole increased the AUC and the half-life of alprazolam nearly threefold, and psychomotor function was impaired.¹

2. *Ketoconazole*. A study in healthy subjects found that ketoconazole 200 mg twice daily decreased the clearance of alprazolam 1 mg by about two-thirds, and prolonged its half-life fourfold, but the maximum serum levels remained unchanged.²

(b) *Bromazepam*

Fluconazole 100 mg daily for 4 days had no effect on the pharmacokinetics or pharmacodynamics of bromazepam in 12 healthy subjects.³

(c) *Brotizolam*

A placebo-controlled study in 10 healthy subjects found that **itraconazole** 200 mg daily for 4 days increased the AUC₀₋₂₄ and maximum plasma levels of a single 500-microgram dose of brotizolam given on day 4 by about 2.5-fold and 25%, respectively. The elimination half-life of brotizolam was also increased, from 4.51 to 23.27 hours, and sedation was increased.⁴

(d) *Chlordiazepoxide*

After taking **ketoconazole** 400 mg daily for 5 days the clearance of chlordiazepoxide 600 micrograms/kg was decreased by 38% in 12 healthy subjects.⁵

(e) *Estazolam*

A placebo-controlled study⁶ found that **itraconazole** 100 mg daily for 7 days did not affect the pharmacokinetics or pharmacodynamics of a single 4-mg dose of estazolam given to 10 healthy subjects on day 4.

(f) *Etizolam*

A placebo-controlled study in healthy subjects found that **itraconazole** 100 mg twice daily for 7 days increased the AUC of a single 1-mg dose of etizolam given on day 6 by about 50%. The elimination half-life of etizolam was also increased, from 12 to 17.3 hours.⁷

(g) *Midazolam*

1. *Fluconazole*. A study in 12 healthy subjects found that fluconazole 200 mg daily for 5 days reduced the clearance of a single 7.5-mg oral dose of midazolam by 51%, and increased the AUC of midazolam 3.5-fold. It was found that the subjects could hardly be wakened during the first hour after taking the midazolam.⁸ Another study found that a single 150-mg dose of fluconazole increased the serum levels of a single 10-mg dose of midazolam by about 30%.⁹ Yet another study found that the route of administration of fluconazole (i.e. whether oral or intravenous) made little or no difference to the pharmacodynamic effects of midazolam.¹⁰ Fluconazole caused a fourfold increase in plasma midazolam levels in intensive care unit patients receiving midazolam infusions. The interaction was most marked in patients with renal failure.¹¹ These reports contrast with another, which found that fluconazole 150 mg only slightly increased the effects of a single 10-mg dose of midazolam.¹²

2. *Itraconazole*. When 9 healthy subjects were given oral midazolam 7.5 mg, before and after taking itraconazole 200 mg daily for 4 days, the itraconazole was found to have increased the AUC of midazolam by about tenfold, increased the peak plasma levels about threefold, and prolonged the half-life from 2.8 to 7.9 hours. The subjects could hardly be wakened during the first hour after taking the midazolam and most of them experienced amnesia lasting several hours.¹³ A later study found that itraconazole 100 mg daily for 4 days increased the AUC of midazolam sixfold and the peak plasma levels 2.5-fold.¹⁴ A further study confirmed the marked effect of itraconazole on oral midazolam, but found that the effects of bolus doses of intravenous midazolam were not increased to a clinically significant extent, although their results suggested that long-term, high-dose infusions of midazolam need to be titrated according to effect to avoid overdose.⁸

3. *Ketoconazole*. When 9 healthy subjects were given oral midazolam 7.5 mg before and after taking ketoconazole 400 mg daily for 4 days, the ketoconazole was found to have increased the AUC of midazolam by almost 17-fold, increased the peak plasma levels about fourfold, and prolonged the half-life from 2.8 to 8.7 hours. The subjects could hardly be wakened during the first hour after taking the midazolam and most of them experienced amnesia lasting several hours.¹³ Ketoconazole has been shown to reduce the metabolism of midazolam and greatly prolong its effects in another study.¹⁵

(h) *Temazepam*

Itraconazole 200 mg daily was given to 10 healthy subjects for 4 days, with a single 20-mg dose of temazepam on day 4. A very small increase in the temazepam AUC was seen, but the psychomotor tests carried out were unchanged.¹⁶

(i) *Triazolam*

1. *Fluconazole*. Eight healthy subjects were given fluconazole or a placebo daily for 4 days, with a single 250-microgram oral dose of triazolam on day 4. The AUC of triazolam was increased by 1.6-fold, 2.1-fold, and 4.4-fold by 50, 100, and 200 mg fluconazole, respectively, and the maximum plasma triazolam levels were more than doubled by the 200-mg fluconazole dose. The 100- and 200-mg fluconazole doses both produced significant changes in the psychomotor tests of triazolam, but the 50-mg dose did not.¹⁷

2. *Itraconazole*. The AUC of a single 250-microgram dose of triazolam was increased by about 28-fold after 9 healthy subjects were given itraconazole 200 mg daily for 4 days. Peak plasma levels were increased threefold. Marked changes in psychomotor and other responses were also seen. The subjects had amnesia and were still very tired and confused as long as 17 hours after taking the triazolam.¹⁸ Another study found that the interaction persists for several days after taking the itraconazole.¹⁹

3. *Ketoconazole*. A study in healthy subjects found that when they were given triazolam 125 micrograms, after ketoconazole 200 mg taken 17 hours and 1 hour earlier, the triazolam half-life was prolonged (from 4 to almost 18 hours in one subject) and the clearance was increased ninefold. Pharmacodynamic testing found an increase in the impairment of a digit-symbol substitution test, and increased effects on EEG beta activity.²⁰ The AUC of a single 250-microgram dose of triazolam was increased by about 23-fold by ketoconazole 400 mg daily for 4 days. Peak plasma levels were increased threefold. Marked changes in psychomotor and other responses were seen. The subjects had amnesia and were still very tired and confused as long as 17 hours after taking the triazolam.¹⁸ Another study similarly found that ketoconazole inhibited the metabolism of triazolam leading to an increase in its sedative effects.²¹

B. Non-benzodiazepine hypnotics

(a) *Zolpidem*

1. *Fluconazole*. In a placebo-controlled study in healthy subjects **itraconazole** 100 mg twice daily for 2 days had no significant effect on the pharmacokinetics of a single 5-mg dose of zolpidem given with the third dose of fluconazole.²²

2. *Itraconazole*. Itraconazole 200 mg daily or a placebo was given to 10 healthy subjects for 4 days. On day 4 they were also given a single 10-mg oral dose of zolpidem. The mean peak serum levels of the zolpidem were increased by 12.5% and the AUC was increased by 35%, but the performance of a number of psychomotor tests (digit symbol substitution, critical flicker fusion, subjective drowsiness, postural sway) remained unaltered.²³ Another study similarly found that itraconazole did not interact significantly with zolpidem.²²

3. *Ketoconazole*. A study in 12 healthy subjects found that following three 200-mg doses of ketoconazole given every 12 hours, the AUC of zolpidem 5 mg was increased 1.7-fold and the subjects were more sedated, as shown by the digit symbol substitution test.²²

(b) *Zopiclone*

Itraconazole 200 mg daily or a placebo was given to 10 healthy young subjects for 4 days. On day 4 they were also given a single 7.5-mg oral dose of zopiclone. The **itraconazole** increased the maximum plasma levels of the zopiclone by 29% (from 49 to 63 nanograms/mL), increased its AUC by 73%, and prolonged its half-life from 5 to 7 hours. But despite these increases, there were no statistical or clinical differences between the performance of the psychomotor tests carried out during the placebo and **itraconazole** phases of the study.²⁴

Mechanism

Itraconazole, ketoconazole, and to a lesser extent fluconazole are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4. The benzodiazepines and zopiclone and zolpidem are, to varying degrees, metabolised by CYP3A4, with the extent of the interaction related to how significant CYP3A4 is in their metabolism. So, for example midazolam, which is predominantly metabolised by CYP3A4 is greatly affected, whereas CYP3A4 is not a significant metabolic route in the metabolism of temazepam, so it is only slightly affected. Other isoenzymes are also involved in the metabolism of zopiclone and zolpidem so they are only moderately affected. The azoles inhibit CYP3A4 in the liver (hence intravenous benzodiazepines can be affected) but studies have also suggested that ketoconazole inhibits metabolism of midazolam¹⁵ and

triazolam²¹ by CYP3A4 in the gut wall, which explains why oral benzodiazepines are most affected.

Ketoconazole appears to inhibit the oxidation of chlordiazepoxide by the liver.⁵

Importance and management

The interactions between midazolam or triazolam and itraconazole or ketoconazole are established and clinically important. In very broad terms the dosage of midazolam would need to be reduced by about 75% or more in the presence of these antifungals to avoid excessive sedation, and even then the effects would still be expected to be prolonged. Unless appropriate precautions are taken (very reduced dosages) these interactions can be dangerous. Patients taking itraconazole or ketoconazole are unlikely to be able to drive (for example) for at least 6 hours after receiving midazolam. Patients should also be warned about the likelihood of increased sedation. There is some evidence that bolus doses of intravenous midazolam given in the presence of itraconazole or fluconazole are not increased to a clinically significant degree, and normal doses can be used.¹⁴ However, where high doses of intravenous midazolam are used long term (e.g. during intensive care treatment) it has been suggested that the dosage will need to be titrated to avoid long-lasting hypnotic effects.⁸ These precautions are equally applicable to triazolam with itraconazole or ketoconazole and midazolam with ketoconazole. Fluconazole interacts less significantly but even so, the midazolam or triazolam dosage probably needs to be reduced, possibly by as much as half.

The effects of alprazolam and brotizolam are increased and prolonged by ketoconazole and itraconazole, but the extent of this is less than that seen with midazolam or triazolam. However, some dosage reductions may still be necessary.

The effects of itraconazole on temazepam or zopiclone and ketoconazole on chlordiazepoxide or zolpidem are small and seem unlikely to be clinically significant in most patients.

Benzodiazepines and related drugs + Beta blockers

Only small and clinically unimportant pharmacokinetic interactions occur between most benzodiazepines and beta blockers, but there is some evidence that patients taking diazepam may possibly be more accident-prone while taking metoprolol. An isolated report describes marked bradycardia when an elderly woman taking propranolol started to take clomethiazole.

Clinical evidence and mechanism

(a) Benzodiazepines

No significant *pharmacokinetic* interaction occurs between:

- alprazolam and propranolol¹
- clorazepate and propranolol²
- diazepam and atenolol³ or propranolol³
- lorazepam and metoprolol⁴ or propranolol¹
- oxazepam and labetalol⁵ or propranolol.⁵

Moderate changes, which seem unlikely to be clinically significant, were found between:

- diazepam and propranolol (diazepam clearance reduced by 17%)¹ or metoprolol (diazepam clearance reduced by 18%,⁶ AUC increased by 25%)³
- bromazepam and metoprolol (bromazepam AUC increased by 35%)⁴ or propranolol (bromazepam half-life increased by 22%).⁷

However, studies of psychomotor performance have shown that simple reaction times with oxazepam combined with either propranolol or labetalol are increased,⁵ and those taking diazepam and metoprolol have a reduced kinetic visual acuity,^{3,8} which is related to driving ability.⁹ Moreover, choice reaction times at 2 hours were also found to be lengthened when taking diazepam and metoprolol, propranolol or atenolol, but at 8 hours they only persisted with diazepam and metoprolol.⁸

(b) Clomethiazole

An 84-year-old woman taking propranolol 40 mg twice daily for hypertension underwent skin grafting. Her pulse was stable (54 to 64 bpm) until the thirteenth day after the operation when she took two oral doses of clomethiazole 192 mg, 9 hours apart. Three hours after taking the second dose her heart rate fell to 43 bpm with a PR interval of 0.24 seconds, and by 5 hours after the dose her pulse rate was down to 36 bpm. Her pulse had risen to 70 bpm twelve hours after stopping both drugs, and had reestablished 2 days later at about 60 bpm with a PR interval of 0.2 seconds. At this time the propranolol was restarted, with haloperidol.¹⁰

Importance and management

Information about interactions between the benzodiazepines and beta blockers is very limited indeed. The current evidence does not seem to justify any additional caution, but bear this interaction in mind in the case of an unexpected response to treatment. The interaction between propranolol and clomethiazole appears to be an isolated case and therefore probably of limited clinical significance.

Benzodiazepines + Black cohosh

The pharmacokinetics of midazolam are unaffected by the use of black cohosh (*Cimicifuga*).

Clinical evidence, mechanism, importance and management

In a study in 19 healthy subjects given black cohosh extract (standardised to triterpene glycosides 2.5%) 40 mg twice daily for 28 days with a single 8-mg oral dose of **midazolam** on day 28, there was no change in the pharmacokinetics of **midazolam**. In addition, black cohosh had no effect on the duration of midazolam-induced sleep.¹ Similarly, in another study in 12 non-smoking healthy subjects given black cohosh root extract (standardised to triterpene glycosides 0.2%) 1090 mg twice daily for 28 days, there was no significant change in the pharmacokinetics of a single 8-mg oral dose of **midazolam**.²

As black cohosh extract does not appear to alter the pharmacokinetics of **midazolam**, a probe substrate for the cytochrome P450 isoenzyme CYP3A4, it is therefore unlikely that it will alter the pharmacokinetics of other substrates of this isoenzyme, see 'Table 1.4', (p.6), for a list.

Benzodiazepines + Buspirone

No adverse interaction appears to occur if buspirone and alprazolam are given together. When buspirone is given with diazepam the adverse effects appear to be mild and short-lived.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects buspirone 15 mg every 8 hours had no effect on the plasma levels of **diazepam** 5 mg daily for 10 days, but the levels of the metabolite nordiazepam were raised by about 20%. All subjects experienced some mild adverse effects (headache, nausea, dizziness, and in two cases muscle twitching). These symptoms subsided after a few days.¹

In 12 healthy subjects buspirone 10 mg every 8 hours increased the maximum plasma levels and AUC of **alprazolam** 1 mg every 8 hours by 7% and 8%, respectively. The maximum plasma levels of buspirone were not altered, but the AUC of buspirone was increased by 29%. However, these changes were within the normal pharmacokinetic variability of these drugs. No unexpected adverse effects were seen.²

There would seem to be no reason for avoiding the concurrent use of either diazepam or alprazolam and buspirone.

Benzodiazepines + Calcium-channel blockers

Of the calcium-channel blockers diltiazem and verapamil are known to inhibit CYP3A4, the route by which benzodiazepines such as midazolam and triazolam are metabolised. Increased effects, such as sedation, which have been marked in some cases, have been seen in patients given these drugs. Alprazolam would be expected to interact similarly. There appear to be no clinically

significant interactions between other calcium-channel blockers and benzodiazepines.

Clinical evidence

(a) Diazepam

1. *Diltiazem*. When single doses of diazepam 5 mg and diltiazem 60 mg were given to 6 subjects it was found that the plasma levels of each drug were not significantly altered by the presence of the other drug.¹ In another study, poor and extensive metabolisers of the cytochrome P450 isoenzyme CYP2C19 (see 'Genetic factors in drug metabolism', (p.4)) were given diltiazem 200 mg daily for 3 days before and 7 days after a single 2-mg dose of diazepam. It was found that there were no differences in the interaction between the phenotypes, and both groups showed an increase in the AUC and half-life of diazepam. However, the clinical effects of the pharmacokinetic changes were not assessed.²

2. *Felodipine*. The pharmacokinetics of a 10-mg intravenous dose of diazepam were unchanged in 12 healthy subjects after they took felodipine 10 mg daily for 12 days but the AUC and peak serum levels of the diazepam metabolite, desmethyldiazepam, were raised by 14% and 16%, respectively.³

3. *Nimodipine*. The serum levels of diazepam 10 mg daily and nimodipine 30 mg three times daily were unaffected by concurrent use in 24 healthy, elderly subjects, and no clinically relevant changes in haemodynamics, ECG recordings, clinical chemistry or haematology occurred.⁴

(b) Midazolam

1. *Diltiazem*. After taking diltiazem 60 mg three times daily for 2 days, 9 healthy female subjects were given midazolam 15 mg orally. The AUC of midazolam was increased fourfold, the maximum serum levels doubled, and the half-life increased by 49%. It was almost impossible for the subjects to stay awake for 90 minutes after taking the midazolam. They suffered several hours of amnesia and there was a marked decrease in the performance of pharmacodynamic tests (digit symbol substitution, Maddox wing test).⁵ Diltiazem 60 mg, given to 15 patients 2 hours before induction of anaesthesia with midazolam and alfentanil, increased the AUC and half-life of midazolam by 15% and 43%, respectively. Tracheal extubation was performed on average 2.5 hours later, when compared with placebo.⁶

2. *Lercanidipine*. Midazolam appears to increase the absorption of lercanidipine by 40%.⁷ The clinical relevance of this interaction is as yet unclear.

3. *Nitrendipine*. A study in 9 healthy subjects found that the pharmacokinetics and pharmacodynamics of midazolam were unaffected by a single 20-mg dose of nitrendipine.⁸

4. *Verapamil*. After taking verapamil 80 mg three times daily for 2 days, 9 healthy female subjects were given midazolam 15 mg orally. The AUC of the midazolam was increased threefold, the maximum serum levels were doubled, and the half-life increased by 41%. It was almost impossible for the subjects to stay awake for 90 minutes after taking the midazolam. They suffered several hours of amnesia and there was a marked decrease in the performance of pharmacodynamic tests (digit symbol substitution, Maddox wing test).⁵

(c) Temazepam

Diltiazem 40 mg had no little or no effect on the hypnotic effects of temazepam in 16 healthy insomniacs.⁹

(d) Triazolam

1. *Diltiazem*. A study in 7 healthy subjects found that diltiazem 60 mg three times daily for 3 days increased the AUC of a single 250-microgram dose of triazolam 2.3-fold and almost doubled its peak serum levels. Pharmacodynamic tests showed an increase in the sedative effects of triazolam.¹⁰ Another study in 10 healthy subjects found that diltiazem 60 mg three times daily for 2 days increased the AUC of a single 250-microgram dose of triazolam 3.4-fold, and approximately doubled its maximum plasma level and half-life. The pharmacodynamic changes were briefly described as profound and prolonged.¹¹ In contrast, diltiazem 40 mg was found to have little or no effect on the hypnotic effects of triazolam in 16 healthy insomniacs in another study.⁹

2. *Isradipine*. Isradipine 5 mg daily reduced the AUC of a single 250-microgram dose of triazolam by 20% in 9 healthy subjects, but no difference in the pharmacodynamic effects of triazolam were seen.¹²

Mechanism

The evidence suggests that diltiazem and verapamil inhibit the metabolism of midazolam and triazolam, by the cytochrome P450 isoenzyme CYP3A4, leading to increased serum levels and increased effects.

Importance and management

The interactions between midazolam and diltiazem, midazolam and verapamil, and triazolam and diltiazem are established and clinically important. The authors of one report say that patients on either of these calcium-channel blockers are probably incapable of doing skilled tasks (e.g. car driving) for up to 6 hours after taking midazolam 15 mg, and possibly even after 8 to 10 hours. They suggest that the usual dose of midazolam should be reduced at least 50% to avoid unnecessary deep sleep and prolonged hypnosis, and they also point out that since the half-life of the midazolam is prolonged, the effects will persist regardless of the dose.⁵ The same seems likely to be true for triazolam and diltiazem, and the interaction is also predicted to occur with triazolam and verapamil.¹¹ As alprazolam is also metabolised by CYP3A4, this interaction would be expected to occur although there do not appear to be any clinical reports of an interaction.

No special precautions appear to be necessary when other calcium-channel blockers are given with a benzodiazepine.

Benzodiazepines + Colestyramine and Neomycin

The clearance of lorazepam is increased by colestyramine with neomycin.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects found that neomycin 1 g every 6 hours with colestyramine 4 g every 4 hours reduced the half-life of oral lorazepam from 15.8 to 11.7 hours, and increased the clearance of free lorazepam by 34%.¹ The reasons for these changes are not clear but parallel studies using intravenous lorazepam¹ suggested that neomycin and colestyramine may interfere with the possible enterohepatic circulation of lorazepam.

The clinical importance of this interaction is uncertain but probably small. Other benzodiazepines do not appear to have been studied.

Benzodiazepines + Corticosteroids

The metabolism of oral midazolam may be increased in patients receiving long-term treatment with corticosteroids.

Clinical evidence, mechanism, importance and management

Intravenous midazolam 200 micrograms/kg was given to 8 patients receiving long-term treatment with corticosteroids (6 taking prednisolone 2.5 mg to 15 mg daily; 1 taking betamethasone 0.5 mg daily; 1 taking methylprednisolone 48 mg daily) and to 10 other patients not taking corticosteroids. In the patients taking corticosteroids the AUC of midazolam was decreased and the clearance increased, when compared with the patients not taking corticosteroids; however the differences were not significant. The onset of anaesthesia between the two groups was also not different. It was suggested that the trend towards increased midazolam metabolism may be due to induction of the cytochrome P450 isoenzyme CYP3A4 and/or UDP-glucuronosyltransferase. Although the results with intravenous metabolism were not significant the authors note that it is possible that the metabolism of oral midazolam may be more markedly affected.¹

Benzodiazepines + Dexamfetamine

Dexamfetamine reverses the sedative effects and some of the memory-impairing effects of triazolam.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 20 healthy subjects found that a single 20-mg/70 kg dose of dexamfetamine sulfate reversed the sedative effects of a single 250-micrograms/70 kg dose of triazolam. The study also found that dexamfetamine selectively reversed some of the memory-impairing effects of triazolam.¹

Benzodiazepines + Disulfiram

An isolated report describes temazepam toxicity due to disulfiram. The serum levels of chlordiazepoxide and diazepam are increased by the use of disulfiram and some patients may possibly experience increased drowsiness. Alprazolam, oxazepam and lorazepam are either not affected, or only minimally affected, by disulfiram.

Clinical evidence

A man taking disulfiram 200 mg daily developed confusion, drowsiness, slurred speech and an unsteady gait within a few days of starting to take temazepam 20 mg at night. This was interpreted as temazepam toxicity. The symptoms disappeared when both drugs were stopped.¹

After taking disulfiram 500 mg daily for 14 to 16 days, the plasma clearance of single doses of chlordiazepoxide and diazepam were reduced by 54% and 41%, respectively, and the half-lives were increased by 84% and 37%, respectively. The plasma levels of chlordiazepoxide were approximately doubled. Oxazepam was also given following disulfiram treatment but changes in oxazepam pharmacokinetics were minimal. There was no difference in the interaction between alcoholic subjects (without hepatic cirrhosis) and healthy subjects.²

Other studies show that the pharmacokinetics of lorazepam and alprazolam are unaffected by disulfiram.^{3,4}

Mechanism

Disulfiram inhibits the initial metabolism (*N*-demethylation and oxidation) of both chlordiazepoxide and diazepam by the liver so that an alternative but slower metabolic pathway is used. This results in the accumulation of these benzodiazepines in the body. In contrast, the metabolism (glucuronidation) of oxazepam and lorazepam is minimally affected by disulfiram so that their clearance from the body remains largely unaffected.^{2,3} The possible interaction between disulfiram and temazepam is not understood, as temazepam is also mainly eliminated in the urine as the inactive glucuronide metabolite, and so its metabolism would not be expected to be affected by disulfiram.

Importance and management

There seems to be only one report (with temazepam) of a clinically significant interaction between disulfiram and the benzodiazepines, and this report is unconfirmed, as the patient did not take temazepam alone. The other reports only describe potential interactions that have been identified by single-dose studies. These do not necessarily reliably predict what will happen in practice. However, it seems possible that some patients will experience increased drowsiness, possibly because of this interaction, and because drowsiness is a very common adverse effect of disulfiram. Reduce the dosage of the benzodiazepine if necessary. Benzodiazepines that are metabolised by similar pathways to diazepam and chlordiazepoxide, may possibly interact in the same way (e.g. bromazepam, clonazepam, clorazepate, prazepam, ketazolam, clobazam, flurazepam, nitrazepam, medazepam) but this needs confirmation. Alprazolam, oxazepam and lorazepam appear to be non-interacting alternatives.

Benzodiazepines + Echinacea

Echinacea does not appear to alter the AUC and clearance of oral midazolam, although the bioavailability may be increased. Clearance of intravenous midazolam may be increased in patients taking echinacea.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 12 healthy subjects were given *Echinacea purpurea* root 400 mg four times daily for 28 days, with a single 50-microgram/kg intravenous dose of midazolam on day 6, and 24 hours later, a single 5-mg oral dose of midazolam. The clearance of intravenous midazolam was increased by 42%, and the AUC was reduced by 23%, but there were no significant changes in these parameters after oral dosing. However, the oral bioavailability of midazolam was increased by 50% by echinacea. The authors suggested that the echinacea may have exerted opposing effects on the cytochrome P450 isoenzyme CYP3A in the liver and the intestine, which resulted in this apparent anomaly.¹ In another study in 12 healthy subjects given *Echinacea purpurea* 800 mg twice daily for 28 days with a single 8-mg oral dose of midazolam, there was no difference in the ratio of midazolam to its 1-hydroxy metabolite.²

The findings of the first study with oral and intravenous midazolam suggest that the effect of echinacea on CYP3A4 substrates might depend on the whether they have high or low oral bioavailability and whether they have high or low hepatic clearance. Further study is needed.

Benzodiazepines + Ethambutol

Ethambutol appears not to interact with diazepam.

Clinical evidence, mechanism, importance and management

A study in 6 patients, newly diagnosed with tuberculosis and taking ethambutol 25 mg/kg, found that although some of the pharmacokinetic parameters of diazepam were different to those obtained in healthy control subjects not taking ethambutol, the differences were not significant.¹ There seems to be nothing in the literature to suggest that ethambutol interacts with other benzodiazepines.

1. Ochs HR, Greenblatt DJ, Roberts G-M, Dengler HJ. Diazepam interaction with antituberculosis drugs. *Clin Pharmacol Ther* (1981) 29, 671–8.

Benzodiazepines + Food

Food can delay and reduce the hypnotic effects of flunitrazepam and lorazepam. Food can markedly enhance the absorption of quazepam.

Clinical evidence, mechanism, importance and management

A study in 2 groups of 8 healthy subjects found that when they took single 2-mg doses of flunitrazepam or lorazepam 2 hours after an evening meal (spaghetti, meat, salad, an apple and wine) and 1 hour before going to bed, the peak plasma levels of flunitrazepam and lorazepam were reduced by 63% and 41%, respectively. The time to reach these levels were delayed by 2.5 hours and 3.6 hours, respectively, and the absorption half-lives of the drugs were considerably prolonged.¹ It seems probable therefore that the onset of sleep with these benzodiazepines may be delayed by food.

In a crossover study 9 healthy subjects were given single 20-mg dose of quazepam after fasting, 30 minutes after a standard meal, and 3 hours after a standard meal. The peak plasma levels and AUC_{0-8h} for quazepam were increased by 3-fold and 2.4-fold, respectively, when given 30 minutes after food, and by 2.5-fold and 2.1-fold, respectively, when given 3 hours after food, when compared with the fasting state. The CNS-depressant effects of quazepam were enhanced to a similar extent by administration 30 minutes or 3 hours after food.² Another study found similar increases in the bioavailability when quazepam was taken 2 hours after food, but did not find any significant difference in the subjective effects of quazepam, such as drowsiness, malaise, and calmness, when compared with fasting.³ In another study by the same authors, it was found that both low-fat and high-fat meals increased the absorption of quazepam.⁴ Some authorities contraindicate the administration of quazepam with food,⁴ and it would be prudent to advise patients taking quazepam to avoid taking it at the same time or for about 2 to 3 hours after eating.

Benzodiazepines + *Ginkgo biloba*

***Ginkgo biloba* does not significantly affect the pharmacokinetics of alprazolam.**

Clinical evidence, mechanism, importance and management

Ginkgo biloba leaf extract 120 mg twice daily for 16 days was given to 12 healthy subjects before and with a single 2-mg dose of alprazolam on day 14. The *Ginkgo biloba* preparation (*Ginkgold*) was standardised to ginkgo flavonol glycosides 24% and terpene lactones 6%. The alprazolam AUC was reduced by 17%, and the maximum concentration was not significantly affected: these findings are unlikely to be of clinical significance.¹

Alprazolam is a probe substrate for the cytochrome P450 isoenzyme CYP3A4 activity, and the findings of this study suggest that *Ginkgo biloba* is unlikely to have clinically relevant effects on substrates of this isoenzyme, see 'Table 1.4', (p.6).

1. Markowitz JS, Donovan JL, DeVane CL, Sipkes L, Chavin KD. Multiple-dose administration of *Ginkgo biloba* did not affect cytochrome P-450 2D6 or 3A4 activity in normal volunteers. *J Clin Psychopharmacol* (2003) 23, 576–81.

Benzodiazepines + Grapefruit juice

Grapefruit juice can increase the bioavailability of oral diazepam and quazepam but there is evidence that this may be of little practical importance. Midazolam and triazolam levels are also raised by grapefruit juice, and this may be of some clinical significance.

Clinical evidence

A study in 8 healthy subjects found that 250 mL of grapefruit juice increased the AUC and maximum plasma levels of a single 5-mg oral dose of **diazepam** by 3.2-fold and 1.5-fold, respectively.¹ Another study in 9 healthy subjects found that grapefruit juice increased the AUC of **quazepam** and its active metabolite, 2-oxoquazepam, by 38% and 28%, respectively, after a single 15-mg oral dose of **quazepam**, although these increases were not statistically significant. The pharmacodynamic effects of **quazepam**, such as sedation, were not enhanced by grapefruit juice.²

Grapefruit juice 200 mL was given to 8 healthy subjects followed 60 minutes later by 5 mg of **intravenous midazolam** or 15 minutes later by 15 mg of **oral midazolam**. The pharmacokinetics of **intravenous midazolam** remained unchanged, but the AUC of the **oral midazolam** was increased by 52%, and its maximum plasma levels rose by 56%. These changes were also reflected in the psychometric measurements made.³

A large scale placebo-controlled study in a total of 120 healthy young medical students used psychomotor tests to measure the effect of benzodiazepines with and without grapefruit juice. Subjects were given **midazolam** 10 mg or **triazolam** 250 micrograms with 300 mL of grapefruit juice. Only a minor increase in the benzodiazepine effects occurred with grapefruit juice, and these effects were of little or no practical importance.⁴

A single oral 250-microgram dose of **triazolam** was given to 10 healthy subjects with either 250 mL grapefruit juice or water. The mean AUC of the **triazolam** was increased 1.5-fold by the grapefruit juice, the peak plasma levels were increased 1.3-fold, and the time when the plasma levels peaked was prolonged from 1.5 to 2.5 hours. A slight decrease in psychomotor performance occurred (more drowsiness and tiredness).⁵ Similar increases in the AUC of **triazolam** were found in another single-dose study, and although grapefruit juice was not found to enhance the sedative effects of **triazolam**, it did result in deterioration of performance in the digit symbol substitution test.²

Another study of the interaction between **triazolam** and grapefruit juice found that the effects of grapefruit juice were much more pronounced when multiple doses of grapefruit juice were given. The **triazolam** AUC and half-life were increased by about 50% and 6%, respectively, when single doses of grapefruit juice were given, and by about 150% and 50%, respectively, by multiple doses of grapefruit juice. The effect of grapefruit juice on psychomotor tests was also greater after multiple dosing.⁶

Mechanism

The evidence suggests that grapefruit juice inhibits the metabolism of these benzodiazepines by the cytochrome P450 isoenzyme CYP3A4, so that more is left to enter the circulation.³ In one study grapefruit juice was found to have a greater effect on the bioavailability and pharmacodynamics of triazolam than on quazepam. This was considered to be because triazolam is metabolised by CYP3A4, while quazepam is metabolised by CYP2C9 as well as by CYP3A4.²

Importance and management

Established interactions. These increases in bioavailability might be expected to increase the extent of the sedation and amnesia due to these benzodiazepines, but in young healthy adults this is apparently of little importance. The clinical effects of the interaction with diazepam appear not to have been investigated. The effects of midazolam and triazolam may be more enhanced than those of other benzodiazepines, because these drugs are more dependent on CYP3A4 for their metabolism (see *Mechanism*, above). What is not clear is whether other factors such as old age or liver cirrhosis might increase the risk of adverse effects with concurrent use.

Benzodiazepines and related drugs + H₂-receptor antagonists

The serum levels of many of the benzodiazepines and related drugs are raised by cimetidine, but normally this appears to be of little or no clinical importance and only the occasional patient may experience an increase in the effects (sedation). The interactions with midazolam, zaleplon, and zolpidem may be more significant, but this is not established. Famotidine, nizatidine and ranitidine do not normally appear to interact with most benzodiazepines. Increased sedation appears to occur with clomethiazole and cimetidine.

Clinical evidence

A. Benzodiazepines

(a) Cimetidine

The combined serum level of **diazepam** and its active metabolite, desmethyldiazepam, was found to be increased by 75% in 10 patients who took cimetidine 300 mg four times daily for 2 weeks, but reaction times and other motor and intellectual tests remained unaffected.¹ Other reports describe a rise in the plasma levels and/or AUC of **diazepam** (associated with increased sedation in one report²) due to cimetidine,^{3–9} and generalised incoordination has also been described in one individual.¹⁰

Cimetidine also raises the serum levels of **adinazolam**,¹¹ **alprazolam**,^{12,13} **chlordiazepoxide**,¹⁴ **clobazam**,¹⁵ **clorazepate**,¹⁶ **flurazepam**,¹⁷ **nitrazepam**,¹⁸ and **triazolam**,^{12,13,19,20} and reduces the clearance of **bromazepam**.²¹

Liver cirrhosis increases the effects of cimetidine on the loss of **chlordiazepoxide**.²² Confusion has been reported in a 50-year-old man taking **clorazepate** when he was given cimetidine,²³ and increased sedation has been seen in some patients taking **adinazolam** and cimetidine.¹¹ Prolonged hypnosis in an elderly woman²⁴ and CNS toxicity (including lethargy and hallucinations)²⁵ in a 49-year-old woman have been attributed to an interaction between **triazolam** and cimetidine but this remains unconfirmed.

In contrast, cimetidine does not normally interact with **clobazam**,²⁶ **clotiazepam**,²⁷ **lormetazepam**,²⁸ **oxazepam**,^{17,29,30} or **temazepam**,^{31,32} although prolonged post-operative sedation was seen in one patient given **oxazepam** and cimetidine.³³

There is some controversy about whether or not **midazolam** is affected by cimetidine. An increase in sedation,^{34,35} an increase in **midazolam** levels^{35–37} and no pharmacokinetic interaction³⁸ have been reported with the combination.

Similarly, one study found an increase in **lorazepam** levels with a 400 mg dose of cimetidine, but no effect with 200 mg;³ other studies suggest that no interaction occurs between **lorazepam** and cimetidine.^{17,29}

(b) Famotidine

Famotidine does not interact with **bromazepam**,³⁹ **clorazepate**,³⁹ **chlordiazepoxide**,³⁹ **diazepam**,^{9,40,41} or **triazolam**.³⁹

(c) Nizatidine

Nizatidine does not interact significantly with **diazepam**.^{42–44}

(d) Ranitidine

Ranitidine does not interact significantly with **adinazolam**,⁴⁵ **diazepam**,^{42,46,47} **lorazepam**,⁴⁷ or **temazepam**,^{32,48} but it can modestly increase the bioavailability (by about 10 to 30%) of oral **triazolam**.^{49,50} There is some controversy about whether or not **midazolam** is affected by ranitidine. Increases in sedation have been reported on a number of occasions,^{34,36,48,51} but a lack of effect has also been documented.^{37,38}

(e) Roxatidine

Roxatidine does not interact with **diazepam** or its active metabolite, desmethyldiazepam.⁵²

B. Non-benzodiazepine hypnotics

(a) Cimetidine

Cimetidine increases plasma levels of **zaleplon**⁵³ and slightly increases sleep duration with **zolpidem**.⁵⁴ Cimetidine reduces the clearance of **clomethiazole** and increases sleep duration from a range of 30 to 60 minutes up to at least 2 hours.⁵⁵

(b) *Ranitidine*

Ranitidine does not interact significantly with **clomethiazole**.⁵⁶

Mechanism

Cimetidine inhibits the liver enzymes concerned with the metabolism of diazepam, alprazolam, chlordiazepoxide, clomethiazole, lorazepam, flurazepam, nitrazepam, triazolam, and zaleplon. As a result their clearance from the body is reduced and their serum levels rise.

Lorazepam, oxazepam and temazepam are metabolised by a different metabolic pathway involving glucuronidation, which is not affected by cimetidine, and so they do not usually interact.

Ranitidine, famotidine and nizatidine appear not to inhibit liver microsomal enzymes. There is some evidence that ranitidine increases the absorption of triazolam, and possibly other benzodiazepines, due to changes in gastric pH,⁵⁰ although it has been suggested that this effect is negligible.²⁰ Cimetidine has been said to similarly affect the absorption of diazepam and lorazepam.³

Importance and management

The interactions between the benzodiazepines or related drugs and cimetidine are well documented (not all the references are listed here) but normally they appear to be of little clinical importance, although a few patients may be adversely affected (increased effects, drowsiness, etc.) and this may be more common with the non-benzodiazepine hypnotic, clomethiazole, and possibly, midazolam. If symptoms occur in any patient taking a benzodiazepine or related drug and cimetidine, reduce the benzodiazepine dose, or alternatively, use a non-interacting benzodiazepine, such as lorazepam, lormetazepam, oxazepam or temazepam, or a non-interacting H₂-receptor antagonist such as ranitidine, famotidine, nizatidine or roxatidine, although note that the effects of oral triazolam are possibly very slightly increased.

Benzodiazepines and related drugs + Hormonal contraceptives

Hormonal contraceptives can increase the effects of alprazolam, chlordiazepoxide, diazepam, nitrazepam and triazolam, and reduce the effects of oxazepam, lorazepam and temazepam, but whether in practice there is a need for dosage adjustments has not been determined. Chlordiazepoxide, diazepam, nitrazepam and meprobamate can possibly increase the incidence of breakthrough bleeding.

Clinical evidence(a) *Effects on benzodiazepines and related drugs*

A controlled study found that the mean half-life of intravenous **chlordiazepoxide** 600 micrograms/kg was virtually doubled (11.6 hours com-

pared with 20.6 hours) and the total clearance was almost two-thirds lower in 6 women taking oral contraceptives when compared with 6 women not taking oral contraceptives.¹

Similar but less marked effects were found in other studies in women taking oral contraceptives given **chlordiazepoxide**,² **diazepam**,^{3,4} **alprazolam**⁵ and to an even lesser extent with **triazolam**⁵ and **nitrazepam**.⁶ No clinically significant pharmacokinetic changes were seen with **bromazepam**,⁷ **clotiazepam**,⁸ **midazolam** (given orally⁹ intramuscularly¹⁰ or intravenously⁹) or **zolpidem**.¹¹

A controlled study, comparing 7 women taking an oral contraceptive with 8 women not taking oral contraceptives found that the mean half-life of intravenous **lorazepam** 2 mg was over 50% shorter in the oral contraceptive group (6 hours compared to 14 hours) and the total clearance was over threefold greater.¹

A smaller increase in the elimination rate was seen in other controlled studies in women taking oral contraceptives and **lorazepam**,^{5,12} or **temazepam**,⁵ and in two other studies small decreases in the half-life of **oxazepam** were observed.^{1,12}

(b) Effects on contraceptives

A study in 72 patients taking combined oral contraceptives (*Rigevidon*, *Anteovin*) found that breakthrough bleeding occurred in 36.1% of patients while taking **chlordiazepoxide** 10 to 20 mg daily, **diazepam** 5 to 15 mg daily, **nitrazepam** 5 to 10 mg daily or **meprobamate** 200 to 600 mg daily, but no pregnancies occurred. Only three cases of bleeding occurred with **diazepam** or **nitrazepam**.¹³ The average values for breakthrough bleeding with these two oral contraceptives were 9.1% for *Rigevidon* and 3.3% for *Anteovin* in the absence of other drugs. It was possible to establish a causal relationship between the bleeding and the use of the hypnotic in 77% of the cases either by stopping the drug or by changing it for another.¹³

Mechanism

Oral contraceptives affect the metabolism of the benzodiazepines by the liver in different ways: oxidative metabolism is reduced (alprazolam, chlordiazepoxide, diazepam, etc.), whereas metabolism by glucuronide conjugation is increased (lorazepam, oxazepam, temazepam, etc.). Just why these hypnotics should cause breakthrough bleeding is not understood.

Importance and management

Established interactions but of uncertain clinical importance. Long-term use of benzodiazepines that are highly oxidised (alprazolam, chlordiazepoxide, diazepam, nitrazepam, etc.) in women taking oral contraceptives should be monitored to ensure that the dosage is not too high. Those taking benzodiazepines that are metabolised to glucuronides (lorazepam, oxazepam, temazepam, etc.) may possibly need a dosage increase but this is not proven. Bromazepam, clotiazepam, midazolam and zolpidem appear not to interact. No firm conclusions could be drawn from the results of one study, which set out to evaluate the importance of this interaction.¹⁴

The increased incidence of breakthrough bleeding (more than one-third) due to these hypnotics, is an unpleasant reaction and it suggests that the contraceptive is possibly unreliable, but no outright contraceptive failures have been reported.¹³ Limited evidence from the study suggests that changing the hypnotic or the contraceptive might avoid breakthrough bleeding. Note that the UK Family Planning Association¹⁵ did not consider that additional contraceptive precautions were necessary with clonazepam or clobazam and it seems unlikely that they will be necessary with any benzodiazepine.

Benzodiazepines + 5-HT₃-receptor antagonists

Lorazepam does not appear to interact with granisetron, and temazepam does not appear to interact with ondansetron.

Clinical evidence, mechanism, importance and management

Lorazepam 2.5 mg, given to 12 healthy subjects, clearly affected the performance of a number of psychometric tests. Statistically significant increases occurred in drowsiness, feebleness, muzziness, clumsiness, lethargy, mental slowness, relaxation, dreaminess, incompetence, sadness, and withdrawal. However, there was very little evidence that **granisetron** 160 micrograms/kg alone had any effect on the performance of these tests except that clumsiness and inattentiveness were increased, nor was there evidence that **granisetron** added to the effects of **lorazepam** when both drugs were taken concurrently.¹

In a placebo-controlled, crossover study in 24 healthy subjects **ondansetron** 8 mg did not affect the pharmacokinetics of **temazepam** 20 mg. The psychomotor performances of the subjects (subjective and objective sedation, memory and other measurements) were not influenced by the presence of the **ondansetron**.²

No additional special precautions would seem to be necessary if either of these pairs of drugs are given.

2. Preston GC, Keene ON, Palmer JL. The effect of ondansetron on the pharmacokinetics and pharmacodynamics of temazepam. *Anaesthesia* (1996) 51, 827–30.

Benzodiazepines + Influenza vaccines

The pharmacokinetics of alprazolam, chlordiazepoxide and lorazepam are not affected by influenza vaccination.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of single doses of oral **alprazolam** 1 mg, or intravenous **lorazepam** 2 mg remained unaffected in healthy subjects when the benzodiazepines were given 7 and 21 days after 0.5 mL of an intramuscular trivalent influenza vaccine.¹ Similarly, in another study, neither **lorazepam** nor **chlordiazepoxide** metabolism was altered when they were given 1 and 7 days after a trivalent influenza vaccine.² There would seem to be no reason for avoiding the concurrent use of these drugs.

1. Scavone JM, Blyden GT, Greenblatt DJ. Lack of effect of influenza vaccine on the pharmacokinetics of antipyrine, alprazolam, paracetamol (acetaminophen) and lorazepam. *Clin Pharmacol Ther* (1989) 46, 180–5.
2. Meredith CG, Christian CD, Johnson RF, Troxell R, Davis GL, Schenker S. Effects of influenza virus vaccine on hepatic drug metabolism. *Clin Pharmacol Ther* (1985) 37, 396–401.

Benzodiazepines + Isoniazid

Isoniazid reduces the clearance of both diazepam and triazolam. Some increase in their effects would be expected. No interaction occurs with oxazepam or clotiazepam.

Clinical evidence*(a) Interacting benzodiazepines*

A study in 9 healthy subjects found that isoniazid 90 mg twice daily for 3 days increased the half-life of a single 5- or 7.5-mg dose of **diazepam** from about 34 to 45 hours, and reduced the total clearance by 26%.¹ A study in 6 healthy subjects found that isoniazid 90 mg twice daily for 3 days, increased the half-life of a single 500 microgram dose of **triazolam** from 2.5 to 3.3 hours, increased the AUC by 46% and reduced the clearance by 43%.²

(b) Non-interacting benzodiazepines

A study in 9 healthy subjects found that isoniazid 90 mg twice daily for 3 days had no effect on the pharmacokinetics of a single 30-mg oral dose of **oxazepam**.² Similarly, in another study, the pharmacokinetics of **clotiazepam** were not altered by isoniazid.³

Mechanism

What is known suggests that isoniazid acts as an enzyme inhibitor, decreasing the metabolism and loss of diazepam and triazolam from the body, thereby increasing and prolonging their effects. Oxazepam which is metabolised by glucuronidation would be unlikely to interact.

Importance and management

Information is limited but the interactions appear to be established. Their clinical importance is uncertain but be alert for the need to decrease the dosages of diazepam and triazolam if isoniazid is started. There seems to be no direct information about other benzodiazepines, but those undergoing high first-pass extraction and/or liver microsomal metabolism may interact similarly. Oxazepam and clotiazepam appear not to interact.

Benzodiazepines + Kava

A man taking alprazolam became semicomatose a few days after starting to take kava, which was suggested to be due to additive sedation. The pharmacokinetics of midazolam were unaffected by kava.

Clinical evidence, mechanism, importance and management*(a) Alprazolam*

A 54-year-old man taking alprazolam, cimetidine and terazosin was hospitalised in a lethargic and disorientated state 3 days after starting to take kava, which he had bought from a local health food store. He denied having overdosed with any of these drugs. The patient became alert again after several hours.¹ The reason for what happened is not known, but the suggested explanation is that the kava α -pyrones might have had additive sedative effects with those of the alprazolam.^{1,2} This is an isolated case and its general importance is not known.

(b) Midazolam

In a study in 6 subjects who regularly took 7 to 27 g of kavalactones weekly as an aqueous kava extract, there was no change in the metabolism of a single 8-mg oral dose of midazolam before or after they stopped kava for 30 days.³ Similar results were found in a study in 12 healthy subjects given kava kava root extract 1 g twice daily for 28 days before receiving a single 8-mg dose of oral midazolam.⁴ In contrast to some *in vitro* data, these studies show that kava has no effect on the cytochrome P450 isoenzyme CYP3A4, of which midazolam is a probe substrate.⁴ It is possible that the kava levels achieved clinically are insufficient to affect CYP3A4. The findings of these studies suggest that it is unlikely that kava will alter the pharmacokinetics of other substrates of CYP3A4 (see 'Table 1.4', (p.6), for a list).

Benzodiazepines and related drugs + Macrolides

The serum levels and effects of midazolam, triazolam and zopiclone are markedly increased and prolonged by erythromycin. The same interaction has been seen with clarithromycin, josamycin, or troleandomycin but not azithromycin. Alprazolam would be expected to be similarly affected. Other benzodiazepines, and the related hypnotic zaleplon, appear not to interact with the macrolides to a clinically significant extent.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

In a randomised study 12 healthy subjects were given **erythromycin** 400 mg three times daily for 10 days with a single 800-microgram dose of alprazolam on day 8. The alprazolam AUC₀₋₄₈ was increased by 61% and the half-life increased from 16 to 40.3 hours. However, no increase in sedation was seen.¹ The manufacturers predict that other macrolides will interact similarly, and they specifically name **erythromycin** and **troleandomycin**.²

(b) Brotizolam

A randomised study in healthy subjects found that **erythromycin** 400 mg three times daily for 7 days increased AUC of a single 500-microgram dose of brotizolam by 2.5-fold. The elimination half-life was also increased from 9.4 hours to 20.7 hours. However, **erythromycin** did not affect the changes in psychomotor function associated with brotizolam.³

(c) Diazepam

In a crossover study, 6 healthy subjects were given a single 5-mg oral dose of diazepam after taking **erythromycin** 500 mg three times daily for one week. The diazepam AUC was increased by a modest 15%, but its pharmacodynamic effects were unchanged.⁴

(d) Flunitrazepam

In a crossover study, 5 healthy subjects were given a single 1-mg oral dose of flunitrazepam after taking **erythromycin** 500 mg three times daily for one week. The flunitrazepam AUC was increased by 25% but its pharmacodynamic effects were unchanged.⁴

(e) Midazolam

1. **Azithromycin.** A study in 64 healthy medical students found that azithromycin 750 mg had no effect on the metabolism of a 10- or 15-mg dose of midazolam, and did not alter the performance of a number of psychomotor tests.⁵ A study in 10 healthy subjects given azithromycin 250 mg daily found that some small changes in pharmacokinetics of midazolam 15 mg (a possible small delay in its onset of action), but its pharmacodynamic effects were unaltered.⁶ Other studies confirm that azithromycin does not interact with midazolam.^{7,8}

2. **Clarithromycin.** Oral 4 mg and intravenous 50 microgram/kg doses of midazolam were given simultaneously to 16 healthy subjects, before and after they took clarithromycin 500 mg twice daily for 7 days. It was found that clarithromycin reduced the systemic clearance of midazolam by about 64%, which resulted in a doubling of the midazolam-induced sleeping time.⁹ Similar results were found in another study.⁸

3. **Erythromycin.** A study in 12 healthy subjects found that erythromycin 500 mg three times daily for 6 days almost tripled the peak plasma levels of a single 15-mg dose of midazolam, more than doubled its half-life and increased the AUC by more than fourfold. The subjects could hardly be wakened during the first hour after being given the midazolam, and most experienced amnesia lasting several hours.¹⁰

The serum levels of a 500-microgram/kg oral dose of midazolam, given to an 8-year-old boy as pre-medication before surgery, were approximately doubled when he was given intravenous erythromycin. He developed nausea and tachycardia, and after 40 minutes (by which point he had received 200 mg of erythromycin) he lost consciousness.¹¹ A patient in a coronary

care unit given 300 mg of intravenous midazolam over 14 hours slept for about 6 days (apart from brief waking when given flumazenil). The midazolam half-life was increased by about tenfold. This was attributed to an interaction due to the combined effects of erythromycin 4 g daily and amiodarone 1.7 g over 3 days.^{12,13} Other studies and reports have also described this interaction.^{5,7,14,15}

4. *Roxithromycin*. In 10 healthy subjects roxithromycin 300 mg daily for 6 days increased the AUC of a single 15-mg dose of midazolam by about 47%, and lengthened the half-life from 1.7 to 2.2 hours. Only minor psychomotor changes were seen.¹⁶ A modest increase in the effects of midazolam were seen in another study in subjects given roxithromycin 300 mg, but the effects were very much weaker than those seen with erythromycin.¹⁵

(f) Nitrazepam

When 10 healthy subjects were given **erythromycin** 500 mg three times daily for 4 days, the AUC of a single 5-mg dose of nitrazepam was increased by 25%, the peak plasma levels were increased by 30% and the concentration peak time was reduced by over 50%. However, hardly any changes were seen in the psychomotor tests undertaken.¹⁷

(g) Temazepam

A randomised, study in 10 healthy subjects found that **erythromycin** 500 mg three times daily for 6 days had no significant effect on the pharmacokinetics or psychomotor effects of a single 20-mg dose of temazepam.¹⁸

(h) Triazolam

1. *Azithromycin*. A clinical study in 12 healthy subjects found that azithromycin did not affect the pharmacokinetics of a single 125-microgram dose of triazolam.¹⁹ These results were supported by an *in vitro* study, which confirmed that azithromycin was only a weak inhibitor of triazolam metabolism.¹⁹

2. *Clarithromycin*. An *in vitro* study found clarithromycin to be a relatively potent inhibitor of triazolam metabolism. These results were confirmed in practice with 12 healthy subjects, who were given both drugs. The oral clearance of triazolam was reduced by 77% by clarithromycin, when compared with placebo.¹⁹

3. *Erythromycin*. A study in 16 healthy subjects found that erythromycin 333 mg three times daily for 3 days, reduced the clearance of a single 500-microgram dose of triazolam by about 50%, doubled the AUC, and increased the maximum plasma levels by about one-third (from 2.8 to 4.1 nanograms/mL).²⁰ Other reports confirm the marked decrease in clearance and an increase in peak levels.^{19,21} Repeated visual hallucinations and abnormal body sensations occurred in one patient with acute pneumonia and chronic renal failure taking erythromycin 600 mg daily after each dose of triazolam and **nitrazepam**. These symptoms had not occurred before the addition of erythromycin.²²

4. *Josamycin*. Josamycin has been reported to increase triazolam levels causing an increase in its effects.²³

5. *Roxithromycin*. A study found that roxithromycin 300 mg had only a slight effect on the effects of triazolam.¹⁵

6. *Troleandomycin*. Troleandomycin 2 g daily given to 7 healthy subjects for 7 days increased the peak triazolam levels by 107%, the AUC by 275% and the half-life from 1.81 to 6.48 hours. Apparent oral clearance was reduced by 74%. Marked psychomotor impairment and amnesia was seen.²⁴ Troleandomycin has been reported to interact similarly in a patient on triazolam, causing an increase in its effects.²³ An *in vitro* study has shown troleandomycin to be a potent inhibitor of triazolam metabolism.¹⁹

B. Non-benzodiazepine hypnotics

(a) Zaleplon

The manufacturers say that a single 800-mg dose of **erythromycin** increased the plasma levels of zaleplon by 34%.²⁵

(b) Zolpidem

In a study in healthy subjects **clarithromycin** had no effects on the pharmacokinetics of zolpidem or on its sedative effects.²⁶

(c) Zopiclone

Zopiclone 7.5 mg was given to 10 healthy subjects before and after taking **erythromycin** 500 mg three times daily for 6 days. The **erythromycin** increased the plasma concentration of the zopiclone fivefold at 30 minutes and twofold at one hour. Peak plasma levels rose by about 40% and occurred at 1 hour instead of 2 hours. The 1-hour and 2-hour AUCs were

increased threefold and twofold, respectively, while the total AUC was increased by nearly 80%.²⁷ These pharmacokinetic changes were reflected in some small changes in a number of psychomotor tests.²⁷

Mechanism

Some of the macrolides (notably erythromycin and troleandomycin) are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4. Benzodiazepines, such as midazolam, that are predominantly metabolised by CYP3A4 are affected more than those such as diazepam, where CYP3A4 plays only a minor part in the metabolism. Further, CYP3A4-mediated metabolism occurs in the liver and also in the intestines. Midazolam and triazolam undergo extensive first-pass metabolism (low bioavailability of about 40%) but alprazolam and brotizolam undergo less first-pass metabolism (bioavailabilities of about 90% and 70%, respectively). Erythromycin causes greater increases in the levels and AUC of midazolam and triazolam than in those of alprazolam and brotizolam, and this may be related to the extent of first-pass metabolism.³ The non-benzodiazepine hypnotics, zaleplon and zopiclone are, to varying degrees, also metabolised by CYP3A4. The macrolides can therefore reduce the metabolism of some of the benzodiazepines and related drugs, raising their serum levels and increasing and prolonging their effects.

Importance and management

The interactions of midazolam with erythromycin and triazolam with clarithromycin, erythromycin or troleandomycin appear to be established, and of clinical importance. The dosages of the midazolam and triazolam should be reduced 50 to 75% when these antibacterials are used if excessive effects (marked drowsiness, memory loss) are to be avoided. Remember too that the hypnotic effects are also prolonged so that patients should be warned about hangover effects the following morning if they intend to drive. Much less is known about the use of midazolam with clarithromycin but similar precautions may be necessary. The manufacturers of zaleplon say that patients should be advised that increased sedation is possible with erythromycin, although a dose adjustment is usually not required.²⁵

Limited information from single-dose studies suggests that erythromycin may increase levels of alprazolam and brotizolam but no pharmacodynamic changes were found. Nevertheless, the manufacturers advise caution if alprazolam is used with a macrolide.²

Azithromycin does not interact with midazolam or triazolam, and the effects of roxithromycin on midazolam and triazolam, and of erythromycin on diazepam, flunitrazepam, nitrazepam, temazepam and zopiclone or clarithromycin on zolpidem appear to be small and unimportant, or the effects negligible, so that no special precautions seem to be necessary.

Benzodiazepines and related drugs + Metoclopramide

Intravenous, but not oral, metoclopramide increases the rate of absorption of diazepam and raises its maximum plasma levels. Metoclopramide increases the rate of absorption of zopiclone.

Clinical evidence, mechanism, importance and management

(a) Diazepam

Intravenous metoclopramide increased the peak plasma levels of diazepam by 38% and increased the rate of absorption (peak levels occurred at 30 minutes instead of 60 minutes),¹ but in 6 healthy subjects oral metoclopramide 10 mg did not increase the rate of absorption of oral diazepam 0.2 mg/kg.² The reason is not understood. The clinical importance of this interaction is not known, but it is probably small.

(b) Zopiclone

The rate of absorption of a single 7.5-mg dose of oral zopiclone was increased by metoclopramide 10 mg given intravenously to 12 healthy subjects. This was presumably because these drugs alter gut motility. Metoclopramide increased the mean plasma levels of zopiclone, from 22.7 to 44.4 nanograms/mL at 1 hour, and from 49.3 to 59.6 nanograms/mL at 2 hours.³ The clinical importance of these findings is not known.

Benzodiazepines + Metronidazole

Metronidazole does not interact with alprazolam, diazepam, lorazepam, or midazolam.

Clinical evidence, mechanism, importance and management

A study in healthy subjects found that metronidazole 400 mg twice daily for 5 days had no effect on the pharmacokinetics of a single 100-microgram/kg intravenous dose of diazepam.¹ Another study in healthy subjects found that metronidazole 750 mg had no effect on the pharmacokinetics of alprazolam or lorazepam.² *In vivo* and *in vitro* studies have shown that metronidazole has no effect on the pharmacokinetics or pharmacodynamics of midazolam.³ Interactions with other benzodiazepines seem unlikely.

Benzodiazepines + Milk thistle

Milk thistle does not alter the pharmacokinetics of midazolam.

Clinical evidence, mechanism, importance and management

In a study 19 healthy subjects were given milk thistle 300 mg three times daily for 14 days (standardised to silymarin 80%) with a single 8-mg oral dose of midazolam on the last day. There was no change in the pharmacokinetics of midazolam, and milk thistle had no effect on the duration of midazolam-induced sleep.¹ Similarly, in another study in 12 healthy subjects, milk thistle 175 mg (standardised to silymarins 80%) given twice daily for 28 days had no significant effects on the metabolism of a single 8-mg dose of midazolam.²

These studies show that the pharmacokinetics of midazolam, a probe substrate for the cytochrome P450 isoenzyme CYP3A4, are not affected by the concurrent use of milk thistle. This suggests that milk thistle is unlikely to affect the metabolism of other drugs that are substrates of CYP3A4, see 'Table 1.4', (p.6), for a list.

In vivo assessment of botanical supplementation on human cytochrome P450 phenotypes: *Citrus aurantium*, *Echinacea purpurea*, milk thistle, and saw palmetto. *Clin Pharmacol Ther* (2004) 76, 428–40.

Benzodiazepines + Misoprostol

A study in 12 subjects found that misoprostol 200 micrograms four times daily for 7 days had no effect on the steady-state plasma levels of diazepam 10 mg daily or on the plasma levels of the metabolite, nordiazepam.¹ No special precautions would therefore seem to be necessary if misoprostol is given with diazepam.

- Lima DR, Santos RM, Werneck E, Andrade GN. Effect of orally administered misoprostol and cimetidine on the steady state pharmacokinetics of diazepam and nordiazepam in human volunteers. *Eur J Drug Metab Pharmacokinet* (1991) 16, 161–70.

Benzodiazepines + Modafinil

Modafinil reduces triazolam levels. It may therefore also affect the metabolism of other similarly metabolised benzodiazepines such as alprazolam and midazolam. Conversely, modafinil might increase diazepam levels.

Clinical evidence, mechanism, importance and management

In a single-dose study, 34 healthy women (all taking an oral contraceptive containing ethinylestradiol and norgestimate) were given a single 125-microgram dose of triazolam, both before and on the last day of taking modafinil (200 mg daily for 7 days then 400 mg daily for 21 days) or placebo. The AUC of triazolam was reduced by almost 60%, its maximum plasma level was reduced by 42% and its elimination half-life was reduced by about 1 hour by modafinil, when compared with placebo.¹

Modafinil is known to induce the cytochrome P450 isoenzyme CYP3A4, by which triazolam is metabolised, and it is therefore likely to reduce triazolam levels by this mechanism. It seems possible that other benzodiazepines metabolised by CYP3A4 (alprazolam, midazolam) may be similarly affected. It would therefore seem prudent to monitor for a reduction in the sedative effects and a reduced duration of action of these benzodiazepines in patients taking modafinil: increase the dose if necessary.²

Conversely, modafinil inhibits the cytochrome P450 isoenzyme CYP2C19. The manufacturers therefore predict that the elimination of diazepam, which is metabolised by this isoenzyme, may be reduced. They suggest that a dosage reduction may be necessary on concurrent use.^{2,3}

- Provigil (Modafinil), Cephalon Ltd. UK Summary of product characteristics, July 2007.

Benzodiazepines and related drugs + Nefazodone

Nefazodone increases the plasma levels and effects of alprazolam, midazolam, triazolam and zopiclone, but not lorazepam.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

A placebo-controlled study in 12 healthy subjects found that nefazodone 200 mg twice daily caused an almost twofold increase in the plasma levels of alprazolam 1 mg twice daily taken for 7 days.¹ Another study found that impairment of psychomotor performance and increased sedation occurred when nefazodone was given with alprazolam.² A case report describes benzodiazepine withdrawal symptoms in a woman taking alprazolam after nefazodone was withdrawn following several years of concurrent use. She needed an alprazolam dosage increase from 500 micrograms to 4 mg daily to control her symptoms.³

(b) Lorazepam

A placebo-controlled study in healthy subjects given nefazodone 200 mg twice daily found no changes in the pharmacokinetics of lorazepam 2 mg twice daily.¹ Another study showed that psychomotor performance was not further impaired and no additional sedation occurred when nefazodone was given with lorazepam.²

(c) Midazolam

A study in 10 healthy subjects found that both the AUC and the maximum plasma level of a single 10-mg dose of midazolam were increased about fivefold and twofold, respectively, when they took nefazodone 200 mg twice daily.⁴

(d) Triazolam

A study in 12 healthy subjects found that the maximum plasma levels, the half-life and the AUC of a single 250-microgram dose of triazolam were increased 1.7-fold, 4.6-fold, and 4-fold, respectively, by nefazodone 200 mg twice daily.⁵ Another study showed that impairment of psychomotor performance and increased sedation occurred when nefazodone was given with triazolam.²

B. Non-benzodiazepine hypnotics

An 86-year-old woman taking diltiazem, irbesartan, lorazepam, and pravastatin started taking nefazodone 50 mg twice daily, increasing to 500 mg daily in divided doses, for the treatment of a major depressive episode. Because of associated insomnia, **zopiclone** was added, starting at 15 mg each night, but this was reduced after 5 days to 7.5 mg because of morning drowsiness. Plasma levels of *S*-zopiclone and *R*-zopiclone were 107 nanograms/mL and 20.6 nanograms/mL, respectively, at this time. After several months, nefazodone was replaced by venlafaxine. The *S*-zopiclone and *R*-zopiclone levels were again measured and found to be only 16.9 nanograms/mL and 1.45 nanograms/mL, respectively.⁶

Mechanism

Nefazodone appears to inhibit the oxidative metabolism of alprazolam, midazolam, triazolam and zopiclone by the cytochrome P450 isoenzyme CYP3A4 so that they accumulate in the body. Lorazepam is unaffected because it is primarily excreted as a conjugate.

Importance and management

The interactions of nefazodone with alprazolam, midazolam, triazolam and zopiclone are established and clinically important. The practical consequences are that the effects of alprazolam, midazolam and triazolam are expected to be increased but the extent is uncertain. Be alert for any evidence of any psychomotor impairment, drowsiness etc. and reduce the benzodiazepine dosage if necessary. More study is needed. Lorazepam does not interact with nefazodone. There seems to be no direct information about other benzodiazepines and related drugs.

Benzodiazepines and related drugs + NSAIDs

Diclofenac reduces the dose of midazolam needed to produce sedation and hypnosis. Diazepam has a small effect on the pharmacokinetics of diclofenac, ibuprofen and naproxen. Diazepam and indometacin appear not to interact adversely, although feelings of dizziness may be increased. Zaleplon and ibuprofen appear not to interact.

Clinical evidence, mechanism, importance and management

(a) Diazepam

1. *Diclofenac*. In a study in 8 healthy subjects, diazepam increased the AUC of diclofenac by 60% while the clearance was reduced by 36%.¹ The effects of diazepam on diclofenac appeared to depend on the time of administration and may reflect time-dependent effects of diazepam on gastrointestinal function. More study is needed.

2. *Ibuprofen*. A study in 8 healthy subjects investigating the effects of diazepam on ibuprofen pharmacokinetics found that the ibuprofen half-life was increased from 2.39 to 3.59 hours and the clearance was reduced by about one-third when diazepam and ibuprofen were given at 10 pm, but no effect was seen with morning dosing.² The clinical importance of this is uncertain.

3. *Indometacin*. Diazepam 10 to 15 mg impaired the performance of a number of psychomotor tests (digit symbol substitution, letter cancellation, tracking and flicker fusion) in 119 healthy medical students. It also caused subjective drowsiness, mental slowness and clumsiness. When indometacin 50 or 100 mg was given the effects were little different from diazepam alone, except that the feeling of dizziness (common to both drugs) was increased and caused subjective clumsiness.³

4. *Naproxen*. A double-blind, crossover study failed to find any clinically important changes in mood or attention in healthy subjects given naproxen and diazepam.⁴ A single-dose study in 10 healthy subjects found that peak serum concentrations of naproxen 500 mg were reduced by 23%, the time to peak concentration was increased (1.36 to 2 hours) and the absorption rate constant was decreased (4.07 to 2.42 h⁻¹) by diazepam 10 mg. Other pharmacokinetic parameters were not affected.⁵ No special precautions appear to be necessary.

(b) Midazolam

A clinical study found that **diclofenac** 75 mg given intravenously to 10 patients reduced the dose of intravenous midazolam needed to produce sedation and hypnosis by 35%, when compared with 10 control subjects not given **diclofenac**.⁶ The clinical importance of this is uncertain.

For the interactions of parecoxib with midazolam see 'NSAIDs; Parecoxib + Miscellaneous', p.160.

(c) Zaleplon

A randomised, single-dose study in 17 healthy subjects found that **ibuprofen** 600 mg had no effect on the pharmacokinetics of zaleplon 10 mg.⁷

Benzodiazepines + Paracetamol (Acetaminophen)

Paracetamol reduces the urinary excretion of diazepam but diazepam plasma levels are little affected.

Clinical evidence, mechanism, importance and management

The 96-hour urinary excretion of a single 10-mg oral dose of **diazepam** and its metabolite, nordiazepam, were reduced from 44% to 12% and from 27% to 8%, respectively, in 2 female subjects, and from 11% to 4.5%, respectively, in a male subject, by a single 500-mg dose of paracetamol. The reasons are not understood. Plasma levels of **diazepam** and its metabolite were not significantly affected.¹ There would seem to be no reason for avoiding concurrent use. There seems to be no information about other benzodiazepines.

1. Mulley BA, Potter BI, Rye RM, Takeshita K. Interactions between diazepam and paracetamol. *J Clin Pharm* (1978) 3, 25–35.

Benzodiazepines + Probenecid

Probenecid reduces the clearance of adinazolam, lorazepam and nitrazepam. Increased effects (e.g. sedation) may be expected. Probenecid does not appear to interact with temazepam.

Clinical evidence

(a) Adinazolam

In a single-dose study in 16 healthy subjects, probenecid 2 g increased the psychomotor effects of sustained-release adinazolam 60 mg. The tests used were symbol-digit substitution, digit span forwards and continuous performance tasks.¹ The peak serum levels of adinazolam and its active metabolite, *N*-desmethyladinazolam, were increased by 37% and 49%, respectively, and the clearances were reduced by 16% and 53%, respectively, by probenecid. Both drugs have uricosuric actions, but when used together the effects appear not to be additive.¹

(b) Lorazepam

Probenecid 500 mg every 6 hours approximately halved the clearance of a single 2-mg intravenous dose of lorazepam in 9 healthy subjects. The elimination half-life was more than doubled, from 14.3 hours to 33 hours.²

(c) Nitrazepam

Probenecid 500 mg daily for 7 days reduced the clearance of nitrazepam by 25% in healthy subjects.³

(d) Temazepam

Probenecid 500 mg daily for 7 days but did not significantly affect the clearance of temazepam in healthy subjects.³

Mechanism

Probenecid inhibits the renal tubular clearance of many drugs and their metabolites, including some of the benzodiazepines. It also inhibits the glucuronidation of nitrazepam and lorazepam by the liver.^{2,3} The overall result is that these benzodiazepines accumulate and their effects are increased. Temazepam, which also undergoes glucuronidation, was not affected, possibly as increased sulfation compensated.³

Importance and management

Established interactions but of uncertain clinical importance. Be alert for increases in the effects (sedation, antegrade amnesia) of adinazolam, lorazepam and possibly nitrazepam. Reduce the dosage as necessary. Note that adinazolam is no longer available. There seems to be no direct information about other benzodiazepines, but those that are metabolised like lorazepam and nitrazepam (e.g. oxazepam) may also interact. Temazepam does not appear to interact with probenecid.

3. Brockmeyer NH, Mertins L, Klimek K, Goos M, Ohnhaus EE. Comparative effects of rifampin and/or probenecid on the pharmacokinetics of temazepam and nitrazepam. *Int J Clin Pharmacol Ther Toxicol* (1990) 28, 387–93.

Benzodiazepines and related drugs + Protease inhibitors

A study and a case report show that saquinavir markedly decreases midazolam metabolism, resulting in a significant increase in sedation. Ritonavir similarly affects triazolam and, to a lesser extent, alprazolam, but appears not to affect zolpidem levels.

Clinical evidence, mechanism, importance and management

A. Benzodiazepines

(a) Alprazolam

A crossover study in 10 healthy subjects found that **ritonavir** 200 mg for 4 doses decreased the clearance of a single 1-mg dose of alprazolam by 59%. The half-life of alprazolam was increased from 13.3 to 29.6 hours and the subjects experienced increased and prolonged sedation.¹

(b) Midazolam

A randomised study in 12 healthy subjects found that **saquinavir** (soft-gel formulation) 1.2 g three times daily increased the bioavailability of oral midazolam from 41 to 90% and increased the AUC fivefold. Psychomotor tests showed impaired skills and greater sedation in the presence of **saquinavir**.² When intravenous midazolam was given, the sedative effects were only marginally altered.² However, a 32-year-old with advanced HIV, taking zidovudine, lamivudine, co-trimoxazole and **saquinavir** 600 mg three times daily, did not wake spontaneously from a 5 mg intravenous dose of midazolam. He was given 300 micrograms of intravenous flumazenil to revert the prolonged sedation, but he was not free from sedation until 5 hours later. On a previous occasion, in the absence of **saquinavir**, he woke spontaneously 2 hours after the dose of midazolam.³ The manufacturers of saquinavir note that in 16 healthy subjects, saquinavir/ritonavir 1000/100 mg twice daily for 2 weeks increased the maximum levels and AUC of a single 7.5-mg oral dose of midazolam by 4.3-fold and 12.4-fold, respectively.⁴

(c) Triazolam

In a crossover study in 6 healthy subjects **ritonavir** 200 mg for 4 doses reduced the clearance of triazolam 125 micrograms to less than 4% of control values and increased the half-life from 3 to 41 hours, which resulted in increased and prolonged sedation.⁵ A very brief case report also describes prolonged sedation in a patient given **ritonavir** and triazolam.⁶

B. Non-benzodiazepine hypnotics

A crossover study in 6 healthy subjects found that **ritonavir** 200 mg twice daily for 4 doses resulted in only a small and clinically unimportant reduction in the clearance of a single 5-mg dose of **zolpidem**.⁵

Mechanism

Alprazolam, midazolam and triazolam are metabolised by the cytochrome P450 isoenzyme CYP3A4, which is inhibited, to varying degrees, by the protease inhibitors. Benzodiazepine levels and effects are therefore increased by saquinavir and ritonavir. Zolpidem metabolism depends on several isoenzymes so inhibition of CYP3A4 alone may not produce clinically significant changes in its clearance.

Importance and management

This interaction is of clinical importance: be alert for the need to reduce the midazolam dosage in the presence of saquinavir. The authors of the study² suggest that continuous intravenous midazolam doses should be reduced by 50%, but do not consider dose adjustments to single intravenous doses necessary.² The same precautions would seem appropriate with triazolam. However, the manufacturer of saquinavir contraindicates the concurrent use of oral midazolam and triazolam.^{4,7} They note that no studies have been conducted with ritonavir-boosted saquinavir but that a 3 to 4-fold increase in intravenous midazolam levels would be expected.⁴ Use of intravenous midazolam with saquinavir is not contraindicated but they

advise that its use be restricted to an intensive care unit or similar setting so that the appropriate management of respiratory depression is available.⁴

The UK manufacturer of ritonavir contraindicates its use with **clorazepate**, **diazepam**, **estazolam**, **flurazepam**, midazolam and triazolam as they are highly metabolised by the cytochrome P450 isoenzymes and therefore may cause extreme sedation and respiratory depression in the presence of ritonavir.⁸ The US manufacturer of ritonavir contraindicates its use with triazolam and midazolam.⁹ This interaction is likely to occur at least to some extent with all protease inhibitors and any of these highly metabolised benzodiazepines, and the use of (oral) midazolam and triazolam is largely contraindicated.

The manufacturer of ritonavir notes that zolpidem and ritonavir may be given concurrently with careful monitoring for excessive sedative effects.⁸

Benzodiazepines + Proton pump inhibitors

Gait disturbances (attributed to benzodiazepine toxicity) occurred in two patients given triazolam and lorazepam or flurazepam with omeprazole, and another patient taking diazepam and omeprazole became wobbly and sedated. Lansoprazole, pantoprazole, or rabeprazole appear not to interact to a clinically relevant extent with diazepam. Diazepam serum levels are increased by esomeprazole but the clinical relevance of this is unknown.

Clinical evidence

(a) Esomeprazole

Esomeprazole inhibits the cytochrome P450 isoenzyme CYP2C19 so the plasma levels of drugs that are metabolised by this isoenzyme might be expected to be increased by concurrent use. This is true for **diazepam**, which showed a 45% decrease in clearance (which would be expected to result in some increase in its levels) when given with esomeprazole 40 mg.¹

(b) Lansoprazole

Lansoprazole 60 mg daily for 10 days was found to have no effect on the pharmacokinetics of a single 100-microgram/kg intravenous dose of **diazepam**.²

(c) Omeprazole

Two elderly patients, both smokers, taking **triazolam** with **lorazepam** or **flurazepam**, developed gait disturbances when they were given omeprazole 20 mg daily. They rapidly recovered when either the benzodiazepines or the omeprazole were stopped.³ A brief report describes a patient taking omeprazole who became wobbly and sedated by small, unspecified doses of **diazepam**,⁴ and another report describes a patient who developed toxic levels of nordiazepam and remained unconscious for 13 days after receiving a high dose of **clorazepate** (1500 mg over about 29 hours) and omeprazole 80 mg daily.⁵

One study in 8 healthy subjects found that omeprazole 40 mg daily for one week reduced the clearance of a single 100-microgram/kg intravenous dose of **diazepam** by 54%,⁶ while another study found that omeprazole 20 mg reduced **diazepam** clearance by 27%.⁷

A further study found that omeprazole 40 mg reduced the oral clearance of **diazepam** by 42% in white American subjects but only by 21% in Chinese subjects.⁸ Metaboliser status (see 'Genetic factors', (p.4)) was also found to be important in another study of this interaction: only extensive metabolisers of CYP2C19 showed a significant decrease in **diazepam** clearance when given omeprazole.⁹

(d) Pantoprazole

In a placebo-controlled study in 12 healthy subjects, intravenous pantoprazole 240 mg for 7 days did not change the half-life, clearance and AUC of a 100-microgram/kg intravenous bolus dose of **diazepam**.¹⁰

(e) Rabeprazole

Rabeprazole 20 mg daily or placebo was given to 15 patients (in 3 groups) for 23 days with a single 100-microgram/kg dose of **diazepam** on day 8. Each group contained at least two poor metabolisers and three extensive metabolisers of the cytochrome P450 isoenzyme CYP2C19 (see 'Genetic factors', (p.4)). No significant changes in the pharmacokinetics of the **diazepam** were seen.¹¹ Another study similarly found that rabeprazole does not affect the pharmacokinetics of **diazepam** in both poor and extensive metabolisers of CYP2C19.⁹

Mechanism

In vitro studies with human liver microsomes suggest that omeprazole inhibits diazepam metabolism because it inhibits the cytochrome P450 isoenzymes CYP3A, and CYP2C19.¹² Studies in humans suggest that CYP2C19 may be the most important isoenzyme in this interaction.⁸ The reaction with lorazepam (and other glucuronidated benzodiazepines) may possibly not be an interaction (so it is suggested) but an adverse effect of giving sedating medications to markedly anaemic patients.⁴

Importance and management

Information is limited, but what is currently known suggests that patients given omeprazole, and possibly esomeprazole, with diazepam may experience increased benzodiazepine effects (sedation, unstable gait etc). If this occurs the benzodiazepine dosage should be reduced. Lansoprazole, pantoprazole and rabeprazole do not appear to interact with diazepam.

Further, an *in vitro* study suggests that omeprazole may possibly interact similarly with **midazolam**,¹³ although this needs confirmation. There seems to be no information regarding other benzodiazepines.

Benzodiazepines + Quinolones

Ciprofloxacin causes a marked reduction in the clearance of diazepam, but this does not appear to be clinically important in most individuals. Ciprofloxacin appears not to interact with temazepam, and gatifloxacin appears not to interact with midazolam.

Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

Ciprofloxacin 500 mg twice daily for 3 days was found to have no effect on the pharmacokinetics of **diazepam** in a study in 10 healthy subjects.¹ However, a later study in 12 healthy subjects found that ciprofloxacin 500 mg twice daily for 5 days increased the AUC of a single 5-mg intra-

venous dose of **diazepam** by 50%, reduced its clearance by 37% and doubled its half-life. These changes caused no significant alteration in the performance of a number of psychometric tests. It was suggested that the clearance of diazepam was reduced because ciprofloxacin inhibited the cytochrome P450-mediated metabolism of diazepam.² Another study by the same group found that ciprofloxacin does not interact with **temazepam**.³

It seems unlikely that any marked increases in **diazepam** effects (drowsiness etc.) will occur in most patients, but it may possibly be significant in those who have reduced renal or hepatic clearance (e.g. the elderly).² This needs confirmation.

(b) *Gatifloxacin*

Gatifloxacin 400 mg daily for 5 days had no effect on the pharmacokinetics of **midazolam** in 14 healthy subjects. The pharmacokinetics of gatifloxacin were also unaffected by concurrent use.⁴

Benzodiazepines and related drugs + Rifampicin (Rifampin)

Rifampicin causes a very marked increase in the metabolism and/or clearance of diazepam and nitrazepam. Rifampicin also causes a marked increase in the clearance of midazolam and triazolam and the non-benzodiazepine hypnotics, zaleplon, zolpidem and zopiclone. Benzodiazepines and related drugs that are metabolised similarly are expected to interact in the same way.

Clinical evidence

A. Benzodiazepines

(a) *Diazepam*

The mean half-life of diazepam was reduced from 58 to 14 hours and the clearance was increased fourfold in 7 patients with tuberculosis who were given daily doses of isoniazid 500 mg to 2.2 g, rifampicin 450 to 600 mg and ethambutol 25 mg/kg, when compared with healthy control subjects.¹ In 21 healthy subjects rifampicin 600 mg or 1.2 g daily for 7 days increased the clearance of diazepam by about threefold.²

(b) *Midazolam*

A pharmacokinetic study in 10 healthy subjects found that rifampicin 600 mg daily for 5 days reduced the AUC of a single 15-mg oral dose of midazolam by 96%, and reduced the half-life by almost two-thirds. The psychomotor effects of the midazolam (as measured by the digit symbol substitution test, Maddox wing test, postural sway and drowsiness) were almost totally lost.³

(c) *Nitrazepam*

A study in healthy subjects found that rifampicin 600 mg daily for 7 days increased the total body clearance of nitrazepam by 83%.⁴

(d) *Temazepam*

A study found that the pharmacokinetics of temazepam were unchanged by rifampicin.⁴

(e) *Triazolam*

Triazolam 500 micrograms orally was given to 10 healthy subjects before and after rifampicin 600 mg daily or a placebo for 5 days. Rifampicin reduced the triazolam AUC by 95% and decreased the maximum plasma triazolam levels by 88% when compared with the placebo group. The elimination half-life was reduced from 2.8 to 1.3 hours. Pharmacodynamic tests (drowsiness, sway, Maddox wing, etc.) showed that rifampicin abolished the effects of triazolam.⁵

B. Non-benzodiazepine hypnotics

(a) *Zaleplon*

A non-randomised, crossover study in healthy subjects found that rifampicin 600 mg daily for 14 days increased the clearance of a 10-mg dose of zaleplon by 5.4-fold, decreasing its maximum serum levels and AUC by 80%.⁶

(b) *Zolpidem*

In a randomised, placebo-controlled, study, 8 healthy subjects were given rifampicin 600 mg daily for 5 days and then on day 6 they were given a single 20-mg oral dose of zolpidem. It was found that the rifampicin reduced the zolpidem AUC by 73%, reduced the maximum plasma level by about 60% and reduced its half-life from 2.5 to 1.6 hours. A significant reduction in the effects of zolpidem was also seen, as measured by a number of psychomotor tests (digital symbol substitution, critical flicker fusion, subjective drowsiness, etc.).⁷

(c) *Zopiclone*

In a two-phase study, 8 healthy subjects were given rifampicin 600 mg or a placebo daily for 5 days, with a single 10-mg oral dose of zopiclone on day 6. The rifampicin reduced the zopiclone AUC by 82%, decreased the peak serum levels by 71% and reduced its half-life from 3.8 to 2.3 hours. A significant reduction in the effects of zopiclone was also seen, as measured by the performance of psychomotor tests.⁸

Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism of several benzodiazepines and the non-benzodiazepine hypnotics, zaleplon, zolpidem and zopiclone, thereby decreasing their levels. The metabolism of midazolam by the cytochrome P450 isoenzyme CYP3A4 in both liver and gut is affected.³ The enzyme inducing effects of rifampicin seem to predominate if isoniazid (an enzyme inhibitor) is also present. Temazepam undergoes glucuronidation and is therefore unaffected by rifampicin.

Importance and management

The documentation of these interactions is limited but what has been reported is consistent with the way rifampicin interacts with many other drugs. The clinical importance of some of these interactions between the benzodiazepines and related drugs and rifampicin has not yet been assessed but what is known suggests that the dosage of diazepam and nitrazepam may need to be increased if rifampicin is given. Be alert for a reduction in the effects of other similarly metabolised benzodiazepines (e.g. chlordiazepoxide, flurazepam).

The effect of rifampicin on oral midazolam, triazolam, zaleplon, zolpidem and zopiclone is so large that they are likely to become ineffective and an alternative should be used instead. Alprazolam is also predicted to interact because CYP3A is involved with its metabolism.⁹

Those benzodiazepines that, like temazepam, undergo glucuronidation (e.g. lorazepam, oxazepam) are not expected to be affected by rifampicin and may be useful alternatives.

Benzodiazepines + Saw palmetto

No pharmacokinetic interaction is expected between saw palmetto and alprazolam or midazolam.

Clinical evidence, mechanism, importance and management

Saw palmetto 320 mg daily, given to 12 subjects for 16 days, did not affect the pharmacokinetics of a single 2-mg dose of **alprazolam** given on day 14.¹ In another study in 12 healthy subjects who took saw palmetto, 160 mg twice daily for 28 days, there was no change in metabolic ratio of a single 8-mg dose of **midazolam**.² These findings suggest that saw palmetto does not alter the activity of the cytochrome P450 isoenzyme CYP3A4, and no dosage adjustments of these benzodiazepines would be expected to be needed on concurrent use.

Benzodiazepines and related drugs + SNRIs

Visual hallucinations have been seen in one patient given zolpidem and venlafaxine. No important interaction normally appears to occur between venlafaxine and alprazolam or diazepam. The pharmacokinetics of duloxetine were not affected by lorazepam or temazepam.

Clinical evidence

A 27-year-old woman who had been taking **venlafaxine** 37.5 mg at night for a week and terfenadine for a few years started taking **zolpidem** 10 mg daily. After 2 days, and within 45 minutes of the **zolpidem** dose, she developed visual hallucinations, which lasted for 2 to 4 hours. A similar episode occurred 2 weeks later when she had discontinued the terfenadine.¹

A double-blind study in 18 healthy subjects taking **venlafaxine** 50 mg every 8 hours found that the concurrent use of **diazepam** 10 mg did not have a clinically significant effect on the pharmacokinetics of either drug, or their major active metabolites (*O*-desmethylvenlafaxine and desmethyldiazepam). **Diazepam** affected the performance of a battery of pharmacodynamic tests, but the addition of **venlafaxine** had no further effects.²

A study in 16 healthy subjects found that **venlafaxine** 75 mg twice daily reduced the AUC of a single 2-mg oral dose of **alprazolam** by 29% and reduced its half-life by 21%, but the performance of psychometric tests were only minimally changed.³

Mechanism

Uncertain. It has been suggested that a pharmacodynamic interaction between serotonin reuptake inhibition and zolpidem may lead to prolonged zolpidem-associated hallucinations in susceptible individuals.¹

Importance and management

The studies suggest that no special precautions are necessary during the concurrent use of venlafaxine and diazepam or alprazolam, or between **duloxetine** and lorazepam or temazepam. Similarly, the manufacturer of **duloxetine** reports that its pharmacokinetics were not affected by lorazepam or temazepam under steady state conditions.⁴

However, a pharmacodynamic interaction may occur. Hallucinations have been seen with zolpidem alone, and they have also occurred, rarely, when zolpidem and some benzodiazepines were given with the 'SSRIs', (below), which are related to venlafaxine. However, adverse effects such as these seem rare and the concurrent use of these drugs need not be avoided, but bear this possible interaction in mind if hallucinations occur.

3. Amchin J, Zarycranski W, Taylor KP, Albano D, Klockowski PM. Effect of venlafaxine on the pharmacokinetics of alprazolam. *Psychopharmacol Bull* (1998) 34, 211–19.
4. Cymbalta (Duloxetine hydrochloride). Eli Lilly and Company. US Prescribing information, May 2007.

Benzodiazepines and related drugs + SSRIs

There is some evidence to suggest that the metabolism of some benzodiazepines (such as alprazolam, bromazepam, diazepam, and also possibly midazolam, nitrazepam and triazolam) may be reduced by some SSRIs (such as fluoxetine and fluvoxamine). On the whole, no clinically significant interaction appears to occur between other SSRIs and the benzodiazepines or related drugs such as cloral hydrate or zaleplon. There is some evidence to support the suggestion that sedation is likely to be increased by the concurrent use of SSRIs and benzodiazepines. Rare cases of hallucinations have been seen with zolpidem and some SSRIs. Symptoms of the serotonin syndrome have been reported in two patients taking paroxetine and a benzodiazepine.

Clinical evidence

(a) Citalopram

The UK manufacturer of citalopram says that no pharmacodynamic interactions have been noted in clinical studies in which citalopram was given with benzodiazepines,¹ although the US manufacturer points out that caution should be used with citalopram and any CNS active drug.²

A general study in psychiatric patients found that when data on benzodiazepines was pooled, they caused a modest 23% increase in serum citalopram levels, which is almost certainly too small to be clinically relevant. **Alprazolam** was the only benzodiazepine to cause an elevation of citalopram levels (by 13%) when analysed alone.³ In another study, citalopram was found to have no effect on **alprazolam** plasma levels, although the time to maximum **alprazolam** concentration was increased by 30 minutes.⁴ Similarly, a study in 17 healthy subjects found no pharmacokinetic interaction between **triazolam** and citalopram, and it was suggested that **triazolam** and other substrates of the cytochrome P450 isoenzyme CYP3A4 are unlikely to have pharmacokinetic interactions with citalopram.⁵

(b) Fluoxetine

The concurrent use of fluoxetine 60 mg daily has been found to reduce the clearance of **alprazolam** 1 mg four times daily by about 21% and to increase its plasma levels by about 30%. These changes were accompanied by increased psychomotor impairment.⁶ This appears to be due to reduced **alprazolam** metabolism.⁷ Another study also reported impaired **alprazolam** metabolism, considered to be due to the inhibition of cytochrome P450 isoenzyme CYP3A4 by fluoxetine, although no significant changes in **alprazolam** pharmacodynamics were found.⁴

Fluoxetine 30 mg, given daily for 1 or 8 days, had no effect on the pharmacokinetics of **diazepam** 10 mg.⁸ A later study by the same group, using 60 mg of fluoxetine suggested that the **diazepam** half-life and AUC were increased, possibly because the fluoxetine decreased the metabolism of **diazepam**. However, they concluded that this was not of any clinical significance.⁹ Another study found that fluoxetine 60 mg alone did not affect psychomotor performance but fluoxetine 60 mg plus **diazepam** 5 mg significantly impaired the divided attention tracking test and vigilance test more than with **diazepam** 5 mg alone.¹⁰ Other studies found that the pharmacokinetics of **clonazepam**,¹¹ **estazolam**,¹² **midazolam**,^{13,14} **triazolam**,¹⁵ and **zolpidem**^{16,17} were not significantly affected by fluoxetine.

In contrast, isolated cases of visual hallucinations lasting up to 7 hours have been reported in patients taking **zolpidem** who were also taking fluoxetine.¹⁸ Marked drowsiness occurred for a whole day in a patient taking fluoxetine 20 mg daily after being given **cloral hydrate** 500 mg the night before. She later tolerated **cloral hydrate** 1 g in the absence of fluoxetine without adverse effects.¹⁹

(c) Fluvoxamine

In 60 healthy subjects fluvoxamine 50 mg daily for 3 days then 100 mg daily for 7 days, doubled the plasma levels of **alprazolam** 1 mg four times daily given on days 7 to 10. The **alprazolam** clearance was more than halved. Psychomotor performance and memory were found to be significantly worsened, even after only one day.²⁰ A study in 23 Japanese patients found that fluvoxamine increased the plasma levels of **alprazolam** by 58%. There was wide interpatient variability, possibly associated with differences in the cytochrome P450 isoenzyme CYP2C19 levels in these patients (see 'Genetic factors', (p.4)), although it is unclear exactly what impact this isoenzyme has on the interaction.²¹

Fluvoxamine 50 mg twice daily increased the plasma levels of a single 12-mg dose of **bromazepam** in 12 healthy subjects by 36% and increased the AUC almost 2.5-fold. Some increased impairment in cognitive function was seen.²²

Fluvoxamine has been found not to interact adversely with **cloral hydrate**.²³ Fluvoxamine (50 mg on day one, 100 mg on day 2, then 150 mg daily thereafter) for 16 days decreased the clearance of a single 10-mg dose of **diazepam** given on day 4 in 8 healthy subjects by about 65%. The half-life was increased from 51 to 118 hours, and the AUC was increased threefold.²⁴

Fluvoxamine 50 mg twice daily caused a very small, non-significant, increase in the serum levels and AUC of a single 4-mg dose of **lorazepam** in 12 healthy subjects.²²

A study in 10 healthy subjects¹⁴ found that fluvoxamine 50 mg twice daily for 8 days then 100 mg twice daily for 6 days had minimal effects on the pharmacokinetics of a single 10-mg dose of **midazolam** given on day 12.

In a placebo-controlled study in 12 healthy subjects it was found that fluvoxamine 25 mg twice daily for 14 days had no effect on the pharmacokinetics of a single 20-mg dose of **quazepam**. However, formation of the metabolite 2-oxoquazepam was decreased, and there was a minor decrease in the sedative effects of **quazepam** at 4 hours, although these changes were considered to be of little clinical significance.²⁵

(d) Paroxetine

No important changes in the pharmacokinetics of paroxetine were seen when 12 healthy subjects given paroxetine 30 mg daily were also given **diazepam** 5 mg three times a day. Adverse events were not increased by the combination.²⁶ In another study it was found that paroxetine did not increase the impairment of a number of psychomotor tests caused by **oxazepam**.²⁷ *In vitro* studies using human liver microsomal enzymes have shown that paroxetine is a relatively weak inhibitor of **alprazolam** metabolism mediated by the cytochrome P450 subfamily CYP3A.^{28,29} Furthermore, a randomised, placebo-controlled study in 22 healthy subjects reported no evidence for a pharmacokinetic or pharmacological interaction between paroxetine and **alprazolam**.³⁰

An isolated report describes worsening anxiety, agitation, mild abdominal cramps and diaphoresis in a woman taking paroxetine, shortly after starting **clonazepam** (dosage stated as one tablet). This toxic response was suggested as being the serotonin syndrome, although in fact many of the usual signs were absent and moreover, **clonazepam** has actually been used to treat the myoclonus that occurs in the serotonin syndrome. She was effectively treated with **lorazepam**.³¹ Another report describes a patient who was admitted to hospital with symptoms of the serotonin syndrome within 6 days of starting daily treatment with paroxetine 20 mg, **etizolam** 1 mg and **brotizolam** 250 micrograms. Paroxetine was discontinued on day 6. The serotonin syndrome usually resolves within 24 hours of discontinuing the causative medication but symptoms in this patient continued for a total of 10 days.³²

In a double-blind study in healthy subjects it was found that paroxetine 20 mg for 9 days had no effect on the pharmacokinetics of **zaleplon** 20 mg, and psychomotor performance was unaffected by concurrent use.³³

An isolated report describes a healthy 16-year-old girl with depression who took paroxetine 20 mg daily for 3 days, and then on the evening of the third night a single 10-mg dose of **zolpidem**. Within 1 hour she began to hallucinate, then became disorientated and was unable to recognise members of her family. She recovered spontaneously within 4 hours.³⁴

(e) Sertraline

No clinically relevant effects were found in interaction studies in which sertraline was given with a single intravenous dose of **diazepam**.^{35,36} One *in vitro* study in human liver microsomes suggested that sertraline inhibits the metabolism of **alprazolam**,⁷ whereas another suggested no interaction occurred.³⁷ *In vivo* studies largely demonstrate a lack of interaction. For example, a pharmacokinetic study in 10 healthy subjects found that sertraline 50 to 150 mg daily had no effect on the pharmacokinetics of **alprazolam**, although some small decreases in a driving simulation score were seen at the 100- and 150-mg doses of sertraline.³⁸ Similarly, sertraline 50 mg daily had no effect on the pharmacokinetics of **alprazolam** 1 mg daily in 12 healthy subjects, after 2 weeks of concurrent use.³⁷

A study in 13 subjects given daily doses of **clonazepam** 1 mg with sertraline 100 mg for 10 days found no evidence that the addition of sertraline

to clonazepam made the subjects more sedated or less able to carry out simple psychometric tests.³⁹

Sertraline appears to have no clinically significant effects on the pharmacokinetics of **zolpidem**,⁴⁰ but isolated cases of visual hallucinations lasting up to 7 hours have been reported in patients on **zolpidem** who were taking sertraline.¹⁸

Mechanism

The evidence suggests that fluvoxamine inhibits the metabolism of those benzodiazepines that undergo oxidation (e.g. alprazolam,²⁹ bromazepam, diazepam) thereby increasing and prolonging their effects, but not those that are metabolised by glucuronidation (e.g. lorazepam). Zaleplon is metabolised by aldehyde oxidase and therefore does not interact.

Importance and management

Evidence is limited, but what is known suggests that the dosages of alprazolam, bromazepam, diazepam and other similarly metabolised benzodiazepines such as nitrazepam should be reduced, probably by half, in the presence of fluvoxamine to avoid adverse effects (drowsiness, reduced psychomotor performance and memory). The US manufacturer recommends avoiding the use of fluvoxamine with diazepam as substantial diazepam accumulation could occur. They also note that as fluvoxamine has non-linear kinetics, the effects of higher doses of fluvoxamine such as 300 mg could be substantially greater, particularly with long-term diazepam use.⁴¹ The UK manufacturer also includes midazolam and triazolam.⁴² Fluvoxamine is unlikely to affect lorazepam and other benzodiazepines metabolised by glucuronidation (e.g. lorazepam, oxazepam, temazepam).⁴¹ It seems unlikely that sertraline will affect any of the benzodiazepines and it may therefore be a useful alternative to fluvoxamine. Nevertheless, the manufacturers of sertraline say that it should not be given with benzodiazepines or other tranquillisers in patients who drive or operate machinery.⁴³

The hallucinations seen with the SSRIs and zolpidem appear rare, and reactions of this kind have been seen with zolpidem alone. The concurrent use of these drugs need not be avoided, but bear this possible interaction in mind if hallucinations occur.

Benzodiazepines + St John's wort (*Hypericum perforatum*)

St John's wort decreases the plasma levels of quazepam, although this did not reduce its effects in one study. Alprazolam appears not to interact, although this needs confirmation. The bioavailability of midazolam was reduced by long-term but not single doses of St John's wort.

Clinical evidence, mechanism, importance and management

(a) Alprazolam

Alprazolam 1 or 2 mg was given to 7 healthy subjects on the third day of a 3-day treatment period with St John's wort (*Solaray*; hypericin content standardised at 0.3%) 300 mg three times daily. The pharmacokinetics of alprazolam were unchanged by the St John's wort, but the authors note that 3 days may have been an insufficient time for St John's wort to fully induce cytochrome P450 isoenzymes.¹ In another study, 16 healthy subjects were given St John's wort extract 120 mg (*Esbericum* capsules; corresponding to 0.5 mg total hypericin and 1.76 mg hyperforin) twice daily for 10 days. A single 1-mg dose of alprazolam was given on the day before treatment with St John's wort and on the last day of treatment. St John's wort extract at this low dosage and low hyperforin content had no clinical-

ly relevant effects on the pharmacokinetics of alprazolam, when compared with 12 subjects given placebo.²

(b) Midazolam

An open-label study in 12 healthy subjects found that a single 900-mg dose of St John's wort had no significant effect on the pharmacokinetics of single doses of either oral midazolam 5 mg or intravenous midazolam 0.05 mg/kg, although there was a trend for increased oral clearance. However, St John's wort 300 mg three times daily for 14 or 15 days decreased the AUC and maximum plasma concentration of oral midazolam by about 50% and 40%, respectively. Intravenous midazolam was not significantly affected. St John's wort appears to increase the metabolism of oral midazolam by induction of the cytochrome P450 isoenzyme CYP3A4 in the gut, resulting in reduced midazolam bioavailability.³ Similar results were found in another study.⁴

(c) Quazepam

In a placebo-controlled study, 13 healthy subjects were given St John's wort (*TruNature*; hypericin content standardised at 0.3%) 300 mg three times daily for 14 days with a single 15-mg dose of quazepam on day 14. Although St John's wort did not affect the pharmacodynamic effects of quazepam it did decrease the quazepam AUC by 26% and the maximum plasma levels by 29%. This was attributed to the effects of St John's wort on the cytochrome P450 isoenzyme CYP3A4, by which quazepam is metabolised.⁵

Benzodiazepines + Sucrose polyesters

Sucrose polyesters (e.g. *Olestra*) do not appear to interact with diazepam.

Clinical evidence, mechanism, importance and management

A single 5-mg dose of **diazepam** was given to 8 healthy subjects with 18 g of sucrose polyester (*Olestra*). Sucrose polyester had no effect on the pharmacokinetics of **diazepam**.¹ Sucrose polyesters, are non-absorbable, non-caloric fat replacements. It has been concluded that sucrose polyesters are unlikely to reduce the absorption of oral drugs in general.²

2. Goldman P. *Olestra*: assessing its potential to interact with drugs in the gastrointestinal tract. *Clin Pharmacol Ther* (1997) 61, 613–18.

Benzodiazepines + Tadalafil

Tadalafil does not alter the pharmacokinetics of midazolam.

Clinical evidence, mechanism, importance and management

An open label study in 12 healthy subjects found that while taking tadalafil 10 mg daily for 14 consecutive days, the pharmacokinetics of a single 15-mg oral dose of midazolam were unchanged.¹ Since midazolam is metabolised by the cytochrome P450 isoenzyme CYP3A4, it was concluded that the absence of any interaction shows that tadalafil does not inhibit or induce the activity of this isoenzyme.² No special precautions are therefore needed if midazolam is given with tadalafil.

2. Eli Lilly and Company. Personal communication, March 2003.

Benzodiazepines + Terbinafine

Terbinafine does not interact with midazolam or triazolam to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

Terbinafine 250 mg daily for 4 days had no effect on the pharmacokinetics of a single 7.5-mg dose of **midazolam**¹ or a single 250-microgram dose of **triazolam**² in 12 healthy subjects. The performance of a number of psychomotor tests was unaffected by concurrent use. No special precautions would seem to be necessary if terbinafine is given with either of these drugs.

2. Varhe A, Olkkola KT, Neuvonen PJ. Fluconazole, but not terbinafine, enhances the effects of triazolam by inhibiting its metabolism. *Br J Clin Pharmacol* (1996) 41, 319–23.

Benzodiazepines and related drugs + Tobacco

Smokers may possibly need larger doses of some benzodiazepines and zolpidem than non-smokers.

Clinical evidence, mechanism, importance and management

Some studies have suggested that smoking does not affect the pharmacokinetics of **diazepam**,^{1,2} **chlordiazepoxide**,³ **clorazepate**,⁴ **lorazepam**,² **midazolam**,² or **triazolam**,⁵ but others have found that the clearance of **alprazolam**,⁶ **clorazepate**,⁷ **diazepam**,⁸ **lorazepam**⁹ and **oxazepam**^{10,11} is increased by smoking, but not all the changes were significant.⁸ The Boston Collaborative Drug Surveillance Program reported a decreased frequency of drowsiness in smokers who took **diazepam** or **chlordiazepoxide**,¹² which confirmed the findings of a previous study.¹³ It has also been noted that two heavy smokers had a very high clearance and did not experience any sedative effects following the use of **zolpidem**.¹⁴

The probable reason for the reduction in sedative effects with these drugs is that some of the components of tobacco smoke are enzyme inducers, which increase the rate at which the liver metabolises these benzodiazepines, thereby reducing their effects. The inference to be drawn is that smokers may possibly need larger doses than non-smokers to achieve the same therapeutic effects. Smoking also possibly reduces the drowsiness that the benzodiazepines and non-benzodiazepine hypnotics, such as **zolpidem**, can cause. However, one study suggested that caffeine intake,¹³ and others suggest age, may affect the response to benzodiazepines, so the picture is not altogether clear. Whether any of these interactions has much clinical relevance awaits assessment.

Benzodiazepines + Vinpocetine

Vinpocetine does not appear to interact adversely with oxazepam. Vinpocetine may improve short-term memory impairment induced by flunitrazepam.

Clinical evidence, mechanism, importance and management

No changes in the steady-state plasma levels of **oxazepam** 10 mg three times daily were seen in 16 healthy subjects who took vinpocetine 10 mg three times daily for 7 days.¹ There would therefore seem to be no reason for taking special precautions if these two drugs are given together.

A study in 8 healthy subjects found that vinpocetine 40 mg three times daily for 2 days did not significantly improve **flunitrazepam**-induced impairment of memory, although the combination did appear to significantly improve patients ability to sleep.²

2. Bhatti JZ, Hindmarch I. Vinpocetine effects on cognitive impairments produced by flunitrazepam. *Int Clin Psychopharmacol* (1987) 2, 325–31.

Benzodiazepines and related drugs + Xanthines

Aminophylline, theophylline and caffeine appear to antagonise the effects of the benzodiazepines (mainly sedative effects, but possibly also anxiolytic effects), and aminophylline and theophylline appear to reduce the levels of alprazolam. The effects of zopiclone may be similarly antagonised.

Clinical evidence

A. Benzodiazepines

In a comparative study, two groups of patients were given **alprazolam** 500 micrograms twice daily for 7 days. One of the patient groups had 6 patients who had chronic obstructive pulmonary disease (COPD) and were taking **theophylline**, and the other group had 7 patients with chronic heart failure or atherosclerotic disease (one patient also with COPD) and were not taking **theophylline**. On day 7, those taking the **theophylline** were found to have lower trough serum **alprazolam** levels of 13.25 nanograms/mL, while in the other group the levels were 43.92 nanograms/mL.¹

A patient who was unrousable and unresponsive having been given **diazepam** 60 mg given over 10 minutes and nitrous oxide/oxygen anaesthesia, rapidly returned to consciousness when given **aminophylline** 56 mg intravenously.² Other reports confirm this antagonism of **diazepam**, by low doses of **aminophylline** (60 mg to 4.5 mg/kg intravenously).^{3–5} Caffeine, and to a lesser extent **theophylline** and **aminophylline**, counteract the drowsiness and mental slowness induced by a single 10- to 20-mg dose of **diazepam**.^{6–9} **Flunitrazepam**,¹⁰ **lorazepam**,¹¹ and **midazolam**¹² also appear to be affected; however, there is some controversy about whether or not **theophylline** and **aminophylline** antagonise the effects of **midazolam**.^{13,14}

There is also some evidence to suggest that **caffeine** and **clonazepam**¹⁵ or **triazolam**¹⁶ have mutually opposing effects.

B. Non-benzodiazepine hypnotics

Zopiclone appears to counter the stimulant effects of **caffeine** more easily than **caffeine** counters the sedative effects of **zopiclone**.¹⁶ No pharmacokinetic interaction occurred between **zolpidem** and **caffeine** (given as one cup of coffee containing **caffeine** 300 mg), and the hypnotic effects of **zolpidem** were unchanged.¹⁷

Mechanism

Uncertain. One suggestion is that the xanthines can block adenosine receptors.³ Another is that the xanthines induce the metabolism of the benzodiazepines by the liver so that levels, and therefore effects, are reduced.¹⁸

Importance and management

The documentation is somewhat sparse and there is a need for more study over the range of benzodiazepines and related drugs, but the overall picture is that these interactions are established. The extent to which these xanthines actually reduce the anxiolytic effects of the benzodiazepines remains uncertain (it needs assessment) but be alert for reduced benzodiazepine effects if both are used. Caffeine in tea or coffee appears to reduce the sedative effects of triazolam and zopiclone. This would appear to be a disadvantage at night, but may possibly be useful the next morning.

Buspiron + Azoles

The plasma levels of buspiron are markedly increased by itraconazole. Ketoconazole is predicted to interact similarly.

Clinical evidence

In a placebo-controlled study, 8 healthy subjects were given buspiron 10 mg, before and after taking **itraconazole** 100 mg twice daily for 4 days. It was found that the buspiron maximum plasma levels and its AUC were increased 13-fold and 19-fold, respectively, by **itraconazole**. These increased buspiron levels caused a moderate impairment of psychomotor performance (digital symbol substitution, body sway, drowsiness, etc.) and an increase in adverse effects.¹

Mechanism

Itraconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which buspiron is metabolised. Itraconazole therefore increases buspiron levels and effects.

Importance and management

Direct information appears to be limited to this study but the interaction would seem to be established. The dosage of buspiron should be greatly reduced if itraconazole is given concurrently. The manufacturers recommend 2.5 mg daily² or twice daily.³ **Ketoconazole** is predicted to interact similarly because it is also a potent CYP3A4 inhibitor.¹

3. Buspar (Buspiron hydrochloride). Bristol-Myers Pharmaceuticals. UK Summary of product characteristics, March 2007.

Buspiron + Calcium-channel blockers

Diltiazem and verapamil can markedly raise the plasma levels of buspiron, increasing the likelihood of adverse effects.

Clinical evidence, mechanism, importance and management

In a randomised study in 9 healthy subjects, **diltiazem** 60 mg three times daily for 5 doses increased the AUC of a single 10-mg dose of buspiron by 5.5-fold and increased its maximum plasma levels by 4.1-fold.

When **verapamil** 80 mg three times daily was similarly given with buspiron, the buspiron AUC and maximum plasma levels were both increased by 3.4-fold.

The increased buspiron levels are thought to occur because both **diltiazem** and **verapamil** inhibit the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of the buspiron.¹

The practical consequences of this interaction are that the effects of buspiron are likely to be increased by **diltiazem** and **verapamil**. Concurrent use need not be avoided but be alert for the need to reduce the buspiron dosage. The US manufacturer suggests adjusting according to response,² while the UK manufacturer suggests starting with buspiron 2.5 mg twice daily.³ Information about other calcium-channel blockers appears to be lacking, but they do not commonly appear to interact by inhibiting CYP3A4 (see 'Calcium-channel blockers', (p.860)).

3. Buspar (Buspiron hydrochloride). Bristol-Myers Pharmaceuticals. UK Summary of product characteristics, March 2007.

Buspiron + Grapefruit juice

Grapefruit juice can significantly increase plasma levels of buspiron.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 10 healthy subjects were given either double-strength grapefruit juice 200 mL or water 200 mL three times daily for 2 days, with a single 10-mg dose of buspiron, given at the same time as the grapefruit juice or water, on the third day, with additional grapefruit juice or water 30 and 90 minutes later. Grapefruit juice increased the peak plasma level and AUC of buspiron by 4.3-fold and 9.2-fold, respectively. The time to peak buspiron level was increased from 0.75 to 3 hours. An increase in the effects of buspiron was seen only in the subjective overall drug effect. Grapefruit juice probably delayed gastric emptying and inhibited the metabolism of buspiron by the cytochrome P450 isoenzyme CYP3A4. The authors of this study recommended that the concurrent use of buspiron and grapefruit juice should be avoided.¹ However the UK manufacturer recommends that a lower dose of buspiron 2.5 mg twice daily should be used with potent inhibitors of CYP3A4 such as grapefruit juice:² the US manufacturer suggests that patients should avoid drinking large quantities of grapefruit juice.³

3. BuSpar (Buspiron hydrochloride). Bristol-Myers Squibb Company. US Prescribing information, March 2007.

Buspiron + Herbal medicines

Two patients taking buspiron developed marked CNS effects after starting to take herbal medicines including St John's wort and ginkgo biloba.

Clinical evidence, mechanism, importance and management

A 27-year-old woman who had been taking buspirone 30 mg daily for over one month started to take **St John's wort** (*Hypericum 2000 Plus*, Herb Valley, Australia) three tablets daily. After 2 months she complained of nervousness, aggression, hyperactivity, insomnia, confusion and disorientation, which was attributed to the serotonin syndrome. The **St John's wort** was stopped, the buspirone was increased to 50 mg daily and her symptoms resolved over a week.¹ A 42-year-old woman who was taking fluoxetine 20 mg twice daily and buspirone 15 mg twice daily started to develop symptoms of anxiety, with episodes of over-sleeping and memory deficits. It was discovered that she had been self-medicating with **St John's wort**, **ginkgo biloba** and melatonin. She was asked to stop the non-prescribed medication and her symptoms resolved.²

The exact mechanism of these interactions are not clear, but it seems most likely they were due to the additive effects of the buspirone and the herbal medicines, either through their effects on elevating mood or through excess effects on serotonin. Fluoxetine may have had a part to play in one of the cases, see 'SSRIs + St John's wort (*Hypericum perforatum*)', p.1224. The clinical significance of these cases is unclear, but they highlight the importance of considering adverse effects from herbal medicines when they are used with conventional medicines.

Buspirone + Macrolides

The plasma levels of buspirone are markedly increased by erythromycin.

Clinical evidence

In a placebo-controlled study buspirone 10 mg was given to 8 healthy subjects before and after they took **erythromycin** 500 mg three times daily for 4 days. It was found that the buspirone maximum plasma levels and its AUC were increased fivefold and sixfold, respectively, by the **erythromycin**. These increased buspirone levels caused a moderate impairment of psychomotor performance (digital symbol substitution, body sway, drowsiness, etc.) and an increase in adverse effects.¹

Mechanism

Erythromycin is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which buspirone is metabolised. Erythromycin therefore increases buspirone levels and hence its effects.

Importance and management

Direct information appears to be limited to this study but the interactions would seem to be established. The dosage of buspirone should be reduced if erythromycin is given concurrently. The manufacturers suggest using buspirone 2.5 mg twice daily,^{2,3} adjusted according to response.³

Other macrolides (such as **clarithromycin**) are also inhibitors of CYP3A4 and may therefore interact similarly.

1. Kivistö KT, Lamberg TS, Kantola T, Neuvonen PJ. Plasma buspirone concentrations are greatly increased by erythromycin and itraconazole. *Clin Pharmacol Ther* (1997) 62, 348–54.
2. Buspar (Buspirone hydrochloride). Bristol-Myers Pharmaceuticals. UK Summary of product characteristics, March 2007.
3. BuSpar (Buspirone hydrochloride). Bristol-Myers Squibb Company. US Prescribing information, March 2007.

Buspirone + Miscellaneous

Buspirone does not appear to interact with amitriptyline, cimetidine or terfenadine. An isolated report describes mania when an alcoholic patient taking buspirone was given disulfiram. Nefazodone greatly increases buspirone levels.

Clinical evidence, mechanism, importance and management

(a) Amitriptyline

Buspirone 15 mg every 8 hours given with amitriptyline 25 mg every 8 hours for 10 days had no significant effect on the steady-state serum levels of amitriptyline or its metabolite, nortriptyline, in healthy subjects. No evidence of a pharmacodynamic interaction was seen.¹ There would seem to be no reason for avoiding concurrent use.

(b) Cimetidine

In 10 healthy subjects, cimetidine 1 g daily for 7 days had no effect on the plasma levels of buspirone 15 mg three times daily. Some small pharmacokinetic changes were seen, but the performance of three psychomotor function tests remained unaltered.² There would seem to be no reason for avoiding concurrent use.

(c) Disulfiram

An isolated report describes mania in an alcoholic patient taking buspirone 20 mg daily, possibly due to an interaction with disulfiram 400 mg daily,³ but buspirone on its own has also apparently caused mania.^{4,5} The reasons for this reaction are not understood, and the general significance of this isolated case is unknown.

(d) Nefazodone

Nefazodone 250 mg twice daily caused a 20-fold increase in the maximum plasma levels of buspirone 2.5 or 5 mg twice daily and a 50-fold increase in its AUC. Buspirone 5 mg twice daily raised the AUC of nefazodone by 23%, which is unlikely to be clinically significant. The manufacturer recommended that buspirone 2.5 mg daily should be used if nefazodone is given.⁶

(e) Terfenadine

A single 10-mg dose of buspirone was given to 10 healthy subjects after they had taken terfenadine 120 mg daily for 3 days. There were no significant effects on the pharmacokinetics or pharmacodynamics of buspirone.⁷

Buspirone + Protease inhibitors

Ritonavir, and possibly indinavir, are predicted to reduce the metabolism of buspirone. A single case report describes Parkinson-like symptoms attributed to concurrent use of buspirone with ritonavir and also possibly indinavir.

Clinical evidence, mechanism, importance and management

A 54-year-old man who had been taking high-dose buspirone (40 mg every morning and 30 mg every evening) developed Parkinson-like symptoms about 6 weeks after starting to take **ritonavir** 400 mg and **indinavir** 400 mg, both twice daily. The dose of buspirone was reduced to 15 mg three times daily, **ritonavir** and **indinavir** were discontinued, and amprenavir 1.2 g twice daily was started. The Parkinson-like symptoms were reduced after about one week and completely resolved after 2 weeks. Buspirone is metabolised by the cytochrome P450 isoenzyme CYP3A4, and it is probable that **ritonavir**, and possibly, but to a lesser extent, **indinavir**, inhibited the metabolism of buspirone resulting in toxic levels.¹ This appears to be an isolated case report however, the manufacturer of buspirone usually recommends that a lower dose of buspirone (2.5 mg twice daily in the UK) should be used with potent inhibitors of CYP3A4,² such as **ritonavir**.

2. Buspar (Buspirone hydrochloride). Bristol-Myers Pharmaceuticals. UK Summary of product characteristics, March 2007.

Buspirone + Rifampicin (Rifampin)

Rifampicin can cause a marked reduction in the plasma levels and effects of buspirone.

Clinical evidence

In a randomised, study, buspirone 30 mg daily was given to 10 healthy subjects, before and after they took rifampicin 600 mg daily for 5 days. It was found that rifampicin reduced the total AUC of buspirone by almost 90% and reduced its peak plasma levels by 87%. The pharmacodynamic effects of buspirone were reduced accordingly (as measured by digit symbol substitution, critical flicker fusion, body sway and visual analogue scales for subjective drowsiness).¹

Mechanism

Not fully established, but it is almost certain that rifampicin induces the cytochrome P450 isoenzyme CYP3A4 in the gut and liver, which metabolises buspirone. Therefore the metabolism and clearance of buspirone are increased.

Importance and management

Direct information appears to be limited to this study but it is consistent with the way rifampicin interacts with many other drugs. This interaction would appear to be clinically important. If both drugs are used be alert for the need to use an increased buspirone dosage.

1. Lambert TS, Kivistö KT, Neuvonen PJ. Concentrations and effects of buspirone are considerably reduced by rifampicin. *Br J Clin Pharmacol* (1998) 45, 381–5.

Buspirone + SSRIs

An isolated report describes the development of the serotonin syndrome when buspirone was given with citalopram. The combination of buspirone and fluoxetine can be effective, but seizures and worsening of symptoms have been reported. Fluvoxamine may possibly reduce the effects of buspirone.

Clinical evidence, mechanism, importance and management

(a) Citalopram

An isolated report describes the development of the serotonin syndrome and hyponatraemia, thought to be caused by an interaction between citalopram and buspirone.¹ The general importance of this interaction is unknown.

(b) Fluoxetine

A 35-year-old man with a long history of depression, anxiety and panic started taking buspirone 60 mg daily. His anxiety abated, but, because of worsening depression he was also given trazodone 200 mg daily for 3 weeks. This had little effect, so fluoxetine 20 mg daily was added. Within 48 hours his usual symptoms of anxiety had returned and persisted even when the dose of buspirone was raised to 80 mg daily. Stopping the buspirone did not increase his anxiety.² Another patient with obsessive-compulsive disorder taking fluoxetine experienced a marked worsening of his symptoms when buspirone 5 mg twice daily was added.³ A patient taking fluoxetine 80 mg daily had a grand mal seizure 3 weeks after buspirone 30 mg daily was added. The drugs were stopped and an EEG showed no signs of epilepsy, so the seizure was attributed to a drug interaction.⁴ Other reports describe the effective concurrent use of fluoxetine and buspirone in patients with treatment-resistant depression⁵ and with obsessive-compulsive disorder.^{6,7}

The reasons for these adverse reactions are not understood, but there would seem to be little reason for avoiding concurrent use, however bear these case reports of interactions in mind when both drugs are used.

(c) Fluvoxamine

A double-blind study in 9 healthy subjects found that after taking fluvoxamine (mean dose 127 mg daily, range 100 to 150 mg daily) for 3 weeks, the plasma levels of a single 30-mg dose of buspirone were increased almost threefold. Even so, the psychological responses to the buspirone were reduced.⁸ However, a study in 10 healthy subjects given a single

10-mg dose of buspirone after taking fluvoxamine 100 mg daily for 5 days, found that although the pharmacokinetics of buspirone were altered (AUC increased 2.4-fold) the pharmacodynamic tests remained unchanged.⁹

It has been suggested that fluvoxamine inhibits the liver enzymes concerned with the metabolism of buspirone. Concurrent use need not be avoided but it would be wise to remain alert to the possibility of reduced buspirone effects until more is known.

Chlorpromazine + Cimetidine

One study found that chlorpromazine serum levels are reduced by cimetidine, while another study suggested that cimetidine can increase chlorpromazine levels.

Clinical evidence, mechanism, importance and management

A study in 8 patients taking chlorpromazine 75 to 450 mg daily found that cimetidine 1 g daily in divided doses for one week decreased their steady-state chlorpromazine levels by one-third, from 37 to 24 micrograms/mL. A two-thirds reduction was noted in one patient.¹ The reasons for this effect are not understood but a decrease in absorption from the gut has been suggested.¹

In contrast, another report describes 2 schizophrenic patients taking chlorpromazine 100 mg four times daily who became excessively sedated when they were given cimetidine 400 mg twice daily. The sedation disappeared when the chlorpromazine dosage was halved. When the cimetidine was later withdrawn it was found necessary to give the original chlorpromazine dosage.² Chlorpromazine serum levels were not measured.

There is no simple explanation for these discordant reports, but they emphasise the need to monitor the concurrent use of chlorpromazine and cimetidine. More study is needed. There seems to be no information about other phenothiazines.

1. Howes CA, Pullar T, Sourindhrin I, Mistra PC, Capel H, Lawson DH, Tilstone WJ. Reduced steady-state plasma concentrations of chlorpromazine and indomethacin in patients receiving cimetidine. *Eur J Clin Pharmacol* (1983) 24, 99–102.
2. Byrne A, O'Shea B. Adverse interaction between cimetidine and chlorpromazine in two cases of chronic schizophrenia. *Br J Psychiatry* (1989) 155, 413–15.

Chlorpromazine + Tetrabenazine

An isolated report describes severe Parkinson-like symptoms when a woman with Huntington's chorea was given tetrabenazine and chlorpromazine.

Clinical evidence, mechanism, importance and management

A woman with Huntington's chorea, successfully treated with tetrabenazine 100 mg daily for 9 years, became motionless, rigid, mute and only able to respond by blinking her eyes within one day of being given two intramuscular injections of chlorpromazine 25 mg. This was diagnosed as severe drug-induced parkinsonism, which rapidly responded to the withdrawal of both drugs and treatment with benzatropine mesilate given intramuscularly and orally. She had previously tolerated chlorpromazine well.¹ The reason for this reaction is not understood, and, as tetrabenazine is used to treat movement disorders its clinical significance is unclear.

1. Moss JH, Stewart DE. Iatrogenic parkinsonism in Huntington's chorea. *Can J Psychiatry* (1986) 31, 865–6.

Clomethiazole + Diazoxide

Clomethiazole and diazoxide, given to pregnant women in labour, can cause marked respiratory depression in their infants for up to 36 hours after birth.

Clinical evidence

An infusion of 0.8% clomethiazole, in a dose of 4 to 24 g, was given during labour to 21 pregnant women of 28 to 40 weeks gestation for eclampsia or pre-eclamptic toxemia. Diazoxide 75 to 150 mg was also given intravenously to 14 of the women for hypertension. All 21 babies were born alive but 13 suffered hypotonia, hypoventilation or apnoea for 24 to 36 hours after birth. All of the neonates affected, apart from one, came from the group of mothers who had been given diazoxide. Three of them died of respiratory distress syndrome; one was only 28 weeks' gestation.¹

Mechanism

Clomethiazole has some respiratory depressant effects, and is contraindicated in patients with respiratory deficiency, but it is not clear why, having passed across the placenta into the foetus, its effects should apparently be so markedly increased by diazoxide.

Importance and management

Although use of this drug combination in eclampsia is historical, the interaction is included on account of its severity. The author of the report says that the respiratory depression was managed successfully with intermittent positive pressure ventilation, provided that respiratory distress syndrome was not also present.¹

1. Johnson RA. Adverse neonatal reaction to maternal administration of intravenous chlormethiazole and diazoxide. *BMJ* (1976) 1, 943.

Clomethiazole + Furosemide

Ten female patients aged 66 to 90 years were given clomethiazole edisilate syrup 500 mg each evening and 250 mg each morning as a sedative, with furosemide 20 to 80 mg. No significant changes in the serum levels or effects of clomethiazole or furosemide were detected, and no other significant adverse reactions were seen.¹

1. Reid J, Judge TG. Chlormethiazole night sedation in elderly subjects receiving other medications. *Practitioner* (1980) 224, 751–3.

Clozapine + Antiepileptics

Clozapine serum levels are approximately halved by carbamazepine and possibly by phenobarbital and phenytoin. An isolated case of fatal pancytopenia has been seen in one patient taking clozapine and carbamazepine, and neuroleptic malignant syndrome occurred in another. Sodium valproate can apparently lower serum clozapine levels, and an isolated case report suggests that lamotrigine may raise them.

Clinical evidence

(a) Carbamazepine

A study by a therapeutic drug monitoring service for clozapine found that the concentration/dose ratio of 17 patients taking carbamazepine was 50% of that found in 124 other patients taking clozapine alone.¹ A 47% decrease in the serum levels of clozapine were seen in another 12 patients when they were given carbamazepine. **Oxcarbazepine** did not interact.² The plasma clozapine levels of 2 patients who had been taking clozapine 600 or 800 mg daily and carbamazepine 600 or 800 mg daily for several months were increased from 1.4 to 2.4 micromol/L and from 1.5 to 3 micromol/L, respectively, within 2 weeks of stopping the carbamazepine.³

A man with mania taking carbamazepine 1.2 g daily and lithium developed muscle rigidity, mild hyperpyrexia, tachycardia, sweating and som-

nolence (diagnosed as neuroleptic malignant syndrome) 3 days after his lithium was stopped and clozapine 25 mg daily started. The symptoms immediately improved when the clozapine was stopped.⁴

A patient taking carbamazepine, lithium, benztropine and clonazepam developed fatal pancytopenia about 10 weeks after starting clozapine 400 mg daily.⁵ A retrospective study of the records of other patients given clozapine and carbamazepine found a significant increase in granulopenia.⁶ A previous report had not found this, due to a statistical error.⁷

A case report describes 2 schizophrenic patients taking clozapine whose treatment was changed from carbamazepine to **oxcarbazepine**. After 3 weeks their plasma clozapine levels had risen from 1.4 to 1.7 micromol/L and from 1.5 to 2.5 micromol/L, respectively.⁸

(b) Lamotrigine

A 35-year-old man, who had been taking clozapine for 3 years, became dizzy and sedated about one month after starting to take lamotrigine. His plasma clozapine levels were found to have increased to 1020 micrograms/L. When the lamotrigine was stopped his levels fell to 450 micrograms/L.⁹

A study in 11 patients taking clozapine in doses of 200 mg to 500 mg daily, and who were also given lamotrigine in increasing doses over 8 weeks to 200 mg daily found no significant changes in the pharmacokinetics of clozapine.¹⁰

(c) Phenobarbital

Mean clozapine plasma levels in 7 patients taking clozapine and phenobarbital were 35% lower than those of 15 patients taking clozapine alone.¹¹

(d) Phenytoin

Two patients developed reduced clozapine levels (falls of 65 to 85%) and worsening psychoses when phenytoin was added to their treatment.¹² Another patient developed neutropenia, which was attributed to concurrent use of phenytoin and clozapine. When the phenytoin was stopped clozapine levels rose from 114 to 137 nanograms/mL, suggesting a pharmacokinetic interaction,¹³ rather than just additive adverse effects.

(e) Valproate

A controlled study in 11 patients found that when sodium valproate (at an average dose of 1.06 g daily) was added to clozapine, the steady-state serum clozapine levels were increased by 39% and the levels of the demethylated metabolite increased by 23%. However, correction of these levels for dose and weight reduced the total clozapine metabolite values to only 6% above those of the controls. No increase in clozapine adverse effects was seen.¹⁴ Another study found that sodium valproate and clozapine had no significant effect on the pharmacokinetics of each other.¹⁵ In contrast, a study in 4 schizophrenics treated with clozapine 550 to 650 mg daily found that when valproate semisodium 750 mg to 1 g daily was added, the serum clozapine levels began to fall, and by 3 weeks had dropped by an average of 41%. No deterioration in clinical condition occurred.¹⁶ A 15% decrease in clozapine levels was seen in another study in 7 patients given clozapine and sodium valproate.¹⁷ Clozapine levels were doubled in a patient after valproic acid treatment was stopped, suggesting that the valproate had increased the metabolism of clozapine. An alternative explanation suggested was that the valproate may have reduced the absorption of clozapine.¹⁸ An isolated report describes sedation, confusion, slurred speech and impaired functioning on two occasions when semisodium valproate was added to clozapine treatment in a 37-year-old man.¹⁹

Mechanism

Not established, but it seems likely that carbamazepine, phenobarbital and phenytoin (recognised potent enzyme inducers) increase the metabolism of clozapine by the liver, thereby reducing its effects. It has been suggested that this is because these drugs induce the activity of the cytochrome P450 isoenzyme CYP1A2.^{1,13} Carbamazepine and phenobarbital may also have an effect via CYP3A4. The case of pancytopenia may possibly have been due to the additive bone marrow depressant effects of the clozapine and carbamazepine.

Importance and management

The interaction between clozapine and carbamazepine is much more firmly established than that between clozapine and phenobarbital or phenytoin, but they appear to be clinically important. Monitor symptoms and be alert for the need to increase the clozapine dosage if any of these drugs are giv-

en concurrently, and reduce the dosage if they are withdrawn. However, because of the substantial risk of bone marrow suppression the manufacturers of clozapine advise that carbamazepine should not be given concurrently.^{20,21}

As yet there only appears to be one case report with lamotrigine, so the situation is unclear. There appears to be no pharmacokinetic mechanism for this interaction, so it awaits confirmation.

The situation with sodium valproate is not entirely clear. There are cases of successful concurrent use,¹⁹ but in the light of the reports cited here it would clearly be prudent to monitor concurrent use closely. A subgroup analysis of 20 patients who received clozapine and carbamazepine, clonazepam, phenobarbital, phenytoin, or valproate suggested that this group of patients showed less clinical improvement than patients who were not also taking an antiepileptic. However, the indication for the antiepileptic drug was not always clear and combined treatment may have been used in patients who were more severely ill, or less responsive to clozapine alone.²²

Clozapine + Antihypertensives

There are isolated cases of apparent hypotensive interactions between clozapine, and enalapril, lisinopril or propranolol. Additive hypotensive effects are possible with clozapine and any antihypertensive drug.

Clinical evidence, mechanism, importance and management

A patient taking enalapril 5 mg twice daily fainted within an hour of being given an initial 25-mg dose of clozapine. Later he was stabilised without problems taking enalapril 2.5 mg twice daily and clozapine, initially 12.5 mg daily, later rising to 800 mg daily. Another patient taking enalapril 5 mg daily fainted within 5 hours of being given clozapine 25 mg. He needed resuscitation, but was later treated with clozapine in doses up to 600 mg daily.¹ The clozapine blood levels of a 39-year-old man rose from 490 to 966 nanograms/mL after the addition of lisinopril 5 mg daily. When the lisinopril dose was increased to 10 mg daily, the levels further rose to 1092 nanograms/mL. The dose of clozapine was reduced, and lisi-

nopril replaced by diltiazem, after which his levels began to return to normal.²

Coma developed in a woman taking propranolol 40 mg daily 1.5 to 2 hours after she was given a single 150-mg dose of clozapine. She had stopped taking fluphenazine 24 hours earlier. The patient recovered, and was subsequently slowly titrated up to a daily clozapine dose of 100 mg in addition to the propranolol, without any problems. Although the authors state that an interaction between propranolol and clozapine was the likely cause of the coma, the effects of fluphenazine cannot be wholly ruled out.³

Clozapine has alpha-blocking effects and therefore may cause orthostatic hypotension. The manufacturers note that this is more likely in the presence of other antipsychotics or benzodiazepines and during initial titration with rapid dose increases. Because of the potential for additive effects they recommend caution when giving clozapine to patients taking any hypotensive drug.^{4,5}

Clozapine + Antimuscarinics

The antimuscarinic effects of clozapine are additive with those of other antimuscarinic drugs, which has led to urinary retention and delirium.

Clinical evidence, mechanism, importance and management

The manufacturers of clozapine warn that the antimuscarinic effects of some drugs may be additive with those of clozapine, which may lead to adverse effects such as dry mouth and constipation.^{1,2} Confirmation of the clinical relevance of this proposed interaction was seen in a patient who developed severe urinary retention while taking clozapine and meclozine.³

A man with a schizoaffective disorder taking nortriptyline, perphenazine and propranolol was also given clozapine 150 mg daily. Some improvement was seen after 8 days, and over the next week the propranolol was gradually discontinued while the clozapine dosage was raised to 225 mg daily. The patient then began to complain of extreme fatigue and slurred speech, and by day 17 was delirious and confused. His serum nortriptyline levels were found to have doubled (from 93 to 185 nanograms/mL) from the time the clozapine was started. He recovered within 5 days of stopping all of the drugs, after which the clozapine was restarted.⁴ The authors of the report interpreted the symptoms as an antimuscarinic delirium arising from the additive antimuscarinic effects of the clozapine, nortriptyline and perphenazine, made worse by the increased levels of nortriptyline.⁴ Just why the nortriptyline levels rose is not clear, but one possible explanation is that the nortriptyline and clozapine compete for metabolism by the same liver enzymes, resulting in a reduction in the clearance of the nortriptyline. 'Table 18.1', (p.672) and 'Table 18.2', (p.674) give lists of drugs that have antimuscarinic activity. Consider also 'Antipsychotics + Antimuscarinics', p.708.

Clozapine + Azoles

Itraconazole and ketoconazole do not interact with clozapine.

Clinical evidence, mechanism, importance and management

A double-blind study in 7 schizophrenic patients taking clozapine found that when itraconazole 200 mg daily was given for a week, no changes in the levels of clozapine or its desmethylclozapine metabolite were seen.¹

A single 50-mg dose of clozapine was given to 5 schizophrenic patients

before and after a 7-day course of **ketoconazole** 400 mg daily. The **ketoconazole** had no significant effect on the pharmacokinetics of the clozapine.²

The conclusion is that the cytochrome P450 isoenzyme CYP3A4 is of only minor importance in clozapine metabolism, and that because no interaction takes place between clozapine and **itraconazole** or **ketoconazole**, both it and other inhibitors of CYP3A4 can be used with clozapine.^{1,2} However, note that raised clozapine levels have been attributed to treatment with the CYP3A4 inhibitor, erythromycin, see 'Clozapine + Erythromycin', p.747.

Clozapine + Benzodiazepines

A handful of reports describe severe hypotension, respiratory depression, unconsciousness and potentially fatal respiratory arrest in patients taking benzodiazepines and clozapine. One case of fatal respiratory arrest has been reported with lorazepam and clozapine. Dizziness and sedation are also increased.

Clinical evidence

A schizophrenic patient failed to respond to fluphenazine, **diazepam**, **clobazam** and **lormetazepam** having taken the combination for several weeks. The fluphenazine was stopped and clozapine started at a dose of 25 mg at noon and 100 mg at night. Toxic delirium and severe hypersalivation developed 3 hours later. The patient collapsed (systolic blood pressure 50 mmHg, diastolic blood pressure unrecordable) and stopped breathing. Resuscitation was started, and the patient remained unconscious for 30 minutes. After a few drug-free days clozapine 12.5 mg was successfully re-introduced, and very slowly titrated upwards; a low benzodiazepine dosage was also given.¹

Another patient taking clozapine died suddenly and unexpectedly during the night, apparently due to respiratory arrest, after being given three 2-mg intravenous doses of **lorazepam** the previous day.²

There are at least 6 other cases of severe hypotension, respiratory depression or loss of consciousness in patients taking clozapine and **flurazepam**, **lorazepam** or **diazepam**,^{1,3–5} as well as other cases of marked sedation, hypersalivation, ataxia and delirium in patients taking **lorazepam** and clozapine.^{6,7} Two of these reports^{1,3} are from the same group of workers and it is not clear whether they are about the same or different patients.

Mechanism

Not understood. Clozapine on its own very occasionally causes respiratory arrest and hypotension.

Importance and management

The authors of the first of these reports¹ say that the relative risk of the cardiovascular/respiratory reaction is only 2.1%. Another report² says that the death cited above is the only life-threatening event among 162 patients given clozapine and benzodiazepines between 1986 and 1991 so that the incidence of serious problems is quite low. Even so, concurrent use should be very well monitored because of the severity of the reaction, even if it is rare.

Clozapine + Caffeine

Caffeine increases serum clozapine levels, which may increase the incidence of its adverse effects.

Clinical evidence

In a crossover study, 6 coffee-drinking patients taking clozapine were given decaffeinated or caffeine-containing instant coffee for 7 days. The plasma levels of clozapine were 26% higher while the patients were taking caffeine.¹ A study in 12 healthy subjects² found that caffeine 400 mg to 1 g daily, raised the AUC and decreased the clearance of a single 12.5-mg dose of clozapine by 19% and 14%, respectively. A previous study in 7 patients had found that clozapine levels decreased by 47% when the subjects avoided caffeine for 5 days, and increased again when caffeine consumption was resumed.³

A 66-year-old woman taking clozapine 300 mg daily developed supraventricular tachycardia (180 bpm) when she was given 500 mg of intravenous caffeine sodium benzoate to increase seizure length during an ECT session. Verapamil was needed to revert the arrhythmia. Before taking clozapine she had received caffeine sodium benzoate in doses of up to 1 g during ECT sessions without problems.⁴ Another patient taking clozapine for schizophrenia had an exacerbation of his psychotic symptoms, which was attributed to caffeinated coffee (5 to 10 cups daily). The problem resolved when the patient stopped drinking caffeine. He had previously not had any problems with caffeine while taking haloperidol 30 mg and procyclidine 30 mg daily.⁵ A 31-year-old woman taking clozapine 550 mg daily developed increased daytime sleepiness, sialorrhoea and withdrawn behaviour after taking about 1.2 g of caffeine daily (as drinks and tablets). Her plasma clozapine levels fell from 1500 to 630 nanograms/mL when her caffeine intake was stopped.⁶

Mechanism

Caffeine is a competitive inhibitor of the cytochrome P450 isoenzyme CYP1A2, which is one of the major isoenzymes involved in the metabolism of caffeine. Consequently clozapine serum levels and effects increase.^{2,3,7}

Importance and management

This would appear to be an established and clinically important interaction, but unlikely to be a problem if clozapine serum levels are established and well monitored, and caffeine intake remains fairly stable and moderate. Possible exceptions are if large doses of caffeine are given during ECT treatment or if for some other reason the caffeine intake suddenly increases or decreases markedly.

Clozapine + Drugs that suppress bone marrow

The manufacturers caution the use of clozapine with other drugs that can cause bone marrow suppression. Low white cells counts have been seen in patients taking clozapine and chloroquine, cotrimoxazole, methazolamide, nitrofurantoin, olanzapine, or thiazamazole.

Clinical evidence, mechanism, importance and management

Clozapine can cause blood dyscrasias and potentially fatal agranulocytosis, therefore the manufacturers say that it should not be given with other drugs that have a well-known potential to cause agranulocytosis.^{1,2} The

UK manufacturer lists **carbamazepine** (see also 'Clozapine + Antiepileptics', p.744), **chloramphenicol**, **cytotoxics**, **penicillamine**, pyrazolone analgesics (e.g. **phenylbutazone**), **sulphonamides** (e.g. **co-trimoxazole**) and, because they cannot be stopped if an adverse reaction occurs, they advise against the use of **depot antipsychotics**.¹ There are several cases that confirm the clinical significance of these predicted interactions.

A woman was taking **thiamazole** for Graves' disease, at times with various different antipsychotics including haloperidol, flupentixol, zuclopentixol and perphenazine for schizophrenia. Because of the severe extrapyramidal reactions and failure to control the schizophrenia, clozapine, increased over 5 days to 250 mg daily, was started instead. Within 5 days her white cell count had fallen to 2200/mm³, which rose to 4000/mm³, one month after both drugs were stopped. Later, after the **thiamazole** was stopped she was given the same dose of clozapine without these adverse effects.³

A patient who had been taking clozapine 500 mg daily for 8 months developed granulocytopenia within 8 days of starting **nitrofurantoin** 200 mg daily.⁴

An 86-year old woman taking clozapine developed neutropenia 2 weeks after **methazolamide** for glaucoma was added. Both drugs were stopped and her white cell count recovered. She later restarted clozapine without problem and so the toxic effect was attributed to the combined use of two drugs.⁵

Neutropenia developed 4 days after **co-trimoxazole** was started in a 47-year-old woman who had been uneventfully taking clozapine for 5 years. **Co-trimoxazole** was stopped and the white cell counts returned to normal over the next 2 weeks.⁶

Three patients have been described who showed a delay in recovery from clozapine-induced agranulocytosis when given **olanzapine**, and it has been suggested that **olanzapine** should therefore be avoided until the patient's haematological status has normalised.⁷

However, in contrast, a patient taking clozapine 25 mg daily had no significant changes in his white cell count after taking **chloroquine** for malaria prophylaxis, over the course of one month.⁸

Clozapine + Erythromycin

A study in healthy subjects found no evidence of an interaction between clozapine and erythromycin, but three case reports describe clozapine toxicity (seizures in one patient, drowsiness, incoordination and incontinence in another and neutropenia in the third) when the patients were given erythromycin.

Clinical evidence

A randomised, crossover study in 12 healthy subjects found that erythromycin 500 mg three times daily did not affect the pharmacokinetics of a single 12.5-mg dose of clozapine.¹

In contrast, a schizophrenic man taking clozapine 800 mg daily, was given erythromycin 250 mg four times daily for a fever and sore throat caused by pharyngitis. After a week he had a single tonic-clonic seizure and his serum clozapine levels were found to be 1300 micrograms/mL. Both drugs were stopped, and the clozapine restarted 2 days later, initially at only 400 mg daily, but after several weeks had increased to 800 mg daily, giving serum clozapine levels of 700 micrograms/mL.² Another schizophrenic taking clozapine 600 mg daily became drowsy, with slurred speech, incontinence, difficulty in walking and incoordination within 2 to 3 days of starting to take erythromycin 333 mg three times daily. His serum clozapine level was found to be 1150 micrograms/L and he had leucocytosis. He recovered when both drugs were stopped. When he later restarted treatment with the same clozapine dosage, but without the eryth-

romycin, his steady-state trough clozapine serum level was 385 micrograms/L.³ Another case also describes a reduced white cell count when erythromycin was added to established clozapine therapy, but no clozapine levels were available.⁴

Mechanism

Uncertain. One suggestion is that erythromycin might have inhibited the cytochrome P450 isoenzyme CYP3A4, which has a minor role in the metabolism of clozapine, leading to a reduced clearance, which resulted in increased serum clozapine levels and toxicity.^{2,3} Clozapine is mainly metabolised by CYP1A2, which is not known to be affected by the macrolides.

Importance and management

Information appears to be limited to this study and the three case reports, but clozapine has not been found to interact with other potent inhibitors of CYP3A4, see 'Clozapine + Azoles', p.745. An interaction seems unlikely, although the case reports do suggest that rarely some patients may be affected. Bear this interaction in mind in the case of an unexpected response to treatment. Note that infection may be a sign of clozapine-induced agranulocytosis.

Clozapine + H₂-receptor antagonists

A single case report describes increased serum clozapine levels and toxicity due to cimetidine, but not ranitidine.

Clinical evidence, mechanism, importance and management

A man with chronic paranoid schizophrenia was taking atenolol and clozapine 900 mg daily. When **cimetidine** 400 mg twice daily was added for gastritis, his serum clozapine levels rose by almost 60% (from a range of 992 to 1081 nanograms/mL to a range of 1559 to 1701 nanograms/mL) but this did not result in any adverse effects. Within 3 days of raising the dosage of **cimetidine** to 400 mg three times daily he developed evidence of clozapine toxicity (marked diaphoresis, dizziness, vomiting, weakness, orthostatic hypotension), all of which resolved over 5 days when the clozapine dosage was lowered to 200 mg daily, and the **cimetidine** was stopped. The serum clozapine levels during this period were not reported. When **cimetidine** was replaced by **ranitidine** 150 mg twice daily his clozapine serum levels were not affected.¹

The suggested reason for this interaction is that the **cimetidine** (a potent non-specific enzyme inhibitor) reduces the metabolism of clozapine by the liver so that it accumulates, causing toxicity. **Ranitidine** does not cause enzyme inhibition and therefore does not interact.

Information appears to be limited to this report but it is consistent with the way **cimetidine** interacts with many other drugs. **Ranitidine**, and possibly other H₂-receptor antagonists such as **famotidine** or **nizatidine**, which do not inhibit liver enzymes, would seem to be preferable and safer alternatives; however, this needs confirmation.

Clozapine + Hormonal contraceptives

A case report describes raised clozapine levels with associated adverse effects when a patient also took a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

A 47-year-old smoker with paranoid schizophrenia taking clozapine 550 mg daily had a good therapeutic response to this dose, but also report-

ed drowsiness, weakness and dizziness. The patient was also taking a combined oral contraceptive containing **norethisterone** 500 micrograms and **ethinylestradiol** 35 micrograms. Clozapine plasma levels ranged from 736 to 792 nanograms/mL (therapeutic range 300 to 700 nanograms/mL). After 2 months she stopped taking her combined oral contraceptive and noted that the adverse effects of clozapine resolved, and clozapine levels were found to be 378 to 401 nanograms/mL. The patient did not stop smoking during this time. It was suggested that the oral contraceptive inhibited the cytochrome P450 isoenzymes CYP1A2, CYP2C19 and CYP3A4 resulting in raised clozapine plasma levels. The authors note that slower titration and smaller doses of clozapine may be needed in patients taking hormonal contraceptives.¹ Further study is needed as this appears to be the only published case report of this interaction.

Clozapine + Lithium

A few patients given lithium carbonate and clozapine have experienced adverse reactions including myoclonus, neuroleptic malignant syndrome, seizures, delirium and psychoses.

Clinical evidence

A man with poorly controlled schizophrenia, taking clozapine 750 mg daily for 6 weeks, was given lithium, initially 900 mg and then subsequently 1.2 g daily. His serum lithium level was 0.86 mmol/L. Within one week he began to experience paroxysmal jerky movements of his upper and lower extremities lasting about 30 minutes. This myoclonus resolved when both drugs were stopped, and did not recur when clozapine was re-started alone.¹ Another patient developed neuroleptic malignant syndrome (stiffness, rigidity, tachycardia, diaphoresis, hypertension) 3 to 4 weeks after clozapine was added to his lithium treatment. The symptoms disappeared within 2 to 3 days of stopping the clozapine.² An elderly man also developed neuroleptic malignant syndrome 3 days after starting to take clozapine 25 mg daily. He was also taking carbamazepine, and had stopped taking lithium 3 days earlier.³

Four out of 10 patients taking lithium carbonate (mean dose of 1.4 g daily) and clozapine (mean maximum dose 900 mg daily) developed reversible neurological symptoms including involuntary jerking of the limbs and tongue, facial spasm, tremor, confusion, generalised weakness, stumbling gait, leaning and falling to the right. One of them also became delirious. Serum lithium levels remained unchanged, and the problems resolved when the lithium was stopped. Three of the four had a recurrence of the symptoms when re-challenged with the drug combination.⁴ A man taking clozapine and lithium carbonate developed psychosis with delusions and visual hallucinations over a 5-day period when clozapine was tapered off and stopped. This was accompanied by a doubling in his serum lithium levels. He recovered completely when the drugs were stopped.⁵ Two patients taking clozapine developed seizures: one developed a tonic clonic seizure within 4 days of adding lithium carbonate 900 mg to clozapine 600 mg daily, and the other a grand mal seizure within 6 days of adding lithium carbonate 900 mg to clozapine 900 mg daily.⁶

A review of the medical records of 44 patients taking clozapine and lithium identified 28 patients who had experienced an adverse effect, three of which were possibly associated with the drug combination. There were two reports of myoclonus and one of a grand mal seizure.⁷

Lithium is thought to have masked a clozapine-induced agranulocytosis in a 59-year-old woman who developed leucopenia and subsequently agranulocytosis after 40 days of treatment with lithium and clozapine.⁸ It has been suggested that lithium may help to protect patients from adverse effects of clozapine, in particular agranulocytosis, although a clozapine re-challenge in a patient who has previously experienced a blood dyscrasia with clozapine should only be undertaken with great caution.⁹

Mechanism

Not understood.

Importance and management

Some patients develop a toxic reaction when given both drugs, and others do not, for reasons that are not understood. Concurrent use should there-

fore be extremely well monitored including close monitoring of full blood counts as well as lithium levels. One group of workers suggest that lithium levels of no more than 0.5 mmol/L may give therapeutic benefits while minimising adverse effects.⁴

Clozapine + Miscellaneous

There are isolated cases of apparent interactions between clozapine, and ampicillin, buspirone, caffeine, haloperidol, loperamide, modafinil, nefazodone, nicotinic acid, tryptophan, or vitamin C. Grapefruit juice, influenza vaccine mirtazapine, reboxetine, or venlafaxine do not appear to interact. Cocaine levels may increase when taken with clozapine.

Clinical evidence, mechanism, importance and management

(a) Ampicillin

An isolated report describes a 17-year-old taking clozapine (12.5 mg increased to 50 mg three times daily) who was given ampicillin 500 mg four times daily, starting on day 15 of clozapine treatment. On the next day the patient became easily distracted, very drowsy and salivated excessively. These adverse reactions stopped when the ampicillin was replaced by doxycycline.¹

(b) Buspirone

A man who had been taking clozapine for a year developed acute and potentially lethal gastrointestinal bleeding and marked hyperglycaemia about 5 weeks after starting buspirone, and one week after the buspirone dosage was raised to 20 mg daily. No gut pathology (e.g. ulceration) was detected and there were no problems when he was subsequently given clozapine alone, so the reaction was attributed to the drug combination.²

(c) Cocaine

A single-dose study in 8 cocaine addicts found that there was a dose-dependent rise in cocaine levels of 6%, 49% and 67% after clozapine was given in doses of 12.5, 25 or 50 mg, respectively, with intranasal cocaine 2 mg/kg. Subjective questioning revealed a reduction in the positive effects of cocaine. One subject also experienced a near-syncopal attack which required medical attention.³

(d) Grapefruit juice

Grapefruit juice did not affect the metabolism of clozapine in two studies in a total of 36 schizophrenic patients.^{4,5}

(e) Haloperidol

A 68-year-old man taking clozapine 600 mg daily and venlafaxine, lorazepam, aspirin, vitamin E and multivitamins, was given haloperidol 4 mg daily to control persistent paranoid delusions and hallucinations. After 27 days he was found collapsed and was lethargic, tachycardic, feverish and delirious. Neuroleptic malignant syndrome was suspected so the antipsychotics were withheld, and the patient recovered over the following 7 days. Clozapine was later re-started without a recurrence of symptoms.⁶ A case of elevated haloperidol levels has been reported in a 40-year-old man who was given haloperidol intramuscular injections 50 mg every 4 weeks. He was also given clozapine in increasing doses from 50 to 250 mg daily. Over this time his haloperidol levels increased from 12 nanogram/mL to 166 nanogram/mL, although it is not clear whether he had attained steady-state levels when the first measurement was reported.⁷

(f) *Influenza vaccine*

In an open-label study in 14 patients the metabolism of clozapine was not altered following a single intramuscular dose of influenza vaccine (*Influvac* 2001 to 2002 formula, Solvay).⁸

(g) *Loperamide*

A patient taking clozapine 500 mg daily died after taking loperamide 6 mg daily during an episode of food poisoning. The authors of the report attribute the death to toxic megacolon brought on by the additive effects of clozapine and loperamide on gut transit.⁹ Toxic megacolon can sometimes occur with loperamide alone, especially in the presence of an infection. Also, the manufacturers of clozapine say that care is necessary in patients given clozapine with drugs known to cause constipation (see also 'Clozapine + Antimuscarinics', p.745) because on rare occasions clozapine alone has been shown to cause significant impairment of intestinal function (such as paralytic ileus).^{10,11}

(h) *Mirtazapine*

A study in 9 patients taking clozapine in doses ranging from 100 to 650 mg daily found no significant change in the pharmacokinetics of clozapine after the addition of mirtazapine 30 mg daily.¹²

(i) *Modafinil*

A 42-year-old man taking clozapine 450 mg daily was given modafinil, titrated up to 300 mg daily, to combat sedation. After about one month of concurrent use he developed dizziness and an unsteady gait, and his clozapine level was found to be 1400 nanograms/mL. His clozapine level had been 761 nanograms/mL while taking clozapine 400 mg daily, and because the 50 mg clozapine dose increase was not thought large enough to almost double his clozapine level, an interaction with modafinil was suspected.¹³

(j) *Nefazodone*

A 40-year-old man who had been successfully treated with risperidone and clozapine 425 to 475 mg daily started taking nefazodone 200 mg daily, increasing to 300 mg daily, for the treatment of persistent depression. After one week on the higher dose he became dizzy and hypotensive and it was noted that his clozapine level had risen from 133 to 233 nanograms/mL. This was thought to be due to an inhibitory effect of nefazodone on the cytochrome P450 isoenzyme CYP3A4,¹⁴ although note that other potent inhibitors of CYP3A4 (such as 'erythromycin', (p.747) or the 'azoles', (p.745)) rarely appear to increase clozapine levels. In contrast, a small study in 6 patients taking clozapine and who were then additionally prescribed nefazodone found no significant effects on the pharmacokinetics of clozapine.¹⁵

A possible case of neutropenia caused by the addition of nefazodone to treatment with sodium valproate and clozapine has been reported. The patient had been receiving treatment with sodium valproate and clozapine for many months when nefazodone was started in increasing doses up to 200 mg twice daily. Within one week her neutrophil count had dropped to $1.8 \times 10^9/L$, and remained low until the nefazodone was discontinued. The patient's serum level of clozapine was reported to remain stable during this time and the patient had not had any previous episodes of leucopenia during treatment with clozapine.¹⁶

(k) *Nicotinic acid/Tryptophan/Vitamin C*

A man with schizophrenia taking tryptophan, lorazepam, vitamin C, benzatropine and nicotinic acid, developed a severe urticarial rash covering his face, neck and trunk 3 days after starting clozapine 150 mg daily. All of the drugs except lorazepam were stopped, and the rash subsided. It did not recur when clozapine was restarted, even at a dose of 600 mg daily, nor when small doses of benzatropine and fluphenazine were briefly added. The authors draw the inference that tryptophan, vitamin C and nicotinic acid may have been responsible for this alleged interaction with clozapine.¹⁷

(l) *Reboxetine*

A small study in 7 patients found that reboxetine 8 mg daily had no effect on the metabolism of clozapine or its major metabolite.¹⁸

(m) *Ritonavir*

Ritonavir is a potent inhibitor of the cytochrome P450 isoenzymes CYP3A4 and CYP2D6, and is therefore expected to increase plasma levels of clozapine. This may result in serious haematologic abnormalities, although there appear to be no published studies or case reports of this effect. The UK manufacturers therefore contraindicate combined use.¹⁹

(n) *Venlafaxine*

In 11 patients venlafaxine in doses of up to 150 mg daily did not affect the pharmacokinetics of established clozapine treatment in doses up to 950 mg daily.²⁰

Clozapine + Proton pump inhibitors

Omeprazole appears to reduce the serum levels of clozapine.

Clinical evidence, mechanism, importance and management

A retrospective study identified 13 patients taking clozapine and **omeprazole** in who the proton pump inhibitor was subsequently changed to **pan-toprazole**. This resulted in an increase in the mean clozapine serum level from 445 to 579 nanograms/mL in 3 non-smokers, but in the 10 smokers there was a slight *reduction* in levels, from 364 to 323 nanograms/mL. Both **omeprazole** and smoking are known to induce the cytochrome P450 isoenzyme CYP1A2, which is the major isoenzyme involved in the metabolism of clozapine. The authors suggest that when **omeprazole** was stopped in the non-smokers there was no CYP1A2 induction, hence clozapine levels rose, whereas CYP1A2 induction continued in the smokers, so their levels were only slightly affected.¹

A case report describes two patients (both smokers) whose clozapine levels were reduced, from 762 to 443 nanograms/mL and from 369 to 204 nanograms/mL, respectively, after **omeprazole** was started. However, no changes in clinical condition were noted.²

Other proton pump inhibitors do not appear to have been studied.

Clozapine + Quinolones

An isolated report describes the development of agitation in an elderly man taking clozapine, which was tentatively attributed to an interaction with ciprofloxacin. A study supports this observation.

Clinical evidence, mechanism, importance and management

An elderly man with multi-infarct dementia and behavioural disturbances, taking clozapine, glibenclamide (glyburide), trazodone and melatonin, was hospitalised for agitation on the last day of a 10-day course of ciprofloxacin 500 mg twice daily. When the ciprofloxacin course was completed, his plasma clozapine serum levels fell from 90 nanograms/mL to undetectable levels (lower limit of detection being 50 nanograms/mL).¹

Ciprofloxacin 250 mg twice daily for 7 days was given to 7 schizophrenic patients taking clozapine. The mean serum clozapine and *N*-desmethylclozapine levels were increased by 29% and 31%, respectively, but no additional adverse effects were reported. Interindividual variation in serum levels was high, so it seems likely that some patients may demonstrate a clinically significant interaction.² This interaction probably occurs because ciprofloxacin inhibits the cytochrome P450 isoenzyme CYP1A2, the major isoenzyme involved in the metabolism of clozapine, resulting in elevated clozapine levels. Monitor the outcome carefully if ciprofloxacin is added to clozapine treatment. There seem to be no other reports of an interaction between clozapine and other quinolones, but as they all inhibit CYP1A2 to a varying extent (see 'Theophylline + Quinolones', p.1192) some interaction seems possible.

2. Raaska K, Neuvonen PJ. Ciprofloxacin increases serum clozapine and *N*-desmethylclozapine: a study in patients with schizophrenia. *Eur J Clin Pharmacol* (2000) 56, 585–9.

Clozapine + Rifampicin (Rifampin)

The serum clozapine levels of a patient were greatly reduced when rifampicin was also given.

Clinical evidence, mechanism, importance and management

A schizophrenic patient taking clozapine developed tuberculosis and was given rifampicin, isoniazid and pyrazinamide. Within 2 to 3 weeks his trough serum clozapine levels had fallen dramatically from about 250 nanograms/mL to 40 nanograms/mL, but rose again rapidly when the rifampicin was replaced by ciprofloxacin. It was suggested that rifampicin (a potent non-specific enzyme inducer) increased the metabolism of clozapine, probably by the cytochrome P450 isoenzymes CYP1A2 and CYP3A, thereby reducing its levels.¹

This appears to be an isolated case but it is consistent with the way rifampicin interacts with other drugs. Clozapine serum levels should be well monitored if rifampicin is added, being alert for the need to increase its dosage. An alternative (as in this case) is to use another antibacterial. However, note that there are reports of an interaction between 'clozapine and ciprofloxacin', (p.749).

1. Joos AAB, Frank UG, Kaschka WP. Pharmacokinetic interaction of clozapine and rifampicin in a forensic patient with an atypical mycobacterial infection. *J Clin Psychopharmacol* (1998) 18, 83–5.

Clozapine + Risperidone

The concurrent use of clozapine and risperidone can be effective and well tolerated but two isolated reports describe a rise in serum clozapine levels when risperidone was added and the development of atrial ectopics. Dystonia has been seen when clozapine was replaced by risperidone.

Clinical evidence

A man with a schizoaffective disorder taking clozapine started to take risperidone, firstly 500 micrograms twice daily, and then after a week 1 mg twice daily. Clinical improvement was seen and it was found that after 2 weeks his serum clozapine levels had risen by 74%, from 344 to 598 nanograms/mL, without any adverse effects.¹ The serum clozapine levels of another patient more than doubled when risperidone was given. No signs of clozapine toxicity were seen, but mild oculogyric crises were reported.² A schizophrenic patient taking clozapine and trihexyphenidyl who developed tachycardia of 120 bpm, which was controlled with propranolol, developed atrial ectopics when risperidone 1.5 mg daily was added. The ectopics stopped when the risperidone was withdrawn and started again when it was re-introduced. Clozapine plasma levels were

normal throughout the duration of risperidone treatment.³ Four patients have been described who developed dystonia after their treatment was changed from clozapine to risperidone.⁴ A single case of agranulocytosis has been seen 6 weeks after risperidone was added to stable clozapine treatment. The patient needed 3 doses of G-CSF before the white cell count returned to normal.⁵ Another case report describes neuroleptic malignant syndrome in a 20-year-old man within 2 days of clozapine being added to risperidone treatment. The drugs were stopped and he recovered over the following 10 days. He subsequently received clozapine alone without problem.⁶

Contrasting with these reports is a study in 12 schizophrenic patients, which found that the addition of risperidone to clozapine was both effective and well tolerated, although 4 patients complained of mild akathisia. Serum clozapine levels were not significantly changed.⁷ A retrospective study in 18 patients also found that risperidone did not alter clozapine serum levels.⁸

Mechanism, importance and management

The suggested reason for the raised clozapine levels is that both drugs compete for metabolism by the cytochrome P450 isoenzyme CYP2D6 resulting in a reduction in the metabolism of the clozapine.^{1,2} The dystonias are attributed to cholinergic rebound and ongoing dopamine blockade caused by a rapid switch of medication. The recommendation is that withdrawal of clozapine should be tapered and possibly that an antimuscarinic drug should be given.⁴ The raised clozapine levels seem to be isolated cases and therefore of doubtful general significance.

Clozapine + SSRIs

Fluoxetine, paroxetine, sertraline and possibly citalopram can raise serum clozapine levels. Escitalopram is predicted to interact similarly. Particularly large increases in clozapine levels can occur with fluvoxamine. Clozapine toxicity has been seen in some patients.

Clinical evidence

(a) Citalopram

Preliminary studies in 5 patients found that their mean plasma clozapine levels were unchanged by citalopram.¹ Another study in 8 patients found similar results.² However, a patient who was stable taking clozapine developed sedation, hypersalivation and confusion shortly after he started to take citalopram 40 mg daily. When total clozapine serum levels were measured they were found to be 1097 nanograms/mL. The citalopram dose was reduced to 20 mg daily, the symptoms resolved over the following 2 weeks, and the total clozapine level dropped to 792 nanograms/mL.³

(b) Fluoxetine

Several studies and case reports have found increased clozapine levels of 30 to 75%, and increased levels of the metabolite norclozapine of 34 to 52% after fluoxetine was added to established clozapine treatment.^{4–6} In one case the levels of clozapine and norclozapine were raised over fivefold, accompanied by hypertension. Clozapine levels became subtherapeutic 2 weeks after fluoxetine was withdrawn, necessitating an increase in dosage.⁷

A patient who had been taking clozapine 500 mg and lorazepam 3 mg daily, developed myoclonic jerks of his whole body 79 days after fluoxetine 20 mg was added. These decreased over the next 2 days when the fluoxetine and lorazepam were stopped.⁸ A case report describes a patient taking clozapine, who developed severe SSRI withdrawal within a day of

stopping treatment with fluoxetine 40 mg daily, which had been taken for 4 months. The symptoms resolved when treatment with fluvoxamine was started. Although it was suggested that clozapine may have been involved in this effect⁹ its role is unclear.

The death of a 44-year old patient who was taking clozapine and fluoxetine was felt to be due to an increase in clozapine levels caused by fluoxetine.¹⁰

In contrast, there are reports of successful use,¹¹ and no pharmacokinetic changes¹² when clozapine and fluoxetine were used together.

A case has also been reported of a patient with schizophrenia and depression, whose cognitive symptoms improved when he took clozapine and fluoxetine, but when treatment was changed to sertraline, this improvement was not sustained. The authors tentatively suggested that the fluoxetine elevated plasma clozapine levels by inhibition of CYP2D6, whereas this effect was not seen with sertraline as it is a much weaker inhibitor of this enzyme.¹³ However, this explanation has been questioned, since the role of other drug metabolising enzymes was not considered.¹⁴

(c) Fluvoxamine

Up to tenfold elevations in plasma clozapine levels have been seen in several studies and case reports when clozapine was given with fluvoxamine.¹⁵⁻²⁵ These elevations occurred as early as 14 days after combined treatment was started,²⁵ but were often not associated with any significant adverse effects, even after treatment had continued for a year in one patient.¹⁸ Another study, which compared 12 patients taking clozapine with 11 patients taking clozapine and fluvoxamine, found that in the combined treatment group, clozapine doses were about half those used when clozapine was given alone. A trend towards decreased granulocyte levels was also seen in the clozapine/fluvoxamine group, but not when clozapine was used alone.²⁶

Another patient had extremely high plasma clozapine levels of up to 4160 micrograms/L as a result of taking fluvoxamine.²⁷

Other cases have also demonstrated worsening psychosis²⁸ or extrapyramidal adverse effects²⁹ (including, rigidity, tremors and akathisia) and sedation within days of giving fluvoxamine with clozapine.

A study in 68 patients taking either clozapine alone or clozapine and fluvoxamine found a trend towards less weight increase after 12 weeks of treatment in the group of patients also taking fluvoxamine. Those patients taking clozapine alone were found to have significantly higher glucose and triglyceride levels.³⁰ Note that fluvoxamine treatment alone can result in weight loss.

(d) Paroxetine

The serum levels of clozapine and norclozapine rose by 57% and 50%, respectively, in 16 schizophrenic patients after they took an average of 31.2 mg of paroxetine daily. One patient taking clozapine 300 mg daily developed reversible cerebral intoxication when given paroxetine 40 mg daily.⁵ Another patient with a delusional disorder developed an antimuscarinic syndrome with doubled serum clozapine levels within about 3 weeks of the addition of paroxetine.³¹ A further study in 9 patients found that the serum levels of clozapine and norclozapine rose by 31% and 20%, respectively, when paroxetine 20 to 40 mg daily was given for 3 weeks. Two patients experienced mild and transient sedation 2 to 3 days after starting paroxetine. The rise in clozapine levels was not associated with an increase in efficacy and was well tolerated.³² In contrast, a study in 14 patients taking clozapine 2.5 to 3 mg/kg daily found that the addition of paroxetine 20 mg daily had no effect on the serum levels of clozapine.²³ This, or similar work, has been published elsewhere.³³

An increase in the plasma levels of clozapine, thought to be due to concurrent treatment with paroxetine, has been suggested as the causative factor in the development of a fatal venous thromboembolism in a 47-year-old woman.³⁴

A fatal case of neuroleptic malignant syndrome which started to develop two days after the introduction of clozapine 25 mg daily to established treatment with paroxetine 20 mg daily has been reported. The patient had previously taken clozapine alone with no problem.³⁵

(e) Sertraline

In 10 schizophrenic patients the serum levels of clozapine and norclozapine increased by 30% and 52%, respectively, when they started to take an average of 92.5 mg of sertraline daily.⁵ Another patient taking clozapine 600 mg daily had a 40% reduction in total clozapine serum levels within one month of stopping sertraline 300 mg daily.³⁶

The serum clozapine levels of a schizophrenic patient doubled within a month of adding sertraline 50 mg daily and her psychosis worsened. When the sertraline was stopped she improved and her serum clozapine levels fell once again.²⁸ In contrast, a study in 8 patients who were taking clozapine 200 to 400 mg daily and were also given sertraline 50 to 100 mg per day for 3 weeks, found no significant changes in the levels of clozapine and its major metabolites.³²

A case report describes sudden cardiac death in a 26-year-old man, which the authors attributed to an interaction between clozapine and sertraline.³⁷ However, this interaction has been questioned as it is said that the patient had other risk factors that were more likely to have caused the fatality.³⁸

Mechanism

The SSRIs (including **escitalopram**) are known to inhibit the cytochrome P450 isoenzyme CYP2D6 to a varying extent. Fluvoxamine is also a potent inhibitor of CYP1A2. Both of these isoenzymes are involved in the metabolism of clozapine, the most significant being CYP1A2, so their inhibition causes clozapine levels to rise. The levels of clozapine and norclozapine rise together, and so it has been suggested that the metabolic step inhibited is after the *N*-dealkylation step.⁵

Importance and management

These interactions are established. Concurrent use need not be avoided, but it would be prudent to monitor the outcome closely when any is used with clozapine because of the rises in serum clozapine and norclozapine levels that can occur, and because of the rare potential for deterioration in clinical status. Adjust the clozapine dosage as necessary. The authors of one study suggest particularly close monitoring if the daily clozapine dosage exceeds 300 mg or 3.5 mg/kg.⁵ The interaction is greatest with fluvoxamine, so other SSRIs may be a more prudent choice, although close monitoring is still required.

Clozapine + Tobacco

Smoking tobacco appears to decrease clozapine levels, although not all studies have found an effect.

Clinical evidence, mechanism, importance and management

Tobacco smoking might be expected to lower serum clozapine levels because the smoke contains aromatic hydrocarbons that are potent inducers of the cytochrome P450 isoenzyme CYP1A2, but studies of this likely interaction have been equivocal. One group of workers found no differences in clozapine levels with smoking,¹ while another group found that smokers had lower clozapine levels.² In addition, a case report describes clozapine-induced seizures in a man when he gave up smoking, although no levels were available so the authors point out it is difficult to be sure that smoking cessation was the cause.³ Two further case reports describe elevations in clozapine plasma levels when the patients stopped smoking abruptly.⁴ A retrospective study found that the clozapine clearance was 86% higher in 9 smokers than in 3 non-smokers, although it should be noted that this study was not specifically looking at the effects of smoking.⁵ A suggestion has been made that in a patient who started to smoke, a 1.5-fold increase in clozapine dose should be anticipated. Likewise, a patient who stops smoking may experience a 1.5-fold increase in clozapine levels within 2 to 4 weeks of stopping smoking. In all cases, dose adjustments should be guided by the clinical status of the patient, and clozapine levels where available.⁶

Droperidol + MAOIs

An isolated report describes hypotension in a patient given droperidol shortly after the withdrawal of phenelzine.

Clinical evidence, mechanism, importance and management

Four days after the withdrawal of **phenelzine** and perphenazine, a patient was given operative premedication of droperidol 20 mg and hyoscine 400 micrograms, orally. About 2 hours later he was observed to be pale, sweating profusely and slightly cyanosed, with a blood pressure of 75/60 mmHg and a pulse rate of 60 bpm. He was not excitable, and no changes in respiration were seen. The blood pressure gradually rose to 115/80 mmHg over the next 45 minutes, but did not return to his normal level of 160/100 mmHg for 36 hours. The same premedication was given 11 days later without any adverse effects.¹ The response was attributed to the residual effects of **phenelzine** treatment. Its general significance is unclear.

1. Penlington GN. Droperidol and monoamine-oxidase inhibitors. *BMJ* (1966) 1, 483–4.

Fluphenazine + Ascorbic acid (Vitamin C)

A single case report describes a reduction in serum fluphenazine levels and signs of a reduction in its effects when a patient was also given ascorbic acid.

Clinical evidence, mechanism, importance and management

A man with a history of manic behaviour, taking fluphenazine 15 mg daily, had a 25% reduction in his plasma fluphenazine levels, from 0.93 to 0.705 nanograms/mL, over a 13-day period while taking ascorbic acid 500 mg twice daily. This was accompanied by a deterioration in his behaviour.¹ The reason for this effect is not understood. There seem to be no other reports of this interaction with fluphenazine or any other phenothiazine so that this interaction would not appear to be of general importance.

1. Dysken MW, Cumming RJ, Channon RA, Davis JM. Drug interaction between ascorbic acid and fluphenazine. *JAMA* (1979) 241, 2008.

Fluphenazine + Spiramycin

Acute dystonia occurred when a man taking fluphenazine was also given spiramycin.

Clinical evidence, mechanism, importance and management

A man with a schizoaffective disorder taking lorazepam, orphenadrine, fluvoxamine and fluphenazine decanoate 12.5 mg every 2 weeks, developed acute and painful dystonia of the trunk, neck, right arm and leg about one week after his last fluphenazine injection and on the fourth day of taking spiramycin 6 million units daily for gingivitis. The problem resolved when he was given biperiden.¹ The reasons for this adverse reaction are not understood, nor is it entirely clear whether this was an interaction between fluphenazine and spiramycin, although the author suggested that a causal link existed. This seems to be the only report of an alleged interaction between fluphenazine and a macrolide antibacterial and it is therefore of little or no general importance.

1. Benazzi F. Spiramycin-associated acute dystonia during neuroleptic treatment. *Can J Psychiatry* (1997) 42, 665–6.

Glutethimide + Tobacco

A study in 7 subjects found that glutethimide worsened psychomotor performance in smokers more than in non-smokers, possibly due to an increase in glutethimide absorption.¹ However there

would seem to be no need for particular caution if smokers take glutethimide.

1. Crow JW, Lain P, Bochner F, Shoeman DW, Azarnoff DL. Glutethimide and 4-OH glutethimide: pharmacokinetics and effect on performance in man. *Clin Pharmacol Ther* (1978) 22, 458–64.

Haloperidol + Alosetron

A placebo-controlled study in 10 patients taking haloperidol found that alosetron 1 mg daily given during weeks 2 and 3 of the 8-week study period caused no change in haloperidol pharmacokinetics.¹

1. Gupta SK, Kunka RL, Metz A, Lloyd T, Rudolph G, Perel JM. Effect of alosetron (a new 5-HT₃ receptor antagonist) on the pharmacokinetics of haloperidol in schizophrenic patients. *J Clin Pharmacol* (1995) 35, 202–7.

Haloperidol + Antimycobacterials

The serum levels of haloperidol can be reduced by rifampicin (rifampin), and possibly raised by isoniazid.

Clinical evidence

A study in schizophrenic patients taking haloperidol, 7 of whom were also taking a range of antimycobacterial drugs (ethambutol, isoniazid, rifampicin), and 18 of whom were taking isoniazid only, showed that those receiving multiple drugs, which included rifampicin had significantly lower haloperidol serum levels. The half-life of haloperidol in 2 patients taking rifampicin was 4.9 hours compared with 9.4 hours in 3 other patients not taking rifampicin.¹ Three of the patients taking isoniazid (without rifampicin or ethambutol) had increased serum haloperidol levels.¹

The trough serum haloperidol levels of 15 schizophrenics fell to 37.4% of the expected level after they took rifampicin 600 mg daily for 7 days.² After 28 days the serum level had dropped further to 30% of the expected level. In another group of 5 patients taking haloperidol and rifampicin, the serum haloperidol levels rose to 229% of the previous level 7 days after rifampicin was stopped, and to 329% 28 days after rifampicin was stopped.² The clinical effects of the haloperidol appeared to be reduced by the rifampicin.²

Mechanism

The likeliest explanation is that the rifampicin, a recognised enzyme inducer, increases the metabolism and loss of the haloperidol from the body.

Importance and management

The interaction between haloperidol and rifampicin would appear to be established and clinically important. Be alert for any evidence of reduced haloperidol effects if rifampicin alone is used, and possibly increased effects if isoniazid alone is used. Adjust the haloperidol dosage if necessary.

1. Takeda M, Nishinuma K, Yamashita S, Matsubayashi T, Tanino S, Nishimura T. Serum haloperidol levels of schizophrenics receiving treatment for tuberculosis. *Clin Neuropharmacol* (1986) 9, 386–97.

Haloperidol + Buspirone

Two studies found that buspirone can cause a rise in plasma haloperidol levels, while another study found that no interaction occurred.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 27 schizophrenic patients taking haloperidol 10 to 40 mg daily found that buspirone 5 mg three times daily for 2 weeks, followed by 10 mg three times daily for 4 weeks, did not significantly affect the steady-state plasma haloperidol levels.¹

These findings contrast with those of a 6-week study, in which 6 out of 7 schizophrenics had 15 to 122% rises in their plasma haloperidol levels when they were given buspirone.² The authors also mention a single-dose study in healthy subjects, which found a 30% rise in haloperidol levels when subjects were given buspirone.²

It is not known why these findings differ, but since no adverse reactions have been reported, there would seem to be no reason for avoiding concurrent use. However, be aware that some patients seem to experience large rises in haloperidol levels, so consider this potential interaction if the effects of haloperidol seem excessive.

1. Huang HF, Jann MW, Wei F-C, Chang T-P, Chen J-S, Juang D-J, Lin S-K, Lam YFW, Chien C-P, Chang W-H. Lack of pharmacokinetic interaction between buspirone and haloperidol in patients with schizophrenia. *J Clin Pharmacol* (1996) 36, 963–9.

Haloperidol + Chlorpromazine

Some patients may show a large increase in haloperidol levels when they are given chlorpromazine.

Clinical evidence, mechanism, importance and management

Haloperidol was given to 43 patients in doses of 2 to 21 mg daily for 2 months, and then chlorpromazine 50 mg to 300 mg daily was added for a further 2 months. Haloperidol plasma levels were found to increase by an average of 28.5%, and levels of the metabolite, reduced haloperidol, were increased by 161%. However, the variation in effect was large. Chlorpromazine was thought to raise haloperidol levels by inhibiting haloperidol metabolism by the cytochrome P450 isoenzyme CYP2D6. The large inter-individual variation suggested that differences in cytochrome P450 genotypes may affect haloperidol metabolism,¹ and therefore some patients may be at risk of developing adverse effects related to high haloperidol levels.

1. Suzuki Y, Someya T, Shimoda K, Hirokane G, Morita S, Yokono A, Inoue Y, Takahashi S. Importance of the cytochrome P450 2D6 genotype for the drug metabolic interaction between chlorpromazine and haloperidol. *Ther Drug Monit* (2001) 23, 363–8.

Haloperidol + Dexamfetamine

Acute dystonia occurred in two healthy subjects when they were given haloperidol with dexamfetamine.

Clinical evidence, mechanism, importance and management

Two healthy young women were given haloperidol 5 mg and dexamfetamine 5 mg as part of a neuropharmacological study. After 29 hours one of them developed stiffness of neck and limbs, parkinsonian facies, her tongue protruded, and she had oropharyngeal spasm. After 34 hours the other woman developed an oculogyric crisis and acute dystonia of the neck with her back slightly arched. Both recovered rapidly after being given 10 mg of intramuscular procyclidine.¹

The reasons for this interaction are not fully understood, but the authors of the study suggest that the acute dystonia was due to a potentiation of dopamine release. The clinical significance of this interaction is unclear.

1. Capstick C, Checkley S, Gray J, Dawe S. Dystonia induced by amphetamine and haloperidol. *Br J Psychiatry* (1994) 165, 276.

Haloperidol + Granisetron

Granisetron appears not to increase the adverse effects of haloperidol.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that while haloperidol 3 mg alone caused some impaired psychometric performance (increased drowsiness, muzziness, lethargy, mental slowness, etc.), the addition of granisetron 160 micrograms/kg did not seem to make performance significantly

worse.¹ If both drugs are used, no additional precautions would seem necessary.

1. Leigh TJ, Link CGG, Fell GL. Effects of granisetron and haloperidol, alone and in combination, on psychometric performance and the EEG. *Br J Clin Pharmacol* (1992) 34, 65–70.

Haloperidol + Grapefruit juice

Ingestion of 200 mL of regular-strength grapefruit juice three times a day for 7 days was found not to affect the pharmacokinetics of haloperidol in 12 schizophrenic patients receiving haloperidol 6 mg twice daily.¹

1. Yasui N, Kondo T, Suzuki A, Otani K, Mihara K, Furukori H, Kaneko S, Inoue Y. Lack of significant pharmacokinetic interaction between haloperidol and grapefruit juice. *Int Clin Psychopharmacol* (1999) 14, 113–8.

Haloperidol + Imipenem

Marked but transient hypotension was seen when three patients receiving intravenous imipenem were given low dose intravenous haloperidol.

Clinical evidence, mechanism, importance and management

Three patients in intensive care who were being treated with intravenous imipenem 500 mg (with cilastatin) every 6 hours for 2, 3, and 7 days, respectively, developed a rapid and short-lived episode of hypotension when they were given a 2.5-mg dose of intravenous haloperidol. For example, the blood pressure of one of the patients fell from 117/75 mmHg to 91/49 mmHg. After 30 minutes her blood pressure had risen to 100/57 mmHg. No treatment for hypotension was given to any of the patients and the reaction was brief and self-limiting. Two of them were also taking famotidine and erythromycin. No acute ECG changes were seen.¹

The reason for this fall in blood pressure is not understood, but the authors attribute what happened to the concurrent use of haloperidol and imipenem, although they point out that intravenous haloperidol alone can cause orthostatic hypotension. One suggestion is that competitive protein binding displacement might have transiently increased the levels of free haloperidol,¹ although this has been questioned, and a suggestion made that the clinical condition of the patients may have had a greater part to play in the development of hypotension than a drug-drug interaction.²

The authors advise that if haloperidol is used, low doses should be given, and the outcome well monitored. They say that no pressor agent was needed in these cases, but they suggest the possible use of metaraminol, phenylephrine or noradrenaline (norepinephrine) rather than dopamine, the vasopressor effects of which might be blocked or reversed by haloperidol.¹

2. Hauben M. Comments on "Hypotension associated with intravenous haloperidol and imipenem". *J Clin Psychopharmacol* (2001) 21, 345–7.

Haloperidol + Indometacin

Profound drowsiness and confusion have been described in patients given haloperidol with indometacin.

Clinical evidence, mechanism, importance and management

A crossover study in 20 patients, designed to find out the possible advantages of combining haloperidol 5 mg daily with indometacin 25 mg three times daily, was eventually abandoned because 13 patients (11 taking haloperidol and 2 taking placebo) failed to complete the study. Profound drowsiness or tiredness caused 6 of the haloperidol-treated patients to withdraw. The authors of this paper said that the combined treatment produced drowsiness and confusion greater than anything expected with haloperidol alone, and sufficiently severe that in some cases independent functioning was affected.¹

Evidence of this interaction appears to be very limited. If concurrent use is thought appropriate, warn patients about this potentially severe effect. It

might be wiser to avoid concurrent use because many patients requiring this type of treatment may not be hospitalised and under the day-to-day scrutiny of the prescriber.

Haloperidol and related drugs + Itraconazole

Itraconazole increases the plasma levels of haloperidol, and its metabolite, reduced haloperidol. Bromperidol may be similarly affected.

Clinical evidence

(a) Bromperidol

A study in 8 patients found that plasma levels of bromperidol 12 or 24 mg daily, were increased by itraconazole 200 mg daily for 7 days. The average increase was approximately 87%, but there was wide variation between patients, with some being unaffected and others having increases of up to 302%. Levels of the metabolite of bromperidol, reduced bromperidol, were similarly increased, by up to 415%.¹

(b) Haloperidol

A study in 13 schizophrenic patients taking haloperidol 6 mg or 12 mg twice daily found an increase in the levels of haloperidol and its metabolite, reduced haloperidol, when itraconazole 200 mg daily was given for 7 days. Haloperidol levels increased by 30%, and levels of the metabolite, reduced haloperidol, were increased by 24%. There was also an increase in neurological adverse effects during itraconazole treatment.² In a randomised study 15 healthy subjects were given itraconazole 200 mg twice daily for 10 days with a single 5-mg dose of haloperidol on day 7. Itraconazole increased the AUC of haloperidol by 55% in the 8 subjects with normal CYP2D6 and by 81% in those with unstable CYP2D6. No significant changes in QT prolongation were seen.³

Mechanism, importance and management

It is likely that itraconazole inhibited the metabolism of bromperidol and haloperidol by CYP3A4. The wide variation in results may be attributed to interindividual variation in CYP3A4 activity.

The clinical significance of the raised levels is unclear, although one study found an increase in neurological adverse effects with haloperidol. It may be prudent to monitor concurrent use, decreasing the haloperidol or bromperidol dose if adverse effects become troublesome. This interaction may be of more importance in those patients have less active CYP2D6, the predominant isoenzyme involved in the metabolism of haloperidol, as CYP3A4, which is inhibited by itraconazole, will then become more important. It is likely that other azoles that are potent inhibitors of CYP3A4, such as ketoconazole, would interact similarly, but this needs confirmation.

Haloperidol + Nefazodone

Nefazodone does not appear to significantly affect the pharmacokinetics of haloperidol.

Clinical evidence, mechanism, importance and management

After taking nefazodone 200 mg twice daily for about 7 days to achieve steady-state pharmacokinetics, the AUC of haloperidol 5 mg in 12 healthy subjects was found to be increased by 36% but the maximum plasma lev-

els of haloperidol were unaltered. The pharmacokinetics of the nefazodone were unaltered.¹ It seems fairly unlikely that this change is enough to be of clinical relevance.

1. Barbhaiya RH, Shukla UA, Greene DS, Breuel H-P, Midha KK. Investigation of pharmacokinetic and pharmacodynamic interactions after coadministration of nefazodone and haloperidol. *J Clin Psychopharmacol* (1996) 16, 26–34.

Haloperidol + Quinidine

Haloperidol levels can be markedly increased by quinidine.

Clinical evidence, mechanism, importance and management

An experimental study in 13 healthy subjects found quinidine bisulfate 250 mg, taken about 1 hour before a single 5-mg dose of haloperidol approximately doubled the maximum plasma levels and the AUC of haloperidol. The reasons for this effect are not understood.¹ The clinical importance of this interaction has not been assessed, but it seems likely that the effects and adverse effects of haloperidol will be increased if quinidine is added. Be alert for this interaction if both drugs are given.

Haloperidol + Risperidone

A case report describes neuroleptic malignant syndrome in a patient taking risperidone and haloperidol.

Clinical evidence, mechanism, importance and management

A case report describes a 57-year-old man who had been taking haloperidol 4 mg three times daily uneventfully for several years. At a review, his treatment was changed to risperidone, in increasing doses to 3 g twice daily, and mirtazapine 15 mg at night. Despite being advised to stop haloperidol when he started risperidone, the patient continued to take haloperidol, and by the third day of concurrent use he had become pyrexial, and exhibited rigidity of his trunk and extremities. He was diagnosed as having the neuroleptic malignant syndrome, was given dantrolene, bromocriptine and lorazepam, and recovered over the next 2 months. The effects seen in this patient were thought to be due to the additive dopamine antagonism from both the haloperidol and risperidone. Mirtazapine may have also contributed, although the patient only took two doses before he was admitted. The authors suggest that if antipsychotic treatment is to be changed, it is advisable to slowly reduce the dose of the old antipsychotic and, simultaneously, slowly increase the dose of the new drug to avoid the risk of a psychotic relapse, and the patient should be closely monitored during this time for signs of neuroleptic malignant syndrome.¹

Haloperidol + Venlafaxine

Venlafaxine can increase the serum levels of haloperidol. This is consistent with an isolated report, which describes a man who developed urinary retention when venlafaxine was added to a previously well-tolerated regimen of haloperidol and alprazolam.

Clinical evidence, mechanism, importance and management

A study in 24 healthy subjects found that steady-state venlafaxine 75 mg every 12 hours reduced the renal clearance of a single 2-mg dose of haloperidol by 42%, resulting in a 70% rise in the AUC and an 88% rise in its maximum serum levels.^{1–3} This rise in haloperidol levels would seem to be consistent with an isolated report of a 75-year-old man taking haloperidol 1 mg and alprazolam 500 micrograms daily, who suddenly developed urinary retention when venlafaxine 37.5 mg daily was added.

Urinary retention resolved spontaneously when all the drugs were stopped.⁴

It was suggested that venlafaxine inhibits the cytochrome P450 isoenzyme CYP2D6, which is concerned with the metabolism of haloperidol. As a result the serum levels of the haloperidol rise, thereby increasing its antimuscarinic effects,⁴ which in this case resulted in urinary retention.

The evidence is very limited but be aware that increased haloperidol adverse effects may occur if venlafaxine is also given. It may be necessary to reduce the haloperidol dosage.

Olanzapine + Antiepileptics

Carbamazepine and valproate appear to lower olanzapine levels. The combination of olanzapine and valproate appears to increase the risk of hepatic injury in children. Olanzapine reduces lamotrigine levels and lamotrigine may increase olanzapine levels, although these changes are not expected to be clinically significant in the majority of patients. Oxcarbazepine dose not appear to affect the pharmacokinetics of olanzapine.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine

Multiple-dose studies in healthy subjects have shown that carbamazepine increases the metabolism of olanzapine (by induction of the cytochrome P450 isoenzyme CYP1A2). The clearance of olanzapine was increased by 44% and its elimination half-life was reduced 20%, but these changes were not considered significant enough to necessitate dosage adjustments of either drug.¹ Another study found that 5 patients taking olanzapine and carbamazepine had a concentration/dose ratio 36% lower than 22 patients taking olanzapine alone.² A later study by the same authors found similar results, and also found that this increased olanzapine metabolism was probably due to an increase in glucuronidation, which was induced by the carbamazepine.³

A retrospective study identified 10 patients taking olanzapine and carbamazepine. The patients taking carbamazepine were taking olanzapine doses that were double those of subjects taking olanzapine alone. When corrected for dose it was found that the concentration/dose ratio of olanzapine was 71% lower in those also taking carbamazepine.⁴ A 23 year-old woman required an olanzapine dose reduction from 15 mg daily to 10 mg daily to maintain similar serum olanzapine concentrations after discontinuing treatment with carbamazepine 600 mg per day.⁵

It would seem prudent to closely monitor the outcome of concurrent use and adjust the olanzapine dose as necessary.

(b) Lamotrigine

A study in 43 healthy subjects found that steady-state olanzapine pharmacokinetics were not affected by lamotrigine 200 mg daily. However, the AUC and maximum plasma concentrations of lamotrigine were reduced by 24% and 20%, respectively. Although this reduction was not considered to be clinically significant, interpatient variation indicated that some patients may require adjustment of their lamotrigine dose if olanzapine is started or discontinued.⁶

A further study in 14 healthy subjects given lamotrigine 50 mg daily, and a single 5-mg dose of olanzapine found no significant changes in the AUC and maximum plasma concentrations of lamotrigine when given with olanzapine, although the time to maximum plasma levels of lamotrigine was increased from 1.8 hours to 4.2 hours. This may be due to antimuscarinic effects of olanzapine slowing the gastrointestinal absorption of lamotrigine.⁷ As only a single dose of olanzapine, and low doses of both drugs were used, the clinical significance of this finding is unclear.

A study in 14 patients taking olanzapine in doses of 10 mg to 20 mg daily, and who were also given lamotrigine in increasing doses over 8 weeks to 200 mg daily found no changes in the pharmacokinetics of olanzapine with a lamotrigine dose of 100 mg daily, but when the dose was increased

to 200 mg daily, an increase of 16% in olanzapine plasma levels occurred. This increase would not be expected to have clinical significance.⁸

(c) Oxcarbazepine

A study in 13 patients taking olanzapine 5 to 20 mg daily found that the addition of oxcarbazepine for 5 weeks, at an initial dose of 300 mg daily increased to 900 mg to 1.2 g after one week, had no significant effects on the pharmacokinetics of olanzapine. Concurrent use was generally well tolerated.⁹ No special consideration or monitoring therefore appears necessary with oxcarbazepine and olanzapine treatment.

(d) Valproate

A retrospective study identified 52 children (under 18 years old) who were treated with olanzapine alone (17), semisodium valproate alone (23) or both drugs together (12). At least one peak liver enzyme level (ALT, AST or lactate dehydrogenase) was found to be above the normal range in 59% of those taking olanzapine alone, 26% of those taking valproate alone, and 100% of patients receiving the combination. Liver enzymes were persistently elevated in 42% of the patients receiving combination treatment, and 2 of these patients had levels that were three times the upper limit of normal. Treatment was discontinued due to pancreatitis in one and steatohepatitis in the other. The authors recommend measuring liver enzymes every 3 to 4 months for the first year of treatment, thereafter monitoring every 6 months if no adverse effects are detected.¹⁰

A significant reduction in olanzapine plasma levels of between 32.3% and 78.8% was found in 4 patients who were additionally given valproate, thought to be due to the valproate inducing the enzymes involved in the metabolism of olanzapine.¹¹

Olanzapine + Lithium

Several case reports suggest that some patients taking olanzapine and lithium may develop adverse reactions (neuroleptic malignant syndrome or serotonin syndrome, encephalopathy, priapism) without raised serum lithium levels. One study found no pharmacokinetic interaction between the drugs, but another analysis suggested that lithium may reduce olanzapine plasma levels.

Clinical evidence, mechanism, importance and management

A 16-year-old boy taking lithium 1.2 g daily with a therapeutic serum lithium level, developed neuroleptic malignant syndrome (generalised rigidity, urinary retention, fever, tachycardia) about 2 weeks after his olanzapine dose was increased from 10 to 20 mg daily. Both drugs were stopped, and the symptoms resolved over 8 days. He had previously taken olanzapine and lithium separately without problem.¹

A 59-year-old man who had been diagnosed with encephalopathy and confusion while taking a combination of carbamazepine, haloperidol and lithium (therapeutic lithium level), developed similar symptoms when he was later given lithium with olanzapine.² Another elderly patient who had taken lithium for 7 years, developed severe delirium and extrapyramidal

symptoms after the addition of olanzapine. Serum lithium levels were found to be 3 mmol/L.³ The serotonin syndrome developed in a patient with bipolar affective disorder taking lithium and citalopram after olanzapine was also given. She became increasingly irritable 3 months after starting the combination and one month later (4 days after increasing the dose of olanzapine from 15 to 20 mg and stopping the citalopram) she became severely agitated, confused and was sweating profusely with hyperreflexia, tremor and a low-grade fever. The symptoms resolved on cessation of her medication.⁴ Citalopram may have contributed to this reaction, as the serotonin syndrome has been reported with 'lithium and SSRIs', (p.1115).

A case of non-ketotic hyperosmolar syndrome has been reported in a non-diabetic patient taking olanzapine, lithium and valproic acid. Symptoms began only 5 days after the olanzapine was started.⁵ Priapism, which was reversed by surgical detumescence, occurred when a 30-year-old man took olanzapine with lithium.⁶

In an open-label study, 12 healthy subjects took a single 32.4-mmol dose of lithium with olanzapine 10 mg, and after a washout period, olanzapine 10 mg daily for 8 days, with a single 32.4-mmol dose of lithium on the last day. No pharmacokinetic interactions were detected.⁷ However, an analysis of olanzapine levels in schizophrenic patients found that concurrent lithium was associated with lower olanzapine plasma levels.⁸

The case reports detailed above suggest that some patients may develop a pharmacodynamic interaction. Concurrent use of lithium and olanzapine need not be avoided but be aware that there is some risk of developing adverse reactions to the combination. The presence of other serotonergic drugs (e.g. antidepressants such as SSRIs) or dopamine antagonists (e.g. antipsychotics such as haloperidol) is likely to increase the risk of an interaction.

Olanzapine + Miscellaneous

Activated charcoal causes a fall in olanzapine levels and venlafaxine moderately raise olanzapine levels. Additive dopaminergic effects have been seen in one patient taking olanzapine and haloperidol. Olanzapine appears not to interact to a clinically relevant extent with aluminium/magnesium hydroxide antacids, cimetidine or diazepam. However, excessive sedation and hypotension may occur with parenteral benzodiazepines and intramuscular olanzapine.

Clinical evidence, mechanism, importance and management

(a) Antacids

The manufacturers of olanzapine say that single doses of an aluminium/magnesium-containing antacid had no effect on the pharmacokinetics of olanzapine.¹ No special precautions would seem to be needed during concurrent use.

(b) Benzodiazepines

In vivo studies have found that no pharmacokinetic interaction occurs between olanzapine and diazepam.¹ This confirms *in vitro* studies using human liver microsomes,¹ which demonstrated that olanzapine did not inhibit the cytochrome P450 isoenzymes CYP3A4 or CYP2C19, which are concerned with the metabolism of diazepam. It was noted that mild increases in heart rate, sedation and dry mouth were seen in patients taking both drugs, but no dosage adjustments were thought to be necessary.² There would therefore appear to be no reason for avoiding concurrent use.

Intramuscular lorazepam 2 mg, given 1 hour after intramuscular olanzapine 5 mg increased the drowsiness seen with either drug alone. The pharmacokinetics of both drugs were not affected.^{3,4} One case report de-

scribes hypotension occurring following the intramuscular use of a single 2-mg dose of **lorazepam** to a patient receiving treatment with intramuscular olanzapine 10 mg, the most recent dose being given 30 minutes before the **lorazepam**. His blood pressure dropped from 124/74 to 66/30 mm Hg; 12 hours later his blood pressure had returned to normal.⁵ Intramuscular olanzapine has been associated with hypotension, bradycardia, respiratory depression, and rarely death, particularly in patients who have also received benzodiazepines. The manufacturers therefore say that concurrent use is not recommended. If both drugs are needed, parenteral benzodiazepines should not be given for 1 hour after intramuscular olanzapine. If a parenteral benzodiazepine has already been given, intramuscular olanzapine should only be given with careful consideration and monitoring of sedation and respiration.⁴

(c) *Charcoal, activated*

The manufacturers report that activated charcoal reduces the bioavailability of oral olanzapine by 50 to 60%,^{1,3} and recommend that administration be separated by 2 hours.¹

(d) *Cimetidine*

The manufacturers say that cimetidine has no effect on the bioavailability of olanzapine.³ No special precautions would seem to be needed during concurrent use.

(e) *Haloperidol*

A 67-year-old man with a long history of bipolar disorder was taking haloperidol 10 mg daily, with valproate and benztropine. Because he had previously had parkinsonian symptoms, olanzapine was started, to be increased as the haloperidol was decreased. On day 6 his parkinsonian symptoms became particularly marked. The haloperidol was stopped and 2 days later the symptoms had resolved. It is thought that either the small amount of dopaminergic activity of olanzapine combined with that of the haloperidol brought on these symptoms, or that olanzapine affected the metabolism of haloperidol, caused increased levels and therefore greater dopaminergic activity.⁶ The significance of this interaction is not clear, but it would be wise to be aware of this interaction if both drugs are used.

(f) *Venlafaxine*

A retrospective study found that venlafaxine caused a 27% increase in olanzapine plasma levels. The clinical significance of this finding is unclear.⁷

Olanzapine + Probenecid

Probenecid may increase the AUC and maximum plasma levels of olanzapine, but the clinical significance of this finding is unclear.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects were given a single 5-mg dose of olanzapine alone, or on day 2 of a 4 day course of probenecid 500 mg twice daily. The AUC and maximum plasma levels of olanzapine were significantly increased by about 20%, but overall bioavailability was not affected. The probenecid is thought to have caused these small effects by reducing the glucuronidation of olanzapine.¹ As this was a single dose study, the clinical implications of this interaction when olanzapine is taken regularly, are unclear, but probably small

1. Markowitz JS, DeVane CL, Liston HL, Bouton DW, Risch SC. The effects of probenecid on the disposition of risperidone and olanzapine in healthy volunteers. *Clin Pharmacol Ther* (2002) 71, 30–8.

Olanzapine + Quinolones

The olanzapine levels of a patient were reduced when ciprofloxacin was stopped.

Clinical evidence, mechanism, importance and management

The olanzapine levels of a patient were rapidly reduced, by more than 50%, when ciprofloxacin 250 mg twice daily was stopped. On the day of the last dose of a 7 day course of ciprofloxacin her olanzapine plasma level was 32.6 nanograms/mL, but within 3 days it had fallen to 14.6 nanograms/mL. It is thought that elevated levels occurred because ciprofloxacin inhibits the cytochrome P450 isoenzyme CYP1A2, which is involved in the metabolism of olanzapine.¹ The UK manufacturers of olanzapine recommend that a lower dose of olanzapine should be given to patients taking ciprofloxacin.² Note that other quinolones can inhibit CYP1A2 to varying degrees (for an example see 'Theophylline + Quinolones', p.1192) and may therefore be expected to interact similarly.

2. Zyprexa (Olanzapine). Eli Lilly and Company Ltd. UK Summary of product characteristics, September 2006.

Olanzapine + Ritonavir

Ritonavir almost halves olanzapine levels.

Clinical evidence, mechanism, importance and management

A single 10-mg dose of olanzapine was given to 14 healthy, non-smoking subjects after they had taken ritonavir for 11 days (initially 300 mg twice daily, escalating to 500 mg twice daily). Ritonavir decreased the AUC and maximum plasma levels of olanzapine by 53% and 40%, respectively, and reduced the half-life from 32 to 16 hours.¹

The authors suggest that ritonavir increased the metabolism of olanzapine by inducing the cytochrome P450 isoenzyme CYP1A2, which is the main metabolic route of olanzapine. They also suggest that increased glucuronidation, mediated by glucuronyltransferases induced by ritonavir, may have contributed.

It seems likely that increased olanzapine doses may be needed in the presence of ritonavir. If concurrent use is necessary monitor for olanzapine efficacy and increase the dose if necessary.

1. Penzak SR, Hon YY, Lawhorn WD, Shirley KL, Spratlin V, Jann MW. Influence of ritonavir on olanzapine pharmacokinetics in healthy volunteers. *J Clin Psychopharmacol* (2002) 22, 366–70.

Olanzapine + SSRIs

Fluvoxamine causes a rise in serum olanzapine levels, which is associated with increased adverse effects. Fluoxetine, paroxetine and sertraline appear to moderately raise olanzapine levels while citalopram appears to have no effect. A case of retarded ejaculation has been seen in one patient taking olanzapine and paroxetine, and the serotonin syndrome has been reported in patients taking citalopram or fluoxetine with olanzapine.

Clinical evidence, mechanism, importance and management

(a) *Fluvoxamine*

In a placebo-controlled study, fluvoxamine 50 to 100 mg daily was given to 10 male smokers daily for 11 days, with olanzapine 2.5 to 7.5 mg daily on days 4 to 11. During the initial 4 days of concurrent use somnolence was increased by 19 to 115%, when compared to the group taking olanzapine and placebo, but the subjects accommodated to this over the next 4 days. Fluvoxamine increased the olanzapine maximum plasma levels and AUC by 84% and 119%, respectively, and the olanzapine clearance fell by 50%.¹ A retrospective study found that in patients taking fluvoxamine and olanzapine the concentration/dose ratio was 2.3-fold higher than those taking olanzapine alone.² In another study 10 schizophrenic patients were given fluvoxamine 50 mg daily from days 1 to 14 followed by fluvoxamine 100 mg daily from days 15 to 28. A single 10-mg dose of

olanzapine was given on day 10 and again on day 24. The maximum plasma levels of olanzapine were raised by 12% and 64% and the clearance was reduced by about 25% and 35%, by 50 and 100 mg of fluvoxamine, respectively. Increased sedation was also seen, which was more frequent with fluvoxamine 100 mg daily.³ Other studies have found 50 to 81% increases in olanzapine levels with fluvoxamine 100 mg daily, which took up to 8 weeks to occur. There was a marked variation between individuals in the extent of the interaction.⁴⁻⁶ In one study, plasma levels of olanzapine were maintained when the dose of olanzapine was reduced by an average of 4.5 mg daily following the addition of fluvoxamine 25 mg daily.⁷

The olanzapine plasma levels of a 21-year-old woman were 6 times the recommended upper limit while she was taking fluvoxamine. During this time she developed rigidity and tremor. After the olanzapine dose was reduced from 15 mg to 5 mg daily the levels were still almost double the recommended level.⁸

(b) Other SSRIs

The manufacturers say that **fluoxetine** 60 mg daily for 8 days caused an increase of 16% in olanzapine maximum serum levels and a 16% decrease in clearance. These differences were considered to be too small to necessitate dosage adjustments.⁹ Similar results were found in a published study.¹⁰ A case report describes a patient who had been taking **fluoxetine** 80 mg daily for several weeks with no adverse effects who developed the serotonin syndrome within 3 weeks of starting to take olanzapine 5 mg daily. His symptoms resolved after discontinuing the **fluoxetine**, and he was later able to tolerate a 20 mg daily dose of **fluoxetine** and olanzapine with no further adverse effects.¹¹ The serotonin syndrome has also been reported in a patient taking olanzapine, **citalopram** and lithium, see 'Olanzapine + Lithium', p.756.

A patient taking fluvoxamine had olanzapine levels double the upper recommended limit; when **paroxetine** was substituted for fluvoxamine the olanzapine levels became almost normal.⁸ Another patient taking **paroxetine** developed retarded ejaculation 2 months after he started to take olanzapine 15 mg daily. This adverse effect resolved when the olanzapine was given in divided doses.¹²

A retrospective study found that **sertraline** had no effect on the concentration/dose ratio of olanzapine, suggesting that it does not interact.²

Another study found that **paroxetine**, **fluoxetine** and **sertraline** increased olanzapine levels by about 32%, but **citalopram** had no effect.⁶

Mechanism

Fluvoxamine inhibits the cytochrome P450 isoenzyme CYP1A2, which is the major isoenzyme involved in the metabolism of olanzapine,¹ resulting in increased olanzapine levels and adverse effects. All SSRIs affect CYP2D6 (to differing extents). This isoenzyme has a minor role in olanzapine metabolism, and therefore SSRIs other than fluvoxamine have only a small effect on olanzapine levels.

Importance and management

The manufacturers of olanzapine suggest that lower olanzapine doses may be needed if fluvoxamine is given.^{9,13} Monitor for fluvoxamine adverse effects. Other SSRIs appear not to interact significantly, although the case report with paroxetine suggests that additive adverse effects are a possibility.

Olanzapine + Tobacco

Smoking tobacco increases the clearance of olanzapine.

Clinical evidence, mechanism, importance and management

A retrospective study found that cigarette smoking reduced olanzapine levels,¹⁻³ in one study by 12%¹ and by about 50% in another,³ and that smokers needed higher doses of olanzapine than non-smokers (10 mg compared with 12.5 mg) yet had lower olanzapine levels (60 nanomol/L compared with 92 nanomol/L).⁴

A study in 17 psychiatric patients found that the olanzapine concentration/dose ratio was directly related to CYP1A2 activity: both CYP1A2 activity and olanzapine levels were sixfold higher in smokers than non-smokers.⁵ A case report describes a patient who was successfully treated with olanzapine 15 mg daily whilst in hospital and smoking up to 12 cigarettes a day. However, on discharge his cigarette consumption increased to 80 per day, and his schizophrenic symptoms worsened. Olanzapine plasma levels reduced from 52 nanograms/mL to 30 nanograms/mL as his cigarette consumption increased to 80 per day.⁶

The manufacturers say that smokers have a 40% greater clearance of olanzapine than non-smokers.⁷ The consequences are that the effects of olanzapine will be reduced to some extent by smoking. The manufacturers say that dosage adjustments are not routinely recommended in smokers because of the overall variability in dosing between individuals.^{7,8}

Olanzapine + Tricyclic and related antidepressants

No pharmacokinetic interaction occurs between imipramine or mirtazapine and olanzapine, but the additive effects of clomipramine and olanzapine was thought to have caused a seizure in one patient.

Clinical evidence, mechanism, importance and management

(a) Mirtazapine

In a study in 7 patients, mirtazapine 30 mg daily did not significantly affect the pharmacokinetics of olanzapine, taken in doses ranging from 10 to 20 mg daily.¹

(b) Tricyclic antidepressants

A randomised, crossover study in 9 healthy men given single doses of olanzapine 5 mg and **imipramine** 75 mg found no clinically relevant pharmacokinetic or pharmacodynamic interactions between the two drugs.² This would seem to confirm *in vitro* studies using human liver microsomes,³ which demonstrated that olanzapine causes minimal inhibition of the cytochrome P450 isoenzyme CYP2D6, an enzyme involved in the metabolism of the tricyclic antidepressants. However, one case report describes seizures, thought to be caused by the additive effects of olanzapine

and **clomipramine**. Neither drug alone had produced this reaction in the patient.⁴ No special precautions would seem to be necessary if both drugs are used concurrently, but be aware that they both have the potential to lower the seizure threshold and that the effect may be additive.

Perospirone + Miscellaneous

Carbamazepine reduces, and itraconazole increases, perospirone levels.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine

Carbamazepine reduced the plasma levels of a single 8-mg dose of perospirone to below the detection limit.¹ This is likely to be as a result of carbamazepine-induced induction of perospirone metabolism by CYP3A4.

(b) Itraconazole

Administration of itraconazole 200 mg daily for 5 days, with a single 8-mg dose of perospirone given on day 6 resulted in a 6-fold increase in perospirone maximum plasma levels. A similar increase in the AUC and the half-life of perospirone was also seen.² As itraconazole is a potent inhibitor of CYP3A4, the increase in levels is likely to be due to inhibition of metabolism of perospirone.

Perphenazine + Disulfiram

A single case report describes a man taking perphenazine whose psychotic symptoms re-emerged when he started to take disulfiram.

Clinical evidence, mechanism, importance and management

A man taking perphenazine 8 mg twice daily developed marked psychosis soon after starting to take disulfiram 100 mg daily.¹ His serum perphenazine levels had fallen from a range of 2 to 3 nanomol/L to less than 1 nanomol/L. Doubling the dosage of perphenazine had little effect, and no substantial clinical improvement or rise in serum levels occurred until he was given intramuscular perphenazine enantate 50 mg weekly, at which point the levels rose to about 4 nanomol/L. The results of clinical biochemical tests suggested that the disulfiram was acting as an enzyme inducer, resulting in increased metabolism and clearance of the perphenazine. However, disulfiram normally acts as an enzyme inhibitor. Too little is known to assess the general importance of this interaction, and there seems to be no information about an interaction with other phenothiazines.

- Hansen LB, Larsen N-E. Metabolic interaction between perphenazine and disulfiram. *Lancet* (1982) ii, 1472.

Phenothiazines + Antimalarials

Chloroquine, amodiaquine and Fansidar (sulfadoxine/pyrimethamine) can markedly increase serum chlorpromazine levels.

Clinical evidence

A total of 15 schizophrenic patients (in three groups of five) taking **chlorpromazine** 400 or 500 mg daily for at least 2 weeks were given single doses of either **chloroquine sulphate** 400 mg, **amodiaquine hydrochloride** 600 mg or three tablets of **Fansidar** (**pyrimethamine** 25 mg with **sulfadoxine** 500 mg) one hour before the **chlorpromazine**. Serum **chlorpromazine** levels 3 hours later were found to be raised about threefold by the **chloroquine** and **amodiaquine**, and almost fourfold by the **Fansidar**. The plasma level of 7-hydroxychlorpromazine, one of the major metabolites of **chlorpromazine**, was also elevated, but not those of the other metabolite, chlorpromazine sulphoxide. The serum **chlorpromazine** levels of the patients given **chloroquine** or **Fansidar** were, to some extent, still elevated 4 days later. There was subjective evidence that the patients were more heavily sedated when given the antimalarials.¹

Mechanism

Not understood. Both chloroquine and *Fansidar* have relatively long half-lives compared with amodiaquine, which may explain the persistence of their effects.

Importance and management

Direct information about this interaction seems to be limited to this study. Its clinical importance is uncertain but it seems possible that these antimalarials could cause chlorpromazine toxicity. Monitor the effects of concurrent use closely and anticipate the need to reduce the chlorpromazine dosage. More study is needed. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257. For mention that promethazine may increase chloroquine levels, see 'Chloroquine + Promethazine', p.223.

Importance and management

1. Makanjuola ROA, Dixon PAF, Oforah E. Effects of antimalarial agents on plasma levels of chlorpromazine and its metabolites in schizophrenic patients. *Trop Geogr Med* (1988) 40, 31–3.

Phenothiazines + Barbiturates

The levels of chlorpromazine, and possibly thioridazine, are decreased by phenobarbital. Phenothiazines also appear to reduce barbiturate levels. However, the clinical importance of these reductions is uncertain. Pentobarbital, promethazine and hyoscine in combination are said to increase the incidence of peri-operative agitation.

Clinical evidence

(a) Phenothiazine levels reduced

A study in 12 schizophrenic patients taking **chlorpromazine** 100 mg three times daily found that **phenobarbital** 50 mg three times daily reduced plasma **chlorpromazine** levels by 25 to 30%, which was accompanied by changes in certain physiological measurements, which clearly reflected a reduced response. The conclusion was made that there was no advantage to be gained by concurrent use.¹

In another study in 7 patients, the plasma levels of **thioridazine** were reduced by **phenobarbital**, but the clinical effects of this were uncertain.² However, another study found that **phenobarbital** caused no changes in serum **thioridazine** levels, but the levels of its active metabolite (mesoridazine) were reduced.³

(b) Phenobarbital levels reduced

A study in epileptic patients found that their serum phenobarbital levels fell by 29% when they were given phenothiazines, which included **chlorpromazine**, **thioridazine** or **mesoridazine**, and increased when the phenothiazine was withdrawn.⁴

This study confirms another, in which **thioridazine** 100 to 200 mg daily was found to reduce serum phenobarbital levels by about 25%.⁵ There is also some limited evidence that the concurrent use of pentobarbital, **promethazine** and hyoscine increases the incidence of pre-operative, peri-operative and postoperative agitation, and it has been suggested that this triple combination should be avoided.⁶

Mechanism

Uncertain. The barbiturates are potent liver enzyme inducers, and so it is presumed that they increase the metabolism of the phenothiazines by the liver.

Importance and management

These interactions appear to be established, but the documentation is limited. Their importance is uncertain, but be alert for evidence of reductions in response to both drugs if a phenothiazine and a barbiturate are given, and to increased responses if one of the drugs is withdrawn. So far only chlorpromazine, mesoridazine, phenobarbital and thioridazine are implicated, but it seems possible that other phenothiazines and barbiturates will behave similarly.

Phenothiazines + Hormonal contraceptives or HRT

Oestrogens can increase the plasma levels of butaperazine. A case report describes a marked rise in serum chlorpromazine levels in a woman taking a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

A severe dystonic reaction to a single dose of **prochlorperazine** in a pregnant woman (presumed to be due to increased plasma levels resulting from high oestrogen levels), prompted further study. Four postmenopausal schizophrenic women. **Conjugated oestrogens** (*Premarin*) 1.25 mg daily increased the plasma **butaperazine** levels by 48% (from 231 to 343 nanograms/mL) and increased the AUC by 92%.¹

A case report describes a woman who had been taking **chlorpromazine** 100 mg three times daily for one week without problems when a combined oral contraceptive (**ethinylestradiol/norgestrel**) was started. Four days later she developed severe dyskinesias and tremor, and her **chlorpromazine** levels were found to have increased by about sixfold.² This case was briefly mentioned in an earlier report by the same authors.³

The reasons are not understood but increased absorption or reduced liver metabolism of the phenothiazines are suggested.^{1,2} The general clinical importance of these findings is not known, and documentation is very limited. There seem to be no other reports of adverse reactions, and the available data are insufficient to justify any general precautions. Further study is needed.

Phenothiazines + Trazodone

Undesirable hypotension occurred in two patients taking chlorpromazine or trifluoperazine with trazodone. Thioridazine causes a moderate rise in trazodone plasma levels. A fatal case of jaundice and hepatic encephalopathy has been reported with the use of trifluoperazine, thioridazine and trazodone.

Clinical evidence, mechanism, importance and management

A depressed patient taking **chlorpromazine** began to complain of dizziness and unstable gait within 2 weeks of starting to take trazodone 100 mg one to three times daily. His blood pressure had fallen to between 92/58 and 126/72 mmHg. Within 2 days of stopping the trazodone his blood pressure had stabilised.¹ A patient taking **trifluoperazine** was given trazodone 100 mg daily and within 2 days she complained of dizziness and was found to have a blood pressure of 86/52 mmHg. Within one day of stopping the trazodone her blood pressure was back to 100/65 mmHg.¹ It would seem that the hypotensive adverse effects of the two drugs can be additive.

A study, undertaken to confirm the involvement of the cytochrome P450 isoenzyme CYP2D6 in the metabolism of trazodone, found that when 11 depressed patients were given trazodone 150 to 300 mg at bedtime for 18 weeks, and then with **thioridazine** 20 mg twice daily for one week, the plasma levels of the trazodone and its active metabolite, *m*-chlorophenylpiperazine, rose by 36% and 54%, respectively.² No adverse reactions were described. In contrast, a case of fatal hepatic necrosis with cholestasis has been attributed to the concurrent use of trazodone and phenothiazines. A 72-year-old woman taking trifluoperazine, trazodone and lithium carbonate developed an elevated alanine aminotransferase level. Trifluoperazine was replaced with **thioridazine**, but 9 weeks later she became jaundiced and developed hepatic encephalopathy, and died 6 weeks after the onset of jaundice. The authors consider that the combination of the phenothiazines and trazodone were the cause of her hepatic necrosis: both phenothiazines and trazodone have been reported to individually cause hepatic adverse effects.³

Patients given phenothiazines and trazodone should be monitored for signs of excessive hypotension and should have their liver function tests closely monitored.

Phenothiazines + Tricyclic antidepressants

The concurrent use of tricyclic antidepressants and phenothiazines is common, but the tricyclic levels are increased by many of the phenothiazines, and the levels of some phenothiazines are also increased by the tricyclics. It has been suggested that concurrent use might contribute to an increased incidence of tardive dyskinesia. Nevertheless, fixed-dose combined preparations are available. Tricyclics have also been shown to reverse the therapeutic effects of chlorpromazine.

Clinical evidence

(a) Effect of phenothiazines on tricyclic antidepressants

An extended study of 4 patients given intramuscular **fluphenazine decanoate** 12.5 mg weekly, with benztropine 2 mg three times daily and **imipramine** 300 mg daily, found that the mean combined plasma concentrations of **imipramine** and its metabolite, desipramine, were 850 nanograms/mL. This appeared high, when compared with 60 other patients who were taking **imipramine** 225 mg daily and had levels of 180 nanograms/mL.¹

A comparative study of 99 patients taking **amitriptyline** or **nortriptyline** alone, and 60 other patients also taking **perphenazine** 10 mg daily, found that although the tricyclic antidepressant dosages were the same, the plasma tricyclic antidepressant levels of the **perphenazine** group were up to 70% higher.²

Other studies have described increased tricyclic antidepressant levels with phenothiazines. There is currently evidence for this interaction between:

- **imipramine**,^{3–5} and **chlorpromazine**
- **nortriptyline**,⁶ and **levomepromazine**
- **amitriptyline**,⁷ **imipramine**,^{5,8,9} **desipramine**¹⁰ or **nortriptyline**,^{6,11–13} and **perphenazine**
- **desipramine**,¹⁴ **imipramine**¹⁵ or **nortriptyline**,⁶ and **thioridazine**.

However, other studies have found no interaction between:

- **amitriptyline**,^{6,11,16} or **nortriptyline**,¹⁷ and **perphenazine**
- **amitriptyline**⁶ and **thioridazine**
- **amitriptyline**⁶ and **levomepromazine**
- **amitriptyline**¹¹ or **nortriptyline**,¹¹ and **zuclopenthixol**.

It should be noted that in the case of **amitriptyline**, although the levels were not affected, levels of nortriptyline, its metabolite, were raised.⁶

(b) Effect of tricyclic antidepressant on phenothiazines

In a controlled study in 8 schizophrenic patients taking **butaperazine** 20 mg daily, 6 of them taking **desipramine** 150 mg or more daily had a rise in serum **butaperazine** levels of between 50 and 300%. The other

2 patients, taking **desipramine** 100 mg or less, had no changes in **butaperazine** levels.¹⁸ Other studies have found a rise in phenothiazine levels when tricyclic antidepressants are added. So far, interactions with **chlorpromazine** and **amitriptyline**,¹⁹ **imipramine**¹⁹ or **nortriptyline**²⁰ have been documented.

One study in 7 chronic schizophrenics also reported that giving **nortriptyline** 50 mg three times daily to patients taking **chlorpromazine** 100 mg three times daily resulted in profound worsening of the clinical state, with marked increases in agitation and tension, despite the fact that the **chlorpromazine** levels were actually raised. The **nortriptyline** was withdrawn.²⁰ A temporary reversion to a disruptive behaviour pattern has been seen in other patients taking **chlorpromazine** when **amitriptyline** was given.²¹ One patient experienced a severe catatonic reaction that was attributed to the use of **thioridazine** and **amitriptyline**,²² and the case of a woman who became anxious with widely staring eyes, a persistent jerking of her head and at times the inability to speak was thought to be due to the use of **imipramine** and **chlorpromazine**.²³ Ventricular tachycardia has also been reported in a 38-year-old woman taking **desipramine** and **thioridazine**, which responded to treatment with lidocaine.²⁴

Mechanism

The rise in the serum levels of both drugs is thought to be due to a mutual inhibition of the liver enzymes concerned with the metabolism of both drugs, which results in their accumulation.^{3,4,8,18,20}

Importance and management

Established interactions, but the advantages and disadvantages of concurrent use are still the subject of debate. These two groups of drugs are widely used together in the treatment of schizophrenic patients who show depression, and for mixed anxiety and depression. A number of fixed-dose combinations have been marketed, e.g. amitriptyline with perphenazine, and nortriptyline with fluphenazine. However, the safety of using both drugs together has been questioned.

One of the problems of phenothiazine treatment is the development of tardive dyskinesias, and some evidence suggests that the higher the dosage, the greater the incidence.²⁵ The symptoms can be transiently masked by increasing the dosage,²⁶ and so it has been suggested that the presence of a tricyclic antidepressant might not only be a factor causing tardive dyskinesia to develop, but might also mask the condition.^{18,27} It has been recommended that the addition of full antidepressant doses of nortriptyline to average antipsychotic doses of chlorpromazine should be avoided because the therapeutic actions of the chlorpromazine may be reversed.²⁰ See also 'Antipsychotics + Antimuscarinics', p.708.

Attention has also been drawn to excessive weight gain associated with several months use of amitriptyline with thioridazine for the treatment of chronic pain,²⁸ but note that excessive weight gain is a recognised adverse effect of the antipsychotics alone.

The tricyclic antidepressants and many antipsychotics increase the QT interval, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257, for further information.

Pimozide + CYP3A4 inhibitors

Inhibition of CYP3A4 results in markedly increased pimozide levels and increases the risk of QT interval prolongation and the development of life-threatening arrhythmias.

Clinical evidence, mechanism, importance and management

The sudden death of a patient taking pimozide and **clarithromycin** prompted a study of a possible interaction between the two drugs. Using human liver microsomes it was found that pimozide is partly metabolised by the cytochrome P450 isoenzyme CYP3A, and that 2 micromol of **clarithromycin** inhibits this enzyme by at least 80%.¹ The practical consequences of this were seen in a later study in 12 healthy subjects, which found that **clarithromycin** 500 mg twice daily for 5 days more than doubled the AUC of a single 6-mg oral dose of pimozide and raised its maximum serum levels by almost 50%. The QTc interval was prolonged by about 17 milliseconds with pimozide alone and by 24 milliseconds when **clarithromycin** was added.² The results were the same in both poor and extensive CYP2D6 metabolisers (see 'Genetic factors', (p.4)). CYP2D6 status was considered as this is the other main metabolic route of pimozide. The authors of this study concluded that **clarithromycin** can therefore increase the cardiotoxicity of pimozide during chronic use, irrespective of the CYP2D6 status of the patient.² Pimozide alone has been associated with ventricular arrhythmias, prolongation of the QT interval, T-wave changes and sudden and unexpected death, even in the young with no previous evidence of cardiac disease.^{3,4} Due to the severity of this interaction the UK manufacturers contraindicate the use of macrolides with pimozide,⁵ whereas the US manufacturers contraindicate pimozide with **azithromycin**, **clarithromycin**, **dirithromycin**, **erythromycin** and **troleandomycin**.⁶ However, note that azithromycin does not usually interact with other drugs by inhibiting CYP3A4.

The use of many inhibitors of the cytochrome P450 isoenzyme CYP3A4 with pimozide is contraindicated since they are expected to increase plasma levels of pimozide, which is likely to result in QT prolongation and associated arrhythmias. The manufacturers specifically mention **azole antifungals**, **fluvoxamine**, **grapefruit juice**, **nefazodone**, **protease inhibitors**, and **zileuton**.^{5,6} Drugs that are known to cause clinically relevant CYP3A4 inhibition are listed in 'Table 1.4', (p.6).

Pimozide + SSRIs

Pimozide levels are expected to rise when used with fluoxetine, fluvoxamine, paroxetine, or sertraline, which would increase the risk of potentially fatal torsade de pointes arrhythmias. The use of SSRIs and pimozide has also led to extrapyramidal adverse effects, oculogyric crises and sedation in rare cases.

Clinical evidence, mechanism, importance and management

(a) Fluoxetine

A patient taking fluoxetine and pimozide had a worsening of extrapyramidal symptoms, and another developed marked sinus bradycardia of 35 to 44 bpm with somnolence.¹ This case was the subject of later discussion on the mechanism of the interaction.^{2,3} One patient also developed extrapyramidal symptoms,⁴ while another became stuporous when given both drugs.⁵

(b) Paroxetine

A boy of about 10 years, with various disorders (motor tics, enuresis, attention deficit hyperactivity disorder, Tourettes's disorder, impulsivity, albinism) was treated for a year with pimozide 2 mg twice, and later three times daily.⁶ Within 3 days of starting paroxetine 10 mg in the morning, he began to complain of his eyes hurting and his mother noted that about 4 hours after taking the paroxetine his eyes were rolled back in his head but the problem had resolved by the evening. This oculogyric crisis occurred on a further occasion, and so the paroxetine was stopped. There was no other evidence of either extrapyramidal or hyperserotonergic reactions. This case needs to be viewed in its particular context (oculogyric crises are associated with albinism) so that it may not be of general importance. In a study of a single 2-mg dose of pimozide given with paroxetine 60 mg daily, a 151% rise in pimozide AUC and a 62% rise in maximum plasma levels occurred.⁷

(c) Sertraline

A study found that sertraline 200 mg daily caused a 40% rise in the AUC and maximum plasma levels of a single 2-mg dose of pimozide. No ECG changes were seen.^{8,9}

A fatality has been reported with an overdose of moclobemide, sertraline and pimozide, with blood levels suggesting that none of the drugs individually would have been fatal.¹⁰

Mechanism

The SSRIs can, to varying degrees inhibit the cytochrome P450 isoenzyme CYP2D6 (and fluvoxamine possibly also inhibits CYP3A4) by which pimozide is metabolised. Concurrent use would therefore be expected to lead to raised pimozide levels.

Importance and management

Evidence is limited, however the interaction is potentially severe as raised pimozide levels can cause torsade de pointes arrhythmias, which can be fatal. The manufacturers of pimozide contraindicate its use with SSRIs, and in the UK they specifically name sertraline, paroxetine, and citalopram; which has been seen to cause QT prolongation with pimozide, and its isomer, escitalopram.⁷ The US manufacturers additionally contraindicate fluvoxamine.¹¹ Neither manufacturer mentions fluoxetine (except with regard to the possibility of additive bradycardia¹¹), but as it is known to have greater effects on CYP2D6 than either sertraline or citalopram, it would seem prudent to also consider it as contraindicated.

Prochlorperazine + Metoclopramide

A single case report describes tongue swelling and respiratory obstruction in a patient given prochlorperazine and then metoclopramide.

Clinical evidence, mechanism, importance and management

A 19-year-old woman experienced progressive swelling of the tongue, partial upper-airways obstruction and a sensation of choking over a period of 12 hours after she was given intramuscular doses of metoclopramide to a total of 30 mg. She had received a 12.5-mg intramuscular dose of prochlorperazine for nausea 24 hours earlier. On examination her tongue was strikingly blue, but within 15 minutes of receiving benzatropine 2 mg it returned to its normal size and colour. The respiratory distress also disappeared.¹ The authors of the report

suggested that the dystonic adverse effects of both drugs were additive, leading to the effects seen.¹ However, it should be noted that oedema of the tongue has also been described with metoclopramide alone.² Young patients, especially women, are particularly susceptible to the adverse effects of metoclopramide, and this patient received the standard total daily dose over just 12 hours, so an interaction is by no means established.

Promazine + Attapulgite-pectin

An attapulgite-pectin antidiarrhoeal preparation caused a small reduction in the absorption of promazine in one subject.

Clinical evidence, mechanism, importance and management

A study in one healthy subject found that attapulgite-pectin reduced the absorption of a single 50-mg dose of promazine by about 25%, possibly due to adsorption of the phenothiazine onto the attapulgite.¹ The clinical importance of this interaction and whether other phenothiazines behave similarly does not appear to have been studied. If a problem does occur, separating administration as much as possible (2 hours or more) to avoid admixture in the gut has been shown to minimise the effects of this type of interaction with other drugs.

Quetiapine + Antipsychotics

Quetiapine does not appear to interact with haloperidol or risperidone. Thioridazine moderately reduces quetiapine levels and a case report describes a seizure in a patient taking olanzapine and quetiapine.

Clinical evidence, mechanism, importance and management

In patients with schizophrenia or bipolar disorder given quetiapine 300 mg twice daily, thioridazine 200 mg twice daily reduced the steady-state quetiapine AUC and its maximum and minimum plasma levels by about 41%, 48% and 33%, respectively. It was suggested that this was due to an increased metabolism of quetiapine, although the mechanism for this effect was unclear.¹ These reductions are only moderate and their importance is not known, but until more information is available it would seem prudent to monitor concurrent use, being alert for the need to raise the quetiapine dosage.

Haloperidol 7.5 mg twice daily and **risperidone** 3 mg twice daily for 9 days had no significant effect on the pharmacokinetics of quetiapine 300 mg twice daily in the same study.¹ However, there is a case report de-

cribing considerable QT prolongation in a patient who took quetiapine 2 g whilst also taking **risperidone**. The authors consider this significant as the overdose was small, and because no QT prolongation was seen in toxicity studies of quetiapine when doses as large as 9.6 g were used,² although there is a single case of prolonged QTc interval associated with an overdose of 9.6 g.³ No special precautions would therefore appear to be routinely necessary if either of these drugs and quetiapine are used concurrently.

A case report describes a seizure lasting 30 to 60 seconds in a 27-year-old woman one day after quetiapine 100 mg daily was added to treatment with **olanzapine** 15 mg daily and sertraline 100 mg daily. The seizure was attributed to an interaction between quetiapine and **olanzapine**, although it seems possible that the sertraline also may have contributed.⁴

Concurrent use need not be avoided, but this case highlights the importance of considering seizure potential when prescribing multiple antipsychotic medications.

Quetiapine + CYP3A4 inducers

The plasma levels of quetiapine are reduced by phenytoin and carbamazepine, and are predicted to be reduced by barbiturates and rifampicin.

Clinical evidence, mechanism, importance and management

When 17 patients taking quetiapine 250 mg three times daily were given **phenytoin** 100 mg three times daily for 10 days, the oral clearance of quetiapine was increased fivefold.¹ This increased clearance appears to occur because **phenytoin** is an inducer of the cytochrome P450 isoenzyme CYP3A4, which is also concerned with the metabolism of quetiapine. In a study 14 patients took quetiapine 300 mg twice daily for 28 days, with **carbamazepine** 200 mg three times daily for 20 days. It was found that the AUC and maximum plasma levels of quetiapine were reduced by 87% and 80%, respectively.² **Carbamazepine** is also an inducer of CYP3A4, and therefore probably reduces quetiapine levels by this mechanism.

The manufacturers of quetiapine suggest that dosage adjustments [increases] may be necessary if quetiapine is given with **carbamazepine**, **phenytoin** or other enzyme inducers (such as **barbiturates** or **rifampicin**)^{3,4}. This is a reasonable prediction but no direct clinical evidence is yet available. However, be alert for the need to use an increased quetiapine dosage in patients given any of these drugs.

See 'Carbamazepine + Antipsychotics', p.524 for comment on the effect of quetiapine on carbamazepine.

Quetiapine + CYP3A4 inhibitors

The plasma levels of quetiapine are increased by erythromycin and ketoconazole. Azoles, macrolides, and protease inhibitors are expected to interact similarly.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects received a single 25-mg dose of quetiapine on day 4 of a 4 day course of **ketoconazole** 200 mg daily. The AUC and maximum plasma levels of quetiapine were increased by 522% and 235%, respectively, and the mean half-life of quetiapine was increased from 2.61 to 6.76 hours.¹ **Ketoconazole** is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 by which quetiapine is metabolised. Concurrent use

therefore reduced quetiapine metabolism and increased its levels.

A study in 19 Chinese patients who received quetiapine 200 mg twice daily and **erythromycin** 500 mg three times daily found that **erythromycin** increased the maximum plasma concentration, half-life and AUC of quetiapine by 68%, 92%, and 129%, respectively.² These increases probably occurred because **erythromycin** inhibited the metabolism of quetiapine by CYP3A4.

The UK manufacturers³ advise caution if quetiapine is given with **macrolides** and **azole antifungals**, and suggest that lower quetiapine doses should be considered. The US manufacturers also advise caution, and specifically name **itraconazole** and **fluconazole**, **erythromycin** and **protease inhibitors**,⁴ all of which are inhibitors of CYP3A4.

4. Seroquel (Quetiapine fumarate). AstraZeneca. US Prescribing information, July 2007.

Quetiapine + Lithium

Quetiapine slightly raised serum lithium levels in one study, but this was not statistically significant. Combined use did not increase the incidence of extrapyramidal symptoms in another study.

Clinical evidence, mechanism, importance and management

The steady-state serum lithium levels of 10 patients with schizophrenia, or schizoaffective or bipolar disorders were studied before, during, and after the concurrent use of quetiapine 250 mg three times daily. The lithium AUC_{0–12} and the maximum serum levels were raised by 12% and 4.5%, respectively, by quetiapine, and concurrent use was well tolerated.¹ This small rise was not statistically or clinically significant.

A randomised, placebo-controlled study in 191 patients found that quetiapine, combined with either lithium or valproate semisodium (divalproex sodium), was superior to lithium or valproate semisodium alone for treating bipolar mania. The incidence of extrapyramidal symptoms in patients receiving quetiapine with lithium or valproate semisodium was similar to those receiving placebo with lithium or valproate semisodium.² No special precautions would therefore appear to be necessary on concurrent use.

1. Potkin SG, Thyrum PT, Bera R, Carreon D, Alva G, Kalali AH, Yeh C. Open-label study of the effect of combination quetiapine/lithium therapy on lithium pharmacokinetics and tolerability. *Clin Ther* (2002) 24, 1809–23.
2. Sachs G, Chengappa KNR, Suppes T, Mullen JA, Brecher M, Devine NA, Sweitzer DE. Quetiapine with lithium or divalproex for the treatment of bipolar mania: a randomized, double-blind, placebo-controlled study. *Bipolar Disord* (2004) 6, 213–23.

Quetiapine + Miscellaneous

Quetiapine dose not appear to interact to a clinically relevant extent with **cimetidine**, **fluoxetine**, **imipramine** or **lorazepam**. Isolated cases of adverse outcomes have been reported with **diphenhydramine**, **lovastatin** and **mirtazapine**.

Clinical evidence, mechanism, importance and management

(a) Antidepressants

Fluoxetine 60 mg daily or **imipramine** 75 mg twice daily for 5 days had no clinically significant effect on the steady-state plasma levels of quetiapine 300 mg twice daily.¹ No special precautions would therefore appear to be necessary if either of these drugs and quetiapine are used concurrently.

A falsely elevated **imipramine** level was recorded when HPLC was used to determine serum **imipramine** levels in a patient taking **imipramine**, quetiapine, fluvoxamine, lithium and docusate. The abnormal readings were found to have been caused by a metabolite of quetiapine, and normal readings were obtained by altering the wavelength for detection of **imipramine**.² **Nortriptyline** levels have been found to be falsely elevated in a patient also taking quetiapine when blood was analysed using fluorescence polarisation immunoassay, but were normal when an HPLC

analysis was undertaken.³ Other immunoassay methods for identifying tricyclic antidepressants in blood and urine have also given false positive results in the presence of quetiapine.⁴

An isolated case of increased prolactin levels after the introduction of **mirtazapine** 15 mg daily has been reported in a woman who was taking quetiapine 400 mg daily. Her prolactin level normalised when the **mirtazapine** was stopped, but rechallenge again produced an increase in prolactin levels, although this was transient and appeared to resolve within one month. The authors suggest that the mirtazapine may have caused an increase in quetiapine-induced dopamine receptor blockade, or alternatively an agonist action at opioid receptors altered dopamine receptor function.⁵

(b) Cimetidine

Quetiapine 150 mg three times daily was given to 7 psychotic men with cimetidine 400 mg three times daily for 4 days. There were some slight alterations in the pharmacokinetics of the quetiapine, but these were within the intraindividual changes seen and so were not considered significant.⁶ There would therefore appear to be no reason for avoiding concurrent use.

(c) Diphenhydramine

A patient taking diphenhydramine 100 mg daily developed urinary retention when she increased her dose of quetiapine from 900 mg daily to 2.4 g daily. When the dose of quetiapine was reduced back to 900 mg daily, her urinary retention resolved. A further episode occurred when the patient again increased her quetiapine dose. Although quetiapine does not normally have antimuscarinic adverse effects at usual therapeutic doses, it is suggested by the authors that the likelihood of these adverse effects is increased at doses of quetiapine greater than 900 mg daily. This effect may have occurred as a result of additive antimuscarinic activity of both diphenhydramine and high-dose quetiapine.⁷

(d) Lorazepam

The pharmacokinetics and pharmacodynamic effects of a single 2-mg dose of lorazepam were studied in 10 men taking quetiapine 250 mg three times daily. It was found that the maximum serum lorazepam levels were not significantly changed by quetiapine, and the alterations in the performance of a number of psychometric tests were small and considered not to be clinically relevant.⁸

(e) Lovastatin

A patient taking quetiapine 800 mg daily and sertraline 100 mg daily developed a prolonged QTc interval of 569 milliseconds after starting to take lovastatin 10 mg daily. Following a reduction in the lovastatin dose to 5 mg daily, her QTc interval returned to her baseline of 424 milliseconds. It is suggested that lovastatin competitively inhibited the metabolism of quetiapine by CYP3A4, as both drugs are substrates for this enzyme, resulting in increased quetiapine levels.⁹ However, the full contribution of sertraline to this case was only briefly considered, and full details relating to the cardiac effects and calculation of the QTc interval are not given.¹⁰

(f) Valproate

Analysis of plasma quetiapine levels of 94 patients, 9 of whom were also taking valproate, found a 77% increase in the concentration dose ratio compared with those patients not taking valproate.¹¹ The US manufacturers¹² report that valproate semisodium (divalproex sodium) increases the maximum plasma levels of quetiapine by 17%, and the UK manufacturers state that these changes are not clinically relevant.¹³

Risperidone + Carbamazepine or Oxcarbazepine

Carbamazepine increases the metabolism of risperidone, resulting in reduced risperidone levels. Oxcarbazepine dose not significantly affect the pharmacokinetics of risperidone.

Clinical evidence

(a) Carbamazepine

A 22-year-old man taking risperidone 4 mg daily and carbamazepine 600 mg daily for schizophrenia had lower than expected risperidone levels, so his dose was doubled and the carbamazepine tailed off. Ten days after carbamazepine had been discontinued it was noted that his plasma 9-hydroxyrisperidone level was 49 micrograms/L; it had only been 19 micrograms/L when he was taking carbamazepine.¹ There are 4 other cases of this interaction between risperidone and carbamazepine.^{2–4} In one case, the addition of carbamazepine to established risperidone treatment resulted in a reduction in the risperidone and 9-hydroxyrisperidone levels of about 75% and 65%, respectively, accompanied by the return of the patients psychotic symptoms.⁴ In 2 other cases, a 20-year-old and an 81-year-old man developed parkinsonian symptoms when carbamazepine was stopped. The symptoms resolved when the doses of risperidone were reduced by about two-thirds.²

These cases are supported by a study in 5 patients taking carbamazepine and risperidone for schizophrenia or bipolar disorders. The dose-normalised plasma level of risperidone and its active metabolite, 9-hydroxyrisperidone, were 68% and 64% lower, respectively, with carbamazepine, when compared to those with risperidone alone.⁵ Another study in 11 patients who had been taking risperidone for 2 to 68 weeks found that carbamazepine 200 mg twice daily for a week approximately halved the plasma levels of risperidone and its active moiety (risperidone plus 9-hydroxyrisperidone).⁶

(b) Oxcarbazepine

A study in 12 patients taking risperidone 2 to 6 mg daily found that the addition of oxcarbazepine for 5 weeks, at an initial dose of 300 mg daily increased to 900 mg to 1.2 g after one week, had no significant effects on the pharmacokinetics of risperidone. Concurrent use was generally well tolerated.⁷

Mechanism

Carbamazepine is a known potent enzyme inducer, which appears to increase the metabolism of risperidone by the cytochrome P450 isoenzyme CYP2D6 (although other isoenzymes may play a part). The extent of the interaction appears to be related to CYP2D6 genotype (see ‘Genetic factors’, (p.4)). Oxcarbazepine is not known to affect CYP2D6-mediated metabolism.

Importance and management

It would seem important to monitor the levels of risperidone and 9-hydroxyrisperidone in patients given carbamazepine, being alert for the need to raise the risperidone dosage, possibly by as much as two-thirds.

For mention that risperidone may moderately increase carbamazepine levels see ‘Carbamazepine + Antipsychotics’, p.524.

No special consideration or monitoring appears necessary with concurrent oxcarbazepine and risperidone treatment.

Risperidone + Itraconazole

Itraconazole increases the plasma levels of both risperidone and its active metabolite, 9-hydroxyrisperidone.

Clinical evidence

A study in 19 patients who were taking risperidone 2 to 8 mg daily found that the addition of itraconazole 200 mg daily for a week increased the plasma levels of risperidone and its active metabolite, 9-hydroxyrisperidone, by 82% and 70%, respectively. The levels returned to pre-treatment values one week after the itraconazole was stopped.¹ There was a small difference in the increase in the levels of risperidone between CYP2D6 extensive and poor metabolisers of risperidone, with extensive metabolisers showing a rise of 67% and poor metabolisers a rise of 70%.

Mechanism

Inhibition of metabolism of risperidone by the cytochrome P450 isoenzyme CYP3A is thought to have caused the increase in levels. The difference in the increase in levels of the extensive and poor metabolisers indicates that CYP2D6 has a minor part in the metabolism of risperidone.

Importance and management

Risperidone levels are expected to increase if itraconazole is given concurrently. Be aware for any signs of increased adverse effects, and consider reducing the dosage as necessary.

- Jung SM, Kim KA, Cho HK, Jung IG, Park PW, Byun WT, Park JY. Cytochrome P450 3A inhibitor itraconazole affects plasma concentrations of risperidone and 9-hydroxyrisperidone in schizophrenic patients. *Clin Pharmacol Ther* (2005) 78, 520–8.

Risperidone + Lamotrigine

One small study found no interaction between risperidone and lamotrigine, although a case report describes increased risperidone levels on concurrent use, and a retrospective study suggests that lamotrigine increases the variability on risperidone levels.

Clinical evidence

An isolated case report describes markedly increased risperidone levels in a patient given increasing doses of lamotrigine. When the lamotrigine dose was increased from 175 mg daily to 200 mg daily, the risperidone level increased from 69 nanogram/mL to 263 nanogram/mL. A further increase in the lamotrigine dose to 225 mg daily, while maintaining the risperidone dose of 8 mg daily resulted in a risperidone plasma level of 412 nanogram/mL, and the patient complained of dizziness and tiredness.¹ A retrospective review of 5 patients taking risperidone and lamotrigine, for whom there was pharmacokinetic data available both before and after the addition of lamotrigine, revealed a wide variation in alterations of risperidone levels, from a reduction of 40.5% to a rise of 73.6% after the addition of lamotrigine, with an average decrease of 7%.² A study in 10 patients taking risperidone 3 mg to 6 mg daily, and who were also given

en lamotrigine in increasing doses over 8 weeks to 200 mg daily also found no changes in the pharmacokinetics of risperidone.³

Mechanism, importance and management

Risperidone is metabolised by CYP2D6, but since lamotrigine is not a known inhibitor of this enzyme, a pharmacokinetic interaction was not thought to explain the change in levels.¹ The retrospective review and small study above failed to find any evidence of a consistent effect of lamotrigine on risperidone pharmacokinetics. However in view of the case report above, and also the fact that some individuals in the review demonstrated large changes in their risperidone levels, it would seem prudent to monitor patients for an increase in adverse effects, or a lack of therapeutic effect, if lamotrigine is given with risperidone.

Risperidone + Levomepromazine

Twenty patients receiving risperidone for at least 2 weeks were also given levomepromazine, in doses of 5 mg to 75 mg daily. There were no changes in the pharmacokinetics of risperidone or its active metabolite, 9-hydroxyrisperidone, and there was no aggravation of extrapyramidal effects.¹

- Yoshimura R, Shinkai K, Kakihara S, Goto M, Yamada Y, Kaji K, Ueda N, Nakamura J. Little effects of low dosage of levomepromazine on plasma risperidone levels. *Pharmacopsychiatry* (2005) 38, 98–100.

Risperidone + Lithium

Extrapyramidal adverse effects have been seen in a patient taking risperidone and lithium. No changes in lithium pharmacokinetics are expected.

Clinical evidence, mechanism, importance and management

A case report describes a 42-year-old woman who developed extrapyramidal adverse effects of the mouth after the addition of risperidone to established lithium treatment of 800 mg daily. Three days after her risperidone dose had reached 5 mg daily, she experienced an abrupt onset of abnormal perioral movements. Her serum lithium level was 0.7 mmol/L. Symptoms resolved after intravenous promethazine was given.¹ A non-diabetic patient developed diabetic ketoacidosis, 2 years after starting treatment with risperidone and lithium. During this acute illness he also experienced neuroleptic malignant syndrome and a myocardial infarction. The authors consider the combination of these two drugs was a causative factor, as the patient was able to continue treatment with lithium alone with no recurrence of this condition, or the need for antidiabetic medication.² The manufacturers of risperidone state that there was no significant change in the AUC and maximum plasma concentration of lithium when it was taken with risperidone.^{3,4} In general no particular caution would seem necessary on concurrent use, but be aware that, in rare cases, adverse effects may occur.

Risperidone + Probenecid

Twelve healthy subjects were given a single 1-mg dose of risperidone alone, or on day 2 of a 4 day course of probenecid 500 mg

twice daily. There were no significant changes in the pharmacokinetics of risperidone.¹

1. Markowitz JS, DeVane CL, Liston HL, Bouton DW, Risch SC. The effects of probenecid on the disposition of risperidone and olanzapine in healthy volunteers. *Clin Pharmacol Ther* (2002) 71, 30–8.

Risperidone + Protease inhibitors

The neuroleptic malignant syndrome, ataxia and severe lethargy leading to a coma, and extrapyramidal adverse effects have been seen in patients given risperidone with indinavir and ritonavir.

Clinical evidence, mechanism, importance and management

A 35-year-old man with AIDS was diagnosed with a Tourette's-like disorder and given risperidone 1 mg twice daily. After 2 weeks the risperidone was increased to 2 mg twice daily and he was also given **indinavir** 800 mg twice daily with **ritonavir** 200 mg twice daily. He discontinued the antiretrovirals after 5 days due to nausea, but started them again 1 month later when the tic disorder had improved. After 1 week he became short of breath and fatigued with worsening tremor and other extrapyramidal adverse effects. The antiretrovirals were stopped and the risperidone dose increased to 3 mg twice daily. Over the next 3 days his symptoms worsened and began to interfere with daily living. Risperidone was discontinued and clonazepam started, and his symptoms resolved.¹ Another patient developed neuroleptic malignant syndrome 3 days after starting to take risperidone with **indinavir** and **ritonavir**. This patient also recovered when the risperidone was stopped.² A third patient taking **indinavir** and **ritonavir** was given risperidone 3 mg twice daily to treat symptoms of mania. After 2 doses he became ataxic, drowsy and disorientated, which further developed into lethargy and coma. He recovered 24 hours after stopping all medication.³

Indinavir inhibits the cytochrome P450 isoenzyme CYP3A4 and **ritonavir** inhibits CYP2D6 and CYP3A4, which are the main isoenzymes involved in the metabolism of risperidone. Therefore concurrent use would be expected to raise risperidone levels. The symptoms reported in the cases above may have all been due to increased risperidone levels.^{1,3}

These appear to be the only reports of an interaction between risperidone and protease inhibitors, and their general significance is unclear. Until more is known it would be prudent to monitor patients taking risperidone who are given these protease inhibitors, particularly **ritonavir**, for risperidone adverse effects.

Risperidone + Reboxetine

No clinically relevant pharmacokinetic interaction appears to occur between risperidone and reboxetine.

Clinical evidence, mechanism, importance and management

Reboxetine 8 mg daily was given to 7 schizophrenic patients taking risperidone 8 mg daily for a period of 3 weeks. Reboxetine had no significant effects on the pharmacokinetics of either risperidone or its active metabolite, 9-hydroxyrisperidone, suggesting that no additional precautions are necessary if reboxetine and risperidone are used together.¹

1. Spina E, Avenoso A, Scordo MG, Ancione M, Madia A, Levita A. No effect of reboxetine on plasma concentrations of clozapine, risperidone, and their active metabolites. *Ther Drug Monit* (2001) 23, 675–8.

Risperidone + SSRIs

Fluoxetine, fluvoxamine, and paroxetine appear to raise risperidone levels. Sertraline appears to only moderately increase risperidone levels at high doses. The combination of SSRIs and risperidone is generally useful, but has resulted in a number of

adverse effects including priapism, extrapyramidal effects and the serotonin syndrome.

Clinical evidence

(a) Citalopram

A study in 7 patients found that citalopram had no effect on the plasma levels of risperidone or its active metabolite 9-hydroxyrisperidone.¹ A 29-year-old man with idiopathic priapism, about one 4-hour erection every 1 to 2 months, which typically woke him up, began to experience much longer bouts lasting 6 to 8 hours when he was given risperidone 4 mg daily. Within about 4 weeks of adding citalopram 40 mg daily to a slightly reduced risperidone dose (3 mg daily), he began to have almost daily erections lasting 12 hours. Three days after his dosages were changed to risperidone 3 mg twice daily with citalopram 20 mg daily he had an episode of such persistent priapism that emergency detumescence was needed. When both drugs were stopped he improved markedly and then only had occasional 4-hour erections, as before.²

(b) Fluoxetine

A pharmacokinetic study in 10 patients found that fluoxetine 20 mg daily raised the levels of risperidone 2 or 3 mg twice daily from 12 to 19 nanograms/mL after 3 weeks and to 56 nanograms/mL after 4 weeks. All patients experienced a rise in risperidone levels, but this varied from two to tenfold. One patient withdrew from the study because of severe akathisia and another two patients needed treatment with biperiden to control parkinsonian adverse effects.³ Similar findings were found in another study.⁴

A 30-year-old woman taking valproate, clonazepam, and risperidone 3 mg daily for schizophrenia was also given fluoxetine 5 mg daily for a depressive disorder. The depression improved, but she noticed painful bilateral breast enlargement, which resolved when risperidone was stopped. Similar symptoms were noted when the risperidone was later restarted.⁵

An 18-year old developed extrapyramidal adverse effects, and later persistent dyskinetic tongue movements when given fluoxetine and risperidone,⁶ and a 46-year-old man taking risperidone 2 mg daily developed urinary retention, extrapyramidal adverse effects, sedation and constipation, which developed over 10 days after fluoxetine 20 mg daily was started.⁷ A 26-year-old man developed severe tardive dyskinesia during treatment with risperidone and fluoxetine.⁸ A deterioration in obsessive-compulsive disorder has been seen when risperidone 3 mg daily was started in a patient who was partially successfully treated with fluoxetine 60 mg daily. After the addition of risperidone his condition returned to his pre-fluoxetine state. His condition gradually improved over a 3-month period once the risperidone was stopped. It was suggested that inhibition of metabolism of risperidone by fluoxetine may have resulted in elevated risperidone levels, leading to a deterioration in his condition.⁹

(c) Fluvoxamine

A 24-year-old woman taking risperidone 3 mg twice daily developed fever, limb rigidity, and confusion 3 days after starting fluvoxamine 50 mg daily. She required ventilation after her condition worsened and was eventually diagnosed as having either the serotonin syndrome or neuroleptic malignant syndrome. Both drugs were stopped and her condition resolved. She was later successfully treated with fluvoxamine 100 mg twice daily.¹⁰ A study, 6 patients who had been taking risperidone 3 to 6 mg daily for at least 4 weeks, with fluvoxamine 100 mg daily for a further 8 weeks, found no changes in the pharmacokinetics of risperidone or its metabolite. However, 5 patients also enrolled into this study were increased to fluvoxamine 200 mg daily for weeks 5 to 8, and there was an 85% increase in plasma risperidone levels by the end of week 8. There was no change in the pharmacokinetics of the active metabolite, 9-hydroxyrisperidone and no adverse reactions to risperidone were noted.¹¹

(d) Paroxetine

Paroxetine 20 mg daily was given to 10 patients taking risperidone 2 to 4 mg twice daily. After 4 weeks paroxetine had increased the levels of risperidone and its active metabolite, 9-hydroxyrisperidone, by 45%. Although the combination was generally well-tolerated one patient developed parkinsonian adverse effects.¹² Another study was undertaken in 12 patients taking risperidone 2 mg twice daily and paroxetine in doses increasing from 10 mg daily to 20 mg and 40 mg at 4 week intervals. The plasma levels of risperidone were increased 3.8-fold, 7.1-fold and 9.7-fold when given with paroxetine 10 mg, 20 mg and 40 mg daily, respectively. There was no change in the pharmacokinetics of the active metabolite,

9-hydroxyrisperidone. Negative symptoms of schizophrenia were improved, but there was an increased incidence of extrapyramidal adverse effects when patients took paroxetine 20 mg or 40 mg daily.¹³

A case report describes two elderly patients taking paroxetine who developed the serotonin syndrome within a couple of days of a risperidone dose increase. One patient's treatment had recently been changed from venlafaxine to paroxetine, which may have contributed to the reaction¹⁴ (see 'SNRIs; Venlafaxine + Antidepressants', p.1212). A further case report describes a 53-year-old man who developed symptoms suggestive of the serotonin syndrome 10 weeks after starting to take risperidone 3 mg daily and paroxetine 20 mg daily. A deterioration in his condition occurred within 2 hours of doubling the dose of both drugs. His symptoms resolved 2 days after stopping both drugs.¹⁵

(e) Sertraline

A study in 11 patients taking risperidone 4 to 6 mg daily found that patients given sertraline 50 to 100 mg daily for 8 weeks had no significant changes in the pharmacokinetics of risperidone. However, 2 patients required a dose increase to 150 mg by week 8, and in these patients the risperidone levels were increased by 36% and 52%, respectively. No significant adverse effects were reported in any of the patients and no signs of risperidone toxicity were seen in the 2 patients with raised risperidone levels.¹⁶

Mechanism

Fluoxetine and paroxetine inhibit the cytochrome P450 isoenzyme CYP2D6 by which risperidone is metabolised, hence risperidone levels rise. This can lead to extrapyramidal adverse effects and, it has been suggested, the increased prolactin levels and gynecomastia seen in one patient.⁵ Sertraline is thought to have a dose-dependent effects on CYP2D6 inhibition.¹⁶

Many of the other reactions (sedation, urinary retention, priapism) appear to be a result of additive adverse effects of the SSRIs and risperidone. The serotonin syndrome can result when two drugs with serotonin effects are given together, see 'Additive or synergistic interactions', (p.9).

Importance and management

The elevated risperidone levels seen with fluoxetine and paroxetine appear to be well-documented and clinically significant. The manufacturers of risperidone^{17,18} say that when adding either of these SSRIs the risperidone dose should be re-evaluated (presumably decreased). A one-third reduction in the risperidone dose has been suggested with fluoxetine.⁴ The concurrent use of risperidone and sertraline in usual therapeutic doses appears to be safe and well-tolerated. The significance of the raised risperidone levels in the two patients taking high-dose sertraline is unclear, however neither patient developed risperidone toxicity. The case reports of the serotonin syndrome appear to be rare, but they should be borne in mind when prescribing SSRIs and risperidone together.

Risperidone + Tetracycline

A patient experienced a worsening of his tics when tetracycline was added to treatment with risperidone and sertraline.

Clinical evidence, mechanism, importance and management

A 15-year-old boy taking risperidone 1.5 mg twice daily and sertraline 100 mg daily was given tetracycline 250 mg twice daily. His tics worsened, and did not respond to an increase in his sertraline dosage from 100 mg to 150 mg daily. After stopping the tetracycline, his tics improved within a few weeks. The exact mechanism of this interaction is unclear, but it has been suggested that the tetracycline somehow reduced the activity of the risperidone. Induction of CYP2D6 by tetracycline was thought unlikely, and inactivation of the risperidone or its active metabolite was considered a possible explanation.¹ This appears to be the only reported case of this interaction and its general significance is unknown.

1. Steele M, Couturier J. A possible tetracycline-risperidone-sertraline interaction in an adolescent. *Can J Clin Pharmacol* (1999) 6, 15-17.

Risperidone + Tricyclic and related antidepressants

No pharmacokinetic interaction normally occurs between risperidone and amitriptyline or mirtazapine, but extrapyramidal reactions have been reported in one patient taking amitriptyline with risperidone.

Clinical evidence, mechanism, importance and management

(a) Amitriptyline

A study in 12 schizophrenic patients found that amitriptyline 50 to 100 mg daily had no effect on the serum levels of risperidone 3 mg twice daily.¹ However, a 26-year-old man taking amitriptyline 25 mg daily developed extrapyramidal reactions after his dosage of risperidone was increased from 2 to 4 mg daily.² On another occasion extrapyramidal adverse effects developed after risperidone 2 mg daily was added to treatment with amitriptyline 25 mg and fluoxetine 20 mg daily.² Both pharmacokinetic and pharmacodynamic reasons for this reaction have been suggested.³ The cases illustrate that there is the potential for an adverse interaction between these drugs, which should be borne in mind when prescribing both drugs.

(b) Mirtazapine

A study in 8 patients taking risperidone in doses ranging from 3 to 8 mg daily found no significant change in the pharmacokinetics of risperidone and its metabolite, 9-hydroxyrisperidone when they were also given mirtazapine 30 mg daily.⁴

Risperidone + Valproate

There are case reports describing oedema in patients taking risperidone and sodium valproate. Studies suggest that risperidone does not alter the pharmacokinetics of sodium valproate or valp-

roic acid, although cases of increased and decreased levels have been reported.

Clinical evidence, mechanism, importance and management

A study comparing 10 patients taking **sodium valproate** and risperidone with 23 patients taking risperidone alone found no significant difference between the two groups, suggesting that **sodium valproate** and risperidone can be safely used together.¹ A study in 21 patients with bipolar disorder who were given **valproate semisodium** 1 g daily with risperidone 2 mg daily for 2 days increasing to 4 mg daily for 12 days found no significant changes in the pharmacokinetics of valproate. Adverse effects were unaltered.² However, the valproate levels of a 10-year-old boy increased from 143 to 191 mg/L 5 days after he started to take risperidone (initially 2 mg daily, then later 3 mg daily). This was attributed to an interaction, the exact mechanism of which is unclear.^{3,4} Conversely, a 15-year-old girl experienced a reduction in her valproate levels, from 80 to 57 microgram/mL when risperidone 1 mg three times daily was added to established treatment with **valproic acid**.⁵ Another case report describes the development of generalised acute oedema in a schizophrenic patient when risperidone (titrated to 10 mg daily) was added to established **sodium valproate** treatment. The oedema was unresponsive to diuretics, but resolved when the risperidone dose was reduced to 2 mg. When the risperidone dose was later increased to 8 mg the oedema reappeared, so the risperidone was withdrawn.⁶ A second case of oedema has been reported in a 35-year-old man who had taken **valproate semisodium** uneventfully for over 6 years. After treatment with risperidone for 2.5 weeks, significant oedema developed, which responded to treatment with hydrochlorothiazide and triamterene.⁷ Note that both drugs can cause oedema alone.^{8,9}

No special precautions seem necessary on concurrent use, but it is worth bearing these cases in mind when these two drugs are used together.

Risperidone + Venlafaxine

No clinically relevant pharmacokinetic interaction appears to occur between risperidone and venlafaxine.

Clinical evidence, mechanism, importance and management

Steady-state venlafaxine 75 mg every 12 hours was found to increase the AUC of a single 1-mg oral dose of risperidone by about 32%, but the pharmacokinetic profile of the risperidone plus its active metabolite (9-hydroxyrisperidone) was not significantly changed, nor were any adverse events seen.¹ There would seem to be no reason for avoiding concurrent use.

Ritanserin + Miscellaneous

Ritanserin does not interact with alcohol, cimetidine or ranitidine.

Clinical evidence, mechanism, importance and management

A study in 20 healthy subjects given ritanserin 10 mg with and without **alcohol** 0.5 g/kg found no pharmacokinetic or pharmacodynamic interac-

tions between these drugs.¹ **Cimetidine** 800 mg daily or **ranitidine** 300 mg daily given to 9 healthy subjects for 11 days caused only small changes in the pharmacokinetics of a single 10-mg dose of ritanserin given on day 3. These changes were attributed to altered absorption,² but were of little or no clinical significance.

Sertindole + Miscellaneous

The manufacturers of sertindole contraindicate the concurrent use of cimetidine, diltiazem, erythromycin, itraconazole, ketoconazole, terfenadine and verapamil because of an increased risk of cardiac arrhythmias. Carbamazepine and phenytoin reduce plasma sertindole levels whereas fluoxetine and paroxetine increase them. No clinically relevant interactions occur with alprazolam, antacids, food or tobacco smoking.

Clinical evidence, mechanism, importance and management

(a) Antacids or Food

A **standardised breakfast** or **Maalox** 45 mL had no significant effect on the AUC of a single 4-mg dose of sertindole in 16 healthy subjects, and only minor and unimportant changes occurred in maximum serum levels.^{1,2} No special precautions are needed if sertindole is given with **Maalox**, and it may be given without regard to meals.

(b) Antiepileptics

The metabolism of sertindole is markedly increased by enzyme inducers, such as **phenytoin** and **carbamazepine**, and plasma sertindole levels may be reduced by 2 to 3-fold. The manufacturers therefore say that the daily dosage of sertindole may need to be increased towards the upper end of the maximum dosage range to accommodate this interaction.^{3,4}

(c) Azoles

No formal studies have been carried out on the use of sertindole with either **itraconazole** or **ketoconazole**, but because both of these antifungals are potent inhibitors of CYP3A it is expected that a marked rise in serum sertindole levels may occur if they are given. The manufacturers therefore say that concurrent use is contraindicated³ because elevated serum levels are associated with a prolongation of the QTc interval and an increased risk of cardiac arrhythmias.

(d) Benzodiazepines

A pharmacokinetic study in 14 healthy subjects found only minor changes in pharmacokinetics of a single 1-mg dose of **alprazolam** due to the presence of sertindole 12 mg daily. The changes were considered to be clinically unimportant.⁵

(e) Calcium-channel blockers

Studies in patients found that **diltiazem**, **nifedipine** or **verapamil** resulted in a 20% reduction in the sertindole clearance, attributed to inhibition of CYP3A metabolism.⁴ The manufacturers contraindicate concurrent use (**diltiazem** and **verapamil** are specifically named) as raised sertindole levels may prolong the QT interval.³

(f) Cimetidine

Because cimetidine is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A it is expected that sertindole levels may be increased. The manufacturers therefore contraindicate concurrent use as raised sertindole levels may prolong the QT interval.³

(g) Erythromycin

A single 4-mg dose of sertindole was given to 10 healthy subjects before and after a course of erythromycin 250 mg every 6 hours for 10 days. The mean maximum serum levels were increased by 15%, probably because erythromycin inhibits the cytochrome P450 isoenzyme CYP3A4, but this was not considered to be clinically significant. The incidence of adverse events also rose (diarrhoea, abdominal pain, dizziness) but no ECG changes were seen.^{6,7} Nevertheless the manufacturers contraindicate erythromycin because raised sertindole levels may prolong the QT interval.³ Also

note that intravenous erythromycin is itself associated with prolongation of the QT interval, see 'drugs that prolong the QT interval', (p.257).

(h) Protease inhibitors

The protease inhibitor are all, to varying degrees, inhibitors of the cytochrome P450 isoenzyme CYP3A4 by which sertindole is metabolised. The manufacturers therefore contraindicate concurrent use, as raised sertindole levels may lead to torsade de pointes arrhythmias, which are potentially life-threatening.³

(i) SSRIs

Fluoxetine and **paroxetine** are inhibitors of the cytochrome P450 isoenzyme CYP2D6. Concurrent use results in a two- to three-fold increase in sertindole plasma levels. The manufacturers advise that low maintenance doses of sertindole may be needed and recommend close ECG monitoring when doses are adjusted.³ An isolated case report describes a man with paranoid psychosis and unipolar depression whose condition unexpectedly seriously worsened when **paroxetine** was stopped while continuing to take sertindole.⁸

(j) Terfenadine

A single 120-mg dose of terfenadine was given to 14 healthy subjects who had taken sertindole 20 mg daily for 5 days. The pharmacokinetics of neither drug was significantly changed, nor that of the metabolite of terfenadine (carboxyterfenadine), although it was concluded that sertindole may be a modest inhibitor of the first pass metabolism of terfenadine.^{9,10} However, it was found that the combination caused an additive increase of 49 milliseconds in the QTc interval and therefore these two drugs are contraindicated by the manufacturer.³

(k) Tobacco

The clearance of sertindole is increased by tobacco smoking (probably because of the induction of cytochrome P450 isoenzymes) but no sertraline dosage alteration is thought necessary.⁴

Thioridazine + Naltrexone

Extreme lethargy occurred when two patients taking thioridazine were given naltrexone.

Clinical evidence, mechanism, importance and management

Two schizophrenic patients taking thioridazine 50 to 200 mg three times daily for at least one year took part in a pilot project to assess the efficacy of naltrexone for the treatment of tardive dyskinesias. Both patients tolerated the first challenge dose of intravenous naltrexone 800 micrograms without problems, but experienced extreme lethargy and slept almost continuously after the second naltrexone dose of 50 to 100 mg orally. The severe lethargy resolved within 12 hours of stopping the naltrexone.¹ The reasons for this reaction are not understood. Information seems to be limited to this report and the general importance of this interaction is unknown. There seems to be nothing documented about other phenothiazines. Note that a case report has described excessive sleepiness

and lethargy in a 58-year-old man who took a single 100-mg dose of naltrexone alone,² so an interaction is by no means established.

2. Malcolm R, Gabel T, Morton A. Idiosyncratic reaction to naltrexone augmented by thioridazine. *Am J Psychiatry* (1988) 145, 773-4.

Thioridazine + Phenylpropanolamine

A single case report describes fatal ventricular fibrillation, which was attributed to the use of thioridazine with phenylpropanolamine.

Clinical evidence, mechanism, importance and management

A 27-year-old schizophrenic woman who was taking thioridazine 100 mg daily and procyclidine 2.5 mg twice daily was found dead in bed 2 hours after taking a single capsule of *Contac C* (phenylpropanolamine 50 mg with chlorphenamine 4 mg). The principal cause of death was attributed to ventricular fibrillation.¹ Just why this happened is not understood but it is suggested that it may have been due to the combined effects of the thioridazine (known to be cardiotoxic and to cause T-wave abnormalities) and the phenylpropanolamine (possibly able to cause ventricular arrhythmias).

The general importance of this alleged interaction is uncertain but the authors of the report suggest that ephedrine-like drugs such as phenylpropanolamine should not be given to patients taking thioridazine or mesoridazine.

1. Chouinard G, Ghadirian AM, Jones BD. Death attributed to ventricular arrhythmia induced by thioridazine in combination with a single Contac C capsule. *Can Med Assoc J* (1978) 119, 729-31.

Tiotixene + Enzyme inhibitors

A group of patients taking enzyme inhibitors (cimetidine, doxepin, isoniazid, nortriptyline, propranolol) had a tiotixene clearance of 9.51 L/minute, which was 71% less than that seen in patients taking tiotixene alone.¹ It seems possible that the tiotixene dose will need to be reduced in those taking these drugs but this needs confirmation. Monitor concurrent use for tiotixene adverse effects and adjust the dose accordingly.

Trifluoperazine + Venlafaxine

A case of neuroleptic malignant syndrome has been reported in a patient taking trifluoperazine 1 mg daily who then took one dose of venlafaxine 75 mg. This may have occurred as a result of dopamine inhibition by the two drugs.¹ A suggestion that the symptoms seen may have been due to 'the serotonin syndrome', (p.9), has also been made.²

2. Cassidy EM, O'Keane V. Neuroleptic malignant syndrome after venlafaxine. *Lancet* (2000) 355, 2164-5.

Ziprasidone + Carbamazepine

Low doses of carbamazepine do not appear to affect the pharmacokinetics of ziprasidone.

Clinical evidence, mechanism, importance and management

In a randomised study, healthy subjects were given ziprasidone 20 mg twice daily with either placebo (10 subjects), or carbamazepine 200 mg twice daily for 5 doses (9 subjects). It was found that the AUC₀₋₁₂ and maximum serum levels of ziprasidone were reduced by 36% and 27%, re-

spectively, in the carbamazepine group. It was concluded that while induction of the cytochrome P450 isoenzyme CYP3A4 by carbamazepine is responsible for this modest reduction in the steady-state levels of ziprasidone, the extent is not clinically relevant.¹ No special precautions would seem to be needed with this dosage of carbamazepine,¹ but there is the possibility that higher doses may interact to a greater extent. In this situation it would be prudent to monitor concurrent use to ensure ziprasidone is effective.

1. Miceli JJ, Anziano RJ, Robarge L, Hansen RA, Laurent A. The effect of carbamazepine on the steady-state pharmacokinetics of ziprasidone in healthy volunteers. *Br J Clin Pharmacol* (2000) 49 (Suppl 1), 65S–70S.

Ziprasidone + Ketoconazole

Ketoconazole moderately increases ziprasidone levels but this is not expected to be clinically relevant.

Clinical evidence, mechanism, importance and management

In a randomised, placebo-controlled study, 14 healthy subjects were given a 40-mg dose of ziprasidone before and after taking ketoconazole 400 mg daily for 6 days. It was found that ketoconazole increased the AUC and maximum serum levels of ziprasidone by 33% and 34%, respectively. This modest rise in levels probably occurs because ketoconazole inhibits the cytochrome P450 isoenzyme CYP3A4 by which ziprasidone is metabolised. However, it was concluded that the increase is not clinically relevant.¹ No special precautions would therefore seem to be needed on concurrent use.

1. Miceli JJ, Smith M, Robarge L, Morse T, Laurent A. The effects of ketoconazole on ziprasidone pharmacokinetics – a placebo-controlled crossover study in healthy volunteers. *Br J Clin Pharmacol* (2000) 49 (Suppl 1), 71S–76S.

Ziprasidone + Lithium

Ziprasidone does not appear to alter the pharmacokinetics of lithium.

Clinical evidence, mechanism, importance and management

A randomised, placebo-controlled study in 25 healthy subjects taking lithium carbonate 450 mg twice daily for 15 days, found that ziprasidone 20 mg twice daily on days 9 to 11, followed by 40 mg twice daily on days 12 to 15 caused only a small increase in the steady-state serum-lithium levels (14% compared with 11% in the placebo group). A 5% reduction in renal clearance was seen in the ziprasidone group and a 9% reduction was seen in the placebo group. These differences were neither statistically nor clinically significant.¹ No special precautions would therefore seem to be necessary if ziprasidone is given to patients taking lithium.

1. Apseoff G, Mullet D, Wilner KD, Anziano RJ, Tensfeldt TG, Pelletier SM, Gerber N. The effects of ziprasidone on steady-state lithium levels and renal clearance of lithium. *Br J Clin Pharmacol* (2000) 49 (Suppl 1), 61S–64S.

Ziprasidone + Miscellaneous

The manufacturers warn of the possible risks of giving ziprasidone with drugs that prolong the QT interval, and of the possible antagonism that may occur with levodopa and other dopamine agonists. Ziprasidone appears not to interact to a clinically relevant extent with an aluminium/magnesium hydroxide antacid, benzatropine, cimetidine, lorazepam, propranolol or tobacco smoking.

Clinical evidence, mechanism, importance and management

(a) Antacids or Cimetidine

A single 40-mg oral dose of ziprasidone were given to 10 healthy subjects either alone, with cimetidine 800 mg daily for 2 days, or with three 30-mL doses of *Maalox* (aluminium/magnesium hydroxide). The only change in the pharmacokinetics of ziprasidone was a 6% increase in the AUC with cimetidine. It was concluded that no special precautions are needed if ei-

ther of these drugs and ziprasidone are given concurrently, and that any inhibition of the cytochrome P450 isoenzyme CYP3A4 is irrelevant because alternative metabolic pathways are available. The results of the study with cimetidine also suggest that other non-specific inhibitors of cytochrome P450 are unlikely to alter the ziprasidone pharmacokinetics.¹

(b) Drugs that prolong the QT interval

Studies in healthy subjects found that ziprasidone 160 mg increased the QTc interval by about 10 milliseconds. While only a relatively moderate increase in the QT interval actually occurs with ziprasidone, because of the possibility of additive effects with some other drugs (and the attendant risk of torsade de pointes), to be on the safe side the manufacturers of ziprasidone contraindicate its use with other drugs that can prolong the QT interval.² A list of QT-prolonging drugs is to be found in 'Table 9.2', (p.257). A case has been reported of a 70-year-old man who took **quetiapine** and ziprasidone and who developed cardiac arrhythmias with extrasystoles, and a prolonged QTc interval of 482 milliseconds, an increase of 65 milliseconds from his value with **quetiapine** alone. On stopping **quetiapine** and reducing the dose of ziprasidone, his QTc interval normalised.³

(c) Levodopa and dopamine agonists

The mechanism by which ziprasidone acts to control schizophrenia is not understood, but it is known to be an antagonist of dopamine type 2 (D₂) receptors and therefore it may possibly oppose the effects of levodopa and other dopamine agonists. There seem to be no clinical reports of problems during concurrent use, but good monitoring would be advisable if ziprasidone is given with any dopamine agonist.

(d) Miscellaneous drugs

The manufacturers say that population pharmacokinetic analysis of schizophrenic patients who were enrolled in clinical studies showed that no significant pharmacokinetic interactions occurred with **benzatropine**, **lorazepam** or **propranolol**.² The manufacturers also point out that since ziprasidone is not metabolised by the cytochrome P450 isoenzyme CYP1A2, smoking should not affect its pharmacokinetics. This is borne out by studies in patients, which did not reveal any differences in the pharmacokinetics of ziprasidone between **tobacco smokers** and non-smokers.²

1. Wilner KD, Hansen RA, Folger CJ, Geoffroy P. The pharmacokinetics of ziprasidone in healthy volunteers treated with cimetidine or antacid. *Br J Clin Pharmacol* (2000) 49 (Suppl 1), 57S–60S.
2. Geodon (Ziprasidone). Pfizer Inc. US prescribing information, May 2005.
3. Minov C. QTc-Zeitverlängerung unter ziprasidon in kombination mit quetiapin. *Psychiatr Prax* (2004) 31, S142–4.

Zotepine + Miscellaneous

There appears to be little or no information about adverse interactions between zotepine and other drugs, but the manufacturers warn about the concurrent use of antihypertensives, anaesthetics, antipsychotics, and drugs that prolong the QTc interval. Two cases of deep vein thrombosis have been reported in patients taking zotepine with paroxetine.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives

Zotepine has alpha-adrenergic blocking properties, which may cause orthostatic hypotension, especially when treatment is first started or if the dosage is increased. The manufacturers advise caution when it is given with hypotensive agents, including some **anaesthetics**, the implication being that any orthostatic hypotension may possibly be worsened. If patients feel faint and dizzy when they stand up, they should be advised to get up more slowly, and if necessary, a smaller dosage should be used.¹

(b) Antimuscarinics

Biperiden 6 mg daily for 2 weeks was found not to affect the pharmacokinetics of zotepine in a study in 21 patients.²

(c) Antipsychotics

The manufacturers point out that, as with some other antipsychotics, zotepine has clear pro-convulsive effects, which may be additive with other antipsychotics, particularly if high doses of either or both drugs are used.

They therefore recommend that zotepine doses above 300 mg daily or the concurrent use of high doses of other antipsychotics should be avoided.¹

(d) *Desipramine*

No pharmacokinetic interaction was seen when zotepine was given with desipramine, indicating that the cytochrome P450 isoenzyme CYP2D6 is not involved in the metabolism of zotepine.¹

(e) *Diazepam or Fluoxetine*

In a clinical interaction study, fluoxetine and diazepam increased the plasma concentrations of zotepine and norzotepine. The manufacturers advise caution if these drugs are given concurrently.¹

(f) *Drugs that prolong the QT interval*

The manufacturers of zotepine advise caution when treating patients taking drugs known to prolong the QTc interval (or those with coronary heart disease or at risk of hypokalaemia) because zotepine also shows a dose-related QTc interval prolongation,¹ the implication being that the effects may be additive. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

(g) *Paroxetine*

Two case reports have described mobile, elderly male patients who developed deep vein thrombosis when taking paroxetine and zotepine. In the first case the patient was taking paroxetine 40 mg daily, and zotepine was added to his treatment 3 weeks later, initially at a dose of 75 mg daily, then increased to 150 mg daily. After 17 days of treatment with zotepine 150 mg daily the patient developed significant swelling of the right leg, and a deep vein thrombosis was diagnosed by Doppler studies and venography. The second patient also received paroxetine 40 mg daily to which was added zotepine 150 mg daily, and within 3 days of starting zotepine, the patient had developed painful swelling of the right calf, dyspnoea and tachycardia. A deep vein thrombosis was confirmed. They were part of a review of 150 patients consecutively admitted to a psychiatric ward. They were the only two patients who received this combination of drugs, and the only two who developed a thromboembolism. The mechanism of this interaction is unclear.³

Antivirals

This section is concerned with the drugs used to treat viral infections. These drugs may be grouped by the viral infections they are used to treat, and also by drug class (see 'Table 21.1', (p.773)). Where antivirals affect other drugs the interactions are generally covered elsewhere.

Antivirals active against herpes

(a) Nucleoside analogues

The nucleoside analogues are principally eliminated unchanged by the kidneys by a process of active tubular secretion as well as glomerular filtration. The few interactions with these drugs mainly involve altered renal clearance (e.g. probenecid), but since they have a wide therapeutic range, even these interactions are of debatable clinical relevance. Cytochrome P450-mediated interactions are not important for this group of drugs.

Antiretrovirals active against HIV

Treatment of HIV infection commonly requires a combination of 3 to 4 antiretrovirals, termed highly active antiretroviral therapy (HAART). In addition, patients often receive a large number of other drugs for comorbid conditions. This markedly increases the risk of drug interactions and complicates their assessment.

(a) CCR5 antagonists

CCR5 antagonists are a new class of entry inhibitors currently under development. Maraviroc is the nearest to marketing, and is a substrate of CYP3A4. Because of this, CYP3A4 inducers (e.g. efavirenz) lower its levels and CYP3A4 inhibitors (e.g. protease inhibitors) increase its levels.

(b) Fusion inhibitors

The fusion inhibitor, enfuvirtide, is a peptide. It does not cause cytochrome P450-mediated drug interactions, and is not affected by potent enzyme inducers (rifampicin) or inhibitors (ritonavir).

(c) Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

The NNRTIs are extensively metabolised by the cytochrome P450 isoenzyme system, particularly by CYP3A4. They are also inducers (nevirapine, efavirenz) or inhibitors (delavirdine) of CYP3A4. NNRTIs would therefore be expected to interact with each other, and with protease inhibitors, but not with NRTIs (see below). They also have the potential to interact with other drugs metabolised by CYP3A4, and are affected by CYP3A4 inhibitors and inducers. Delavirdine and efavirenz may also inhibit some other P450 isoenzymes. For a summary, see 'Table 21.2', (p.773).

(d) Nucleoside reverse transcriptase inhibitors (NRTIs)

NRTIs are prodrugs, which need to be activated by phosphorylation within cells to a triphosphate anabolite. Drugs may therefore interact with

NRTIs by increasing or decreasing intracellular activation. NRTIs may also interact with each other by this mechanism. This interaction mechanism is studied *in vitro*, and clinical data are often not available, or the clinical relevance is unclear. Nevertheless, it is generally recommended that drugs inhibiting the intracellular activation of NRTIs are not used concurrently (e.g. 'doxorubicin and stavudine', (p.808), or 'zidovudine and stavudine', (p.800)). 'Hydroxycarbamide', (p.799), may increase the intracellular activation of NRTIs.

NRTIs are water soluble, and are mainly eliminated by the kidneys (didanosine, lamivudine, stavudine, and zalcitabine) or undergo hepatic glucuronidation (abacavir, zidovudine). The few important interactions with these drugs primarily involve altered renal clearance. For zidovudine (and possibly abacavir) some interactions occur via altered glucuronidation, but the clinical relevance of these are less clear (e.g. 'rifampicin', (p.792)). Cytochrome P450-mediated interactions are not important for this class of drugs.

Some of the didanosine preparations (e.g. chewable tablets) are formulated with antacid buffers that are intended to facilitate didanosine absorption by minimising acid-induced hydrolysis in the stomach. These preparations can therefore alter the absorption of other drugs that are affected by antacids (e.g. azole antifungals, quinolone antibacterials, tetracyclines). This interaction may be minimised by separating administration by at least 2 hours. Alternatively, the enteric-coated preparation of didanosine (gastro-resistant capsules) may be used.

(e) Protease Inhibitors

The protease inhibitors are extensively metabolised by the cytochrome P450 isoenzyme system, particularly by CYP3A4. All of them inhibit CYP3A4, with ritonavir being the most potent inhibitor, followed by indinavir, nelfinavir, amprenavir, and saquinavir. The protease inhibitors therefore have the potential to interact with other drugs metabolised by CYP3A4, and are also affected by CYP3A4 inhibitors and inducers. Ritonavir and nelfinavir also affect some other cytochrome P450 isoenzymes, as summarised in 'Table 21.2', (p.773). In addition, protease inhibitors are substrates as well as inhibitors of P-glycoprotein. Protease inhibitors therefore have the potential to interact with each other, and with NNRTIs, but are not likely to interact with NRTIs.

The plasma level of protease inhibitors is thought to be critical in maintaining efficacy and minimising the potential for development of viral resistance. Therefore even modest reductions in levels are potentially clinically important.

Aciclovir and related drugs + Antacids

Valaciclovir does not interact with an aluminium/magnesium hydroxide antacid.

Clinical evidence, mechanism, importance and management

On three separate occasions, 18 healthy subjects were given a single 1-g oral dose of valaciclovir, either alone, 65 minutes before, or 30 minutes after they took 30 mL of *Maalox* (aluminium/magnesium hydroxide). The pharmacokinetics of aciclovir (the active metabolite of valaciclovir) remained unchanged. It was concluded that no special precautions are needed if these drugs are taken together, and the authors of the report also suggest that it is unlikely that other antacids will interact.¹

Aciclovir and related drugs + Cephalosporins

Retrospective data from children suggest that ceftriaxone might have increased the renal toxicity of intravenous aciclovir. Cefalexin does not appear to alter the absorption of valaciclovir to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

(a) Cefalexin

In a single-dose, crossover study involving 16 healthy subjects, the concurrent use of cefalexin 500 mg and valaciclovir 500 mg caused only a minimal mean 7.1% reduction in the AUC of aciclovir (the metabolite of valaciclovir). However, this reduction was only seen if one subject who had an increase in aciclovir AUC was excluded. Furthermore, there was considerable interindividual variability in the effects of cefalexin.

Both cefalexin and valaciclovir are substrates for human peptide transporter 1 (hPEPT1), and *in vitro* and *animal* data indicated that cefalexin might markedly reduce valaciclovir absorption.¹ However, the findings in this clinical study show a minimal interaction. No special precautions appear to be needed on concurrent use.

(b) Ceftriaxone

A retrospective analysis of 17 children who had received intravenous aciclovir and ceftriaxone for suspected meningo-encephalitis revealed that 12 developed a significant increase in serum creatinine, and three of these developed acute renal failure. This rate of renal toxicity is higher than that seen with aciclovir alone, and was attributed to the concurrent use of ceftriaxone. The dose of aciclovir correlated with nephrotoxicity. The authors concluded that caution is required with the combination, and that renal function should be monitored if both drugs are needed.²

2. Vomiero G, Carpenter B, Robb I, Filler G. Combination of ceftriaxone and acyclovir - an underestimated nephrotoxic potential? *Pediatr Nephrol* (2002) 17, 633–7.

Aciclovir and related drugs + Cimetidine

Single-dose studies have found that cimetidine increases the AUC of aciclovir and valaciclovir, but this is thought unlikely to be clinically important. No clinically important interaction appears to occur if famciclovir is given with cimetidine.

Clinical evidence

(a) Aciclovir or Valaciclovir

Twelve healthy subjects were given a 1-g dose of valaciclovir alone or with cimetidine 800 mg, taken 10 hours and 1 hour before. The AUC_{0–3} for the prodrug valaciclovir was increased by 73% by cimetidine, and the AUC_{0–24} for the active metabolite of valaciclovir, aciclovir, was increased by 27%. The renal clearance of aciclovir was reduced by 22%, although the total urinary recovery of aciclovir was unchanged.¹

(b) Famciclovir

In a study, 12 healthy subjects were given cimetidine 400 mg twice daily for 8 days with a single 500-mg dose of famciclovir, a prodrug for penciclovir, on the last day. The AUC of penciclovir was increased by about 18% by cimetidine, but there was no change in renal clearance.^{2,3}

Mechanism

The increase in aciclovir AUC with cimetidine is attributable to a reduction in its renal excretion, probably due to competition for secretion by the kidney tubules.¹ When 'probenecid', (p.775), a renal tubular secretion competitor, and cimetidine were both given the effects on aciclovir were greater than either drug alone.¹ Cimetidine does not significantly alter the pharmacokinetics of famciclovir/penciclovir.³

Importance and management

These interactions are established but, because aciclovir has such a wide therapeutic index,⁴ the authors of the study suggest that its interaction with cimetidine is probably clinically unimportant.¹ It seems likely that no changes in the usual dosages of aciclovir or valaciclovir will be needed in patients also taking cimetidine. However, the UK manufacturer states that caution is required with high doses of valaciclovir, and that alternatives to cimetidine could be considered in this situation.⁴ No special precautions would seem necessary if cimetidine is used with famciclovir.

4. Valtrex (Valaciclovir). GlaxoSmithKline UK. UK Summary of product characteristics, September 2005.

Aciclovir and related drugs + Hydrochlorothiazide

Hydrochlorothiazide does not affect the pharmacokinetics or safety profile of valaciclovir.

Clinical evidence, mechanism, importance and management

A study in a group of elderly subjects (65 to 83 years old) given valaciclovir 500 mg or 1 g three times daily for 8 days found that its safety profile was unchanged in the presence of hydrochlorothiazide, and was similar to that in young healthy subjects.¹ The pharmacokinetics of the active metabolite of valaciclovir, aciclovir, were not significantly different.¹ There would seem to be no reason for avoiding the concurrent use of either valaciclovir or aciclovir and hydrochlorothiazide.

1. Wang LH, Schultz M, Weller S, Smiley ML, Blum MR. Pharmacokinetics and safety of multiple-dose valaciclovir in geriatric volunteers with and without concomitant diuretic therapy. *Antimicrob Agents Chemother* (1996) 40, 80–5.

Aciclovir and related drugs + Mycophenolate

The concurrent use of aciclovir or ganciclovir and mycophenolate mofetil does not appear to significantly affect the pharmacokinetics of either drug, but the manufacturers recommend care in renal impairment. There are reports of neutropenia in patients taking mycophenolate with valaciclovir or ganciclovir.

Clinical evidence, mechanism, importance and management

(a) Aciclovir or Valaciclovir

In a three-period crossover study healthy subjects were given a single dose of oral aciclovir 800 mg and mycophenolate mofetil 1 g, both together and alone. The renal clearances of both drugs were not significantly altered by concurrent use. The AUC of aciclovir was increased by about 17% (not statistically significant), that of mycophenolic acid by about 9% (not significant), and that of the glucuronide metabolite of mycophenolate by about 9%. It was concluded that none of these changes was likely to be clinically significant.^{1,2} In another single-dose study in healthy subjects, a

bigger 31% increase in the AUC of aciclovir was seen when it was given with mycophenolate mofetil: there were no changes to mycophenolic acid pharmacokinetics. The concurrent use of valaciclovir 2 g with mycophenolate mofetil 1 g did not alter aciclovir pharmacokinetics, and the only change in mycophenolate pharmacokinetics was a 12% decrease in AUC of its glucuronide metabolite.³ None of these changes are likely to be clinically important in patients with normal renal function. The manufacturers of mycophenolate state that, in renal impairment there may be competition for tubular secretion and that further increases in concentrations of both aciclovir and mycophenolate may occur.^{4,5}

Note that some data suggest that mycophenolate potentiates the antiherpes virus activity of aciclovir, which may be clinically useful.⁶ There is a case report of a renal transplant patient taking, amongst other drugs, mycophenolate mofetil 1 g twice daily who developed neutropenia after starting valaciclovir 6 g daily for prophylactic treatment of a cytomegalovirus infection after successful treatment with ganciclovir. The neutropenia resolved on stopping the valaciclovir. The authors suggested that mycophenolate may increase the haematotoxic effect of valaciclovir especially at high doses.⁷ Neutropenia is a rare adverse effect of valaciclovir alone. Bear the possibility of an interaction in mind should neutropenia occur with the combination.

(b) Ganciclovir or Valganciclovir

A crossover study in 12 transplant patients found no pharmacokinetic interaction between a single 1.5-g oral dose of mycophenolate mofetil and intravenous ganciclovir 5 mg/kg, but the renal clearance of ganciclovir was slightly reduced, by 12%.⁸ However, the manufacturers note that it is anticipated that the concurrent use of these two drugs will result in increases in ganciclovir levels, and levels of the inactive metabolite of mycophenolate, due to competition for renal tubular secretion. They suggest careful monitoring in patients with renal impairment given both drugs.^{4,5,9} These cautions are also applied to the ganciclovir prodrug valganciclovir.^{10,11}

Five cases of neutrophil dysplasia in transplant patients appeared to be related to the combination of ganciclovir and mycophenolate, rather than mycophenolate alone.¹² This emphasises the need for caution with concurrent use. The manufacturer of valganciclovir says that since both mycophenolate mofetil and ganciclovir have the potential to cause neutropenia and leucopenia, patients should be monitored for additive toxicity.¹⁰

Note that some data suggests that mycophenolate potentiates the antiherpes virus activity of ganciclovir, which may be clinically useful.⁶

Aciclovir and related drugs + Probenecid

Probenecid reduces the renal excretion and increases the plasma levels of aciclovir, valaciclovir, and ganciclovir. Famciclovir and valganciclovir are predicted to interact similarly.

Clinical evidence

(a) Aciclovir or Valaciclovir

Twelve healthy subjects were given valaciclovir 1 g alone, or with probenecid 1 g, taken 2 hours earlier. Probenecid increased the AUC₀₋₃ for the prodrug valaciclovir by 22%, and the AUC₀₋₂₄ for its active metabolite, aciclovir, by 48%. The renal clearance of aciclovir was reduced by 33%, although the total urinary recovery of aciclovir was unchanged.¹ An earlier study had found that oral probenecid 1 g caused a similar increase in the AUC of intravenous aciclovir.²

(b) Ganciclovir

A pharmacokinetic study³ in HIV-positive patients found that probenecid 500 mg every 6 hours increased the AUC of oral ganciclovir 1 g every 8 hours by 53.1%, and reduced the renal clearance by 12.3%.

Mechanism

The increases in aciclovir and ganciclovir AUCs are attributable to a reduction in their renal excretion by probenecid, probably due to competition for secretion by the kidney tubules.^{1,3} The effects on aciclovir of combining probenecid and 'cimetidine', (p.774) were greater than either drug alone.¹

Importance and management

These interactions are established, but because aciclovir has such a wide therapeutic index,⁴ the authors of the study suggest that its interaction with *cimetidine* is probably clinically unimportant.¹ Therefore it seems likely that no changes in the usual dosages of aciclovir or valaciclovir will be needed in patients taking probenecid. However, the UK manufacturer states that caution is required with high doses of valaciclovir, and that alternatives to probenecid could be considered in this situation.⁴ The US manufacturer suggests that the dosage of valaciclovir does not need to be altered in patients with normal renal function taking probenecid.⁵

It may be prudent to be alert for increased ganciclovir effects and toxicity if probenecid is used concurrently. **Valganciclovir** is a prodrug of ganciclovir, and the manufacturers recommend that patients taking valganciclovir with probenecid should be closely monitored for ganciclovir toxicity.^{6,7} The manufacturers of **famciclovir** suggest that a similar interaction might also occur with probenecid and famciclovir, resulting in an increase in the plasma levels of penciclovir (the active metabolite of famciclovir).^{8,9}

Adefovir + Miscellaneous

No clinically significant interaction appears to occur between adefovir and co-trimoxazole, didanosine, delavirdine, efavirenz, ibuprofen, indinavir, lamivudine, nelfinavir, nevirapine, paracetamol, tenofovir, or zidovudine. Adefovir possibly reduces saquinavir levels.

Clinical evidence, mechanism, importance and management

(a) Antiretrovirals

The UK manufacturer notes that at doses 6 to 12 times higher than the 10-mg dose of adefovir recommended for hepatitis B infection, there was no interaction with the NRTIs **lamivudine** or **zidovudine**, the NNRTIs

delavirdine, efavirenz or nevirapine, or the protease inhibitors **indinavir or nelfinavir**.¹ The concurrent use of adefovir 60 mg with **saquinavir** soft capsules increased the adefovir AUC by 20%, which is not clinically relevant.¹ In a population pharmacokinetic analysis, combination of **saquinavir** with adefovir appeared to result in a 49% increase in the clearance of saquinavir.² The concurrent use of adefovir 60 mg with **didanosine** buffered tablets increased the **didanosine** AUC by 29%, which is not clinically relevant.¹ See also *Lamivudine* and *Tenofovir*, below.

(b) *Drugs undergoing, or affecting, tubular secretion*

Adefovir is excreted by the kidneys, by a combination of glomerular filtration and active secretion via the renal transporter, human Organic Anion Transporter 1 (hOAT1). The potential for pharmacokinetic interactions with **co-trimoxazole, ibuprofen, lamivudine, paracetamol** and **tenofovir** (other drugs that also undergo, or may affect tubular secretion) has been investigated.^{1,3}

1. *Co-trimoxazole (Trimethoprim/Sulfamethoxazole)*. The manufacturers note that there was no pharmacokinetic interaction between adefovir 10 mg once daily and **co-trimoxazole** 960 mg twice daily in 18 healthy subjects.^{1,3}

2. *Ibuprofen*. The concurrent use of adefovir 10 mg and ibuprofen 800 mg three times daily modestly increased the AUC and maximum level of adefovir by 23% and 33%, respectively. These changes were considered to be due to higher bioavailability rather than a reduction in renal clearance, and are not considered clinically relevant. Adefovir did not alter ibuprofen pharmacokinetics.^{1,3}

3. *Lamivudine*. The manufacturers note that there was no pharmacokinetic interaction between adefovir 10 mg once daily and lamivudine 100 mg once daily in healthy subjects.^{1,3}

4. *Paracetamol*. The manufacturers note that there was no pharmacokinetic interaction between adefovir 10 mg once daily and paracetamol 1 g four times daily in healthy subjects.^{1,3}

5. *Tenofovir*. In 24 healthy subjects there was no pharmacokinetic interaction between a single 10-mg dose of adefovir dipivoxil given alone and on day 7 of tenofovir disoproxil fumarate 300 mg daily for 7 days. In particular, renal clearances of both drugs were not changed on concurrent use.⁴ However, the manufacturers still advise close monitoring during concurrent use, since the clinical safety, including renal effects, has not yet been assessed.^{1,3}

Cidofovir + Miscellaneous

Cidofovir with probenecid modestly decreased levels of trimethoprim and sulfamethoxazole (co-trimoxazole), and caused moderate increases in didanosine levels, but did not alter fluconazole pharmacokinetics. None of these drugs altered cidofovir pharmacokinetics.

Clinical evidence

(a) *Co-trimoxazole (Trimethoprim/Sulfamethoxazole)*

In a study, 6 HIV-positive subjects were given co-trimoxazole 960 mg daily with a single 3-mg/kg dose of cidofovir with probenecid given on day 7. The AUC and maximum plasma concentrations of both trimethoprim and sulfamethoxazole were decreased by about 30% and renal clearance was significantly increased. The pharmacokinetics of cidofovir were not affected.¹

(b) *Didanosine*

In a study, 6 HIV-positive subjects were given didanosine 100 or 200 mg twice daily for 7 days with a single 3-mg/kg dose of cidofovir

with probenecid given on day 7. The AUC of didanosine was increased 1.6-fold, but the pharmacokinetics of cidofovir were not affected.¹

(c) *Fluconazole*

In a study, 6 HIV-positive subjects were given fluconazole 100 mg daily for 13 days with a single 3-mg/kg dose of cidofovir with probenecid given on day 13. The pharmacokinetics of both drugs were unaffected.¹

Mechanism

It was suggested that cidofovir/probenecid might alter the renal elimination of these drugs.¹

Importance and management

The modest decreases in trimethoprim and sulfamethoxazole levels, and moderate increases in didanosine levels caused by cidofovir are considered unlikely to be clinically relevant because of the infrequent dosing schedule of cidofovir/probenecid. No dose adjustments are considered necessary.¹

1. Luber A, Lalezari J, Rooney J, Jaffe H, Flaherty J. Drug-drug interaction study with intravenous cidofovir (CDV) and either trimethoprim/sulfamethoxazole (TMP/SMX), didanosine (DDI), or fluconazole (FLU) in HIV-infected individuals. *Intersci Conf Antimicrob Agents Chemother* (2002) 42, 27.

Cidofovir + Probenecid

Probenecid reduces the nephrotoxicity of cidofovir, and it is recommended it should always be used concurrently.^{1,2} Therefore, when using cidofovir/probenecid the interactions of probenecid should be considered. Of particular note, zidovudine should be temporarily discontinued or the dosage halved when cidofovir/probenecid is used,^{1,2} see ‘NRTIs + Probenecid’, p.803.

2. Vistide (Cidofovir). Gilead Sciences, Inc. US Prescribing information, September 2000.

Enfuvirtide + Cytochrome P450 isoenzyme substrates

Enfuvirtide had no effect on the metabolism of dapsone or debrisoquine, and had little effect on the metabolism of caffeine, chlorzoxazone, and mephenytoin. Thus, it is not anticipated that enfuvirtide would cause clinically important drug interactions with drugs metabolised by the cytochrome P450 isoenzymes.

Clinical evidence, mechanism, importance and management

A single oral dose of five drugs (**caffeine** 100 mg, **chlorzoxazone** 250 mg, **dapsone** 100 mg, **debrisoquine** 10 mg and **mephenytoin** 100 mg) was given to 12 HIV-positive subjects, before, and after they were given subcutaneous enfuvirtide 90 mg twice daily for 6 days. Enfuvirtide had no effect on the urinary **dapsone** recovery ratio (a measure of the activity of the cytochrome P450 isoenzyme CYP3A4), plasma monoacetyldapsone-to-**dapsone** ratio (a measure of *N*-acetyltransferase (NAT) activity) or urinary **debrisoquine** recovery ratio (a measure of CYP2D6 activity). Enfuvirtide had little effect (less than 30% change) on the plasma paraxanthine-to-**caffeine** ratio (a measure of CYP1A2 activity), the plasma 6-hydroxychlorzoxazone-to-**chlorzoxazone** ratio (a measure of CYP2E1 activity) and urinary recovery of 4-hydroxy**mephenytoin** (a measure of CYP2C19 activity). Subjects in this study were taking up to 3 NRTIs in stable doses, and were not taking any NNRTIs or protease inhibitors.¹

This type of study is being increasingly used to assess the potential for new drugs to cause clinically important cytochrome P450-mediated drug interactions. The results indicate that enfuvirtide is unlikely to cause clinically important changes in the pharmacokinetics of drugs metabolised by CYP3A4, NAT and CYP2D6. They also give some reassurance that drugs metabolised by CYP1A2, CYP2E1 and CYP2C19 are unlikely to be significantly affected, although the modest changes seen introduce some cau-

tion. No substrate for CYP2C9 was included in this study, but enfuvirtide does not affect CYP2C9 *in vitro*.¹

1. Zhang X, Lalezari JP, Badley AD, Dorr A, Kolis SJ, Kinchelov T, Patel IH. Assessment of drug-drug interaction potential of enfuvirtide in human immunodeficiency virus type 1-infected patients. *Clin Pharmacol Ther* (2004) 75, 558–68.

Enfuvirtide + Protease inhibitors

Ritonavir caused a minor increase in enfuvirtide exposure, which is not clinically relevant. Saquinavir/ritonavir had little effect on enfuvirtide.

Clinical evidence, mechanism, importance and management

Subcutaneous enfuvirtide 90 mg twice daily was given for 7 days to 24 HIV-positive subjects with either **ritonavir** 200 mg twice daily or **saquinavir/ritonavir** 1 g/100 mg twice daily given for the last 4 days. **Ritonavir** caused a minor 24% increase in the AUC of enfuvirtide, and **saquinavir/ritonavir** caused a 14% increase in the AUC of enfuvirtide. Such small increases in enfuvirtide exposure are not clinically relevant. No special precautions appear warranted during concurrent use.¹

1. Ruxrungtham K, Boyd M, Bellibas SE, Zhang X, Dorr A, Kolis S, Kinchelov T, Buss N, Patel IH. Lack of interaction between enfuvirtide and ritonavir or ritonavir-boosted saquinavir in HIV-1-infected patients. *J Clin Pharmacol* (2004) 44, 793–802.

Enfuvirtide + Rifampicin (Rifampin)

Rifampicin has no effect on the pharmacokinetics of enfuvirtide.

Clinical evidence, mechanism, importance and management

Subcutaneous enfuvirtide 90 mg twice daily for 3 days was given to 12 HIV-positive subjects before, and during, the last 3 days of a 10-day course of rifampicin 600 mg daily. The AUC of enfuvirtide and its metabolite were not significantly altered by rifampicin.¹

Enfuvirtide is a peptide, and would not be expected to be affected by enzyme inducers such as rifampicin. The findings of this study support this. No special precautions are required during concurrent use.

Entecavir + Miscellaneous

There appears to be no pharmacokinetic interaction between entecavir and adefovir, lamivudine or tenofovir. However, interactions with other renally excreted drugs cannot be excluded. No interactions mediated by cytochrome P450 isoenzymes are expected with entecavir.

Clinical evidence, mechanism, importance and management

(a) Renally excreted drugs

Since entecavir is predominantly eliminated by the kidney, the concurrent use of drugs that reduce renal function or compete for active tubular secretion may increase serum concentrations of either entecavir or the concurrent drug. However, the manufacturers note that there was no pharmacokinetic interaction between entecavir and **lamivudine**, **adefovir** or **tenofovir** at steady state.^{1,2} They say that, apart from these drugs, the effects of concurrent use of entecavir with drugs that are excreted renally or affect renal function have not been evaluated, and they therefore recommend that patients should be monitored closely for adverse reactions when entecavir is given.¹

(b) Cytochrome P450-mediated interactions

The manufacturers say that entecavir is not a substrate, an inducer or an inhibitor of cytochrome P450 isoenzymes. Therefore drug interactions are unlikely to occur with entecavir by this mechanism.^{1,2}

2. Baraclude (Entecavir). Bristol-Myers Squibb Company. US Prescribing information, March 2007.

Famciclovir + Miscellaneous

No clinically important pharmacokinetic interactions appear to occur when famciclovir is given with allopurinol, digoxin or theophylline.

Clinical evidence, mechanism, importance and management

When 12 healthy subjects were given famciclovir 500 mg after taking **allopurinol** 300 mg daily for 5 days there were no clinically relevant changes in the pharmacokinetics of either drug.¹ It was concluded that xanthine oxidase does not play an important role in the metabolism of famciclovir to penciclovir.^{1,2}

Similarly, no clinically significant changes in the pharmacokinetics of famciclovir were seen in healthy subjects given famciclovir with **theophylline**³ or **digoxin**. The pharmacokinetics of **theophylline** and **digoxin** were also unaffected.^{4,5}

No special precautions would therefore seem necessary if any of these drugs is given with famciclovir.

Foscarnet + Ciprofloxacin

Two patients developed tonic-clonic seizures when they were given foscarnet with ciprofloxacin.

Clinical evidence

An HIV-positive patient taking multiple drugs (including ciprofloxacin 750 mg twice daily, clarithromycin, cimetidine, fluconazole, morphine, rifampicin and vancomycin) was also given intravenous foscarnet 60 mg/kg every 8 hours for a cytomegalovirus infection. He was only given half of the first dose, but 9 hours later he developed a tonic-clonic seizure. On completion of infusion of the first dose he again experienced similar seizure activity. About 45 minutes after the start of the second foscarnet dose, he had a third grand mal seizure. No further seizures occurred when the foscarnet was stopped.¹ Another HIV-positive patient was given foscarnet 60 mg/kg every 8 hours for 10 days without problem, until he started ciprofloxacin 750 mg twice daily, clobazamine, ethambutol, pyrazinamide and rifampicin for mycobacterial sepsis. Within 2 days, a few minutes after the start of the foscarnet infusion, he developed a seizure. This resolved when the foscarnet was stopped, and recurred when the foscarnet was restarted.¹

Mechanism

Both foscarnet and ciprofloxacin have the potential to cause seizures and it seems that some enhancement of this activity occurs if they are used in combination. Subsequent study in *mice* has shown that the combination of ciprofloxacin and foscarnet does increase the likelihood of seizures, and that the interaction is likely to be due to altered GABA-receptor binding. An interaction was not found for **enoxacin** and foscarnet.²

Importance and management

Direct information seems to be limited to these two cases. It is impossible to know for certain if the seizures were due to the combined effects of these two drugs or not, but the evidence seems to point in that direction. The general importance of this interaction is uncertain, but it would seem prudent to monitor very closely if these drugs are used together.

1. Fan-Havard P, Sancharawala V, Oh J, Moser EM, Smith SP. Concurrent use of foscarnet and ciprofloxacin may increase the propensity for seizures. *Ann Pharmacother* (1994) 28, 869–72.

Foscarnet + NRTIs

No pharmacokinetic interactions occur between foscarnet and didanosine, zalcitabine or zidovudine. The UK manufacturer does not recommend the concurrent use of lamivudine and foscarnet.

Clinical evidence, mechanism, importance and management

(a) Didanosine

In a three-phase study, 12 HIV-positive patients were given 4 doses of intravenous foscarnet 90 mg/kg, 4 doses of oral didanosine 200 mg, and 4 doses of both drugs together. Based on the data obtained from these patients (drug clearance, volume of distribution, half-life, mean residence time), no pharmacokinetic interactions were said to occur between these two drugs. This suggests that no dosage adjustments will be needed during concurrent use.¹ The antiretroviral effects of foscarnet and didanosine were synergistic.²

(b) Lamivudine

The UK manufacturer says that lamivudine should not be given with foscarnet,³ presumably because of possible interference with renal excretion. Note that the US manufacturer does not make any recommendation.⁴ Foscarnet does not affect lamivudine intracellular activation.⁵

(c) Stavudine

Foscarnet does not affect stavudine intracellular activation.⁶

(d) Zalcitabine

Intravenous foscarnet 90 mg/kg every 12 hours and oral zalcitabine 750 micrograms every 8 hours were given to 12 HIV-positive subjects for 2 days. There were no clinically significant alterations in the pharmacokinetics of either drug.⁷ However, the manufacturers of zalcitabine^{8,9} suggested that the concurrent use of zalcitabine and foscarnet should be well monitored, because foscarnet may possibly decrease the renal clearance of the zalcitabine, thereby increasing its serum levels and its toxicity, particularly peripheral neuropathy. The antiretroviral effects of foscarnet and zalcitabine were synergistic.²

(e) Zidovudine

The antiviral effects of foscarnet and zidovudine appear to be additive or synergistic. No significant alteration in the pharmacokinetics of either drug was seen in a 14-day study in 5 AIDS patients given both drugs.¹⁰ Foscarnet does not appear to affect zidovudine intracellular activation,¹¹ and the manufacturer notes that there was no evidence of increased myelotoxicity when foscarnet was used with zidovudine.¹² No special precautions are required on concurrent use.

Foscarnet + Pentamidine

Four patients had marked hypocalcaemia when they were given foscarnet with intravenous pentamidine. One of them died.

Clinical evidence, mechanism, importance and management

Four patients with suspected AIDS-related cytomegaloviral infections of the chest developed signs of hypocalcaemia within 10 days of starting treatment with foscarnet and intravenous pentamidine (dosages not stated). All 4 had paraesthesia of the hands and feet, and 3 of them had Chvostek's and Trousseau's signs (signs of tetany). The serum calcium levels of 3 of them fell but normalised when one of the drugs was stopped. The fourth patient died with severe hypocalcaemia of 1.42 mmol/L.¹

Both drugs have been associated with hypocalcaemia in HIV-positive patients, and in these 4 patients their effects appear to have been additive. Very close monitoring of calcium levels is advised if foscarnet is used with parenteral pentamidine.

1. Youle MS, Clarbour J, Gazzard B, Chanas A. Severe hypocalcaemia in AIDS patients treated with foscarnet and pentamidine. *Lancet* (1988) 1, 1455-6.

Foscarnet + Probenecid

Probenecid does not alter the pharmacokinetics of foscarnet.

Clinical evidence, mechanism, importance and management

A study in 10 HIV-positive patients found that probenecid 1 g twice daily for 3 days had no effect on the pharmacokinetics of foscarnet 90 mg/kg given intravenously over 2 hours. The authors conclude that, because of the lack of interaction with probenecid, almost all of the renal elimination of foscarnet is by glomerular filtration, with only a minimal contribution of active tubular secretion.¹ No special precautions seem to be necessary.

Ganciclovir or Valganciclovir + Imipenem

Based on an early possible report,¹ the manufacturer notes that generalised seizures have been reported in patients who received ganciclovir with imipenem-cilastatin. They recommend that ganciclovir and its prodrug valganciclovir should not be used with imipenem unless the benefits outweigh the risks.²⁻⁴ No further reports of this interaction appear to have been published, or reported to the manufacturer.¹ Note that both ganciclovir and imipenem alone may cause seizures.

4. Cytovene-IV (Ganciclovir sodium). Roche Pharmaceuticals. US Prescribing information, January 2006.

Ganciclovir + Trimethoprim

There is no clinically relevant pharmacokinetic interaction between ganciclovir and trimethoprim.

Clinical evidence, mechanism, importance and management

Ganciclovir 1 g every 8 hours was given to 12 HIV-positive subjects with trimethoprim 200 mg daily for 7 days. Ganciclovir clearance was decreased by 13%, and the half-life was increased by 18%, while the trimethoprim minimum plasma concentration was raised by 13%. The combination was well tolerated and none of these changes were considered clinically significant, so no dose alteration appears necessary on concurrent use.¹ Both ganciclovir and trimethoprim are known to be myelosuppressive,² and the manufacturer of ganciclovir and its prodrug

valganciclovir notes that there is the possibility that the risk of this toxicity may be increased when they are used together. Therefore, they recommend that the combination should only be used if the benefits outweigh the risks of treatment.³⁻⁵

Idoxuridine + Miscellaneous

The topical solution of idoxuridine, *Herpid*, contains the solvent dimethyl sulfoxide as an absorption enhancer. This can increase the absorption of many substances, and therefore no other topical medications should be used concurrently on the same areas as *Herpid*.¹

1. Herpid (Idoxuridine). Astellas Pharma Ltd. UK Summary of product characteristics, November 2005.

Influenza vaccines + Paracetamol (Acetaminophen)

Paracetamol does not affect antibody production in response to influenza vaccination and appears to reduce its adverse effects. The pharmacokinetics of paracetamol do not appear to be affected by influenza vaccine.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of a single 650-mg dose of intravenous paracetamol were unaffected in healthy subjects when it was given 7 and 21 days after 0.5 mL of trivalent influenza vaccine given intramuscularly.¹ Paracetamol 1 g four times daily for 2 days had no effect on the production of influenza virus antibodies in a group of 39 elderly patients given an inactivated influenza virus vaccine, and the paracetamol appeared to reduce the adverse effects of the vaccine (e.g. fever), although this was not statistically significant.² There would seem to be no reason for avoiding the concurrent use of paracetamol and influenza vaccine.

Influenza vaccine, live + Antivirals active against influenza

The manufacturers advise that antivirals active against influenza such as oseltamivir and rimantadine should not be given until 2 weeks after the administration of live influenza virus vaccines, and that these vaccines should not be given until 48 hours after stopping the antiviral.¹⁻³ This is because of the theoretical concern that these antiviral drugs will inhibit replication of live vaccine virus, and therefore reduce its effect. Note that most influenza vaccines are inactivated (split virion or surface antigen), and that these would not be expected to be affected by antivirals active against influenza.

3. Flumadine (Rimantadine hydrochloride). Forest Pharmaceuticals, Inc. US Prescribing information, June 2006.

Interferons + ACE inhibitors

A case series suggests that severe granulocytopenia can develop if ACE inhibitors and interferon are given concurrently.

Clinical evidence

Patients with cryoglobulinaemia were treated with 3 million units of recombinant **interferon alfa-2a** (35 patients) or natural **interferon beta** (3 patients), usually given daily for 3 months, then on alternate days for periods of 6 to 17 months. Severe toxicity developed in 3 patients, who were the only ones amongst the group to also be taking ACE inhibitors. Granulocytopenia developed in 2 patients within a few days of starting **enalapril** 10 mg daily or **captopril** 50 mg daily, and subsided 1 to 2 weeks after both drugs were stopped. Another patient, already taking **enalapril** 5 mg daily, developed severe granulocytopenia when interferon was started, and again when re-challenged with both drugs. None of the other 35 patients receiving interferon alone developed any significant haematological problems. The reasons for this severe reaction are not understood but the authors of the report suggest that it may be an autoimmune response.¹

A follow-up letter commenting on this report described 2 further patients with hepatitis C infection, cryoglobulinaemia and glomerulonephritis, who took **captopril** 75 mg or **enalapril** 20 mg daily for several weeks, and who had granulocytopenia within 9 days of being given 3 million units of recombinant **interferon alfa-2a**, daily or on alternate days. However, this resolved without any change in treatment. Another patient with multiple myeloma given **interferon alfa-2a** 3 million units 3 times weekly and long-term **benazepril** 10 mg daily had a normal granulocyte count after 3 months.²

Mechanism

Interferons alone are associated with myelosuppression, particularly granulocytopenia. ACE inhibitors have, rarely, caused neutropenia and agranulocytosis.

Importance and management

These two reports appear to be the only information suggesting an interaction. Regular full blood counts are generally recommended when interferons are used, and therefore, no extra precautions would appear to be required if ACE inhibitors are also given. Bear the possibility of an interaction in mind.

2. Jacquot C, Caudwell V, Belenfant X. Granulocytopenia after combined therapy with interferon and angiotensin-converting enzyme inhibitors: evidence for a synergistic hematologic toxicity. *Am J Med* (1996) 101, 235-6.

Interferons + Analgesics or Corticosteroids

Prednisone and paracetamol have disparate effects on some measures of the antiviral activity of interferon, but the clinical relevance of this is unclear. Isolated cases of acute hepatitis have been seen when interferon was given with paracetamol.

Clinical evidence, mechanism, importance and management

A single intramuscular dose of recombinant human **interferon alfa-2a** 18 million units was given to 8 healthy subjects alone, or after one day of either **aspirin** 650 mg every 4 hours, **paracetamol** 650 mg every 4 hours or **prednisone** 40 mg daily, for a total of 8 days. None of these additional drugs reduced the interferon adverse effects of fever, chills, headache, or myalgia. Only **prednisone** appeared to reduce one of the two measures of interferon activity.¹ In a later similar study by the same research group, the effect of the same drugs and doses (started 3 days before the interferon) was evaluated with a lower dose of **interferon alfa-2a** (3 million units). When data for **aspirin**, **paracetamol** or **prednisone** was combined the

subjects had a 47% reduction in symptom score, when compared with control subjects not taking any of these three drugs. The **prednisone** group also had fewer hours of fever. In this study, neither **prednisone** nor **aspirin** consistently altered measures of the antiviral activity of interferon, but **paracetamol** appeared to enhance them.²

Taken together, the results of these two studies suggest that these drugs may reduce the flu-like adverse effects of interferon, perhaps more so at lower doses of interferon. The clinical relevance of the measures of antiviral activity of interferon is uncertain, so the disparate effects found with **paracetamol** and **prednisone** are unclear.

The authors of a report describing an unusual acute form of hepatitis, occurring in 3 patients receiving **interferon alfa-2a**, vinblastine and **paracetamol**, suggested that this might have been due to a drug interaction.³ Another two similar cases have been reported with **interferon alfa-2b** and **paracetamol**, but no liver toxicity occurred when one of these patients was given **indometacin** with interferon instead.⁴ The general relevance of these isolated reports is unclear.

4. Fabris P, Dalla Palma M, de Lalla F. Idiosyncratic acute hepatitis caused by paracetamol in two patients with melanoma treated with high-dose interferon- α . *Ann Intern Med* (2001) 134, 345.

Interferons + Ribavirin

There was no evidence of any changes in pharmacokinetic parameters when ribavirin and interferon alfa-2b were given together.¹ Another study using peginterferon alfa-2b also found no pharmacokinetic interactions with ribavirin.² The combination of interferon alfa and ribavirin has enhanced efficacy against hepatitis C.

Maraviroc + CYP3A4 inducers

Efavirenz reduces the plasma levels of maraviroc by about 50% and rifampicin reduces them by about two-thirds. A regimen containing nevirapine appeared to have little effect on the levels of a single dose of maraviroc.

Clinical evidence

(a) Efavirenz

In a placebo-controlled study in healthy subjects, efavirenz 600 mg once daily for 14 days reduced the steady-state AUC and maximum plasma level of maraviroc 100 mg twice daily by about 50%. Doubling the dose of maraviroc to 200 mg twice daily overcame this increase in metabolism, resulting in a minor 10% increase in AUC and 20% increase in maximum level, when compared with maraviroc 100 mg twice daily alone.¹ Similarly, in another study, the AUC of a single 300-mg dose of maraviroc was about 50% lower in two groups of 8 patients; one group taking efavirenz, lamivudine and zidovudine and the other taking efavirenz, didanosine and tenofovir.² When efavirenz 600 mg daily was added to lopinavir/ritonavir 400/100 mg twice daily with maraviroc 300 mg twice daily, the increase in maraviroc AUC seen with these 'protease inhibitors', (p.780), was reduced from about 300% to about 150%, when compared with the AUC for maraviroc alone.³ Similarly, when efavirenz 600 mg daily was added to saquinavir/ritonavir 1000/100 mg twice daily with maraviroc 100 mg twice daily, the increase in maraviroc AUC seen with these protease inhibitors was reduced from 877% to 400%, when compared with the AUC for maraviroc alone.³

(b) Nevirapine

In 8 patients taking nevirapine, lamivudine and tenofovir the AUC of a single 300-mg dose of maraviroc was unchanged and its maximum plasma level was about 50% higher, when compared with HIV-positive subjects taking maraviroc alone.²

(c) Rifampicin (Rifampin)

In a placebo-controlled study in healthy subjects, rifampicin 600 mg once daily for 14 days reduced the steady-state AUC and maximum and minimum plasma levels of maraviroc 100 mg twice daily by about two-thirds. Doubling the dose of maraviroc to 200 mg twice daily overcame this increased metabolism, resulting in an AUC comparable to that of maraviroc 100 mg twice daily alone.¹

Mechanism

Maraviroc is a substrate of the cytochrome P450 isoenzyme CYP3A4, and its levels would therefore be expected to be reduced by inducers of this enzyme, such as efavirenz and rifampicin. For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

Importance and management

The pharmacokinetic interactions with efavirenz and rifampicin are likely to be clinically important. The reduction in maraviroc plasma levels seen could result in decreased efficacy and the development of viral resistance. Doubling the dose of maraviroc overcame this interaction, and this is the suggested approach of the manufacturer when maraviroc is used in the absence of protease inhibitors.⁴ Efavirenz appears to halve the increase in maraviroc levels seen with ritonavir-boosted protease inhibitors.

Maraviroc + CYP3A4 inhibitors

Atazanavir, atazanavir/ritonavir, lopinavir/ritonavir and saquinavir markedly increased the AUC of maraviroc by about three to fivefold in healthy subjects. Ritonavir-boosted saquinavir had an even greater effect (about tenfold). In contrast, tipranavir/ritonavir had no effect. Ketoconazole caused a fivefold increase. The manufacturer suggests that the dose of maraviroc should be halved when used with protease inhibitors.

Clinical evidence

(a) Protease inhibitors

Saquinavir 1.2 g three times daily increased the AUC and maximum level of maraviroc 100 mg twice daily by 4.2-fold and 3.3-fold, respectively, in healthy subjects.¹ Furthermore, combining **saquinavir** 1 g with **ritonavir** 100 mg twice daily, increased the AUC of maraviroc by almost tenfold.² **Lopinavir/ritonavir** 400/100 mg twice daily increased the AUC and maximum level of maraviroc 300 mg twice daily by almost fourfold and twofold, respectively.²

Atazanavir 400 mg daily increased the AUC and maximum level of maraviroc by 257% and 109%, respectively.³ **Atazanavir/ritonavir** 300/100 mg increased the AUC of maraviroc by almost fivefold.³ In a study in HIV-positive patients, the AUC of a single 300-mg oral dose of

maraviroc was doubled in 5 patients taking **lopinavir/ritonavir** 400/100 mg twice daily, stavudine and lamivudine when compared with that after one dose in a study in HIV-positive subjects taking maraviroc 300 mg daily alone.⁴ Adding 'efavirenz', (p.780) halved the effect of **lopinavir/ritonavir** and **saquinavir/ritonavir** on the maraviroc AUC.²

In contrast, **tipranavir/ritonavir** 500/200 mg twice daily had no clinically significant effect on the AUC or maximum level of maraviroc 150 mg twice daily in healthy subjects.⁵

(b) *Ketoconazole*

Ketoconazole 400 mg once daily increased the AUC and maximum level of maraviroc 100 mg twice daily by fivefold and 3.4-fold, respectively, in healthy subjects.¹

Mechanism

Maraviroc is a substrate of the cytochrome P450 isoenzyme CYP3A4 of which most protease inhibitors and ketoconazole are potent inhibitors.

Importance and management

Established and clinically important interactions. Increases of this magnitude are likely to result in increased adverse effects. The manufacturer has suggested that the dose of maraviroc is halved when it is used with protease inhibitors.⁶ For a list of other inhibitors of CYP3A4, which might be expected to interact similarly, see 'Table 1.4', (p.6).

Maraviroc + Drugs that affect renal clearance

Neither co-trimoxazole nor tenofovir had any important effect on maraviroc levels.

Clinical evidence

(a) *Co-trimoxazole*

Co-trimoxazole (sulfamethoxazole/trimethoprim 800/160 mg) twice daily had no clinically relevant effect on the pharmacokinetics of maraviroc 300 mg twice daily (a 10% increase in AUC and a 19% increase in maximum level).¹

(b) *Tenofovir*

In a placebo-controlled, crossover study in healthy subjects, the concurrent use of maraviroc 300 mg twice daily and tenofovir disoproxil fumarate 300 mg once daily had no effect on the pharmacokinetics of maraviroc.^{1,2}

Mechanism

Maraviroc undergoes some renal clearance (about 20% of total clearance).¹ Co-trimoxazole affects renal tubular transport, and tenofovir is

predominantly excreted renally, so it was of interest to see if these had any effect on maraviroc levels.¹

Importance and management

The pharmacokinetic data suggest that no maraviroc dose adjustment is likely to be needed if it is given with tenofovir or co-trimoxazole.

2. Muirhead G, Russell D, Abel S, Turner K, Taylor-Worth R, Tan LH, Toh M. An investigation of the effects of tenofovir on the pharmacokinetics of the novel CCR5 inhibitors UK-427,857. 7th International Congress on Drug Therapy in HIV Infection, 14-18 November 2004, Glasgow. Available at: <http://www.aegis.com/conferences/hiv-glasgow/2004/P282.html> (accessed 21/08/07).

Maraviroc + Miscellaneous

Maraviroc had no clinically relevant effect on the pharmacokinetics of lamivudine, zidovudine, or a combined oral contraceptive containing ethinylestradiol and levonorgestrel. No clinically important effect was seen with the CYP3A4 substrate midazolam. Food may reduce the absorption of maraviroc, but this is probably not clinically relevant.

Clinical evidence, mechanism, importance and management

(a) *Food*

In healthy male subjects, food significantly reduced the rate and extent of absorption of maraviroc.¹ However, the manufacturer reported that food appeared to have little effect on the antiviral activity of maraviroc, and so food restriction was not considered necessary.²

(b) *Hormonal contraceptives*

Maraviroc 100 mg twice daily had no effect on contraceptive steroid levels after administration of the combined oral contraceptive **ethinylestradiol/levonorgestrel** 30/150 micrograms daily for 7 days in a placebo-controlled crossover study in 15 healthy women.³

(c) *Midazolam*

In a placebo-controlled study in 12 healthy subjects maraviroc 300 mg twice daily for 7 days slightly increased the AUC of a single 7.5-mg dose of midazolam given on day 7 by 18%, after to. This increase is unlikely to be clinically relevant.⁴ Midazolam is a probe substrate of the cytochrome P450 isoenzyme CYP3A4, and the findings suggest that maraviroc is unlikely to have an important effect on other CYP3A4 substrates. For a list see 'Table 1.4', (p.6).

(d) *NRTIs*

In a placebo-controlled, crossover study in healthy subjects maraviroc 300 mg twice daily had no clinically relevant effect on the pharmacokinetics of **zidovudine/lamivudine (Combivir)** 300/150 mg twice daily, when they were given together for one week.⁵ For the effect of other NRTIs in combination with protease inhibitors or NNRTIs on maraviroc, see 'CYP3A4 inhibitors', (p.780) and 'CYP3A4 inducers', (p.780), and for the effect of tenofovir, see 'Drugs that affect renal clearance', (above).

NNRTIs + Antiepileptics; Enzyme-inducing

The concurrent use of carbamazepine and efavirenz leads to a modest reduction in the plasma levels of both drugs; similar effects may be expected with phenytoin and phenobarbital. The use of nevirapine and carbamazepine may also result in decreased levels of both drugs.

Clinical evidence

The manufacturer notes that there was a pharmacokinetic interaction between efavirenz 600 mg daily and carbamazepine 400 mg daily in a study in healthy subjects. The steady-state AUC, and maximum and minimum plasma concentrations of carbamazepine decreased by 27%, 20% and 35%, respectively, while the steady-state AUC, and maximum and minimum plasma concentrations of efavirenz decreased by 36%, 21%, and 47%, respectively. The steady-state levels of the active carbamazepine epoxide metabolite remained unchanged.^{1,2}

Mechanism

Efavirenz and carbamazepine are both inducers and substrates of the cytochrome P450 isoenzyme CYP3A4, and so they can both increase the metabolism of the other drug. Nevirapine would be expected to interact similarly (see 'Table 21.2', (p.773)).

Importance and management

The manufacturers of efavirenz note that an alternative to carbamazepine should be considered (especially with doses of greater than 400 mg daily, the study dose).^{1,2} The US manufacturer of nevirapine recommends caution with the concurrent use of carbamazepine.³

In the UK, the manufacturer states that no data are available on the potential interactions of efavirenz with phenytoin or phenobarbital. They say that when efavirenz is given with these drugs, there is a potential for reduction or increase in the plasma concentrations of each drug. They therefore recommend periodic monitoring of plasma levels.¹

NNRTIs + Antiepileptics; Valproate

Efavirenz levels were not altered by valproic acid in one study in HIV-positive patients, and valproic acid levels were not different to those in a control group not taking efavirenz. However, one patient had a marked decrease in valproate levels after starting efavirenz. A case of hepatotoxicity has occurred in a patient taking valproic acid with nevirapine and saquinavir/ritonavir.

Clinical evidence

In a study in 11 HIV-positive patients taking efavirenz 600 mg once daily with various NRTIs, there was no change in the pharmacokinetics of efavirenz after they took valproic acid 250 mg twice daily for 7 days. Valproic acid levels achieved in these patients were not significantly different from those in 11 HIV-positive control patients mainly taking NRTI antiretrovirals, even when the 3 control patients taking a protease inhibitor or NNRTI (amprenavir, indinavir, or nelfinavir plus nevirapine) were excluded.¹

However, a bipolar patient with multidrug addiction had a decrease in plasma valproic acid levels of more than 50% shortly after starting an antiretroviral regimen including efavirenz. Even though the valproate dose was increased to 4 g daily, it was found difficult to achieve a target plasma level of 50 mg/dL. About 3 months later, following a valproate dose reduction to 1.5 g daily due to adverse effects, his level was unaltered, at 52 mg/dL.²

A case of valproate-associated hepatotoxicity occurred in a 51-year-old man about 3 weeks after he started nevirapine 200 mg twice daily, saquinavir/ritonavir 400/400 mg twice daily, and stavudine. Serum valproic acid levels remained therapeutic.³

Mechanism

Uncertain.

Importance and management

The findings of the study¹ suggest that valproate can be used with efavirenz-based regimens without any anticipated pharmacokinetic drug interaction. However, the case report introduces a note of caution. It may be appropriate to monitor valproate levels in patients taking efavirenz. It is unclear whether the case of hepatotoxicity was a result of a drug interaction. Note that there has been some concern about using valproate in HIV infection but there seems to be no established reason to avoid or specifically promote the use of valproate in HIV-infection *per se*.

NNRTIs + Azoles; Fluconazole

Fluconazole doubles nevirapine exposure, and the combination should be used with caution. Fluconazole causes a minor rise in efavirenz steady-state levels, and does not alter delavirdine levels. Fluconazole levels are not altered by these NNRTIs.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

Delavirdine mesilate 300 mg three times daily was given to 13 HIV-positive subjects for 30 days. Fluconazole 400 mg daily was given to 8 of them on days 16 to 30. No differences in the pharmacokinetics of either drug were noted between the two groups.¹ On the basis of these results, it would appear that no dosage adjustments are needed if these drugs are used together.

(b) Efavirenz

Fluconazole 400 mg daily for one day, then 200 mg daily for 6 days was given to 20 healthy subjects with efavirenz 400 mg daily. The pharmacokinetics of fluconazole were not affected, and although the AUC of efavirenz was raised by 15%, no clinically significant effects are anticipated.²

(c) Nevirapine

The concurrent use of fluconazole and nevirapine doubled the exposure to nevirapine compared with historical control data, although nevirapine did not have any clinically relevant effect on fluconazole pharmacokinetics.^{3,4} The manufacturer suggests that patients should be closely monitored for nevirapine-associated adverse effects if fluconazole and nevirapine are used concurrently.^{3,4} However, in a retrospective study of patients who had received a nevirapine-based HAART regimen, there was no increase in the incidence of clinical hepatitis, elevated aminotransferases or skin rashes, when the outcomes of 225 patients not receiving fluconazole, 392 patients treated with fluconazole 400 mg weekly, and 69 patients receiving fluconazole 200 mg daily with nevirapine were compared.⁵

5. Manosuthi W, Chumpathat N, Chaovavanich A, Sungkanuparph S. Safety and tolerability of nevirapine-based antiretroviral therapy in HIV-infected patients receiving fluconazole for cryptococcal prophylaxis: a retrospective cohort study. *BMC Infect Dis* (2005) 5, 67.

NNRTIs + Azoles; Itraconazole

Itraconazole had no effect on efavirenz levels, whereas efavirenz modestly decreased itraconazole levels. Nevirapine may also decrease itraconazole levels.

Clinical evidence

In a study in healthy subjects, **efavirenz** 600 mg daily decreased the steady-state maximum plasma levels and the AUC of itraconazole 200 mg twice daily by 37% and 39%, respectively, and caused a similar decrease in hydroxyitraconazole levels. The steady-state maximum plasma levels and the AUC of **efavirenz** were not affected by itraconazole.^{1,2}

Mechanism

The metabolism of itraconazole by the cytochrome P450 isoenzyme CYP3A4 is induced by efavirenz. Nevirapine might interact similarly as it also induces CYP3A4.

Importance and management

On the basis of the pharmacokinetic study, the manufacturers of efavirenz say that alternatives to itraconazole should be considered.^{1,2} If there are no appropriate alternatives, it might be prudent to increase the dose of itraconazole, with increased monitoring for efficacy and toxicity of the combination.

Nevirapine might be expected to interact similarly to efavirenz, therefore monitor itraconazole efficacy carefully and anticipate the need to increase the dose.

1. Sustiva (Efavirenz). Bristol-Myers Squibb Pharmaceuticals Ltd. UK Summary of product characteristics, May 2007.
2. Sustiva (Efavirenz). Bristol-Myers Squibb Company. US Prescribing information, January 2007.

NNRTIs + Azoles; Ketoconazole

Nevirapine markedly reduces the AUC of ketoconazole. In theory, efavirenz may interact similarly, whereas delavirdine may increase ketoconazole levels. The NNRTI plasma levels may be raised by ketoconazole.

Clinical evidence

(a) Delavirdine

The manufacturer notes that the minimum level of delavirdine was 50% higher than population pharmacokinetic data in 26 patients taking ketoconazole.¹

(b) Nevirapine

The manufacturers of nevirapine quote a study in which nevirapine 200 mg twice daily was given with ketoconazole 400 mg daily. The ketoconazole AUC was markedly reduced by 72% and its maximum plasma levels were reduced by 44%.^{2,3} In addition, the nevirapine plasma levels were raised by 15 to 28% compared with historical control data.²

Mechanism

Ketoconazole is likely to inhibit the metabolism of the NNRTIs by the cytochrome P450 isoenzyme CYP3A4. Nevirapine induces the metabolism of ketoconazole by CYP3A4, and, in theory, **efavirenz** is likely to interact similarly, whereas delavirdine is likely to inhibit ketoconazole metabolism by CYP3A4 (see 'Table 21.2', (p.773)).

Importance and management

The manufacturer of nevirapine states that ketoconazole and nevirapine should not be used together, because of the likely reduced efficacy of ketoconazole.^{2,3} Efavirenz might be expected to interact similarly although the manufacturer of efavirenz says that the potential for an interaction has not been studied.⁴ NNRTI levels might be raised by ketoconazole, which might increase adverse effects. Cautious monitoring of efficacy and adverse effects would be prudent if concurrent use is necessary.

1. Rescriptor (Delavirdine mesylate). Pfizer Inc. US Prescribing information, June 2006.
2. Viramune (Nevirapine anhydrate). Boehringer Ingelheim Ltd. UK Summary of product characteristics, January 2007.
3. Viramune (Nevirapine). Boehringer Ingelheim Pharmaceuticals, Inc. US Prescribing information, June 2007.
4. Sustiva (Efavirenz). Bristol-Myers Squibb Pharmaceuticals Ltd. UK Summary of product characteristics, May 2007.

NNRTIs + Azoles; Posaconazole

The manufacturer of posaconazole predicts that it will increase the plasma levels of the NNRTIs because it inhibits the cytochrome P450 isoenzyme CYP3A4, by which they are metabolised. They recommend patients should be carefully monitored for any occurrence of toxicity during concurrent use.¹

1. Noxafil (Posaconazole). Schering-Plough Ltd. UK Summary of product characteristics, October 2006.

NNRTIs + Azoles; Voriconazole

Efavirenz markedly decreases voriconazole levels and voriconazole modestly increases efavirenz levels. Voriconazole is predicted to increase levels of both delavirdine and nevirapine. Like efavirenz, nevirapine is predicted to decrease voriconazole levels, whereas delavirdine is predicted to increase voriconazole levels.

Clinical evidence

In a study in healthy subjects, **efavirenz** 400 mg daily decreased the steady-state maximum plasma levels and the AUC of voriconazole 200 mg twice daily by 61% and 77%, respectively. At the same time, the steady-state maximum plasma levels and the AUC of **efavirenz** were increased by 38% and 44%, respectively.¹ In a dose-adjustment study, when voriconazole 300 mg twice daily and **efavirenz** 300 mg daily were used together, the AUC of voriconazole was 55% lower than that seen with the standard dose of voriconazole 200 mg twice daily alone, and the **efavirenz** AUC was equivalent to that seen with efavirenz 600 mg daily alone.²⁻⁴ In a further dose-adjustment study, when voriconazole 400 mg twice daily was given with **efavirenz** 300 mg once daily, the AUC of voriconazole was just 7% lower than that seen with voriconazole 200 mg twice daily alone. The AUC of **efavirenz** was increased by 17% and the maximum plasma concentration was equivalent, when compared with efavirenz 600 mg once daily alone.²⁻⁴

There is one case of a patient taking a variety of antiretrovirals and antibacterials who developed oral candidiasis while taking voriconazole 200 mg twice daily, which was attributed to an interaction with **efavirenz**. The dose of voriconazole was titrated upwards to 350 mg twice daily to achieve higher trough levels. The candidiasis was eventually found to be resistant to voriconazole, and it was postulated that this developed because of under-dosing in the presence of **efavirenz**.⁵

Mechanism

The metabolism of voriconazole by the cytochrome P450 isoenzyme CYP3A4 is induced by efavirenz. **Nevirapine** is predicted to interact similarly, whereas **delavirdine** is predicted to inhibit the metabolism of voriconazole. All the NNRTIs are substrates of CYP3A4, which is inhibited by voriconazole.

Importance and management

On the basis of the pharmacokinetic studies the manufacturers contraindicate the concurrent use of efavirenz and voriconazole,⁶ unless the doses of both drugs are adjusted.²⁻⁴ The recommendation is to double the usual dose of voriconazole to 400 mg twice daily, and to halve the usual efavirenz dose to 300 mg once daily.²⁻⁴

Nevirapine might be expected to interact similarly to efavirenz, whereas delavirdine might increase voriconazole levels. The manufacturers of voriconazole suggest that patients given delavirdine or nevirapine should be carefully monitored for evidence of drug toxicity and/or loss of efficacy during concurrent use.^{2,3}

NNRTIs + Drugs that affect gastric pH

Antacids roughly halve the AUC of delavirdine, and the H₂-receptor antagonists or proton pump inhibitors would be expected to interact similarly. Aluminium/magnesium antacids do not interact to a clinically relevant extent with efavirenz or nevirapine, and famotidine does not alter the absorption of efavirenz.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

Delavirdine is poorly soluble at pHs greater than 3, so the effect of giving delavirdine 300 mg ten minutes after an antacid was studied in 12 healthy subjects. The AUC and maximum serum levels of delavirdine were reduced by 48% and 57%, respectively, suggesting that delavirdine should not be given with antacids.¹ The manufacturer recommends separating administration by at least one hour.² Although it has not been studied, it is predicted that other drugs that reduce gastric acidity, such as H₂-receptor antagonists and proton pump inhibitors, will also reduce the absorption of delavirdine, and their long-term use with delavirdine is not recommended.²

(b) Efavirenz

The manufacturer notes that neither **aluminium/magnesium hydroxide** antacids nor **famotidine** had any effect on the absorption of efavirenz.³ No efavirenz dosage adjustment is expected to be necessary with these drugs.⁴ Other drugs that reduce gastric acidity are not expected to affect efavirenz absorption.³

(c) Nevirapine

In a study in 24 healthy subjects it was found that 30 mL of *Maalox* (**aluminium/magnesium hydroxide**) caused some moderate changes in the pharmacokinetics of nevirapine 200 mg, but none of them was considered to be clinically relevant.⁵ No special precautions would seem to be necessary.

NNRTIs + Food

Food has no clinically relevant effect on the levels of delavirdine or nevirapine. Food modestly increases efavirenz levels, and the manufacturer suggests that this might increase the frequency of adverse effects.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

In a randomised, crossover study in 13 HIV-positive patients taking delavirdine 400 mg daily, there were no changes in the steady-state serum levels of delavirdine taken with or without food for 2 weeks.¹ This differed from a previous single-dose study, in which there was a 26% fall in the AUC of delavirdine given with food.² There would appear to be no need to avoid taking delavirdine with food. For mention that orange juice increased the absorption of delavirdine in patients with gastric hypoacidity, see 'NNRTIs; Delavirdine + Acids', p.791.

(b) Efavirenz

The manufacturer of efavirenz notes that taking a 600-mg efavirenz *tablet* with a **high-fat meal** increased its AUC by 28%, when compared with fasting conditions, and increased its maximum concentration by 79%.^{3,4} After a similar meal, the AUC and maximum level of the *capsule* formulation was increased by 22% and 39%, respectively, and after a **low-fat meal** the increases were 17% and 51%, respectively.⁴ The manufacturer says that these increases might increase the frequency of adverse effects. They recommend that efavirenz is taken without food, preferably at bedtime.^{3,4}

(c) Nevirapine

In a study in 24 healthy subjects, a **high-fat breakfast** caused some moderate changes in the pharmacokinetics of oral nevirapine 200 mg, but the AUC was not affected and none of the changes were considered to be clinically relevant.⁵ Nevirapine may be taken with or without food.

NNRTIs + Macrolides

Delavirdine may increase the levels of clarithromycin, whereas efavirenz and nevirapine may reduce clarithromycin levels, and increase those of its hydroxy metabolite. Clarithromycin does not appear to affect the pharmacokinetics of delavirdine, efavirenz or nevirapine to a clinically relevant extent. There is no pharmacokinetic interaction between azithromycin and efavirenz. A case of a neuropsychiatric reaction has been attributed to the use of clarithromycin in a man taking nevirapine.

Clinical evidence

(a) Delavirdine

In 7 HIV-positive patients **clarithromycin** 500 mg twice daily for 15 days did not cause a clinically significant change in the pharmacokinetics of delavirdine 300 mg three times daily, when compared with 4 other HIV-positive patients taking only delavirdine. The combination was well tolerated and no serious adverse events occurred.¹ However, although delavirdine levels are unaffected, the manufacturer notes that the AUC of **clarithromycin** was doubled by delavirdine.²

(b) Efavirenz

The manufacturer notes that the concurrent use of **clarithromycin** 500 mg twice daily and efavirenz 400 mg daily for 7 days reduced the AUC of **clarithromycin** by 39% and increased the AUC of its hydroxy metabolite by 34%. Moreover, 46% of subjects receiving the combination developed a rash.^{3,4} Clarithromycin had minimal effect on the pharmacokinetics of efavirenz.⁴

The manufacturer also notes that there was no clinically significant pharmacokinetic interaction when a single 600-mg dose of **azithromycin** was given to healthy subjects who had been taking efavirenz 400 mg daily for 7 days.^{3,4}

(c) Nevirapine

The manufacturer notes that the AUC of nevirapine was increased by 26% by **clarithromycin**, when compared with historical controls. The AUC of **clarithromycin** was reduced by 31% and the AUC of its hydroxy metabolite was increased by 42%.^{5,6} A man developed hyperactivity (poor concentration, anxiety, suicidal and homicidal ideation) when taking **clarithromycin** and antiretroviral drugs, including nevirapine. This was thought to be due to accumulation of the hydroxy metabolite of **clarithromycin**.⁷

Mechanism

The NNRTIs are substrates of the cytochrome P450 isoenzyme CYP3A4, which is inhibited by clarithromycin. Delavirdine is also reported to inhibit CYP3A4, whereas efavirenz and nevirapine induce CYP3A4. Therefore alterations in the metabolism of these drugs by CYP3A4 results in the altered levels seen.

Importance and management

It appears that clarithromycin has minimal effects on the pharmacokinetics of the NNRTIs. However, delavirdine may increase levels of clarithromycin. The manufacturer of **delavirdine** recommends that when the drugs are used concurrently the dose of clarithromycin should be reduced in pa-

tients with renal impairment.² In contrast, efavirenz and nevirapine may decrease clarithromycin levels and increase the levels of the hydroxy metabolite of clarithromycin. The manufacturer of **nevirapine** suggests that no dose adjustment of clarithromycin is needed; however, they say that alternatives to clarithromycin should be considered for the treatment of Mycobacterium-avium complex, as the hydroxy metabolite is not as active against this bacterium.^{5,6} The manufacturer of **efavirenz** says that the clinical significance of the changes to clarithromycin pharmacokinetics is not known, but they suggest alternatives to clarithromycin should be considered.^{3,4} Further study and experience of these combinations is needed.

NNRTIs + NNRTIs

Nevirapine modestly reduces the levels of efavirenz, whereas efavirenz has no effect on nevirapine levels.

Clinical evidence, mechanism, importance and management

In a study in HIV-positive patients taking efavirenz 600 mg daily, the addition of **nevirapine** 400 mg daily resulted in a median decrease in the AUC of **efavirenz** of 22%, and a decrease in its minimum plasma concentration of 36%. The steady-state pharmacokinetics of **nevirapine** were not altered by **efavirenz**, when compared with historical control data.¹ However, the UK manufacturer does not recommend this combination as concurrent use of **efavirenz** and **nevirapine** could lead to a higher risk of adverse effects. Moreover they say that concurrent use does not improve efficacy over either NNRTI alone.²

2. Viramune (Nevirapine anhydrate). Boehringer Ingelheim Ltd. UK Summary of product characteristics, January 2007.

NNRTIs + NRTIs

Delavirdine absorption is reduced by the buffered preparation of didanosine. This interaction would not be expected with the enteric-coated preparation of didanosine. Delavirdine does not affect the pharmacokinetics of zidovudine. There is no pharmacokinetic interaction between efavirenz and zidovudine or lamivudine. There is no clinically relevant pharmacokinetic interaction between nevirapine and didanosine, lamivudine, stavudine, zalcitabine or zidovudine.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

A study in 34 HIV-positive patients taking **zidovudine** 200 mg three times daily found that delavirdine mesilate 400 mg to 1.2 g daily for 9 days had no clinically significant effect on the pharmacokinetics of **zidovudine**.¹

In a steady-state study, 9 HIV-positive patients taking **didanosine** 200 mg twice daily were also given delavirdine mesilate 400 mg three times daily for 14 days. **Didanosine** caused a 37% reduction in the maximum delavirdine serum levels, but when the drugs were given 1 hour apart no significant effect occurred.² A single-dose study in 12 HIV-positive patients found similar results.³ The buffered preparation of **didanosine** contains antacids to increase its absorption, and antacids decrease the absorption of delavirdine (see 'NNRTIs + Drugs that affect gastric pH', p.784). The authors of one report suggest that separating the doses by about one hour is preferable.² The enteric-coated preparation of **didanosine**,

which does not contain antacids, would not be expected to reduce the absorption of delavirdine.

(b) Efavirenz

The manufacturer notes that there were no clinically significant pharmacokinetic interactions between efavirenz and **zidovudine** or **lamivudine** in patients with HIV.^{4,5} No dosage adjustments are required on concurrent use.⁵ No pharmacokinetic interactions are anticipated with other NRTIs.^{4,5}

(c) Nevirapine

The pharmacokinetics of **didanosine** and **zidovudine** with or without nevirapine were assessed in 175 HIV-positive subjects. The bioavailability of **didanosine** was not affected, but the bioavailability of **zidovudine** was decreased by about one-third by nevirapine.⁶ In a steady-state study in 24 HIV-positive patients, nevirapine 200 mg every 12 hours was added to regimens of **didanosine**, **didanosine** with **zidovudine**, or **zidovudine** with **zalcitabine** for a 4-week period. No significant changes in the pharmacokinetics of **didanosine** or **zalcitabine** were seen. However, in the **didanosine/zidovudine** group the peak **zidovudine** plasma levels and AUC were reduced by 27% and 32%, respectively. The **zidovudine** pharmacokinetics in the **zidovudine/zalcitabine** group were not affected.⁷ The reasons for these changes are not clear, but the clinical consequences are thought to be small, and the safety data indicate that the concurrent use of these drugs is safe and well tolerated. In another study, the simultaneous administration of nevirapine with **didanosine** tablets containing antacids had no effect on nevirapine absorption in 4 patients.⁸ The manufacturer says that no dosage adjustments are needed if **didanosine**, **zalcitabine** or **zidovudine** is taken with nevirapine.⁹

Nevirapine 200 mg once daily for 2 weeks then 200 mg twice daily had no effect on the AUC of **stavudine** 30 to 40 mg twice daily in a study in 22 patients.^{10,11} Nevirapine appears to have no effect on **lamivudine** clearance, based on a population pharmacokinetic study.¹²

NNRTIs + Protease inhibitors

In general, efavirenz and nevirapine decrease the levels of protease inhibitors, whereas delavirdine increases them. Ritonavir is sometimes used to elevate the levels of other protease inhibitors when efavirenz or nevirapine are required. Amprenavir and nelfinavir decrease the levels of delavirdine. Most protease inhibitors do not appear to affect the levels of efavirenz or nevirapine. There is some evidence of increased adverse effects with antiviral doses of ritonavir and efavirenz, or saquinavir and delavirdine, including raised liver enzymes. Note that NNRTIs are not given with protease inhibitors in current first-line regimens for HIV infection: either an NNRTI or protease inhibitors are combined with dual NRTIs.

Table 21.3 Summary of the pharmacokinetic interactions of NNRTIs and protease inhibitors

Drug combination	No. of healthy subjects (unless specified)	Change in AUC (unless specified)		Refs
		NNRTI	Protease inhibitor	
Delavirdine studies (usually 400 mg three times daily or 600 mg twice daily)				
Amprenavir	6 HIV-positive children		3-fold increase in C _{max} * 5 to 10-fold increase in C _{min} *	1
Amprenavir 1200 mg	12	21% increase	4-fold increase	2
Amprenavir 1200 mg twice daily alone then 600 mg twice daily in combination	11	47% decrease	32% increase versus twice the dose given alone	
Amprenavir 600 mg twice daily	18	61% decrease	130% increase	3
Indinavir 800 mg alone then 600 mg in combination	14	No change	44% increase versus higher dose given alone	4, 5
Nelfinavir 750 mg three times daily	24	42% decrease	92% increase	6
Ritonavir 300 mg twice daily		No change in steady state level	No change in steady state level	4
Ritonavir 600 mg twice daily	12 HIV-positive subjects	No change*	64% increase 81% increase in C _{min}	7
Ritonavir 100 mg twice daily	19	No change	80% increase	8
Saquinavir 600 mg three times daily		No change in steady state level	5-fold increase in steady state level	4
Efavirenz studies (600 mg once daily)				
Amprenavir	2 HIV-positive children		Undetectable levels in less than 4 hours†	1
Amprenavir 1200 mg twice daily	7 HIV-positive subjects		About an 80% decrease in trough levels†	9
Amprenavir 1200 mg twice daily	11 HIV-positive subjects	No change*	24% decrease 43% decrease in C _{min}	10
Atazanavir 400 mg once daily			74% decrease	11
Atazanavir/Ritonavir 300/100 mg once daily			39% increase	11
Darunavir/Ritonavir 300/100 mg twice daily		21% increase	31% decrease in C _{min} (darunavir)	12
Fosamprenavir/Ritonavir 1395 mg/200 mg once daily	11		31% decrease in C _{min} (amprenavir)	13
Fosamprenavir/Ritonavir 700 mg/100 mg twice daily	14		Slight decrease in C _{min} (amprenavir)	13
Fosamprenavir/Ritonavir 1395 mg/300 mg once daily	11		Amprenavir levels comparable to that seen with 1395 mg/200 mg alone	13
Indinavir 800 mg three times daily alone then 1000 mg three times daily in combination			33% to 46% decrease versus lower dose given alone	14
Indinavir/Ritonavir 800/100 mg twice daily	14	No change*	25% decrease (indinavir) 36% decrease (ritonavir)	15
Indinavir/Ritonavir 800/100 mg twice daily	20 HIV-positive subjects	31% increase in C _{min} *	C _{min} halved* (indinavir)	16
Lopinavir/Ritonavir 400/100 mg twice daily	24 HIV-positive subjects		44% decrease in C _{min} * (lopinavir)	17
Lopinavir/Ritonavir 533/133 mg twice daily	26 HIV-positive subjects		No significant change in C _{min} versus lower dose given without efavirenz* (lopinavir)	17
Lopinavir/Ritonavir 600/150 mg twice daily			28 to 44% increase (lopinavir), 62 to 95% increase (ritonavir) compared with standard dose alone	18

Clinical evidence, mechanism, importance and management

(a) Delavirdine

For a summary of the studies of the pharmacokinetic interactions of delavirdine and various protease inhibitors, see ‘Table 21.3’, (p.786). In general, these studies show that delavirdine can markedly increase protease inhibitor exposure. In addition, **amprenavir** and **nelfinavir** have been shown to approximately halve the AUC of delavirdine.

Delavirdine and the protease inhibitors are known to be both inhibitors of, and substrates for the cytochrome P450 isoenzyme CYP3A4, see ‘Table 21.2’, (p.773).

It has been suggested that delavirdine could be used clinically to boost the exposure to protease inhibitors, and this has been tried in at least one study.¹ However, this combination is complicated by the reduction in de-

lavirdine levels with some protease inhibitors, and the combination may not be appropriate if the antiviral effect of delavirdine is required.² Moreover, if the combination is used, patients should be closely monitored for toxicity since in one study of **nelfinavir** and delavirdine, 4 out of 24 subjects had to stop both drugs before completing the study because of neutropenia, which resolved over several days.³ The UK manufacturer of **saquinavir** says that liver function should be monitored frequently if delavirdine is also given, because in a small preliminary study hepatic enzymes were raised in 13% of subjects (grade 3 or 4 in 6%) receiving the combination.⁴

(b) Efavirenz

For a summary of the studies of the pharmacokinetic interactions of efavirenz and various protease inhibitors, see ‘Table 21.3’, (p.786). Most of the

protease inhibitors did not affect efavirenz levels, although **ritonavir** caused a 20% increase in levels. Efavirenz is an inducer of the cytochrome P450 isoenzyme CYP3A4, by which the protease inhibitors are metabolised. With the exceptions of **nelfinavir** and **ritonavir**, which showed minor to modest increases in levels, efavirenz reduces the levels of the protease inhibitors, often to levels likely to lead to reduced antiviral efficacy. Ways to overcome this include the addition of low-dose **ritonavir** to boost the levels of the protease inhibitor (recommended for **amprenavir**, **atazanavir**, **fosamprenavir**, **saquinavir**) or increasing the dose for protease inhibitors already boosted by **ritonavir** (recommended for **lopinavir/ritonavir**). For a summary of the manufacturers' recommended regimens for use with efavirenz 600 mg daily see 'Table 21.4', (below). However, the manufacturers of efavirenz note that increased adverse effects, including dizziness, nausea, paraesthesia and elevated liver enzyme levels occurred with the combination of efavirenz and **ritonavir** 500 or 600 mg twice daily (antiretroviral dosage), and the combination was not well tolerated.^{5,6} They recommend monitoring liver enzyme levels with this combination.⁶ The UK manufacturer says that the tolerability of low-dose **ritonavir** with efavirenz has not been assessed, and they caution that the possibility of an increase in the incidence of efavirenz-associated adverse events should be considered with any **ritonavir**-boosted regimen used with efavirenz, due to a possible interaction.⁵

With **lopinavir/ritonavir**, although an increased dose of 533/133 mg twice daily with efavirenz or nevirapine produced similar plasma levels of

lopinavir to those seen with the lower dose of 400/100 mg twice daily without an NNRTI, the proportion of patients with a suboptimal minimum lopinavir level tended to be higher in those patients receiving the NNRTI.⁷ This suggests that some patients may need a further increase in lopinavir/ritonavir dose. Another study with **atazanavir/ritonavir** also found that the increased dose of atazanavir for use with NNRTIs did not appear to overcome the inducer effect of NNRTIs (efavirenz or nevirapine) and led to a 43% lower median minimum atazanavir level, and a greater proportion of patients with suboptimal minimum levels (25% versus 7%).⁸

(c) Nevirapine

For a summary of the studies of the pharmacokinetic interactions of nevirapine and various protease inhibitors, see 'Table 21.3', (p.786). Most protease inhibitors do not appear to affect the levels of nevirapine, although some caused a minor to modest increase. Nevirapine is an inducer of the cytochrome P450 isoenzyme CYP3A4, and so would be expected to reduce the levels of some of the protease inhibitors (see 'Table 21.2', (p.773)), sometimes to levels that are unlikely to be effective. Low-dose **ritonavir** has been used to boost the levels of some protease inhibitors when they were given with nevirapine. For a summary of the manufacturers' recommended regimens for use with nevirapine see 'Table 21.4', (below). If nevirapine is used with protease inhibitors, therapy should be closely monitored. For studies suggesting that increased doses of lopina-

Table 21.4 Summary of the manufacturers' dosage recommendations (unless stated otherwise) for combined use of protease inhibitors and NNRTIs

	Dose of protease inhibitor to be used with standard dose of the NNRTI		
	Delavirdine 400 mg three times daily	Efavirenz 600 mg daily	Nevirapine 200 mg twice daily
Amprenavir	Appropriate dose not established. Care (potentially subtherapeutic)	Appropriate dose not established (amprenavir levels reduced)	Appropriate dose not established (amprenavir levels may be decreased)
Amprenavir/Nelfinavir	No dosage adjustments required		
Amprenavir/Ritonavir*	Appropriate dose not established. Care (unpredictable effect)	600/100 mg twice daily	
Amprenavir/Saquinavir	Avoid		
Atazanavir	Avoid		In the absence of data, avoid
Atazanavir/Ritonavir*	400/100 mg once daily [†] (UK) 300/100 mg once daily (US)		In the absence of data, avoid
Darunavir/Ritonavir*	Care		No dose adjustments required
Fosamprenavir	Caution (delavirdine potentially subtherapeutic)	Appropriate dose not established	Avoid
Fosamprenavir/Ritonavir*	700/100 mg twice daily or 1400/300 mg once daily		700/100 mg twice daily
Indinavir	Consider reducing dose to 400 to 600 mg three times daily. Optimum dose not established	Optimum dose not known. Increasing the dose to 1 g three times daily does not compensate for induced metabolism	Consider increasing to 1 g three times daily. Optimum dose not known
Indinavir/Ritonavir*	Appropriate dose not established. 800/100 mg twice daily has been tried		
Lopinavir/Ritonavir*	Appropriate dose not established	533/133 mg twice daily [†] or 600/150 mg twice daily. Avoid once daily regimens	533/133 mg twice daily [†] or 600/150 mg twice daily. Avoid once daily regimens
Nelfinavir	Avoid	No dose adjustments required	No dose adjustment likely (UK). Appropriate dose not established (US)
Ritonavir*	Ritonavir dose reductions might be appropriate	No dose adjustments required, but not well tolerated. Monitor liver function	No dose adjustments required
Saquinavir	Appropriate dose not established. Monitor liver function	Avoid	Appropriate dose not established
Saquinavir/Ritonavir*	No dose adjustments required. Monitor liver function		Dose adjustments unlikely to be needed
Tipranavir/Ritonavir*	Appropriate dose not established. Care		Appropriate dose not established. Care

*The UK manufacturer of efavirenz advises caution, because the possibility of an increase in the incidence of efavirenz-associated adverse events should be considered with any ritonavir-boosted regimen used with efavirenz, due to a possible interaction. This is because the combination of efavirenz with ritonavir at antiviral doses caused increased dizziness, nausea, paraesthesia and elevated transaminase levels.

[†]This dose increase may not be sufficient in some patients, so some caution is required.

vir/ritonavir and atazanavir/ritonavir may not be sufficient in all patients given NNRTIs (including nevirapine), see *Efavirenz*, above.

NNRTIs + Rifamycins

Rifabutin and rifampicin (rifampin) cause a very marked fall in delavirdine plasma levels: rifabutin levels are raised when the delavirdine dose is increased to compensate for this. Rifabutin does not affect efavirenz levels, whereas efavirenz decreases rifabutin levels. There is usually no important interaction between rifabutin and nevirapine, although some patients may have a higher risk of rifabutin adverse effects.

Neither efavirenz nor nevirapine affect rifampicin levels, but rifampicin modestly reduces the levels of these NNRTIs, and there is some debate about whether it is necessary to increase their dose.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

In a controlled study in 7 HIV-positive patients taking delavirdine mesilate 400 mg three times daily for 30 days, the addition of **rifabutin** 300 mg daily from days 16 to 30 caused a fivefold increase in the delavirdine clearance, and an 84% fall in the steady-state plasma levels.¹ This was presumably due to the enzyme-inducing effects of the **rifabutin**. A similar study using **rifampicin** in place of **rifabutin** found that **rifampicin** caused a 27-fold increase in clearance of delavirdine, and the steady-state plasma levels became almost undetectable.²

In another study,³ where the dose of delavirdine was titrated to achieve a trough level of at least 5 micromol/L, the AUC of **rifabutin** was found to increase by 242%.

It has been recommended that the combination of delavirdine and **rifampicin** should be considered as contraindicated because the effects of the interaction are so large.² The CDC in the US and the manufacturer recommend that neither **rifabutin** nor **rifampicin** should be used with delavirdine.^{4,5}

(b) Efavirenz

1. *Rifabutin*. In a study in healthy subjects the concurrent use of efavirenz 600 mg once daily and rifabutin 300 mg once daily for 2 weeks resulted in a modest 38% decrease in the AUC of rifabutin and a 45% decrease in the minimum levels, but no change in efavirenz levels.⁶

The CDC in the US state that the combination is probably clinically useful, and they suggest increasing the dose of rifabutin to 450 mg or 600 mg daily, or 600 mg two to three times weekly.⁴ In one study doubling the rifabutin dose from 300 mg twice weekly to 600 mg twice weekly when starting efavirenz resulted in rifabutin AUCs that were 20% higher than baseline values.⁷ However, in one analysis, 8 of 35 patients (23%) taking efavirenz and given rifabutin 450 mg once daily were found to have subtherapeutic rifabutin levels, and they were switched to isoniazid.⁸ Concurrent use should therefore be closely monitored.

2. *Rifampicin (Rifampin)*. In patients with HIV and tuberculosis the concurrent use of HAART including efavirenz 600 mg once daily with antitubercular therapy including rifampicin 480 to 720 mg daily decreased the AUC of efavirenz by 22% and decreased the trough concentration by 25% (although large interpatient variability was observed). Overall the pharmacokinetics of efavirenz 800 mg daily with rifampicin were similar to those

of efavirenz 600 mg daily without rifampicin. The pharmacokinetics of rifampicin were not substantially altered by efavirenz.⁹ A similar 26% reduction in efavirenz AUC was reported in a study in healthy subjects.¹⁰ The CDC in the US suggest that it may be advisable to increase the efavirenz dose to 800 mg daily when used with rifampicin,⁴ and the UK manufacturer also recommends this.¹¹ However, in one analysis 7 of 9 patients receiving rifampicin and efavirenz 800 mg daily developed significant clinical toxicity and were found to have efavirenz levels markedly higher than the therapeutic range.¹² In another study in Thai patients taking rifampicin, median efavirenz plasma levels were comparable between those receiving 600 mg daily and 800 mg daily and similar virological outcomes were seen.^{13,14} Therefore, a 600 mg dose of efavirenz may be sufficient in some patients. Concurrent use should be well monitored.

(c) Nevirapine

1. *Rifabutin*. In one study, the pharmacokinetics of nevirapine were only minimally affected by rifabutin in 19 patients, when compared with historical data.¹⁵ The manufacturer notes that the concurrent use of rifabutin with nevirapine caused a minor 9% increase in nevirapine clearance and a 17% increase in its AUC, and a 28% increase in maximum steady-state rifabutin levels.^{16,17} They say that because of the high intersubject variability, some patients may experience large increases in rifabutin exposure and may be at higher risk of adverse effects. Concurrent use should be well monitored and undertaken cautiously. The CDC in the US state that the combination of nevirapine and rifabutin can be used.⁴

2. *Rifampicin (Rifampin)*. The manufacturer states that the AUC of nevirapine was reduced by 58% by rifampicin in 14 subjects, when compared with historical data. There was no change in steady-state rifampicin pharmacokinetics.^{16,17} Based on these pharmacokinetic data, the manufacturer suggests that the concurrent use of rifampicin with nevirapine is not recommended, and that rifabutin may be considered instead, with close monitoring of adverse effects.^{16,17}

A further study in HIV-positive patients with tuberculosis found that the rifampicin caused a 31% decrease in the AUC of nevirapine and a non-significant 21% decrease in its trough concentration.¹⁸ The authors of this study suggested that there is probably no need to increase the nevirapine dose, since the trough levels were still sufficiently above the level needed for antiviral activity.¹⁸ Moreover, subsequent observational data supported the continued efficacy of standard dose nevirapine when it was used with rifampicin.¹⁹ Similarly, others have reported the successful use of nevirapine with twice weekly rifampicin with little effect on trough nevirapine levels.²⁰ In yet another study, the concurrent use of rifampicin and nevirapine reduced nevirapine levels by about 18% with no reduction in virological response, although the proportion of patients with trough levels below the recommended level was much higher (29.7% versus 6.8%) at 8 weeks.²¹ In contrast, in another study in 13 patients taking nevirapine 200 mg twice daily, the addition of rifampicin 450 mg or 600 mg daily caused a 46% reduction in the AUC of nevirapine, and a 53% reduction in the minimum levels, with 8 of the patients having a nevirapine trough level below the therapeutic range (3 micrograms/mL). In 7 of the patients who had a reduction in the minimum levels to less than the therapeutic range, increasing the dose of nevirapine to 300 mg twice daily for 2 weeks increased the levels to above the therapeutic range in all patients without increasing adverse effects.²² The CDC in the US state that the combination of nevirapine and rifampicin should only be used if clearly indicated and with careful monitoring, because of insufficient data on whether dose adjustments are necessary.⁴ Further study is needed.

NNRTIs + St John's wort (*Hypericum perforatum*)

There is some evidence to suggest that St John's wort may decrease the levels of nevirapine. Delavirdine and efavirenz would be expected to be similarly affected.

Clinical evidence, mechanism, importance and management

Nevirapine levels, obtained by routine monitoring, were noted to be lower in 5 men who were also taking St John's wort. Based on a pharmacokinetic modelling analysis, it was estimated that St John's wort increased the oral clearance of nevirapine by about 35%.¹ This finding supports predictions based on the known metabolism of the NNRTIs by the cytochrome P450 isoenzyme CYP3A4 (see 'Table 21.2', (p.773)), of which St John's wort is a known inducer. It confirms advice issued by the CSM in the UK,² that St John's wort may decrease blood levels of the NNRTIs with possible loss of HIV suppression, so combined use should be avoided.

NNRTIs + Tenofovir

No pharmacokinetic interaction appears to occur between tenofovir and efavirenz or nevirapine. Some clinical data have shown a high rate of treatment failure when tenofovir is given with enteric-coated didanosine and either efavirenz or nevirapine.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, there was no interaction between efavirenz 600 mg daily and tenofovir disoproxil fumarate 300 mg daily.^{1,2} Similarly, in a retrospective analysis, plasma levels of nevirapine 200 mg twice daily or 400 mg once daily did not differ between patients taking tenofovir disoproxil fumarate 300 mg once daily and those not. Also, efavirenz plasma levels did not differ between patients taking tenofovir and patients not taking tenofovir. It appeared that neither nevirapine nor efavirenz altered tenofovir levels.³

Some clinical data have shown a high rate of treatment failure with a once daily combination of tenofovir disoproxil fumarate 300 mg, enteric-coated didanosine 200 or 250 mg and either efavirenz 600 mg daily or ne-

virapine 400 mg daily.⁴ These specific combinations should probably not be used. However, there are clinical data supporting the use of other tenofovir and efavirenz-based regimens, and the manufacturers specifically caution against the use of tenofovir with didanosine,^{1,2} see 'NRTIs + Tenofovir', p.806.

NNRTIs; Delavirdine + Acids

In patients with poor gastric acid production, orange juice and glutamic acid increase the absorption of delavirdine.

Clinical evidence, mechanism, importance and management

When glutamic acid 1.36 g three times daily was given with delavirdine 400 mg three times daily to 8 HIV-positive subjects with gastric hypoacidity, the AUC of delavirdine was increased by 50%.¹ Similarly, orange juice increased delavirdine absorption by 50% to 70% in subjects with gastric hypoacidity, but had less effect (0 to 30%) in those with normal gastric acidity. However, despite the use of orange juice, the AUC of delavirdine was still about 50% lower in patients with gastric hypoacidity than those without.²

Delavirdine is a weak base that is poorly soluble at neutral pH (note that antacids reduce its absorption, see 'NNRTIs + Drugs that affect gastric pH', p.784). Therefore, in subjects with gastric hypoacidity, the absorption of delavirdine is reduced, and substances that lower gastric pH increase its absorption.

The clinical value of using glutamic acid or acidic beverages with delavirdine is unknown. Nevertheless, the manufacturer recommends that, in patients with achlorhydria, delavirdine should be taken with an acidic beverage such as orange or cranberry juice.³

NRTIs + Aciclovir and related drugs

The concurrent use of zidovudine and aciclovir normally appears to be uneventful, but an isolated report describes overwhelming fatigue in one patient given zidovudine and intravenous aciclovir. Famciclovir did not alter the pharmacokinetics of zidovudine or emtricitabine.

Clinical evidence, mechanism, importance and management

(a) Aciclovir

A study in 20 HIV-positive men found no pharmacokinetic interaction between zidovudine 100 mg and aciclovir 400 or 800 mg, both given every 4 hours, 5 times a day, and the combination was well tolerated over a 6-month period.¹ When 41 HIV-positive patients taking zidovudine were given aciclovir, no changes in the pharmacokinetics of the zidovudine occurred and the adverse effects were unchanged.² In a group of AIDS patients taking zidovudine, some of whom were also given aciclovir, no obvious problems developed that could be attributed to the use of the aciclovir.³

In contrast, a man with herpes who had been treated with intravenous aciclovir 250 mg every 8 hours for 3 days, developed overwhelming fatigue and lethargy within about an hour of starting oral zidovudine 200 mg every 4 hours. This lessened slightly on changing from intravenous to oral aciclovir, which was continued for 3 days, and symptoms resolved when the

aciclovir was withdrawn. The symptoms developed again when intravenous aciclovir was given as a test.⁴ This isolated case of fatigue is not understood, and no other cases appear to have been reported. There would seem to be no reason for avoiding concurrent use.

(b) *Famciclovir*

Only minimal changes in **zidovudine** pharmacokinetics were seen when 12 HIV-positive patients taking **zidovudine** 400 mg to 1 g daily were given a single 500-mg dose of famciclovir.⁵

In a study in 12 healthy subjects there was no important pharmacokinetic interaction between single doses of **emtricitabine** 200 mg and famciclovir 500 mg.⁶

NRTIs + Antacids

Aluminium/magnesium hydroxide caused a 25% reduction in the bioavailability of zalcitabine. Antacids would not be expected to have any additional pharmacokinetic effect on buffered didanosine preparations.

Clinical evidence, mechanism, importance and management

(a) *Didanosine*

Didanosine is acid labile. To increase its absorption, some didanosine preparations (e.g. buffered tablets) have been formulated with antacids.¹ Additional concurrent antacids would not be expected to have any further clinically relevant effect on didanosine pharmacokinetics, although the US manufacturers of the oral powder for solution² suggest that additional antacids may increase the adverse effects of the components of this preparation (presumably both the antacid and didanosine components).

(b) *Zalcitabine*

A study in 12 HIV-positive patients given a single 1.5-g dose of zalcitabine found that 30 mL of *Maalox* [aluminium/magnesium hydroxide] caused a 25% reduction in the bioavailability of the zalcitabine.³ The changes are moderate and of uncertain clinical importance. The manufacturer recommended that zalcitabine should not be taken at the same time as aluminium/magnesium-containing antacids.^{4,5}

NRTIs + Antiepileptics

Valproate increases the bioavailability of zidovudine, and one case of severe anaemia was attributed to the interaction. A case of liver toxicity with combined use has also been reported. Phenytoin and phenobarbital are predicted to slightly decrease abacavir levels.

Clinical evidence

(a) *Abacavir*

The UK manufacturer of abacavir says that **phenobarbital** and **phenytoin** may slightly decrease abacavir concentrations by affecting glucuronyltransferases.¹ There appears to be no other information on this.

(b) *Zidovudine*

The AUC and mean plasma levels of zidovudine 100 mg every 8 hours were increased by 80% in 6 HIV-positive subjects when they were given **valproic acid** 250 or 500 mg every 8 hours for 4 days. No adverse reactions, changes in hepatic or renal function, or alterations in the blood picture were reported.² A case report describes an AIDS patient taking zidovudine 100 mg five times daily who had a two- to threefold increase in trough and peak serum zidovudine levels, and a 74% increase in the CSF zidovudine levels while taking **valproic acid** 500 mg three times daily.³ In another report, a patient taking **carbamazepine**, **clobazam** and **gabapentin** was given zidovudine, **lamivudine** and **abacavir**. Nine months later, **valproic acid** 500 mg twice daily was added because of a seizure frequency of greater than one per month. At this time, his haemoglobin level was normal. About 2 months later, he was found to have severe anaemia, requiring a blood transfusion. **Stavudine** was substituted for zidovudine in his antiretroviral therapy, and 4 months later his haemoglobin was normal. The adverse haematological effects were attributed to an interaction between the valproate and zidovudine.⁴ Another HIV-positive patient, who had been taking valproate for 2 years and, zidovudine, developed severe encephalopathy, adult respiratory distress syndrome and liver failure (steatosis). Both valproate and zidovudine were stopped, and the patient gradually recovered.⁵

For the possible effect of zidovudine on phenytoin levels, see 'Phenytoin + Zidovudine', p.569.

Mechanism

The evidence indicates that the metabolism (glucuronidation) of zidovudine is inhibited by valproate so that its bioavailability is increased.^{2,3} It was suggested that this caused zidovudine haematological toxicity in the case reported.⁴ The glucuronidation of abacavir is predicted to be increased by drugs that can induce UDP-glucuronyltransferase, such as phenobarbital and phenytoin.¹

Importance and management

Information seems to be limited to the papers cited, but an interaction between zidovudine and valproate would appear to be established. It would therefore seem prudent to monitor for any evidence of increased zidovudine effects and possible toxicity if valproate is added. The other NRTIs do not undergo significant glucuronidation (see 'Antivirals', (p.772)), and would therefore not be expected to interact with valproate. For a discussion of drug-disease considerations when using valproate in HIV infection, see under Importance and management in 'protease inhibitors', (p.812).

NRTIs + Antimycobacterials

Didanosine, stavudine and zalcitabine are not expected to interact with rifabutin, but rifabutin may modestly increase the clearance of zidovudine. An isolated case describes undetectable rifabutin levels in a patient taking antiretrovirals including buffered didanosine.

Rifampicin (rifampin) appears to modestly increase the clearance of zidovudine, and is predicted to interact similarly with abacavir.

Isoniazid, pyrazinamide and ethambutol appear not to interact with zidovudine.

The clearance of isoniazid is increased by zalcitabine, and there is a theoretical increased risk of peripheral neuropathy.

Clinical evidence, mechanism, importance and management

(a) Abacavir

The UK manufacturer of abacavir¹ says that potent enzyme inducers such as **rifampicin** (**rifampin**) may slightly decrease abacavir plasma concentrations due to their ability to induce UDP-glucuronyltransferases (see also *Zidovudine*, below). As yet, there appears to be no other information on this.

(b) Didanosine

Rifabutin 300 to 600 mg daily for 12 days did not significantly affect the pharmacokinetics of [buffered] didanosine 167 to 250 mg twice daily in 12 patients with AIDS.² The steady-state pharmacokinetics of **rifabutin** were not affected by didanosine (buffered sachet preparation),³ which suggests that the buffer used in the didanosine preparation had no effect on **rifabutin** absorption.³ However, a case has been reported of a patient taking lopinavir/ritonavir, efavirenz, lamivudine and buffered didanosine who had impaired **rifabutin** absorption. When **rifabutin** was taken 30 minutes after didanosine, **rifabutin** levels were undetectable, but when **rifabutin** was taken 3 hours after didanosine, **rifabutin** levels were apparent.⁴

The controlled study³ suggests that no special precautions are necessary if both drugs are given. However, the case report⁴ introduces an element of caution, especially if other drugs that may affect **rifabutin** pharmacokinetics are used. If indeed **rifabutin** absorption is affected by antacids (there appear to be no clinical data on this), then giving the drugs at least 2 hours apart, or using the enteric-coated didanosine preparation should avoid the interaction.⁴

(c) Stavudine

A study in 10 HIV-positive subjects found that **rifabutin** 300 mg daily had no significant effects on the pharmacokinetics of the stavudine 30 or 40 mg twice daily and the incidence of adverse effects did not increase.⁵ No special precautions would seem necessary if both drugs are given.

(d) Zalcitabine

A study in 12 HIV-positive patients found that when zalcitabine 1.5 mg three times daily was given with **isoniazid** 300 mg daily the pharmacokinetics of the zalcitabine remained unchanged but the clearance of the **isoniazid** was approximately doubled.⁶ The UK manufacturer of zalcitabine⁷ recommended caution with the combination because of the possibility of an increased risk of peripheral neuropathy; the US manufacturer recommended that the combination should be avoided where possible.⁸

The UK manufacturer of **rifabutin** suggests that no significant interaction would be expected between **rifabutin** and zalcitabine.⁹

(e) Zidovudine

The pharmacokinetics of **rifabutin** are not affected by the concurrent use of zidovudine in AIDS patients,^{10,11} and **rifabutin** does not affect the pharmacokinetics of zidovudine in HIV-positive patients,¹² although one review found a trend towards increased zidovudine clearance.¹³ No increase in adverse effects appears to occur when **rifabutin** is given with zidovudine.¹¹

In a retrospective study of healthy subjects and HIV-positive individuals, the clearance of zidovudine was increased by 132% by **rifampicin** and by 50% by **rifabutin**, suggesting that the enzyme-inducing effects of **rifabutin** are less than those of **rifampicin**, so less significant interactions would be expected.¹⁴

A comparative study in HIV-positive patients given zidovudine and antitubercular treatment (**isoniazid**, **rifampicin**, **pyrazinamide**, **ethambutol** initially, then **isoniazid** and **rifampicin**) for 8 months found no evidence of an adverse interaction. However, marked anaemia occurred in those subjects given both groups of drugs, but it was not necessary to permanently stop zidovudine in any patient. The authors advise careful monitoring for haematological toxicity.¹⁵ Another study in 4 HIV-positive patients found that **rifampicin** lowered the AUC and increased the clearance of zidovudine in all patients, probably due to the enzyme-inducing activity of the **rifampicin**, which increases the glucuronidation of zidovudine. When the **rifampicin** was stopped in one patient, his zidovudine AUC doubled.¹⁶ A later study of the same interaction in 8 HIV-positive men found that **rifampicin** significantly induced the glucuronidation of

zidovudine and suggested that the effect wore off 14 days after stopping the **rifampicin**. The authors of this study suggest that dosage alterations may not be necessary on concurrent use.¹⁷

NRTIs + Atovaquone

Moderate increases in the AUC of zidovudine, not usually requiring dose adjustments, have been seen with atovaquone. However, it may be prudent to regularly monitor for adverse effects. Atovaquone decreased the AUC of didanosine. Neither didanosine nor zidovudine affected atovaquone pharmacokinetics.

Clinical evidence

(a) Didanosine

The manufacturer of atovaquone notes that it decreased the AUC of didanosine by 24% in a multiple dose interaction study. There was no change in the pharmacokinetics of atovaquone.¹

(b) Zidovudine

A study in 14 HIV-positive patients given atovaquone 750 mg every 12 hours and zidovudine 200 mg every 8 hours found that under steady-state conditions the zidovudine had no effect on the pharmacokinetics of atovaquone.² This confirmed the findings of a previous analysis of pharmacokinetic data from a small number of patients enrolled in clinical studies.³ However, the AUC of the zidovudine was increased by about 30%, and its clearance was reduced by 25% by the concurrent use of atovaquone.²

Mechanism

Atovaquone might inhibit the metabolism (glucuronidation) of zidovudine.²

Importance and management

The manufacturer of atovaquone notes that the decrease in didanosine levels is unlikely to be clinically relevant.¹ They also say that the increased plasma levels of zidovudine likely with a 3-week course of atovaquone for acute *Pneumocystis pneumonia* are unlikely to increase the adverse effects of zidovudine,¹ and routine dose adjustments are not required.⁴ Nevertheless, the manufacturers of atovaquone and zidovudine do recommend reg-

ular monitoring for zidovudine-associated adverse effects when the drugs are used together, particularly if atovaquone suspension is used, as this achieves higher atovaquone levels, which might have a greater effect.^{1,5} The authors of the study with zidovudine² suggest that increases could possibly be important in patients also taking other drugs causing bone marrow toxicity (such as ganciclovir, amphotericin B, flucytosine). If bone marrow toxicity is seen, it is suggested that the zidovudine dosage may need to be reduced by a third.²

NRTIs + Azoles

Fluconazole has no significant effect on the pharmacokinetics of didanosine or stavudine, but it may cause an increase in serum zidovudine levels although the clinical importance of this is uncertain. Fluconazole serum levels remain unchanged.

Itraconazole appears not to affect the pharmacokinetics of zidovudine. Serum levels of itraconazole are markedly reduced when buffered didanosine is given at the same time, but itraconazole and ketoconazole are not affected if buffered didanosine is given 2 hours later. Enteric-coated didanosine has no clinically relevant effect on the pharmacokinetics of fluconazole, itraconazole or ketoconazole. The frequency of haematological toxicity with zidovudine was not increased by ketoconazole.

Clinical evidence

(a) Didanosine

1. *Buffered preparation.* A 35-year-old patient with AIDS was given **itraconazole** capsules 200 mg twice daily following an episode of cryptococcal meningitis. When he relapsed it was noted that he had been taking the **itraconazole** at the same time as his buffered didanosine. Subsequent study in this patient indicated a marked delay in **itraconazole** absorption when it was taken with didanosine. Two hours after the dose, plasma **itraconazole** concentrations of 1.6 micrograms/mL were observed without didanosine, but were undetectable with didanosine. A peak **itraconazole** level of 1.4 micrograms/mL was observed when it was given 8 hours after a dose of didanosine.¹ In 6 healthy subjects when [buffered] didanosine was given with a single 200-mg oral dose of **itraconazole**, the peak levels of **itraconazole** were undetectable; in the absence of didanosine, **itraconazole** levels were 0.9 micrograms/mL.² A later study in 12 HIV-positive patients found that the AUC of **itraconazole** after a single 200-mg dose was not significantly different when buffered didanosine 200 mg was given 4 hours before or 2 hours after **itraconazole**.³ Twelve HIV-positive patients were given buffered didanosine 375 mg twice daily either alone or 2 hours after **ketoconazole** 200 mg daily, for 4 days. Didanosine maximum plasma levels were slightly reduced by 12% and no significant changes in the pharmacokinetics of the **ketoconazole** were seen when dosing was separated in this way.⁴ A group of 12 HIV-positive subjects taking buffered didanosine 100 to 250 mg twice daily were also given **fluconazole** for 7 days (two 200-mg doses on the first day, followed by 200 mg daily). The pharmacokinetics of the didanosine remained unchanged in the presence of the **fluconazole**, and concurrent use was well tolerated. **Fluconazole** pharmacokinetics were not assessed.⁵

2. *Enteric-coated preparation.* Enteric-coated didanosine 400 mg had no significant effect on the pharmacokinetics of **fluconazole** 200 mg in 14 healthy subjects, and no clinically relevant effect on the pharmacokinetics of **itraconazole** 200 mg in 25 healthy subjects.⁶ Similarly, enteric-coated didanosine 400 mg had no clinically relevant effect on the pharmacokinetics of **ketoconazole** 200 mg in 24 healthy subjects. Three of the subjects had increased concentrations of **ketoconazole** with didanosine, but their

values for **ketoconazole** alone appeared unusually low. When their data were excluded, no effect on AUC was seen in the remaining 21 subjects.⁷

(b) Stavudine

A study in 10 HIV-positive subjects taking stavudine 40 mg twice daily, found that the addition of **fluconazole** 200 mg daily for one week had no significant effect on the pharmacokinetics of the stavudine.⁸

(c) Zidovudine

On two occasions, 12 HIV-positive men were given zidovudine 200 mg every 8 hours with and without **fluconazole** 400 mg daily for 7 days. While taking **fluconazole** the AUC of the zidovudine increased by 74%, the maximum serum levels increased by 84%, the terminal half-life was increased by 128% and the clearance was reduced by 43%.⁹ In contrast, another study in 10 HIV-positive patients found only a very small change in the pharmacokinetics of a single 500-mg dose of zidovudine given before and after 7 days treatment with **fluconazole** (e.g. a 7% increase in zidovudine AUC). In another 10 patients, zidovudine had no effect on the pharmacokinetics of a single dose of **fluconazole**.¹⁰

Itraconazole 200 mg daily for 2 weeks was reported to have no effect on the pharmacokinetics of zidovudine in 7 patients, but the serum levels in 2 patients were higher.¹¹

A study of zidovudine use in 282 AIDS patients found that haematological abnormalities (anaemia, leucopenia, neutropenia) were very common, but this was not increased by the concurrent use of **ketoconazole** in some of these patients.¹²

Mechanism

Itraconazole capsules and ketoconazole depend on stomach acidity for absorption. A raised gastric pH, caused by the antacids in the buffered didanosine formulation appears to reduce itraconazole absorption (consider, 'Azoles + Antacids', p.215). The didanosine itself appears to have no part to play in this interaction. The enteric-coated preparation of didanosine does not contain any antacids and therefore does not interact.

In vitro data suggest that the altered zidovudine pharmacokinetics may, in part, occur because fluconazole inhibits zidovudine glucuronidation.¹³

Importance and management

The most significant interaction occurs between the buffered preparation of didanosine and itraconazole. Patients should avoid taking both drugs at the same time, but giving the itraconazole at least 2 hours before the didanosine appears to solve any problem. Any possible interaction with ketoconazole can similarly be avoided by giving ketoconazole at least 2 hours before didanosine. Alternatively, the interaction may be avoided by using the enteric-coated preparation of didanosine.

There is no pharmacokinetic interaction between stavudine and fluconazole. No interaction would be expected with other similar NRTIs such as **lamivudine** and **zalcitabine** (see 'Antivirals', (p.772)).

There is evidence of a minor interaction between zidovudine and fluconazole, but this is unlikely to be clinically significant.

NRTIs + Co-trimoxazole or Trimethoprim

Trimethoprim, both alone and as co-trimoxazole (trimethoprim with sulfamethoxazole) reduces the renal clearance of lamivudine, zalcitabine and zidovudine, and therefore raises their plasma levels. However, the extent of the interaction does not usually appear to be clinically significant in patients with normal renal function. No clinically significant adverse pharmacokinetic interaction occurs if didanosine is given with co-trimoxazole or trimethoprim.

Clinical evidence

(a) Didanosine

A study in 10 HIV-positive subjects investigated the pharmacokinetics of didanosine 200 mg, trimethoprim 200 mg and sulfamethoxazole 1 g in combination. Most pharmacokinetic parameters were unchanged. However, didanosine clearance was reduced by 35%, trimethoprim clearance was decreased by 32% and sulfamethoxazole clearance was increased by 39%, when all 3 drugs were given together. When only 2 of the 3 drugs were given, trimethoprim caused a 27% decrease in the clearance of didanosine, and didanosine caused an 82% increase in the clearance of sulfamethoxazole.¹ Despite these alterations in clearance, the maximum serum concentration, AUC and half-life of each of the three drugs were minimally affected.¹

(b) Lamivudine

In a study of 14 HIV-positive patients taking co-trimoxazole 960 mg daily for 5 days, it was found that the AUC of a single 300-mg dose of lamivudine given on day 4 was increased by 43% and the renal clearance was decreased by 35%. The pharmacokinetics of the trimethoprim and the sulfamethoxazole were unaffected.² Similarly, in a population pharmacokinetic analysis, the concurrent use of lamivudine and co-trimoxazole was associated with a 31% reduction in the apparent oral clearance of lamivudine, and an estimated 43% increase in steady-state lamivudine levels.³ The UK manufacturer notes that the interaction is due to trimethoprim, and that sulfamethoxazole did not interact.⁴

(c) Stavudine

The UK manufacturer notes that an interaction with trimethoprim is possible, since both drugs are actively secreted by the renal tubules.⁵

(d) Zalcitabine

In a steady-state study, 8 HIV-positive patients received zalcitabine 1.5 mg three times daily with and without trimethoprim 200 mg twice daily. The trimethoprim increased the AUC and decreased the clearance of zalcitabine by about 35%.⁶

(e) Zidovudine

A study in 9 HIV-positive patients given zidovudine 3 mg/kg by infusion over 1 hour found that neither trimethoprim 150 mg nor co-trimoxazole 960 mg affected the metabolic clearance of the zidovudine. However, the renal clearances of zidovudine were reduced by 48% and 58%, by trimethoprim and co-trimoxazole respectively, and the renal clearances of its glucuronide metabolite were reduced by 20% and 27%, respectively.⁷ Another study also found that co-trimoxazole did not alter zidovudine pharmacokinetics.⁸ A further 5 HIV-positive patients had a 30% increase in the AUC of zidovudine when they were given trimethoprim [dosages not stated].⁹ Zidovudine renal clearance was reduced by 58% in 8 HIV-positive subjects when they were also given trimethoprim 200 mg, but the AUC₀₋₆ of the zidovudine glucuronide/zidovudine ratio was unchanged, suggesting that the metabolism was unaffected.¹⁰

Increases in the half-lives of trimethoprim, sulfamethoxazole and N-acetyl sulfamethoxazole of 72%, 39%, and 115%, respectively,

were seen when co-trimoxazole was given to 4 patients with AIDS taking zidovudine 250 mg every 8 hours for 8 days.¹¹

A study of zidovudine use in 282 AIDS patients found that haematological abnormalities (anaemia, leucopenia, neutropenia) were common. However, the frequency was not increased in the patients [number unknown] also taking co-trimoxazole.¹²

Mechanism

A likely reason is that the trimethoprim inhibits the secretion of both zidovudine and its glucuronide by the kidney tubules. It is not known why the half-life of co-trimoxazole is increased. The other NRTIs that interact are likely to do so by the same mechanism.

Importance and management

Established interactions. With the NRTIs that are actively excreted via the kidneys (e.g. lamivudine, stavudine, and zalcitabine), it is unlikely that dosage alterations are necessary unless the patient has renal impairment. However, when both drugs are needed, patients should be closely monitored for signs of toxicity. Moreover, the UK manufacturer of lamivudine recommends that the use of lamivudine with high-dose co-trimoxazole for the treatment of *Pneumocystis pneumonia* and toxoplasmosis should be avoided.⁴ Since renal clearance represents only 20 to 30% of the total clearance of zidovudine, the authors of two of these reports^{7,10} suggest that this interaction is unlikely to be clinically important for zidovudine unless the glucuronidation by the liver is impaired by liver disease or other drugs. Didanosine also does not appear to interact to a clinically relevant extent.

Nevertheless concurrent use should be well monitored, especially because co-trimoxazole alone has been associated with a high incidence of adverse effects in patients with AIDS.¹³

NRTIs + Cytokines

Interferon alfa does not alter the pharmacokinetics of didanosine or lamivudine to a clinically relevant extent. Interferon alfa and, particularly, interferon beta can cause an increase in the serum levels of zidovudine. HIV-positive patients infected with hepatitis C and treated with interferon alfa and ribavirin may be at special risk of NRTI-associated lactic acidosis. Interleukin-2 appears not to interact significantly with zidovudine.

Clinical evidence

(a) Interferon

AIDS patients who had been taking **zidovudine** 200 mg every 4 hours for 8 weeks were also given subcutaneous **recombinant beta interferon** 45 million units daily. After 3 and 15 days the **zidovudine** metabolism was reduced by 75% and 97%, respectively. By day 15 the **zidovudine** half-life was increased by about twofold.¹ Another study in 6 children aged 3 months to 17 years found that after 5 weeks of concurrent use **interferon alfa** increased the AUC of **zidovudine** by 36%, increased its maximum serum level by 69% and reduced its clearance by 20%.²

Interferon alfa 1 to 15 million units daily was given to 26 HIV-positive patients taking **didanosine** sachets 100 to 375 mg twice daily. The interferon appeared to have no clinically significant effects on the pharmacokinetics of the **didanosine**.³ Similarly, a single subcutaneous injection of **interferon alfa** 10 million units had no clinically significant effects on the pharmacokinetics of **lamivudine** 100 mg daily, given to 19 healthy subjects for 7 days (the **lamivudine** AUC was decreased by about 10%). **Lamivudine** did not appear to alter the pharmacokinetics of **interferon alfa**.⁴

(b) Interleukin-2

A study found that a 4-week course of interleukin-2 (0.25 million units/m² daily) by continuous infusion had no clinically significant effect on the pharmacokinetics of a 100-mg intravenous dose of **zidovudine**.⁵ Another study in 8 HIV-positive men given oral **zidovudine** 200 mg every 4 hours found similar results.³ No special precautions would seem necessary.

Mechanism

Interferon beta appears to inhibit the metabolism (glucuronidation) of the zidovudine by the liver.

Importance and management

Information seems to be limited to these reports. The results of the first report suggest that the zidovudine dosage may need to be reduced if interferon beta is added in order to avoid increased zidovudine toxicity. A dosage reduction of two-thirds, or even more, may be necessary. More study is needed to confirm these observations. Interferon alfa appears to interact to a lesser extent. The manufacturers warn that the risk of haematological toxicity may be increased if zidovudine and interferon are used together, and combined use in hepatitis C may increase the risk of NRTI-associated lactic acidosis: patients at risk should be carefully monitored.^{6,7} Interferon alfa does not appear to affect the pharmacokinetics of didanosine or lamivudine. Nevertheless, all manufacturers note that, because of the risk of NRTI-associated lactic acidosis, caution should be exercised when giving NRTIs (**abacavir**, didanosine, **emtricitabine**, lamivudine, **stavudine**, zidovudine) to any patient with hepatomegaly, hepatitis or other known risk factors for liver disease and hepatic steatosis, and that HIV-positive patients infected with hepatitis C and treated with interferon alfa and ribavirin may constitute a special risk. Patients at increased risk should be monitored closely.

NRTIs + Dapsone

Buffered didanosine does not alter the pharmacokinetics of dapsone, but there is some circumstantial evidence to suggest that it may reduce the prophylactic effects of dapsone in preventing Pneumocystis pneumonia. Dapsone has no effect on the pharma-

cokinetics of zalcitabine, whereas zalcitabine causes a small rise in the serum levels of dapsone, and there is a theoretical increased risk of peripheral neuropathy with the combination. Dapsone appears not to affect the pharmacokinetics of zidovudine, although concurrent use may be associated with increased blood dyscrasias.

Clinical evidence, mechanism, importance and management

(a) Didanosine

An early report of the use of buffered didanosine described the development of *Pneumocystis pneumonia* in 11 out of 28 HIV-positive patients taking dapsone prophylaxis, compared with only 1 of 12 taking aerosolised pentamidine, and none of 17 taking co-trimoxazole. Of the 11 patients where prophylaxis failed, 4 died from respiratory failure.¹ The authors suggested that the most likely explanation of the high failure rate of dapsone with didanosine, was reduced dapsone absorption due to the citrate-phosphate buffer in the didanosine formulation.¹ This has led to some recommending that the drugs be taken at least 2 hours apart.

However, in a controlled study in 6 HIV-positive subjects, dapsone pharmacokinetics were not altered when a dose of buffered didanosine was taken within 5 minutes.² Similarly, in 6 healthy subjects, dapsone pharmacokinetics were not altered by the aluminium/magnesium antacids and other excipients contained in didanosine tablets.² Another study in healthy subjects also failed to confirm that a marked rise in gastric pH affects the absorption of dapsone, see 'Dapsone + Antacids', p.303. Furthermore, low dapsone levels have been found in patients receiving a weekly dapsone regimen who took dapsone at least 2 hours before or 6 hours after didanosine, and in patients taking zidovudine or no antiretrovirals (although this study did not look at whether dapsone levels were correlated with efficacy).³ In a retrospective analysis, other authors found no evidence to confirm a correlation between failure of *Pneumocystis pneumonia* prophylaxis with dapsone and use of drugs that increase gastric pH (didanosine, H₂-receptor antagonists, antacids).⁴

It has therefore been adequately demonstrated that the buffered preparation of didanosine and antacids do not affect dapsone absorption. The explanation for the apparent failure of *Pneumocystis pneumonia* prophylaxis in the original report¹ is unresolved. Despite the use of both didanosine and dapsone in the management of HIV and opportunistic infections there do not appear to be any further reports of problems with the combination.

(b) Zalcitabine

A pharmacokinetic study in 12 HIV-positive patients who were given zalcitabine 1.5 mg three times daily and dapsone 100 mg daily, alone or together, found that dapsone did not significantly affect the kinetics of the zalcitabine. However, zalcitabine decreased the clearance of dapsone by 21%, increased its maximum serum levels by 19% and increased its half-life by 34%.⁵ These changes are relatively small and seem unlikely to have much clinical relevance, but until this is confirmed it would seem prudent to monitor the concurrent use of these two drugs. The UK manufacturer⁶ recommended caution with the combination because of the possibility of an increased risk of peripheral neuropathy; the US manufacturer advised avoiding the combination where possible.⁷

(c) Zidovudine

Dapsone 100 mg daily had no effect on the pharmacokinetics of a single 200-mg dose of zidovudine in 8 HIV-positive subjects.⁸ In a further study, which considered the safety of dapsone in combination with zidovudine, dapsone was shown to increase the risk of zidovudine-related blood dyscrasias.⁹ Therefore it would seem that dapsone and zidovudine can be given concurrently, but monitoring for an increase in adverse events would seem advisable.

NRTIs + Drugs that cause pancreatitis

Additive pancreatic toxicity has been described with zalcitabine and intravenous pentamidine, and is expected when didanosine or stavudine are given with other drugs that can cause pancreatitis. An isolated case describes pancreatitis with lamivudine and azathioprine.

Clinical evidence

(a) Lamivudine

A single case report describes a 51-year-old woman with a kidney transplant who developed pancreatitis after starting lamivudine. **Azathioprine** had been discontinued only 3 days before and it is possible (although the evidence is weak) that the residual serum **azathioprine** had interacted with lamivudine to cause the pancreatitis.¹

(b) Zalcitabine

Fatal fulminant pancreatitis occurred in a patient given zalcitabine and intravenous **pentamidine**.²

Mechanism

Possible additive toxicity.

Importance and management

Of the NRTIs, **didanosine**, **stavudine** and zalcitabine have been associated with fatal pancreatitis.^{2,7}

The manufacturers of zalcitabine recommended that if a drug that has the potential to cause pancreatitis is required, treatment with zalcitabine should be interrupted.^{2,7} They specifically applied this to the use of pentamidine to treat *Pneumocystis pneumonia*.^{2,7}

The manufacturers of **didanosine** have a similar recommendation and state that, if concurrent use is unavoidable, there should be close observation.^{3,4} Similarly, other authors recommend temporarily discontinuing didanosine in patients needing systemic pentamidine or **sulfonamide**-containing regimens.⁸ The UK manufacturer of **stavudine** recommends that patients receiving concurrent treatment with drugs known to cause pancreatitis should be carefully observed,⁵ and the US manufacturer specifically recommends caution with combined use of **didanosine** and **stavudine**,⁶ see 'NRTIs + NRTIs', p.800. Note that **hydroxycarbamide (hydroxyurea)** may increase the risk of pancreatitis with didanosine and stavudine, and the combination should probably be avoided, see 'NRTIs + Hydroxycarbamide', p.799.

The UK manufacturer states that lamivudine is rarely associated with pancreatitis, but recommend that treatment with lamivudine should be stopped if there is any suspicion of pancreatitis:⁹ no firm conclusions can be drawn from the case discussed above.

NRTIs + Food

Food can reduce the extent of absorption of didanosine, possibly causing a loss in efficacy. The extent of absorption of zalcitabine and zidovudine is reduced slightly by food. Food does not affect the extent of absorption of abacavir, emtricitabine, lamivudine, and stavudine.

Clinical evidence, mechanism, importance and management

(a) Abacavir

The manufacturer of abacavir notes that food delayed its rate, but not extent, of absorption. Therefore, abacavir can be taken with or without food.^{1,2}

(b) Didanosine

1. *Buffered preparations.* Didanosine (as two 150-mg chewable tablets) was given to 10 HIV-positive subjects on four occasions: 30 minutes before breakfast, 1 hour before breakfast, 1 hour after breakfast, and 2 hours after breakfast. When the dose was given before breakfast the results were very similar to those obtained for subjects in the fasting state. When given after a breakfast, the didanosine AUC and maximum plasma concentration were both decreased by about 50%.³ Similar results were found in another study.⁴ A further study⁵ using sachets containing didanosine, sucrose and citrate-phosphate buffer, similarly found that food reduced the bioavailability by 41% (a reduction from 29% to 17%). The reason would appear to be that food delays gastric emptying so that the didanosine is exposed to prolonged contact with gastric acid, which causes decomposition (see 'Antivirals', (p.772)), with a resultant fall in bioavailability.⁶ To achieve maximum bioavailability the didanosine buffered preparations should be taken on an empty stomach at least 30 minutes before food^{6,7} or 2 hours after food.⁷

2. *Enteric-coated preparation.* Giving didanosine gastro-resistant capsules with a high-fat meal or a light meal reduced the AUC by 19% and 27%, respectively, compared with the fasting state. A similar 24% decrease in the AUC was also seen when didanosine was taken 1 hour before a light meal. However, the effect on the AUC was negligible when it was taken 1.5 to 3 hours before a light meal.⁸ Sprinkling the capsule contents on yoghurt or apple sauce also decreased the AUC by 20% or 18%, respectively.⁸ Despite these modest changes in AUC, the manufacturer recommends that didanosine gastro-resistant capsules are taken intact on an empty stomach,^{8,9} at least 2 hours before or 2 hours after a meal.⁸

(c) Emtricitabine

The manufacturer says that giving emtricitabine hard capsules with a high-fat meal did not affect the AUC of emtricitabine but slightly reduced the maximum level by 29%. Similarly, giving emtricitabine oral solution with a low-fat or high-fat meal did not affect the AUC or maximum level of emtricitabine. Therefore, both these formulations of emtricitabine may be given with or without food.^{10,11}

(d) Lamivudine

The manufacturer notes that food delayed the rate and reduced the maximum plasma concentration (by about 45%), but not the extent (AUC), of lamivudine absorption. Therefore, lamivudine can be taken with or without food.^{12,13}

(e) Stavudine

The UK manufacturer of stavudine notes that a standardised high-fat meal reduced, and delayed the time to reach the maximum plasma concentration (specific details not given), but did not alter the extent of systemic exposure of stavudine, when compared with the fasting state. Nevertheless, they recommend that, for optimal absorption, stavudine should be taken on an empty stomach at least 1 hour before meals. However, if this is not possible, they suggest giving stavudine with a light meal; in addition the contents of the capsule may be mixed with food.¹⁴ The US manufacturer states that stavudine can be taken with food or on an empty stomach.¹⁵

(f) Zalcitabine

The manufacturers of zalcitabine^{16,17} noted that food decreased the maximum plasma concentration by 39% and prolonged the time to achieve maximum concentrations from 0.8 to 1.6 hours compared with the fasting state. The extent of absorption was decreased by 14%. The UK manufacturer stated that zalcitabine could be taken with or without food.¹⁶

(g) Zidovudine

Zidovudine was given to 13 AIDS patients either with breakfast or when fasting. The maximum plasma level of zidovudine was 2.8-fold greater in the fasted patients, and the AUC was reduced by 22% when zidovudine was given with food.¹⁸ Zidovudine rate and extent of absorption was reduced in another study by a standard breakfast (14% decrease in AUC with a 200-mg dose and 33% with a 100-mg dose).¹⁹ In a study²⁰ of 8 patients, a high-fat meal reduced the maximum zidovudine serum levels by about 50%. In all these cases inter-individual variation in zidovudine absorption was high.¹⁸⁻²⁰ However, when a sustained-release formulation of zidovudine was used, the absorption was delayed, but the AUC was increased by 28% by a high-fat meal.²¹ In contrast zidovudine AUC was not affected by 25 g of a **protein supplement**.²²

Inter-individual variation appears high and the practical consequences of the changes caused are uncertain. Some have suggested that zidovudine should be taken on an empty stomach;^{19,20} the US manufacturer states that zidovudine can be taken with or without food,²³ but the UK manufacturer gives no specific recommendations regarding its administration in relation to food.²⁴

NRTIs + Ganciclovir

The concurrent use of zidovudine and ganciclovir produces a very marked increase in haematological toxicity, without any apparent increase in efficacy. Didanosine serum levels are raised by ganciclovir, but there is some evidence suggesting that the efficacy of ganciclovir prophylaxis is reduced. Ganciclovir does not appear to interact with stavudine, and there is no clinically important pharmacokinetic interaction between ganciclovir and zalcitabine. Until further information is available, the manufacturers of lamivudine advise the avoidance of intravenous ganciclovir.

Clinical evidence

(a) Didanosine

Buffered didanosine 200 mg twice daily was given to 12 HIV-positive patients with oral ganciclovir 1 g three times daily. When the didanosine was given 2 hours before ganciclovir, the maximum serum levels and AUC of didanosine were raised by about 47% and 83%, respectively, and those of ganciclovir were decreased by about 26% and 22%, respectively. When the didanosine was given simultaneously with ganciclovir, the maximum serum levels and AUC of didanosine were similarly raised, by about 53% and 77%, respectively, but those of ganciclovir were unchanged. The renal clearance of didanosine was not significantly changed by ganciclovir.¹ Similar increases in didanosine levels with ganciclovir given intravenously² and high-dose oral ganciclovir 2 g every 8 hours have also been reported.³ However, in contrast, an earlier study found that the pharmacokinetics of didanosine (sachet preparation) were not altered by intravenous ganciclovir.⁴

Rates of dose-limiting intolerance to the combination of didanosine and ganciclovir were reported to be similar to those seen with didanosine alone in one small study (15 of 32 patients tolerated usual doses of didanosine with the ganciclovir).⁵ Analysis of the results of a large randomised study unexpectedly suggested that there was an increased risk of cytomegalovirus infection in those patients taking ganciclovir and didanosine, when compared with those not taking didanosine.⁶

(b) Lamivudine

The UK manufacturer of lamivudine says that concurrent use with intravenous ganciclovir is not recommended until further information becomes available,⁷ although they give no reason for this advice. They do not mention oral ganciclovir.⁷

(c) Stavudine

In a study of 11 HIV-positive patients, oral ganciclovir 1 g three times daily had no significant effect on the pharmacokinetics of stavudine 40 mg twice daily, nor were the pharmacokinetics of ganciclovir affected by the stavudine.⁸ There were no serious or severe adverse events attributed to the combination.

(d) Zalcitabine

In a study in 10 HIV-positive patients, zalcitabine 750 micrograms every 8 hours increased the AUC of oral ganciclovir 1 g three times daily by 22%. There was no change in zalcitabine pharmacokinetics. There were no serious or severe adverse events attributed to the combination.⁸

(e) Zidovudine

The efficacy of zidovudine 100 or 200 mg every 4 hours, given alone or with intravenous ganciclovir 5 mg/kg twice daily for 14 days, then once daily for 5 days of each week, was assessed in 40 patients for the treatment of cytomegalovirus (CMV). Severe haematological toxicity occurred in all of the first 10 patients given zidovudine 1.2 g daily and ganciclovir. Consequently the dose of zidovudine was reduced to 600 mg daily. Overall 82% of the 40 patients enrolled experienced profound and rapid toxicity (anaemia, neutropenia, leucopenia, gastrointestinal disturbances). Zidovudine dosage reductions to 300 mg daily were needed in many patients. No change in the pharmacokinetics of zidovudine or ganciclovir was noted.⁹

Another study in 6 AIDS patients with CMV retinitis given zidovudine and ganciclovir found increased bone marrow toxicity but no improved efficacy over ganciclovir alone.¹⁰ Increased toxicity (myelotoxicity and pancytopenia) following the use of both drugs has also been reported elsewhere.^{11,12}

In contrast to the first study,⁹ a specific study on the pharmacokinetics of zidovudine and ganciclovir in HIV-positive subjects reported that oral ganciclovir increased the maximum levels and AUC of zidovudine by 38% and 15%, respectively, without altering renal clearance. Zidovudine did not alter ganciclovir pharmacokinetics.¹

Mechanism

It is not known why ganciclovir increases the levels of didanosine and zidovudine: it does not appear to be due to competition for active secretion by the kidney tubules.¹

The toxicity of the zidovudine/ganciclovir combination may be simply additive,⁹ but *in vitro* studies with three human cell lines found synergistic cytotoxicity when both drugs were used.¹³

There is some *in vitro* evidence to suggest that ganciclovir antagonises the anti-HIV activity of zidovudine and didanosine.¹⁴

Importance and management

The interactions between ganciclovir and didanosine or zidovudine would appear to be established, but the clinical importance is uncertain. Zidovudine seems to be associated with greater toxicity than didanosine. However, there is also some evidence suggesting reduced ganciclovir efficacy in the presence of didanosine, and this requires further study. Close and careful monitoring is required if either combination is used.

Ganciclovir does not appear to alter the pharmacokinetics of stavudine or zalcitabine. Zalcitabine increased ganciclovir levels to a minor extent, although this is probably not clinically important.

NRTIs + H₂-receptor antagonists

The concurrent use of buffered didanosine and ranitidine results in a minor increase in the serum levels of didanosine, and a minor decrease in the serum levels of ranitidine. Both changes seem to be clinically unimportant. Cimetidine raises serum zalcitabine levels, but this is of uncertain importance. Cimetidine and ranitidine do not have a clinically significant effect on zidovudine or lamivudine serum levels.

Clinical evidence, mechanism, importance and management

(a) Didanosine

Didanosine 375 mg (buffered sachet preparation) was given to 12 HIV-positive subjects either alone, or 2 hours after a single 150-mg dose of ranitidine. The didanosine AUC was increased by 14% by the ranitidine.¹ The reason for this effect is not known but the ranitidine possibly enhanced the effects of the citrate-phosphate buffer with which the didanosine sachet was formulated. The ranitidine AUC was reduced by 16% for reasons that are not understood, but it is possible that antacids (such as the citrate-phosphate buffer) reduce the absorption of ranitidine¹ (see 'H₂-receptor antagonists + Antacids', p.966).

These bioavailability changes appear to be too small to matter clinically, and no particular precautions would seem necessary if the drugs are taken in this way. It is not known whether other H₂-receptor antagonists behave similarly.

(b) Lamivudine

Lamivudine is cleared predominantly from the body by the kidneys using the organic cationic transport system; however, cimetidine and ranitidine, which partly use this mechanism, do not interact with lamivudine.²

(c) Zalcitabine

A study in 12 HIV-positive patients given a single 1.5-mg dose of zalcitabine found that cimetidine 800 mg caused a 24% reduction in the renal clearance of zalcitabine (assumed to be due to a reduction in renal tubular secretion) and a 36% increase in the AUC of zalcitabine.³ These changes are relatively moderate and of uncertain clinical importance. Monitor concurrent use for possible toxicity.

(d) Zidovudine

In a randomised crossover study zidovudine 600 mg daily was given to 5 HIV-positive men and one man with AIDS. The zidovudine was given either alone, with cimetidine 300 mg four times daily, or with ranitidine 150 mg twice daily, each for 7 days. Cimetidine reduced the renal elimination of the zidovudine by 56%, but had no effect on its AUC. It was suggested that the reduction in clearance was due to inhibition of tubular secretion. Ranitidine had no effect on zidovudine pharmacokinetics. No clinical toxicity occurred and the immunological parameters measured (CD4 and CD8) were not significantly altered. The authors concluded that no change in the dosage of zidovudine is needed if either of these H₂-receptor antagonists is given concurrently.⁴ Information about other H₂-receptor antagonists seems to be lacking.

NRTIs + Hydroxycarbamide

Hydroxycarbamide appears to increase the antiviral activity of NRTIs, particularly didanosine. However, the combination of hydroxycarbamide and didanosine may carry a higher risk of adverse effects including neuropathy and pancreatitis, especially if stavudine is also given.

Clinical evidence, mechanism, importance and management

Data from *in vitro* studies have shown that hydroxycarbamide increases the antiviral activity of NRTIs, particularly didanosine, possibly by increasing their intracellular activation (phosphorylation).^{1,2} The combination is therefore under clinical investigation. Some randomised studies^{3,4} have shown that the addition of hydroxycarbamide to reverse transcriptase inhibitors improves virologic response, whereas others have not demonstrated this.⁵

Of concern is that a number of studies have shown increased toxicity. One study reported that the relative risk of neuropathy when didanosine was given with hydroxycarbamide was 2.35, compared with didanosine alone, and increased to 7.8 when stavudine was also added.⁶ Another study reported an increased incidence of neuropathy, and an increased incidence of fatigue and nausea and vomiting.⁷ The risk of pancreatitis may also be increased. In one study, 3 patients randomised to indinavir, didanosine, stavudine and hydroxycarbamide developed pancreatitis and died, compared with no deaths in those receiving the same antivirals without hydroxycarbamide.⁸ Another case of pancreatitis (non-fatal) has been reported when hydroxycarbamide was given with stavudine, didanosine and nevirapine.⁹ Hepatotoxicity and hepatic failure resulting in death have also been reported in patients given hydroxycarbamide, didanosine and stavudine.^{10,11} In response to these data, the manufacturers of didanosine and stavudine specifically state that use of these two NRTIs with hydroxycarbamide should be avoided.^{10–13} Moreover, the UK manufacturers go as far as to say that hydroxycarbamide should not be used in the treatment of HIV infection.^{12,13}

Further studies are needed to define the role of hydroxycarbamide in combination with NRTIs in HIV infection.¹⁴

NRTIs + Macrolides

Clarithromycin causes some reduction in the bioavailability of zidovudine, but this is minimised if the two drugs are given at least 2 hours apart. Clarithromycin does not appear to interact with didanosine, stavudine or zalcitabine, and azithromycin does not interact with didanosine or zidovudine.

Clinical evidence

(a) Didanosine

When **azithromycin** 1.2 g daily for 14 days was given to 12 HIV-positive subjects with didanosine 200 mg twice daily there was no significant change in the pharmacokinetics of either drug.¹

Clarithromycin 1 g twice daily for 7 days was given to 4 HIV-positive patients and 8 AIDS patients already taking oral didanosine. For the group as a whole the pharmacokinetics of the didanosine remained unchanged, but there were large differences in the AUC between subjects that could have hidden an interaction.²

(b) Stavudine

A study in 10 HIV-positive subjects found that the addition of **clarithromycin** 500 mg twice daily to stavudine 30 or 40 mg twice daily had no significant effects on the pharmacokinetics of the stavudine and the incidence of adverse effects did not increase.³ No special precautions would seem necessary if both drugs are given.

(c) Zalcitabine

A 7-day course of **clarithromycin** 500 mg twice daily was given to 12 HIV-positive subjects already taking zalcitabine. The addition of **clarithromycin** caused no change to the pharmacokinetics of zalcitabine.⁴

(d) Zidovudine

Azithromycin 600 mg to 1.2 g daily for 14 days did not affect the pharmacokinetics of zidovudine 100 mg five times daily in 12 HIV-positive subjects.¹ Similarly, **azithromycin** 1 g given weekly to 9 HIV-positive subjects caused no change in the pharmacokinetics of zidovudine 10 mg/kg daily. The **azithromycin** pharmacokinetics also remained unchanged.⁵

Fifteen HIV-positive patients were given zidovudine 100 mg every 4 hours 5 times a day and oral **clarithromycin** 500 mg, 1 g or 2 g every 12 hours, both together and alone. The pharmacokinetics of the **clarithromycin** were not substantially changed but the zidovudine levels and AUCs were reduced by 23 to 58% and 12 to 36%, respectively. However, these effects were not seen in all patients.^{6,7} Another study similarly found that **clarithromycin** caused a moderate reduction in the AUC of oral zidovudine (by up to 27%). No changes were seen when the zidovudine was given

en 4 or more hours after the **clarithromycin**.⁸ Zidovudine and **clarithromycin** were given to 16 AIDS patients 2 hours apart for 4 days. The maximum plasma levels of the zidovudine rose by about 50%, but the minimum levels and the AUC over 8 hours did not change.⁹

Mechanism

Not understood but the interaction between clarithromycin and zidovudine may possibly be due to some changes in absorption.

Importance and management

The overall picture is slightly confusing, but it seems that some reductions in zidovudine levels are likely if clarithromycin is taken at the same time, but no important changes seem to occur if the administration of the drugs is separated. The authors of one study recommend that the clarithromycin is given at least 2 hours before or after the zidovudine.⁷ The UK manufacturer of zidovudine includes this recommendation,¹⁰ but the US manufacturer does not include any information on use with clarithromycin.¹¹

The authors of the report on didanosine conclude that clarithromycin may safely be given with didanosine,² and it also seems likely that didanosine or zidovudine and azithromycin; stavudine and clarithromycin; and zalcitabine and clarithromycin can be used safely together.

NRTIs + NRTIs

Some combinations of NRTIs are potentially antagonistic (stavudine with zidovudine, lamivudine with zalcitabine) and some are expected to result in additive toxicity (didanosine with stavudine or zalcitabine, and possibly stavudine with zalcitabine). Some do not appear to result in additional benefits (emtricitabine with lamivudine), and some are considered inferior to other combinations (stavudine with lamivudine, zidovudine with zalcitabine or didanosine). None of these combinations are recommended. Combinations that are specifically recommended (with other antiretrovirals) include lamivudine with abacavir, didanosine or zidovudine, or didanosine with emtricitabine. Sole use of all triple NRTI regimens should generally be avoided, with the possible exception of abacavir or 'tenofovir', (p.806) with zidovudine and lamivudine.

Clinical evidence, mechanism, importance and management

A. Abacavir

(a) Lamivudine

A single 150-mg dose of lamivudine was given with abacavir 600 mg to 13 HIV-positive subjects. The pharmacokinetics of abacavir were not significantly affected, but the lamivudine maximum plasma levels and AUC were decreased by 35% and 15%, respectively. These changes were considered to be consistent with a change in absorption. The extent of the

change is not thought to be clinically significant and so no dose alteration would seem necessary on concurrent use.¹ In UK and US guidelines, the combination of abacavir plus lamivudine is currently a recommended dual NRTI option for use with an NNRTI or a protease inhibitor for the treatment of HIV-infection in treatment naïve patients.^{2,3} The triple NRTI combination of abacavir, lamivudine and zidovudine may also be considered if protease inhibitors or NNRTIs cannot be used.³

(b) Zidovudine

A single 300-mg dose of zidovudine was given with abacavir 600 mg to 13 HIV-positive subjects. The pharmacokinetics of abacavir were not significantly affected. The zidovudine maximum plasma level decreased by 20%, but the AUC was unchanged. This change is not thought to be clinically significant and so no dose alteration would seem necessary on concurrent use.¹ These results were confirmed in a steady-state study in which 79 HIV-positive subjects received 8 weeks of treatment with abacavir 600 mg to 1.8 g daily, in divided doses, and zidovudine 600 mg daily, in divided doses.⁴ The triple NRTI combination of abacavir, lamivudine and zidovudine may also be considered if protease inhibitors or NNRTIs cannot be used.³

B. Didanosine

(a) Emtricitabine

In UK and US guidelines, the combination of didanosine with emtricitabine is currently a recommended alternative dual NRTI option for use with an NNRTI or a protease inhibitor, for the treatment of HIV-infection in treatment naïve patients.^{2,3}

(b) Lamivudine

Lamivudine is cleared predominantly from the body by the kidneys using the organic cationic transport system. Didanosine is not cleared by this mechanism and so is unlikely to interact with lamivudine by this mechanism.⁵ Didanosine does not affect the intracellular activation of lamivudine *in vitro*.⁶ In UK and US guidelines, the combination of didanosine with lamivudine is currently a recommended alternative dual NRTI option for use with an NNRTI or a protease inhibitor, for the treatment of HIV-infection in treatment naïve patients.^{2,3}

(c) Stavudine

Didanosine does not interfere with the intracellular activation of stavudine *in vitro*.⁷ Didanosine 100 mg twice daily was given to 10 HIV-positive subjects with stavudine 40 mg twice daily for 9 doses. The didanosine pharmacokinetics were unchanged by concurrent use. The half-life of the stavudine increased from 1.56 to 1.96 hours, but the AUC was unchanged and adverse effects were minimal. The authors of the report concluded that no clinically significant pharmacokinetic interaction, and no change in acute safety and tolerance, are likely if both drugs are given concurrently.⁸

However, both didanosine and stavudine can cause peripheral neuropathy and pancreatitis, and there is some evidence that this risk may be additive. In one early study, combination treatment with stavudine and didanosine was given to 13 HIV-positive subjects for 8 weeks. Neuropathy occurred in 3 patients, with only 2 restarting treatment.⁹ In another study, the relative risk of neuropathy was 1.39 for stavudine alone relative to didanosine alone, and 3.5 for combined use of both drugs.¹⁰ In 1999, the manufacturer of didanosine issued a stronger warning about the risk of pancreatitis with didanosine, and noted this risk was higher in patients also taking stavudine,¹¹ see also 'NRTIs + Hydroxycarbamide', p.799. Combined use should be carefully monitored. See also 'NRTIs + Drugs that cause pancreatitis', p.797.

A case of symptomatic hyperlactataemia occurred in a patient after changing his antiretroviral therapy to didanosine, stavudine and nevirapine.¹² The combination of stavudine and didanosine has been associated with a high incidence of toxicity, particularly peripheral neuropathy, pancreatitis, and lactic acidosis. The development of lactic acidosis has resulted in fatalities in pregnant women.³ It has been suggested that this combination of NRTIs is associated with the greatest toxicity.¹² US guidelines say that the combination of didanosine and stavudine should not be recommended at any time, with the exception of when no other antiretroviral options are available, and only if the potential benefits outweigh the risks.³ UK guidelines say that stavudine is not recommended for use as one of the NRTIs for initial therapy of HIV because of its toxicity.²

(d) Zalcitabine

In vitro, didanosine had no significant effect on the intracellular activation of zalcitabine.¹³ A 29-year-old man with persistent mild neuropathy due to zalcitabine developed severe neuropathy when given didanosine

3 weeks after discontinuing zalcitabine. As the didanosine neuropathy developed so rapidly it was suggested that it was caused by additive toxicity with zalcitabine.¹⁴ Note also that both drugs are associated with pancreatitis. The manufacturers advise caution and careful monitoring if drugs that share these serious adverse effects are used concurrently. See also 'NRTIs + Drugs that cause pancreatitis', p.797. US guidelines say that the combination of didanosine and zalcitabine should not be recommended at any time because of additive peripheral neuropathy.³

(e) Zidovudine

A study in 8 HIV-positive patients found that when they were given zidovudine 250 mg with didanosine 250 mg (buffered sachet formulation), the pharmacokinetics of the didanosine were unaltered but the zidovudine AUC was raised by 35%, possibly due to altered absorption.¹⁵ Conversely, in another study zidovudine plasma levels were lower in 4 out of 5 HIV-positive patients when given didanosine (chewable tablets) and there was an average 14% reduction in the zidovudine AUC. The zidovudine clearance was increased by 29% but the didanosine pharmacokinetics were unchanged.¹⁶ A study in over 50 young subjects ranging in age from 3 months to 21 years found that when compared with day 3 (start of concurrent use), no significant changes in AUCs occurred after 4 or 12 weeks of them taking zidovudine 60 to 180 mg/m² every 6 hours with didanosine 60 to 180 mg/m² every 12 hours (given 2 minutes after an antacid).¹⁷ Several other studies have not found a pharmacokinetic interaction or evidence of increased toxicity when didanosine and zidovudine are used concurrently.¹⁸⁻²¹

The reports are slightly contradictory, but the weight of evidence seems to be that no clinically relevant interaction occurs. UK guidelines say there are no data on the use of zidovudine with enteric-coated didanosine as part of HAART, and that the combination cannot be recommended.²

C. Emtricitabine

(a) Lamivudine

US guidelines state that the combination of emtricitabine and lamivudine should not be offered at any time because of the similar resistance profile of the two drugs and there being no potential benefit.³

(b) Stavudine

There was no important pharmacokinetic interaction between single doses of emtricitabine 200 mg and stavudine 40 mg in 6 healthy subjects.²² UK guidelines say that stavudine is not recommended for use as one of the NRTIs for initial therapy of HIV because of its toxicity.²

(c) Zidovudine

In a single-dose study in 6 healthy subjects the AUC and maximum level of zidovudine 300 mg were increased by 26% and 66%, respectively, by emtricitabine 200 mg. The pharmacokinetics of emtricitabine were not altered.²² The authors suggest that these increases in zidovudine levels are unlikely to be clinically relevant based on experience of using the two drugs together for 48 weeks in a phase III clinical study.²² Further experience is needed.

D. Lamivudine

(a) Stavudine

Nucleoside reverse transcriptase inhibitors such as lamivudine need to be activated by phosphorylation within cells to a triphosphate anabolite. Since stavudine does not affect this phosphorylation *in vitro*⁶ it is predicted that no interaction is likely to occur by this mechanism. The manufacturer briefly states that no clinically relevant pharmacokinetic interaction was noted between stavudine 40 mg and lamivudine 150 mg in a single-dose study.^{23,24} Nevertheless, current US guidelines state that the combination of stavudine and lamivudine is not a preferred or alternative dual NRTI combination for use in initial antiretroviral regimens because of significant toxicities including lipoatrophy, peripheral neuropathy and serious, life-threatening lactic acidosis with hepatic steatosis, with or without pancreatitis, and rapidly progressive neuromuscular weakness.³ Similarly, UK guidelines say that stavudine is not recommended for use as one of the NRTIs for initial therapy of HIV because of its toxicity.²

(b) Zalcitabine

Lamivudine is cleared predominantly from the body by the kidneys using the organic cationic transport system. Zalcitabine is not cleared in this way and so is unlikely to interact with lamivudine by this mechanism.⁵ However, the manufacturers^{5,13,25,26} and US guidelines³ say that lamivudine is not recommended to be used with zalcitabine, since lamivudine may inhibit the intracellular activation of zalcitabine.

(c) Zidovudine

Lamivudine 300 mg twice daily was given to 12 HIV-positive patients for 5 doses, with a 200-mg dose of zidovudine with the last dose. No major changes in the pharmacokinetics of the zidovudine occurred and it was concluded that dosage adjustments are not needed if these two drugs are given concurrently.²⁷ Another study found the same results,¹ and an extensive study in over 200 patients has shown that combined use can be safe and effective.²⁸

However there are case reports of blood dyscrasias occurring with concurrent use. Zidovudine 500 to 600 mg daily was given with lamivudine 300 mg daily to 8 HIV-positive men. Zidovudine or lamivudine alone had previously been given to 6 of these 8 without problem. However, when the drugs were combined, blood dyscrasias occurred in all patients within 7 weeks. Anaemia, with a 50% fall in haemoglobin, occurred in 7 patients, while the other patient developed leucopenia and thrombocytopenia. The drug combination was stopped, blood transfusions were given, and all patients improved or recovered over 5 weeks. Zidovudine or lamivudine alone was later started in 5 patients without further haematological problems.²⁹ Similar precipitous falls in haemoglobin occurred in another 2 patients when lamivudine 300 mg daily was added to their long-term zidovudine treatment. Again both recovered when the drugs were stopped and blood was given.³⁰ Anaemia is a common adverse effect of zidovudine, but these patients had no problems until the lamivudine was added. The available evidence indicates that concurrent use can be safe and effective, with the adverse interactions cited here being uncommon. It has been suggested that a complete baseline blood count should be done, both when combined treatment is started, and every month for the first 3 months of treatment.³⁰ In UK and US guidelines, the combination of zidovudine with lamivudine is currently a preferred dual NRTI option for use with an NNRTI or a protease inhibitor for the treatment of HIV-infection in treatment naïve patients.^{2,3} The triple NRTI combination of abacavir, lamivudine and zidovudine may also be considered if protease inhibitors or NNRTIs cannot be used.³

E. Stavudine

(a) Zalcitabine

In vitro, stavudine had no significant effect on the intracellular activation of zalcitabine.¹³ Both stavudine and zalcitabine have the potential to cause peripheral neuropathy and pancreatitis. Combined use of drugs causing these serious adverse effects should be closely monitored (see also 'NRTIs + Drugs that cause pancreatitis', p.797). US guidelines say that the combination of stavudine and zalcitabine should not be recommended at any time because of additive peripheral neuropathy.³

(b) Zidovudine

Nucleoside reverse transcriptase inhibitors such as stavudine need to be phosphorylated within cells to a triphosphate anabolite before they become effective. *In vitro* studies using mononucleated blood cells found that zidovudine significantly inhibited this phosphorylation.⁷ Antagonism between zidovudine and stavudine has also been seen in a clinical study.³¹ The manufacturers^{23,24} and US guidelines³ currently do not recommend the combination.

F. Zalcitabine

In vitro, zalcitabine had no significant effect on the intracellular activation of zidovudine.¹³ In a study in 56 patients with advanced HIV infection, taking zidovudine 50 to 200 mg every 8 hours and zalcitabine 5 to 10 micrograms/kg every 8 hours, neither drug affected the pharmacokinetics of the other nor was toxicity increased.³² No special precautions would appear to be necessary. Nevertheless, current US guidelines state that the combination of zalcitabine and zidovudine is not recommended as a dual NRTI combination for use in initial antiretroviral regimens because of inferior virological activity and a higher rate of adverse effects than other dual NRTI alternatives.³

NRTIs + Paracetamol (Acetaminophen)

Limited and unconfirmed evidence suggests that paracetamol possibly increases the bone marrow suppressant effects of zidovudine. Single case reports describe severe liver toxicity when patients were given paracetamol with either zidovudine or didanosine.

Clinical evidence

(a) Didanosine

Increasing abdominal pain occurred in a 47-year-old HIV-positive man one month after he started didanosine (his other medications included nevirapine, hydroxycarbamide, aciclovir and lorazepam). He had been treating the pain with paracetamol, and had taken 4 g over 3 days. Severe

hepatitis and pancreatitis was diagnosed, which slowly resolved over the following 3 weeks.¹

(b) Zidovudine

An early study of zidovudine use in 282 AIDS patients found that haematological abnormalities (anaemia, leucopenia, neutropenia) were very common and 21% needed multiple red cell transfusions. Some of the patients also received paracetamol, which increased the haematological toxicity (neutropenia) by an unstated amount.²

Short-term clinical studies using paracetamol 650 mg up to every 4 hours found that it had no clinically significant effects on the pharmacokinetics of zidovudine,³⁻⁶ although in one case clearance was slightly increased.⁷ An 8-month study in a single patient suggested that long-term concurrent use did not affect the pharmacokinetics of either drug. However, in this individual very rapid absorption and a high peak serum level of zidovudine were seen, so for safety the zidovudine dosage was reduced from 200 mg every 4 hours to 100 mg every 6 hours.⁸

A patient taking zidovudine and co-trimoxazole took 3.3 g of paracetamol over 36 hours. Within 2 days he developed severe hepatotoxicity, and as other causes were excluded, the reaction was attributed to the paracetamol. The authors suggested that zidovudine may have augmented the paracetamol toxicity.⁹ However, in a single-dose study, reduced paracetamol glucuronidation and increased formation of hepatotoxic metabolites was seen in patients with advanced HIV infection compared with healthy HIV-positive subjects and those without HIV, and this effect was independent of zidovudine use.¹⁰ In contrast, in another study, disease state (AIDS versus healthy HIV-positive subjects) was not found to alter paracetamol metabolism, and zidovudine was found to increase paracetamol glucuronidation in some patients.¹¹

Mechanism

Not understood. Paracetamol does not increase the serum levels of zidovudine,^{3-5,7} which might have provided an explanation for the apparent increased toxicity. One *in vitro* study found that paracetamol does not affect the glucuronidation of zidovudine,¹² whereas another found that paracetamol did inhibit zidovudine metabolism to the glucuronide.¹³ The effect of zidovudine on paracetamol metabolism is also unclear.

Didanosine may cause pancreatitis or hepatic disease, and zidovudine may also rarely cause hepatic disease. It has been suggested that the hepatotoxicity of didanosine and paracetamol are augmented when they are given together.¹

Importance and management

The authors suggest extreme caution when potentially hepatotoxic drugs such as paracetamol are used with didanosine.¹ Note that paracetamol is a widely used non-prescription analgesic, and this appears to be an isolated report of potential combined toxicity with didanosine. Further study is needed to assess any association of combined use of these drugs with hepatotoxicity.

The short-term use of zidovudine and paracetamol does not appear to alter the pharmacokinetics of either drug. Whether paracetamol can increase the haematological toxicity of zidovudine and whether the drugs have combined hepatotoxicity is unclear from the available data. More study is needed.

NRTIs + Probenecid

Probenecid reduces the loss of zalcitabine and zidovudine, increasing their serum levels. The combination of zalcitabine and probenecid is well tolerated, but the incidence of adverse effects appears to be greatly increased with the combination of probenecid and zidovudine.

Clinical evidence

(a) Zalcitabine

In a single-dose study, 12 HIV-positive or AIDS patients were given zalcitabine 1.5 mg alone or with probenecid 500 mg, given 8 and 2 hours before then 4 hours after. The renal clearance of the zalcitabine was decreased 42% by probenecid, its half-life was increased by 47% and its AUC was increased by 54%.¹

(b) Zidovudine

In 12 patients with AIDS or AIDS-related complex the concurrent use of zidovudine and probenecid 500 mg every 8 hours for 3 days increased the AUC of zidovudine by an average of 80% (range 14 to 192%).²

Other studies in patients³⁻⁵ and healthy subjects⁶ found that probenecid roughly doubled the AUC of zidovudine when given in a variety of dosing schedules.^{3,4} However, the effects on zidovudine pharmacokinetics were minimal if the two drugs were given 6 hours apart.⁵ Another report describes a very high incidence of rashes in 6 out of 8 HIV-positive men given zidovudine with probenecid 500 mg every 6 hours. The rash and other symptoms (such as malaise, fever and myalgia) were sufficiently severe for the probenecid to be withdrawn in 4 of them.⁷ A later study found that when using only 250 mg of probenecid every 8 hours the AUC of zidovudine was increased by 70% but the adverse effects still occurred, although the incidence was possibly somewhat lower.⁸ Conversely, others reported the successful use of probenecid 500 mg three times daily with a reduced dose of zidovudine (600 mg daily) in 7 patients without any occurrence of rash.⁹

Mechanism

Experimental clinical evidence indicates that probenecid reduces metabolism (glucuronidation) of zidovudine by the liver enzymes, and inhibits renal secretion of the zidovudine glucuronide metabolite.^{2-4,6,10,11} The interaction with zalcitabine is presumably due to inhibition of zalcitabine secretion in the renal tubules.¹

Importance and management

The concurrent use of zidovudine and probenecid should be well monitored to ensure that zidovudine levels do not rise excessively. Reduce the zidovudine dosage as necessary. However, the apparent increase in adverse effects during concurrent use seen by one group of researchers^{7,8} should be borne in mind.

The concurrent use of zalcitabine and probenecid was well tolerated, and because the zalcitabine half-life is short compared to its dosing schedule significant accumulation would not be expected.

It would seem prudent to monitor for any signs of toxicity if either drug combination is used long-term. The safety of combined use needs further assessment.

NRTIs + Protease inhibitors

Buffered didanosine decreases the AUC of indinavir, and the drugs should be given one hour apart. Buffered didanosine interacts similarly with atazanavir. Tipranavir with low-dose ritonavir modestly reduced the AUC of abacavir and zidovudine, and such combinations are not recommended in the UK. The changes in pharmacokinetics seen when giving other combinations of protease inhibitors with NRTIs do not appear to be clinically significant. Protease inhibitors do not affect the intracellular activation of NRTIs.

Clinical evidence, mechanism, importance and management

The protease inhibitors **indinavir**, **ritonavir**, and **saquinavir** had no effect on intracellular activation of various NRTIs (**didanosine**, **lamivudine**, **stavudine**, **zalcitabine** and **zidovudine**).¹ No interaction would be expected by this mechanism. Other potential interactions are discussed below.

(a) Abacavir

1. *Amprenavir*. A phase I study in HIV-positive patients given amprenavir 900 mg twice daily with abacavir 300 mg twice daily for 3 weeks found that neither drug had any clinically significant effect on the pharmacokinetics of the other.² The manufacturer of amprenavir notes that its AUC, and minimum and maximum levels were increased by 29%, 27%, and 47%, respectively, by abacavir,^{3,4} without any change in abacavir pharmacokinetics, but no dosage adjustments are considered necessary.³

2. *Lopinavir/Ritonavir*. The manufacturer of lopinavir/ritonavir notes that it induces glucuronidation and therefore has the potential to reduce abacavir plasma levels. However this, and its clinical relevance, have yet to be studied.^{5,6}

3. *Tipranavir with Ritonavir*. Tipranavir given with low-dose ritonavir decreased the AUC of abacavir by approximately 40%. The clinical relevance of this reduction has not been established,^{7,8} but it may decrease the efficacy of abacavir.⁷ Therefore the UK manufacturer states that the concurrent use of tipranavir and low-dose ritonavir with abacavir is not recommended unless there are no other available NRTIs suitable for patient management.⁷

(b) Didanosine

1. *Amprenavir*. The AUC and the minimum level of amprenavir 600 mg twice daily were not altered to a clinically relevant extent when it was given simultaneously with, or one hour before, buffered didanosine; or simultaneously with the enteric-coated preparation of didanosine. The only notable change was a 15% decrease in the maximum levels of amprenavir when it was given with buffered didanosine, which was not considered clinically significant.⁹ Nevertheless, the manufacturers of amprenavir suggest that it should be given at least one hour apart from didanosine,^{3,4} and this has also been recommended for regimens containing amprenavir and ritonavir.⁹

2. *Atazanavir*. The manufacturer of atazanavir found that buffered didanosine markedly decreased atazanavir plasma levels, with little change in didanosine levels,¹⁰ and they recommend that administration should be separated.^{10,11} Conversely, although enteric-coated didanosine did not alter atazanavir levels, simultaneous administration with food reduced didanosine levels, and therefore administration should be separated.¹⁰ Note that 'didanosine', (p.797), is preferably taken on an empty stomach, whereas 'atazanavir', (p.818), should be taken with food.

3. *Indinavir*. The concurrent use of [buffered] didanosine and indinavir reduced the AUC of indinavir by 80%, but when indinavir was given one hour before didanosine its pharmacokinetics were not significantly affected.¹² Similarly, another study found that the pharmacokinetics of indinavir 800 mg were unchanged when it was given one hour after buffered didanosine 400 mg.¹³ An enteric-coated preparation of didanosine had no effect on the pharmacokinetics of indinavir in a single-dose study in 23 healthy subjects.¹⁴ Indinavir may require a normal acidic gastric pH for optimal absorption, whereas some didanosine preparations are formulated with buffering agents to raise gastric pH. Any increase in pH would therefore be expected to reduce indinavir absorption.¹⁵ The manufacturers of indinavir recommend that indinavir and didanosine should be given at least one hour apart.^{15,16} This recommendation would not apply to the enteric-coated preparation of didanosine.¹⁴ Note that both 'didanosine', (p.797), and 'indinavir', (p.818), are preferably taken on an empty stomach.

4. *Nelfinavir*. The pharmacokinetics of nelfinavir were not significantly altered after concurrent use with didanosine.¹⁷ Note that 'nelfinavir', (p.818), should preferably be taken with food, and all 'didanosine preparations', (p.797), without food.

5. *Ritonavir*. Buffered didanosine 200 mg twice daily was given with ritonavir 600 mg twice daily to 13 HIV-positive subjects. Administration of the two drugs was separated by 2.5 hours, and treatment was given for 4 days. Treatment was staggered in this way since 'ritonavir', (p.818), should be given with food, and 'didanosine', (p.797) without food. There was little or no change in the pharmacokinetics of ritonavir, and the maximum serum levels and AUC of didanosine were reduced by 16% and 13%, respectively, which was not considered to be clinically significant. It was suggested that these changes may have been due to altered absorption in the presence of ritonavir.¹⁸

6. *Saquinavir*. In 8 healthy subjects a single 400-mg dose of didanosine decreased the AUC and maximum plasma concentration of saquinavir (as saquinavir/ritonavir 1600/100 mg soft capsules) by approximately 30% and 25%, respectively, but did not significantly affect the minimum plasma concentration of saquinavir. The manufacturer considers these changes are of doubtful clinical significance.¹⁹ Note also that 'saquinavir', (p.818), should preferably be taken with food, and all 'didanosine preparations', (p.797) without.

7. *Tipranavir with Ritonavir*. Tipranavir plus low-dose ritonavir caused a 33% reduction in the AUC of didanosine in one of 3 studies,⁸ but the clinical relevance of this has not been established.^{7,8} Consequently, the manufacturer recommends that dosing of enteric-coated didanosine and tipranavir plus low-dose ritonavir should be separated by at least 2 hours to avoid formulation incompatibility.^{7,8}

(c) Lamivudine

Lamivudine metabolism does not involve the cytochrome P450 isoenzyme CYP3A4. Therefore it is unlikely that it will interact with drugs, such as the protease inhibitors, which are metabolised by this system.²⁰ No pharmacokinetic interaction appears to occur between lamivudine and **amprenavir**,^{3,4} **atazanavir**,^{10,11} **indinavir**,¹⁶ and **nelfinavir**.^{21,22} The manufacturer of **lopinavir/ritonavir** notes that lamivudine did not alter the pharmacokinetics of **lopinavir**,^{5,6} and **tipranavir** plus low-dose **ritonavir** did not cause a significant change in the AUC of lamivudine.^{7,8}

(d) Stavudine

The manufacturer of **atazanavir**^{10,11} notes that there was no pharmacokinetic interaction with stavudine.

The AUC of stavudine was increased by 25% when stavudine 40 mg twice daily was given with **indinavir** 800 mg every 8 hours for a week, which was not considered to be clinically significant. The serum levels of **indinavir** were unchanged.²³ Similarly, **indinavir/ritonavir** 800 mg/200 mg twice daily increased the AUC of stavudine by 24% in a study in 24 healthy subjects, but this change was not considered clinically relevant and does not require dosage modification.²⁴

The manufacturer of **lopinavir/ritonavir** notes that stavudine did not alter the pharmacokinetics of **lopinavir**.^{5,6}

In an early pilot study, combined **nelfinavir** and stavudine was well tolerated, and the adverse effects were similar to those seen when stavudine was given alone, although the incidence of diarrhoea did increase.²⁵ The manufacturer of **nelfinavir** notes that no clinically significant interactions have been observed with stavudine.^{21,22}

In a study in HIV-positive children, **ritonavir** oral clearance was about 50% slower and the AUC about 2.5-fold higher in 6 children who received

stavudine than in 7 who received zidovudine and lamivudine, although these differences did not reach statistical significance.²⁶

Tipranavir plus low-dose **ritonavir** did not cause a significant change in the AUC of stavudine.^{7,8}

(e) *Zalcitabine*

The manufacturer of zalcitabine noted that there is no pharmacokinetic interaction with **saquinavir**.^{27,28} They stated that pharmacokinetic interactions with protease inhibitors would not be expected, since zalcitabine is mainly excreted unchanged in the urine.²⁷

(f) *Zidovudine*

1. *Amprenavir*. The AUC and maximum levels of zidovudine were increased by 31% and 40%, respectively, when given with amprenavir. The pharmacokinetics of amprenavir were unchanged.^{3,4} The UK manufacturer of amprenavir states that no dose adjustment of either drug is necessary when amprenavir and zidovudine are used together.³

2. *Atazanavir*. The manufacturer of atazanavir^{10,11} notes that there was no clinically relevant pharmacokinetic interaction with zidovudine.

3. *Indinavir*. A study found that when zidovudine 200 mg every 8 hours and indinavir 1 g every 8 hours were given together for a week the AUC of zidovudine was increased by 17% and the AUC of indinavir was increased by 13%.²³ In another study, combined use of indinavir and zidovudine with lamivudine increased the zidovudine AUC by 39% but did not change indinavir pharmacokinetics.¹⁶ These changes are not clinically relevant.

4. *Lopinavir/Ritonavir*. The manufacturer of lopinavir/ritonavir notes that it induces glucuronidation and therefore has the potential to reduce zidovudine levels. However this, and its clinical relevance, have yet to be studied.^{5,6}

5. *Nelfinavir*. The manufacturer of nelfinavir notes that clinically significant interactions have not been observed with zidovudine, and no dose adjustments are needed.^{21,22}

6. *Ritonavir*. A crossover study in 18 HIV-positive subjects found that the pharmacokinetics of ritonavir 300 mg every 6 hours were unchanged by zidovudine 200 mg every 8 hours. However, the maximum plasma levels and AUC of the zidovudine were both reduced by about 25%. The lack of change in the other pharmacokinetic parameters suggested that these changes were not due to altered metabolism.²⁹ Nevertheless, dose alternations are not considered necessary.³⁰

7. *Saquinavir*. The UK manufacturer of saquinavir notes that there was no pharmacokinetic interaction with zidovudine.¹⁹

8. *Tipranavir with Ritonavir*. Tipranavir plus low-dose ritonavir decreased the AUC of zidovudine by approximately 35%, without affecting glucuronidated-zidovudine levels. The clinical relevance of this reduction has not been established,^{7,8} but it may decrease the efficacy of zidovudine.⁷ Therefore the UK manufacturer states that concurrent use of tipranavir plus low-dose ritonavir with zidovudine is not recommended unless there are no other available NRTIs suitable for patient management.⁷

NRTIs + Ribavirin

The use of ribavirin with the NRTIs may result in increased toxicity (lactic acidosis, blood dyscrasias and hepatotoxicity), which may be more frequent with didanosine than other NRTIs. These effects may also be exacerbated by the additional use of interferon for hepatitis C. Early *in vitro* data suggested that ribavirin may reduce the antiretroviral effects of some NRTIs but this does not appear to have been demonstrated in practice.

Clinical evidence, mechanism, importance and management

In the UK, the manufacturers of **all NRTIs** state that patients co-infected with hepatitis C and treated with interferon alfa and ribavirin may be at increased risk of lactic acidosis. Patients at increased risk should be monitored closely.

(a) *Didanosine*

Ribavirin did not alter the pharmacokinetics of didanosine in HIV-positive adults or children.^{1,2} However, *in vitro*, ribavirin increases the intracellular activation of didanosine, and the manufacturers note that this could result in increased adverse effects.^{3–5} In one early study, no increase in adverse effects was seen when ribavirin 600 mg daily was given to 16 HIV-positive patients who had already been taking didanosine 125 to 200 mg twice daily for 4 weeks. Ribavirin was given 6 hours after the morning dose of didanosine. Over the 8 or 20 weeks of the study the combination was well tolerated.¹ Nevertheless, cases of mitochondrial toxicity (hepatotoxicity, pancreatitis, lactic acidemia) have been reported when ribavirin was added to didanosine-containing antiretroviral regimens,^{6–8} and fatalities have occurred.^{6,9} In an analysis of data from the adverse event reporting system of the FDA in the US, 31 patients were identified who had adverse events suggestive of mitochondrial toxicity while taking ribavirin with an NRTI. Of these, nearly 90% had received didanosine, 71% stavudine, and 65% both didanosine and stavudine. Five patients died; all of who were taking didanosine, with stavudine in three of these cases. Use of ribavirin with didanosine was associated with an increased risk of mitochondrial toxicity (odds ratio 12.4) compared with patients receiving ribavirin in combination with other NRTIs (odds ratios: didanosine with stavudine, 8; stavudine, 3.3; abacavir, 1.1; lamivudine, 0.2; zidovudine, 0.06).⁹ Some other studies have shown an increased risk of mitochondrial toxicity when ribavirin was given with didanosine.^{10,11} As a result of these data, the manufacturers of ribavirin^{4,12–14} and the US manufacturer of didanosine⁵ say that concurrent use of ribavirin and didanosine is not recommended. Conversely, the UK manufacturer of didanosine³ just advises that if these drugs need to be given together, caution is required, and that patients should be monitored closely. They advise that treatment with nucleoside analogues [such as didanosine] should be discontinued in the setting of

symptomatic hyperlactataemia and metabolic/lactic acidosis, progressive hepatomegaly, or rapidly elevating aminotransferase levels. Similarly, others consider that didanosine should not be systematically replaced in patients requiring treatment for hepatitis C because the risk of lactic acidosis is only small.¹⁵ Nevertheless, they suggest that if a modification of antiretroviral treatment is needed then it is best to avoid didanosine.¹⁵

(b) Lamivudine

In vitro, ribavirin reduced the intracellular activation and antiretroviral activity of lamivudine.¹⁶ However, in a study in 22 HIV-positive patients with hepatitis C, ribavirin 800 mg daily had no statistically significant effect on the pharmacokinetics of lamivudine (a 27% increase in AUC), and no effect on the intracellular activation of lamivudine, when compared with 24 similar patients who received placebo.¹⁷ As with all NRTIs, lamivudine has, rarely, been associated with lactic acidosis, and the UK manufacturers of all NRTIs state that patients co-infected with hepatitis C and treated with interferon alfa and ribavirin may be at increased risk of lactic acidosis. Patients at increased risk should be monitored closely.¹⁸

(c) Stavudine

In vitro, ribavirin reduced the intracellular activation and antiretroviral activity of stavudine.^{4,19} However, in a study in 5 HIV-positive patients with hepatitis C, ribavirin 800 mg daily had no statistically significant effect on the pharmacokinetics of stavudine (a 45% increase in AUC), and no effect on intracellular activation of stavudine, when compared with similar patients who received placebo.¹⁷ Similarly, no decrease in antiviral activity of stavudine (as assessed by plasma HIV-RNA levels) has been seen when ribavirin was given with interferon for hepatitis C infection in patients with HIV.^{20,21} Nevertheless, the UK manufacturers of ribavirin continue to recommend that plasma HIV-RNA levels are closely monitored in patients taking ribavirin with stavudine to ensure continued efficacy.^{4,13} In contrast, based on an analysis of data from the adverse event reporting system of the FDA in the US, (see *didanosine* above), the UK manufacturers of ribavirin consider that concurrent use of stavudine should be avoided to limit the risk of mitochondrial toxicity.^{4,13} The UK manufacturer of stavudine notes that patients co-infected with hepatitis C and treated with interferon alfa and ribavirin may be at increased risk of NRTI-associated lactic acidosis. Patients at increased risk should be monitored closely.²² Similarly, the US manufacturer of stavudine states that patients receiving interferon with or without ribavirin and stavudine should be closely monitored for treatment-associated toxicities, especially hepatic decompensation.²³

(d) Zidovudine

In vitro, ribavirin reduced the intracellular activation and antiretroviral activity of zidovudine.^{4,24} However, in a study in 7 HIV-positive patients with hepatitis C, ribavirin 800 mg daily had no statistically significant effect on the pharmacokinetics of zidovudine (a 22% decrease in AUC), and no effect on the intracellular activation of zidovudine, when compared with similar patients who received placebo.¹⁷ Moreover, in a study in 8 patients taking zidovudine, there was no significant variation in HIV viral load or CD4 counts after 3 or 6 months of ribavirin treatment, compared with baseline values.²¹ Nevertheless, the UK manufacturers of ribavirin continue to recommend that plasma HIV RNA levels are closely monitored in patients given ribavirin with zidovudine to ensure continued efficacy.^{4,13} The US manufacturer of zidovudine states that nucleoside analogues that antagonise the antiretroviral activity of zidovudine, such as ribavirin, should be avoided.²⁵ However, they also state that patients receiving interferon alfa with or without ribavirin and zidovudine should be closely monitored for treatment-associated toxicities, especially hepatic decompensation, neutropenia, and anaemia.²⁵ In the UK, the manufacturers of all NRTIs state that patients co-infected with hepatitis C and treated with interferon alfa and ribavirin may be at increased risk of lactic acidosis. Patients at increased risk should be monitored closely. One US manufacturer of ribavirin includes details of a study in which patients treated with zidovudine, interferon alfa and ribavirin had a higher incidence of severe neutropenia (15% versus 9%) and severe anaemia (5% versus 1%) than other similar patients not receiving zidovudine.¹²

NRTIs + Tenofovir

Tenofovir increases the levels of didanosine: an increased risk of pancreatitis and peripheral neuropathy has been reported, and a high level of treatment failure. There is no pharmacokinetic interaction between tenofovir and abacavir, emtricitabine, lamivudine or stavudine. However, the combination of tenofovir, lamivudine and abacavir was unexpectedly associated with a high level of treatment failure. Triple-NRTI regimens involving tenofovir are not recommended, with the possible exception of tenofovir, lamivudine and zidovudine.

Clinical evidence, mechanism, importance and management

Note that tenofovir is a nucleotide (nucleoside monophosphate) analogue and is often classed as an NRTI.

(a) Abacavir

There was no clinically relevant pharmacokinetic interaction between tenofovir and abacavir in 8 healthy subjects.^{1,2} However, the combination of tenofovir, lamivudine and abacavir was unexpectedly associated with a high rate of treatment failure (early virological non-response) in clinical studies.³ Consequently, in July 2003 the manufacturer and others recommended that this triple therapy should not be used alone, and if these three drugs are used with other antiretrovirals, virological response should be closely monitored.³ US guidelines (October 2006) for treatment of HIV infections state that triple NRTI regimens like this should not be used routinely (with 2 specific exceptions) because of suboptimal virological activity or lack of data.⁴ Similarly, UK guidelines (2006) state that nonthymidine-containing triple NRTI regimens such as tenofovir, abacavir and lamivudine should not be used because of unacceptably high rates of virological failure.⁵

(b) Didanosine

The AUC of buffered didanosine 250 or 400 mg was increased by 44% when it was given 1 hour before tenofovir.¹ Similarly the AUC of enteric-coated didanosine 400 mg was increased by 48% and 60% when didanosine was given 2 hours before and with tenofovir disoproxil fumarate 300 mg, respectively.⁶ The pharmacokinetics of tenofovir were unchanged.^{1,6} Another study found that the AUC of enteric-coated didanosine 250 mg (simultaneously or 2 hours apart, fasted or with food) was about equivalent to that seen with didanosine 400 mg alone when tenofovir was given.⁶

The main concern with raised didanosine levels is the increased risk of adverse effects, particularly pancreatitis and peripheral neuropathy. One retrospective analysis found that 5 of 185 patients receiving didanosine with tenofovir developed pancreatitis compared with one of 182 taking didanosine without tenofovir and none of 208 taking tenofovir without didanosine, suggesting an increased risk of pancreatitis with the combination. All 6 cases of pancreatitis were in women without renal impairment, who weighed less than 60 kg. Five had received a reduced dose of didanosine (250 mg) and one had received 400 mg. Pancreatitis developed after 12 to 24 weeks.⁷ Similarly, another analysis found that use of tenofovir with didanosine (400 mg daily or 250 mg daily if weight less than 60 kg) was associated with a higher incidence of peripheral neuropathy (12% versus 4%) and pancreatitis (4% versus 0%) than use with lower doses of didanosine (100 to 250 mg daily).⁸ However, another analysis failed to find an enhanced risk of toxicity with the combination of didanosine and tenofovir at full dose during the first 6 months of use.⁹ Tenofovir is rarely associated with acute renal failure, and in one analysis it was suggested that since didanosine was one drug that appeared to be more commonly used in cases of tenofovir-associated renal failure, this might be due to an interaction,¹⁰ although others contend that this does not necessarily infer an association.¹¹ Cases of pancreatitis^{12,13} or lactic acidosis and renal failure¹⁴⁻¹⁶ have been reported (the use of ritonavir may be a factor in at least one of these cases¹⁶).

Furthermore, a once daily combination of tenofovir disoproxil fumarate 300 mg, enteric-coated didanosine 250 mg and lamivudine 300 mg was unexpectedly associated with a high rate of treatment failure (early virological non-response) in a clinical study in treatment-naïve patients.¹⁷ Similarly, other studies have shown a high rate of treatment failure with a once daily combination of tenofovir disoproxil fumarate 300 mg, enteric-coated didanosine 250 mg and either efavirenz or nevirapine in treatment-naïve patients with high baseline viral loads and low CD4 counts.¹⁸ A poor immune response (lack of increase in CD4 cell counts) has also been seen with full-dose didanosine plus tenofovir regimens in treatment-experienced patients.¹⁹

The pharmacokinetic interaction is established, and raised didanosine levels would be expected when it is given with tenofovir. The US manufacturers recommend that the dose of didanosine should be reduced to 250 mg once daily when given with tenofovir in patients weighing more than 60 kg,^{1,20} and 200 mg once daily in patients weighing less than 60 kg.²⁰ Nevertheless, because of the high rates of treatment failure seen with didanosine in combination with tenofovir and an NNRTI or lamivudine, and the potential for tenofovir to potentiate didanosine-related toxicity, the EMEA,²¹ the MHRA in the UK²² and UK guidelines⁵ now recommend that didanosine should not be used with tenofovir in any antiretroviral combination. Similarly, US guidelines (October 2006) also say that didanosine should not be used with tenofovir as part of initial therapy because of a high rate of early virological failure, rapid selection of resistant mutations, and the potential for immunological non-response/CD4 decline.⁴ If the combination is considered necessary, the patient should be carefully monitored for didanosine-related adverse effects (e.g. pancreatitis, peripheral neuropathy) and for antiviral efficacy.

(c) Emtricitabine

There was no pharmacokinetic interaction between tenofovir disoproxil fumarate 300 mg daily and emtricitabine 200 mg daily in a study in healthy subjects.^{1,23} UK and US guidelines (2006) for treatment of HIV infections recommend the combination of tenofovir and emtricitabine plus either an NNRTI or a protease inhibitor.^{4,5} Tenofovir and emtricitabine are available in a fixed dose combination product.

(d) Lamivudine

The manufacturer briefly notes that there was no pharmacokinetic interaction between tenofovir and lamivudine.²⁴ UK guidelines (2006) for treatment of HIV infections recommend the combination of tenofovir and lamivudine plus either an NNRTI or a protease inhibitor.⁵

However, for studies showing a high rate of virological failure with the combination of tenofovir, lamivudine and one other NRTI, see *Abacavir*, and *Didanosine*, above. UK and US guidelines say to avoid sole use of all regimens of tenofovir plus two NRTIs (triple-NRTI regimens), with the possible exception of tenofovir plus lamivudine and zidovudine when a protease inhibitor or NNRTI-based regimen cannot be used.^{4,5}

(e) Stavudine

There is information to suggest that tenofovir disoproxil fumarate 300 mg does not alter levels of stavudine 100 mg.²⁵

NRTIs; Didanosine + Allopurinol

Allopurinol markedly raises didanosine levels.

Clinical evidence, mechanism, importance and management

Buffered didanosine 400 mg was given to 14 healthy subjects, with and without allopurinol 300 mg daily for 7 days. The allopurinol significantly increased didanosine absorption, shown by a twofold increase in the AUC and a 69% rise in its maximum serum levels.¹ Similar findings were seen in HIV-positive subjects.² Moreover, the addition of allopurinol 300 mg daily allowed the dosage of didanosine to be halved from 400 mg to 200 mg daily in 4 patients taking buffered didanosine, hydroxycarbamide and chloroquine. Didanosine plasma levels and antiviral efficacy were unchanged.³

The manufacturer notes that allopurinol may increase the exposure to didanosine by inhibiting xanthine oxidase, an enzyme involved in didanosine metabolism.⁴ This interaction has been studied for its therapeutic benefit.³ However, if the dose of didanosine is not reduced, there is the potential for an increase in didanosine adverse effects.

The UK manufacturer recommends close monitoring for adverse effects if allopurinol is used with didanosine,⁴ but the US manufacturer says that coadministration is not recommended.⁵

NRTIs; Didanosine + Loperamide or Metoclopramide

Looperamide and metoclopramide do not appear to alter didanosine pharmacokinetics.

Clinical evidence, mechanism, importance and management

In 6 men and 6 women who were HIV-positive, the pharmacokinetics of oral buffered didanosine 300 mg were not altered to a clinically relevant extent by 4 mg of loperamide, given 19, 13, 7 and 1 hour before the didanosine. The rate of didanosine absorption was slightly decreased but the extent of absorption was unchanged. Similarly, the pharmacokinetics of oral buffered didanosine 300 mg were found to be unaffected by 10 mg of intravenous metoclopramide.¹ It appears that neither delaying nor accelerating gastrointestinal transit time appreciably alters the pharmacokinetics of didanosine, which is acid labile. On the basis of this study the authors conclude that neither the dose nor the frequency of didanosine administration need be altered if either loperamide or metoclopramide is given concurrently.¹

- Knapp CA, Milbrath RL, Barbhuiya RH. Effect of metoclopramide and loperamide on the pharmacokinetics of didanosine in HIV seropositive asymptomatic male and female patients. *Eur J Clin Pharmacol* (1993) 45, 409–13.

NRTIs; Stavudine + Doxorubicin

In vitro evidence suggests that doxorubicin may inhibit the activation of stavudine.

Clinical evidence, mechanism, importance and management

Nucleoside reverse transcriptase inhibitors such as stavudine need to be phosphorylated within cells before they become effective. *In vitro* studies using mononucleated blood cells found that doxorubicin may interfere with stavudine phosphorylation at clinically relevant concentrations.¹ The

clinical importance of this interaction awaits assessment. Until then, caution is required on concurrent use.

- Hoggard PG, Kewn S, Barry MG, Khoo SH, Back DJ. Effects of drugs on 2',3'-dideoxy-2',3'-dideoxythymidine phosphorylation *in vitro*. *Antimicrob Agents Chemother* (1997) 41, 1231–6.

NRTIs; Zidovudine + Benzodiazepines

Oxazepam causes a modest increase in the bioavailability of zidovudine, and the combination can increase the incidence of headaches. Lorazepam possibly behaves similarly.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 6 HIV-positive patients found that **oxazepam** did not significantly affect the bioavailability of zidovudine. All of the patients were sleepy and fatigued while taking **oxazepam** (as expected), but 5 of the 6 complained of headaches while taking both drugs, compared with only 1 of 6 while taking zidovudine alone and none while taking **oxazepam** alone. The authors of the report suggest that if headaches occur during concurrent use, the benzodiazepine should be stopped.¹ A previous *in vitro* study using human liver microsomes confirmed that **oxazepam** inhibits the metabolism of zidovudine to its glucuronide, and **lorazepam** behaves in the same way.² The same precautions suggested for **oxazepam** would therefore also appear to apply to **lorazepam**.

- Mole L, Israelski D, Bupp J, O'Hanley P, Merigan T, Blaschke T. Pharmacokinetics of zidovudine alone and in combination with oxazepam in the HIV infected patient. *J Acquir Immune Defic Syndr* (1993) 6, 56–60.
- Unadkat JD, Chien J. Lorazepam and oxazepam inhibit the metabolism of zidovudine (ZDV or azidothymidine) in an *in vitro* human liver microsomal system. *Pharm Res* (1988) 5 (Suppl), S177.

NRTIs; Zidovudine + Drugs that inhibit glucuronidation

In vitro evidence suggests that chloramphenicol, indometacin and naproxen inhibit the glucuronidation of zidovudine. However, neither indometacin nor naproxen altered zidovudine pharmacokinetics in subsequent clinical studies. Dipyridamole did not alter zidovudine pharmacokinetics.

Clinical evidence and mechanism

(a) Aspirin or NSAIDs

A study of zidovudine use in 282 AIDS patients found that haematological abnormalities were not increased by aspirin in 47 patients.¹ An *in vitro* study using human liver microsomes found that **indometacin** and **naproxen** inhibited the glucuronidation of zidovudine by 50% or more, and aspirin also had some inhibitory effect.² This suggested that these drugs might possibly increase the effects and the toxicity of zidovudine. However, other *clinical* studies found no changes in the pharmacokinetics of zidovudine given with **indometacin** 25 mg twice daily for 3 days³ or **naproxen** 500 mg to 1 g daily for 3 or 4 days.^{3,4}

(b) Chloramphenicol

An *in vitro* study using human liver microsomes found that chloramphenicol inhibited the glucuronidation of zidovudine by 50% or more, suggesting that the effects and toxicity of zidovudine may be increased.² The effect of concurrent use in patients awaits assessment.

(c) Dipyridamole

Theoretically, dipyridamole and zidovudine might inhibit the metabolism of each other by competing for glucuronidation, the major clearance mechanism for both drugs. However, a study in 11 asymptomatic HIV-positive patients found that dipyridamole 75 to 100 mg every 4 hours for 5 days caused no significant changes in the pharmacokinetics of zidovudine 500 mg daily, but the dipyridamole adverse effects (headaches, nausea) when taking the higher dose were found to be intolerable.⁵

Importance and management

Many drugs that inhibit the glucuronidation of zidovudine *in vitro* appear to have only modest effects on zidovudine levels, which are unlikely to be

clinically important in most patients. Consider also 'NRTIs + Atovaquone', p.793.

NRTIs; Zidovudine + Lithium

Lithium can apparently oppose the neutropenic effects of zidovudine.

Clinical evidence, mechanism, importance and management

A study in 5 patients with AIDS found that serum lithium carbonate levels of 0.6 to 1.2 mmol/L increased their neutrophil counts sufficiently to allow the re-introduction of zidovudine, which had previously been withdrawn due to neutropenia. Withdrawal of the lithium resulted in a rapid fall in neutrophil levels in two patients.¹ Improvement in neutropenia occurred in another AIDS patient taking zidovudine 1.2 g daily when lithium carbonate 300 mg three times daily was also given.² Lithium has been found to induce granulopoiesis, and these reports suggest that no adverse reaction occurred in patients taking zidovudine and lithium, and that there may be some advantages to their use. However, lithium itself has a narrow therapeutic range and its toxic symptoms might be difficult to distinguish from neurological complications caused by the disease. The addition of lithium could also increase the risk of interactions with other drugs.^{3,4} A study of 3 further patients found a lack of beneficial effect with lithium in 2 of the patients and only a short-term improvement in the neutrophil count in the third. In addition, one patient experienced severe diarrhoea necessitating discontinuation of the lithium.⁵

5. Worthington M. Lack of effect of lithium carbonate on zidovudine-associated neutropenia in patients with AIDS. *J Infect Dis* (1990) 162, 777-8.

NRTIs; Zidovudine + Megestrol

Megestrol acetate does not affect the pharmacokinetics of zidovudine.

Clinical evidence, mechanism, importance and management

In 12 asymptomatic HIV-positive subjects megestrol acetate 800 mg daily for 13 days had no effect on the steady-state pharmacokinetics of zidovudine or its glucuronide metabolite.¹ Megestrol does not appear to affect the metabolism of zidovudine. No dose adjustments appear necessary.

1. Van Harken DR, Pei JC, Wagner J, Pike IM. Pharmacokinetic interaction of megestrol acetate with zidovudine in human immunodeficiency virus-infected patients. *Antimicrob Agents Chemother* (1997) 41, 2480-3.

NRTIs; Zidovudine + Myelosuppressive drugs

There have been reports of serious myelotoxicity when zidovudine was given with vancomycin or antineoplastics, and, on theoretical grounds, any drug causing bone marrow suppression might be additive with the effects of zidovudine. Moderate phar-

macokinetic changes have been seen when zidovudine was given with chemotherapy regimens used for Kaposi's sarcoma, Hodgkin's disease, and non-Hodgkin's lymphoma.

Clinical evidence and mechanism

(a) Antineoplastics

In one preliminary report, the addition of **vinblastine** to zidovudine resulted in severe bone marrow depression.¹ Similarly, 9 of 21 patients could not tolerate zidovudine while receiving a chemotherapy regimen (**cyclophosphamide**, **doxorubicin**, **teniposide**, **prednisone**, **vincristine** and **bleomycin**) because of haematological toxicity.²

The pharmacokinetic interaction of chemotherapy with zidovudine was assessed in HIV-positive patients being treated for Kaposi's sarcoma, non-Hodgkin's lymphoma or Hodgkin's disease. The antineoplastics used were **bleomycin**, **cyclophosphamide**, **doxorubicin**, **epirubicin**, **etoposide**, **vinblastine**, **vincristine**, **vindesine** and **vinorelbine**. The zidovudine metabolism was unchanged, but a 43% decrease was noted in the maximum plasma levels of zidovudine and the time to peak level was prolonged by 51%, which was independent of the chemotherapy given.³ The authors concluded that dose changes of zidovudine were not needed with the antineoplastics used, based on these pharmacokinetic changes alone, since the zidovudine AUC remained unchanged and maximum plasma levels have not been shown to clearly correlate with its activity.³ Thus it appears that any interaction is likely to be attributable to additive myelosuppressive effects.

(b) Vancomycin

A report describes marked neutropenia in 4 HIV-positive patients receiving zidovudine when they were given vancomycin (which can also, rarely, have neutropenic effects).⁴

Importance and management

On theoretical grounds any drug causing bone marrow suppression might be additive with the effects of zidovudine. The UK manufacturer recommends that extra care be taken in monitoring haematological parameters if concurrent treatment with any myelosuppressive drug and zidovudine is required.⁵ They specifically mention systemic **pentamidine**, **'dapsone'**, (p.796), **pyrimethamine**, **'co-trimoxazole'**, (p.795), **amphotericin** (myelotoxicity and nephrotoxicity seen in a study in *dogs*⁶), **flucytosine**, **'ganciclovir'**, (p.798), **'interferon'**, (p.795), **vinblastine**, and **doxorubicin**.⁵ However, they also state⁵ that limited clinical data do not indicate a significantly increased risk of adverse reactions to zidovudine if it is given with prophylactic doses of **co-trimoxazole**, aerosolised **pentamidine**, **pyrimethamine**, and **'aciclovir'**, (p.791).

Oseltamivir + Drugs that affect renal clearance

Probenecid inhibits the renal secretion of the active metabolite of oseltamivir and markedly raises its plasma levels, but this is not clinically relevant because of the wide safety margin of oseltamivir. There was no pharmacokinetic interaction between amoxicillin and oseltamivir, and cimetidine did not alter oseltamivir pharmacokinetics.

Clinical evidence

(a) Amoxicillin

In a study in healthy subjects, oseltamivir 75 mg twice daily for 4.5 days had no effect on the pharmacokinetics of a single 500-mg dose of amoxi-

cillin given with the last dose of oseltamivir. Similarly, the amoxicillin had no effect on the pharmacokinetics of the active metabolite of oseltamivir.¹

(b) *Cimetidine*

In a crossover study in 18 healthy subjects cimetidine 400 mg every 6 hours for 4 days had no effect on the pharmacokinetics of a single 150-mg dose of oseltamivir given on day 2.¹

(c) *Probenecid*

In a crossover study in 18 healthy subjects probenecid 500 mg every 6 hours for 4 days approximately halved the renal clearance of the active metabolite of oseltamivir, and increased its AUC by about 2.5-fold when a single 150-mg dose of oseltamivir was given on day 2.¹

Mechanism

Probenecid appears to completely inhibit the renal tubular secretion of the active metabolite of oseltamivir via the anionic renal transporter process. Oseltamivir does not alter amoxicillin pharmacokinetics, suggesting minimal potential to inhibit the renal anionic transport process.¹ Cimetidine, which inhibits the renal tubular secretion of drugs via the cationic secretion transport process, had no effect on oseltamivir.

Importance and management

Probenecid markedly increased the AUC of the active metabolite of oseltamivir, but because of the large safety margin of oseltamivir, this increase is not considered to be clinically relevant.¹⁻³ Oseltamivir did not alter amoxicillin pharmacokinetics, and is therefore unlikely to interact with other renally secreted organic acids. Other drugs that are involved in the active anionic tubular secretion mechanism are also unlikely to interact. Cimetidine does not interact with oseltamivir, and other drugs that are inhibitors of the renal cationic secretion transport process are unlikely to interact.¹

Although the UK manufacturer does state that clinically important drug interactions involving competition for renal tubular secretion are unlikely, they recommend care should be taken when prescribing oseltamivir to patients taking other similarly excreted drugs with a narrow therapeutic margin, and they give **chlorpropamide**, **methotrexate**, and **phenylbutazone** as examples.²

- Tamiflu (Oseltamivir phosphate). Roche Products Ltd. UK Summary of product characteristics, March 2007.
- Tamiflu (Oseltamivir phosphate). Roche Pharmaceuticals. US Prescribing information, July 2007.

Oseltamivir or Zanamivir + Miscellaneous

Antacids do not affect the pharmacokinetics of oseltamivir, and there is no pharmacokinetic interaction between aspirin or paracetamol (acetaminophen) and oseltamivir. Aspirin and a variety of other drugs used for influenza management do not affect the antiviral activity of zanamivir *in vitro*.

Clinical evidence, mechanism, importance and management

(a) *Oseltamivir*

1. *Antacids*. In a single-dose study, the pharmacokinetics of oseltamivir 150 mg and its active carboxylate metabolite were not affected by antacids. The antacids used were an **aluminium/magnesium hydroxide** suspension (*Maalox*) and **calcium carbonate** tablet (*Titalac*).¹

2. *Aspirin*. In a study, 12 healthy subjects were given a single 900-mg dose of aspirin before, during and/or after oseltamivir 75 mg twice daily for 9 doses. There was no pharmacokinetic interaction between aspirin and oseltamivir.² A possible interaction was postulated since both drugs are hydrolysed by esterases and secreted by anionic tubular secretion.²

3. *Paracetamol (Acetaminophen)*. The manufacturer notes that there is no pharmacokinetic interaction between paracetamol and oseltamivir.^{3,4}

(b) *Zanamivir*

The *in vitro* antiviral potency of zanamivir was not affected by **aspirin**, **paracetamol**, **ibuprofen**, **phenylephrine**, **oxymetazoline**, **promethaz-**

ine, or **co-amoxiclav**.⁵ Zanamivir is used as an inhalation, and has low systemic bioavailability, so interactions would not generally be expected.

Protease inhibitors + Antiepileptics; Barbiturates

It is likely that phenobarbital and other barbiturates will increase the metabolism of the protease inhibitors, thereby reducing their levels and possibly resulting in failure of the antiretrovirals. However, one case suggested that this may not have occurred with primidone and ritonavir/saquinavir, although this should be viewed with caution.

Clinical evidence, mechanism, importance and management

The manufacturers of many of the protease inhibitors predict that their levels may be reduced by **phenobarbital**, due to induction of the cytochrome P450 isoenzyme CYP3A4 by which they are metabolised (see 'Table 21.2', (p.773)). There do not appear to be any controlled studies to demonstrate the extent of the pharmacokinetic interaction with different protease inhibitors. Data from one case report of carbamazepine toxicity with 'ritonavir/saquinavir', (p.810), provide indirect evidence to suggest the interaction with **primidone** is not clinically important. In this report, a patient taking an antiretroviral regimen including **ritonavir** and **saquinavir** had his antiepileptic medication changed from carbamazepine to **primidone** 500 mg daily. The authors noted that during follow-up (duration not stated), viral load was still undetectable and seizures remained under control.¹ **Primidone** is metabolised to **phenobarbital**, and might have been expected to cause antiretroviral therapy failure. Alternatively, the effect of **ritonavir**, which is a potent inhibitor of CYP3A4, may have been sufficient to offset the increased clearance associated with phenobarbital.

Another patient² taking phenobarbital, phenytoin and carbamazepine was found to have an unchanged phenobarbital level 2 days after switching from an antiretroviral regimen including indinavir to one containing ritonavir 300 mg twice daily and saquinavir. His plasma levels of 'carbamazepine', (p.810), had doubled, and there was a 32.7% drop in the levels of 'phenytoin', (p.812).

The combination of protease inhibitors and barbiturates should be used with caution, with increased monitoring of antiviral efficacy.

Protease inhibitors + Antiepileptics; Carbamazepine

Case reports suggest that ritonavir markedly increases carbamazepine levels and toxicity. Cases have also been reported with lopinavir/ritonavir and nelfinavir. Carbamazepine reduces indinavir levels and efficacy, and would also be expected to decrease levels of other protease inhibitors.

Clinical evidence

(a) *Indinavir*

A report describes a 48-year-old man whose antiretrovirals (indinavir 800 mg every 8 hours, lamivudine 150 mg twice daily and zidovudine 200 mg three times daily) became ineffective after a 10-week course of carbamazepine for postherpetic neuralgia. Over this time indinavir levels were up to 16 times lower than those measured in the absence of car-

bamazepine.¹ In two further cases, patients taking carbamazepine had partial failure of indinavir-containing antiretroviral regimens, which prompted a change in their therapy to include ritonavir rather than indinavir.^{2,3}

In 3 of the case reports described under *Ritonavir*, below, in which ritonavir increased carbamazepine levels,²⁻⁴ patients had previously received indinavir (800 mg three times daily^{2,4}) and carbamazepine (600 mg daily^{2,3} or 400 mg three times daily⁴) without experiencing carbamazepine toxicity (therapeutic carbamazepine levels were reported in 2 of the cases^{2,3}). This suggests that indinavir does not increase carbamazepine levels. However, in the case described above,¹ carbamazepine levels reached the therapeutic range for epilepsy even though the dosage of carbamazepine was only 200 mg daily, suggesting indinavir may increase carbamazepine levels.

(b) Lopinavir/Ritonavir

An HIV-positive patient who had a serum carbamazepine level of 10.3 mg/L while taking carbamazepine 400 mg three times daily reported feeling very drowsy within 9 days of starting to take tenofovir, lamivudine and lopinavir/ritonavir 400/100 mg twice daily. His carbamazepine serum level was found to have increased by 46%, to 15 mg/L. The carbamazepine dose was reduced to 400 mg twice daily, and 2 days later the carbamazepine level was 7.4 mg/L.⁵

(c) Nelfinavir

An HIV-positive patient who had a serum carbamazepine level of 9.8 mg/L while taking carbamazepine 400 mg three times daily started feeling more tired and unsteady on his feet 3 days after starting to take tenofovir, lamivudine and nelfinavir 1.25 g twice daily. His carbamazepine level was found to have increased by 53%, to 15 mg/L. The carbamazepine dose was reduced to 400 mg twice daily, and 2 days later the carbamazepine level was 9.3 mg/L.⁵

(d) Ritonavir

An 20-year-old HIV-positive man with epilepsy, who had his seizures controlled with carbamazepine 350 mg twice daily and zonisamide 140 mg twice daily, was admitted to hospital for review of his antiretrovirals. He started taking ritonavir 200 mg three times daily, but after the first dose of ritonavir his serum carbamazepine levels rose from 9.5 to 17.8 mg/L. This was accompanied by intractable vomiting and vertigo, so after 2 days the ritonavir was stopped. Symptoms resolved over the next few days. Subsequently ritonavir 200 mg daily was started, with the same effect, so the dose of carbamazepine dose was reduced to one-third, which resulted in carbamazepine levels of 6.2 micrograms/mL. Levels of ritonavir were not measured.⁶ Three other cases also document two- to threefold rises in carbamazepine levels with associated toxicity caused by the addition of ritonavir 300 mg, 400 mg or 600 mg twice daily and **saquinavir** 400 mg twice daily.²⁻⁴ In one case a carbamazepine dose reduction from 600 to 100 mg daily was needed to keep the levels within the therapeutic range before ritonavir was discontinued.³

Mechanism

Ritonavir is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 and consequently markedly increases carbamazepine levels. Other protease inhibitors would be expected to interact similarly, although to a lesser degree (see also 'Antivirals', (p.772)). Moreover, carbamazepine is an inducer of CYP3A4 and therefore can increase the metabolism of the protease inhibitor causing the levels to become subtherapeutic. Use of ritonavir-boosted protease inhibitors could theoretically offset this effect, but it may lead to increased carbamazepine toxicity.

Importance and management

Although the evidence is limited, these interactions seem to be established. It would therefore appear that the use of carbamazepine with protease inhibitors should be avoided where possible (mainly because of the risk of antiviral treatment failure). If both must be used then extremely close monitoring of both antiviral efficacy and carbamazepine levels/toxicity is warranted. Symptoms of carbamazepine toxicity include nausea,

vomiting, ataxia and drowsiness. The authors of one report suggest that amitriptyline or gabapentin would be possible alternatives for carbamazepine used for pain, or valproic acid or lamotrigine for carbamazepine used for seizures.¹

Protease inhibitors + Antiepileptics; Lamotrigine

Lopinavir/ritonavir halved lamotrigine plasma levels, whereas the protease inhibitor levels did not appear to be altered. Saquinavir/ritonavir had similar effects in another patient and therefore reduced lamotrigine levels should be anticipated with any ritonavir-boosted regimen.

Clinical evidence

In a study in 18 healthy subjects taking lamotrigine 100 mg twice daily, **lopinavir/ritonavir** 400/100 mg twice daily for 10 days decreased the steady-state minimum plasma level of lamotrigine by 55%, decreased the AUC of lamotrigine by 46%, and increased its clearance by 85%. Doubling the dose of lamotrigine to 200 mg twice daily increased the AUC to a similar level to that seen with the lower dose without **lopinavir/ritonavir**. Pharmacokinetic parameters for **lopinavir** and **ritonavir** were similar to those in historical controls.¹ The authors of a review describe a patient taking lamotrigine 25 mg twice daily who had a favourable decline in viral load 2 months after starting to take **lopinavir/ritonavir**, lamivudine and stavudine. There was no toxicity and no recurrence of seizures.²

A 30-year-old woman taking nevirapine, **saquinavir** 1.2 g daily, and **ritonavir** 600 mg daily with an undetectable viral load had her epilepsy medication changed from gabapentin and lorazepam to lamotrigine and phenytoin because of an increased frequency and severity of seizures. The lamotrigine dose was eventually increased to 1.8 g daily to achieve serum levels of 5 to 8 mg/L. The **ritonavir** dose was doubled and the **saquinavir** dose increased to 2 g daily to compensate for the enzyme-inducing effects of 'phenytoin', (p.812). The patient's viral load remained undetectable, and her seizures decreased over the next 6 months, but she died suddenly of unexplained causes following a tonic-clonic seizure (autopsy not performed).³

Mechanism

Lopinavir/ritonavir probably decreases lamotrigine levels by induction of glucuronidation (suggested by the increase in the AUC ratio of lamotrigine 2N-glucuronide to lamotrigine).

Importance and management

The pharmacokinetic interaction would appear to be established; however, since the relationship between lamotrigine levels and efficacy is not clear, the clinical relevance of the decrease is uncertain.¹ Lamotrigine efficacy should be monitored in patients taking lopinavir/ritonavir, and probably any ritonavir-boosted regimen. Anticipate the need to increase the lamotrigine dose.

Protease inhibitors + Antiepileptics; Miscellaneous

Stiripentol did not alter single-dose saquinavir pharmacokinetics in a controlled study. In one case report, ritonavir did not alter zonisamide levels.

Clinical evidence, mechanism, importance and management

(a) Stiripentol

In a crossover study in 12 healthy subjects,¹ stiripentol 1 g twice daily for 8 days had no effect on the pharmacokinetics of a single 400-mg dose of saquinavir given on day 8.

(b) Zonisamide

A 20-year-old HIV-positive man with epilepsy, who had his seizures controlled with carbamazepine 350 mg twice daily and zonisamide 140 mg twice daily, was admitted to hospital for review of his antiretrovirals. He started taking ritonavir, and after the first 200-mg dose of ritonavir his zonisamide levels remained unchanged.² However, his levels of 'carbamazepine', (p.810), were almost doubled.

2. Kato Y, Fujii T, Mizoguchi N, Takata N, Ueda K, Feldman MD, Kayser SR. Potential interaction between ritonavir and carbamazepine. *Pharmacotherapy* (2000) 20, 851–4.

Protease inhibitors + Antiepileptics; Phenytoin

Nelfinavir and lopinavir/ritonavir modestly reduced phenytoin levels in pharmacokinetic studies. In case reports, ritonavir has decreased, increased or not altered phenytoin levels. Phenytoin decreased lopinavir levels, and possibly also indinavir and ritonavir levels, but did not alter nelfinavir levels.

Clinical evidence

(a) Indinavir

A 39-year-old HIV-positive man, taking phenytoin 300 mg daily, started to take indinavir 800 mg three times daily. When the phenytoin dose was reduced to 200 mg daily, the viral load dropped by almost half and his CD4 count doubled.¹

(b) Lopinavir/Ritonavir

The concurrent use of phenytoin 300 mg once daily and lopinavir/ritonavir 400/100 mg twice daily resulted in a 30% decrease in the AUC of lopinavir and a 23% decrease in the AUC of phenytoin in studies in healthy subjects.²

(c) Nelfinavir

An HIV-positive man taking phenytoin and phenobarbital for epilepsy had been taking nelfinavir 750 mg three times daily and stavudine 30 mg twice daily for nearly 3 months when he had a tonic-clonic seizure. After starting nelfinavir and stavudine, serum phenytoin levels were found to have dropped from around 10 mg/L to around 5 mg/L.³ Similarly, nelfinavir 1.25 g twice daily for 7 days decreased the AUC of phenytoin by about 30% and the maximum serum level by 21%, in healthy subjects, whereas the nelfinavir levels were not altered.⁴

(d) Ritonavir

A case report describes the intentional use of ritonavir 600 mg twice daily to boost phenytoin levels in a 14-year-old boy who had been having seizures for 28 days, despite the use of several antiepileptics. Phenytoin at 20 mg/kg daily had originally failed to produce satisfactory plasma levels, although it did reduce the rate of seizures. After starting the ritonavir his seizures were controlled and the phenytoin level became therapeutic. Seizures started again after the ritonavir was stopped.⁵ Conversely, an HIV-positive patient taking carbamazepine and phenytoin had little change in his phenytoin levels, which remained at around 15 mg/L, 2 months after switching from an antiretroviral regimen including indinavir to one con-

taining ritonavir 600 mg twice daily and saquinavir.⁶ This was despite a 2.8-fold increase in the levels of 'carbamazepine', (p.810). Another patient taking phenobarbital, phenytoin and carbamazepine had a 32.7% drop in his phenytoin level 2 days after switching from an antiretroviral regimen including indinavir to one containing ritonavir 300 mg twice daily and saquinavir. The level of 'carbamazepine', (p.810) had doubled, and the level of 'phenobarbital', (p.810) was unchanged.⁷

A 30-year-old woman taking nevirapine, saquinavir 1.2 g daily and ritonavir 600 mg daily with undetectable viral load had her epilepsy medication changed from gabapentin and lorazepam to lamotrigine and phenytoin because of increased frequency and severity of seizures. She required phenytoin 8 mg/kg daily to maintain therapeutic serum levels. The ritonavir dose was doubled and the saquinavir dose increased to 2 g daily to compensate for the enzyme-inducing effects of phenytoin. The patient's viral load remained undetectable, and her seizures decreased over the next 6 months but she died suddenly of unexplained causes following a tonic-clonic seizure (autopsy not performed).⁸

Mechanism

Phenytoin is an inducer of the cytochrome P450 isoenzyme CYP3A4, and would be expected to increase the metabolism of the protease inhibitors, although nelfinavir levels were not altered, possibly because it is a substrate for several other isoenzymes. Phenytoin is principally metabolised by CYP2C9 and CYP2C19, and would therefore, not be expected to be substantially affected by most protease inhibitors. However, both increases and modest decreases in phenytoin levels have been seen.

Importance and management

Although information is limited, some of these interactions are expected. Phenytoin may decrease plasma levels of indinavir, lopinavir and possibly ritonavir, and the manufacturers of darunavir^{9,10} and saquinavir^{11,12} also predict that their levels may be reduced by phenytoin, although they note that the effect on ritonavir-boosted saquinavir has not been assessed.^{11,12} Phenytoin appears not to alter nelfinavir levels.

In addition, protease inhibitors appear to alter phenytoin levels. Therefore an alternative antiepileptic, such as sodium valproate, which does not affect cytochrome P450 isoenzymes, may be more appropriate in patients taking protease inhibitors. However, if there is no option but to use phenytoin, close monitoring of antiviral efficacy and phenytoin levels is essential.

Protease inhibitors + Antiepileptics; Valproate

Lopinavir levels appeared to be raised by valproic acid in one study in HIV-positive patients, whereas valproic acid levels were not significantly different to those in a control group not taking lopinavir with ritonavir. However, in one case, starting a lopinavir/ritonavir-based antiretroviral regimen caused a decrease of

about 50% in the valproic acid level, which resulted in an exacerbation of mania. A case of hepatotoxicity has occurred in a patient taking valproic acid with nevirapine and saquinavir/ritonavir.

Clinical evidence

In a study in 8 HIV-positive patients taking **lopinavir/ritonavir** 400/100 mg twice daily plus various NRTIs, the median AUC of **lopinavir** increased by 75% without any change in the estimated half-life after taking valproic acid 250 mg twice daily for 7 days. Although the maximum and minimum **lopinavir** levels were also higher, the difference was not statistically significant. **Ritonavir** levels were not assessed. Valproic acid levels achieved in the patients taking **lopinavir/ritonavir** were not significantly different from those in 11 HIV-positive control patients mainly taking NRTI antiretrovirals, even when the 3 patients taking a protease inhibitor or NNRTI (amprenavir, indinavir, or nelfinavir plus nevirapine) were excluded.¹

However, there is one report of a possible decrease in valproate levels in a 30-year-old man after starting **lopinavir/ritonavir**.² This patient, who had been taking valproic acid 375 mg daily as divalproex sodium for 7 months after an episode of mania, had a subtherapeutic valproic acid level of 197 micromol/L, and the dose was increased to 250 mg three times daily. After 25 days his trough valproic acid level was 495 micromol/L, and an antiretroviral regimen of lamivudine, zidovudine, **lopinavir/ritonavir** was started, and paroxetine for depression. Four days later he was hypomanic and the paroxetine was replaced with sertraline, which the patient discontinued. Twenty-one days later he had become increasingly manic, and the valproic acid level was found to be 238 micromol/L, about 50% lower than the previous level. An increase in valproic acid dose to 1.5 g daily was eventually required to achieve a therapeutic level of 392 micromol/L.

A case of valproate-associated hepatotoxicity occurred in a 51-year-old man about 3 weeks after starting nevirapine 200 mg twice daily, **saquinavir** 400 mg twice daily, **ritonavir** 400 mg twice daily, and stavudine. Serum valproic acid levels remained therapeutic.³

Mechanism

Lopinavir/ritonavir might decrease the plasma levels of valproic acid by induction of glucuronidation. See also 'lamotrigine', (p.811), which is similarly affected.

Importance and management

It has been predicted that ritonavir might reduce valproate levels,^{4,5} but the case report² appears to be the first clinical evidence of this occurring. Other evidence from the earlier study¹ suggested valproate levels were not affected by ritonavir to a statistically significant extent, although there was a downward trend in valproic acid levels. In addition, this study unexpectedly found that lopinavir levels appeared to be higher in patients taking valproic acid, although the increase is probably not clinically relevant.¹ If possible, monitor valproate levels when any antiretroviral regimen that includes ritonavir is used. Further study is needed. Note that there has been some concern about using valproate in HIV infection but there seems to be no established reason to avoid or specifically promote the use of valproate in HIV-infection *per se*.

Protease inhibitors + Atovaquone

Atovaquone modestly reduces the minimum level of indinavir. Ritonavir alone and ritonavir-boosted protease inhibitors are predicted to decrease atovaquone levels.

Clinical evidence, mechanism, importance and management

(a) Indinavir

Preliminary results from a study in healthy subjects suggest that the concurrent use of atovaquone 750 mg twice daily and indinavir 800 mg three times daily results in a minor 5% decrease in the AUC of indinavir, and a 13% increase in the AUC of atovaquone.¹ The UK manufacturer of atovaquone notes that concurrent use decreased the minimum level and AUC of indinavir by 23% and 9%, respectively. They recommend that caution should be exercised on concurrent use because of the potential risk of failure of indinavir treatment.² However, note that the effect was small and that indinavir is often used with other antiretrovirals, which might modify the interaction by affecting indinavir levels.

(b) Ritonavir and ritonavir-boosted protease inhibitors

The manufacturer of ritonavir predicts that it will decrease the plasma levels of atovaquone,^{3,4} by inducing atovaquone glucuronidation.⁴ They say that the clinical significance of this prediction is unknown, but that an increase in the atovaquone dose might be needed.³ Careful monitoring of serum levels and/or therapeutic effects is recommended when atovaquone is given with ritonavir as a pharmacokinetic enhancer or as an antiretroviral.⁴ This predicted interaction would therefore apply to **lopinavir/ritonavir**⁵ and any other boosted protease inhibitors. However, there does not appear to be any actual data to prove that the interaction occurs or is clinically relevant.

Protease inhibitors + Azoles; Fluconazole

Fluconazole may modestly increase the levels of saquinavir and tipranavir, but does not significantly affect ritonavir, indinavir or nelfinavir levels.

Clinical evidence

Fluconazole 400 mg on day one, followed by 200 mg daily for 4 days did not alter any of the pharmacokinetic parameters of **ritonavir** 200 mg every 6 hours by more than 15%, when given to 8 healthy subjects.¹ Similarly, fluconazole had no effect on the pharmacokinetics of **ritonavir** in 3 HIV-positive subjects.²

The pharmacokinetics of both **indinavir** 1 g every 8 hours and fluconazole 400 mg daily were not significantly affected by concurrent use in 11 HIV-positive patients.³ Another study also found no significant interaction between **indinavir** and fluconazole.⁴

A population pharmacokinetic analysis estimated that fluconazole decreased **nelfinavir** clearance by 26 to 30%, but this was not considered clinically significant.⁵

Fluconazole 400 mg on day 2, followed by 200 mg daily for 6 days increased the median AUC of **saquinavir** by 50%, and the maximum level by 56% in 5 HIV-positive subjects.²

Fluconazole increased the AUC of **tipranavir**, and its maximum and minimum levels by 50%, 32%, and 69%, respectively, when tipranavir/ritonavir 500/200 mg was given twice daily. Fluconazole levels were not affected.⁶

Mechanism

Fluconazole is a moderate inhibitor of CYP3A4 by which the protease inhibitors are metabolised.^{1,3}

Importance and management

The small to modest changes in protease inhibitor pharmacokinetics seen with fluconazole are unlikely to be of clinical significance. Because fluconazole causes a more significant increase in tipranavir levels, the manufacturer of tipranavir states that fluconazole, in doses of greater than

200 mg daily, is not recommended. No dosage adjustments are recommended for lower doses of fluconazole.^{6,7}

Protease inhibitors + Azoles; Itraconazole

Itraconazole increases the levels of amprenavir, indinavir, lopinavir/ritonavir, and saquinavir, and may theoretically increase the levels of other protease inhibitors.

Clinical evidence

Shortly after 2 patients taking **indinavir** and another taking **saquinavir/ritonavir** were given itraconazole they were noted to have eczematous eruptions and raised serum transaminases. These effects are seen with protease inhibitors alone, and were attributed to raised levels of both medications, arising from concurrent use. The patient taking **saquinavir/ritonavir** had a very prolonged itraconazole half-life.¹ In another patient, the itraconazole dose was halved when **lopinavir/ritonavir** was started, and after 5 weeks of concurrent use the itraconazole half-life had increased about tenfold, but no signs of itraconazole toxicity were observed.² In a study, itraconazole caused a median fivefold increase in the AUC of **saquinavir**, and it was considered that itraconazole may be an alternative to **ritonavir** for boosting **saquinavir** levels,³ and another study has investigated this.⁴ The UK manufacturer of **indinavir** says that giving **indinavir** 600 mg every 8 hours with itraconazole 200 mg twice daily produces an AUC similar to that achieved when **indinavir** 800 mg every 8 hours is given alone.⁵ The manufacturer of **amprenavir** notes that it is possible that plasma levels of itraconazole may be raised by concurrent use.⁶ The manufacturer of itraconazole^{7,8} says that **ritonavir** and **indinavir** may increase the bioavailability of itraconazole, since they are potent inhibitors of CYP3A4.

Mechanism

Itraconazole is a known substrate and inhibitor of the cytochrome P450 isoenzyme CYP3A4, and the protease inhibitors also inhibit and share this pathway of metabolism. Thus enzyme inhibition, and competition for metabolism results in raised serum levels of both drugs.

Importance and management

The information about the interactions of protease inhibitors with itraconazole is limited. On the basis of the available data, it is possible that itraconazole has greater effects than 'ketoconazole', (below), on protease inhibitor levels. The manufacturers of indinavir advise modestly reducing the indinavir dose to 600 mg every 8 hours if it is to be given with itraconazole.^{5,9} The UK manufacturer of saquinavir recommends monitoring for saquinavir toxicity if itraconazole is used.¹⁰ Some protease inhibitors, especially ritonavir and possibly indinavir, may increase itraconazole levels and most manufacturers say that doses of itraconazole greater than 200 mg a day are not recommended. The US manufacturers of amprenavir recommend increased monitoring for adverse effects and state that the dose of itraconazole may need to be reduced if it is greater than 400 mg daily.¹¹

Protease inhibitors + Azoles; Ketoconazole

Ketoconazole may increase the levels of protease inhibitors, but this is usually not clinically significant. The exception may be indinavir. Most protease inhibitors increase the levels of ketoconazole.

Clinical evidence

(a) Amprenavir or Fosamprenavir

The AUC of amprenavir was increased by 32% in one study,¹ but in another, the pharmacokinetics of amprenavir were not affected when ketoconazole was given with fosamprenavir/ritonavir.² In a single-dose study amprenavir 1.2 g caused a 44% rise in the AUC of ketoconazole 400 mg.¹ Similarly, the AUC of ketoconazole was increased by 2.7-fold by **fosamprenavir/ritonavir**.²

(b) Atazanavir

The pharmacokinetics of **atazanavir** 400 mg daily were not affected by the concurrent use of ketoconazole 200 mg daily for 7 days.³

(c) Darunavir

Pharmacokinetic changes have been seen with the concurrent use of ketoconazole and darunavir/ritonavir: the darunavir AUC was raised by 42% and the ketoconazole AUC was increased about threefold.⁴

(d) Indinavir

Ketoconazole raises the AUC of indinavir by 62%.⁵

(e) Lopinavir

A single 200-mg dose of ketoconazole had no effect on the pharmacokinetics of lopinavir.⁶ However, ketoconazole 200 mg once daily for 14 days was associated with a 68% increase in trough lopinavir levels and a 33% increase in ritonavir levels in an HIV-positive patient.⁷ The AUC of a single 200-mg dose of ketoconazole was increased threefold in patients taking lopinavir/ritonavir 400/100 mg twice daily.⁶

(f) Nelfinavir

Ketoconazole raises the AUC of nelfinavir by 35%.⁸

(g) Ritonavir

Ritonavir increased the AUC of ketoconazole 3.4-fold and the maximum plasma level 1.6-fold.⁹

(h) Saquinavir with Ritonavir

In one early clinical study, patients who received the combination of ketoconazole and saquinavir had a greater drop in viral load after 3 months than those not receiving ketoconazole.¹⁰ However, in one pharmacokinetic study, ketoconazole 200 mg for 7 days then 400 mg daily for 7 days had no consistent effect on saquinavir peak and trough plasma levels in 7 HIV-positive patients, although inter-individual variability was great. Saquinavir [as hard gelatin capsules¹¹] was given at the low dose of 600 mg three times daily.¹² Conversely, when saquinavir (soft gel capsule) 1.2 g three times daily was given to 12 healthy subjects with ketoconazole 400 mg daily for 7 days, the saquinavir AUC and maximum plasma levels were raised by 190% and 171%, respectively.¹¹ A similar study in 22 HIV-positive patients, using ketoconazole 200 mg daily, found that the saquinavir AUC and maximum plasma levels were raised by 69% and 36%, respectively.¹¹ In 12 HIV-positive patients, ketoconazole 200 or 400 mg increased the AUC of saquinavir and ritonavir in combination (both 400 mg twice daily) by 37% and 29%, respectively. The distribution of ritonavir was also affected, with disproportionate rises seen in CSF con-

centrations. All these changes appeared to be unrelated to the dose of ketoconazole used.¹³

The peak plasma level of ketoconazole 400 mg daily was similar to that usually seen with ketoconazole 800 mg alone when saquinavir/ritonavir were given.¹³ Moreover, in this study, dose escalation to higher doses of ketoconazole was discontinued after the first patient given ketoconazole 600 mg daily stopped treatment early because of adverse gastrointestinal effects.¹³ However, **saquinavir** alone did not affect ketoconazole pharmacokinetics.¹¹

Mechanism

Ketoconazole is a known substrate and inhibitor of the cytochrome P450 isoenzyme CYP3A4, and the protease inhibitors also inhibit and share this pathway of metabolism.^{1,11,13} Thus enzyme inhibition, and competition for metabolism results in raised serum levels of both drugs. Ketoconazole may also inhibit P-glycoprotein transport of saquinavir and ritonavir, causing a decrease in their clearance, and raising serum levels.^{11,13} Inhibition of P-glycoprotein may reduce efflux of protease inhibitors from the CSF, so increasing CSF levels.¹³

Importance and management

The magnitude of the changes in protease inhibitor pharmacokinetics seen with **ketoconazole** are unlikely to warrant dose changes of the protease inhibitors or cause significant increase in their adverse effects. However, the US manufacturer of indinavir recommends that the dose of indinavir be reduced to 600 mg every 8 hours when used with ketoconazole.¹⁴ Whether the ability of ketoconazole to boost CSF exposure to protease inhibitors has a role in improving therapeutic efficacy in the CNS remains to be seen.¹³

The data on the effect of protease inhibitors on ketoconazole are more limited. Amprenavir caused a modest increase in ketoconazole levels, and the UK manufacturer of amprenavir suggests that no ketoconazole dose adjustment is necessary with amprenavir alone,¹⁵ although the US manufacturer recommends increased monitoring for adverse effects and states that a dose reduction may be needed in patients receiving ketoconazole in doses of more than 400 mg daily.¹⁶ However, a marked effect was seen for ritonavir alone and for ritonavir combined with darunavir, fosamprenavir, lopinavir, saquinavir and theoretically **tipranavir**. This may increase the adverse effects of ketoconazole. Most protease inhibitor manufacturers say that doses greater than 200 mg a day of ketoconazole are not recommended. Similarly, the UK manufacturers of ketoconazole and ritonavir say that a dose reduction of ketoconazole should be considered when it is given with ritonavir.^{9,17}

Protease inhibitors + Azoles; Posaconazole

The manufacturer of posaconazole predicts that it will increase plasma levels of protease inhibitors via inhibition of cytochrome P450 isoenzyme CYP3A4. They recommend patients should be carefully monitored for any occurrence of toxicity during concurrent use.¹

- Noxafil (Posaconazole). Schering-Plough Ltd. UK Summary of product characteristics, October 2006.

Protease inhibitors + Azoles; Voriconazole

The current use of protease inhibitors and voriconazole is predicted to interfere with the metabolism of both drugs. Studies suggest that ritonavir decreases voriconazole levels, but no interaction was seen between indinavir and voriconazole in one study.

Clinical evidence

In a study in 18 healthy subjects, the pharmacokinetics of both **indinavir** 800 mg three times daily and voriconazole 200 mg twice daily were unaffected by at least a week of concurrent use.¹ However, *in vitro* studies suggest that the metabolism of HIV-protease inhibitors may be inhibited by voriconazole, and the metabolism of voriconazole may be inhibited by HIV-protease inhibitors. The manufacturer therefore suggests that patients should be carefully monitored for evidence of drug toxicity and/or loss of efficacy during concurrent use of other HIV-protease inhibitors (**amprenavir**, **nelfinavir** and **saquinavir** are specifically mentioned).²

In healthy subjects **ritonavir** 400 mg twice daily for 9 days decreased the steady-state maximum levels and AUC of oral voriconazole (400 mg twice daily for 1 day, then 200 mg twice daily for 8 days) by 66% and 82%, respectively.³ The pharmacokinetics of the **ritonavir** remained unchanged. Low-dose ritonavir (100 mg daily) decreased the AUC of voriconazole by 39% and the AUC of the ritonavir was decreased by 14%.³

Mechanism

Voriconazole is an inhibitor and a substrate of the cytochrome P450 isoenzyme CYP3A4: protease inhibitors are also metabolised by this route, and can, to varying degrees, also inhibit this isoenzyme.

Importance and management

The manufacturers of **voriconazole** say that the concurrent use of ritonavir (at doses of 400 mg and above twice daily) is contraindicated,^{2,3} presumably because the efficacy of the voriconazole is expected to be markedly reduced. The manufacturer of ritonavir also recommends that when it is used as a pharmacokinetic enhancer (usually 100 mg twice daily) voriconazole should only be given if the benefits outweigh the risks.⁴ Most protease inhibitors are given with ritonavir as a pharmacokinetic enhancer; however, caution is also warranted if they are given alone, as all the protease inhibitors can inhibit CYP3A4 to some extent and may therefore also increase voriconazole levels. Voriconazole may also affect protease inhibitor levels, but other than ritonavir and indinavir, which are not affected this does not appear to have been studied. Be aware that some increase in their levels is theoretically possible if voriconazole is given.

Protease inhibitors + Cannabinoids

The short-term use of cannabis cigarettes or dronabinol did not appear to adversely affect indinavir or nelfinavir levels or viral loads in HIV-positive patients.

Clinical evidence

In 9 HIV-positive patients on a stable regimen containing **indinavir** (mostly 800 mg every 8 hours), smoking a **cannabis cigarette** (3.95% tetrahydrocannabinol) three times a day before meals for 14 days resulted in a median 14% decrease in AUC and maximum level and a 34% decrease in minimum indinavir level. However, only the change in maximum level was statistically significant.¹ Similarly, **dronabinol** 2.5 mg three times daily for 14 days had no significant effect on **indinavir** pharmacokinetics.¹

In another 11 patients on a stable regimen containing **nelfinavir** 750 mg three times daily, there was a non-significant 10% decrease in AUC, 17% decrease in maximum level, and 12% decrease in minimum nelfinavir level after 14 days of **cannabis cigarettes**.¹ Similarly, **dronabinol** 2.5 mg three times daily for 14 days had no significant effect on **nelfinavir** pharmacokinetics.¹

There was no adverse effect on viral load or CD4 count in the patients receiving cannabis cigarettes or dronabinol.²

Mechanism

Unknown.

Importance and management

Short-term use of cannabis cigarettes or dronabinol does not appear to have any important effect on levels of indinavir or nelfinavir, nor on markers of HIV infection.

Short-term effects of cannabinoids in patients with HIV-1 infection: a randomized, placebo-controlled clinical trial. *Ann Intern Med* (2003) 139, 258–66.

Protease inhibitors + Co-trimoxazole

Minor pharmacokinetic changes have been seen when co-trimoxazole is given with the protease inhibitors, but these changes are not considered to be clinically significant.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given **indinavir** 400 mg every 6 hours with co-trimoxazole 960 mg every 12 hours found that there was no change in the AUC of **indinavir**, but a small 17% decrease in **indinavir** trough levels. In addition, there was an 18% increase in the AUC of **trimethoprim**, and a 5% increase in the AUC of **sulfamethoxazole**. None of these changes were considered to be clinically important.¹

Ritonavir 500 mg twice daily caused a 20% increase in the AUC of **trimethoprim** and a 20% decrease in the AUC of **sulfamethoxazole** when a single 960-mg dose of co-trimoxazole was given to 15 healthy subjects. These changes were considered too small to be of clinical relevance.² The pharmacokinetics of **ritonavir** were not assessed.

The combination of **saquinavir** 600 mg three times daily and co-trimoxazole 960 mg three times weekly caused no changes in the pharmacokinetics of **saquinavir**.³

There would seem to be no reason for avoiding the use of co-trimoxazole with any of the protease inhibitors.

3. Maserati R, Villani P, Cocchi L, Regazzi MB. Co-trimoxazole administered for *Pneumocystis carinii* pneumonia prophylaxis does not interfere with saquinavir pharmacokinetics. *AIDS* (1998) 12, 815–6.

Protease inhibitors + Drugs that affect gastric pH

Proton pump inhibitors (marked effect) and H₂-receptor antagonists (modest effect) reduce atazanavir levels. Other drugs that increase gastric pH are also predicted to reduce plasma levels of atazanavir. Fosamprenavir may be similarly affected (moderate effects seen with ranitidine), although antacids and esomeprazole had little effect in one study. Omeprazole decreases indinavir levels and an antacid modestly decreased tipranavir levels. Neither ranitidine nor omeprazole had any effect on darunavir/ritonavir or lopinavir/ritonavir levels. In contrast, cimetidine, ranitidine and omeprazole have been shown to increase saquinavir levels.

Clinical evidence

(a) Atazanavir

1. *H₂-receptor antagonists*. In a study in healthy subjects **famotidine** 40 mg twice daily reduced the atazanavir AUC, maximum, and minimum levels by 18%, 14%, and 28%, respectively, when given simultaneously with atazanavir/ritonavir 300/100 mg once daily.^{1,2} A greater effect (41% reduction in AUC) was seen when the drugs were given again without ritonavir, but little effect was seen when the atazanavir was given 10 hours after and 2 hours before the **famotidine**.² In a randomised study in healthy subjects, **ranitidine** 150 mg one hour before breakfast reduced the atazanavir AUC, maximum, and minimum levels by 48%, 52%, and 43%, respectively, when atazanavir/ritonavir 300/100 mg once daily was taken 30 minutes after breakfast.³

2. *Proton pump inhibitors*. The AUC of atazanavir was reduced by 76% and the trough plasma level by 78% when atazanavir/ritonavir 300/100 mg was given with **omeprazole** 40 mg. Increasing the dose of atazanavir/ritonavir to 400/100 mg did not negate the effects of this interaction.^{4,5} An even greater effect (94% reduction in AUC) was seen when atazanavir alone was given with omeprazole,² and the same effect was seen with **lansoprazole**.⁶ Similar results were found in another study with **omeprazole**: ritonavir levels were not affected.³

Atazanavir trough levels were significantly lower in patients taking proton pump inhibitors than in those taking H₂-receptor antagonists in another study.⁷ A 65-year-old HIV-positive man had a marked reduction in atazanavir trough levels and AUC in a 12-hour study while receiving **esomeprazole** and atazanavir/ritonavir.⁸

However, 9 of 12 subjects had a successful virological outcome while taking atazanavir with or without ritonavir together with a proton pump inhibitor (**esomeprazole**, **lansoprazole**, **omeprazole**, **pantoprazole**, **rabeprazole**) in a retrospective analysis of concurrent use.⁹ Another retrospective analysis also found no difference in virological outcome in patients taking atazanavir/ritonavir with proton pump inhibitors (**rabeprazole**, **omeprazole**; 10 patients) and 66 patients not taking proton pump inhibitors.¹⁰ Similarly, in one patient taking atazanavir/ritonavir 300/100 mg once daily, tenofovir and lamivudine, and **lansoprazole** 30 mg twice daily, the AUC, maximum, and minimum levels of atazanavir were higher than those seen historically with atazanavir/ritonavir plus tenofovir.¹¹ Another patient maintained virological suppression when **omeprazole** 20 mg daily was taken with ritonavir-boosted atazanavir 150 mg twice daily.¹²

(b) Darunavir with Ritonavir

In a crossover study in 16 healthy subjects, neither **omeprazole** 20 mg daily nor **ranitidine** 150 mg twice daily had a significant effect on the AUC or minimum level of darunavir after darunavir/ritonavir 400/100 mg was given twice daily for 5 days.¹³

(c) Fosamprenavir

In a crossover study in healthy subjects the AUC of amprenavir (derived from a single 1.4-g dose of fosamprenavir) was decreased by 18% and the maximum plasma level by 35%, but the minimum level was not significantly altered by the concurrent use of 30 mL of an **aluminium/magnesium hydroxide antacid (Maalox TC)**.¹⁴

In the same study, **ranitidine** 300 mg given one hour before fosamprenavir 1.4 g decreased the AUC of amprenavir by 30% and the maximum level by 51% without altering the minimum level.¹⁴

In contrast, **esomeprazole** 20 mg once daily had no effect on the steady-state pharmacokinetics of amprenavir after either fosamprenavir 1.4 g

twice daily or fosamprenavir/ritonavir 700/100 mg twice daily in studies in healthy subjects. However, fosamprenavir 1.4 g twice daily increased the **esomeprazole** AUC by 55%. In this study, the daily dose of esomeprazole was given simultaneously with the first dose of protease inhibitor.¹⁵ Similarly, no pharmacokinetic interaction was apparent in an 8-hour study in a 65-year-old HIV-positive who was given fosamprenavir/ritonavir with **esomeprazole**.⁸

(d) Indinavir

The manufacturer notes that **cimetidine** 600 mg twice daily for 6 days had no clinically significant effect on the pharmacokinetics of a single 400-mg dose of indinavir in a study in 12 healthy subjects.¹⁶

In a study in 8 healthy subjects given **omeprazole** 40 mg daily with a single 800-mg dose of indinavir, half of them had a clinically significant decrease in the plasma levels of indinavir; no significant pharmacokinetic changes occurred in the others.¹⁷ In a review by the same authors, 4 of 9 patients taking **omeprazole** with indinavir had plasma levels of indinavir lower than expected. In two patients, increasing the indinavir dose from 800 mg to 1 g, three times daily, resulted in acceptable plasma levels.¹⁸ In a later randomised controlled study, **omeprazole** 40 mg once daily for 7 days reduced the AUC of indinavir 800 mg by 47% in 14 subjects. However, the addition of ritonavir 200 mg to the indinavir negated the effect of the **omeprazole**.¹⁹

Note that 'buffered didanosine tablets', (p.804), has also been shown to reduce indinavir levels.

(e) Lopinavir/Ritonavir

In a randomised study in healthy subjects, **omeprazole** 40 mg once daily or **ranitidine** 150 mg one hour before breakfast had no effect on the relative bioavailability of either lopinavir or ritonavir when lopinavir/ritonavir 800/200 mg once daily was taken 30 minutes after breakfast, or when lopinavir/ritonavir 400/100 mg twice daily (30 minutes after a meal) was given 1.5 hours after the acid-reducing drug. The lopinavir/ritonavir was taken in a tablet form.³

In a clinical study of lopinavir/ritonavir once daily (8 study patients, 86 control patients) or twice daily (7 study patients, 45 control patients) in combination with tenofovir and emtricitabine, trough levels of lopinavir were assessed at 4, 8, 16, 24 and 48 weeks: patients taking acid-reducing drugs (**proton pump inhibitors** 67%, **H₂-receptor antagonists** or **antacids**) were then compared with control patients not using acid-reducing drugs. There was no significant difference in trough lopinavir levels between the patients taking acid-reducing drugs and the controls, except that at week 24 the trough level of lopinavir was 50% higher, and at week 48 it was 73% higher, in users of acid-reducing drugs taking lopinavir/ritonavir once daily. No difference was seen in the group taking lopinavir/ritonavir twice daily.²⁰

(f) Saquinavir

When cimetidine was given with saquinavir the AUC of saquinavir 1.2 g twice daily was 120% greater when it was given with cimetidine 400 mg twice daily, when compared with saquinavir 1.2 g three times daily alone.²¹ In a study in 12 healthy subjects, the AUC of saquinavir given with food was 67% higher when it was given after two 150-mg doses of **ranitidine** given 12 hours and 1 hour before the saquinavir.²²

Omeprazole 40 mg daily increased the AUC of saquinavir by 82% when saquinavir/ritonavir 1000/100 mg was given twice daily to 18 healthy subjects.²³

(g) Tipranavir

In a single-dose study in healthy subjects, 20 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox Plus*) decreased the AUC, minimum and maximum levels of tipranavir by 25 to 29%, after simultaneous ingestion of tipranavir/ritonavir 500/200 mg.²⁴⁻²⁶

Mechanism

The UK manufacturer of indinavir states that a normal (acidic) gastric pH may be necessary for optimum absorption of indinavir.²⁷ Any drug that increases the gastric pH could therefore potentially reduce absorption. Altered gastric pH may also account for the interaction with atazanavir.⁴ Cimetidine probably boosts saquinavir levels by inhibiting the first-pass metabolism of saquinavir.²¹ It is not understood why ranitidine and omeprazole increase saquinavir levels.

Importance and management

The marked pharmacokinetic interaction of omeprazole with **atazanavir** (with or without ritonavir) is established, and lansoprazole appears to act similarly. Based on the available data, advice in Europe⁴ and the USA⁵ is that atazanavir or atazanavir/ritonavir should not be given with omeprazole or other proton pump inhibitors. Modest effects were seen with atazanavir and simultaneous famotidine, whereas ranitidine taken 1.5 hours before atazanavir/ritonavir had a more marked effect. The manufacturer says that no dosage adjustment of atazanavir/ritonavir is required when it is given with an H₂-receptor antagonist, all as a single daily dose with food. However, they caution that the magnitude of the interaction may be more pronounced in HIV-positive patients (as the intragastric pH may be higher in this population). To avoid any interaction they suggest that atazanavir/ritonavir should be given once daily with food, 2 hours before and at least 10 hours after the dose of the H₂-receptor antagonist. In addition, they recommend atazanavir should be given 2 hours before or 1 hour after buffered medicinal products.^{1,2} This would include didanosine buffered tablets (see 'NRTIs + Protease inhibitors', p.804).

Based on the limited data with other protease inhibitors, the manufacturer of **amprenavir** also recommends it should not be given within 1 hour of antacids.^{28,29} The decrease in amprenavir levels seen when **fosamprenavir** is given with an antacid are not considered clinically relevant, and no fosamprenavir dose adjustments are likely to be necessary. Greater decreases were seen with ranitidine, although the minimum levels were unchanged. The UK manufacturer³⁰ states that no fosamprenavir dose adjustment is needed with ranitidine or other H₂-receptor antagonists; however, the US manufacturer³¹ says the combination should be used with caution because fosamprenavir may be less effective. However, no interaction occurred with esomeprazole, and this, or other proton pump inhibitors may be given at the same time as fosamprenavir.

The interaction between omeprazole and indinavir would appear to be established. Omeprazole should probably not be used with indinavir unless ritonavir is used to boost the indinavir levels.¹⁹ This would likely apply to other proton pump inhibitors used with indinavir as well.

Antacids modestly decreased **tipranavir** levels, and administration should be separated by at least 2 hours.²⁶

Cimetidine very markedly increases **saquinavir** levels, and further study is required to discover whether this is clinically useful.²¹ Ranitidine and omeprazole cause a fairly marked increase in saquinavir levels, although this is probably not clinically relevant.

Omeprazole and ranitidine do not appear to alter the pharmacokinetics of **darunavir/ritonavir** or **lopinavir/ritonavir**.

Protease inhibitors + Food

Food increases the bioavailability of atazanavir, darunavir, lopinavir/ritonavir soft capsules and solution, nelfinavir, saquinavir (all formulations) and tipranavir, but decreases that of indinavir. Food only minimally affects the bioavailability of amprenavir, fosamprenavir, lopinavir/ritonavir tablets and ritonavir. Mixing ritonavir with enteral feeds does not affect the pharmacokinetics of ritonavir.

Clinical evidence, mechanism, importance and management

(a) Absorption decreased

A single 600-mg dose of **indinavir** was given to 7 HIV-positive subjects immediately after various types of meal. The **protein, carbohydrate, fat and high-viscosity meals** reduced the AUC of **indinavir** by 68%, 45%, 34% and 30%, respectively. The fat meal was associated with the largest inter-subject variation in bioavailability. The effect of the protein meal was attributed to the fact that it raised gastric pH and therefore impaired the absorption of **indinavir** (a weak base). The impairment of **indinavir** absorption caused by the other meals, which did not alter gastric pH, may have been due to delayed gastric emptying.¹ A similar study comparing a full breakfast with light breakfasts (toast or cereal) on indinavir absorption found that the full breakfast reduced the absorption of **indinavir** by 78% and reduced its maximum serum levels by 86%, while the light breakfasts had no significant effect.² The manufacturers advise that **indinavir** is given 1 hour before or 2 hours after meals, or with low-fat light meals only.^{3,4} The US information gives examples of a light meal, such as dry toast with jam, juice, and coffee with skimmed milk and sugar; or corn flakes, skimmed milk and sugar.⁴

(b) Absorption increased

1. **Atazanavir.** The manufacturers of atazanavir note that administration with a light or high-fat meal decreased the wide variation in plasma levels. They recommend that atazanavir should be taken with food to enhance bioavailability and minimise variability.^{5,6}

2. **Darunavir with Ritonavir.** The manufacturers of darunavir notes that the relative bioavailability of darunavir (with low-dose ritonavir) is 30% lower when it is given without food, compared with intake with food. Therefore, darunavir tablets should be taken with ritonavir and with food. They say that the type of food does not affect exposure to darunavir.^{7,8}

3. **Lopinavir/Ritonavir.** A moderate-fat meal increased the AUC and maximum level of lopinavir capsules by 48% and 23%, respectively, and a high-fat meal by 96% and 43%, respectively. The corresponding increases for lopinavir solution were 80% and 54% for the moderate-fat meal, and 130% and 56% for the high-fat meal.⁹ The manufacturers of lopina-

vir/ritonavir soft capsules and oral solution say that it should be taken with food.^{9,10} No clinically significant difference was seen in the bioavailability of lopinavir/ritonavir tablets between fasting and fed subjects, therefore the manufacturers say that it can be taken with or without food.^{10,11}

4. **Nelfinavir.** When nelfinavir 400 or 800 mg was given to 12 healthy subjects in the fasted state, the AUC was only 27% to 50% of that observed when nelfinavir was given with a meal.¹² Nelfinavir should be taken with food.^{13,14}

5. **Saquinavir.** The manufacturer of saquinavir hard capsules and tablets notes that, in a crossover study in 22 HIV-positive patients taking saquinavir/ritonavir 1000/100 mg twice daily and receiving three consecutive doses under fasting conditions or after a high-fat, high-calorie meal, the AUC, maximum and minimum levels of saquinavir under fasting conditions were about 70% lower than with a high-fat meal. There were no clinically significant differences in the pharmacokinetic profile of ritonavir in fasting and fed conditions but the ritonavir minimum level was about 30% lower in the fasting state, when compared with its administration with a meal.^{15,16} Saquinavir/ritonavir should be given with, or up to 2 hours after, a meal.¹⁵⁻¹⁷

6. **Tipranavir.** The US manufacturer states that the bioavailability of tipranavir is increased if it is taken with a high-fat meal.¹⁸ In a study, tipranavir capsules were given with a high-fat meal or a light snack of toast and skimmed milk. A high-fat meal enhanced the AUC by 31%, but had minimal 16% effect on peak tipranavir levels. The UK manufacturer states that food improves the tolerability of tipranavir/ritonavir.¹⁹ Both manufacturers recommend that tipranavir with ritonavir should be taken with food.^{18,19}

(c) Absorption minimally affected

1. **Amprenavir.** Food resulted in a 25% reduction in the AUC of amprenavir, but no change in the steady-state trough level. Consequently, the manufacturers say it can be given with or without food,^{20,21} but the US manufacturer says not with a high-fat meal.²¹

2. **Fosamprenavir.** The manufacturer states that taking the fosamprenavir tablet formulation with a high-fat meal did not alter plasma amprenavir pharmacokinetics (derived from fosamprenavir) when compared with taking this formulation in the fasted state. Fosamprenavir tablets may be taken without regard to food intake.^{22,23}

3. **Ritonavir.** The US manufacturer notes that a meal increased the absorption of ritonavir capsules by 13%, when compared with the fasting state, whereas the absorption of the oral solution was decreased by 7%.²⁴ See also *Lopinavir* and *Saquinavir*, above. Although these changes are modest the manufacturers state that ritonavir capsules and solution are preferably taken with food.²⁴⁻²⁶ There is also some evidence that mixing ritonavir with **enteral feeds** does not affect ritonavir pharmacokinetics. A 600-mg dose of **ritonavir** oral solution was mixed with 240 mL of **enteral feeds** (either *Advera* or *Ensure*), **chocolate milk** or water within 1 hour of dosing. When given up to 15 minutes after a low-fat meal, the pharmacokinetics of ritonavir in either of the **enteral feeds** or the **milk** were almost identical to those when ritonavir was given in water.²⁷

Protease inhibitors + Garlic

A garlic supplement reduced the plasma levels of saquinavir by 50% in one study, but had little effect in another. Another garlic supplement did not significantly affect the pharmacokinetics of a single dose of ritonavir.

Clinical evidence

In a study in 9 healthy subjects garlic reduced the AUC, and maximum and minimum plasma levels of **saquinavir** by about 50%. The garlic was taken in the form of a dietary supplement (*GarliPure, Maximum Allicin Formula* caplets) twice daily for 20 days. **Saquinavir** 1.2 g three times daily was given for 4-day periods before, during, and after the garlic supplement. Fourteen days after the garlic supplement was stopped the **saquinavir** pharmacokinetics had still not returned to baseline values. Of the 9 subjects, 6 had a substantial drop in the AUC of **saquinavir** while taking garlic, then a rise when garlic was stopped. The remaining 3 had no change in the AUC of **saquinavir** while taking garlic, but had a drop when garlic was stopped.¹ However, in another study, garlic extract (*Garlipure*) 1.2 g daily for 3 weeks had no significant effect on the pharmacokinetics of a single 1.2-g dose of **saquinavir** (a slight decrease in AUC in 7 subjects and a slight increase in 3).²

Gastrointestinal toxicity was noted in 2 patients taking garlic or garlic supplements when they started to take **ritonavir**-containing regimens.³ However, in a study in 10 healthy subjects the use of a garlic extract (10 mg, equivalent to 1 g of fresh garlic) twice daily for 4 days did not significantly affect the pharmacokinetics of a single 400-mg dose of **ritonavir**. There was a non-significant 17% decrease in the AUC of **ritonavir**. The garlic was given in the form of capsules (*Natural Source Odourless Garlic Life Brand*).⁴

Mechanism

The mechanism of this interaction is uncertain, but it is thought that garlic reduced the bioavailability of saquinavir by increasing its metabolism in the intestine.¹ Why there was a disparity in the effect of garlic on saquinavir between patients is unclear.

Importance and management

Although information is limited, a reduction in saquinavir plasma levels of the magnitude seen in the first study could diminish its antiviral efficacy. All garlic supplements should probably be avoided in those taking saquinavir as the sole protease inhibitor (no longer generally recommended). While the pharmacokinetic effect on single-dose ritonavir was not clinically important, this requires confirmation in a multiple-dose study.

Protease inhibitors + Grapefruit and other fruit juices

Grapefruit juice does not have any clinically significant effects on the pharmacokinetics of either amprenavir or indinavir. Although the saquinavir AUC was doubled by grapefruit juice, these increases are not thought to be clinically relevant. Seville orange juice did not alter indinavir pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Amprenavir and Fosamprenavir

The manufacturer of fosamprenavir notes that taking amprenavir with grapefruit juice was not associated with clinically significant changes in plasma amprenavir pharmacokinetics.¹ Note that fosamprenavir is metabolised to amprenavir in the gut.

(b) Indinavir

In a single-dose study in 10 healthy subjects grapefruit juice (8 oz, about 200 mL) reduced the AUC of indinavir 400 mg by 27%, although this was not considered clinically significant.² Conversely, in another study in 13 healthy subjects, grapefruit juice or Seville orange juice (both about 200 mL) had no effect on the pharmacokinetics of indinavir. In this study indinavir 800 mg was given every 8 hours for 4 doses; with water, grapefruit juice, or Seville orange juice given with the last 2 doses.³ Similarly, in 15 HIV-positive subjects, grapefruit juice (about 150 mL of double strength) had no effect on the steady-state pharmacokinetics of indinavir (a non-significant 4.8% increase in AUC was seen).⁴

(c) Saquinavir

In a study of the effects of the concurrent use of grapefruit juice 400 mL and saquinavir (*Invirase*; hard capsules) 600 mg, grapefruit juice was found to increase the AUC of saquinavir by 50%, possibly by affecting the cytochrome P450 isoenzyme CYP3A4 in the intestine.⁵ The manufacturer notes that the increase was 100% when double-strength grapefruit juice was used.⁶ The manufacturer says that these increases are unlikely to be clinically relevant, and no dosage adjustment is necessary.⁶ Various components of grapefruit juice have been shown to inhibit the metabolism of saquinavir *in vitro*.⁷

Protease inhibitors + Macrolides

Nelfinavir approximately doubles the serum levels of azithromycin, but the clinical significance of this is uncertain. Single doses of azithromycin have no effect on the levels of indinavir and nelfinavir. Ritonavir and atazanavir increase clarithromycin levels. Amprenavir, indinavir and saquinavir do not have a clinically significant effect on clarithromycin pharmacokinetics. Clarithromycin has no important effect on the pharmacokinetics of amprenavir, atazanavir, darunavir, indinavir or ritonavir, but it increases tipranavir levels. Although both clarithromycin and erythromycin markedly raise saquinavir levels, this is not considered clinically important for short courses of these antibacterials.

Clinical evidence

(a) Azithromycin

1. *Indinavir*. A single 1.2-g dose of azithromycin had no effect on the pharmacokinetics of indinavir in healthy subjects who had taken indinavir 800 mg three times daily for 5 days.¹

2. *Nelfinavir*. A single 1.2-g dose of azithromycin was given to 12 healthy subjects who had taken nelfinavir 750 mg every 8 hours for 8 days. The pharmacokinetics of nelfinavir were minimally affected, but the AUC and maximum serum levels of azithromycin were about doubled.²

(b) Clarithromycin

1. *Amprenavir*. In a study in 12 healthy adults, amprenavir 1.2 g twice daily was given with clarithromycin 500 mg twice daily, for 4 days. The AUC and maximum serum levels of amprenavir were increased by 18% and 15%, respectively, whereas the pharmacokinetics of clarithromycin were not significantly altered. None of the changes were considered to be clinically significant.³

2. *Atazanavir*. The concurrent use of atazanavir 400 mg once daily and clarithromycin 500 mg twice daily for 4 days increased the AUC of clarithromycin by 94%, and reduced the AUC of the active metabolite 14-hydroxyclearithromycin by 70%. In addition, there was a minor 28% increase in the AUC of atazanavir.⁴

3. *Darunavir*. The manufacturer notes that the concurrent use of clarithromycin 500 mg twice daily and darunavir/ritonavir 400/100 mg twice daily increased the AUC of clarithromycin by 57% and increased its minimum level by 174%. The active metabolite 14-hydroxyclearithromycin was not detectable. Darunavir levels were not significantly changed.^{5,6}

4. *Indinavir*. In 11 healthy subjects clarithromycin 500 mg every 12 hours, given with indinavir 800 mg every 8 hours caused no clinically important alterations in the pharmacokinetics of indinavir (the only significant change was a 52% increase in the trough level). The AUC of clarithromycin was increased by about 50%, and that of 14-hydroxyclearithromycin reduced by about 50%, but neither of these changes were considered clinically important because of the wide safety margin of clarithromycin.⁷

5. *Ritonavir*. When ritonavir 200 mg every 8 hours was given with clarithromycin 500 mg every 12 hours there were only minimal changes in ritonavir pharmacokinetics (12.5% increase in AUC and 15.3% increase in maximum plasma level). However, the AUC of clarithromycin increased by 77% with an almost total inhibition of 14-hydroxyclearithromycin formation (99.7% decrease in AUC).⁸

6. *Saquinavir*. In a study in healthy subjects the concurrent use of saquinavir soft capsules (*Fortovase*) [no longer available] 1.2 g three times daily and clarithromycin 500 mg twice daily increased the AUC and maximum serum levels of saquinavir by 177% and 187%, respectively. The AUC and maximum serum levels of clarithromycin were about 40% higher than when it was given alone.^{9,10} The manufacturer notes that there are no data on the interaction using ritonavir-boosted saquinavir hard capsules or tablets (*Invirase*).^{9,10}

7. *Tipranavir*. The manufacturer notes that tipranavir given with low-dose ritonavir increased the AUC and minimum levels of clarithromycin by 19% and 68%, respectively, and decreased the AUC of the 14-hydroxy active metabolite by over 95%. Clarithromycin more than doubled the minimum levels of tipranavir.^{11,12}

(c) Erythromycin

The concurrent use of saquinavir soft capsules (*Fortovase*) [no longer available] 1.2 g three times daily and erythromycin 250 mg four times daily doubled the AUC and maximum serum levels of saquinavir in HIV-infected subjects.¹³ The manufacturer notes that there are no data on the interaction using ritonavir-boosted saquinavir hard capsules or tablets (*Invirase*).⁹

Mechanism

Ritonavir is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 and consequently markedly inhibits the 14-hydroxylation of clarithromycin by this isoenzyme. Other protease inhibitors would be expected to interact similarly, although to a lesser degree (see also 'Antivirals', (p.772)). Clarithromycin is a moderate to weak inhibitor of CYP3A4, and generally has only a small effect on the protease inhibitors, except for saquinavir. The effect of clarithromycin on saquinavir, and nelfinavir on azithromycin may involve inhibition of P-glycoprotein.^{2,3}

Importance and management

The interaction of amprenavir or indinavir with **clarithromycin** does not appear to be clinically significant. Similarly, although large increases in saquinavir levels have been seen, the manufacturers say that for short courses no dosage adjustment is needed.^{9,10} However, with ritonavir, because the hepatic metabolism of clarithromycin is so strongly inhibited it becomes more dependent on renal clearance, therefore the interaction may be significant in patients with renal failure.⁸ The manufacturers of ritonavir and clarithromycin suggest that no dosage reductions should be needed in those with normal renal function, but they recommend a 50% reduction in the dose of clarithromycin for those with a creatinine clearance of 30 to 60 mL/minute and a 75% reduction for clearances of less than 30 mL/minute.¹⁴⁻¹⁷ Some advise avoiding clarithromycin in dosages exceeding 1 g daily.^{14,15} Similar clarithromycin dose reductions in renal impairment are recommended for ritonavir-boosted darunavir,^{5,6} and ritonavir-boosted tipranavir.^{11,12} Although there are no formal studies or specific dosage recommendations for other ritonavir-boosted protease inhibitors (fosamprenavir, lopinavir and saquinavir), similar precautions would seem prudent. Atazanavir also reduces the conversion of clarithromycin to its active metabolite, and is usually given with ritonavir. However, the UK manufacturer¹⁸ cautions that reducing the dose of clarithromycin to avoid high levels of the parent drug may result in sub-therapeutic levels of the active metabolite. The US manufacturer says that, other than for *Mycobacterium avium* complex infections, an alternative to clarithromycin should be considered.¹⁹ If the combination is used they suggest a 50% dose reduction for the clarithromycin.

The increase in **azithromycin** levels with nelfinavir is likely to be of clinical significance,² and, although the outcome is presumed to be positive, this has yet to be assessed in practice. If concurrent use is necessary, monitor for azithromycin adverse effects. Single doses of azithromycin did not affect the pharmacokinetics of nelfinavir or indinavir, and the manufacturers of a combination product of lopinavir/ritonavir do not expect a clinically significant interaction with azithromycin.^{20,21}

Despite the increases in saquinavir levels, the UK manufacturer says that no dose adjustment is needed when saquinavir is given with **erythromycin**.⁹ The UK manufacturer of nelfinavir suggests that an interaction with erythromycin is unlikely, although it cannot be excluded.²² The UK manufacturer of ritonavir suggests that because erythromycin levels may rise, due to inhibition of its metabolism by ritonavir, care should be taken if both drugs are given.¹⁴ It would seem prudent to monitor for erythromycin adverse effects. A similar warning has been issued by the UK manufacturer of amprenavir about the use of erythromycin.²³

Note that clarithromycin and erythromycin have been associated with QT prolongation, and rises in their levels may increase this risk. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Protease inhibitors + Mefloquine

Data from individual patients suggest there is no pharmacokinetic interaction between mefloquine and indinavir or nelfinavir. In pharmacokinetic studies in healthy subjects, ritonavir did not alter mefloquine pharmacokinetics, but mefloquine modestly decreased steady-state ritonavir levels.

Clinical evidence

Two HIV-positive patients using HAART, one taking **indinavir** 800 mg three times daily, the other taking **nelfinavir** 1.25 g twice daily were given mefloquine 250 mg weekly, before a trip to Africa. Mefloquine achieved therapeutic levels, and its half-life was similar to that found in healthy subjects. In addition, no consistent changes in the plasma levels of the protease inhibitors were found.¹

In 12 healthy subjects **ritonavir** 200 mg twice daily for one week had no significant effect on the pharmacokinetics of mefloquine.² Conversely, mefloquine (250 mg once daily for 3 days, then 250 mg weekly) significantly reduced the steady-state AUC, and maximum and minimum plasma levels of **ritonavir** 200 mg twice daily, by 31%, 36%, and 43%, respectively, but had no effect on the pharmacokinetics of single-dose **ritonavir**.²

Mechanism

Despite being inhibitors of the cytochrome P450 isoenzyme CYP3A4, the protease inhibitors do not appear to alter mefloquine pharmacokinetics.^{1,2} It was suggested that the decrease in ritonavir levels was due to decreased absorption, perhaps due to mefloquine-induced inhibition of bile acid production or induction of P-glycoprotein.²

Importance and management

The limited evidence suggests that protease inhibitors do not affect mefloquine pharmacokinetics. The data on the effect of mefloquine on ritonavir are less clear. Until further evidence is available, it may be prudent to closely monitor ritonavir levels/efficacy if mefloquine is required.

Protease inhibitors + Miscellaneous

Indinavir levels are raised by interleukin-2, but not affected by influenza vaccine or quinidine. Protease inhibitors are predicted to increase quinidine levels. Nelfinavir does not appear to interact with pancreatic enzyme supplements. In one case report, the combination of ritonavir/saquinavir and fusidic acid raised plasma levels of all three drugs.

Clinical evidence, mechanism, importance and management

(a) Fusidic acid

A 32-year-old HIV-positive man was admitted with suspected fusidic acid toxicity after taking fusidic acid 500 mg three times daily for one week, with his usual treatment of **ritonavir** 400 mg twice daily, **saquinavir** 400 mg twice daily and stavudine 40 mg twice daily. His plasma fusidic acid level was found to be twice the expected level, and his **ritonavir** and **saquinavir** levels were also elevated. He improved spontaneously, but

4 days later he returned with jaundice, nausea and vomiting. All medications were stopped, but after 6 days his fusidic acid level was still 1.3 times that expected, his **saquinavir** level was 16.3 micrograms/mL (expected range 1 to 4 micrograms/mL) and his **ritonavir** level was 43.4 micrograms/mL (expected range 4 to 12 micrograms/mL). He was later able to restart his antivirals without problem. It is possible that there was mutual inhibition of drug metabolism. The authors recommend avoiding this drug combination.¹ Further study is needed.

(b) Influenza vaccine

Influenza whole virus vaccine was given to 9 patients taking **indinavir** containing HAART. No significant changes were found in **indinavir** pharmacokinetics.²

(c) Interleukins

In a pharmacokinetic study in 9 HIV-positive patients, the subjects continued taking their usual antiretrovirals and were given a 4-week course of **indinavir** 800 mg three times daily followed by 3 to 12 million-unit infusions of interleukin-2 daily for 5 days. The AUC of **indinavir** increased in 8 of the 9 subjects (average increase 88%). During this time interleukin-6 was also elevated, so it was thought that the increased **indinavir** concentrations were due to the inhibitory effects of interleukin-6 on the cytochrome P450 isoenzyme CYP3A4. Increased **indinavir** trough levels were also seen in a further 8 patients not participating in the pharmacokinetic study.³

(d) Pancreatic enzymes

Combined use of pancreatic enzymes (pancrelipase 20,000 USP units, amylase 65,000 USP units and protease 65,000 USP units) and **nelfinavir** 1.25 g twice daily for 14 days resulted in no significant changes in the pharmacokinetics of **nelfinavir** in 9 HIV-positive subjects.⁴

(e) Quinidine

Quinidine sulphate 200 mg was given to 10 healthy subjects, followed 1 hour later by a single 400-mg dose of **indinavir**. Quinidine had no clinically significant effects on the pharmacokinetics of **indinavir**.⁵ However, **indinavir** is predicted to increase quinidine levels, and the US manufacturer recommends caution and monitoring of quinidine levels.⁶

Lopinavir/ritonavir is also predicted to increase quinidine levels, and the combination should be monitored.^{7,8} Similarly, **atazanavir/ritonavir**, **darunavir/ritonavir**, **amprenavir** and **fosamprenavir** are predicted to increase quinidine levels, and the UK manufacturers contraindicate the combinations^{9–11} while the US manufacturers recommend monitoring quinidine concentrations.^{12–14} Conversely, for **saquinavir/ritonavir**, the UK manufacturer recommends caution and monitoring quinidine levels,¹⁵ and the US manufacturer contraindicates the combination.¹⁶ Both the UK and US manufacturers contraindicate the use of quinidine with **nelfinavir**,^{17,18} **ritonavir**,^{19,20} or **tipranavir/ritonavir**.^{21,22}

Protease inhibitors + Protease inhibitors

Various dual combinations of protease inhibitors have been tried, or are used, to boost the levels and consequently the efficacy of one of the protease inhibitors. Ritonavir is the most potent at boosting levels of the other protease inhibitors, and current guidelines recommend the use of low-dose ritonavir in combination with atazanavir, darunavir, fosamprenavir, lopinavir, saquinavir, or tipranavir. Some protease inhibitor combinations may result in additive toxicity (indinavir and ritonavir or atazanavir). Although this monograph summarises the pharmacokinetic interactions and dosing recommendations current guidelines should be consulted when choosing protease inhibitor combinations.

Clinical evidence

A. Amprenavir or Fosamprenavir

(a) Indinavir

The steady-state AUC of amprenavir was 33% higher when amprenavir 750 or 800 mg three times daily was given with indinavir 800 mg three times daily. In this study, the AUC of indinavir was 38% lower than historical control data.¹ Similarly, in a model-based pharmacokinetic analysis of data from a clinical study, amprenavir intrinsic clearance was reduced by 54% by indinavir.² This agrees with *in vitro* data.³ It was suggested¹ that the effect of amprenavir on indinavir was due to the lipid-like formulation of amprenavir reducing the absorption of indinavir (analogous to 'food', (p.818)). The changes in amprenavir levels were not considered to be clinically relevant.¹

- No dose adjustment of amprenavir or indinavir needed.⁴
- The appropriate dose of fosamprenavir with indinavir is not established.⁵

(b) Lopinavir/Ritonavir

Preliminary data suggest that the combination of amprenavir 600 mg twice daily with lopinavir/ritonavir 400/100 mg twice daily resulted in amprenavir trough plasma levels that were lower than with the combination of amprenavir/ritonavir at the same doses. Similarly the lopinavir levels were lower than those without amprenavir.⁶ Others have reported similar findings,⁷ and increasing the dose of ritonavir did not prevent a decrease in amprenavir levels with lopinavir.⁸ Similar findings were also reported for fosamprenavir with lopinavir/ritonavir,⁹ and further study showed that separation of doses reduced the effect of amprenavir on lopinavir/ritonavir levels, but increased the effect on amprenavir levels.¹⁰ However, the manufacturer notes that combining lopinavir/ritonavir 400/100 mg with fosamprenavir/ritonavir 700/100 mg, both twice daily, increased the AUC and minimum level of lopinavir by 37% and 52%, respectively, whereas the AUC and minimum level of amprenavir were decreased by 63% and 65%, respectively.^{5,11} In addition, the US manufacturer says that the rate of adverse effects was higher with this combination.⁵

- An optimum dosage for concurrent use has not been established. A dose increase of lopinavir/ritonavir *oral solution* to 533/133 mg twice daily (dose rounded to 6.5 mL) or 600/150 mg twice daily may be needed if amprenavir is given. Avoid once daily regimens.¹²
- An optimum dosage for concurrent use has not been established.^{5,12} A dose increase of lopinavir/ritonavir *tablets* to 600/150 mg twice daily may be needed if fosamprenavir is given.¹²

(c) Nelfinavir

The trough concentration of amprenavir 750 or 800 mg three times daily was increased by 189% by nelfinavir 750 mg three times daily, but the AUC and maximum level of amprenavir were not significantly altered. In this study, the pharmacokinetics of nelfinavir were not altered when compared with historical control data.¹ In a model-based pharmacokinetic analysis of data from a clinical study, amprenavir intrinsic clearance was

reduced by about 40% by nelfinavir,² which agrees with *in vitro* data.³ The increase in amprenavir trough concentration could result in improved antiviral efficacy, but further study is needed.¹

- No dose adjustment of either drug is needed when amprenavir is given with nelfinavir (UK).^{4,13}
- Appropriate dose of fosamprenavir with nelfinavir is not established.⁵

(d) Ritonavir

The AUC, minimum, and maximum levels of amprenavir 1.2 g twice daily were increased by 131%, 484%, and 33%, respectively, by ritonavir 200 mg twice daily.⁴ This agrees with *in vitro* data.³ The manufacturer recommends that doses of both protease inhibitors be reduced when they are used together.^{4,14} Based on modelling of pharmacokinetic data, a dose of amprenavir 600 mg with ritonavir 100 mg, both twice daily, has been suggested.¹⁵ This combination has shown good clinical efficacy in at least one study,¹⁶ and resulted in satisfactory amprenavir levels when efavirenz was also used¹⁷ (see also 'NNRTIs + Protease inhibitors', p.785). Amprenavir levels with fosamprenavir/ritonavir 700/100 mg twice daily were similar to those achieved with amprenavir/ritonavir 600/100 mg twice daily.¹⁸

- If ritonavir is given as a pharmacokinetic booster the recommended dose is amprenavir/ritonavir 600/100 mg twice daily.
- If ritonavir is given as a pharmacokinetic booster the recommended dose is fosamprenavir/ritonavir 700/100 mg twice daily.⁵

(e) Saquinavir

The steady-state AUC of amprenavir was reduced by 32% when amprenavir 750 or 800 mg three times daily was given with saquinavir (soft gel capsule) 800 mg three times daily, and the maximum plasma level was reduced by 37%. In this study, the pharmacokinetics of saquinavir were not changed when compared with historical control data.¹ In a model-based pharmacokinetic analysis of data from a clinical study, amprenavir intrinsic clearance was not altered by saquinavir,² which agrees with *in vitro* data.³ It was suggested that, as amprenavir was given with 'food', (p.818), in the first study, this may have accounted for the reduced amprenavir levels.¹

- No dose adjustment of amprenavir or saquinavir is needed when they are given together.⁴
- Appropriate dose of fosamprenavir with saquinavir not established.⁵

(f) Tipranavir with Ritonavir

In a clinical study of dual-boosted protease inhibitor combination therapy in multiple-treatment experienced HIV-positive adults there was a 55% reduction in minimum amprenavir levels when tipranavir/ritonavir 500/200 mg twice daily was added to amprenavir/ritonavir 600/100 mg twice daily.^{19,20} Therefore the use of tipranavir/ritonavir with amprenavir/ritonavir is not recommended, as the clinical relevance of the reduction in amprenavir levels has not been established. If the combination is nevertheless considered necessary, a monitoring of the plasma levels of the protease inhibitors is strongly encouraged.²⁰

- Combination not recommended.

B. Atazanavir

(a) Darunavir with Ritonavir

The manufacturer notes that combining atazanavir 300 mg once daily with darunavir/ritonavir 400/100 mg twice daily did not significantly alter the AUC and minimum level of darunavir. In addition, the AUC and minimum level of atazanavir were not significantly changed, when compared with atazanavir/ritonavir 300/100 mg once daily alone, although the minimum level was increased by 52%.^{21,22}

- No dose change needed.^{21,22}

(b) Indinavir

There are no pharmacokinetic data on the combination of atazanavir plus indinavir, but it is predicted that there may be an additive risk of hyperbilirubinaemia, so the combination is not recommended.²³⁻²⁵

- Combination not recommended.

(c) Ritonavir

The addition of ritonavir 100 mg to atazanavir 300 mg increased the AUC of atazanavir about twofold, and the trough plasma level sevenfold, in healthy subjects. The effect on the trough level was less marked in patients (about a threefold increase).²³ The manufacturer of atazanavir recom-

mends that it is given with ritonavir when used in patients who have already received antiretroviral treatment.^{23,24}

- Ritonavir is recommended as a pharmacokinetic booster with atazanavir.

(d) Saquinavir

The addition of atazanavir 400 mg once daily to saquinavir soft capsules 1.2 g once daily increased the AUC of saquinavir about 5.5-fold, and the trough plasma level sevenfold.²⁴ However, the manufacturer notes that a regimen including this combination did not provide adequate efficacy.²⁴

- Not an effective combination

(e) Tipranavir with Ritonavir

The manufacturer notes that concurrent use of atazanavir 300 mg once daily with tipranavir/ritonavir 500/100 mg twice daily increased tipranavir exposure (minimum plasma level by 75%) and ritonavir exposure (AUC by 51%) while markedly reducing atazanavir exposure (AUC by 68%, and minimum level by 81%). Consequently, this combination is not recommended.²⁰

- Combination not recommended.

C. Darunavir with Ritonavir

(a) Indinavir

The manufacturer notes that combining indinavir 800 mg twice daily with darunavir/ritonavir 400/100 mg twice daily increased the AUC and minimum level of darunavir by 24% and 44%, respectively. In addition, the AUC and minimum level of indinavir were increased by 23% and 125%, respectively, when compared with indinavir/ritonavir 800/100 mg twice daily alone.^{21,22}

- No dose change is usually needed. Decreasing the dose of indinavir to 600 mg twice daily may be necessary if the combination is poorly tolerated.²¹

(b) Lopinavir/Ritonavir

The manufacturer notes that combining lopinavir/ritonavir 400/100 mg with darunavir/ritonavir 300/100 mg, both twice daily, increased the AUC and minimum level of lopinavir by 37% and 72%, respectively, whereas the AUC and minimum level of darunavir were decreased by 53% and 65%, respectively.^{21,22}

- Combination not recommended.^{21,22}

(c) Saquinavir

The manufacturer notes that combining saquinavir hard capsules 1 g twice daily with darunavir/ritonavir 400/100 mg twice daily decreased the AUC and minimum level of darunavir by 26% and 42%, respectively. The levels of saquinavir were not changed when compared with using saquinavir/ritonavir 1000/100 mg twice daily alone.^{21,22}

- Combination not recommended.^{21,22}

D. Indinavir

(a) Lopinavir/Ritonavir

Indinavir 600 mg twice daily in combination with lopinavir/ritonavir 400/100 mg twice daily produced a similar indinavir AUC, higher minimum level (by 3.5-fold) and 29% lower maximum level relative to indinavir 800 mg three times daily alone.^{12,26} Based on historical comparisons, lopinavir levels were similar to those seen without indinavir.²⁶

- Reduce the dose to indinavir 600 mg twice daily if lopinavir/ritonavir given.¹²

(b) Nelfinavir

The combination of indinavir 1.2 g every 12 hours with nelfinavir 1.25 g every 12 hours produced plasma levels that were equivalent to the standard dose of indinavir 800 mg every 8 hours in HIV-positive subjects. This suggests that nelfinavir only modestly inhibits indinavir metabolism. In this multiple-dose study, indinavir did not affect the pharmacokinetics of nelfinavir.²⁷ In contrast, a single 750-mg dose of nelfinavir, given after indinavir 800 mg every 8 hours for 7 days resulted in an 83% increase in the AUC of nelfinavir and a 22% increase its elimination half-life. In addition, administration of a single 800-mg dose of indinavir after nelfinavir 750 mg three times daily for 7 days resulted in a 51% increase in the indinavir plasma AUC, with a fivefold increase in trough concentrations measured at 8 hours, but no increase in peak concentrations.^{13,28}

- Appropriate dose of indinavir with nelfinavir not established.²⁹

(c) Ritonavir

The effects of a range of doses of ritonavir (200, 300, or 400 mg every 12 hours) on indinavir pharmacokinetics were assessed in 39 healthy subjects. The AUC of indinavir 400 or 600 mg was increased two- to fivefold by the ritonavir. It is suggested that the combination of indinavir 400 mg every 12 hours with ritonavir 400 mg every 12 hours will result in an AUC of indinavir roughly equivalent to that of indinavir 800 mg every 8 hours, without any effect on the pharmacokinetics of ritonavir.³⁰ In another similar study, when compared with historical data for indinavir 800 mg every 8 hours, the AUC of indinavir was at least 1.4-, 2.3-, and 3.3-fold higher when given indinavir/ritonavir in twice daily doses of 400/400 mg, 800/100 mg, and 800/200 mg, respectively. The regimens also produced markedly higher trough indinavir levels. The 800/100 mg regimen was the best tolerated.³¹

- If ritonavir is given as a pharmacokinetic booster the recommended dose is indinavir/ritonavir 800/100 or 200 mg twice daily.^{31,32}
- Caution is needed when indinavir is used at a dose of 800 mg twice daily with ritonavir, because of the possibility of an increased risk of nephrolithiasis.^{29,33} Appropriate hydration is strongly recommended.³³
- The US guidelines say that the combination is not recommended as part of initial therapy because of the risk of nephrolithiasis.²⁵

(d) Saquinavir

In a single-dose study, the concurrent use of indinavir and saquinavir 600 mg (hard capsule) or 800 mg or 1.2 g (soft capsule) increased the AUC of saquinavir by 500%, 620% and 360%, respectively.³³ This is supported by *in vitro* data.³⁴ However, in another *in vitro* study of antiviral activity, the combination of saquinavir and indinavir was antagonistic.³⁵ Further study is needed.

- Appropriate dose of indinavir with saquinavir not established.²⁹

E. Lopinavir/Ritonavir

(a) Nelfinavir

The US manufacturer notes that the concurrent use of nelfinavir 1 g twice daily and lopinavir/ritonavir 400/100 mg twice daily resulted in similar nelfinavir pharmacokinetics to nelfinavir 1.25 g twice daily alone, but with markedly increased levels of the M8 metabolite of nelfinavir. Lopinavir levels were modestly reduced (27% decrease in AUC and 38% decrease in minimum level).¹²

- Dosage decrease of nelfinavir to 1 g twice daily recommended. Avoid once daily regimens. A dose increase of lopinavir/ritonavir *oral solution* to 533/133 mg twice daily or lopinavir/ritonavir *tablets* to 600/150 mg twice daily may be needed.¹²

(b) Ritonavir

Ritonavir is used to increase the plasma levels of lopinavir. The marketed dose combination is lopinavir/ritonavir 400/100 mg twice daily.^{12,26} When an additional 100 mg of ritonavir twice daily was added to the marketed combination, the AUC of lopinavir increased by 33% and the trough concentration by 64%.²⁶

- The use of lopinavir with ritonavir as a pharmacokinetic enhancer is established. The dose of additional ritonavir is not established.

(c) Saquinavir

Saquinavir 800 mg twice daily given with lopinavir/ritonavir produced a 9.6-fold increase in saquinavir AUC relative to saquinavir 1.2 g three times daily given alone. When compared with saquinavir/ritonavir 1000/100 mg twice daily, the increase in saquinavir AUC was about 30%, and was similar to that reported after saquinavir/ritonavir 400/400 mg twice daily. When saquinavir 1.2 g twice daily was combined with lopinavir/ritonavir, no further increase of concentrations was noted. Lopinavir levels did not appear to be affected by saquinavir, based on historical comparison with lopinavir/ritonavir alone.²⁶

- In the US, the manufacturer recommends that saquinavir 1 g twice daily be used with lopinavir/ritonavir 400/100 mg twice daily.¹²

(d) Tipranavir with Ritonavir

In a clinical study of dual-boosted protease inhibitor combination therapy in multiple-treatment experienced HIV-positive adults there was a 70% reduction in minimum lopinavir levels when tipranavir/ritonavir 500/200 mg twice daily was added to lopinavir/ritonavir 400/100 mg

twice daily.^{19,20} The clinical relevance of the reduction in lopinavir levels has not been established.

- Combination not recommended, but if it is given monitoring the plasma levels of the protease inhibitors is strongly encouraged.²⁰

E. Nelfinavir

(a) Ritonavir

Single-dose data indicate that ritonavir increases the AUC of nelfinavir by 1.8- to 2.5-fold, whereas the AUC of ritonavir is unchanged.³⁶ In a multiple-dose study in healthy subjects, ritonavir 100 or 200 mg twice daily increased the steady-state AUC of nelfinavir 1.25 g twice daily by 20% and 39%, after morning and evening doses, respectively. The AUC of the M8 metabolite of nelfinavir was increased by 74% and 86%, respectively. There was no difference in the effect of the two doses of ritonavir on nelfinavir AUC.³⁷

- Appropriate dose of nelfinavir with ritonavir not established.²⁸

(b) Saquinavir

A single 1.2-g dose of saquinavir (soft gel capsules), given after 3 days of nelfinavir 750 mg every 8 hours had no effect on the pharmacokinetics of nelfinavir, but the nelfinavir caused a fourfold increase in the AUC of saquinavir.³⁸ Similar two- to twelvefold increases have been found in other studies in HIV-positive subjects.³⁹⁻⁴² A study in which 157 patients received 12 weeks of combined saquinavir/nelfinavir treatment (doses unstated) found that the combination was well tolerated.⁴³ It appears that nelfinavir inhibits the hepatic clearance of saquinavir.⁴⁴

- Appropriate dose of nelfinavir with saquinavir not established.²⁸

F. Ritonavir

(a) Saquinavir

A study in 6 patients with advanced HIV disease found that while taking saquinavir 600 mg three times daily the addition of ritonavir 300 mg twice daily increased the maximum saquinavir plasma levels 33-fold, and increased the AUC 58-fold at steady state.⁴⁵ A pilot study in HIV-positive patients given both drugs together (saquinavir 800 mg daily, ritonavir 400 to 600 mg daily) found that the ritonavir serum levels were unaffected. However, the saquinavir levels were substantially higher than those achieved with saquinavir alone in daily doses of 3.6 to 7.2 g.⁴⁶ A study of a range of ritonavir and saquinavir (*Invirase*) doses (200 to 600 mg) in 57 healthy subjects found that saquinavir did not affect ritonavir pharmacokinetics, but ritonavir increased the AUC of saquinavir 50 to 132-fold. The authors suggested that giving both drugs in the dosage 400 mg every 12 hours might be optimal.⁴⁷ Subsequent study has revealed that the effect of ritonavir on saquinavir is not related to the ritonavir dose in the range of 100 to 400 mg twice daily,⁴⁸⁻⁵⁰ and that the use of a combination with a higher dose of saquinavir and a lower dose of ritonavir may be preferable, as the lower doses of ritonavir are associated with fewer adverse effects.⁵⁰ A dose of saquinavir 1 g twice daily with ritonavir 100 mg twice daily is suggested by the manufacturer of saquinavir.^{51,52} The UK manufacturer of ritonavir also says that doses of ritonavir higher than 100 mg twice daily should not be used in combination with saquinavir,⁵³ whereas the US manufacturer of ritonavir gives information solely on the saquinavir/ritonavir 400/400 or 600 mg twice daily regimen.⁵⁴ The UK manufacturer of ritonavir notes that higher doses of ritonavir have been associated with an increased incidence of adverse events. Concurrent use of saquinavir and ritonavir has led to severe adverse events, mainly diabetic ketoacidosis and liver disorders, especially in patients with pre-existing liver disease.⁵³

- When ritonavir is given as a pharmacokinetic booster the recommended dose is saquinavir/ritonavir 1000/100 mg twice daily. Higher ritonavir doses are associated with increased adverse effects.⁵³

G. Saquinavir with Ritonavir

(a) Tipranavir with Ritonavir

In a clinical study of dual-boosted protease inhibitor combination therapy in multiple-treatment experienced HIV-positive adults there was a marked, approximately 80%, reduction in minimum saquinavir levels when tipranavir/ritonavir 500/200 mg twice daily was added to saquinavir/ritonavir 600/100 mg twice daily.^{19,20} The clinical relevance of the reduction in saquinavir levels has not been established.

- Combination is not recommended, but if it is given monitoring the plasma levels of the protease inhibitors is strongly encouraged.²⁰

Mechanism

Protease inhibitors are inhibitors and substrates of the cytochrome P450 isoenzyme CYP3A4, with ritonavir being the most potent inhibitor and saquinavir the least (see 'Antivirals', (p.772)). They probably interact by inhibiting each other's gut (pre-absorption) and hepatic (post-absorption) metabolism, so resulting in increased absorption and decreased elimination.^{44,47} A mechanism involving inhibition of P-glycoprotein may also be involved.⁴⁴

Importance and management

Ritonavir inhibits the metabolism of amprenavir (and amprenavir derived from fosamprenavir), atazanavir, darunavir, indinavir, lopinavir, nelfinavir, tipranavir, and especially saquinavir. Ritonavir is therefore used in combination with other protease inhibitors to boost their levels, and allow a reduction in the protease inhibitor dose and the frequency of dosing. In US guidelines, the combination of atazanavir with ritonavir, fosamprenavir with ritonavir or lopinavir with ritonavir are currently the protease inhibitors preferred as alternative options to efavirenz for use with dual NRTIs for the treatment of HIV-infection in treatment naïve patients. Ritonavir-boosted saquinavir is considered inferior to the preferred options.²⁵ In UK guidelines, dual NRTIs plus a boosted protease inhibitor is a recommended alternative option to dual NRTIs plus efavirenz. The preferred boosted protease inhibitors are lopinavir with ritonavir and fosamprenavir with ritonavir, with saquinavir plus ritonavir as an alternative regimen, and atazanavir plus ritonavir recommended for specific groups.⁵⁵ The newer ritonavir-boosted protease inhibitors, darunavir and tipranavir are not currently recommended as initial therapy, and are used in extensively pre-treated patients with resistance to other protease inhibitors. The US guidelines state that ritonavir-boosted indinavir should be avoided because of a high incidence of nephrolithiasis, and that atazanavir plus indinavir should never be used because of potential additive hyperbilirubinaemia.²⁵ There appears to be no clinically important pharmacokinetic interactions between amprenavir with indinavir, nelfinavir, or saquinavir, between atazanavir with darunavir and ritonavir, and probably also indinavir with nelfinavir. Various dual ritonavir-boosted protease inhibitor combinations act to lower the levels of one of the protease inhibitors and should therefore probably be avoided. These include lopinavir/ritonavir with amprenavir or fosamprenavir, darunavir/ritonavir with lopinavir/ritonavir or saquinavir, and tipranavir/ritonavir with ritonavir-boosted amprenavir, lopinavir or saquinavir, or with atazanavir. When considering appropriate protease inhibitor combinations, in addition to pharmacokinetic interactions, cross resistance patterns and adverse effects should also be considered.

Protease inhibitors + Rifamycins

Rifabutin bioavailability is increased by amprenavir, atazanavir, fosamprenavir/ritonavir, indinavir, lopinavir/ritonavir, nelfinavir, tipranavir/ritonavir, and especially ritonavir, with an increased risk of toxicity. Rifabutin modestly decreases the bioavailability of indinavir, nelfinavir, and particularly saquinavir (with an increased risk of therapeutic failure), but has no effect on amprenavir, atazanavir, and ritonavir-boosted fosamprenavir. The combination of rifabutin with protease inhibitors may be used, but dosage adjustments of rifabutin or both drugs are often necessary.

Rifampicin (rifampin) bioavailability is increased by indinavir, but amprenavir has no effect. Rifampicin markedly reduces the bioavailability of amprenavir, atazanavir/ritonavir, indinavir, indinavir with ritonavir, lopinavir/ritonavir, nelfinavir and saquinavir, but only modestly reduces that of ritonavir. The effects of rifampicin on lopinavir/ritonavir and saquinavir/ritonavir can be overcome by increasing the protease inhibitor dose, but this appears to increase adverse effects (hepatotoxicity).

Clinical evidence

(a) Amprenavir or Fosamprenavir

1. *Rifabutin*. When amprenavir 1.2 g twice daily was given with rifabutin 300 mg daily to 11 healthy subjects for 10 days there was an almost three-fold increase in the AUC of rifabutin, but the pharmacokinetics of amprenavir were not significantly altered. The combination was poorly tolerated, with 5 of 11 subjects stopping treatment between days 1 and 9 due to adverse events.¹ When reduced doses of rifabutin (150 mg every other day) were given with fosamprenavir/ritonavir 700/100 mg twice daily the rifabutin AUC was unchanged and the maximum level was decreased by 14%, when compared with rifabutin 300 mg once daily given alone. However, the 25-*O*-desacetyl-rifabutin AUC and maximum level were increased 11-fold and sixfold, respectively, which could potentially lead to an increase of rifabutin-related adverse events such as uveitis. Based on historical comparison, rifabutin did not appear to reduce amprenavir exposure from fosamprenavir/ritonavir.^{2,3}

2. *Rifampicin (Rifampin)*. When 11 healthy subjects were given amprenavir 1.2 g twice daily with rifampicin 600 mg daily to for 4 days the pharmacokinetics of rifampicin were not affected, but the AUC of amprenavir was reduced by 82%. The maximum plasma level of amprenavir was also reduced by 70%, from 9.2 to 2.78 micrograms/mL.¹

It is expected that concurrent use of fosamprenavir or fosamprenavir/ritonavir with rifampicin will also result in large decreases in plasma concentrations of amprenavir.^{2,3}

(b) Atazanavir

1. *Rifabutin*. The manufacturer notes that atazanavir 400 mg daily given with rifabutin 150 mg once daily for 14 days did not have any important effect on the AUC of atazanavir. However, the AUC of rifabutin 150 mg was 2.3-fold higher than historical data for a standard 300-mg dose.⁴

2. *Rifampicin (Rifampin)*. When rifampicin 600 mg daily was given with atazanavir/ritonavir 300/100 mg once daily, the AUC and minimum levels of atazanavir were markedly reduced, by 72% and 98%, respectively.⁵

(c) Darunavir

Although there are no data, the manufacturer predicts that **rifabutin** will decrease ritonavir-boosted darunavir levels, and that darunavir/ritonavir will increase rifabutin levels. They also predict that **rifampicin** will markedly reduce ritonavir-boosted darunavir levels.^{6,7}

(d) Indinavir

1. *Rifabutin*. When 10 healthy subjects were given rifabutin 300 mg once daily with indinavir 800 mg every 8 hours to for 10 days, the indinavir maximum serum levels and AUC were reduced by about one-third, whereas the rifabutin maximum serum levels and AUC were increased two-

threefold.⁸ When the same dose of indinavir (800 mg every 8 hours) was given with half the dose of rifabutin (150 mg once daily), the AUC of indinavir was similarly reduced (by 32%), but the increase in the AUC of rifabutin was less (54% increase).⁸ In a further study, the pharmacokinetics of indinavir 1 g every 8 hours (increased dose) and rifabutin 150 mg daily (reduced dose) were investigated in healthy and HIV-positive subjects. The indinavir AUC was the same with this increased dose as with indinavir 800 mg every 8 hours alone. However, despite halving the rifabutin dose, the AUC was still up to 70% higher than with the 300-mg dose alone.⁹ When the combination was used in practice, there were no treatment failures in 25 patients being treated with rifabutin while receiving HAART (containing indinavir and/or nelfinavir). The rifabutin was given as 300 mg twice weekly and the indinavir dose was increased from 800 mg to 1.2 g every 8 hours to achieve satisfactory levels.¹⁰

2. *Rifampicin (Rifampin)*. A study in 11 AIDS patients given indinavir 800 mg every 8 hours and rifampicin 600 mg daily for 14 days found that the AUC of rifampicin was increased by 73%.¹¹ In a similar study looking at the effects of the rifampicin on indinavir, the indinavir AUC and maximum serum levels were decreased by 92% and 86%, respectively.¹² In another study, giving rifampicin 300 mg daily for 4 days to 6 HIV-positive patients already receiving ritonavir-boosted indinavir (indinavir/ritonavir 800/100 mg twice daily) decreased the median indinavir plasma levels (measured 12 hours after the last dose) by 87% and the median ritonavir levels by 94%.¹³

(e) Lopinavir

1. *Rifabutin*. When healthy subjects were given lopinavir/ritonavir 400/100 mg twice daily with rifabutin 150 or 300 mg daily for 10 days the AUC of rifabutin was increased threefold and the AUC of lopinavir was increased by 17%.¹⁴

2. *Rifampicin (Rifampin)*. Rifampicin 600 mg daily for 10 days decreased the AUC of lopinavir (given as lopinavir/ritonavir 400/100 mg twice daily) by 75% in a study in healthy subjects.¹⁴ A dose titration of lopinavir/ritonavir was carried out in healthy subjects to try and overcome the interaction with rifampicin.¹⁵ In 10 evaluable subjects, use of rifampicin 600 mg daily with lopinavir/ritonavir 800/200 mg twice daily decreased the minimum lopinavir level by 57% without affecting the maximum level, when compared with lopinavir/ritonavir 400/100 mg twice daily without rifampicin. In another 9 evaluable subjects, rifampicin 600 mg daily with lopinavir/ritonavir 400/400 mg twice daily did not alter the maximum or minimum level of lopinavir, but markedly increased ritonavir levels, when compared with lopinavir/ritonavir 400/100 mg twice daily without rifampicin. Of 29 subjects who received the adjusted doses of lopinavir/ritonavir with rifampicin, 9 subjects had grade 2 to 3 elevations in liver enzymes, and this was more common in the lopinavir/ritonavir 400/400 mg group than the lopinavir/ritonavir 800/200 mg group.¹⁵

(f) Nelfinavir

1. *Rifabutin*. When rifabutin 300 mg daily for 8 days was given with nelfinavir 750 mg every 8 hours for 7 to 8 days, the nelfinavir AUC was reduced by 32% and the rifabutin AUC was increased by 207%.¹⁶ When nelfinavir 750 mg every 8 hours was given with half the dose of rifabutin (150 mg daily), the nelfinavir AUC was reduced by a similar amount (23%), whereas the rifabutin AUC was increased by a lower amount (83%).^{17,18}

2. *Rifampicin (Rifampin)*. Rifampicin 600 mg daily for 7 days decreased the AUC of nelfinavir 750 mg every 8 hours for 6 days by 82%.¹⁶ A 7-month-old infant with HIV and tuberculosis was given a rifampicin-based antimycobacterial regimen with nelfinavir-based HAART. Nelfinavir plasma levels were found to be very low, so ritonavir was added. This improved nelfinavir levels, and also greatly increased those of the principal active metabolite of nelfinavir. The regimen was well tolerated and had a good clinical response.¹⁹

(g) Ritonavir

1. *Rifabutin*. In a study in 5 healthy subjects when ritonavir 500 mg twice daily was given with rifabutin 150 mg daily for 8 days, the maximum serum level of rifabutin was increased threefold and the AUC was increased fourfold (and the AUC of its active metabolite, 25-*O*-desacetylirifabutin, 35-fold). Seven subjects had to be withdrawn due to adverse events, primarily leucopenia.²⁰ Retrospective analysis of regimens containing ritonavir found that the concurrent use of rifabutin was associated with a higher incidence of rifabutin-related adverse effects including arthralgia, joint stiffness, uveitis and leucopenia.²¹

2. *Rifampicin (Rifampin)*. When ritonavir 500 mg every 12 hours was given with rifampicin 300 or 600 mg daily for 10 days, the AUC of ritonavir was 35% lower and the maximum level 25% lower than in subjects receiving ritonavir alone.²²

(h) Saquinavir

1. *Rifabutin*. The AUC of saquinavir 600 mg three times daily was reduced by about 40% by rifabutin 300 mg daily, in 12 HIV-positive subjects.²³ Similarly, the AUC of saquinavir (soft capsules) 1.2 g three times daily was decreased by 47% by rifabutin 300 mg once daily in 14 HIV-positive patients. In addition, the rifabutin AUC was increased by 44% by saquinavir.²⁴ However, combined use of ritonavir and saquinavir (hard capsules), both 400 mg twice daily, with intermittent rifabutin dosing (300 mg weekly or 150 mg every 3 days) for 8 weeks was reported to be safe and manageable. Rifabutin did not significantly alter the protease inhibitor levels, and the rifabutin pharmacokinetics were similar to those usually seen with rifabutin 300 mg daily alone.²⁵

2. *Rifampicin (Rifampin)*. Rifampicin 600 mg once daily decreased the AUC of saquinavir (soft capsules) 1.2 g three times daily by 70%.²⁶ It was suggested that the combination of ritonavir and saquinavir (both 400 mg twice daily) could cancel out the effects of rifampicin on saquinavir, so therapeutic levels of all three drugs could be achieved. This assumption has been confirmed in HIV-positive patients.^{27,28} Five of 20 patients originally given the combination developed hepatotoxicity, 2 of whom had comorbidities.²⁸ However, in a further study in healthy subjects, severe hepatotoxicity with transaminase elevations of about 20 times the upper limit of normal occurred in 11 of 17 subjects after they took saquinavir/ritonavir 1000/100 mg twice daily with rifampicin 600 mg once daily for 1 to 5 days.^{29,30}

(i) Tipranavir

The manufacturer notes that tipranavir/ritonavir 500/200 mg twice daily increased plasma rifabutin levels by up to threefold, and its active metabolite by up to 20-fold after a single 150-mg dose of rifabutin.^{31,32}

Although there are no data, the manufacturer predicts that rifampicin will markedly reduce ritonavir-boosted tipranavir levels.^{31,32}

Mechanism

Rifampicin is a potent inducer of the cytochrome P450 isoenzyme CYP3A4, by which the protease inhibitors are at least partially metabolised, and therefore it markedly reduces protease inhibitor levels. Rifabutin is a weak inducer of CYP3A4. The protease inhibitors are inhibitors of CYP3A4, with ritonavir being the most potent, and can therefore increase the levels of the rifamycins.

Importance and management

Established interactions of clinical importance. The protease inhibitors increase the levels of rifabutin, with a consequent increase in adverse effects unless the rifabutin dose is reduced. Ritonavir is the most potent protease inhibitor in this regard, and the combination has been considered contraindicated. However, the CDC in the US say that the combination may be used if the dose of rifabutin is markedly reduced.³³ In addition, rifabutin decreases the levels of some protease inhibitors, particularly saquinavir, increasing the risk of treatment failure. Rifabutin should not be used when saquinavir is the sole protease inhibitor (no longer recommended). However, there is some evidence that rifabutin can be used with ritonavir-boosted saquinavir. 'Table 21.5', (p.827) summarises the clinical recommendations for the concurrent use of protease inhibitors and rifabutin. Therapy should be well monitored. Note that, in one analysis, the use of rifabutin 150 mg twice weekly with low-dose ritonavir and a second protease inhibitor was associated with low rifabutin levels.³⁴ Recommended doses of rifabutin in patients taking ritonavir-boosted protease inhibitors are 150 mg every other day or three times per week.³⁵

Rifampicin markedly reduces the levels of many of the protease inhibitors, and its use with unboosted protease inhibitors should be avoided, because of the risk of reduced antiviral efficacy and emergence of resistant viral strains. There are limited data to suggest that ritonavir as the sole protease inhibitor, or ritonavir used as a pharmacokinetic enhancer with other protease inhibitors such as saquinavir, can be used with rifampicin.³³ However, further study has shown a high incidence of hepatotoxicity with saquinavir/ritonavir 1000/100 mg twice daily and rifampicin, and the manufacturers of ritonavir and saquinavir advise that these drugs should not be given together with rifampicin.^{22,29,30,35} Current UK guidelines state that, until more data are available, ritonavir-boosted protease inhibi-

Table 21.5 Summary of the manufacturers' dosage recommendations (unless stated otherwise) for combined use of protease inhibitors and rifamycins

Protease inhibitor	Rifabutin	Rifampicin	Refs
Protease inhibitors			
Amprenavir	Rifabutin dose at least halved (150 mg daily or every other day, or 300 mg three times per week). Amprenavir dose unchanged.	Not recommended (amprenavir levels markedly reduced).	1-3
Fosamprenavir	Rifabutin dose at least halved (150 mg daily or 300 mg three times per week). Fosamprenavir dose unchanged.	Not recommended (amprenavir levels expected to be markedly reduced).	3-5
Indinavir	Rifabutin dose halved (150 mg daily or 300 mg three times per week). Indinavir dose increased (1 to 1.2 g every 8 hours).	Not recommended (indinavir levels markedly reduced, rifampicin levels raised).	3, 6-8
Nelfinavir	Rifabutin dose at least halved (150 mg once daily or 300 mg three times per week). Nelfinavir dose unchanged (1.25 g twice daily preferred) or increase to 1 g every 8 hours.	Not recommended (nelfinavir levels markedly reduced).	3, 9, 10
Ritonavir alone	Rifabutin dose reduced by at least 75% (150 mg every other day or three times per week). Further dose reductions may be necessary.* Ritonavir dose unchanged.	May be used at usual doses, although limited data (ritonavir levels reduced). May lead to loss of virologic response.	3, 11
Saquinavir alone	Not recommended (saquinavir levels reduced).	Not recommended (saquinavir levels markedly reduced).	3
Ritonavir boosted protease inhibitors			
Atazanavir/ritonavir	Rifabutin dose reduced by up to 75% (150 mg every other day or three times per week). Atazanavir/ritonavir dose unchanged.	Not recommended (atazanavir levels markedly reduced).	3, 12, 13
Darunavir/ritonavir	Rifabutin dose reduced to 150 mg every other day.	Not recommended (darunavir levels predicted to be markedly reduced).	14, 15
Fosamprenavir/ritonavir	Rifabutin dose reduced by at least 75% (150 mg every other day or three times per week). Fosamprenavir/ritonavir dose unchanged.	Not recommended (amprenavir levels predicted to be markedly reduced).	3-5
Indinavir/ritonavir	Rifabutin dose reduced by at least 75% (150 mg every other day or three times per week). Indinavir/ritonavir dose unchanged.	Not recommended (indinavir levels markedly reduced).	3, 16
Lopinavir/ritonavir	Rifabutin dose reduced by at least 75% (150 mg every other day or three times per week). Lopinavir/ritonavir dose unchanged.	Not recommended (lopinavir levels markedly reduced). However, adjusted doses of lopinavir/ritonavir (800/200 mg or 400/400 mg twice daily) may overcome the pharmacokinetic interaction, but have a high incidence of elevated liver enzymes, and so if used, close monitoring is needed.	3, 17-19
Saquinavir/ritonavir	Rifabutin dose reduced by at least 75% (150 mg every other day or three times per week). Appropriate saquinavir/ritonavir dose not established. Consider usual dose (1000/100 mg twice daily).	Rifampicin dose unchanged. Saquinavir/ritonavir 400/400 mg twice daily. Note that a regimen of 1000/100 mg twice daily with rifampicin was associated with severe hepatotoxicity, and the combination is contraindicated.	3, 20, 21
Tipranavir/ritonavir	Rifabutin dose reduced by at least 75% (150 mg every other day or three times per week). Further dose reductions may be necessary. Tipranavir/ritonavir dose unchanged.	Not recommended (tipranavir levels predicted to be markedly reduced).	22, 23

*Formerly considered contraindicated (rifabutin levels markedly increased with risk of toxicity)

tors should not be used with rifampicin. They say that rifampicin should be switched to rifabutin for use with protease inhibitors, or the protease inhibitor should be changed to an alternative antiretroviral if this is possible.³⁶ Similarly, US guidelines say that rifampicin may only be used with full-dose ritonavir, and cannot be used safely with ritonavir-boosted regimens. They recommend the use of rifabutin.³⁷

Protease inhibitors + St John's wort (*Hypericum perforatum*)

St John's wort causes a marked reduction in the serum levels of indinavir, which may result in HIV treatment failure. Other protease inhibitors, whether used alone or boosted by ritonavir, are predicted to interact similarly.

Clinical evidence

In a single-drug pharmacokinetic study, 8 healthy subjects were given three 800-mg doses of **indinavir** on day 1 of to achieve steady-state serum levels, and then an 800-mg dose on day 2. For the next 14 days they were given St John's wort extract 300 mg three times daily. Starting on day 16, the indinavir dosing was repeated. It was found that the St John's wort reduced the mean AUC of **indinavir** by 54% and decreased the 8-hour **indinavir** trough serum level by 81%.¹

Mechanism

Not fully understood, but it seems highly likely that the St John's wort induces the activity of the cytochrome P450 isoenzyme CYP3A4, thereby increasing the metabolism of indinavir and therefore reducing its levels.

Importance and management

Direct information seems to be limited to this study, but the interaction would appear to be established. Such a large reduction in the serum levels of indinavir is likely to result in treatment failures and the development of viral resistance. Therefore St John's wort should be avoided. There seems to be no direct information about other protease inhibitors, but since they are also metabolised by CYP3A4 it is reasonable to expect that they will be similarly affected by St John's wort. The FDA in the US has suggested

that concurrent use of St John's wort and protease inhibitors is not recommended.² Similarly, the CSM in the UK has advised that patients taking protease inhibitors should avoid St John's wort and that anyone already taking both should stop the St John's wort and have their HIV RNA viral load measured.³ The manufacturers of indinavir give similar advice,^{4,5} and also note that protease inhibitor levels may increase on stopping St John's wort, and the dose may need adjusting.⁴ They note the inducing effect may persist for up to 2 weeks after stopping treatment with St John's wort.⁴ US and UK manufacturers of all protease inhibitors (**amprenavir**, **atazanavir**, **darunavir**, **fosamprenavir**, **lopinavir/ritonavir**, **nelfinavir**, **ritonavir**, **saquinavir**, **tipranavir**) either contraindicate or advise against the use of St John's wort.

Protease inhibitors + Tenofovir

Atazanavir/ritonavir, darunavir/ritonavir and lopinavir/ritonavir modestly increased the levels of tenofovir, and there is at least one case report of nephrotoxicity with the combination of tenofovir, didanosine, and lopinavir/ritonavir. Saquinavir/ritonavir, tipranavir/ritonavir, and probably also fosamprenavir/ritonavir, have little effect on tenofovir levels. Tenofovir modestly decreased atazanavir levels, and this was minimised when ritonavir was also given. Tenofovir had no important effect on ritonavir-boosted darunavir, lopinavir, and tipranavir levels, and modestly increased those of ritonavir-boosted saquinavir in one of two studies. Indinavir and nelfinavir do not interact pharmacokinetically with tenofovir.

Clinical evidence

(a) Atazanavir

The AUC of atazanavir was decreased by 25%, and the trough level by 40% when atazanavir 400 mg daily was given with tenofovir disoproxil fumarate 300 mg daily, and the AUC of tenofovir was increased by 24%.^{1–3} Similar results were seen when administration was separated by 12 hours.³

When atazanavir 300 mg once daily was given with ritonavir 100 mg once daily (as a pharmacokinetic booster), tenofovir disoproxil fumarate 300 mg once daily reduced the AUC of atazanavir by a similar amount (25%), but had less effect on the trough level (23% reduction), when compared with atazanavir/ritonavir alone.⁴ Similarly, the pharmacokinetics of atazanavir/ritonavir did not differ significantly between patients taking tenofovir and those not.⁵ Combined use increased the tenofovir AUC by 37% and the minimum level by 29%.^{2,3}

(b) Darunavir with Ritonavir

The manufacturer notes that concurrent use of darunavir/ritonavir 300/100 mg twice daily with tenofovir disoproxil fumarate 300 mg once daily modestly increased the tenofovir AUC and minimum level by 22% and 37%, respectively. Darunavir levels were not significantly changed (minimum level increased by 24%).^{6,7}

(c) Fosamprenavir with Ritonavir

The US manufacturer notes that, in a phase III clinical study plasma amprenavir trough levels (derived from fosamprenavir) were similar in subjects receiving tenofovir with fosamprenavir and ritonavir to those in subjects not receiving tenofovir.⁸ Similarly, in a pharmacokinetic study in healthy subjects, tenofovir disoproxil fumarate 300 mg once daily had no significant effect on the pharmacokinetics of amprenavir after fosamprenavir/ritonavir 1400/100 mg once daily or fosamprenavir/ritonavir 1400/200 mg once daily.⁹

(d) Indinavir

The manufacturer of tenofovir notes that there was no pharmacokinetic interaction between tenofovir disoproxil fumarate 300 mg once daily and indinavir 800 mg three times daily in healthy subjects.^{1,10}

(e) Lopinavir/Ritonavir

The concurrent use of lopinavir/ritonavir 400/100 mg twice daily and tenofovir resulted in a 30% increase in the AUC and a 50% increase in the trough level of tenofovir, but no change in the pharmacokinetics of lopinavir/ritonavir.^{1,10} There is one case report of Fanconi syndrome with nephrogenic diabetes insipidus, which developed in a patient taking lopinavir/ritonavir 800/200 mg daily, tenofovir disoproxil fumarate 300 mg daily, didanosine and lamivudine (for an interaction between tenofovir and didanosine, see 'NRTIs', (p.806)). The tenofovir level was 3.7-fold higher than expected and the didanosine level was eightfold higher than it had been before tenofovir was started. Lopinavir levels were unchanged.¹¹

(f) Nelfinavir

The manufacturer of tenofovir notes that there was no pharmacokinetic interaction between tenofovir disoproxil fumarate 300 mg once daily and nelfinavir 1.25 g twice daily in healthy subjects.^{1,10}

(g) Saquinavir with Ritonavir

Tenofovir disoproxil fumarate 300 mg once daily modestly increased the saquinavir AUC and minimum level by 29% and 47%, respectively, after administration of saquinavir/ritonavir 1000/100 mg twice daily in healthy subjects. The only change in tenofovir pharmacokinetics was a slight 23% increase in minimum level.^{10,12} In another study,¹³ mentioned by the manufacturer of saquinavir,^{14,15} in 18 HIV-positive patients treated with saquinavir/ritonavir 1000/100 mg twice daily and tenofovir disoproxil fumarate 300 mg once daily, saquinavir AUC and maximum values were just 1% and 7% lower, respectively, than those seen with saquinavir/ritonavir alone.

(h) Tipranavir with Ritonavir

Tipranavir/ritonavir 500/100 mg twice daily had no effect on the AUC and minimum level of a single 300-mg dose of tenofovir disoproxil fumarate, but it decreased the tenofovir maximum level by 23%. The tipranavir AUC and minimum level were decreased by 18% and 21%, respectively. With an increased dose of tipranavir/ritonavir 750/200 mg twice daily, the maximum level of tenofovir was reduced by 38% with no change in AUC or minimum level, and the decreases in tipranavir AUC and minimum levels were less (9% AUC and 12% minimum level).¹⁶

Mechanism

It has been suggested that ritonavir increases tenofovir levels via its effect on drug transporter proteins in the renal tubuli.^{6,11}

Importance and management

The modest increase in tenofovir levels with ritonavir-boosted **atazanavir**, **darunavir** and **lopinavir** is of uncertain clinical relevance. However, it has been suggested that higher tenofovir levels could potentiate tenofovir-associated adverse events, including renal disorders.^{2,3,17} For this reason, the UK manufacturer of darunavir says that monitoring of renal function may be indicated when ritonavir-boosted darunavir is given in combination with tenofovir, particularly in patients with underlying systemic or renal disease, or in patients taking nephrotoxic drugs.⁶ The US manufacturer of lopinavir/ritonavir also recommends monitoring,¹⁸ and this seems a prudent precaution.

The decrease in atazanavir levels with tenofovir is not of clinical importance if ritonavir is also used, and this combination has been used successfully as part of antiretroviral therapy in clinical studies.^{1,2} Unboosted atazanavir should be used with caution¹⁹ or not given³ with tenofovir because of the potential for reduced efficacy and development of resistance. Ritonavir-boosted darunavir and lopinavir levels were not significantly affected by tenofovir, **amprenavir** levels were also unaffected following boosted fosamprenavir administration, and the increase in ritonavir-boosted **saquinavir** levels are not likely to be clinically relevant. The slight interaction between tenofovir and **tipranavir**/ritonavir is unlikely to be clinically relevant. There is no clinically relevant interaction between **nelfinavir** or **indinavir** and tenofovir.

Current UK guidelines give tenofovir as one of the preferred drugs as part of a dual NRTI regimen, to be used with either fosamprenavir/ritonavir or lopinavir/ritonavir, for the treatment of HIV infection in treatment

naïve patients. They say that saquinavir/ritonavir is an alternative, and atazanavir/ritonavir may be used in specific groups.²⁰ US guidelines are similar.²¹

Protease inhibitors; Fosamprenavir + Miscellaneous

Fosamprenavir is a prodrug of amprenavir, and is rapidly and almost completely hydrolysed to amprenavir and inorganic phosphate primarily in the lining of the gut.^{1,2} The interactions of fosamprenavir are therefore primarily those of amprenavir.

1. Telzir (Fosamprenavir calcium). GlaxoSmithKline UK. UK Summary of product characteristics, February 2007.

Protease inhibitors; Indinavir + Ascorbic acid (Vitamin C)

Vitamin C 1 g daily caused a minor decrease in indinavir levels in healthy subjects.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects high-dose vitamin C 1 g daily for 7 days caused a 14% reduction in the AUC of indinavir and a 20% reduction in its maximum plasma level: indinavir 800 mg was given every 8 hours for 4 doses beginning on day 6.¹ However, whether this is a real effect needs

further study as a similar reduction in plasma levels after a similar indinavir regimen was thought to be a time-dependent effect, see 'milk thistle', (p.830).

1. Slain D, Amsden JR, Khakoo RA, Fisher MA, Lalka D, Hobbs GR. Effect of high-dose vitamin C on the steady-state pharmacokinetics of the protease inhibitor indinavir in healthy volunteers. *Pharmacotherapy* (2005) 25, 165–70.

Protease inhibitors; Indinavir + Goldenseal (Hydrastis)

Goldenseal root had no effect on the pharmacokinetics of a single dose of indinavir in one study.

Clinical evidence

In a study in 10 healthy subjects, the peak plasma level and oral clearance of indinavir after a single 800-mg dose was not changed by goldenseal root (*Nature's Way*) 1.14 g twice daily for 2 weeks. In addition, there was no change in the indinavir half-life. Eight of the subjects had less than a 20% change in oral clearance, but one subject had a 46% increase and one a 46% decrease.¹

Mechanism

Goldenseal (*Hydrastis canadensis*) was found to be an inhibitor of cytochrome P450 isoenzyme CYP3A4 *in vitro*.² This was confirmed in a clinical study using oral midazolam as a probe substrate for CYP3A4, which found a decrease of about 40% in the metabolism of midazolam to hydroxymidazolam.³ Goldenseal root might therefore be expected to inhibit the metabolism of indinavir.

Importance and management

This study suggests that goldenseal root has no effect on indinavir levels, and may be taken without any undue concern in patients on this protease inhibitor, although confirmation may be required in the light of the midazolam probe study, and the two subjects who experienced greater effects. The contrasting results from the indinavir study and the midazolam study might be explained by indinavir having a relatively high oral bioavailability compared with midazolam.³

Protease inhibitors; Indinavir + Milk thistle

Although some studies have found that milk thistle slightly lowers indinavir levels, it appears that this is a time-dependent effect rather than a drug interaction, since it also occurred in a control group in one study. The balance of evidence suggests that no important pharmacokinetic interaction occurs.

Clinical evidence

Milk thistle (*Silybum marianum*) 175 mg three times daily (*Thisilyn; Nature's Way*, standardised for silymarin content) for 3 weeks caused a 9% reduction in the AUC of indinavir and a 25% reduction in its trough plasma level after four doses of indinavir 800 mg every 8 hours, but only the value for the trough level reached statistical significance.¹ The authors suggested that the effect on the trough level could represent a time-dependent effect of indinavir pharmacokinetics, since the plasma levels without milk thistle were found to be similarly lowered after a washout phase.¹ In another similar study, in 10 healthy subjects, milk thistle standardised for silymarin 160 mg (*General Nutrition Corp.*) three times daily for 13 days and then with indinavir 800 mg every 8 hours for 4 doses did not cause any statistically significant changes in the indinavir pharmacokinetics (6% reduction in AUC and 32% reduction in minimum level).² In yet another similar study, in 8 healthy subjects, milk thistle extract 456 mg, standardised for silymarins (*Kare and Hope Ltd*) three times daily for 28 days had

no effect on the pharmacokinetics of indinavir 800 mg every 8 hours for four doses when compared with 6 subjects in a control group not receiving milk thistle extract. Both the control and indinavir group had a lower indinavir AUC after the second and third time of administration compared with the first, and this decline was greater in the control group.³ A meta-analysis of these 3 studies showed no effect of milk thistle on indinavir levels.³

Mechanism

Based on *animal* data, milk thistle might be expected to increase indinavir levels by inhibiting its metabolism,¹ or to have effects via P-glycoprotein.²

Importance and management

The currently available data suggest that milk thistle extract does not have an effect on the pharmacokinetics of indinavir, although it is not totally conclusive. The reduction in indinavir levels appears to be just a time-dependent effect rather than an effect of the milk thistle, and further study is needed with longer exposure to indinavir than just four doses.

Protease inhibitors; Indinavir + Venlafaxine

In a single-dose study, venlafaxine lowered indinavir levels.

Clinical evidence, mechanism, importance and management

In a study, 9 healthy subjects were given a single dose of indinavir before and after 10 days of venlafaxine 150 mg daily in divided doses. Indinavir did not affect the pharmacokinetics of venlafaxine, but venlafaxine reduced the AUC and maximum plasma levels of indinavir by 28% and 36%, respectively. This is possibly enough to reduce the efficacy of indinavir.¹ Quite why this happens is not clear. More study is needed to establish the effects of multiple doses. Until more is known it would seem prudent to monitor closely to ensure that the antiviral effects of indinavir are not compromised.

1. Levin GM, Nelson LA, DeVane CL, Preston SL, Eisele G, Carson SW. A pharmacokinetic drug-drug interaction study of venlafaxine and indinavir. *Psychopharmacol Bull* (2001) 35, 62–71.

Protease inhibitors; Nelfinavir + Calcium

Calcium supplements do not affect the plasma levels of nelfinavir.

Clinical evidence, mechanism, importance and management

Calcium supplements had no effect on plasma levels of nelfinavir or its M8 metabolite in 15 patients receiving nelfinavir 1.25 g twice daily as part of a HAART regimen. Calcium was given as calcium carbonate 1350 mg twice daily to 9 patients, and calcium gluconate/calcium carbonate 2950/300 mg twice daily to 6 patients, both for 14 days. Plasma levels of nelfinavir were measured before a dose and 3 hours after a dose.¹ Similar results were reported in another study.² No nelfinavir dosage adjustments appear necessary if calcium supplements are given.

Ribavirin + Antacids

The manufacturers of ribavirin note that there was a minor 14% decrease in the AUC of ribavirin 600 mg when it was given with

an antacid containing aluminium, magnesium, and simeticone,¹⁻³ but this is not considered clinically relevant.^{1,2} No special precautions are needed.

2. Rebetol (Ribavirin). Schering-Plough Ltd. UK Summary of product characteristics, January 2007.
3. Rebetol (Ribavirin). Schering Corporation. US Prescribing information, June 2004.

Rimantadine + Aspirin or Paracetamol (Acetaminophen)

Both aspirin and paracetamol slightly reduce the levels of rimantadine, but this is unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Aspirin

In a study in healthy subjects, rimantadine 100 mg twice daily was given for 13 days. On day 11, aspirin 650 mg four times daily was started and continued for 8 days. The peak plasma levels and AUC of rimantadine were reduced by about 10% in the presence of aspirin.¹ This reduction is unlikely to be clinically relevant.

(b) Paracetamol

In a study in healthy subjects, rimantadine 100 mg twice daily was given for 13 days. On day 11, paracetamol 650 mg four times daily was started and continued for 8 days. The peak plasma levels and AUC of rimantadine were reduced by about 11% in the presence of paracetamol.¹ This reduction is unlikely to be clinically relevant.

1. Flumadine (Rimantadine hydrochloride). Forest Pharmaceuticals, Inc. US Prescribing information, June 2006.

Rimantadine + Cimetidine

Cimetidine causes a small but probably clinically unimportant rise in the plasma levels of rimantadine.

Clinical evidence, mechanism, importance and management

In 23 healthy subjects the AUC of a single 100-mg dose of rimantadine was increased by 20% and the apparent total clearance reduced by 18% when it was taken one hour after the first dose of cimetidine 300 mg four times daily for 6 days. The authors of the study suggest that these changes are likely to have little, if any, clinical consequences.¹ The effects of multiple dose concurrent use are not known.

1. Holazo AA, Choma N, Brown SY, Lee LF, Wills RJ. Effect of cimetidine on the disposition of rimantadine in healthy subjects. *Antimicrob Agents Chemother* (1989) 33, 820–3.

Telbivudine + Miscellaneous

There appears to be no pharmacokinetic interaction between telbivudine and adefovir, ciclosporin or lamivudine. Peginterferon-alfa 2a and food do not alter telbivudine pharmacokinetics. No interactions mediated by the cytochrome P450 isoenzymes are predicted for telbivudine.

Clinical evidence, mechanism, importance and management

(a) Adefovir

In a study in healthy subjects the concurrent use of telbivudine 600 mg daily and adefovir 10 mg daily for 7 days did not alter the pharmacokinetics of either drug, when compared to their use alone.¹ No dosage adjustments of either drug are anticipated to be needed if they are used together.

(b) Ciclosporin

The manufacturer notes that there was no pharmacokinetic interaction between ciclosporin and telbivudine.²

(c) Food

In a study in healthy subjects, when a single 600-mg dose of telbivudine was given immediately after a high-fat/high-calorie meal there was no effect on the pharmacokinetics of telbivudine, when compared with the fasting state.³ Telbivudine may be taken with or without food.

(d) Interferons

The manufacturer notes that peginterferon-alfa 2a did not alter the pharmacokinetics of telbivudine. However, no conclusion could be made about the effect of telbivudine on peginterferon-alfa 2a because of high interindividual variability in its levels.²

(e) Lamivudine

In a study in healthy subjects, when telbivudine 200 mg daily and lamivudine 100 mg daily were given concurrently for 7 days the pharmacokinetics of both drugs were unchanged.¹ No dosage adjustments of either drug are anticipated to be needed if they are used together.

(f) Cytochrome P450-mediated interactions

The manufacturer notes that telbivudine is not metabolised and is principally excreted by the kidneys. It is therefore unlikely to be affected by drugs that induce or inhibit cytochrome P450 isoenzymes.²

Furthermore, *in vitro* studies suggest that telbivudine does not inhibit any of the cytochrome P450 isoenzymes commonly responsible for drug metabolism, and is therefore unlikely to interact with drugs that are substrates for these isoenzymes.²

2. Tyzeka (Telbivudine). Idenix Pharmaceuticals, Inc. US Prescribing information, October 2006.
3. Zhou X-J, Lloyd DM, Chao GC, Brown NA. Absence of food effect on the pharmacokinetics of telbivudine following oral administration in healthy subjects. *J Clin Pharmacol* (2006) 46, 275–81.

Tenofovir + Miscellaneous

Tenofovir absorption is increased by high-fat food. Caution is recommended with drugs causing renal toxicity. Tenofovir did not alter the pharmacokinetics of ribavirin, and there was no clinically significant pharmacokinetic interaction with rifampicin (rifampin).

Clinical evidence, mechanism, importance and management

(a) Cidofovir

Tenofovir is actively secreted by human organic anion transporter 1 (hOAT1) in the kidneys. Therefore, the manufacturers suggest that if it is given with other drugs that are also secreted by this renal transporter, such as cidofovir, increased levels of tenofovir or the other drug could result. In the UK, they specifically recommend that tenofovir and cidofovir are not given together, unless clearly necessary, when renal function should be monitored weekly.¹

(b) Food

Administration of tenofovir with a high-fat meal increased its AUC by about 40%, and its maximum level by about 14%, when compared with the fasted state, whereas administration with a light meal had no effect.^{1,2} The UK manufacturer recommends that tenofovir is taken with food,¹ whereas the US manufacturer says that it can be taken without regard to food.²

(c) Other nephrotoxic drugs

Tenofovir has the potential to cause nephrotoxicity, and the manufacturer recommends monthly monitoring of renal function. Although the concur-

rent administration of other nephrotoxic drugs has not been studied, the manufacturer suggests that renal function should be monitored more frequently (weekly) if concurrent use is unavoidable. They specifically name **aminoglycosides, amphotericin B, cidofovir** (see above), **foscarnet, ganciclovir, interleukin-2, pentamidine** and **vancomycin**.¹

(d) Ribavirin

Tenofovir disoproxil fumarate 300 mg daily did not alter the pharmacokinetics of a single 600-mg dose of ribavirin in 22 subjects, and the pharmacokinetics of tenofovir did not appear to be changed by ribavirin when compared with historical data.³ Note that, there is evidence that HIV-positive patients co-infected with hepatitis C and treated with interferon alfa and ribavirin may be at increased risk of lactic acidosis and hepatic decompensation when receiving any 'NRTI', (p.805), including tenofovir, and increased monitoring is recommended.¹

(e) Rifampicin (Rifampin)

In 23 subjects when rifampicin 600 mg once daily was given with tenofovir disoproxil fumarate 300 mg once daily the pharmacokinetics of both drugs were not significantly changed (tenofovir compared with historical data). One subject who was withdrawn from the study had raised liver enzyme values.⁴

Vidarabine + Allopurinol

There is some evidence to suggest that if allopurinol and vidarabine (adenine arabinoside) are given together the toxicity of vidarabine may be increased.

Clinical evidence

Two patients with chronic lymphocytic leukaemia taking allopurinol 300 mg daily developed severe neurotoxicity (coarse rhythmic tremors of the extremities and facial muscles, and impaired mentation) 4 days after vidarabine was added for the treatment of viral infections.¹ A retrospective search to find other patients who had taken both drugs for 4 days revealed a total of 17 patients, 5 of whom had experienced adverse reactions including tremors, nausea, pain, itching and anaemia.¹ Another possible case of neurological toxicity has also been reported.²

Mechanism

Uncertain. One suggestion is that the allopurinol causes hypoxanthine arabinoside, the major metabolite of vidarabine, to accumulate by inhibiting xanthine oxidase. A study with *rat* liver cytosol found that allopurinol greatly increased the half-life of this metabolite.³

Importance and management

Information seems to be limited to these reports, and so the general clinical importance of this possible interaction is uncertain, but it would be prudent to exercise particular care if these drugs are used together.

Beta blockers

The adrenoceptors of the sympathetic nervous system are of two main types, namely alpha and beta. Drugs that block the beta adrenoceptors (better known as the beta blockers) are therapeutically exploited to reduce, for example, the normal sympathetic stimulation of the heart. The activity of the heart in response to stress and exercise is reduced, its consumption of oxygen is diminished, and in this way exercise-induced angina can be managed. Beta blockers given orally can also be used in the management of cardiac arrhythmias, hypertension, myocardial infarction, and heart failure. They may also be used for some symptoms of anxiety and for migraine prophylaxis. Some beta blockers are used in the form of eye drops for glaucoma and ocular hypertension.

Not all beta receptors are identical but can be further subdivided into two groups, beta₁ and beta₂. The former are found in the heart and the latter in the bronchi. Since one of the unwanted adverse effects of generalised beta blockade can be the loss of the normal noradrenaline-stimulated bronchodilation (leading to bronchospasm), cardioselective beta₁-blocking drugs (e.g. atenolol, metoprolol) were developed, which have less effect on beta₂ receptors. However, it should be emphasised that the selectivity is not absolute because bronchospasm can still occur with these drugs, particularly at high doses. 'Table 22.1', (below) includes an indication of the cardioselectivity of commonly used systemic beta blockers. Some beta blockers also have alpha₁-blocking activity, which causes vasodilatation,

and this is also indicated in 'Table 22.1', (below). Some beta blockers, such as celiprolol and nebivolol, also have vasodilator activity but produce this by mechanisms other than blocking alpha₁ receptors. Other beta blockers also possess intrinsic sympathomimetic activity in that they can *activate* beta receptors and are therefore partial agonists. Sotalol has additional class III antiarrhythmic activity, and therefore it has a range of interactions not shared by most other beta blockers.

Beta blockers may be lipophilic drugs (such as metoprolol) or hydrophilic (such as atenolol). The lipophilic beta blockers are more likely to be involved in pharmacokinetic interactions than the hydrophilic drugs. Many of the lipophilic beta blockers are principally metabolised by the cytochrome P450 isoenzyme CYP2D6 (see 'Table 22.1', (below)), and drugs that are inhibitors or inducers of this isoenzyme (see 'Table 1.3', (p.6)) increase or decrease their levels. Propranolol is also metabolised in part by CYP1A2 (see 'Beta blockers + SSRIs', p.855).

Beta blockers may also be involved in pharmacodynamic interactions with other drugs that are based on enhancement or antagonism of pharmacological effects (such as additive blood pressure reduction).

This section is generally concerned with those drugs that affect the activity of the beta blockers. Where the beta blocker is the affecting drug, the interaction is dealt with elsewhere.

Table 22.1 The actions and metabolism of widely used systemic beta blockers

Drug	Beta ₁ -receptor selectivity	Alpha-blocking activity?	ISA*	Lipophilicity	Bioavailability	First pass metabolism	Metabolism
Acebutolol	Selective	No	Yes (weak)	Hydrophilic	50 to 70%	30 to 50%	Rapidly metabolised to an active metabolite after which about 50% is excreted by the liver and 50% excreted in the urine.
Atenolol	Selective	No	No	Hydrophilic	40 to 50%	Less than 10%	Largely excreted unchanged in the urine.
Bisoprolol	Selective	No	No	Intermediate	88%	Less than 10%	50% hepatic metabolism and 50% excreted unchanged in the urine.
Carvedilol	Non-selective	Yes (alpha ₁)	No	Lipophilic	25 to 35%	60 to 80%	Primarily metabolised by CYP2D6, although other isoenzymes do contribute.
Celiprolol	Selective	Yes (weak alpha ₂)	Yes	Hydrophilic	30 to 70%	Little	Mostly excreted unchanged (only 1-3% metabolised) with 50% excreted in the bile and 50% excreted in the urine.
Esmolol	Selective	No	No	Relatively hydrophilic	N/A	Extensive	Rapidly hydrolysed in red blood cells (half-life 9 minutes).
Labetalol	Non-selective	Yes (postsynaptic alpha ₂)	No	Moderately lipophilic	25 to 40%	Extensive	Conjugated in the liver.
Metoprolol	Selective	No	No	Lipophilic	50%	About 40 to 60%	Metabolised by CYP2D6.
Nadolol	Non-selective	No	No	Hydrophilic	20 to 40%	Little	Largely excreted unchanged in the urine.
Nebivolol	Selective	No	No		12 to 96%	Extensive	Metabolised by CYP2D6.
Oxprenolol	Non-selective	No	Yes	Lipophilic	19 to 74%	25 to 80%	Extensively metabolised by the liver.
Pindolol	Non-selective	No	Yes	Moderately lipophilic	90 to 100%	Little	30 to 40% excreted unchanged in the urine, rest excreted by liver and kidney as inactive metabolites.
Propranolol	Non-selective	No	No	Lipophilic	30 to 70%	Up to 95%	Mainly metabolised by CYP2D6 with some contribution by CYP1A2.
Sotalol	Non-selective	No	No	Hydrophilic	75 to 90%	None	Largely excreted unchanged in the urine.
Timolol	Non-selective	No	No	Lipophilic	61%	About 50 to 70%	Mostly metabolised by the liver, with some involvement from CYP2D6. 20% excreted unchanged. Timolol and metabolites renally excreted.

*Intrinsic sympathomimetic activity (partial agonists)

Beta blockers + Antacids or Antidiarrhoeals

Some antacids and antidiarrhoeals may cause a modest reduction in the absorption of atenolol, indenolol, propranolol, or sotalol, and possibly a slight increase in the absorption of metoprolol. However, the clinical importance of these interactions is probably minimal.

Clinical evidence

(a) Atenolol

Aluminium hydroxide 5.6 g given to 6 healthy subjects caused an insignificant 20% fall in the plasma levels of a single 100-mg dose of atenolol, which had no effect on the atenolol-induced reduction in exercising heart rate. Similarly, **aluminium hydroxide** had no significant effect on atenolol pharmacokinetics when both drugs were given together for 6 days.¹ Conversely, in 6 healthy subjects a single 500-mg dose of **calcium** (as the lactate, gluconate and carbonate) caused a 51% reduction in the peak plasma level of a single 100-mg dose of atenolol. **Calcium** also reduced the AUC of atenolol by 32%, and increased the elimination half-life from 6.2 to 11 hours. The effect of atenolol on heart rate was decreased by 12%. However, these changes were no longer significant after 6 days of concurrent use, except for a 21% reduction in peak plasma atenolol levels. In a further 6 hypertensive subjects, neither **calcium** 500 mg daily nor **aluminium hydroxide** 5.6 g daily had any influence on the blood pressure lowering effect of atenolol 100 mg daily for 4 weeks.¹

Another study in 6 healthy subjects found that 30 mL of *Novalucol forte* (an **aluminium/magnesium-containing antacid**) reduced the peak plasma level and AUC of a single 100-mg dose of atenolol by 37% and 33%, respectively, which was considered to be of possible significance in some patients.²

(b) Indenolol

A study in *rats* found that when indenolol was given with either *Simeco* (**aluminium/magnesium hydroxide** with **simeticone**) or *Kaopectate* (**kaolin-pectin**), the AUC₀₋₆ was reduced by 15% and 30%, respectively.³

(c) Metoprolol

In 6 healthy subjects, 30 mL of *Novalucol forte* (an **aluminium/magnesium-containing antacid**) increased the peak plasma level and AUC of a single 100-mg dose of metoprolol by 25% and 11%, respectively.²

(d) Propranolol

Aluminium hydroxide gel 30 mL did not affect the plasma level of a single 40-mg dose of propranolol in 6 healthy subjects: the reduction in exercise heart rate was also unaffected.⁴ In contrast, a study in 5 healthy subjects found that 30 mL of an **aluminium hydroxide gel** reduced the levels and AUC of a single 80-mg dose of propranolol by almost 60%.⁵ *In vitro* and *animal* data suggest that **bismuth subsalicylate**, **kaolin-pectin** and **magnesium trisilicate** can also reduce the absorption of propranolol.^{6,7}

(e) Sotalol

A study in 5 healthy subjects found that single doses of **aluminium hydroxide** suspension (*Neutragerl*) or **calcium carbonate** suspension, given after an overnight fast, had negligible effects on the pharmacokinetics of a single 160-mg dose of sotalol.⁸ In contrast, a single dose of **magnesium hydroxide** slightly reduced the AUC of sotalol by 16%.⁸ A further study in 6 healthy subjects found that when 20 mL of *Maalox* (**aluminium/magnesium hydroxide**) was given at the same time as 160 mg of sotalol, the maximum plasma level of the sotalol was reduced by 26% and its AUC was reduced by 21%. Changes in heart rates reflected these pharmacokinetic changes.⁹ No interaction occurred when the *Maalox* was given 2 hours after the sotalol.⁹

Mechanism

Uncertain. The reduction in absorption could possibly be related to a delay in gastric emptying caused by the antacid, delayed dissolution due to an increase in gastric pH, or to the formation of a complex of the two drugs in the gut, which reduces absorption. However, one *in vitro* study indicated that sotalol was only subject to minor absorption or complexation inter-

actions.⁹ Another study found that 35 to 40% of sotalol was bound by magnesium hydroxide, but this may be reversible under physiological conditions and therefore unlikely to be relevant during long-term clinical use.⁸

Importance and management

The documentation is limited, in some instances somewhat contradictory, and largely confined to *animal* or single-dose studies, which may not be clinically relevant. Some changes in absorption may possibly occur but no study seems to have shown that there is a significant effect on the therapeutic effectiveness of the beta blockers. The one study using atenolol in patients found that the pharmacokinetic changes seen with single doses of **aluminium** or calcium-containing antacids were not clinically significant.¹ However, be alert for any changes during concurrent use. Separating the dosages by 2 hours was shown to avoid the interaction in one study,⁹ and would seem a simple way of avoiding problems should they occur.

Beta blockers + Anticholinesterases

A small number of reports describe marked bradycardia and hypotension during the recovery period from anaesthesia and neuromuscular blockade, when patients taking beta blockers were given anticholinesterase drugs. However, normally no adverse reaction seems to occur. Myasthenic symptoms and myasthenia gravis have occurred when oral or topical beta blockers were given alone, and so beta blockers could oppose the efficacy of anticholinesterases in treating myasthenia gravis.

Clinical evidence

(a) Anticholinesterase effects

Three patients developed myasthenic symptoms when given beta blockers (two taking **propranolol** and one taking **oxprenolol**). Two of them were effectively treated with **pyridostigmine**.¹ Another patient developed fulminant myasthenia gravis within 2 weeks of starting to take **acebutolol**.² Similarly, in a patient with myasthenia gravis, the use of **timolol** eye drops was associated with a deterioration in muscle strength,³ and in another patient, a serious deterioration in myasthenia.⁴

However, in a study in 10 myasthenic patients with mild to moderate symptoms, intravenous **propranolol** 100 micrograms/kg did not result in a worsening of neuromuscular transmission (assessed by muscle function tests and repetitive nerve stimulation), even though 8 of those with mild symptoms had reduced their **pyridostigmine** dose during the study to allow the effects of the additional drug to be more readily seen.⁵

(b) Bradycardia

A patient taking **nadolol** 40 mg daily, recovering from surgery during which suxamethonium (succinylcholine) and pancuronium had been given, developed prolonged bradycardia of 32 to 36 bpm and hypotension (systolic pressure 60 to 70 mmHg) when **neostigmine** and atropine were given to reverse the neuromuscular blockade. Isoprenaline and phenylephrine infusions were required to maintain a systolic blood pressure of 90 mmHg, and were gradually reduced over 3 days. **Propranolol** was substituted for **nadolol**, and about 10 weeks later the patient underwent general anaesthesia again (this time without a neuromuscular blocker/**neostigmine**) and she recovered uneventfully.⁶ A patient taking **pro-**

pranolol 20 mg twice daily, recovering from surgery during which alcuronium had been used, received glycopyrronium and **neostigmine** without any change in heart rate. However, one hour later he developed severe bradycardia (a fall from 65 to 40 bpm) and hypotension (systolic blood pressure 70 mmHg) when given intravenous **physostigmine** 2 mg over 5 minutes, for extreme drowsiness attributed to the premedication. His symptoms responded to glycopyrronium.⁷ Prolonged bradycardia and hypotension, requiring isoprenaline then adrenaline (epinephrine), were seen in an elderly woman taking **atenolol** 50 mg daily and nitrates when she was given **neostigmine** and atropine for the reversal of muscle relaxation at the end of general anaesthesia.⁸ Another report similarly describes bradycardia in a patient taking **propranolol** when intravenous **neostigmine** was used to reverse pancuronium-induced blockade. This responded to atropine.⁹

However, a study in 8 hypertensive patients taking long-term **atenolol** or **propranolol** found no significant changes in heart rate and no serious adverse reactions when they were given low-dose oral **pyridostigmine** 30 mg three times daily for 2 days.¹⁰

Mechanism

It would appear that the bradycardic effects of the beta blockers and the acetylcholine-like effects of these anticholinesterase drugs can be additive. These were inadequately controlled by the use of atropine in some of the instances cited. The myasthenic symptoms may be due to beta blockers exerting a depressant effect on the neuromuscular junction.^{2,3}

Importance and management

The information available indicates that marked adverse reactions between beta blockers and anticholinesterases after surgery are uncommon, but be aware of the possibility of an interaction if a patient becomes bradycardic or hypotensive shortly after surgery.

Limited information suggests that beta blockers given orally or topically could oppose the efficacy of anticholinesterases in the treatment of myasthenia gravis. However, one study suggests that, in cardiovascular emergencies, propranolol may be given to patients with myasthenia gravis, provided that resuscitation equipment and specific antidotes are available.⁵ Strictly speaking this is a drug-disease rather than a drug-drug interaction.

Beta blockers + Aspirin or NSAIDs

There is evidence that most NSAIDs can increase blood pressure in patients taking antihypertensives, although some studies have not found the increase to be clinically relevant. In various small studies, indometacin reduced the antihypertensive effects of the beta blockers. There is some evidence that piroxicam usually interacts similarly. Ibuprofen and naproxen have reduced the effect of beta blockers in some small studies but not others. Two isolated cases of hypertension have been reported with naproxen and ibuprofen in patients treated with propranolol and pindolol, respectively. Celecoxib, but not rofecoxib, inhibits the metabolism of metoprolol. Limited information suggests that normally di-

clofenac, imidazole salicylate, oxaprozin, tenoxicam and probably sulindac do not interact.

Multiple-dose aspirin, both in high and low dose, did not reduce the efficacy of antihypertensives including beta blockers in three studies, but one study using single, high doses showed antagonism of the effect of intravenous beta blockers. Another study suggested aspirin may attenuate the benefit of carvedilol in heart failure.

Clinical evidence

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with **antihypertensives**, and the findings of these are summarised in 'Table 23.2', (p.862). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both COX-2 inhibitors and non-selective NSAIDs. In two meta-analyses,^{1,2} the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between **indometacin** and **sulindac** in one analysis.¹ Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,¹ the effect was greatest for **piroxicam**, **indometacin**, and **ibuprofen**, intermediate for **naproxen**, and least for **sulindac** and **flurbiprofen**. In the other meta-analysis,² the effect was greatest for **indometacin** and **naproxen**, intermediate for **piroxicam**, and least for **ibuprofen** and **sulindac**. An attempt was also made to evaluate the effect by **antihypertensive** in one analysis.¹ The mean effect was greatest for beta blockers, intermediate for vasodilators (includes ACE inhibitors and calcium-channel blockers), and least for diuretics. However, the differences between the groups were not significant.

The findings of individual clinical and pharmacological studies that have studied the effects of aspirin or specific NSAIDs on beta blockers are outlined in the subsections below.

(a) Aspirin and other salicylates

A small study in patients taking various antihypertensives (including beta blockers and diuretics) found that aspirin, in both low doses (650 mg daily) and high doses (3.9 g daily) for 3 or 4 weeks, did not cause clinically significant increases in blood pressure.³ Similarly, a study in 11 patients taking a number of antihypertensives (which included a few patients taking **propranolol** or **pindolol**) found that aspirin 650 mg three times daily for 7 days did not affect the control of blood pressure.⁴ In contrast, another study found that 5 g of aspirin given over 24 hours prevented the antihypertensive effects of a single 1-mg intravenous dose of **pindolol**, and a single 1- to 1.5-g dose of aspirin reduced the antihypertensive effect of a single 5-mg intravenous dose of **propranolol**.⁵ Aspirin was reported not to affect the control of hypertension by **metipranolol**.⁶ A retrospective study of patients with heart failure taking **carvedilol** found that aspirin did not significantly affect systolic blood pressure or heart rate but did observe that left ventricular ejection fraction improved less in those patients taking aspirin in addition to **carvedilol**. The effect appeared to be dose-related.⁷

A single-dose study in 6 healthy subjects found that aspirin 500 mg did not affect the pharmacokinetics of **atenolol**.⁸ Another study in 6 healthy subjects found that aspirin did not affect the pharmacokinetics of **metoprolol**, but the maximum plasma levels of aspirin were increased by **metoprolol**, although this was not considered to be clinically relevant.⁹

Sodium salicylate did not affect either the pharmacokinetics of **alprenolol** or its effects on heart rate and blood pressure during exercise in a single-dose study in healthy subjects.¹⁰ **Imidazole salicylate** did not affect the blood pressure control of patients treated with **atenolol**.¹¹

(b) Celecoxib or Rofecoxib

In an open, randomised crossover study in 12 healthy subjects, celecoxib 200 mg twice daily for 7 days increased the AUC of a single 50-mg dose of **metoprolol** by 64%. In contrast, rofecoxib 25 mg daily for 7 days did not significantly affect the pharmacokinetics of **metoprolol**.

(c) Diclofenac

A study in 16 patients taking **atenolol**, **metoprolol**, **propranolol** or **pindolol** and/or a diuretic found that diclofenac 50 mg three times daily had no effect on the control of blood pressure.¹²

(d) *Flurbiprofen*

A study in 10 patients with hypertension found that flurbiprofen 100 mg daily for 7 days did not affect the pharmacokinetics of single-doses of either **propranolol** 80 mg or **atenolol** 100 mg. However, the hypotensive effects of **propranolol** but not **atenolol** were reduced by the flurbiprofen.¹³

(e) *Ibuprofen*

In a randomised study, ibuprofen 400 mg every 8 hours caused significant increases in blood pressure (mean increases of about 5 to 7 mmHg) in 6 hypertensive patients treated with thiazides and beta blockers.¹⁴ The antihypertensive effect of **pindolol** was antagonised by ibuprofen in one patient.¹⁵ However, ibuprofen 400 mg four times daily had no effect on the control of blood pressure in patients taking **propranolol** in one randomised controlled study.¹⁶

(f) *Indometacin*

A study found that when indometacin 25 mg three times daily was given to hypertensive patients taking thiazides with or without beta blockers, their blood pressure increased by 8 to 10 mmHg.³ The diastolic blood pressures of 7 hypertensive patients treated with **pindolol** 15 mg daily or **propranolol** 80 to 160 mg daily rose from 82 to 96 mmHg when they were given indometacin 100 mg daily over a 10-day period. Changes in systolic pressures were not statistically significant.¹⁷

In another study, indometacin 50 mg twice daily raised the systolic/diastolic blood pressures of patients taking **propranolol** 60 to 320 mg daily by 14/5 mmHg when lying and 16/9 mmHg when standing.¹⁸ This interaction has also been seen in other studies in patients taking **atenolol**,^{11,19,20} **labetalol**,²¹ **metipranolol**,⁶ **oxprenolol**,^{22,23} and **propranolol**.^{4,24} Two women with pre-eclampsia taking **propranolol** or **pindolol** became markedly hypertensive (rises in blood pressure from 135/85 to 240/140 mmHg, and from 130/70 to 230/130 mmHg, respectively) within 4 to 5 days of being given indometacin to inhibit premature contractions.²⁵

(g) *Naproxen*

A study in hypertensive patients taking **timolol** and hydrochlorothiazide with amiloride found that naproxen 250 mg twice daily caused a significant 4 mmHg rise in diastolic blood pressure, but did not significantly increase systolic blood pressure.²⁶ Similarly, in another study, naproxen 500 mg twice daily caused an average 4 mmHg rise in systolic blood pressure in patients taking **atenolol**, but did not significantly increase diastolic blood pressure.²⁷ In contrast, another study found that naproxen caused no changes in hypertension controlled with **propranolol**,²⁸ and a study in patients taking antihypertensives [drugs not specified] found that naproxen did not cause clinically significant increases in blood pressure.³ A case report describes one patient taking **propranolol** who had a marked rise in blood pressure when given naproxen.²⁹

(h) *Oxaprozoin*

A study in 32 hypertensive arthritic patients found that oxaprozoin 1.2 g daily for 4 weeks did not affect the antihypertensive effects of **metoprolol** 100 mg twice daily, although at 2 weeks there was a significant increase in systolic blood pressure.³⁰

(i) *Piroxicam*

A double-blind study found that about one-quarter of the patients given piroxicam 20 mg daily and **propranolol** 80 to 160 mg daily developed diastolic pressure rises of 10 mmHg or more when lying or standing.^{31,32} Increases in both systolic and diastolic pressures (8.1/5.2 mmHg lying and 8.5/8.9 mmHg standing) were seen in another study in 3 patients.³³ In contrast, patients taking **propranolol** and piroxicam 20 mg daily had blood pressure rises of 5.8/2.4 mmHg when lying and 3.5/0.5 mmHg when standing, after 2 weeks, but these increases were not statistically significant.³⁴ Blood pressure showed a trend towards higher levels in another study in 20 patients given **timolol** and piroxicam 20 mg daily.²⁶

A study in 6 healthy subjects given **atenolol** 100 mg daily and piroxicam 20 mg daily for 7 days found no pharmacokinetic interaction. An associated study in another 6 healthy subjects given **metoprolol** 100 mg twice daily and piroxicam 20 mg daily for 7 days found that **metoprolol** levels were increased by piroxicam, but not to a statistically significant extent.³⁵

(j) *Sulindac*

Sulindac 200 mg twice daily had little or no effect on the control of hypertension in patients taking hydrochlorothiazide with amiloride and **atenolol**, **metoprolol**, **propranolol** or **pindolol**.¹² In another study, diastolic blood pressure was slightly and significantly lower when sulindac was given with **timolol**.²⁶ No statistically significant rises in blood pressure occurred in other studies in patients taking **propranolol**^{28,31-33} or **atenolol**^{20,27} or unspecified antihypertensives³ given sulindac 200 mg twice daily. In contrast, another study claimed that patients given **propranolol** with sulindac 200 mg twice daily had blood pressure rises of 10.3/4.8 mmHg when standing and 2.4/7.1 mmHg when lying, after 2 weeks, but only the increase in standing systolic blood pressure statistically significant.³⁴ Similarly, a crossover study in 26 hypertensive patients taking **labetalol** found that sulindac 200 mg twice daily for 7 days raised the mean systolic blood pressure by 6 mmHg when sitting, and by 9 to 14 mmHg when standing, which was considered potentially clinically significant. Diastolic pressures were not affected.²¹

(k) *Tenoxicam*

The control of hypertension in 16 patients taking **atenolol** was found not to be affected by tenoxicam 40 mg daily.³⁶

Mechanism

Indometacin alone can raise blood pressure (13 hypertensive patients given indometacin 150 mg daily for 3 days had a mean systolic blood pressure rise from 118 to 131 mmHg).³⁷ One suggested reason is that indometacin inhibits the synthesis and release of two prostaglandins (PGA and PGE), which have a potent dilating effect on peripheral arterioles throughout the body. In their absence the blood pressure rises. Thus the hypotensive actions of the beta blockers are opposed by the hypertensive actions of indometacin. This mechanism has been questioned and it is possible that other physiological and pharmacological mechanisms have a part to play.^{3,38,39} One study found that although indometacin caused increases in blood pressure in treated hypertensive patients, other inhibitors of prostaglandin synthesis (aspirin, naproxen and sulindac) did not.³ Further, all four drugs caused similar reductions in plasma renin activity and aldosterone concentration, which suggests that the effect of indometacin on blood pressure may not be dependent on such changes.³

Celecoxib, but not rofecoxib, inhibits the metabolism of metoprolol by the cytochrome P450 isoenzyme CYP2D6.⁴⁰

Importance and management

Overall, the evidence suggests that some patients treated with beta blockers can show a rise in blood pressure when given NSAIDs, but this may not always be clinically relevant. Some consider that the use of NSAIDs should be kept to a minimum in patients on antihypertensives.⁴¹ The effects may be greater in the elderly and in those with blood pressures that are relatively high, as well as in those with high salt intake.⁴¹ However, others consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.⁴² While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inadequate control of blood pressure, other reasons may be more likely than any effect of concurrent NSAIDs.⁴² There is insufficient data at present to clearly differentiate between NSAIDs, although there is some evidence that the effects of indometacin are greatest and sulindac least. Further study is needed.

For the effects of NSAIDs on other antihypertensive drug classes see 'ACE inhibitors', (p.28), 'calcium-channel blockers', (p.861) and 'thiazide diuretics', (p.956).

A few multiple-dose studies have not found aspirin to alter the antihypertensive effect of beta blockers, even in high doses, but one single-dose high-dose study reported an interaction. Another study suggested that aspirin might attenuate the benefit of carvedilol in heart failure, but the evidence is currently too slim to warrant a change in practice.

Although celecoxib increased levels of metoprolol, increases in plasma metoprolol levels of this size are unlikely to be clinically relevant.

Beta blockers + Barbiturates

The plasma levels and the effects of beta blockers that are mainly metabolised by the liver (e.g. alprenolol, metoprolol, timolol) are reduced by the barbiturates. Alprenolol concentrations are halved, but the other beta blockers are possibly not affected as much. Beta blockers that are mainly excreted unchanged in the urine (e.g. atenolol, sotalol, nadolol) would not be expected to be affected by the barbiturates.

Clinical evidence

Pentobarbital 100 mg daily for 10 days at bedtime reduced the plasma levels of **alprenolol** 400 mg twice daily by 59% in 6 hypertensive patients. On day 11, the mean pulse rate at rest had risen from 70 to 74 bpm and blood pressure had risen from 134/89 to 145/97 mmHg. The changes were seen within 4 to 5 days of starting the barbiturate, and decreased within 8 to 9 days of stopping it.¹ These results confirm previous studies by the same research group using **pentobarbital** 100 mg daily in healthy subjects.^{2,3} In one of these studies, **pentobarbital** was found to cause a 38% reduction in plasma **alprenolol** levels 90 minutes after a single 200-mg dose of **alprenolol** was given, and a 43% reduction in the **alprenolol** AUC, with no change in the elimination half-life. There was also a 20% reduction in the effects of the beta blocker on heart rate during exercise.³ In the other study, the AUC of oral **alprenolol** was reduced by about 80%, but that of intravenous **alprenolol** was unaffected.²

Another study in 8 healthy subjects has shown that **pentobarbital** 100 mg daily for 10 days reduced the AUC of **metoprolol** 100 mg by 32% (range 2 to 46%).⁴ **Phenobarbital** 100 mg daily for 7 days reduced the AUC of **timolol** by 24% in 12 healthy subjects, but this was not statistically significant.⁵

Mechanism

Barbiturates are potent liver enzyme inducers that can increase the metabolism and clearance of other drugs from the body. Beta blockers that are removed from the body principally by liver metabolism (e.g. alprenolol, metoprolol, timolol) can therefore possibly be cleared more quickly in the presence of a barbiturate.

Importance and management

The interaction between alprenolol and pentobarbital is well documented and likely to be of modest clinical importance when the beta blocker is being used to treat hypertension, and possibly angina. Monitor the effects of alprenolol and increase the dose as necessary. Where possible it may be preferable to replace the barbiturate with a non-interacting alternative, such as one of the 'benzodiazepines', (p.723), which only have minor effects on the beta blockers, or consider using an alternative non-interacting beta blocker.

A reduced response is possible with any of the beta blockers that are extensively metabolised (see 'Table 22.1', (p.833)), but the effects on the AUCs of metoprolol and timolol appear to be less than the effects on alprenolol. Detailed information about the clinical importance of this interaction is largely lacking, but seems likely to be minor. However, if a problem does occur consider the alternative measures suggested for alprenolol, above. Any possible interaction can almost certainly be avoided by using one of the beta blockers that are primarily excreted unchanged in the urine (see 'Table 22.1', (p.833)). Evidence is largely lacking, but all barbiturates would be expected to interact similarly, although the extent of the interaction may vary.

Beta blockers + Bile-acid binding resins

Although both colestyramine and colestipol can moderately reduce the absorption of propranolol, this does not seem to reduce its effects. Colesevelam does not appear to affect the absorption of metoprolol.

Clinical evidence

(a) Colesevelam

A single-dose study in 33 healthy subjects found that colesevelam 4.5 g did not cause a clinically relevant alteration in the plasma levels of sustained-release metoprolol 100 mg.¹

(b) Colestipol

When 6 healthy subjects took a single 120-mg dose of propranolol with a 10-g dose of colestipol the peak plasma propranolol levels were raised by 30%. However, if an additional 10 g dose of colestipol was taken 12 hours before the propranolol the peak plasma levels were decreased by 36% and the AUC was reduced by about 30%. No changes in blood pressure or pulse rates were seen.²

(c) Colestyramine

When 6 healthy subjects took a single 120-mg dose of propranolol with an 8-g dose of colestyramine the peak propranolol plasma levels were reduced by almost 25% and the AUC was reduced by 13%. An additional dose of colestyramine 12 hours before the propranolol reduced the AUC by 43%. However, no changes in blood pressure or pulse rate were seen.² Preliminary results of another study found that colestyramine (single unstated dose) caused no significant changes in the blood levels of propranolol in 5 patients with type II hyperlipidaemia taking propranolol 40 mg four times daily.³

Mechanism

Uncertain. It seems probable that both colestyramine and colestipol can bind to propranolol in the gut, thereby reducing its absorption.

Importance and management

Information is limited. Even though both colestyramine and colestipol can apparently reduce the absorption of a single dose of propranolol, no changes in its effects were reported,² suggesting that the interaction is of minimal clinical importance. There is therefore no obvious reason for avoiding concurrent use. However, note that it is usually recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine, and 1 hour before or 4 hours after colestipol.

Beta blockers + Bupropion

A patient taking metoprolol developed bradycardia and hypotension when bupropion was also given.

Clinical evidence, mechanism, importance and management

A 50-year-old man taking metoprolol 75 mg twice daily and diltiazem 240 mg twice daily for hypertension developed fatigue 12 days after starting to take bupropion 150 mg twice daily. He was found to have a pulse rate of 43 bpm, a blood pressure of 102/65 mmHg, and signs of mild heart failure. He recovered within 24 hours of stopping all three drugs.¹ It was suggested that these effects had occurred as a result of raised metoprolol levels, which had occurred because bupropion inhibited the metabolism of metoprolol by the cytochrome P450 isoenzyme CYP2D6.

The manufacturers of bupropion have predicted this interaction and recommend that if metoprolol is added to treatment with bupropion, doses at the lower end of the range should be used. If bupropion is added to existing treatment, decreased dosages of metoprolol should be considered.^{2,3}

It seems likely that this interaction could occur with any of the beta blockers metabolised by CYP2D6 (see 'Table 22.1', (p.833)).

Beta blockers + Calcium-channel blockers; Dihydropyridines

The use of beta blockers with felodipine, isradipine, lacidipine, nicardipine, nimodipine and nisoldipine normally appears to be useful and safe. However, severe hypotension and heart failure have occurred rarely when a beta blocker was given with nifedipine or nisoldipine. Changes in the pharmacokinetics of the beta blockers and calcium-channel blockers may also occur on concurrent use, but they do not appear to be clinically important.

Clinical evidence

(a) Felodipine

A double-blind, crossover study in 8 healthy subjects found that over a 5-day period, metoprolol 100 mg twice daily did not affect the pharmacokinetics of felodipine 10 mg twice daily. On the other hand, the bioavailability and peak plasma levels of metoprolol were increased by 31% and 38%, respectively.¹ Another study in 10 healthy subjects given felodipine 10 mg with either metoprolol 100 mg, pindolol 5 mg, propranolol 80 mg, or timolol 10 mg found no changes in heart rate, PR interval or blood pressure that might be considered to be harmful to patients with hypertension or angina. However, 7 of the 10 subjects reported some increase in adverse effects.²

(b) Isradipine

A preliminary report of a study in 24 healthy subjects found that propranolol 40 mg twice daily given with isradipine 5 mg twice daily caused some modest changes in the pharmacokinetics of both drugs (peak propranolol plasma levels increased by 17%, peak isradipine plasma levels reduced by 18%), but the AUCs were not significantly altered.³ However, an earlier preliminary report by the same research group in 17 subjects found an increase in the propranolol AUC of 28%, a reduction in the isradipine AUC of 22% and a 59% increase in the peak propranolol levels.⁴

(c) Lacidipine

Twelve patients with mild to moderate hypertension not satisfactorily controlled by atenolol alone were given lacidipine 4 mg once daily with or without atenolol 100 mg daily for 14 days. There was no evidence of a significant change in drug levels, but there was a significant additive reduction in blood pressure during concurrent use, when compared with the reductions observed with either drug alone.⁵

Single-dose studies in 24 healthy subjects found that propranolol 160 mg reduced the peak plasma levels and AUC of lacidipine 4 mg by 38% and 42%, respectively, while the peak plasma levels and AUC of the propranolol were increased by 35% and 26%, respectively. There was a modest additive reduction of 4 to 6 mmHg in blood pressure, and the combination reduced the heart rate, but not to an extent greater than propranolol alone. No significant adverse effects were seen.⁶ However, a further preliminary report of a study by the same authors, in which 12 hypertensive patients were given propranolol 160 mg twice daily and lacidipine 4 mg daily for 2 weeks, found a non-significant 30% increase in systemic availability of lacidipine, and no change in propranolol pharmacokinetics. In addition, no clinically significant alterations in ECG recordings, blood pressure, or pulse rate were seen.⁷

(d) *Lercanidipine*

The manufacturer notes that when lercanidipine was given with **metoprolol**, the bioavailability of lercanidipine was reduced by 50% while the bioavailability of **metoprolol** was not changed. They suggest this may occur with any beta blocker, and that some adjustment of the lercanidipine dose may be needed.⁸

(e) *Nicardipine*

Nicardipine 30 mg did not affect the pharmacokinetics or pharmacodynamics of **atenolol** 100 mg in a single-dose study in healthy subjects.⁹

In another study, 14 healthy subjects were given nicardipine 50 mg every 12 hours and **metoprolol** 100 mg every 12 hours, both together and alone, for 11 doses. **Metoprolol** plasma levels were raised by 28% by the nicardipine in the 7 subjects who were of the extensive CYP2D6 metaboliser phenotype, but had no significant effect in the poor metabolisers. The extent of the beta-blockade was unchanged in all of them.¹⁰

Preliminary analysis of another study in healthy subjects found that the pharmacokinetics of both **propranolol** 80 mg twice daily and nicardipine 30 mg three times daily were unaffected when they were given together for 6 days.¹¹ However, this contrasts with two single-dose studies, which found that nicardipine 30 mg increased the AUC and peak plasma levels of a single 80-mg dose of **propranolol** by 47% and 80%, respectively,¹² and raised the AUC and peak plasma levels of an 80-mg dose of sustained-release **propranolol** to a lesser extent (17% and 22%, respectively).¹³ A related single-dose study found that in elderly healthy subjects nicardipine 30 mg increased the maximum plasma levels and AUC of **propranolol** 40 mg by about 100% and 80%, respectively. Nicardipine caused a further decrease in blood pressure, and attenuated the reduction in heart rate seen with **propranolol** alone.¹⁴

A study in 8 healthy subjects found that the increase in heart rate during exercise associated with a single 40-mg dose of nicardipine was reduced by one drop of **timolol** 0.5% put into each eye. Systolic blood pressure was also reduced during concurrent use, but nicardipine did not cause any further reduction in the intraocular pressure reduction produced by **timolol**.¹⁵

(f) *Nifedipine*

Nifedipine 10 mg three times daily did not alter the pharmacokinetics of **atenolol** 100 mg daily,^{16,17} **betaxolol**,¹⁸ **metoprolol** 100 mg twice daily^{16,17} or **propranolol** 80 mg twice daily.¹⁶ A single-dose study also found no pharmacokinetic interaction between nifedipine and **atenolol**.¹⁹ However, another study found that nifedipine 10 mg three times daily caused an increase in the peak plasma level and AUC of **propranolol** 80 mg twice daily of 56% and 23%, respectively.¹⁸ Another study found that the absorption of a single-dose of **propranolol** appeared to be faster, leading to higher initial concentrations, when it was given after nifedipine.²⁰ Regardless of the pharmacokinetic changes, none of these studies in healthy subjects found any adverse haemodynamic effects from the combination of nifedipine and these beta blockers.^{16,18,19}

Similarly, in studies in patients with normal left ventricular function there was no evidence of adverse haemodynamic effects when nifedipine (single-dose sublingual^{21,22} or intravenously,²³ or daily dose orally²³) was given with **atenolol**,²³ **celiprolol**²² or **propranolol**.^{21,24}

However, there are a few earlier isolated case reports of hypotension and heart failure with the combination. Two patients with angina taking **alprenolol** or **propranolol** developed heart failure when they were given nifedipine 10 mg three times daily. The signs of heart failure disappeared when the nifedipine was withdrawn.²⁵ One out of 15 patients with hypertension and exertional angina progressively developed hypotension (90/60 mmHg) when given nifedipine 10 mg twice daily in addition to treatment with **atenolol** 50 mg daily and a diuretic for one month.²⁶ A patient with angina taking **propranolol** 160 mg four times daily developed severe and prolonged hypotension (blood pressure initially not recordable, then 60 mmHg systolic) 18 days after nifedipine 10 mg three times daily was substituted for 'isosorbide', and this may have been a factor that led to fatal myocardial infarction.²⁷ Heart failure is also described in another patient with angina taking **atenolol** (and various other drugs) when nifedipine 20 mg three times daily was given.²⁸

A patient developed hypotension and severe bradycardia on two occasions after being given her usual antihypertensive medication of **labetalol** and extended-release nifedipine crushed and given via a nasogastric tube. Crushing the nifedipine tablet altered its release characteristics so that the

total dose was released quickly resulting in profound hypotension. The **labetalol** produced additional hypotensive effects and prevented a compensatory increase in heart rate.²⁹

(g) *Nimodipine*

In a preliminary report of a study in 12 healthy subjects, nimodipine 30 mg three times daily for 4 days had no significant effect on the changes in heart rate, blood pressure or cardiac output seen with either **propranolol** 40 mg or **atenolol** 25 mg three times daily. The pharmacokinetics of the beta blockers were also unaltered.³⁰

(h) *Nisoldipine*

A single 20-mg dose of nisoldipine increased the steady-state AUC and peak plasma level of **propranolol** 160 mg daily by 35% and 55%, respectively. After combined treatment for 7 days, the AUC of **propranolol** was increased by 60% and the peak plasma level was increased by 55%. The combination enhanced blood pressure reduction to a small extent, but nisoldipine did not significantly reduce the effect of **propranolol** on heart rate.³¹ Similarly, another study found that a single 20-mg dose of nisoldipine increased the AUC and peak plasma level of a single 40-mg dose of **propranolol** by 43% and 68%, respectively, and that the AUC and peak plasma level of nisoldipine increased 30% and 57%, respectively. In this study, nisoldipine was reported to enhance beta-blockade.³² However, the same research group later found that the steady-state pharmacokinetics of **propranolol** 80 mg twice daily and nisoldipine 10 mg twice daily were not affected by concurrent use for 7 days, but nisoldipine attenuated the decrease in forearm blood flow seen with **propranolol**.³³ The manufacturer of nisoldipine notes that severe hypotension can occur when it is given at the same time as beta blockers, and that, in isolated cases, signs of heart failure can also occur.³⁴

Mechanism

Not understood. Where pharmacokinetic changes are seen, a possible reason is that the metabolism of the beta blockers is altered by changes in blood flow through the liver. The pharmacodynamic changes with nifedipine may be explained by the fact that nifedipine reduces the contractility of the heart muscle. This is counteracted by a sympathetic reflex increase in heart rate due to nifedipine-induced peripheral vasodilation, so that the ventricular output stays the same or is even improved. The presence of a beta blocker may oppose this to some extent by slowing the heart rate, which allows the negative inotropic effects of nifedipine to go unchecked.

Importance and management

The concurrent use of beta blockers and the dihydropyridine calcium-channel blockers is common, and normally valuable. However, isolated cases of severe hypotension and heart failure have been seen in a few patients taking beta blockers and nifedipine or nisoldipine. It has been suggested that those likely to be most at risk are patients with impaired left ventricular function³⁵ (which is a caution for the use of nifedipine anyway) and/or those taking beta blockers in high dosage. Bear this in mind. It should also be noted that the topical use of beta blockers (such as **timolol** eye drops) may reduce heart rate and blood pressure. Changes in the pharmacokinetics of the beta blockers and calcium-channel blockers may also occur, but these do not appear to be clinically important. It may also be worth noting that all but one of the cases of an adverse reaction with a beta blocker and nifedipine occurred with 'short-acting' formulations, which are now considered unsuitable for long-term management of angina or hypertension, since they are associated with larger variations in blood pressure and heart rate. The remaining case was associated with the incorrect use of an extended-release nifedipine preparation.

Beta blockers + Calcium-channel blockers; Diltiazem

The cardiac depressant effects of diltiazem and beta blockers are additive, and although concurrent use can be beneficial, close monitoring is recommended. A number of patients, (usually those with pre-existing ventricular failure or conduction abnormalities) have developed serious and potentially life-threatening bradycardia. Diltiazem increases the serum levels of propranolol and metoprolol, but not those of atenolol, but these changes are probably not clinically important.

Clinical evidence

(a) Cardiac depressant effects

Ten patients were admitted to an intensive coronary care unit during one year with severe bradycardia (heart rates of 24 to 44 bpm) after taking

diltiazem 90 to 360 mg daily with **propranolol** 30 to 120 mg daily, **atenolol** 50 to 100 mg daily, or **pindolol** 90 mg daily. All were relatively elderly and presented with lethargy, dizziness, syncope, chest pain, and in one case pulmonary oedema. The ECG abnormalities were localised in the sinus node, the primary rhythm disorders being junctional escape rhythms, sinus bradycardia and sinus pause. These resolved within 24 hours of withdrawing the drugs, although a temporary pacemaker was needed in 4 patients.¹

Symptomatic and severe bradyarrhythmias of this kind have been described in case reports in 16 other patients taking diltiazem with **atenolol**,² **carateolol**,³ **metoprolol**,^{2,4,5} **nadolol**,⁶ **pindolol**,⁷ **propranolol**,^{2,4,6,8} or **sotalolol**.^{3,7} AV block with unusual ECG changes (T-wave inversion and ST-segment depression) was found in a 16-year-old girl following an overdose of diltiazem and **propranolol**.⁹ In a later prospective study of hospital admissions due to cardiovascular adverse drug reactions, bradycardia, hypotension, syncope and worsening heart failure were noted in 21 patients taking beta blockers with diltiazem. The beta blockers involved were **propranolol** (13 patients), **atenolol** (5), **metoprolol** (2) and **oxprenolol** (1).¹⁰ Similarly severe sinus bradycardia occurred in 8 of 59 patients in three early clinical studies of the combination of diltiazem and **propranolol**.^{11–13} One patient developed congestive heart failure.¹³ In contrast, four other similar clinical trials did not report any adverse effects,^{14–17} and in a single-dose study, one drop of **timolol** 0.5% eye drops did not cause an additional reduction in heart rate when it was given to healthy subjects with a 60-mg dose of diltiazem.¹⁸

(b) Pharmacokinetics

In healthy subjects, diltiazem increased the AUC of **propranolol** and **metoprolol** by 48% and 33%, respectively, and increased the maximum serum levels by 45% and 71%, respectively, but **atenolol** was not significantly affected.¹⁹ Another study found that diltiazem caused a 24% to 27% reduction in **propranolol** clearance.²⁰

Mechanism

The bradycardic effects of the beta blockers can be additive with the delay in conduction through the atrioventricular node caused by diltiazem.⁷ This advantageously increases the antianginal effects in most patients, but in a few these effects may exacerbate existing cardiac abnormalities. Diltiazem apparently also inhibits the metabolism of propranolol and metoprolol, but the exact mechanism for this is not clear.¹⁹

Importance and management

Concurrent use is unquestionably valuable and uneventful in many patients, but severe adverse effects can develop. This is well established. A not dissimilar adverse interaction can occur with 'verapamil', (p.841). On the basis of 6 reports, the incidence of symptomatic bradyarrhythmia was estimated to be about 10 to 15%.¹ It can occur with different beta blockers, even with very low doses, and at any time from within a few hours of starting treatment to 2 years of concurrent use.¹ The main risk factors seem to be ventricular dysfunction, or sinoatrial or AV nodal conduction abnormalities.¹ Note that these are usually contraindications to the use of diltiazem. Patients with normal ventricular function and no evidence of conduction abnormalities are usually not at risk. Concurrent use should be well monitored for evidence of adverse effects. Changes in the pharmacokinetics of the beta blockers may also occur, but these changes are probably not clinically important.

Beta blockers + Calcium-channel blockers; Verapamil

The cardiac depressant effects of verapamil and beta blockers are additive, and although concurrent use can be beneficial, serious cardiodepression (bradycardia, asystole, sinus arrest) sometimes occurs. It has been suggested that the combination should only be given to those who can initially be closely supervised. An adverse interaction can also occur with beta blockers given as eye drops.

Clinical evidence

(a) Adverse interactions

1. *Intravenous administration.* Ventricular asystole developed in 2 cases when intravenous verapamil was given after the unsuccessful use of intravenous **practolol**, to treat supraventricular tachycardia in a 70-year-old man and a 6-month-old baby.¹ In a later study, the combination of intravenous verapamil and intravenous **practolol** produced a marked reduction in cardiac contractility, which was more evident when **practolol** was given first.²

2. *Oral administration.* In one series, 34 out of 42 patients taking beta blockers (daily dose: **atenolol** 100 mg (34 patients), **atenolol** 50 mg (2), **propranolol** 160 mg (4), **pindolol** 20 mg (1), or **metoprolol** 100 mg (1)) with verapamil 360 mg daily experienced a reduction in anginal episodes over a mean period of 6.5 months while taking both drugs. However, 12 patients needed a reduced dosage or withdrawal of one or both drugs. One had non-specific symptoms (drugs withdrawn), 2 had bradyarrhythmias (drugs withdrawn) and 6 experienced dyspnoea (3 withdrawals and 3 dosage reductions), presumed to be secondary to left ventricular failure. Other complications were tiredness (2 patients) and postural hypotension (1 patient), which were dealt with by reducing the dosage.³ In another study in 15 patients with angina who were taking **atenolol** with verapamil, 4 experienced profound lethargy, one had left ventricular failure and 4 had bradyarrhythmias.⁴

Other case reports and studies describe heart failure,^{5,6} dyspnoea,^{5,7,8} sinus arrest,^{9,10} heart block,^{9,11–13} hypotension,^{5,6,8,10,13–16} and bradycardia^{4,5,8,10,11,14–18} in patients taking verapamil with **alprenolol**,⁹ **atenolol**,^{6,9,10,12} **metoprolol**,^{5,11,13,15} **propranolol**^{7,8,14,16–18} or **pindolol**.⁵ In two further cases, bradycardia occurred in patients taking verapamil and using **timolol** eye drops.^{19,20} Another case has been reported, but this was complicated by the presence of 'flecainide', (p.844). A number of reports noted that patients experiencing this interaction had reasonable left ventricular function.^{5,10,12,19} Heart block and hypotension or cardiogenic shock has also been reported after verapamil was given with **atenolol**²¹ or **propranolol**²² in overdose.

(b) Pharmacokinetic interactions

The pharmacokinetics of **atenolol** were not altered by verapamil in one study in a single patient.²³ In a study in 15 patients the plasma levels of verapamil and **atenolol** varied greatly during individual and concurrent use but mean concentrations were not significantly changed.⁴ In another study in 10 patients the mean AUC of **atenolol** was not significantly increased by verapamil, but individual patients had **atenolol** AUC increases of up to 112%.²⁴

Verapamil raised the **metoprolol** AUC in 10 patients by 33% and the peak plasma levels by 41%. The minimum pulse rate and systolic blood pressure (1 to 3 hours post dose) were also lower in those taking the combination than with **metoprolol** alone.¹⁵ Similarly, in a single-dose study in 9 healthy subjects, the AUC and maximum plasma level of **metoprolol** increased by 35% and 64%, respectively, and the AUC and half-life of verapamil increased by 57% and 29%, respectively, on concurrent use.²⁵

In healthy subjects, verapamil reduced the clearance of **propranolol** by 26 to 32% and increased its AUC by 46 to 58% after 6 days of concurrent use.²⁶ Similarly, in 5 patients, verapamil increased the peak plasma levels of **propranolol** by 94%, and its AUC by 66%.¹⁸ **Propranolol** did not affect the pharmacokinetics of verapamil.¹⁸ However, in another study in healthy subjects no pharmacokinetic interaction was noted between **propranolol** and verapamil after they were taken together for 6 days.²⁷

In a randomised, crossover study, a single 120-mg dose of (*R*)-verapamil reduced the bioavailability of a single 50-mg dose of **talinalol** by 25% in 9 healthy subjects.²⁸

Mechanism

Both beta blockers and verapamil have negative inotropic effects on the heart, which can be additive.²⁷ Given together they can cause marked bradycardia and may even depress the contraction of the ventricle completely. Verapamil can also raise the serum levels of beta blockers that are extensively metabolised in the liver (e.g. metoprolol, propranolol), probably by inhibiting their metabolism,²⁹ although the exact mechanism for this is unclear. It is thought that verapamil affects talinalol bioavailability by modulating intestinal P-glycoprotein.^{28,30}

Importance and management

Well documented and well established interactions. Although concurrent use can be uneventful and successful, the reports cited here amply demonstrate that it may not always be safe. The difficulty is identifying the patients most at risk. In the UK, the BNF says that oral concurrent use should only be considered if myocardial function is well preserved, and that verapamil should not be injected in patients recently given beta blockers because of the risk of hypotension and asystole. They also note that, although 30 minutes has been suggested as a sufficient interval before giving a beta blocker when a verapamil injection has been given first, the safety of this has not been established.³¹ The manufacturers of verapamil contraindicate its intravenous use in those receiving intravenous beta blockers.³²

It has been advised that the initiation of treatment should be restricted to hospital practice, where the dose of each drug can be carefully titrated and the patient closely supervised, particularly during the first few days when adverse effects are most likely to develop.^{3,4,18} Some have suggested that beta blockers that are extensively metabolised (e.g. metoprolol, propranolol) may possibly carry some additional risk because verapamil raises their serum levels.²⁵ However, others contend that, since the interaction occurs with atenolol (which is largely excreted unchanged in the urine), the pharmacodynamic effects are more important than any pharmacokinetic changes.^{4,10,18} Note that the latter argument is probably valid, as changes of this size, or even more, in the AUC of beta blockers have proved not to be clinically important.

Beta blockers + Chloroquine or Hydroxychloroquine

Hydroxychloroquine and possibly chloroquine may increase the blood levels of metoprolol, but this is probably not clinically important.

Clinical evidence, mechanism, importance and management

Hydroxychloroquine 400 mg daily for 8 days increased the AUC and peak plasma levels of a single 100-mg dose of **metoprolol** by 65% and 72%, respectively, in 7 healthy subjects who were of the extensive CYP2D6 metaboliser phenotype,¹ see ‘Genetic factors’, (p.4). Hydroxychloroquine may inhibit the metabolism of **metoprolol** by the cytochrome P450 isoenzyme CYP2D6. The clinical significance of this interaction is unknown, but changes of this size in the AUC of beta blockers have proved not to be clinically important. Other beta blockers that are extensively metabolised (see ‘Table 22.1’, (p.833).) may behave like **metoprolol**, but those that are excreted unchanged in the urine would not be expected to interact. *In vitro*

study suggests that **chloroquine** may interact with **metoprolol** in the same way as hydroxychloroquine.² More study is needed.

Beta blockers + Dextropropoxyphene (Propoxyphene)

A single-dose study has shown that the bioavailability of metoprolol is markedly increased by dextropropoxyphene and a case report supports these findings. The bioavailability of propranolol is also increased, but to a lesser extent.

Clinical evidence

A 48-year-old man taking **metoprolol** 100 mg daily developed dizziness and sweating 3 hours after taking dextropropoxyphene 200 mg and paracetamol (acetaminophen) 1.3 g. He was found to have a heart rate of 30 to 40 bpm and a blood pressure of 98/65 mmHg, which returned to normal over the following 8 hours. Assessment of blood samples showed that his normal **metoprolol** level was 89 nanograms/mL, but that this had risen to 160 nanograms/mL in the presence of dextropropoxyphene.¹

Preliminary results of a study suggest that after taking dextropropoxyphene [dose not stated] for a day the bioavailability of a single 100-mg oral dose of **metoprolol** was increased by almost 260% and the total body clearance was reduced by 18% in healthy subjects. The bioavailability of a single 40-mg oral dose of **propranolol** was increased by about 70%.²

Mechanism

Dextropropoxyphene inhibits the metabolism of metoprolol and propranolol by the cytochrome P450 isoenzyme CYP2D6, which results in increased levels and therefore increased effects. Propranolol is probably affected to a lesser extent as it is also metabolised by CYP1A2.

Importance and management

Evidence is limited, but an interaction seems established. It seems likely that this interaction could occur with any of the beta blockers metabolised by CYP2D6 (see ‘Table 22.1’, (p.833)). Therefore it would be prudent to be alert for evidence of an increased response but so far there seems to be very little evidence to suggest that concurrent use causes problems. No interaction would be expected with those beta blockers that are largely excreted unchanged in the urine (see ‘Table 22.1’, (p.833)).

Beta blockers + Diphenhydramine

Diphenhydramine inhibits the metabolism of metoprolol, but this is probably not clinically important.

Clinical evidence

In a placebo-controlled study, a single 100-mg dose of **metoprolol** was given to 16 healthy male subjects on day 3 of a 5-day course of diphenhydramine 50 mg three times daily. Diphenhydramine decreased the clearance of **metoprolol** by 46% and increased its AUC by 61% in the 10 subjects who were of the extensive CYP2D6 metaboliser phenotype, but had no significant effect in the 6 poor metabolisers. However, the **metoprolol** AUC in the extensive metabolisers taking diphenhydramine was still only about one-third of that in the poor metabolisers taking placebo. The effect of **metoprolol** on heart rate and systolic blood pressure during exercise was also increased by diphenhydramine in extensive metabolisers. However, as before, it was not as great as the effect of **metoprolol** alone in poor metabolisers.¹ The same group of researchers repeated this study in 20 healthy women and found broadly similar results.²

Mechanism

Diphenhydramine inhibits the cytochrome P450 isoenzyme CYP2D6, which is responsible, in part, for the metabolism of metoprolol and some other beta blockers. CYP2D6 shows polymorphism, with some individuals lacking significant CYP2D6 activity (poor metabolisers), in whom diphenhydramine would have little or no effect. See 'Genetic factors', (p.4), for more on polymorphism.

Importance and management

Information appears to be limited to these studies. Increases in plasma metoprolol levels of this size are unlikely to be clinically relevant. Indeed, despite the likely widespread use of 'extensively metabolised' beta blockers (see 'Table 22.1', (p.833)) and diphenhydramine, no problems seem to have been reported.

Beta blockers + Dronedarone

Dronedarone increases the AUC of metoprolol in patients with a CYP2D6 extensive metaboliser phenotype. The increase in negative inotropic effects are modest at the recommended therapeutic dose of dronedarone.

Clinical evidence

In a study, 44 healthy subjects (39 extensive and 5 poor CYP2D6 metabolisers) were given **metoprolol** 200 mg daily for 13 days. Concurrent dronedarone 800 mg, 1.2 g or 1.6 g daily from day 5 increased the AUC of **metoprolol** in a dose-dependent manner in the 39 subjects who were extensive metabolisers by 1.63-, 2.08- and 2.53-fold, respectively. In addition, concurrent use resulted in an additive dose-dependent negative inotropic effect. In contrast, **metoprolol** plasma levels were not affected by dronedarone.¹

Mechanism

Dronedarone is structurally related to amiodarone, which is known to inhibit the cytochrome P450 isoenzyme CYP2D6, by which metoprolol is metabolised (see 'Amiodarone + Beta blockers', p.246). This study also shows that dronedarone inhibits CYP2D6, effectively making extensive metabolisers into poor metabolisers. For more information on metaboliser status see 'Genetic factors', (p.4).

Importance and management

A pharmacokinetic interaction is established, but its clinical relevance is uncertain. The negative inotropic effect of metoprolol was almost doubled by the addition of dronedarone 1.6 g daily, but at the anticipated therapeutic dose of 800 mg the effects were modest. Other beta blockers that are metabolised by CYP2D6 (see 'Table 22.1', (p.833)) would be expected to interact similarly.

Beta blockers + Ergot derivatives

The use of beta blockers with ergot derivatives in the management of migraine is not uncommon, but concurrent use has resulted in three cases of severe peripheral vasoconstriction and one of hypertension.

Clinical evidence

A man with recurrent migraine headaches, reasonably well-controlled over a 6-year period with 2 daily suppositories of **Cafergot** (containing **ergotamine tartrate**) developed progressively painful and purple feet a short while after starting to take **propranolol** 30 mg daily. When he eventually resumed taking the **Cafergot** alone there was no further evidence of peripheral vasoconstriction.¹

A similar case has been reported elsewhere, although an interaction is inconclusive in this patient, as neither the **ergotamine** nor the **propranolol** were taken alone.² Another similar case occurred in a woman taking **oxprenolol** and **ergotamine tartrate** [dosages unknown] for some considerable time. Arteriography showed severe spasm in a number of arteries, which responded eventually to an intra-arterial infusion of glyceryl trinitrate and heparin.³ Severe pain in the legs and feet occurred in another man after he took **methysergide** 3 mg and **propranolol** 120 mg daily for 2 weeks. He did not respond to various therapies, and in 6 days it was necessary to amputate both his legs below the knee because of gangrene.³ A woman taking **propranolol** for migraine prophylaxis became hypertensive (BP 180/120 mmHg) with a crushing substernal pain immediately after being given oxygen, prochlorperazine 5 mg and intravenous **dihydroergotamine** 750 micrograms for an acute migraine headache. She recovered uneventfully. She was later found to be hyperthyroid.⁴

These reports contrast with another stating that the use of **propranolol** with **ergotamine** was both effective and uneventful in 50 patients.⁵

Mechanism

Uncertain. One suggestion is that additive vasoconstriction occurs.^{1,3} Ergot derivatives cause vasoconstriction, and the beta blockers do the same by blocking the normal (beta₂-stimulated) sympathetic vasodilatation. The beta blockers also reduce blood flow by reducing cardiac output.

Importance and management

Concurrent use is usually safe and effective, and there are only a handful of reports of adverse interactions. It was suggested that at least one of these could have been due to the ergotamine alone (i.e. ergotism).⁵ However, it would clearly be prudent to be extra alert for any signs of an adverse response, particularly those suggestive of reduced peripheral circulation (coldness, numbness or tingling of the hands and feet).

Beta blockers + Finasteride

Finasteride 5 mg daily for 10 days caused no change in the pharmacokinetics or pharmacodynamics of a single 80-mg dose of propranolol in healthy subjects.¹ Further, the manufacturers say that finasteride was used with beta blockers in clinical studies without any evidence of an interaction.^{2,3} Similarly, 'dutasteride', (p.1257) does not appear to interact with beta blockers.

3. Proscar (Finasteride). Merck and Co. Inc. US Prescribing information, March 2007.

Beta blockers + Fish oils

The hypotensive effect of propranolol may be enhanced by fish oil.

Clinical evidence, mechanism, importance and management

In a study 36 patients with mild hypertension were given either **propranolol** 80 mg daily or fish oil 9 g daily (as capsules and equivalent to **eicosapentaenoic acid** 1.8 g and **docosahexaenoic acid** 1.1 g daily) for 36 weeks followed by placebo for 4 weeks. A further group of 16 patients were given **propranolol** 80 mg daily for 12 weeks, **propranolol** plus fish oil 9 g daily for 12 weeks, **propranolol** plus fish oil placebo for 12 weeks, and finally **propranolol** placebo for 4 weeks. Fish oil alone decreased blood pressure to a similar extent to **propranolol**, and decreases in blood pressure with the combination were greater than with either **propranolol** or fish oil alone.¹ A further similar study in 14 patients taking a beta blocker found that when they were also given 4 capsules of *Omacor* (equivalent to **eicosapentaenoic acid** 1.9 g and **docosahexaenoic acid** 1.5 g) daily for 6 weeks their blood pressure decreased by a further 3.3/1.9 mmHg.²

The mechanism is uncertain, but as fish oil seems to have a hypotensive effect of its own, it may enhance the hypotensive effect of any beta blocker.

Beta blockers + Flecainide

The combined use of flecainide and beta blockers may have additive cardiac depressant effects. An isolated case of bradycardia and fatal AV block has been reported during the use of flecainide with sotalol, and bradycardia has been reported in a patient taking flecainide who was given timolol eye drops.

Clinical evidence, mechanism, importance and management

A study on cardiac function and drug clearance in 10 healthy subjects found that when **propranolol** 80 mg three times daily was given with flecainide 200 mg twice daily for 4 days the AUCs of both drugs were increased by 20 to 30%, and they had some additive negative inotropic effects.¹ A report describes a patient taking flecainide 100 mg twice daily who developed bradycardia and fatal atrioventricular conduction block 3 hours after taking a second dose of **sotalol** 40 mg.² Another report describes a patient with chronic atrial fibrillation that had been stable for 5 years during treatment with flecainide and verapamil. Within 3 days of starting **timolol** 0.1% eye drops twice daily, she developed bradycardia with a heart rate of 35 to 40 bpm. The eye drops were stopped and 16 hours after the last dose, her heart rate had increased to 90 to 100 bpm.³ Careful monitoring has therefore been recommended if beta blockers are added to flecainide. Note that serious cardiac depression has been seen following the use of flecainide with other drugs that have negative inotropic effects such as 'verapamil', (p.261).

Beta blockers + Food

Food can increase, decrease or not affect the bioavailability of beta blockers, but none of the changes has been shown to be of clinical importance.

Clinical evidence, mechanism, importance and management

Food increased the AUC of **propranolol** by 50 to 80%,^{1–3} **metoprolol** by about 40%¹ and **labetalol** by about 40%,⁴ probably by changing the extent of their first pass metabolism through the liver.^{2–4} Food did not affect the extent of absorption of a sustained-release formulation of **propranolol**.² Food had very little effect on the absorption of **oxprenolol**^{5,6} or **pindolol**,⁷ whereas the AUC of **atenolol** was reduced by about 20%.⁸ A later study suggested that **atenolol** (and possibly other hydrophilic beta blockers, see

'Table 22.1', (p.833)) become tightly associated with bile acid micelles, preventing their absorption.⁹ None of these changes have been shown to be of clinical importance, nor is it clear whether it matters if patients take these drugs in a regular pattern in relation to meals. Beta blocker serum levels vary widely between patients (a 20-fold difference in propranolol AUC has been noted between individuals),¹ and individualising the dose is therefore more of an issue than food intake.

Beta blockers + Grapefruit and other fruit juices

The bioavailability of celiprolol is markedly reduced by both grapefruit juice and orange juice, the bioavailability of atenolol is moderately reduced by orange juice, and the bioavailability of talinolol is reduced by grapefruit juice.

Clinical evidence, mechanism, importance and management

(a) Acebutolol

In a randomised, crossover study, 10 healthy subjects were given a 200-mL drink of normal-strength **grapefruit juice** three times a day for 4 days (total of 11 drinks), with a single 400-mg dose of acebutolol on the morning of day 3. **Grapefruit juice** decreased the maximum levels and AUC of acebutolol by a modest 19% and 6%, respectively. No significant changes in the heart rate or blood pressure were seen.¹

(b) Atenolol

In a randomised crossover study 10 healthy subjects were given 200 mL of **orange juice** (from concentrate) three times daily with a single 50-mg dose of atenolol on the third day. **Orange juice** reduced the AUC and maximum serum levels of atenolol by 40% and 49%, respectively, and also attenuated the atenolol-induced reduction in heart rate. The effect of atenolol on blood pressure was unchanged.² This suggests that orange juice may make atenolol less effective when it is used for rate control, but the clinical significance of this effect is unclear.

(c) Celiprolol

In a study 12 healthy subjects were given **grapefruit juice** 200 mL three times daily for 2 days. On the third day celiprolol 100 mg was given with the second of four 200 mL volumes of **grapefruit juice**, and on day 4 two further 200 mL volumes of **grapefruit juice** were given. The AUC and peak plasma levels of celiprolol were reduced by about 87% and 95%, respectively. The half-life of celiprolol was slightly prolonged. However, **grapefruit juice** did not affect the changes in blood pressure or heart rate caused by celiprolol.³ In a similar study in 10 healthy subjects, 200 mL of 'normal-strength' **orange juice**, given 2 to 4 times daily for 4 days, reduced the AUC and peak plasma levels of a single 100-mg dose of celiprolol given on day 3 by 83% and 89%, respectively. The half-life of celiprolol was prolonged from 4.6 to 10.8 hours and the renal excretion of celiprolol was reduced by 77%. However, **orange juice** did not alter the effects of celiprolol on blood pressure or heart rate.⁴

The mechanism of this effect is not known, but suggestions include an effect on intraduodenal pH and the lipid solubility of celiprolol, or the formation of a complex between celiprolol and an ingredient of **grapefruit** or **orange juice** that interfered with celiprolol absorption. Alternatively, inhibition of uptake transporter proteins in the intestine may have reduced absorption.^{3,4}

Although the clinical relevance of these effects has not been fully assessed, the studies suggest that the effects of celiprolol on blood pressure and heart rate are not affected. Nevertheless the marked reduction in celiprolol bioavailability in the presence of **grapefruit** or **orange juice** suggests this interaction may be of clinical significance in some patients.^{3,4}

(d) *Talinolol*

Grapefruit juice 300 mL decreased the AUC of a single 50-mg dose of talinolol by 44%, increased the maximum level by 42%, and increased the oral clearance by 62%. Similar results were seen after repeated administration of **grapefruit juice** over 6 days. However, the haemodynamic effects of talinolol were not altered by **grapefruit juice**.⁵ Because P-glycoprotein levels did not appear to be affected by **grapefruit juice**, it was suggested that constituents in the juice might inhibit an uptake process other than P-glycoprotein. [Note that, in contrast, a study in *animals* found that the bioavailability of talinolol was increased by **grapefruit juice**.⁶] The decreases in talinolol levels are unlikely to be clinically relevant.

Beta blockers + H₂-receptor antagonists; Cimetidine

No clinically significant interaction appears to occur between the beta blockers and cimetidine, although the blood levels of some extensively metabolised beta blockers (e.g. metoprolol, propranolol) can be doubled. Isolated case reports describe bradycardia, an irregular heart beat, or hypotension in patients taking cimetidine with atenolol, metoprolol, or labetalol, respectively.

Clinical evidence

(a) *Acebutolol*

A study *in animals* found that the pharmacokinetics of acebutolol were not affected by cimetidine, which suggests that a clinical interaction is unlikely.¹

(b) *Atenolol*

A report briefly mentions a patient taking a beta blocker for angina who developed profound sinus bradycardia (36 bpm) and hypotension when cimetidine was also given.² The beta blocker was not specified, but it was identified as atenolol elsewhere.³ Three well controlled studies in healthy subjects and patients found that cimetidine did not significantly alter blood levels of atenolol, nor did it alter the effect of atenolol on heart rate.^{4–9} Atenolol did not affect cimetidine pharmacokinetics.⁶

(c) *Betaxolol*

The blood levels and pharmacokinetics of betaxolol were unaffected by cimetidine in one study.¹⁰

(d) *Bisoprolol*

A study in 6 healthy subjects found that the maximum plasma level, AUC and clearance of bisoprolol were not significantly affected by cimetidine^{11,12} although an analysis of the results by other authors suggested that cimetidine may cause a significant reduction in the renal clearance of bisoprolol.¹³

(e) *Carvedilol*

The blood levels and pharmacokinetics of carvedilol were unaffected by cimetidine in one study.¹⁴

(f) *Labetalol*

The AUC and bioavailability of a single 200-mg oral dose of labetalol was increased by 66% and 56%, respectively, in 6 healthy subjects who took cimetidine 400 mg four times daily for 4 days.¹⁵ One subject developed postural hypotension (70/40 mmHg), felt light-headed and almost fainted on standing.¹⁵ Conversely, the AUC of intravenous labetalol was unaffected by cimetidine.¹⁵

(g) *Metoprolol*

A study in 6 healthy subjects given metoprolol 100 mg twice daily for a week found that the cimetidine 1 g daily in divided doses increased the peak plasma levels of metoprolol by 70% and the AUC by 61%, but this did not increase the effect of metoprolol on the heart rate during exercise.^{4–6} Metoprolol did not affect cimetidine pharmacokinetics.⁶

Three other studies confirmed that cimetidine increased metoprolol serum levels after single or multiple doses, but none of the studies found that this interaction resulted in an increase the effect of metoprolol on the heart rate during exercise.^{16–19} An isolated case describes one patient who complained of a “very irregular heart beat” while taking both drugs, which was much less marked when he took the two drugs separated by as much time as possible.²⁰ In contrast, two other studies found that cimetidine did not affect the serum levels of a single 100-mg dose of metoprolol.^{7,8}

(h) *Nadolol*

The blood levels and pharmacokinetics of nadolol were unaffected by cimetidine, and the effects of the beta blocker on heart rate and blood pressure were not changed.²¹

(i) *Nebivolol*

Cimetidine 400 mg twice daily increased the AUC and peak plasma levels of a single 5-mg dose of nebivolol by 48% and 23%, respectively, but did not alter the effect of nebivolol on blood pressure or heart rate.²²

(j) *Penbutolol*

The blood levels and pharmacokinetics of penbutolol^{9,23} were unaffected by cimetidine, and the effects of the beta blocker on heart rate and blood pressure were not changed.²³

(k) *Pindolol*

Cimetidine 1 g daily in divided doses increased the AUC and peak plasma levels of pindolol 10 mg twice daily by 30% and 33%, respectively, although these changes were not statistically significant.⁹ In another study, cimetidine 400 mg twice daily increased the AUC of the pindolol by about 40% and decreased the renal clearance by about 35%.²⁴

(l) *Propranolol*

Cimetidine 300 mg four times daily for a week was given to 12 healthy subjects with propranolol 80 mg every 12 hours from day 3 onwards. The mean steady-state blood levels and the AUC of propranolol were raised by 47%, and the half-life was prolonged by 17%, but cimetidine did not alter the effect of propranolol on heart rate.²⁵ A number of other single-dose and steady-state studies confirmed that cimetidine caused rises of 35 to 136% in the blood levels, AUC and clearance of propranolol,^{4–6,10,21,26–32} but this did not increase the effect of the beta blocker on blood pressure,^{21,27,29} or on heart rate, either at rest or during exercise.^{4,21,27–29} In contrast, one study did show a further reduction in heart rate when cimetidine was given with propranolol.³³ A letter describes one patient given cimetidine 1 g daily for 6 weeks who had an increase in the serum propranolol level of about threefold and an AUC increase of 340% when a single 80-mg dose of propranolol was given.² In one study, the increase in the steady-state AUC of propranolol tended to be higher when cimetidine was given simultaneously with propranolol than when they were given separated by 10 hours (41% versus 26%), but the difference was not significant.³⁴

In one study propranolol did not affect cimetidine pharmacokinetics.⁶

(m) *Timolol*

A double-blind study in 12 healthy subjects found that cimetidine 400 mg twice daily for 3 days did not modify the effect of a single drop of timolol 0.5%, put into each eye on heart rate or intraocular pressure to either a statistically or clinically relevant extent.³⁵

Mechanism

The blood levels of beta blockers extensively metabolised in the liver by the cytochrome P450 isoenzyme CYP2D6 (e.g. metoprolol, nebivolol and propranolol) are increased because cimetidine reduces their metabolism by inhibiting the activity of the liver enzymes. However, this does not seem to be a complete explanation as cimetidine does not affect carvedilol, which is metabolised by CYP2D6, but affects labetalol, a beta blocker that is not metabolised by CYP2D6.¹⁵ Pindolol is partly excreted by an active renal tubular secretion mechanism, and cimetidine increases pindolol blood levels by inhibiting this mechanism.²⁴ Cimetidine may reduce the renal clearance of bisoprolol by a similar mechanism.¹² Those beta blockers that are largely excreted unchanged in the urine (e.g. atenolol, nadolol) are not affected by cimetidine.^{8,21}

Importance and management

Well studied and established interactions but, despite the considerable rises in blood levels that can occur when some beta blockers are given with cimetidine, the effects normally appear to be clinically unimportant. Concurrent use is common, but only one isolated case of profound bradycardia (involving atenolol) appears to have been reported. Marked hypotension also seems to be rare. Combined use need not be avoided. However, it has been suggested that patients with impaired liver function who are given cimetidine with beta blockers that are extensively metabolised in the liver (see 'Table 22.1', (p.833)) might possibly develop grossly elevated blood levels, which could cause adverse effects. It would seem prudent to either monitor this type of patient (for effects such as hypotension) until more is known, or to use a non-interacting H₂-receptor antagonist such as 'ranitidine', (below).

Beta blockers + H₂-receptor antagonists; Famotidine

Famotidine does not appear to interact with the beta blockers.

Clinical evidence, mechanism, importance and management

A survey of 15 patients taking beta blockers (**acebutolol, atenolol, betaxolol, nadolol, pindolol, propranolol or sotalol**) for 6 to 8 weeks found no evidence of changes in antihypertensive effects or bradycardia while they were taking famotidine 40 mg daily.¹ No interaction would be expected, and no special precautions would seem necessary if famotidine is taken with these or any other beta blocker.

- Chichmanian RM, Mignot G, Spreux A, Jean-Girard C, Hoflioger P. Tolérance de la famotidine. Étude due réseau médecins sentinelles en pharmacovigilance. *Thérapie* (1992) 47, 239–43.

Beta blockers + H₂-receptor antagonists; Nizatidine

The bradycardic effects of atenolol are increased by nizatidine.

Clinical evidence, mechanism, importance and management

After taking **atenolol** 100 mg daily for 7 days the mean resting heart rate of 12 healthy subjects fell from about 64 to 53 bpm 3 hours after dosing. A further fall of 6 bpm occurred when they were also given nizatidine 300 mg daily for 7 days. Nizatidine alone caused a fall in heart rate of about 8 bpm.¹ Thus the effects of nizatidine and **atenolol** on heart rate appear to be additive. It seems likely that nizatidine would have the same effects in the presence of other beta blockers. The clinical significance of these effects is uncertain, but it might be important in elderly patients.¹ More study is needed.

- Halabi A, Kirch W. Negative chronotropic effects of nizatidine. *Gut* (1991) 32, 630–4.

Beta blockers + H₂-receptor antagonists; Ranitidine

Ranitidine does not alter either the steady-state plasma levels or the therapeutic effects of atenolol, nebivolol, propranolol or tertatolol. Some studies have shown moderate rises in metoprolol levels in those also given ranitidine, but this is not clinically important.

Clinical evidence

The plasma levels of **metoprolol** 100 mg twice daily were unaffected by ranitidine 300 mg daily for 7 days in 12 healthy subjects.¹ Two other studies have confirmed that ranitidine did not significantly affect the plasma levels of **metoprolol**.^{2–5} However, these studies found increases of up to 38% in the AUC of single intravenous or oral doses of **metoprolol**,^{2–5} and

another study found that ranitidine increased the AUC and plasma levels of **metoprolol** 100 mg twice daily by 55 and 34%, respectively.^{6,8} All of these studies found that ranitidine did not alter the effect of **metoprolol** on heart rate during exercise.^{1,2,5,6}

Ranitidine 300 mg daily for 6 days did not affect the steady-state plasma levels of **propranolol** 160 mg daily nor did it alter the effect of **propranolol** on heart rate or blood pressure in 5 healthy subjects.⁹ Similarly no changes in plasma **propranolol** levels were seen in other multiple-dose¹⁰ or single-dose studies.¹¹⁻¹⁴

Similarly, in other studies, ranitidine 150 mg twice daily did not significantly alter the pharmacokinetic or pharmacodynamic effects of a single 5-mg dose of **nebivolol**,¹⁵ a single 5-mg dose of **tertatolol**,¹⁶ or **atenolol** 100 mg daily for 7 days.^{6,8}

Mechanism

The rises in metoprolol serum levels caused by ranitidine in the two single-dose metoprolol studies are not understood, nor is it clear why one of four studies found an increase after multiple doses.

Importance and management

The possible effects of ranitidine on the plasma levels and effects of propranolol and metoprolol have been well studied. Although some studies have shown moderate rises in metoprolol levels, particularly after single-doses, these increases are of a magnitude that is unlikely to be clinically important. Less is known about atenolol, nebivolol and tertatolol, although no clinically relevant interactions have been seen. There is nothing to suggest that the concurrent use of ranitidine and any beta blocker should be avoided, nor that there is any need to take particular precautions.

Beta blockers + Haloperidol

An isolated case report describes severe hypotension and cardiopulmonary arrest in a woman shortly after she was given haloperidol and propranolol. Plasma levels of haloperidol in three patients were not significantly changed by propranolol. The concurrent use of sotalol and haloperidol should generally be avoided because of the possible increased risk of QT prolongation.

Clinical evidence, mechanism, importance and management

A middle-aged woman with schizophrenia and hypertension experienced three episodes of severe hypotension within 30 to 120 minutes of being given **propranolol** 40 to 80 mg and haloperidol 10 mg.¹ On two of the occasions she had a cardiopulmonary arrest. She fainted each time, became

cyanotic, had no palpable pulses and had severe hypotension, but rapidly responded to cardiopulmonary resuscitation. She suffered no adverse consequences.¹ The reasons for the severe hypotension are not understood, although both drugs alone can cause hypotension.

A study found that the steady-state plasma levels of haloperidol 6 to 15 mg daily were not significantly changed in 3 patients by long-acting **propranolol**, in incremental doses up to 480 mg daily.²

There seems to be only one case of an interaction between haloperidol and **propranolol** on record. Bearing in mind the widespread use of these drugs, this interaction would appear to be rare. There would seem to be little reason for avoiding concurrent use.

Note that both haloperidol and **sotalol** can prolong the QT interval and should therefore not generally be used together, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Beta blockers + Hormonal contraceptives

The blood levels of metoprolol are increased in women taking oral contraceptives, but the clinical importance of this is probably very small. Acebutolol, oxprenolol and propranolol pharmacokinetics are minimally affected by contraceptive use.

Clinical evidence

The peak plasma levels and the AUC of a single 100-mg dose of **metoprolol** were 36 and 70% higher, respectively, in 12 women taking low-dose combined oral contraceptives, when compared with a similar group not taking contraceptives. The elimination half-life of **metoprolol** was unaffected.¹ In a further study by the same research group, the AUC of **metoprolol** was 71% higher, the AUC of **oxprenolol** was 26% higher, the AUC of **propranolol** was 42% higher, and the AUC of **acebutolol** was marginally lower in women taking combined oral contraceptives, when compared to those not taking contraceptives, but only the **metoprolol** difference was statistically significant.² In another study, the total clearance of a single 80-mg dose of **propranolol** was increased (although not significantly) in 8 women given **ethinylestradiol** 50 micrograms daily, and an even smaller increase was seen when they were taking a combined oral contraceptive containing **ethinylestradiol** and **norethisterone**.³

Mechanism

The reason for the changes appears to be that ethinylestradiol alters the metabolism of these beta blockers. In the case of propranolol its conjugation and oxidation are increased by the ethinylestradiol.³

Importance and management

The changes seen with propranolol, oxprenolol and acebutolol are almost certainly too small to matter, but with metoprolol the changes are somewhat larger. Even so, changes of this size caused by the interactions of other drugs with beta blockers are not usually clinically relevant. No special precautions are generally necessary if any of these beta blockers are given to women taking combined oral contraceptives containing ethinylestradiol, or those taking ethinylestradiol alone, although note that the effects of a moderate rise may be more significant in those taking metoprolol for heart failure. Also be aware that some of the indications for beta blockers are cautions for, or preclude the use of, combined oral contraceptives.

Beta blockers + Hydralazine

The plasma levels of propranolol and other extensively metabolised beta blockers (such as metoprolol and oxprenolol) are

increased by hydralazine, but no increase in adverse effects seems to have been reported.

Clinical evidence

(a) Effect of hydralazine on beta blockers

Single 25- and 50-mg doses of hydralazine increased the AUC of a single 40-mg dose of **propranolol** by 60% and 110%, respectively, and raised the peak plasma levels by 144 and 240%, respectively, in 5 healthy subjects.¹ Similarly, in another single-dose study, hydralazine increased the AUC of **propranolol** by 62 to 77%.² However, a further single-dose study using sustained-release **propranolol** found that hydralazine had no effect on **propranolol** pharmacokinetics.³

In other studies hydralazine increased the AUC of sustained-release **oxprenolol** by 41% at steady-state;⁴ and of **metoprolol** by 30% after a single dose,⁵ and by 38% at steady-state.⁶ In contrast, single-dose studies found that hydralazine did not affect the AUC of **acebutolol** or **nadolol**.⁵

(b) Effect of beta blockers on hydralazine

Oxprenolol was found not to have a significant effect on the pharmacokinetics of hydralazine.⁴

Mechanism

Uncertain. Hydralazine appears to increase the bioavailability only of those beta blockers that undergo high hepatic extraction and not those that are largely excreted unchanged in the urine. Hepatic extraction is discussed in more detail under 'Changes in first-pass metabolism', (p.4), and 'Table 22.1', (p.833), lists the metabolic routes of the commonly used systemic beta blockers. It has been suggested that hydralazine may alter hepatic blood flow or inhibit hepatic enzymes,^{1,5,6} although other mechanisms may also be involved.^{3,7,8}

Importance and management

Moderately well documented and established interactions, but the increased beta blocker serum levels appear to cause no adverse clinical effect. Concurrent use is usually valuable in the treatment of hypertension. No particular precautions seem to be necessary.

Beta blockers + Inotropes and Vasopressors

Effects on blood pressure and heart rate: The hypertensive effects of adrenaline (epinephrine) can be markedly increased in patients taking non-selective beta blockers such as propranolol. A severe and potentially life-threatening hypertensive reaction and/or marked bradycardia can develop. Cardioselective beta blockers such as atenolol and metoprolol interact minimally. An isolated report describes a fatal hypertensive reaction in a patient given propranolol and phenylephrine, but concurrent use normally seems to be uneventful. Paradoxically, marked hypotension occurred in one patient given low-dose carvedilol and dobutamine. Anaphylaxis: Some evidence suggests that anaphylactic shock in

patients taking beta blockers may be resistant to treatment with adrenaline (epinephrine).

Clinical evidence

A. Effects on blood pressure and heart rate

(a) Adrenaline (Epinephrine)

An early study in 10 healthy subjects found that intravenous adrenaline (epinephrine) 5 micrograms/minute increased heart rates and caused minimal changes in blood pressure. However, after pretreatment with intravenous **propranolol** 10 mg, the same dose of adrenaline caused a *fall* in heart rate of 12 bpm and an increase in arterial pressure of 20/10 mmHg.¹ One case report describes 6 patients taking **propranolol** 20 to 80 mg daily, undergoing plastic surgery, who experienced marked hypertensive reactions (blood pressures in the range of 190/110 to 260/150 mmHg) and bradycardia when their eyelids and/or faces were infiltrated with 8 to 40 mL of local anaesthetic solutions of lidocaine containing 1:100 000 or 1:200 000 (10 or 5 micrograms/mL) of adrenaline. Cardiac arrest occurred in one patient.²

Similar marked increases in blood pressure, associated with marked bradycardia, have been described in other studies and case reports involving **propranolol**.^{3–11} In contrast, only a small blood pressure rise was seen in a comparative study with **metoprolol**.⁴ This was confirmed in another study in which patients given identical infusions of adrenaline developed a hypertensive/bradycardic reaction while taking **propranolol** but not while taking **metoprolol**.⁵ After pretreatment with a single 5-mg dose of **pindolol**, only small reductions in blood pressure (4 mmHg) and heart rate (about 5 bpm) were seen with the intra-oral injection of 3.6 mL of 2% lidocaine containing 1:80 000 adrenaline (45 micrograms of adrenaline) in healthy subjects.¹² In 24 healthy subjects given either **nadolol**, **atenolol** or placebo for 1 week followed by an infusion of adrenaline, mean arterial pressure and calf vascular resistance rose markedly in the **nadolol**-treated group but not the **atenolol** group. Marked bradycardia also occurred in those given **nadolol** and adrenaline.¹³

In 6 healthy subjects, giving adrenaline after intravenous **labetalol** 1 mg/kg, resulted in a 13 to 21 mmHg increase in mean arterial pressure and a 23 to 29 bpm reduction in heart rate, compared with adrenaline alone.¹⁴

(b) Dobutamine

A 54-year-old man with severe heart failure was given **carvedilol** 3.125 to 6.25 mg twice daily. His symptoms worsened and he was admitted for treatment with intravenous dobutamine; the **carvedilol** was discontinued and other medications apart from furosemide were withheld short-term. Dobutamine was started at 1 microgram/kg per minute and gradually increased to 5 micrograms/kg per minute. However, with each 1 microgram/kg increment the systolic blood pressure *dropped* to about 70 mmHg for 5 to 10 minutes and then quickly returned to the baseline level of 80 to 84 mmHg. When the dose of dobutamine reached 5 micrograms/kg per minute, his systolic blood pressure dropped to 56 mmHg and the dobutamine was discontinued. The blood pressure returned to normal over the next 30 minutes. Two months later when the patient was no longer taking **carvedilol** he was again given intravenous dobutamine and his systolic blood pressure increased, as would be expected.¹⁵

(c) Phenylephrine

A woman taking **propranolol** 40 mg four times daily for hypertension was given one drop of a 10% phenylephrine hydrochloride solution in each eye during an ophthalmic examination. About 45 minutes later she complained of a sudden and sharp bi-temporal pain and shortly afterwards became unconscious. She later died of an intracerebral haemorrhage due to the rupture of a berry aneurysm. She had received a similar dose of phenylephrine on a previous occasion in the absence of **propranolol** without any problems.¹⁶

However, no change in blood pressure was seen in a study in both normotensive subjects and patients taking **metoprolol** who were given 0.5 to 4-mg doses of phenylephrine intranasally every hour, to a total of 7.5 to 15 mg (4 to 30 times the usual dose).¹⁷ Similarly, in a placebo-controlled study in 12 hypertensive patients, neither **propranolol** nor **metoprolol** significantly altered the dose of intravenous phenylephrine required to cause a 25 mmHg increase in systolic blood pressure.¹⁸

B. Anaphylaxis: resistance to treatment

A patient taking **propranolol** who suffered an anaphylactic reaction after receiving an allergy injection for desensitisation did not respond to adrenaline (epinephrine) and required intubation.¹⁹ Resistance to adrenaline treatment for anaphylaxis occurred in another patient using **timolol** eye drops.²⁰ It has also been proposed that the incidence and severity of anaphylactic reactions may be increased in those taking beta blockers,^{21,22} one idea being that the adrenoceptors concerned with suppressing the release of the mediators of anaphylaxis may be blocked by either beta₁ or beta₂ antagonists.²¹ However, one study failed to find any evidence to support an increased incidence of systemic reactions in patients taking beta blockers receiving allergen immunotherapy.²³ See also 'X-ray contrast media', (p.857), and 'penicillins', (p.850), for other anaphylactic reactions potentially exacerbated by beta blockers.

A beta-agonist bronchodilator (e.g. isoprenaline, salbutamol) may be effective in patients taking beta blockers with anaphylaxis resistant to adrenaline,²¹ and glucagon was effective in treating a severe anaphylactoid reaction in one patient taking a beta blocker.²² Severe hypertension, sometimes with bradycardia, has been described following the use of adrenaline to treat allergic reactions, including presumed anaphylaxis, in patients taking **propranolol**.⁶⁻⁸ These are discussed under A. above.

Mechanism

Adrenaline (epinephrine) stimulates alpha- and beta-receptors of the cardiovascular system, the former results in vasoconstriction (mainly alpha₁) and the latter in both vasodilatation (mainly beta₂) and stimulation of the heart (mainly beta₁). The net result is usually a modest increase in heart rate and a small rise in blood pressure. However, if the beta-receptors are blocked by a non-selective beta blocker, such as propranolol or nadolol (see 'Table 22.1', (p.833) for a list), the unopposed alpha vasoconstriction causes a marked rise in blood pressure, followed by reflex bradycardia. Cardioselective beta blockers such as atenolol and metoprolol, which are more selective for beta₁ receptors, do not prevent the vasodilator action of adrenaline at beta₂ receptors to the same extent, and therefore the effect of any interaction is relatively small. Consequently, adrenaline has been used to assess the degree of beta blockade produced by propranolol and other beta blockers.^{13,24} Phenylephrine is largely an alpha stimulator, therefore beta blockers should have a minimal effect on its action.

Dobutamine is a beta₁, beta₂ and alpha₁ adrenergic agonist and carvedilol is a non-selective beta blocker, but at low doses it is primarily a selective beta₁ adrenergic antagonist and it is also an alpha₁ antagonist. It was proposed that the drop in blood pressure was caused by vasodilation due to vascular beta₂ receptor activation, which was not blocked by low doses of carvedilol.¹⁵

Importance and management

The interaction between propranolol and adrenaline (epinephrine) is established. It may be serious and potentially life-threatening, depending on the dosage of adrenaline used. Marked and serious blood pressure rises and severe bradycardia have occurred in patients given 300 micrograms of adrenaline (0.3 mL of 1:1000) subcutaneously⁶⁻⁸ or 40 to 400 micrograms by infiltration of the skin and eyelids during plastic surgery.² Adrenaline 15 micrograms given intravenously can cause an almost 40% fall in heart rate.⁹ Patients taking non-selective beta blockers such as propranolol (see 'Table 22.1', (p.833) for a list) should only be given adrenaline in very reduced dosages because of the marked bradycardia and hypertension that can occur. A less marked effect is likely with the cardioselective beta blockers,⁴ such as atenolol and metoprolol (see 'Table 22.1', (p.833) for a list). Local anaesthetics used in dental surgery usually contain very low concentrations of adrenaline (e.g. 5 to 20 micrograms/mL, i.e. 1:200 000 to 1:50 000) and only small volumes are usually given, so that an undesirable interaction is unlikely.

No interaction between phenylephrine and the beta blockers would be expected, and apart from the single unexplained case cited above, the literature appears to support this. Concurrent use normally appears to be clinically unimportant, particularly bearing in mind the widespread use of beta blockers and the ready availability of phenylephrine in the form of non-prescription cough-and-cold remedies and nasal decongestants.

Acute hypertensive episodes have been controlled with chlorpromazine or phentolamine (both of which are alpha blockers). Hydralazine,^{2,10} nifedipine⁷ and aminophylline¹⁰ have also been used. Reflex bradycardia may be managed with atropine and the pre-emptive use of glycopyrrolate has also been suggested.¹⁰

The paradoxical case of hypotension with dobutamine and low-dose carvedilol suggests that this combination should be monitored carefully.

Beta blockers + Itraconazole

Itraconazole markedly increased the bioavailability of celiprolol and only slightly affected the pharmacokinetics of atenolol, without affecting heart rate or blood pressure. These interactions are not expected to be clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Atenolol

In a study in 10 healthy subjects itraconazole 200 mg twice daily for 5 doses had only minor effects on the pharmacokinetics of a single 50-mg dose of atenolol and no effects on heart rate or blood pressure were seen.¹

(b) Celiprolol

In a study in 12 healthy subjects itraconazole 200 mg twice daily for 5 doses increased the AUC of a single 100-mg dose of celiprolol by 80%, without increasing the half-life. However, itraconazole did not increase the effect of celiprolol on heart rate or blood pressure.²

It was suggested that itraconazole probably increases the absorption of celiprolol by inhibiting P-glycoprotein in the intestinal wall.²

Although the increase in plasma levels was marked, it was suggested that

it is unlikely to be clinically relevant because celiprolol has a wide therapeutic range.²

2. Lilja JJ, Backman JT, Laitila J, Luurila H, Neuvonen PJ. Itraconazole increases but grapefruit juice greatly decreases plasma concentrations of celiprolol. *Clin Pharmacol Ther* (2003) 73, 192–8.

Beta blockers + Macrolides

The serum levels of talinolol and possibly nadolol are increased by erythromycin, but the clinical importance of this is uncertain. Telithromycin does not appear to adversely affect sotalol-induced QT prolongation. However, the combined use of sotalol and intravenous erythromycin should generally be avoided because of the possible additive effects on QT interval prolongation.

Clinical evidence, mechanism, importance and management

(a) Nadolol

A study, in which 7 healthy subjects were given a single 80-mg dose of nadolol after erythromycin 500 mg plus neomycin 500 mg every 6 hours for 2 days, suggested an increase in the rate of beta blocker absorption (reduced time to maximum plasma level, but no effect on AUC). A decrease in the elimination half-life was also seen.¹ More study is needed to determine the clinical significance of these findings.

(b) Sotalol

Sotalol prolongs the QT interval and should generally not be given with other drugs that do the same, such as intravenous erythromycin, because of the increased risk of torsade de pointes arrhythmia (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257). **Telithromycin** does not appear to be associated with QT prolongation and a study in 24 healthy women found that a single 800-mg dose of telithromycin had no adverse effect on the QT-prolongation induced by a 160-mg dose of sotalol. The telithromycin slightly reduced the AUC and maximum serum levels of sotalol, which was attributed to a decrease in its absorption,² but this is expected to be of little clinical significance.

(c) Talinolol

A single-dose study in 8 healthy subjects found that the AUC and serum levels of talinolol 50 mg were increased by 51% and 26%, respectively, by erythromycin 2 g. It was suggested that the increased bioavailability of talinolol was due to increased intestinal absorption caused by the inhibition of P-glycoprotein by erythromycin.³

Beta blockers + Metoclopramide

A patient with scleroderma suffered a fatal cardiac arrest after receiving postoperative intravenous labetalol and intravenous metoclopramide. Metoclopramide increased the rate of absorption of a conventional formulation of propranolol, but did not affect a sustained-release preparation.

Clinical evidence, mechanism, importance and management

(a) Labetalol

A 38-year-old patient with scleroderma, hypertension (for which she was taking lisinopril) and gangrene of her left index finger underwent minor hand surgery. While in postoperative care her blood pressure rose to 153/120 mmHg and she was given intravenous labetalol 10 mg. About 15 minutes later she experienced nausea and vomiting, which was treated with intravenous metoclopramide 10 mg. About 5 minutes later her heart rate decreased to 38 bpm and she became unresponsive with no palpable pulse: an ECG showed junctional bradycardia. She was initially resusci-

tated but died about 13 hours later after a further episode of bradycardia, despite full supportive treatment. It was noted that the bradycardia did not respond well to atropine, and there was persistent hypotension, despite escalating vasopressor use. Scleroderma and lisinopril may have contributed to the failure to resuscitate the patient. However, bradycardia or heart block and hypotension may occur with intravenous metoclopramide. In this patient the use of labetalol may have exacerbated the effects of metoclopramide by causing reductions in ventricular contractility due to its beta-adrenergic effects and limiting vasoconstrictive compensatory mechanisms due to alpha-adrenergic effects.¹ However, it has subsequently been suggested that this reaction may have been due to local anaesthetic toxicity rather than a drug interaction,² although this was disputed by the original authors.³ A study in 11 untreated hypertensive patients found that intravenous metoclopramide (7.5 micrograms/kg per minute for 30 minutes) caused a slight decrease in the responsiveness to labetalol 400 to 600 mg daily. However, as metoclopramide only attenuated the systolic blood pressure response to labetalol by 3 mmHg this effect seems unlikely to be clinically significant in most patients.⁴

(b) Propranolol

Oral metoclopramide syrup 20 mg, given 30 minutes before sustained-release propranolol 160 mg, had no effect on the pharmacokinetics of propranolol in 12 healthy subjects.⁵ In contrast, an earlier brief report found that the rate of absorption of a conventional formulation of propranolol 80 mg was increased by intravenous metoclopramide 10 mg in 4 healthy subjects. In the first 2 hours after dosing, propranolol levels were increased by 1.3 to 2.5-fold.⁶ However, these changes are unlikely to be clinically relevant.

Beta blockers + Morphine

Morphine may moderately raise the serum levels of esmolol, but this is unlikely to be clinically important. The fatal doses of morphine and propranolol are markedly reduced by concurrent use in animals, but the clinical relevance of this in man is uncertain.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy men a 3-mg injection of morphine sulfate increased the steady-state levels of a 300 microgram/kg per minute infusion of esmolol, given over 4 hours. However, the increases were only statistically significant in 2 of the subjects (increase of 46%), and were considered to be of no clinical importance. The pharmacokinetics of morphine were unchanged.¹

Studies in animals have shown that the median fatal dose of propranolol was reduced two to sevenfold by morphine in mice² and the median lethal dose of morphine was reduced fifteen to sixteenfold by propranolol in rats.³ The same interaction has also been seen in dogs.³ There do not appear to be any published reports of synergistic toxicity involving morphine and propranolol, so the clinical relevance of this is uncertain.

Beta blockers + Penicillins

Plasma atenolol levels are halved by 1-g doses of ampicillin. The clinical importance of this is uncertain, but probably small. No important interaction occurs if atenolol is given with ampicillin

250 mg every 6 hours. One brief report suggests that anaphylactic reactions to penicillins may be more severe in patients taking beta blockers.

Clinical evidence

A single 1-g dose of **ampicillin** reduced the AUC of a single 100-mg dose of **atenolol** by 40%, and decreased its bioavailability from 60 to 36% in 6 healthy subjects. Similarly, when **atenolol** 100 mg was given with **ampicillin** 1 g daily for 6 days, the mean steady-state plasma atenolol level was reduced by 52% (from 199 to 95 nanograms/mL), and the AUC was reduced by 52%. The blood pressure lowering effect of **atenolol** at rest was not affected, but after exercise a small rise in systolic pressure of up to 17 mmHg occurred, whereas diastolic pressure was unchanged. The effects of **atenolol** on reducing heart rate during exercise were diminished from 24% to 11% at 12 hours.¹

Another study showed that when a single 50-mg oral dose of **atenolol** was given with a single 1-g oral dose of **ampicillin** the AUC of **atenolol** was reduced by 51.5%, whereas when **ampicillin** 250 mg four times daily was given for 24 hours, the AUC was only reduced by 18.2%.²

A brief report describes 2 patients, one taking **nadolol** and one taking **propranolol**, who developed fatal anaphylactic shock after taking **phenoxymethylpenicillin**. The authors suggested that, as fatal reactions to penicillins are rare, the reaction had been exacerbated by the presence of a non-selective beta blocker.³

Mechanism

Uncertain. Ampicillin apparently affects the absorption of atenolol.

Importance and management

Information is limited, but the absorption interaction appears to be established. The clinical importance awaits full evaluation but the modest effects on blood pressure and heart rate¹ suggest that it is of limited importance. Information about other beta blockers and penicillins is lacking. Information on potentiation of anaphylaxis is too limited to make comment, but note that some evidence suggests that anaphylactic shock in patients taking beta blockers may be resistant to treatment with adrenaline (epinephrine), see 'Beta blockers + Inotropes and Vasopressors', p.848.

Beta blockers + Phenothiazines

The concurrent use of chlorpromazine with propranolol, or thioridazine with pindolol, can result in a marked rise in the plasma levels of both drugs. Propranolol markedly increases plasma thioridazine levels. Both beta blockers and phenothiazines can cause hypotension, and these effects could be additive: a handful of case reports suggest that this could occasionally be serious. The concurrent use of sotalol and phenothiazines that prolong the QT interval should generally be avoided.

Clinical evidence

(a) Chlorpromazine

In 4 healthy subjects and one hypertensive patient the mean steady-state levels of **propranolol** 80 mg every 8 hours were raised by 70% (from 41.5 to 70.2 nanograms/mL) when they were given chlorpromazine 50 mg every 8 hours.¹ The increase was considerable in some subjects but barely detectable in others. A sixth subject taking **propranolol** promptly fainted when getting out of bed after the first dose of chlorpromazine. He was found to have a pulse rate of 35 to 40 bpm and a blood pressure of 70/0 mmHg. He rapidly recovered, achieving a pulse rate of 85 bpm and a blood pressure of 120/70 mmHg when given atropine 3 mg. However, it is unclear whether the adverse effect was due to chlorpromazine alone, or to an interaction with **propranolol**.¹

Propranolol (mean daily dose 8.1 mg/kg) increased the serum chlorpromazine levels of 7 schizophrenics by about 100 to 500%, and raised the plasma levels of the active metabolites of chlorpromazine by about 50 to

100%.² The same or similar work by the same authors is described elsewhere.³ One of the patients was withdrawn from the study because he suffered a cardiovascular collapse while taking both drugs.³ It has been suggested that the value of **propranolol** in the treatment of schizophrenia probably results from the rise in serum chlorpromazine levels.³

A report briefly mentions a diabetic girl who had an episode of minor hypotension with chlorpromazine that appeared to have been exacerbated by **sotalol**.⁴ A schizophrenic patient taking chlorpromazine and **tiotixene** experienced delirium, grand mal seizures and skin photosensitivity, attributed to a rise in the serum levels of the antipsychotic drugs caused by increasing doses of **propranolol** (up to a total of 1200 mg daily).⁵

(b) Thioridazine

Serum **pindolol** levels were 2.5-fold higher in 7 patients taking thioridazine than in 17 patients taking haloperidol, phenytoin, and/or phenobarbital.⁶ Furthermore, **pindolol** 40 mg daily increased serum thioridazine levels by about 50% in 8 patients.⁶

Two patients stable taking thioridazine 600 or 800 mg daily had three and fivefold rises in plasma levels, respectively, when given **propranolol**, in increasing doses up to a total of 800 mg daily, over 26 to 40 days. No signs or symptoms of thioridazine toxicity were seen even though plasma levels had risen into the toxic range.⁷ Similarly, in another study thioridazine levels rose by about 55 to 370% in 5 patients taking **propranolol** 320 to 520 mg daily.⁸

Mechanism

Pharmacokinetic evidence¹ and animal studies⁹ suggest that propranolol and chlorpromazine mutually inhibit the liver metabolism of the other drug so that both accumulate within the body. The mechanism of the interaction between propranolol and thioridazine is probably similar. Both beta blockers and phenothiazines can cause hypotension, and these effects could be additive.

Importance and management

The interaction between propranolol and chlorpromazine appears to be established although information is limited. Concurrent use should be well monitored and the dosages reduced if necessary. The same precautions apply with propranolol and thioridazine.⁷ There seems to be no information about any interaction between other beta blockers and phenothiazines, but if the mechanism of interaction suggested above is true, it seems possible that other beta blockers that are mainly cleared from the body by liver metabolism might interact similarly with chlorpromazine, whereas those mainly cleared unchanged in the urine are less likely to have a pharmacokinetic interaction, although additive hypotensive effects would still be expected. See 'Table 22.1', (p.833), for information on the metabolism of the commonly used systemic beta blockers.

Note that **sotalol** and some phenothiazines, including chlorpromazine and thioridazine prolong the QT interval (see 'Table 9.2', (p.257) for a more extensive list). Combined use should therefore generally be avoided, because of the increased risk of torsade de pointes. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Beta blockers + Phenylpropanolamine

A small rise in blood pressure may occur in patients taking beta blockers who take single doses of phenylpropanolamine. A marked rise in blood pressure has been seen in one patient taking

oxprenolol with methyldopa when phenylpropranolamine was also taken. Propranolol attenuates the blood pressure rise seen with phenylpropranolamine.

Clinical evidence, mechanism, importance and management

(a) Effect on beta blockers

A study in 13 patients taking various antihypertensives including 5 taking unnamed beta blockers found that a single dose of *Dimetapp Extentabs* (phenylpropranolamine 75 mg with brompheniramine 12 mg) caused a blood pressure rise of 1.7/0.9 mmHg over a 4-hour period, which was not statistically or clinically significant.¹ These rises in blood pressure after single doses are small and relatively short-lived, and probably of little clinical importance. Another study in 7 stabilised hypertensive patients taking beta blockers (**atenolol** 5 patients, **metoprolol** 1, **propranolol** 1) found that a single 25-mg dose of rapid-release phenylpropranolamine (*Super Odrinex*) increased the mean peak blood pressures by about 8/5 mmHg over a 6-hour period.² A later multiple dose study in the same subjects (only 5 of whom completed the study), taking the same beta blockers, found that on day 1 phenylpropranolamine increased diastolic blood pressure by 9 to 16 mmHg, and on day 7 by 0 to 14 mmHg. The day 1 and day 7 results were not statistically different, which suggests that the increase in blood pressure is not enhanced by multiple dosing.³ Note that a marked rise in blood pressure was seen in one patient taking methyldopa and **oxprenolol** when phenylpropranolamine was also given, see 'Methyldopa + Sympathomimetics; Indirectly-acting', p.898.

(b) Effect on phenylpropranolamine

In a placebo-controlled study in 6 healthy subjects, **propranolol** given either orally as a pretreatment or intravenously after phenylpropranolamine, was found to antagonise the rise in blood pressure induced by the phenylpropranolamine. Oral phenylpropranolamine 75 mg alone increased blood pressure from 116/63 to 148/83 mmHg; pretreatment with oral **propranolol** 80 mg every 6 hours reduced the baseline blood pressure to 107/62 mmHg and the increase with phenylpropranolamine was lower, reaching only 119/72 mmHg. Intravenous **propranolol** 0.3 mg/kg given after the phenylpropranolamine decreased blood pressure from 144/87 to 121/84 mmHg.⁴

4. Pentel PR, Asinger RW, Benowitz NL. Propranolol antagonism of phenylpropranolamine-induced hypertension. *Clin Pharmacol Ther* (1985) 37, 488–94.

Beta blockers + Potassium-depleting drugs

The use of potassium-depleting diuretics can precipitate the development of potentially life-threatening torsade de pointes arrhythmias in patients taking sotalol unless potassium levels are maintained. This would also be expected with other potassium-depleting drugs such as corticosteroids, some laxatives, and intravenous amphotericin. Chlortalidone and hydrochlorothiazide may reduce the bioavailability of celiprolol, but the evidence for this is sparse.

Clinical evidence

(a) Pharmacokinetic effects

A study in 12 healthy subjects found that when **sotalol** 160 mg was given with **hydrochlorothiazide** 25 mg the pharmacokinetics of both drugs were unchanged.¹

The manufacturers of **celiprolol** suggest that **chlortalidone** and **hydrochlorothiazide** reduce its bioavailability.² This appears to be based on an *in vitro* study,³ which found that **chlortalidone** and **hydrochlorothiazide** blocked the active transport of **celiprolol** across the intestinal epithelium. The authors of this study also cite a single dose study that found that **chlortalidone** decreased the bioavailability of **celiprolol** but details are not given.

(b) QT-prolongation

A 4-year study in cardiac clinics in South Africa identified 13 patients who developed syncope and a prolonged QT interval while taking **sotalol** 80 to 480 mg daily. Twelve patients were taking a combined preparation (*Sotazide*) containing **sotalol** 160 mg and **hydrochlorothiazide** 25 mg. Eleven patients were being treated for hypertension, one for ventricular asystoles, and one for both. Polymorphous ventricular tachycardia was seen in 12 of the patients, and torsade de pointes were seen in 10 of these 12. Arrhythmias occurred within 72 hours of starting **sotalol** in 6 patients, and at varying intervals from 10 days to 3 years in the other 6 patients. Definite hypokalaemia (defined by the study as serum potassium of less than 3.5 mmol/L) was detected in 8 of the 13 patients. Four of the patients were also taking other drugs known to prolong the QT interval, namely disopyramide and tricyclic antidepressants. The problems resolved in all of the cases within 12 hours of stopping the **sotalol** and giving potassium supplements when indicated.⁴ A further case has also been reported.⁵

Mechanism

Potassium-depleting drugs may cause hypokalaemia, which increases the potential for torsade de pointes arrhythmia with any drug that prolongs the QT interval, including sotalol.

Importance and management

The interaction between potassium-depleting diuretics such as hydrochlorothiazide and sotalol that results in QT prolongation is established, clinically important and potentially life threatening. Prolongation of the QT interval and the development of torsade de pointes in patients taking sotalol, particularly at high doses (said to be greater than 320 mg daily),⁶ is a recognised adverse effect, but it can occur even with small doses of sotalol if potassium depletion is allowed to develop. It is clearly very important therefore to ensure that potassium levels are maintained if potassium-depleting drugs are given with sotalol. A list of potassium-depleting diuretics is given in 'Table 26.1', (p.944). Other drugs that may cause potassium depletion include **corticosteroids**, some **laxatives**, and intravenous **amphotericin**.

The interactions of chlortalidone and hydrochlorothiazide with celiprolol are poorly documented and their clinical significance is unclear, although it would be expected to be limited.

Beta blockers + Propafenone

Plasma metoprolol and propranolol levels can be markedly raised (two to fivefold) by propafenone. Toxicity may develop.

Clinical evidence

Four patients with ventricular arrhythmias taking **metoprolol** 150 to 200 mg daily had a two to fivefold rise in steady-state **metoprolol** serum levels when they were given propafenone 150 mg three times daily. One of them developed distressing nightmares, and another had acute left ventricular failure with pulmonary oedema and haemoptysis, which disappeared when the **metoprolol** dosage was reduced or stopped. In 4 other patients taking **metoprolol** 50 mg three times daily and propafenone 150 mg three times daily, it was found that stopping **metoprolol** did not affect propafenone plasma levels.¹ Single-dose studies in healthy subjects found a twofold decrease in the clearance of **metoprolol** and a further 20% reduction in exercise-induced tachycardia at 90 minutes when propafenone was also given.¹

A patient developed neurotoxicity (including vivid nightmares, fatigue, headache) when given **metoprolol** 100 mg daily in divided doses, which

worsened while it was being withdrawn and replaced by propafenone 300 mg daily. The symptoms disappeared when both drugs were stopped.²

Propafenone 225 mg every 8 hours more than doubled the steady-state levels of **propranolol** 50 mg every 8 hours in 12 healthy subjects. However, the beta-blocking effects were only modestly increased and the propafenone pharmacokinetics remained unchanged.³

Mechanism

It is suggested that propafenone reduces the metabolism of metoprolol and propranolol by the liver, thereby reducing their clearance and raising serum levels.^{1,3}

Importance and management

Information is limited but the interaction would seem to be established. Concurrent use need not be avoided but anticipate the need to reduce the dosage of metoprolol and propranolol. Monitor closely because some patients may experience adverse effects. If the suggested mechanism of interaction is correct it is possible (but not confirmed) that other beta blockers that undergo liver metabolism will interact similarly but not those largely excreted unchanged in the urine. See 'Table 22.1', (p.833) for the metabolism of some commonly used beta blockers. Also note that propafenone and the beta blockers have negative inotropic effects, which could be additive and result in unwanted cardiodepression.

Beta blockers + Proton pump inhibitors

Omeprazole does not interact with metoprolol or propranolol, and lansoprazole does not interact with propranolol.

Clinical evidence, mechanism, importance and management

Omeprazole 20 mg daily for 8 days had no effect on the steady-state plasma levels of **propranolol** 80 mg twice daily, and no effect on resting and exercised heart rates or blood pressure in 8 healthy subjects.¹ Another study found that **omeprazole** 40 mg daily for 8 days had no effect on the steady-state plasma levels of **metoprolol** 100 mg daily.²

A double-blind crossover study in 18 healthy subjects found that **lansoprazole** 60 mg daily for 7 days did not significantly affect the pharmacokinetics of a single 80-mg dose of **propranolol**.³

No special precautions would seem necessary if these proton pump inhibitors are used with **propranolol** or **metoprolol**.

Beta blockers + Quinidine

An isolated report describes a patient taking quinidine who developed marked bradycardia when using timolol eye drops. Other reports describe orthostatic hypotension when quinidine was given with atenolol or propranolol. Quinidine can raise plasma metoprolol, propranolol, and timolol levels, but the clinical relevance of this is uncertain.

Both sotalol and quinidine can prolong the QT interval, which may increase the risk of torsade de pointes arrhythmia if they are used together.

Clinical evidence

(a) Atenolol

Orthostatic hypotension occurred in a 56-year-old woman taking isosorbide dinitrate, diltiazem and quinidine sulfate 300 mg four times daily, 3 days after she started atenolol 50 mg daily. This resolved within 2 days

of stopping the atenolol. Before starting the quinidine, she had previously taken atenolol and the other drugs without problems.¹

(b) Metoprolol

A metabolic study in 5 healthy subjects who were extensive CYP2D6 metabolisers found that a single 50-mg dose of quinidine markedly inhibited the metabolism of a single 100-mg dose of metoprolol, which effectively made the subjects into poor metabolisers. The plasma levels of metoprolol were approximately tripled. Quinidine had no effect on metoprolol pharmacokinetics in 5 poor metabolisers.² Similar results have been found when quinidine 50 mg daily was given with metoprolol 100 mg twice daily for 7 days,³ and when a 20-mg dose of metoprolol was given intravenously following either a single 50-mg dose of quinidine or quinidine slow-release tablets 250 mg twice daily for 3 days.⁴ The effect on heart-rate reduction was small given the increase in metoprolol levels.³

(c) Propranolol

A single-dose pharmacokinetic study found that quinidine 200 mg doubled the AUC and the peak plasma levels of a 20-mg dose of propranolol. Maximum heart rates during exercise were suppressed by a further 45%.⁵ A similar study by the same research group found that the AUC of propranolol was increased by about threefold by quinidine.⁶ A further study found that quinidine doubled the AUC of propranolol and halved its clearance resulting in increased beta-blockade.⁷

After a single 200-mg dose of quinidine the peak plasma quinidine levels were over 50% higher and its clearance almost 40% lower in 7 patients taking propranolol 40 to 400 mg daily, when compared with 8 control patients, but the quinidine elimination half-life did not differ.⁸ However, this interaction was not found in two other studies.^{9,10}

A man taking propranolol 40 mg four times daily developed orthostatic hypotension, with symptoms of dizziness and faintness on standing, when he took quinidine 200 mg four times daily. This resolved when quinidine was withdrawn.¹¹ The same authors subsequently briefly reported another two cases of orthostatic hypotension when quinidine was given with unnamed beta blockers.¹²

(d) Sotalol

Although one study reports the safe concurrent use of sotalol and quinidine,¹³ both drugs can prolong the QT interval, which may increase the risk of torsade de pointes arrhythmia if they are used together. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257, for a general review of QT-prolongation and drug interactions.

(e) Timolol

An elderly man taking quinidine sulfate 500 mg three times daily for premature atrial beats was hospitalised with dizziness 12 weeks after starting to use timolol 0.5% eye drops for open-angle glaucoma. He was found to have a sinus bradycardia of 36 bpm. The symptoms abated when the drugs were withdrawn and normal sinus rhythm returned after 24 hours. The same symptoms developed within 30 hours of re-starting both drugs, but disappeared when the quinidine was withdrawn.¹⁴ In a later study in healthy subjects, a single 50-mg oral dose of quinidine was given 30 minutes before 2 drops of timolol 0.5% ophthalmic solution, put into each nostril. In 13 extensive CYP2D6 metabolisers, quinidine caused a further decrease in heart rate and increase in plasma timolol levels compared with timolol alone. Giving quinidine with timolol in these extensive metabolisers gave results similar to giving timolol alone in 5 poor metabolisers.¹⁵ In another study, quinidine augmented the plasma levels and cardiac effects of intravenous timolol.¹⁶

Mechanism

Quinidine appears to increase metoprolol, propranolol and timolol plasma levels by inhibiting the cytochrome P450 isoenzyme CYP2D6, thereby reducing their clearance.^{2,7,15} As CYP2D6 shows polymorphism, these interactions would be most apparent in patients with high CYP2D6 activity (extensive metabolisers), effectively making them poor metabolisers. See 'Genetic factors', (p.4), for further information on polymorphism.

Importance and management

The pharmacokinetic interaction would seem to be established, but of uncertain clinical importance. Only one isolated case of possible excessive beta-blockade has been reported (with quinidine and timolol eye drops). Concurrent use need not be avoided (and may be beneficial in the treatment of atrial fibrillation), but some care is warranted as both quinidine

and the beta blockers have negative inotropic effects, which could be additive and result in unwanted cardiodepression. The general relevance of the isolated reports of orthostatic hypotension with atenolol or propranolol and quinidine is uncertain.

The general consensus is that the combination of two drugs that prolong the QT interval such as quinidine and sotalol should usually be avoided, or only used with great caution. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Beta blockers + Quinolones

Ciprofloxacin reduces metoprolol clearance, but this is probably clinically unimportant. The concurrent use of sotalol and quinolones that prolong the QT interval should generally be avoided.

Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

Preliminary evidence from 7 healthy subjects given a single 100-mg dose of **metoprolol** suggested that pretreatment with 5 doses of ciprofloxacin 500 mg, given every 12 hours, increased the AUC of (+)-metoprolol by 54% and reduced its clearance by 38.5%. The AUC of (–)-metoprolol was increased by 29% and its clearance reduced by 12%.¹ It has been suggested that this interaction may occur because ciprofloxacin inhibits the activity of the cytochrome P450 isoenzymes concerned with the metabolism and clearance of **metoprolol**. However, this is questionable as **metoprolol** is metabolised, predominantly, by CYP2D6 while ciprofloxacin inhibits CYP1A2. Changes of this size, or even more, in the AUC of beta blockers have proved not to be clinically important with other enzyme-inhibiting drugs, and it seems probable that this will be the case with ciprofloxacin, but this needs confirmation.

(b) Quinolones that prolong the QT interval

In an analysis of cases of torsade de pointes associated with fluoroquinolones on the FDA Adverse Events Reporting System database, two cases of torsade de pointes were noted in patients taking a fluoroquinolone with **sotalol** (there were 37 cases identified, and 19 occurred in patients also taking other drugs known to prolong the QT interval).² **Sotalol** has class III antiarrhythmic effects and prolongs the QT interval, and this could be additive with the effects of quinolones that prolong the QT interval (e.g. **gatifloxacin**, **moxifloxacin**, **sparfloxacin**, see 'Table 9.2', (p.257)). The

concurrent use of **sotalol** and these quinolones should generally be avoided (see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257).

Beta blockers + Rifampicin (Rifampin)

Rifampicin increases the clearance of bisoprolol, carvedilol, celiprolol, metoprolol, propranolol, tertatolol and talinolol, and reduces their serum levels. The extent to which this reduces the effects of these beta blockers is uncertain, but it is probably small. Similar effects have been seen when atenolol is given with rifampicin, but a case report suggests that occasionally the effects may be of clinical relevance.

Clinical evidence

(a) Atenolol

A case report describes a man taking atenolol for angina whose exercise threshold before developing angina symptoms appreciably worsened when he was given rifampicin. Rifampicin was stopped, and after a week **rifabutin** was started. **Rifabutin** did not cause any change in his baseline exercise tolerance.¹ In a randomised, placebo-controlled, crossover study, 9 healthy subjects were given rifampicin 600 mg daily for 5 days, with a single 100-mg dose of atenolol on day 6. Although some pharmacokinetic changes were seen they were variable between subjects and in most cases slight. Heart rate and blood pressure were on average slightly higher in the presence of rifampicin (3.5 bpm and 4.3/3.9 mmHg, respectively), suggesting a modest reduction in the effects of atenolol, which was expected to be of only minor clinical relevance.²

(b) Bisoprolol

The AUC of bisoprolol 10 mg daily was reduced by 34% in healthy subjects given rifampicin 600 mg daily.³

(c) Carvedilol

Rifampicin 600 mg daily for 12 days caused a 60% decrease in the maximum serum levels and the AUC of carvedilol.⁴

(d) Celiprolol

In a study in healthy subjects, rifampicin 600 mg daily reduced the AUC of a single 200-mg dose of celiprolol by 55%.⁵

(e) Metoprolol

In a study in healthy subjects, rifampicin 600 mg daily reduced the AUC of a single 100-mg dose of **metoprolol** by 33%.⁶

(f) Propranolol

Rifampicin 600 mg daily for 3 weeks increased the oral clearance of propranolol in 6 healthy subjects by almost threefold. Increasing the rifampicin dosage to 900 or 1200 mg daily did not further increase the clearance. Four weeks after withdrawing the rifampicin the blood levels of propranolol had returned to normal.⁷ In a similar study the oral clearance of propranolol was increased by about fourfold by rifampicin 600 mg daily for 3 weeks in both poor and extensive metabolisers of propranolol.⁸

(g) Talinolol

Rifampicin 600 mg daily decreased the AUC of a single-dose of talinolol 30 mg intravenously or 100 mg orally by 21 and 35%, respectively, in 8 healthy subjects.⁹

(h) Tertatolol

Rifampicin 600 mg daily for a week increased the clearance of tertatolol almost threefold and reduced the half-life from 9 to 3.4 hours. A slight reduction in the effects of tertatolol on blood pressure was seen and heart rates were raised from 68 to 74 bpm.¹⁰

Mechanism

Rifampicin is a potent liver-enzyme inducer that increases the metabolism and loss of extensively metabolised beta blockers such as propranolol and metoprolol. Rifampicin may also interact by mechanisms other than enzyme induction. Rifampicin increases duodenal P-glycoprotein expres-

sion, so increased clearance of talinolol (which is not metabolised) may be due to induction of P-glycoprotein excretion.⁹ The effects on atenolol, which is not extensively metabolised, are also possibly due to induction of P-glycoprotein,² although this needs confirmation.

Importance and management

These interactions are established. Their clinical importance is uncertain but probably small.¹⁰ Nevertheless, they cannot be completely dismissed as the case report with atenolol shows. Consider increasing the dosage of the beta blocker if there is any evidence that the therapeutic response is inadequate. Beta blockers that undergo extensive liver metabolism would be expected to be affected by the enzyme-inducing effects of rifampicin (see 'Table 22.1', (p.833)). Those beta blockers mainly lost unchanged in the urine would not be expected to be affected, but it appears that a reaction may occur with non-metabolised drugs, such as talinolol, that are substrates for P-glycoprotein. More study is required.

Beta blockers + Sevelamer

The concurrent use of a single 2.418-g dose of sevelamer did not alter the AUC of a single 100-mg dose of metoprolol in 31 healthy subjects.¹

- Burke SK, Amin NS, Incerti C, Plone MA, Lee JW. Sevelamer hydrochloride (Renagel[®]), a phosphate-binding polymer, does not alter the pharmacokinetics of two commonly used antihypertensives in healthy volunteers. *J Clin Pharmacol* (2001) 41, 199–205.

Beta blockers + SSRIs

Fluoxetine can increase serum pindolol and carvedilol levels, but the clinical effects of this are minimal. Isolated reports describe lethargy and bradycardia in patients taking metoprolol with fluoxetine and propranolol with fluoxetine or fluvoxamine. Fluvoxamine may increase the levels of propranolol, but not atenolol. Paroxetine may increase levels of metoprolol resulting in increased beta-blocking effects. Citalopram and escitalopram may interact similarly. Sertraline does not interact with atenolol.

Clinical evidence

(a) Citalopram

The UK manufacturers of citalopram say that no pharmacodynamic interactions have been noted in clinical studies in which citalopram was given with beta blockers.¹ However the US manufacturers say that although the concurrent use of **metoprolol** and citalopram has no clinically significant effect on heart rate and blood pressure, the plasma levels of **metoprolol** are increased twofold, which may decrease its cardioselectivity.²

(b) Escitalopram

The manufacturers say that escitalopram causes a 50% increase in the plasma levels of **metoprolol** and an 82% increase in its AUC. They note that although the concurrent use of **metoprolol** and escitalopram has no clinically significant effect on heart rate and blood pressure, this increase in plasma levels may decrease the cardioselectivity of **metoprolol**.³

(c) Fluoxetine

Metoprolol 100 mg daily improved the angina of a man who had undergone a coronary artery bypass 4 years earlier. A month later he was given fluoxetine 20 mg daily for depression. Within 2 days he complained of profound lethargy, and his resting heart rate was found to have fallen from 64 to 36 bpm. The fluoxetine was withdrawn, and within 5 days his heart rate returned to 64 bpm. The **metoprolol** was replaced by **sotalol** 80 mg twice daily and fluoxetine reintroduced without problems.⁴

A patient taking **propranolol** 40 mg twice daily developed bradycardia of 30 bpm, heart block and syncope 2 weeks after starting fluoxetine 20 mg daily. This patient possibly also had some pre-existing conduction disease contributing to the effect.⁵

When 9 healthy subjects were given **pindolol** 5 mg every 6 hours with fluoxetine 20 mg daily for 3 days and then 60 mg daily for another 7 days, the **pindolol** AUC rose by about 75% and its clearance fell by about 45%, when compared with a single 5-mg dose of **pindolol**. Only mild to moderate alterations in pulse rate and blood pressure were seen.⁶ Some studies including a high proportion of patients with first-episode depression have suggested that the antidepressant response to fluoxetine is accelerated by **pindolol**⁷ while other studies in patients with predominantly chronic or recurrent depression did not find an enhanced response.⁸ A double-blind crossover study in 10 patients with heart failure, taking **carvedilol** 25 to 50 mg twice daily, found that the addition of fluoxetine 20 mg daily for 28 days increased the AUC of (**R**)-**carvedilol** by 77%, and decreased the clearance of both enantiomers by 44 to 56%. However, these pharmacokinetic changes were of little clinical significance, since there were no changes in blood pressure, heart rate, and heart rate variability.⁹

(d) Fluvoxamine

A 79-year-old man who had taken **propranolol** for prophylaxis of migraine for several years developed fatigue and lightheadedness within a few days of starting fluvoxamine. He was admitted to hospital with syncope and bradycardia of 38 bpm but recovered after both drugs were discontinued.¹⁰ Fluvoxamine 100 mg daily raised the plasma levels of **propranolol** 160 mg daily fivefold in healthy subjects, but the bradycardic effects were only slightly increased (by 3 bpm). The diastolic pressure following exercise was only slightly reduced but the general hypotensive effects remained unaltered.¹¹ Fluvoxamine did not change the plasma levels of **atenolol** 100 mg daily, but the heart-slowing effects were slightly increased and the hypotensive effects were slightly decreased.¹¹

(e) Paroxetine

A study in 8 healthy subjects found that paroxetine 20 mg daily for 6 days increased the AUCs of (**R**)- and (**S**)-**metoprolol** by eightfold and fivefold, respectively, after a single 100-mg dose of **metoprolol**. The maximum plasma concentration and elimination half-life were increased about twofold. The beta-blocking effects of **metoprolol** were more sustained and the reduction in exercise systolic pressure was more pronounced when paroxetine was also taken, when compared with **metoprolol** alone.¹²

(f) Sertraline

No changes in the beta-blocking effects of **atenolol** were found in a single-dose study in 10 healthy subjects given sertraline 100 mg five hours before **atenolol** 50 mg.^{13,14}

Mechanism

Fluoxetine and paroxetine inhibit the cytochrome P450 isoenzyme CYP2D6 thus inhibiting the metabolism of some beta blockers (e.g. propranolol, metoprolol, carvedilol) so that they accumulate, the result being that their effects, such as bradycardia, may be increased.⁴ Citalopram and escitalopram may also inhibit CYP2D6. *In vitro* studies with human liver microsomes found that fluoxetine and paroxetine are potent inhibitors of metoprolol metabolism and fluvoxamine, sertraline and citalopram less potent.¹⁵ However, fluvoxamine also potently inhibits the metabolism of propranolol by CYP1A2.^{10,16} Beta blockers that are not extensively me-

tabolised, such as atenolol and sotalol, would not be expected to be affected.

Pindolol may augment the antidepressant effect of fluoxetine by its antagonistic effects at 5-HT_{1A} receptors.^{7,8,17}

Importance and management

Pharmacokinetic interactions have been found between fluoxetine, fluvoxamine or paroxetine and some beta blockers, but despite marked pharmacokinetic changes, the clinical effects are not generally significant. However, be aware that there are a few isolated reports of severe bradycardia with beta blockers and fluoxetine or fluvoxamine. If problems arise, the interaction can apparently be avoided by giving a beta blocker (such as atenolol), which is not extensively metabolised. Alternatively, sertraline and citalopram seem to be less likely than the other SSRIs to interact with extensively-metabolised beta blockers.¹⁵ However, because metoprolol is considered to have a narrow therapeutic index in the treatment of heart failure, the UK manufacturers of escitalopram say that caution and possible dosage adjustments are warranted on concurrent use.¹⁸ Similarly the manufacturers of paroxetine suggest that concurrent use should be avoided if metoprolol is being used for heart failure.¹⁹ Remember that fluoxetine and particularly its metabolite have long half-lives so that this interaction may possibly still occur for some days after the fluoxetine has been stopped. Also note that bradycardia occurs rarely with fluoxetine alone and in some cases an interaction may be pharmacodynamic rather than pharmacokinetic, and so swapping the beta blocker could, rarely, be ineffective.

The combination of pindolol with fluoxetine may be advantageous in the treatment of depression in some patients.^{7,8}

Beta blockers + Sulfinpyrazone

The antihypertensive effects of oxprenolol can be reduced or abolished by sulfinpyrazone. The pharmacokinetics of metoprolol are not affected by sulfinpyrazone.

Clinical evidence

Oxprenolol 80 mg twice daily was given to 10 hypertensive subjects for 15 days, which reduced their mean supine blood pressure from 161/101 to 149/96 mmHg, and their heart rate from 72 to 66 bpm. When they were additionally given sulfinpyrazone 400 mg twice daily for 15 days, their mean blood pressure rose to about the former level. The reduction in mean heart rate remained unaffected. Sulfinpyrazone attenuated the reduction in cardiac workload seen with **oxprenolol** alone by about half.¹

A study in 9 healthy subjects found that sulfinpyrazone 400 mg twice daily did not affect the pharmacokinetics of **metoprolol** 100 mg twice daily. No adverse effects were noted in healthy subjects during concurrent use.²

Mechanism

Not understood. One idea is that the sulfinpyrazone inhibits the production of vasodilatory (antihypertensive) prostaglandins by the kidney. This would oppose the actions of the oxprenolol.

Importance and management

Information seems to be limited. If sulfinpyrazone is given to patients taking oxprenolol for hypertension, the effects should be monitored. It seems likely that this interaction could be accommodated by raising the dosage of the oxprenolol but this needs confirmation. The effect of this interaction on cardiac workload appears to be less important, but it would still be prudent to monitor concurrent use if oxprenolol is used for angina. Metoprolol may be a suitable alternative to oxprenolol as it does not appear to interact with sulfinpyrazone.

Beta blockers + Tobacco ± Coffee and Tea

Tobacco smoking can reduce the beneficial effects of beta blockers on heart rate and blood pressure. Some increase in the dosage of the beta blocker may be necessary. Drinking tea or coffee may have a similar but smaller effect.

Clinical evidence

(a) Caffeine

Two 150-mL cups of coffee (made from 24 g of coffee) increased the mean blood pressure of 12 healthy subjects taking **propranolol** 240 mg, **metoprolol** 300 mg or a placebo. Mean blood pressure rises were 7%/22% with **propranolol**, 7%/19% with **metoprolol** and 4%/16% mmHg with placebo. The beta blockers and placebo were given in divided doses over 15 hours before the test.¹

(b) Tobacco smoking

A double-blind study in 10 smokers with angina pectoris, taking daily doses of either **propranolol** 240 mg, **atenolol** 100 mg or a placebo, found that smoking reduced their plasma **propranolol** levels by 25% when compared with a non-smoking phase. Plasma **atenolol** levels were not significantly altered. Both of the beta blockers reduced heart rate at rest and during exercise, but the reductions were less when subjects smoked (effects attenuated by 8 to 14%).²

Other studies found that serum **propranolol** levels in smokers were about half those in non-smokers.^{3,4} Smoking caused an increase in blood pressure and heart rate in patients with angina and these effects were still evident, to a reduced extent, during **propranolol** treatment. In addition smoking abolished the beneficial effects of **propranolol** on ST-segment depression.⁵

(c) Tobacco smoking and caffeine

Eight patients with mild hypertension taking **propranolol** 80 mg twice daily, **oxprenolol** 80 mg twice daily or **atenolol** 100 mg daily over a 6-week period had their blood pressure monitored after smoking 2 tipped cigarettes and drinking coffee, containing 200 mg of caffeine.

Their mean blood pressure rises over the following 2 hours were 8.5/8 mmHg in those taking **propranolol**, 12.1/9.1 mmHg in those taking **oxprenolol** and 5.2/4.4 mmHg in those taking **atenolol**.⁶

Mechanism

Smoking tobacco increases heart rate, blood pressure and the severity of myocardial ischaemia, probably as a direct effect of the nicotine and due to the reduced oxygen-carrying capacity of the blood.^{2,5} These actions oppose and may even totally abolish the beneficial actions of the beta blockers. In addition, smoking stimulates the liver enzymes concerned with the metabolism of some beta blockers (e.g. propranolol) so that their serum levels are reduced.

Caffeine causes the release of catecholamines, such as adrenaline, into the blood, which could account for the increases in heart rate and blood pressure that are seen.⁶ The blood pressure rise may be exaggerated in the presence of non-selective beta blockers, which block vasodilatation leaving the alpha (vasoconstrictor) effects of adrenaline unopposed. This will also oppose the actions of the beta blockers.

Importance and management

Established interactions. Smoking tobacco and (to a very much lesser extent) drinking tea or coffee oppose the effects of the beta blockers in the treatment of angina or hypertension. Patients should be encouraged to stop smoking because, quite apart from its other toxic effects, it aggravates myocardial ischaemia, increases heart rate and can impair blood pressure control. If patients continue to smoke, it may be necessary to raise the dosages of the beta blockers. The effects of the caffeine in tea, coffee, cola drinks, etc. are quite small and there seems to be no strong reason to forbid them, but the excessive consumption of large amounts may not be a good idea, particularly in those who also smoke.

Beta blockers + X-ray contrast media

There is some evidence that use of beta blockers is a risk factor for anaphylactoid reactions to X-ray contrast media. Severe hypotension has been seen in two patients taking beta blockers who were given sodium meglumine amidotrizoate and in a further patient taking atenolol who was given iohexol.

Clinical evidence

A case-control study of anaphylactoid reactions to X-ray contrast media found that the risk of bronchospasm during intravenous contrast media procedures was associated with beta blocker use and also with asthma, while the risk of major and life-threatening anaphylactoid reactions were associated with cardiovascular disorders. Use of beta blockers also increased the risk of hospitalisation in those patients who had a severe anaphylactoid reaction.¹

Two patients, one taking **nadolol** and the other **propranolol**, developed severe hypotensive reactions when given **sodium meglumine amidotrizoate** as a contrast agent for X-ray urography. Both patients developed slowly progressive erythema on the face and arms followed by tachycardia and a weak pulse. Each was successfully treated with subcutaneous adrenaline (epinephrine) and hydrocortisone.²

Another patient who had developed a transient rash during cardiac catheterisation 6 years earlier and who was subsequently given **atenolol** developed generalised urticaria and severe hypotension immediately after an injection of **iohexol** for coronary angiography. The hypotension was refractory to aggressive standard treatment with adrenaline, atropine, and

dopamine and the patient remained in shock (BP 60/34 mmHg). Noradrenaline (norepinephrine) infusion produced a modest improvement (BP 80/40 mmHg), but significant improvement in blood pressure occurred only after intravenous injections of glucagon 1 mg.³

See also, Anaphylaxis under 'Beta blockers + Inotropes and Vasopressors', p.848.

Mechanism

Iodinated contrast media are associated with hypersensitivity reactions due to the release of histamine. It is suggested that beta blockers compromise the ability of the body to cope with the effects of histamine release.²

Importance and management

Limited documentation. Withdrawal of the beta blocker 2 to 3 days before use of contrast media has been suggested,² but because of the potential for beta blocker withdrawal syndromes this must be considered on an individual risk/benefit basis.¹ Pretreatment with an antihistamine such as diphenhydramine and a corticosteroid such as prednisone may reduce the risk of reactions.^{3–5} Ephedrine and cimetidine have also been tried, but their use is controversial.⁵ Use of low osmolality, non-ionic contrast media may reduce the risk of adverse reactions, including anaphylaxis.^{1,5,6} However, even mild reactions to contrast media may sensitise the patient and a serious anaphylactoid reaction may occur on further exposure despite pretreatment and the use of low osmolality contrast media.³ Pre-testing with a small amount of the contrast media has been shown to be a poor predictor of a reaction.⁵

When anaphylactic reactions do occur in patients taking beta blockers, it may be preferable to use a beta-agonist bronchodilator such as isoprenaline rather than adrenaline (epinephrine).² Glucagon, which has inotropic and chronotropic actions that are only minimally antagonised by beta blockers, may also be effective in reversing anaphylactoid shock in patients taking beta blockers.³

Atenolol + Allopurinol

Allopurinol 300 mg daily for 6 days did not affect the steady-state pharmacokinetics of atenolol 100 mg daily in 6 healthy subjects.¹ No special precautions would therefore appear to be necessary on concurrent use.

1. Schäfer-Korting M, Kirch W, Axthelm T, Köhler H, Mutschler E. Atenolol interaction with aspirin, allopurinol, and ampicillin. *Clin Pharmacol Ther* (1983) 33, 283–8.

Metoprolol + Acetylcholine

An isolated case describes bronchospasm, which developed in a patient taking metoprolol when intra-ocular acetylcholine was given.

Clinical evidence, mechanism, importance and management

An elderly patient with a history of hypertension, obstructive pulmonary disease and stable angina, taking several drugs including metoprolol, experienced severe bronchospasm and pulmonary oedema immediately following the intra-ocular injection of acetylcholine chloride during cataract surgery. Her blood pressure rapidly increased, and she became tachycardic. She had also received phenylephrine eye drops before surgery. The

patient may have been more sensitive to the pulmonary effects of acetylcholine, such as bronchospasm, because of pre-existing disease and the presence of metoprolol. Phenylephrine may also have been involved,¹ (see also 'Beta blockers + Inotropes and Vasopressors', p.848). The general clinical relevance of this single case is uncertain but it seems likely to be small.

1. Rasch D, Holt J, Wilson M, Smith RB. Bronchospasm following intraocular injection of acetylcholine in a patient taking metoprolol. *Anesthesiology* (1983) 59, 583–5.

Propranolol + Ascorbic acid (Vitamin C)

Vitamin C reduces the bioavailability of propranolol but the extent is too small to be of clinical significance.

Clinical evidence, mechanism, importance and management

A study in 5 healthy subjects given a single 80-mg dose of propranolol found that a single 2-g dose of vitamin C reduced the maximum plasma levels of propranolol by 28%, reduced the AUC by 37% and reduced its recovery in the urine by 66%. The fall in heart rate was also slightly reduced. The reason for this interaction appears to be that vitamin C reduces both the absorption and the metabolic conjugation of propranolol.¹ However, none of the changes seen would appear to be of clinical relevance.

1. Gonzalez JP, Valdivieso A, Calvo R, Rodríguez-Sasiaín JM, Jimenez R, Aguirre C, du Souich P. Influence of vitamin C on the absorption and first pass metabolism of propranolol. *Eur J Clin Pharmacol* (1995) 48, 295–7.

Propranolol + Dextromoramide

An isolated report describes two patients who developed marked bradycardia and severe hypotension when they were given propranolol and dextromoramide following the induction of anaesthesia.

Clinical evidence, mechanism, importance and management

Two women about to undergo a partial thyroidectomy were given propranolol 30 mg and dextromoramide 1.25 or 4 mg by injection during the pre-operative period, after which anaesthesia was induced with a barbiturate. Each woman developed marked bradycardia and severe hypotension, which responded rapidly to intravenous atropine.¹ The reasons for this response are not understood and the general significance of this interaction is unclear.

Propranolol + Miscellaneous

The manufacturers predict that propranolol levels will be raised by a number of drugs, but only the possible interaction with ritonavir appears to be of much concern.

Clinical evidence, mechanism, importance and management

(a) CYP2D6 inhibitors

As propranolol is metabolised by CYP2D6 the US manufacturers¹ suggest that inhibitors of this isoenzyme may inhibit propranolol metabolism. Some CYP2D6 inhibitors have been seen to interact (such as 'quinidine', (p.853)), but the pharmacokinetic effects seem modest in many cases, probably because propranolol is also metabolised by CYP1A2. An interaction with **ritonavir** (as predicted by the manufacturers) therefore seems possible, and the effects may be greater than those seen with other CYP2D6 inhibitors (see (b) below).

(b) CYP1A2 substrates or inhibitors

As propranolol is partly metabolised by CYP1A2 the US manufacturers¹ predict that its levels may be raised by substrates or inhibitors of this isoenzyme.

However, data for 'imipramine', (p.1246), 'isoniazid', (p.310), and 'the-

ophylline', (p.1175), (substrates of CYP1A2) suggest that in fact propranolol raises the levels of these drugs.

Inhibitors of CYP1A2 raise propranolol levels (as seen with 'fluvoxamine', (p.855)) and therefore an interaction with **ciprofloxacin** (as predicted by the manufacturers) seems possible. However, note that propranolol levels fluctuate greatly between individuals, and propranolol is not exclusively metabolised by CYP1A2, and so any interaction seems likely only to produce moderate clinical effects. Note that the manufacturers of propranolol also list **ritonavir** as an inhibitor of CYP1A2, and this possible interaction may be of greater clinical significance as **ritonavir** can also inhibit CYP2D6, the other main route of propranolol metabolism (see (a) above). A large rise in propranolol levels may therefore occur. It would therefore seem prudent to be cautious if **ritonavir** is given with propranolol.

(c) CYP2C19 substrates or inhibitors

The US manufacturers¹ suggest that raised propranolol levels may occur with **fluconazole** or **tolbutamide**, which are inhibitors of CYP2C19 and a substrate for CYP2C19, respectively. However, CYP2C19 only plays a small part in propranolol metabolism. Further, the manufacturers also note that **omeprazole** and **lansoprazole** (inhibitors and substrates for CYP2C19) do not interact, and so a clinically significant interaction involving CYP2C19 seems unlikely.

1. Inderal (Propranolol hydrochloride). Wyeth Pharmaceuticals Inc. US Prescribing information, January 2007.

Propranolol + Misoprostol

Misoprostol does not significantly alter the pharmacokinetics of propranolol.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects misoprostol 400 micrograms twice daily raised the AUC of propranolol 80 mg twice daily by about 20 to 40%, and this remained raised 7 days after misoprostol was discontinued.¹ However, as these findings were unexpected, the authors conducted a randomised, crossover, placebo-controlled study and ensured that propranolol was at steady state before assessing the effect of misoprostol. No significant effects on the pharmacokinetics of propranolol were found.² No special precautions would therefore seem necessary during concurrent use.

1. Bennett PN, Fenn GC, Notarianni LJ. Potential drug interactions with misoprostol: effects on the pharmacokinetics of antipyrine and propranolol. *Postgrad Med J* (1988) 64 (Suppl 1), 21–4.
2. Bennett PN, Fenn GC, Notarianni LJ, Lee CE. Misoprostol does not alter the pharmacokinetics of propranolol. *Postgrad Med J* (1991) 67, 455–7.

Propranolol + Nefazodone

Nefazodone does not significantly affect the pharmacokinetics of propranolol.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects found that nefazodone 200 mg every 12 hours reduced the AUC of propranolol 40 mg every 12 hours by 14% and decreased the maximum plasma levels by 29%, but no clinically significant changes in the response to propranolol or relevant adverse responses were seen. The pharmacokinetics of the nefazodone were largely unchanged.¹ No special precautions would therefore seem to be necessary if both drugs are used.

1. Salazar DE, Marathe PH, Fulmor IE, Lee JS, Raymond RH, Uderman HD. Pharmacokinetic and pharmacodynamic evaluation during coadministration of nefazodone and propranolol in healthy men. *J Clin Pharmacol* (1995) 35, 1109–18.

Propranolol + Sucrose polyesters

There is evidence that sucrose polyesters (e.g. *Olestra*) do not interact with propranolol.

Clinical evidence, mechanism, importance and management

Eight healthy subjects were given sucrose polyester 18 g and a single un-stated dose of propranolol. Sucrose polyester had no effect on the pharmacokinetics of propranolol.¹ Sucrose polyesters, are non-absorbable, non-calorific fat replacements. It has been concluded that sucrose polyesters are unlikely to reduce the absorption of oral drugs in general.²

2. Goldman P. Olestra: assessing its potential to interact with drugs in the gastrointestinal tract. *Clin Pharmacol Ther* (1997) 61, 613–18.

Sotalol + Terfenadine

Episodes of torsade de pointes arrhythmia developed in a woman taking sotalol when terfenadine was added.

Clinical evidence, mechanism, importance and management

A 71-year-old woman with a history of atrial fibrillation was successfully treated with sotalol 80 mg twice daily. She started to take terfenadine 60 mg twice daily, and 8 days later she developed repeated self-limiting episodes of torsade de pointes arrhythmia. On one occasion she required resuscitation. Both drugs were stopped and no further episodes of arrhythmia occurred 72 hours after temporary pacing was discontinued.¹ It seems likely that what happened resulted from the additive effects of both drugs on the QT interval, which can lead to the development of torsade de pointes. This case confirms a previous mention of the possibility of this interaction.²

Although this seems to be the first report of this interaction, it is consistent with the known pharmacology of both drugs. Torsade de pointes is potentially life threatening, so the concurrent use of these two drugs should

generally be avoided. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

2. Woosley RL, Chen Y, Freiman JP, Gillis RA. Mechanism of the cardiotoxic actions of terfenadine. *JAMA* (1993) 269, 1532–6.

Talinolol + Sulfasalazine

Sulfasalazine markedly reduces the absorption of talinolol.

Clinical evidence

The AUC of talinolol 50 mg was reduced by 91% (from 958 to 84 nanograms/mL per hour) in 8 healthy subjects given sulfasalazine 4 g. The maximum serum levels were also markedly reduced, from 112 to 23 nanograms/mL in 3 subjects, and to undetectable levels in the other 5 subjects.¹

Mechanism

Not known. It is suggested that talinolol is adsorbed onto the sulfasalazine, thereby preventing its absorption.¹

Importance and management

Information is limited to this study, but it would appear to be an established and probably clinically important interaction. The efficacy of the talinolol would be expected to be markedly reduced, but this does not appear to have been studied. If the mechanism suggested by the authors is true, their advice to separate the dosages by 2 to 3 hours should minimise this interaction.¹ More study is needed to confirm how effective this action is, and whether other beta blockers behave similarly.

1. Terhaag B, Palm U, Sahre H, Richter K, Oertel R. Interaction of talinolol and sulfasalazine in the human gastrointestinal tract. *Eur J Clin Pharmacol* (1992) 42, 461–2.

23

Calcium-channel blockers

Calcium-channel blockers in current clinical usage affect the slow L-type channel. They are usually classified by their chemical structure, which determines their selectivity for vascular smooth muscle over myocardium, and hence their potential to slow the heart rate (negative inotropic activity) see 'Table 23.1', (below). Interactions due to additive inotropic effects will therefore apply only to the benzothiazepine (diltiazem) and phenylalkylamine-type (verapamil) calcium-channel blockers, and usually not to the dihydropyridine-type (e.g. nifedipine) calcium-channel blockers. All three types of calcium-channel blocker will have additive hypotensive effects with other drugs with blood-pressure lowering activity.

Calcium-channel blockers also undergo interactions due to altered metabolism. Both verapamil and diltiazem are principally metabolised by the cytochrome P450 isoenzyme CYP3A4, and also inhibit this enzyme (see 'Table 1.4', (p.6)). They are therefore affected by drugs that induce or inhibit CYP3A4, and also themselves interact with drugs metabolised by CYP3A4.

Many of the dihydropyridine-type calcium-channel blockers are also metabolised by CYP3A4, and are affected by inducers or inhibitors of this isoenzyme. However, they do not generally inhibit CYP3A4, or other isoenzymes to a clinically relevant extent. The exception is perhaps nifedipine, which may cause a clinically relevant inhibition of CYP3A4 (see 'Table 1.4', (p.6)).

This section is primarily concerned with those interactions where the activity of the calcium-channel blockers is changed by the presence of another drug. Where the calcium-channel blocker is the affecting agent, the relevant monograph is usually categorised under the heading of the affected drug.

Mibefradil is a calcium-channel blocker that acts on the fast T-type calcium channel. It was withdrawn soon after it was launched because of identification of an increasing number of serious drug interactions caused

by its inhibitory effects on CYP3A4 and 2D6. It was thought that the practical problems of implementing all the warnings relating to these interactions were too difficult and risky.

Table 23.1 Classification of calcium-channel blockers that act on slow L-type channels

Class	Rate limiting?	Effect on AV or SA node	Examples
Dihydropyridine	No	Little or none	Amlodipine, Barnidipine, Benidipine, Felodipine, Isradipine, Lacidipine, Lercanidipine, Manidipine, Nicardipine, Nifedipine, Nilvadipine, Nimodipine, [†] Nisoldipine, Nitrendipine
Benzothiazepine	Yes	Depression (negative inotropic activity)	Diltiazem
Phenylalkylamine	Yes	Depression (negative inotropic activity)	Gallopamil, Verapamil

[†]Nimodipine crosses the blood-brain barrier and therefore affects cerebral blood vessels, and is used for cerebral ischaemia.

Calcium-channel blockers + Antihistamines

An isolated report describes increased adverse effects in two patients when terfenadine was given to patients taking nifedipine or verapamil. Verapamil markedly increased the AUC of a single dose of fexofenadine in one study, but another study found a much more modest effect. However, even a marked increase may not be clinically important.

No pharmacodynamic interaction appears to occur between diltiazem and mizolastine, and mizolastine did not alter diltiazem pharmacokinetics. Nifedipine is predicted to increase the levels of mizolastine.

Clinical evidence, mechanism, importance and management

(a) Fexofenadine

In a study in 12 healthy subjects verapamil 240 mg daily for 6 days increased the AUC of a single 120-mg dose of fexofenadine 2.5-fold and increased the maximum level 2.9-fold with marked interindividual variation. Fexofenadine is not metabolised by the cytochrome P450 system, and it was suggested that verapamil may have increased fexofenadine bioavailability by inhibiting the drug transporters, P-glycoprotein or OATPs.¹ Another study showed a smaller 30% increase in maximum level of fexofenadine when a single 60-mg dose was given to subjects who had taken verapamil 240 mg daily for 10 days. Moreover, after 38 days of verapamil, the maximum level and clearance of fexofenadine was not significantly changed.²

Note that marked increases in fexofenadine levels with 'erythromycin', (p.589) and 'ketoconazole', (p.584) did not increase adverse effects and were not associated with any prolongation of the QT interval. This suggests that a clinically relevant interaction between verapamil and fexofenadine is not expected, but some caution may be warranted until further experience is gained.

(b) Mizolastine

A double-blind crossover study in 12 healthy subjects taking diltiazem 60 mg three times daily found that the concurrent use of mizolastine 10 mg daily for 5 days did not alter ECGs or blood pressures. No significant increases in adverse effects were seen and the pharmacokinetics of the diltiazem remained unchanged. However, mizolastine pharmacokinetics were not assessed.³ Some manufacturers of nifedipine⁴ and those of mizolastine⁵ suggest that concurrent use may raise mizolastine levels by inhibition of the cytochrome P450 isoenzyme CYP3A4, and caution is therefore advised,⁵ presumably because mizolastine has a weak potential to prolong the QT interval. If caution is required with nifedipine, then this should be extended to both diltiazem and verapamil, since these are both more potent inhibitors of CYP3A4 than nifedipine. Further study is needed.

(c) Terfenadine

An isolated report describes severe angina in a patient stabilised on nifedipine 10 mg three times daily when she took terfenadine 60 mg for seasonal allergy. A second patient taking verapamil 80 mg three times daily also experienced adverse effects (including severe headache and confusion) when a single 60-mg dose of terfenadine was taken.⁶ Verapamil, diltiazem, and to a lesser extent some dihydropyridine calcium-channel blockers (e.g. nifedipine) are inhibitors of CYP3A4, but there appear to be no other reports of interactions with either terfenadine or astemizole (substrates of CYP3A4). Of all the calcium-channel blockers, only the manufacturers of lercanidipine advise caution during the concurrent use of terfenadine and astemizole.⁷

Calcium-channel blockers + Antineoplastics

The absorption of verapamil can be modestly reduced by antineoplastic regimens containing cyclophosphamide, vincristine, and procarbazine, or vindesine, doxorubicin, cisplatin.

Clinical evidence, mechanism, importance and management

A study in 9 patients with a variety of malignant diseases found that treatment with antineoplastics reduced the absorption of a single 160-mg oral dose of verapamil. The verapamil AUC in 8 patients was reduced by 40% (range 7 to 58%), and one patient conversely had a 26% increase. Five patients received a modified COPP regimen (cyclophosphamide, vincristine, procarbazine, prednisone) and four received VAC (vindesine, doxorubicin, cisplatin).¹ It is believed that these antineoplastics damage the lining of the upper part of the small intestine, which impairs the absorption of verapamil. The clinical relevance of this reduction does not appear to have been studied. Note that verapamil may affect levels of 'anthracyclines', (p.611), 'etoposide', (p.631), and possibly 'docetaxel', (p.662). In addition, nifedipine may affect the levels of 'vincristine', (p.671).

Calcium-channel blockers + Aprepitant

The concurrent use of aprepitant and diltiazem markedly increases the levels of both drugs.

Clinical evidence, mechanism, importance and management

The US manufacturer notes that the use of aprepitant 230 mg daily with diltiazem 120 mg three times daily for 5 days increased the AUC of aprepitant twofold and increased the diltiazem AUC 1.7-fold in patients with hypertension. Nevertheless, aprepitant did not alter the effects of diltiazem on heart rate or blood pressure.¹

Both aprepitant and diltiazem are substrates and inhibitors of the cytochrome P450 isoenzyme CYP3A4, therefore they each inhibit the other drugs metabolism. The clinical relevance of this interaction is uncertain, but the manufacturers recommend caution with diltiazem and other moderate inhibitors of CYP3A4.¹

Calcium-channel blockers + Aspirin or NSAIDs

There is evidence that most NSAIDs can increase blood pressure in patients treated with antihypertensives, although some studies have not found the increase to be clinically relevant. In various small studies, indometacin appeared not to reduce the hypotensive effects of amlodipine, felodipine, nicardipine, nimodipine or verapamil, but it did in one of two studies with nifedipine, and one study with nitrendipine. Similarly, ibuprofen caused a small reduction in the antihypertensive effects of amlodipine. Diclofenac and sulindac appear not to interact with nifedipine, nor ibuprofen, naproxen, piroxicam or sulindac with verapamil, nor naproxen with nicardipine. Low-dose aspirin did not alter the antihypertensive effect of felodipine or nifedipine in one study, and long-term aspirin did not alter the cardiovascular benefits of nitrendipine in another. Diclofenac reduces verapamil serum levels and raises those of isradipine, but these changes are probably unimportant.

Two reports describe abnormal bruising and prolonged bleeding times in two patients and one healthy subject taking verapamil with aspirin. There are conflicting reports as to whether or not gastrointestinal bleeding is increased by giving NSAIDs with calcium-channel blockers.

Clinical evidence

A. Antagonism of antihypertensive effects

Various large epidemiological studies and meta-analyses of clinical trials have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with **antihypertensives**, and the findings of these are summarised in 'Table 23.2', (below). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both COX-2 inhibitors and non-selective NSAIDs. In two meta-analyses,^{1,2} the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between **indometacin** and **sulindac** in one analysis.² Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,¹ the effect was greatest for **piroxicam**, **indometacin**, and **ibuprofen**, intermediate for **naproxen**, and least for **sulindac** and **flurbiprofen**. In the other meta-analysis,² the effect was greatest for **indometacin** and **naproxen**, intermediate for **piroxicam**, and least for **ibuprofen** and **sulindac**. An attempt was also made to evaluate the effect by **antihypertensive** in one analysis.¹ The mean effect was greatest for beta blockers, intermediate for vasodilators (includes ACE inhibitors and calcium-channel blockers), and least for diuretics. However, the differences between the groups were not significant.

The findings of individual clinical and pharmacological studies that have studied the effects of aspirin or specific NSAIDs on specific calcium-channel blockers are outlined in the subsections below.

(a) Aspirin

1. **Felodipine**. In the Hypertension Optimal Treatment (HOT) study, 18 790 treated hypertensive patients, about 82% of whom received a calcium-channel blocker, usually felodipine alone or in combination, were also given either aspirin 75 mg daily or placebo for an average of 3.8 years. It was found that long-term low-dose aspirin does not interfere with the blood pressure-lowering effects of the antihypertensive drugs studied.³

2. **Nifedipine**. In a small study in 18 patients, low-dose aspirin 100 mg daily for 2 weeks did not alter the blood pressure lowering effect of nifedipine 30 to 60 mg daily, given as a modified-release preparation.⁴

3. **Nitrendipine**. A post-hoc analysis of the Syst-Eur trial of nitrendipine-based antihypertensive treatment found no difference in cardiovascular outcome between 861 patients who were also using long-term aspirin (700 patients) and/or other NSAIDs (161) and 2882 patients who had never taken aspirin or NSAIDs. Patients in this trial were randomised to receive nitrendipine, which could be combined or replaced by enalapril, hydrochlorothiazide, or both.⁵

4. **Unnamed calcium-channel blockers**. In a randomised study, the use of low-dose aspirin 100 mg daily for 3 months did not alter blood pressure control in patients taking calcium-channel blockers or ACE inhibitors, when compared with placebo.⁶

(b) Diclofenac

Hypertensive subjects taking slow-release **verapamil** 240 mg daily had a 26% reduction in the AUC of **verapamil** when they took diclofenac 75 mg twice daily.⁷ The AUC of **isradipine** 5 mg twice daily for a week was unaffected in 18 healthy subjects by a single 50-mg dose of diclofenac but the maximum serum levels were raised by about 20%. Platelet aggregation

Table 23.2 Summary of epidemiological studies and meta-analyses of the effect of NSAIDs on blood pressure in patients taking antihypertensive drugs

Study type	Patients	Antihypertensives	NSAIDs	Findings	Refs
Case-control (2005)	184 cases 762 controls (UK primary care)	Not stated. Median of 2 different drugs.	Ibuprofen (78 cases) Diclofenac (60) Other (25)	BP control in treated hypertensives was not affected by use of NSAIDs. No evidence that either SBP or DBP differed according to type of NSAID.	1
Retrospective analysis (2004)	8538 patients with rheumatic disease and hypertension	Not stated	NSAID (1164 patients) Celecoxib (654) Rofecoxib (417)	Other NSAID or celecoxib therapy not associated with difficulty in controlling blood pressure, but rofecoxib was (odds ratio 1.38).	2
Meta-analysis (1994)	50 randomised controlled trials in 771 patients or healthy subjects	Beta blockers (15) Vasodilators (18) Diuretics (12)	Indometacin (33 trials) Sulindac (7) Ibuprofen (5) Piroxicam (4) Flurbiprofen (4)	NSAIDs elevated mean supine BP by 5 mmHg. NSAIDs antagonised all antihypertensives, but only beta blockers was statistically significant (6.2 mmHg). Among the NSAIDs, only the effect of piroxicam was statistically significant, with piroxicam, indometacin and ibuprofen causing the greatest increase, and sulindac and flurbiprofen the least.	3
Case-control (1993)	133 cases 133 controls	Hydrochlorothiazide, furosemide, methyldopa, propranolol	Ibuprofen (30% of cases) Indometacin (22%) Naproxen (18%) Sulindac (13%)	SBP was about 5 mmHg higher (not statistically significant) in those on NSAIDs, but DBP did not differ. Findings the same if indometacin users removed.	4
Cross-sectional cohort (1993)	2800 elderly (12% on both an NSAID and antihypertensives)	Not stated	Not stated	NSAID use was associated with a 29% increased risk of hypertension in those on antihypertensives, but not in those not on antihypertensives.	5
Meta-analysis (1993)	54 studies with 108 NSAID treatment arms in 1213 hypertensive patients	Not stated	Indometacin (600 patients) Naproxen (72) Piroxicam (51) Ibuprofen (55) Sulindac (277)	Increase in mean arterial pressure with indometacin 3.6 mmHg, naproxen 3.7, piroxicam 0.5, decrease in mean arterial pressure with ibuprofen 0.8, sulindac 0.16. The difference between indometacin and sulindac was statistically significant.	6

was unaffected and the pharmacokinetics of the diclofenac were unchanged.⁸

A study in elderly women with hypertension found that diclofenac sodium 25 mg three times daily for one week had no effect on the control of their blood pressure with **nifedipine**.⁹

(c) Ibuprofen

Fifty-three hypertensive patients had no changes in their blood pressure control with **verapamil** 240 or 480 mg daily when they also took ibuprofen 400 mg three times daily for 3 weeks.¹⁰ However, another study in 12 patients with mild or moderate essential hypertension controlled with **amlodipine** 10 mg daily, found that ibuprofen 400 mg three times daily for 3 days increased the mean blood pressure by 7.8/3.9 mmHg.¹¹

(d) Indometacin

Indometacin 100 mg daily for a week did not significantly affect the hypotensive effects of **nifedipine** 20 mg twice daily in 10 patients with mild to moderate essential hypertension.¹² In contrast, in another study, indometacin 100 mg in divided doses over 24 hours was found to raise the mean arterial pressure by 17 to 20 mmHg in 5 out of 8 hypertensive patients taking **nifedipine** 15 to 40 mg daily.¹³

Five other studies, two in healthy subjects^{14,15} and 3 in patients with hypertension¹⁶⁻¹⁸ found that indometacin did not alter the blood pressure-lowering effects of **amlodipine**,¹⁸ **felodipine**,^{14,16} **nicardipine**¹⁵ or **verapamil**.¹⁷ Similarly, the haemodynamic effects of **nimodipine** 30 mg three times daily were not affected to a clinically relevant extent by indometacin 25 mg twice daily in 24 healthy elderly subjects, although the AUC of **nimodipine** and its maximum plasma levels were slightly increased.¹⁹ However, indometacin 25 mg three times daily raised systolic and diastolic blood pressure by a mean of 4 mmHg in 15 patients taking **nitrendipine** 5 to 20 mg twice daily.²⁰

(e) Naproxen

Naproxen 375 mg twice daily had no effect on the pharmacokinetics of **verapamil** in hypertensive subjects.⁷ Fifty-five hypertensive patients had no changes in their blood pressure control with **verapamil** 240 to 480 mg daily when they were given naproxen 250 mg twice daily for 3 weeks.¹⁰

A placebo-controlled study in 100 patients taking **nicardipine** 30 mg three times daily found that naproxen 375 mg twice daily caused no clinically relevant changes in the control of their blood pressure.²¹

(f) Piroxicam

A study in hypertensive patients given up to 440 mg of **verapamil** daily found that piroxicam 20 mg once daily for 4 weeks did not significantly alter the antihypertensive effects of **verapamil**.²²

(g) Sulindac

A study in elderly women with hypertension found that sulindac 100 mg three times daily for one week had no effect on the control of their blood pressure with **nifedipine**.⁹

A study in hypertensive patients given up to 440 mg of **verapamil** daily found that sulindac 200 mg twice daily for 4 weeks did not significantly alter the antihypertensive effects of **verapamil**.²²

B. Antiplatelet effects and gastrointestinal bleeding

Abnormal bruising and prolonged bleeding times occurred in a woman taking **verapamil** 80 mg three times daily when she took **aspirin** 650 mg several times a week for headaches. The bruising ceased when the **verapamil** was stopped. Her normal bleeding time of 1 minute rose to 4.5 minutes while she was taking **verapamil**, and to 9 minutes while she was taking **verapamil** and **aspirin**. A healthy subject taking the same dose of **verapamil** and **aspirin** observed the appearance of new petechiae and her bleeding time rose from a normal 4.5 minutes to more than 15 minutes in the presence of both drugs.²³ An 85-year-old man taking enteric-coated **aspirin** 325 mg daily developed widespread and serious ecchymoses of his arms and legs and a retroperitoneal bleed about 3 weeks after starting **verapamil** 240 mg daily.²⁴

A prospective cohort study²⁵ in 1636 elderly hypertensive patients and a case-control study²⁶ found that calcium-channel blockers were associated with an increased risk of gastrointestinal bleeding compared with beta blockers; in one of the studies, **verapamil** had the highest rate of bleeding, followed by **diltiazem** and **nifedipine**.²⁵ Two studies indicated that gastrointestinal bleeding was not increased by calcium-channel blockers.^{27,28} A post-hoc analysis of the Syst-Eur data found that there was no interaction between chronic NSAID intake (81% **aspirin**) and antihypertensive therapy based on **nitrendipine** in terms of incidence of gastrointestinal

bleeding. Further, the results suggested that chronic NSAID therapy tended to be associated with a lower incidence of bleeding in patients taking **nitrendipine**-based therapy than those on placebo.⁵

Mechanism

A. Antagonism of antihypertensive effects

There is some evidence that NSAIDs may increase blood pressure in patients treated with antihypertensives. Possible explanations for this include inhibition of vasodilator and natriuretic prostaglandins in the kidney and/or a decrease in vascular or endothelial prostaglandin synthesis resulting in salt retention and vasoconstriction.²⁹ In contrast, low-dose aspirin appears not to affect the blood pressure-lowering effects of calcium-channel blocker-based antihypertensive therapy.³

B. Antiplatelet effects and gastrointestinal bleeding

The prolonged bleeding times noted with **verapamil**²³ are probably a result of inhibition of platelet aggregation, because calcium-channel blockers interfere with the movement of calcium ions through cell membranes, which can affect platelet function. This appears to be additive with the effects of other antiplatelet drugs. It was suggested that vasodilation produced by calcium-channel blockers in conjunction with inhibition of platelet aggregation may increase the risk of bleeding, or at least prevent the normal vasoconstrictive response to bleeding,²⁵ although a protective effect of beta blockers rather than an adverse effect of calcium-channel blockers may also be the reason.²⁷

Importance and management

Although several studies exist, the evidence for an interaction between the calcium-channel blockers and NSAIDs or aspirin is still somewhat inconclusive. Some consider that the use of NSAIDs should be kept to a minimum in patients on antihypertensives. The effects may be greater in the elderly and in those with blood pressures that are relatively high, as well as in those with high salt intake.³⁰ However, others consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.³¹ While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inadequate control of blood pressure, other reasons may be more likely than any effect of concurrent NSAIDs.³¹ There is insufficient data at present to clearly differentiate between NSAIDs. Further study is needed.

There is some limited evidence that the interaction of NSAIDs with calcium-channel blockers is less than with ACE inhibitors.^{4,16,18}

For the effects of NSAIDs on other antihypertensive drug classes see 'ACE inhibitors', (p.28), 'beta blockers', (p.835) and 'thiazide diuretics', (p.956).

Clinically significant interactions between NSAIDs and calcium-channel blockers that result in bleeding appear rare.

Calcium-channel blockers + Azoles

Itraconazole can markedly raise the serum levels of felodipine, which increases its adverse effects, in particular ankle and leg oedema. A few case reports suggest that isradipine and nifedipine can interact similarly with itraconazole, and that fluconazole can also interact with nifedipine. Ketoconazole can markedly raise the plasma levels of lercanidipine and nisoldipine. Caution is warranted with all calcium-channel blockers when azole antifungals, particularly itraconazole and ketoconazole, are used.

Clinical evidence

(a) Felodipine

When **itraconazole** 200 mg daily or a placebo was given to 9 healthy subjects for 4 days, followed by a single 5-mg dose of felodipine, it was found that the felodipine AUC was increased sixfold and the maximum plasma levels were increased eightfold. The effects of the felodipine on blood pressure and heart rate were also increased.¹

A 52-year-old woman taking felodipine 10 mg daily for hypertension for a year, without problems, developed ankle and leg swelling within 7 days of starting **itraconazole** 100 mg daily for tinea pedis. The oedema disappeared within 2 to 4 days of stopping the **itraconazole**.² Virtually the same reaction occurred in another woman taking both drugs. Later tests found that her AUC_{0–6} of a single 5-mg dose of felodipine was increased at least fourfold (possibly up to tenfold) while taking **itraconazole**, and ankle swelling was noted.²

(b) Isradipine

Ankle swelling was noted in a patient taking isradipine 5 mg daily when **itraconazole** 200 mg twice daily was also taken.²

(c) Lercanidipine

The manufacturer notes that an interaction study found that **ketoconazole** increased the S-lercanidipine AUC and peak plasma levels 15-fold and eightfold, respectively.³

(d) Nifedipine

A report describes massive pitting oedema in the legs and ankles of a patient taking nifedipine when **itraconazole** 100 mg twice daily was also taken.⁴ Another patient similarly had ankle oedema and markedly raised serum nifedipine levels (trough levels raised almost fivefold) while taking **itraconazole**.⁵ A patient with malignant pheochromocytoma whose persistent hypertension was controlled with nifedipine had a rise in blood pressure when **fluconazole** 200 mg daily was stopped. His blood pressure fell again when the **fluconazole** was restarted. A later study found that his maximum nifedipine plasma levels and AUC_{0–5} were raised about three-fold by **fluconazole**.⁶

(e) Nisoldipine

A study in 7 healthy subjects found that **ketoconazole** 200 mg daily for 5 days increased the AUC and peak plasma levels of a single 5-mg dose of nisoldipine by 24-fold and 11-fold, respectively. The levels of nisoldipine metabolite were similarly increased.⁷

Mechanism

Ankle swelling due to precapillary vasodilatation is a relatively common adverse effect of the dihydropyridine calcium-channel blockers, and this effect appears to be dose-related. Calcium-channel blockers are metabolised in the gut wall and liver by the cytochrome P450 CYP3A subfamily of isoenzymes, which are inhibited by itraconazole, ketoconazole and to a lesser extent by fluconazole, so that in the presence of these antifungals the levels of the calcium-channel blockers are raised and the adverse effects increased.

Importance and management

The interaction between felodipine and itraconazole would appear to be established and clinically important. It also seems that isradipine, lercanidipine, nifedipine and nisoldipine can interact similarly with fluconazole, itraconazole or ketoconazole and, because they are metabolised by CYP3A4, it is likely that other calcium-channel blockers will behave in the same way. If itraconazole, ketoconazole, or fluconazole is given to a patient on established treatment with any calcium-channel blocker be alert for the need to lower the dosage of the calcium-channel blocker. However, some manufacturers (e.g. felodipine,⁸ lercanidipine³) actually contraindicate concurrent use of itraconazole or ketoconazole, and others (e.g. nisoldipine⁹) additionally contraindicate fluconazole. In the US the guidance differs slightly and only caution is considered necessary with felodipine.¹⁰ The manufacturers of nimodipine predict that fluconazole, itraconazole and ketoconazole will substantially raise nimodipine levels. They say that concurrent use should be avoided, but, if this is not possible then the patient's blood pressure should be carefully monitored.¹¹

Calcium-channel blockers + Bile-acid binding resins

Colesevelam slightly reduces the bioavailability of verapamil and colestipol slightly reduces the bioavailability of diltiazem. These interactions are unlikely to be clinically important.

Clinical evidence, mechanism, importance and management

(a) Colesevelam

A study in 31 healthy subjects found that a single 4.5-g dose of colesevelam reduced the peak plasma levels and AUC of a single 240-mg dose of **verapamil** by about 33% and about 15%, respectively. These changes were not considered to be clinically significant.¹

(b) Colestipol

A study in 12 healthy subjects found that colestipol reduced the AUC and peak plasma levels of a single 120-mg dose of sustained-release **diltiazem** by 22% and 36%, respectively, and those of a single 120-mg dose of immediate-release **diltiazem** by 27% and 33%, respectively. In a further study sustained-release **diltiazem** 120 mg was given alone, or 1 hour before or 4 hours after multiple doses of colestipol. The AUC of **diltiazem** was decreased by 17% when it was taken 1 hour before colestipol and by 22% when taken 4 hours after colestipol. This suggests that the effects of colestipol on **diltiazem** bioavailability are not reduced by separating their administration. However, these small reductions in levels are unlikely to result in reduced **diltiazem** efficacy, but the authors advise caution if these drugs are used concurrently.²

Calcium-channel blockers + Bile acids

Chenodeoxycholic acid and ursodeoxycholic acid reduce the bioavailability of nitrendipine.

Clinical evidence, mechanism, importance and management

In a single-dose study, 6 healthy subjects were given **nitrendipine** 10 mg with or without either **chenodeoxycholic acid** 200 mg or 600 mg, or **ursodeoxycholic acid** 50 mg. **Ursodeoxycholic acid** reduced the peak plasma level and AUC of **nitrendipine** by 54% and 75%, respectively. **Chenodeoxycholic acid** 200 mg decreased the peak plasma level and AUC of **nitrendipine** by about 20%, but the 600-mg dose reduced the peak plasma level and AUC of **nitrendipine** by 54% and 68%, respectively. The reduction in bioavailability of **nitrendipine** was possibly due to the effects of the bile acids on tablet disintegration or more probably on drug solubilisation. The clinical importance of the interaction is not known.¹

1. Sasaki M, Maeda A, Sakamoto K-I, Fujimura A. Effect of bile acids on absorption of nitrendipine in healthy subjects. *Br J Clin Pharmacol* (2001) 52, 699–701.

Calcium-channel blockers + Calcium-channel blockers

Plasma levels of both nifedipine and diltiazem are increased by concurrent use and blood pressure is reduced accordingly. Verapamil is predicted to interact similarly. There are isolated reports of intestinal occlusion attributed to the concurrent use of nifedipine and diltiazem. Note that if nimodipine is used with another calcium-channel blocker, monitoring, with possible dose reduction or discontinuation of the other calcium-channel blocker is recommended.

Clinical evidence

Pretreatment of 6 healthy subjects with **diltiazem** 30 or 90 mg three times daily for 3 days was found to increase the AUC of a single 20-mg dose of **nifedipine** two- and threefold, respectively.¹ Similar and related results are reported elsewhere.² In another study it was found that **nifedipine** 10 mg three times daily for 3 days increased the maximum plasma levels of a single 60-mg dose of **diltiazem** by 54% and increased its AUC by 49%.³

A patient taking **nifedipine** 20 mg twice daily developed abdominal distension and vomiting 2 days after also being given **diltiazem** 100 mg twice daily. Both calcium-channel blockers were stopped and abdominal

X-ray suggested paralytic ileus, which resolved but then recurred when the drugs were restarted. The excessive relaxation of the intestine was attributed to elevated **nifedipine** plasma levels, which were said to be caused by **diltiazem**.⁴ Another report describes complete or partial intestinal occlusion in a patient taking **diltiazem** on three occasions, each time when **nifedipine** was added.⁵

Mechanism

A reduction in the metabolism of both the nifedipine and diltiazem in the liver seems to be the explanation for the increase in drug levels.³ An increased relaxant effect on smooth muscle is suggested for the cases of intestinal occlusion.⁵

Importance and management

Established interactions but of uncertain clinical importance. The manufacturers of nifedipine advise caution when it is used with diltiazem^{6,7} because of possible increases in nifedipine levels. They say a reduction in the dose of nifedipine should be considered.⁷ **Verapamil** is predicted to interact similarly.⁷ Information about the use of combinations of other calcium-channel blockers appears to be lacking. However, the UK manufacturers of **nimodipine**⁸ advise that if it is used with other antihypertensive drugs, including other calcium-channel blockers such as nifedipine, diltiazem, or **verapamil**, blood pressure monitoring and careful dose titration of **nimodipine** should be carried out with possible reduction or discontinuation of the other calcium-channel blocker.

Calcium-channel blockers + Calcium compounds

An isolated report describes antagonism of the antiarrhythmic effects of oral verapamil due to the use of oral calcium and calciferol. Note that intravenous calcium compounds may be used prior to intravenous verapamil where the hypotensive effects of verapamil would be detrimental.

Clinical evidence, mechanism, importance and management

An elderly woman with atrial fibrillation, successfully treated for over a year with **verapamil**, developed atrial fibrillation within a week of starting to take an oral calcium compound 1.2 g with calciferol (vitamin D) 3000 units daily for diffuse osteoporosis. Her serum calcium levels had risen from 2.45 to 2.7 mmol/L. Normal sinus rhythm was restored by giving 500 mL of saline and repeated doses of furosemide 20 mg and **verapamil** 5 mg by intravenous injection.¹

Verapamil acts by inhibiting the passage of calcium ions into cardiac muscle cells and it would appear that in this case the increased concentration of calcium ions outside the cells opposed the effects of the **verapamil**.

The general importance of this isolated case is uncertain, but bear it in mind in the event of an unexpected reduction in **verapamil** effects.

Note that intravenous calcium compounds are sometimes given prior to intravenous verapamil for the treatment of ventricular arrhythmias to prevent verapamil-induced hypotension in situations where a reduction in blood pressure could be detrimental. This use does not affect the antiarrhythmic efficacy.² Calcium, usually in the form of intravenous calcium gluconate, is used as an antidote in cases of overdose of calcium-channel blockers.

Calcium-channel blockers + Ceftriaxone and Clindamycin

An isolated report describes the development of complete heart block in a man taking verapamil, which was attributed to the use of intravenous ceftriaxone and clindamycin. The validity of this interaction has been questioned.

Clinical evidence, mechanism, importance and management

A 59-year-old man who had been taking sustained-release verapamil 240 mg twice daily for 2 years and phenytoin 300 mg daily for several years, developed complete heart block an hour after being given intravenous ceftriaxone 1 g and clindamycin 900 mg for bilateral pneumonia. He needed cardiopulmonary resuscitation and the insertion of a temporary pacemaker, but spontaneously recovered normal sinus rhythm after 16 hours. He made a full recovery. The reasons for this serious reaction are not known, but the authors of the report postulate that these two antibacterials precipitated acute verapamil toxicity, possibly by displacing it from its plasma protein binding sites. Although both antibacterials are highly protein-bound (93% or more),¹ they are acidic and do not bind to the same sites as the verapamil (a base), so that this mechanism of interaction seems very unlikely. This seems to be the first and only report of this reaction, and the suggestion by the authors that it was due to a drug interaction has been seriously questioned.² There seems to be no other evidence that either of these antibacterials interact with verapamil, either given orally or intravenously.

2. Horn JR, Hansten PD. Comment: pitfalls in reporting drug interactions. *Ann Pharmacother* (1993) 27, 1545–6.

Calcium-channel blockers + Chlorpromazine

A patient taking chlorpromazine who was given nifedipine [dose not stated] for 2 days before surgery, developed marked hypotension during surgery, which was eventually controlled with noradrenaline (norepinephrine).¹ Other phenothiazines and calcium-channel blockers may interact similarly, see 'Antihypertensives + Other drugs that affect blood pressure', p.880.

1. Stuart-Taylor ME, Crosse MM. A plea for noradrenaline. *Anaesthesia* (1989) 44, 916–7.

Calcium-channel blockers + Clonidine

Two hypertensive patients taking verapamil developed complete heart block when clonidine was added. The hypotensive effects of nifedipine and clonidine were additive in hypertensive patients. Transdermal clonidine has been successfully used with nifedipine or diltiazem in small studies.

Clinical evidence

(a) Diltiazem

In a clinical trial, transdermal clonidine decreased blood pressure in 58 of 60 patients with hypertension inadequately controlled by sustained-release diltiazem 90 mg twice daily. The addition of clonidine did not cause a significant decrease in heart rate.¹

(b) Nifedipine

Sustained-release clonidine 250 micrograms daily for 2 weeks increased the hypotensive effects of nifedipine 20 mg twice daily by about 5 mmHg (mean blood pressure reduction) in 12 patients. Clonidine did not alter the slight heart rate increase seen with nifedipine.² In a clinical trial in 39 patients with hypertension inadequately controlled by nifedipine GITS 30 to 60 mg daily, transdermal clonidine successfully decreased blood pressure in all 35 patients who completed a one-week titration phase then an 8-week maintenance phase.³

(c) Verapamil

A 54-year-old woman with refractory hypertension (240/140 mmHg) and hyperaldosteronism, took verapamil 160 mg three times daily and spironolactone 100 mg daily for 10 days, and had a reduction in her blood pressure to 180/100 mmHg. She was additionally given clonidine 150 micrograms twice daily, and after the second dose she became confused and her blood pressure was found to have fallen to 90/70 mmHg, with a heart rate of 50 bpm. She had developed complete AV block, which resolved when all the drugs were stopped. A 65-year-old woman with persistent hypertension did not have a satisfactory reduction in blood pressure with extended-release verapamil 240 mg daily (blood pressure 165/100 mmHg). Clonidine 150 micrograms twice daily was then added, and the next day a routine ECG showed that she had a nodal rhythm of 80 bpm, which developed into complete AV block. Her blood pressure had fallen to 130/80 mmHg.⁴

Mechanism

Not fully understood. Verapamil very occasionally causes AV node disturbances, but both of these patients had normal sinus rhythm before the clonidine was added. Clonidine alone has been associated with AV node dysfunction in hypertensive patients. It would seem therefore that these effects were additive in these two patients.⁴

Importance and management

Information about the interaction between verapamil and clonidine seems to be limited to this report.⁴ Its authors say that a review of the literature from 1966 to 1992 revealed no reports of any adverse interactions between these drugs. Nonetheless, they suggest that it would now be prudent to give these two drugs together with caution and good monitoring in any patient, even in those without sinus or AV node dysfunction. There was no adverse effect on heart rate in one trial in patients taking diltiazem and using transdermal clonidine. There seems to be no particular need for additional caution when nifedipine is given with clonidine.

4. Jaffe R, Livshits T, Bursztyn M. Adverse interaction between clonidine and verapamil. *Ann Pharmacother* (1994) 28, 881–3.

Calcium-channel blockers + Co-trimoxazole

Adverse effects (leg cramps, facial flushing) have been reported in one patient taking nifedipine when co-trimoxazole was also taken. One study found that co-trimoxazole had no effect on the pharmacokinetics and hypotensive action of a single dose of nifedipine.

Clinical evidence, mechanism, importance and management

The observation of a patient taking nifedipine who developed leg cramps and facial flushing (possibly as a result of raised plasma nifedipine levels) when given co-trimoxazole, prompted further study of this possible interaction in 9 healthy subjects. After taking co-trimoxazole 960 mg twice daily for 3 days the pharmacokinetics and hypotensive effects of a single 20-mg dose of nifedipine were found to be unchanged.¹ No special precautions would therefore normally seem to be necessary on concurrent use.

1. Edwards C, Monkman S, Cholerton S, Rawlins MD, Idle JR, Ferner RE. Lack of effect of co-trimoxazole on the pharmacokinetics and pharmacodynamics of nifedipine. *Br J Clin Pharmacol* (1990) 30, 889–91.

Calcium-channel blockers + Dantrolene

An isolated report describes acute hyperkalaemia and cardiovascular collapse when dantrolene was given to a patient taking verapamil, but not when he was subsequently given nifedipine. Animal studies have found similar effects with the combination of dantrolene and verapamil or diltiazem, but not with nifedipine or amlodipine.

Clinical evidence, mechanism, importance and management

A case report describes a 60-year-old man with insulin-dependent diabetes undergoing a right hemicolectomy. Due to inoperable coronary artery disease, which was causing angina pain he was taking **verapamil** 80 mg three times daily. On the morning of surgery he was given **verapamil** 80 mg with his pre-operative sedation and then, 2 hours later at the start of surgery, he was given intravenous dantrolene 220 mg over 30 minutes, because he was known to have previously had malignant hypertension. After surgery, when he was on ITU, it was found that his potassium had risen from 4.6 mmol/L before surgery to 6.1 mmol/L at the end of surgery (about 90 minutes after the dantrolene infusion). He was given 10 units of insulin, but an hour later his potassium was 7.1 mmol/L. He was given more insulin, but then developed metabolic acidosis and some cardiac depression, which resolved when he was given bicarbonate and hetastarch 5%. He received three further doses of dantrolene without incident.¹

The authors of the report attributed the effects seen to an interaction between **verapamil** and dantrolene. They note that hyperkalaemia has been seen following dantrolene infusions, but the case they cite was in response to suxamethonium, and the UK and US manufacturers of dantrolene do not include hyperkalaemia as an adverse effect.^{2,3} Nevertheless, the overall picture is that hyperkalaemia, of whatever cause, can apparently increase the myocardial depression caused by **verapamil**.^{4,5} This case seems to be the only report of an interaction between **verapamil**, and several factors do not make this a clear-cut case of an interaction. However, hyperkalaemia and cardiovascular collapse have been seen in *pigs* and *dogs* given dantrolene and **verapamil**,⁶⁻⁸ and so an interaction cannot be completely ruled out. The manufacturers of dantrolene contraindicate its use in patients taking **verapamil**.^{2,3} One animal study suggests that **diltiazem** may interact similarly,⁹ and the combination of **diltiazem** and dantrolene may also cause ventricular arrhythmias.¹⁰ The manufacturers of **diltiazem** similarly contraindicate concurrent use.¹⁰ Studies suggest that **amlodipine**⁴ and **nifedipine**⁹ do not interact and they may therefore be safer alternatives. In the case above¹ the patient later underwent further surgery while taking **nifedipine**, without any significant adverse effect (although the potassium was moderately raised to 5.4 mmol/L).

Calcium-channel blockers + Diuretics

No pharmacokinetic interaction appears to occur between **hydrochlorothiazide** and **diltiazem** or **isradipine**. Similarly, **hydrochlorothiazide** and **triamterene** did not alter **nifedipine** pharmacokinetics, and **spironolactone** does not alter **felodipine** pharmacokinetics. Combinations of diuretics and calcium-channel blockers are used clinically for their additive antihypertensive effects.

Clinical evidence, mechanism, importance and management

(a) Diltiazem

A study in 21 healthy subjects given **diltiazem** 60 mg 4 times daily (for 21 doses) and **hydrochlorothiazide** 25 mg twice daily (for 11 doses) either alone or in combination found that at steady-state there was no clinically significant pharmacokinetic interaction between the two drugs.¹

(b) Dihydropyridine-type calcium-channel blockers

The pharmacokinetics of **isradipine** and **hydrochlorothiazide** are not affected by concurrent use,² and the pharmacokinetics of **nifedipine** are not affected by either **hydrochlorothiazide** or **triamterene**.³ **Spironolactone** 50 mg was found not to affect either the pharmacokinetics or the clinical effects of **felodipine**.⁴

The manufacturers say that **amlodipine** has been safely given with **thiazide diuretics** and no dosage adjustment of **amlodipine** is required.⁵

Additive antihypertensive effects are expected when diuretics such as **hydrochlorothiazide** are used in combination with calcium-channel blockers, and such combinations are used clinically.

Calcium-channel blockers + Fluoxetine

Two patients taking **verapamil** and two taking **nifedipine** developed increased adverse effects (oedema, headaches, nausea, flushing, orthostatic hypotension) due to the concurrent use of **fluoxetine**. **Fluoxetine** appears to increase **nimodipine** levels, whereas **nimodipine** may decrease **fluoxetine** levels. **Fluoxetine** does not appear to alter **lercanidipine** pharmacokinetics.

Clinical evidence

(a) Lercanidipine

The manufacturer notes that a study in elderly subjects found that **fluoxetine** had no clinically relevant effects on the pharmacokinetics of **lercanidipine**. No other details were given.¹

(b) Nifedipine

A patient taking **nifedipine** 60 mg daily developed nausea and flushing after also starting to take **fluoxetine** 20 mg every other day. The adverse effects gradually disappeared over the next 2 to 3 weeks when the **nifedipine** dosage was halved.² An 80-year-old woman taking **nifedipine** developed tachycardia, hypotension and profound weakness 10 days after starting **fluoxetine** 20 mg daily. On admission to hospital 8 days later she was unable to stand, her standing blood pressure was 90/50 mmHg and her heart rate was 120 bpm. She fully recovered within a week of stopping the **fluoxetine**.³

(c) Nimodipine

The manufacturer notes that, in elderly patients, **nimodipine** 30 mg twice daily given with **fluoxetine** 20 mg daily resulted in an increase in plasma levels of **nimodipine**, a reduction in plasma levels of **fluoxetine**, and a trend towards increased levels of the metabolite **norfluoxetine**,⁴ but no specific values were given.

(d) Verapamil

A woman taking **verapamil** 240 mg daily developed oedema of the feet and ankles, and neck vein distension within 6 weeks of starting **fluoxetine** 20 mg every other day. The oedema resolved within 2 to 3 weeks of reducing the **verapamil** dosage to 120 mg daily.² Another patient taking **verapamil** 240 mg daily for the prophylaxis of migraine developed morning headaches (believed by the patient not to be migraine) about one week after increasing his **fluoxetine** dosage from 20 to 40 mg daily. The headaches stopped when the **verapamil** dosage was reduced and then stopped.²

Mechanism

The calcium-channel blockers are metabolised by the cytochrome P450 isoenzyme CYP3A4, which can be inhibited by **fluoxetine**. This results in a marked reduction in the metabolism and clearance of the calcium-channel blockers. The reactions reported appear to be the exaggeration of the adverse effects of these calcium-channel blockers, possibly due to an increase in their levels.

Importance and management

Although a pharmacokinetic interaction might be predicted, information on an important clinical interaction appears to be limited to these reports.^{2,3} This suggests that the incidence is very rare. Bear the possibility of a pharmacokinetic interaction in mind if a patient shows an exaggerated response to a calcium-channel blocker after starting fluoxetine, being alert for the need to reduce the drug dosages. The clinical significance of the interaction between nimodipine and fluoxetine is not known.⁴ Information about other calcium-channel blockers with fluoxetine or other SSRIs appears to be lacking.

Calcium-channel blockers + Food

Some modified-release preparations of felodipine, nifedipine, and nisoldipine show markedly increased levels when given with food, particularly when high in fat. The bioavailability of lercanidipine is markedly increased by food, and it should therefore be given on an empty stomach. Manidipine should be given with food, as this improves its absorption. Food modestly decreases the rate and extent of absorption of nimodipine capsules. Food had no effect on the absorption of amlodipine, bepridil, diltiazem, isradipine, or verapamil in the studies cited.

Clinical evidence

(a) Amlodipine

There was no difference in rate or extent of absorption of amlodipine capsules between the fed and fasted state in a study in healthy subjects.¹

(b) Diltiazem

The rate and extent of absorption of both a slow-release and a conventional tablet of diltiazem were unaffected by food in healthy subjects.² Similarly, the pharmacokinetic parameters of another sustained-release formulation of diltiazem (*Mono-Tildiem LP*) showed only minor changes when given with food in a study in healthy subjects.³

(c) Felodipine

The manufacturer of one prolonged-release tablet of felodipine (*Vascalpha*) notes that taking it with a high-fat meal markedly increased the maximum level (2 to 2.5-fold) without altering the extent of absorption.⁴

(d) Isradipine

The pharmacokinetic parameters of isradipine differed by less than 20% when modified-release and nonretard formulations of isradipine were given with a light meal compared with the fasted state.⁵

(e) Lercanidipine

The manufacturer notes that the oral bioavailability of lercanidipine is increased up to fourfold when it is taken up to 2 hours after a high-fat meal.⁶

(f) Manidipine

The bioavailability of single 20-mg doses of manidipine was increased by 42% when given to 12 healthy subjects after a standard breakfast rather than in the fasting state. Peak plasma levels were increased by about 25% by food (not significant), and the rate of absorption was unaffected.⁷

(g) Nifedipine

Some single-dose studies suggested that food might delay the absorption of nifedipine⁸ and reduce its peak levels,^{9,10} but a multiple dose study found that food did not have an important effect on the steady-state levels of nifedipine in a 'biphasic' formulation.¹¹ A further single-dose study in healthy subjects found that the bioavailability of two modified-release preparations of nifedipine (*Adalat OROS* or *Nifedipine*) were not significantly different when they were given in the fasting state, although the maximum plasma levels were 31 and 53 micrograms/L respectively. The bioavailability and maximum plasma level (38 micrograms/L) of *Adalat OROS* were similar after a high-fat breakfast to those in the fasting state. However, the maximum plasma level of *Nifedipine* increased 2.4-fold to

128 micrograms/L after a high-fat breakfast. Although the bioavailability of *Nifedipine* was only modestly increased by food, the increase in plasma levels indicates a loss of modified-release characteristics and suggests that the effect of food on nifedipine may depend on the product formulation.¹² The manufacturer of another modified-release preparation of nifedipine (*Adalat CC*) also notes that administration immediately after a high-fat meal increased the peak plasma level by 60% without altering the AUC.¹³

(h) Nimodipine

The US manufacturer notes that taking nimodipine capsules after a standard breakfast reduced the AUC by 38% and the peak level by 68% when compared with the fasted state in healthy subjects.¹⁴

(i) Nisoldipine

The manufacturer of an extended-release nisoldipine preparation (*Sular*) notes that food with a high fat content markedly increases the maximum plasma level (by up to 300%), but decreases total exposure by 25%. They note that this appears to be specific to the controlled-release preparation, as food had a lesser effect on the immediate-release tablet.¹⁵ A similar food interaction has been noted with *Syscor MR*, another extended-release nisoldipine preparation.¹⁶

(j) Verapamil

The absorption of verapamil from a multiparticulate sustained-release preparation was not affected when it was given with food.¹⁷

Mechanism

The increase in bioavailability of manidipine in the presence of food may be because it is lipophilic and solubilised by food and bile secretions. Other lipophilic dihydropyridine calcium-channel blockers include felodipine and nisoldipine.⁷ Food may alter the release characteristics of modified-release preparations of drugs, increasing the rate of absorption of the drug, and thereby potentially increasing effects.

Importance and management

Some modified-release preparations of felodipine, nifedipine and nisoldipine have shown markedly increased peak levels when given with meals, particularly if they are high in fat content. Because of this increase, the manufacturers of *Vascalpha* (felodipine),⁴ *Adalat CC* (nifedipine)¹³ and *Sular* or *Syscor MR* (nisoldipine)^{15,16} recommend that they are given on an empty stomach^{4,13} before breakfast,¹⁶ or with a light meal,⁴ avoiding high fat meals.^{4,15} Note that these precautions do not apply to all preparations of these calcium-channel blockers (e.g. *Plendil* (felodipine) can be taken irrespective of meals), so the manufacturers literature needs to be consulted. Food markedly increases the extent of absorption of lercanidipine, and this should therefore be taken at least 15 minutes before food.⁶ Because food modestly increases the extent of absorption of manidipine, it has been recommended that manidipine should be given with food.⁷

In contrast, food modestly decreases the rate and extent of absorption of nimodipine capsules, and the US manufacturer says they should preferably be taken not less than one hour before, or two hours after, a meal.¹⁴ Food also modestly decreases the peak level of nifedipine, but the clinical relevance of this is uncertain.

Food had no effect on the absorption of amlodipine, diltiazem, isradipine, or verapamil from the preparations studied (see *Clinical evidence*, above).

Calcium-channel blockers + Grapefruit juice

Grapefruit juice very markedly increases the bioavailability of felodipine and nisoldipine and alters their haemodynamic effects. The bioavailability of nifedipine, nimodipine or nitrendipine is increased without significantly altering haemodynamic effects, whereas the bioavailability of amlodipine, diltiazem and verapamil is only minimally affected. An isolated report describes peripheral oedema and weight gain in a black man taking nifedipine when also drinking grapefruit juice.

Clinical evidence

(a) Dihydropyridine calcium-channel blockers

1. *Grapefruit juice.* Drinking 200 to 250 mL of grapefruit juice can increase the bioavailability of **felodipine** two to threefold in healthy subjects and patients with hypertension.^{1–11} Its effects are proportionately increased. One study found that diastolic pressures were reduced by 20% (11% with water) and heart rates increased by 22% (9% with water) when blood **felodipine** levels were at their highest after a drink of grapefruit juice.¹ Adverse effects such as headaches, facial flushing and lightheadedness were also increased.¹ The interaction develops after taking the first glass of grapefruit juice and persists for about 24 hours.^{7,12} The bioavailabilities of **nifedipine**,¹³ **nifedipine**,^{1,14–17} **nimodipine**^{18,19} and **nitrendipine**²⁰ have also been found to be increased, even about doubled in some instances, but usually only minor changes in haemodynamic effects (blood pressure and heart rate) were reported in healthy subjects.^{17,19–21} However, the effect may be more pronounced in some hypertensive patients.¹⁷ An isolated report describes a 54-year-old black African man taking **nifedipine** retard 60 mg daily, lisinopril 5 mg daily and aspirin 75 mg who presented with peripheral oedema, weight gain, and apparently improved blood pressure control of about 6 months' duration. Over this time he had been drinking about 400 mL of freshly squeezed grapefruit juice every morning as part of a diet regimen. He was advised to stop drinking grapefruit juice, and 2 weeks later the oedema had disappeared, he had lost 2 kg in weight, and his blood pressure was slightly higher (140/85 mmHg) than when he presented (130/80 mmHg).²² One study in 8 healthy subjects found that when **nisoldipine** was given with grapefruit juice it produced significantly larger decreases in blood pressure for 8 hours compared to **nisoldipine** alone. The effect of grapefruit juice decreased with time but lasted for at least 3 days.²³ However, in a further study in healthy subjects, grapefruit juice increased the maximum **nisoldipine** plasma levels fivefold, but only minor effects on blood pressure and heart rate were found.²¹

Other studies found that the bioavailability of **amlodipine** was at most only slightly increased by grapefruit juice.^{24–26}

2. *Whole Grapefruit.* Some studies have found that grapefruit pulp, segments, or extract may increase the AUCs of **nifedipine**, **nisoldipine** and **felodipine** by 1.3-fold, 1.3-fold and threefold respectively.^{27,28}

(b) Diltiazem

In one study grapefruit juice had no significant effect on the bioavailability of diltiazem,²⁹ and in another it increased the AUC of diltiazem by about 20% but differences in blood pressure and heart rate were not significant.³⁰

(c) Verapamil

A study in 10 hypertensive patients found that a single drink of grapefruit juice had no significant effects on the pharmacokinetics of verapamil.³¹ However, studies in healthy subjects^{32,33} found that grapefruit juice given

2 to 4 times daily for 3 to 5 days increased the AUC of verapamil by about 40%. Pharmacodynamic parameters (blood pressure heart rate and PR interval) were not significantly altered by grapefruit juice in one study,³² but prolongation of PR intervals occurred in the other³³ and were of borderline significance, with increases to above 350 milliseconds in 2 subjects (maximal PR intervals of 200 to 260 milliseconds were usually observed).

Mechanism

Uncertain. It has been suggested that the increases in bioavailability are due to components of the fruit juice including flavonoids such as naringin,^{1,5,21} (but not quercetin¹⁴), sesquiterpenoids,³⁴ or furanocoumarins including bergamottin (also found in Seville oranges and lime juice) and 6',7'-dihydroxybergamottin.^{9,23,35,36} These components inhibit the activity of the cytochrome P450 isoenzymes CYP3A subfamily in the intestinal wall so that the first-pass metabolism of these calcium-channel blockers is reduced, thereby increasing their bioavailability and therefore their effects. Grapefruit juice has little effect on hepatic CYP3A4 and this is borne out by the fact that it interacts with oral but not intravenous preparations. See also 'Grapefruit juice', (p.11).

Therefore, the sensitivity of the interaction with grapefruit juice may be related to the oral bioavailability of the calcium-channel blocker.³⁰ Thus, amlodipine and diltiazem with high bioavailability are least affected, nifedipine is intermediate, and felodipine,³⁰ which has a lower bioavailability, is most sensitive to the activity of grapefruit juice. The exception is verapamil, which has low bioavailability and appears to be only slightly affected by grapefruit juice, but this is possibly because cytochrome P450 isoenzymes other than CYP3A4 are involved in its metabolism.³⁰ In the reported case, it was suggested that black Africans may be more susceptible to any interaction, as they already show reduced systemic clearance of nifedipine when compared with caucasians.²²

Furanocoumarins and possibly other components of grapefruit juice may also increase the levels of calcium-channel blockers by inhibition of intestinal P-glycoprotein efflux transport.^{9,23,30}

Importance and management

These are established interactions and the manufacturers of felodipine^{37,38} say that it should not be taken with grapefruit juice. It has been suggested that **whole grapefruit** or products made from **grapefruit peel** such as marmalade should also be avoided in patients on felodipine.²⁸ The manufacturers of **lercandipine**,³⁹ and verapamil^{40,41} also contraindicate grapefruit juice, although this interaction is normally of little clinical relevance in the majority of patients. The manufacturers of nifedipine,^{42,43} and nisoldipine⁴⁴ say that grapefruit juice should not be taken concurrently, whereas the manufacturers of nimodipine⁴⁵ advise against concurrent use. It is noteworthy that only one probable case report of the interaction appears to have been published. Generally speaking the concurrent use of grapefruit juice and most calcium channel-blockers other than felodipine, and possibly nisoldipine or verapamil, need not be avoided. However, it would be worth checking the diet of any patient who complains of increased adverse effects with any of the calcium-channel blockers that are known to interact with grapefruit juice. Any problems can be solved either by avoiding grapefruit juice, or possibly by swapping the calcium-channel blocker for a non-interacting one (amlodipine appears not to interact).

Calcium-channel blockers + H₂-receptor antagonists

The plasma levels of diltiazem, isradipine and nifedipine are increased by cimetidine and it may possibly be necessary to reduce the dosages of these calcium-channel blockers. High doses of cimetidine may increase the bioavailability of lercanidipine. Although studies suggest no important interactions occur between nicardipine or nisoldipine and cimetidine, the manufacturers advise caution. Plasma felodipine, lacidipine, nimodipine, and

nitrendipine levels are also increased by cimetidine, but this seems to be clinically unimportant. Cimetidine does not interact with amlodipine. It is uncertain whether cimetidine interacts significantly with verapamil. Ranitidine appears to interact only minimally with calcium-channel blockers, if at all. Famotidine does not interact pharmacokinetically with nifedipine.

Clinical evidence

(a) Amlodipine

A crossover study in 12 healthy subjects found that **cimetidine** 400 mg twice daily for 14 days had no effect on the pharmacokinetics of amlodipine 10 mg.¹

(b) Diltiazem

Cimetidine 300 mg before meals and at bedtime for a week increased the AUC of a single 60-mg oral dose of diltiazem by 50% in 6 healthy subjects and increased peak plasma levels by 57%. **Ranitidine** 150 mg twice daily for a week increased the AUC of diltiazem by 15%, but this was not statistically significant.² Increases in the serum levels and AUC of diltiazem of 40% and 25 to 50%, respectively, were seen in another study using **cimetidine**.³

(c) Felodipine

Cimetidine 1 g daily increased the AUC of felodipine 10 mg by 56%, and raised the peak serum level by 54% in 12 subjects. There was a short lasting effect on their heart rates but the clinical effects were minimal.⁴

(d) Isradipine

The manufacturer of isradipine⁵ notes that **cimetidine** increases the bioavailability of isradipine by about 50%.

(e) Lacidipine

A single 800-mg dose of **cimetidine** increased the maximum plasma level of a single 4-mg dose of lacidipine by 59% and increased the AUC by 74% in one study in healthy subjects. Pulse rates and blood pressures were unaffected.⁶

(f) Lercanidipine

Cimetidine 800 mg daily causes no significant alteration in plasma levels of lercanidipine but the manufacturer says that the bioavailability of lercanidipine and its hypotensive effects may be increased by higher doses of **cimetidine**.⁷

(g) Nicardipine

No adverse interaction was seen in 22 patients given calcium-channel blockers, including nicardipine, with oral **famotidine** for 6 to 8 weeks.⁸ No changes in the pharmacokinetics or pharmacodynamics of a 12-hour intravenous infusion of nicardipine 24 mg were seen in 12 healthy subjects given intravenous **cimetidine** 300 mg every 6 hours for 48 hours.⁹

(h) Nifedipine

Cimetidine 1 g daily for a week increased the AUC of nifedipine 40 mg daily by about 60% and increased the maximum plasma levels by about 90%. **Ranitidine** 150 mg twice daily for a week caused an insignificant rise of about 25% in maximum nifedipine plasma levels and AUC.¹⁰ Seven hypertensive patients had a fall in mean blood pressure from 127 to 109 mmHg after taking nifedipine 40 mg daily for 4 weeks, and a further fall to 95 mmHg after they also took **cimetidine** 1 g daily for 3 weeks. When they took **ranitidine** 300 mg instead of cimetidine, there was an insignificant fall in blood pressure.^{10,11}

Other studies clearly confirm that **cimetidine** causes a very significant rise in plasma nifedipine levels and an increase in its effects, whereas **ranitidine** interacts only minimally.^{12–18}

A study found no pharmacokinetic interaction between nifedipine and **famotidine**, but the **famotidine** reversed the effects of nifedipine on systolic time intervals and significantly reduced the stroke volume and cardiac output.^{19,20} No adverse interaction was seen in 22 patients given calcium-channel blockers, including nifedipine, with **famotidine** for 6 to 8 weeks.⁸

(i) Nimodipine

Cimetidine 1 g daily for 7 days increased the bioavailability of nimodipine 30 mg three times daily in 8 healthy subjects by 75%, but the haemodynamic effects were unchanged. **Ranitidine** did not interact.²¹

(j) Nisoldipine

A study in 8 healthy subjects found that taking **cimetidine** 1 g in divided doses on the day before the study and then three 200 mg doses every 4 hours on the study day, increased the bioavailability of a single 10-mg dose of nisoldipine by about 50%, but the haemodynamic effects of the nisoldipine were unaltered.²² **Ranitidine** does not interact with nisoldipine.²³

(k) Nitrendipine

Cimetidine 800 mg given before, and 400 mg in divided doses given after, a single 20-mg dose of nitrendipine was found to increase its bioavailability by 154% but the haemodynamic effects were unchanged.²⁴ Another study found that **ranitidine** increased the AUC of oral nitrendipine 20 mg daily for 1 week by about 50% and decreased its clearance, but there were no changes in the haemodynamic measurements (systolic time intervals, impedance cardiography).^{25,26} A further study found that **ranitidine** increases the AUC of nitrendipine by 89%, but this does not appear to be clinically significant.²⁷

(l) Verapamil

A study in 8 healthy subjects found that **cimetidine** 300 mg every 6 hours for 8 days did not affect the pharmacokinetics of a single 10-mg intravenous dose of verapamil, but the bioavailability of a 120-mg oral dose of verapamil was increased from 26 to 49%. A small insignificant change in clearance occurred but no change in AUC. The changes in the PR interval caused by the verapamil were unaltered in the presence of **cimetidine**.²⁸

Another study found that **cimetidine** 300 mg four times daily for 5 days reduced the clearance of a single intravenous dose of verapamil by 21% and increased its elimination half-life by 50%.²⁹ **Cimetidine** 400 mg twice daily for a week increased the bioavailability of verapamil from 35 to 42% and its clearance was reduced by almost 30% in another study.³⁰ A further study found a small increase in the bioavailability of both enantiomers of verapamil.³¹ In contrast, other studies have found that the pharmacokinetics of verapamil were unaffected by **cimetidine**.^{32,33}

Mechanism

It is believed that cimetidine increases nifedipine levels by inhibiting its oxidative metabolism by the liver. Like ranitidine, it may also increase the bioavailability of nifedipine by lowering gastric acidity.¹⁴ The mechanisms of the other interactions are probably similar.

Importance and management

The interactions of cimetidine with diltiazem and nifedipine are established. Concurrent use need not be avoided but the increase in the calcium-channel blocker effects should be taken into account. It has been suggested that the dosage of diltiazem should be reduced by 30 to 50%^{34,35} and that of nifedipine by 40 to 50%.^{34,35} The interaction between verapamil and cimetidine is not well established, but monitor the effects until more is known. It has been suggested that the verapamil dose may need to be reduced by 50%.³⁵ Monitoring is advised if isradipine is given with cimetidine and a reduction in isradipine dose may be required.⁵

Similarly, high doses of cimetidine may increase the hypotensive effects of lercanidipine and caution is advised.⁷ The evidence available suggests that, although cimetidine increases the serum levels of felodipine, lacidipine, nimodipine, and nitrendipine, the haemodynamic changes are unimportant. However, this needs confirmation. The manufacturer of nisoldipine warns that the antihypertensive effect may be potentiated by cimetidine,²³ but the study available suggests that this is not significant. Although some studies indicate no interaction between nicardipine and cimetidine, the manufacturer notes that cimetidine increases nicardipine plasma levels and monitoring is recommended.³⁶ Amlodipine and cimetidine do not interact.

Ranitidine does not interact significantly with diltiazem, nimodipine, nisoldipine or nifedipine, and is possibly a non-interacting alternative for cimetidine with other calcium-channel blockers. Note that the nitrendipine AUC was increased by 50% and 89% by ranitidine, although this was not considered clinically relevant.

Famotidine does not have a pharmacokinetic interaction with nifedipine.

Calcium-channel blockers + Macrolides

Erythromycin markedly increases the bioavailability of felodipine. Isolated reports describe increased felodipine, nifedipine or verapamil effects and toxicity in patients also given erythromycin. There are also a few reports of verapamil toxicity with clarithromycin, and one with telithromycin.

A prolonged QT interval in one patient may have been due to increased levels of erythromycin in the presence of verapamil. A retrospective analysis revealed 3 cases of sudden cardiac death in patients taking erythromycin with diltiazem or verapamil, which represented about a fivefold increase in risk. No increased risk was seen with nifedipine and erythromycin.

Clinical evidence

(a) Diltiazem

A patient who had marked hypotension and bradycardia when **erythromycin** was added to verapamil and propranolol (see under verapamil, below) had previously taken **erythromycin** with diltiazem and a beta blocker without any reported adverse effects.¹

In a retrospective cohort study, there was one sudden cardiac death in 106 person-years among patients taking diltiazem with **erythromycin**. When combined with the two deaths with concurrent verapamil and **erythromycin**, this represented about a fivefold increase in risk of sudden death when compared with those who used neither CYP3A4 inhibitors (defined as ketoconazole, itraconazole, fluconazole, diltiazem, verapamil or troleandomycin) nor **erythromycin**.²

(b) Felodipine

Twelve healthy subjects were given felodipine 10 mg before and after taking **erythromycin** 250 mg four times daily for a day.³ The felodipine AUC was increased almost threefold by the **erythromycin**, the maximum plasma levels were more than doubled and the half-life prolonged from 6.9 to 11.1 hours.³

A hypertensive woman taking felodipine 10 mg daily developed tachycardia, flushing and massive ankle oedema within 2 to 3 days of starting to take **erythromycin** 250 mg twice daily. Her blood pressure had fallen from 120/90 to 110/70 mmHg. She fully recovered within a few days of stopping the **erythromycin**.⁴

(c) Nifedipine

1. *Clarithromycin*. A 77-year-old man taking sustained-release nifedipine 60 mg twice daily, captopril and doxazosin, and with slight renal impairment, had persistent systolic hypertension (170 to 180 mmHg). Two days after starting clarithromycin 500 mg twice daily for breathing difficulty and cough, his blood pressure was 140/70 mmHg at a routine appointment, and the doxazosin dose was halved and valsartan substituted for captopril. Later that day, he was admitted with hypotension (80/40 mmHg) and bradycardia (40 bpm). Clarithromycin was replaced with erythromycin and the antihypertensives stopped. After 3 days his blood pressure was stabilised with nifedipine 60 mg daily and furosemide, and the clarithromycin was restarted. Septic shock was ruled out as a cause of the hypotension.⁵

2. *Erythromycin*. In a retrospective cohort study, there were no sudden deaths from cardiac causes in 114 person-years of the use of oral erythromycin with calcium-channel blockers that do not inhibit CYP3A4 to a clinically relevant extent (stated as nearly all nifedipine).² This was in contrast to the increased risk of sudden death with erythromycin and diltiazem (see above) or verapamil (see below).

(d) Verapamil

1. *Clarithromycin*. A 53-year-old woman on haemodialysis 3 times a week, and a range of medicines including digoxin, was given clarithromycin 250 mg and verapamil 120 mg both twice daily because of an acute exacerbation of chronic obstructive pulmonary disease and a recurrence of atrial fibrillation. After 24 hours she experienced dizziness and episodes of fainting. A day later her supine blood pressure was 89/39 mmHg and her pulse rate 50 bpm. Verapamil was stopped and she recovered within 2 days, after which verapamil was re-started at a dose of 40 mg before each dialysis session.⁶ Another report¹ describes a 77-year-old woman with hypertension, taking propranolol and verapamil, who developed marked bradycardia (37 to 50 bpm), within 4 days of starting a course of clarithromycin 500 mg twice daily. The problem was solved by temporarily reducing the dose of the verapamil from 80 mg to 40 mg twice daily and the propranolol to a half until the clarithromycin course was over. Essentially the same thing happened 2 years later while taking the same drugs when erythromycin was added (see below).

2. *Erythromycin*. A 79-year-old woman taking verapamil 240 mg twice daily and ramipril was admitted to hospital with extreme fatigue and dizziness one week after starting a course of erythromycin 2 g daily for a respiratory-tract infection. Her blood pressure was 80/60 mmHg and her respiratory rate was 18 breaths per minute. ECG showed complete AV block, escape rhythm of 50 bpm, pattern of left bundle-branch block and QTc interval prolongation (583 milliseconds compared with 436 milliseconds 20 days before admission). Verapamil and erythromycin were stopped and intravenous fluids, dopamine and calcium were given. Her blood pressure increased to 110/70 mmHg and after 4 days the QTc interval prolongation had resolved and her heart rate was 76 bpm.⁷ Another

patient taking verapamil and propranolol developed marked bradycardia and hypotension 2 days after starting to take erythromycin 333 mg three times daily.¹ Two years previously she had experienced a similar interaction with clarithromycin and verapamil, but not with erythromycin and diltiazem (see above).

In a retrospective cohort study, there were two sudden cardiac deaths in 78 person-years among patients taking verapamil with erythromycin. When combined with the one death with current diltiazem and erythromycin, this represented about a fivefold increase in risk of sudden death when compared with those who used neither CYP3A4 inhibitors (defined as ketoconazole, itraconazole, fluconazole, diltiazem, verapamil or troleandomycin) nor erythromycin.²

3. *Telithromycin*. A 76-year-old woman taking verapamil 180 mg daily experienced shortness of breath and weakness 2 days after starting telithromycin 800 mg daily for a sinus infection. She was found to have marked hypotension (systolic BP 50 to 60 mmHg) and bradycardia (30 bpm). She required a transvenous pacemaker for 3 days and pressor drugs.⁸

Mechanism

Calcium-channel blockers are metabolised in the gut wall and liver by the cytochrome P450 CYP3A subfamily of isoenzymes, which are inhibited by erythromycin, clarithromycin, and telithromycin, so that in their presence a normal oral dose becomes in effect an overdose with its attendant adverse effects.^{1,3,4,8} Verapamil, erythromycin⁷ and possibly clarithromycin are also P-glycoprotein inhibitors, which may contribute to the pharmacokinetic interaction by reducing the elimination of the calcium-channel blocker,⁶ or by increasing macrolide absorption.⁷

Erythromycin has been associated with prolongation of the QT interval; an effect that is likely to be increased by drugs that increase erythromycin levels such as diltiazem and verapamil.²

Importance and management

Information seems to be limited but the interaction would appear to be established and clinically important, although its incidence is probably low. Anticipate the need to reduce the felodipine or verapamil dosage if erythromycin or clarithromycin, or possibly also telithromycin, is added. Nifedipine may also interact. Other reports suggests that the cardiac toxicity of erythromycin may be increased by verapamil,^{2,7} and diltiazem,² and the authors of one of these reports consider that erythromycin should not be used with CYP3A4 inhibitors (that is diltiazem and verapamil).² There seem to be no reports of interactions between any of the other calcium-channel blockers and macrolides. However, because of the theoretical possibility of an interaction, many of the manufacturers of calcium-channel blockers warn of the possibility of increased plasma levels and the need to either avoid use with macrolides such as erythromycin, or **troleandomycin**, or to monitor and reduce doses where necessary.

Calcium-channel blockers + Magnesium compounds

Two pregnant women developed bilateral hand contractures after receiving magnesium sulfate either alone or with nifedipine. Two other pregnant women developed muscular weakness and then paralysis when they were given both nifedipine and intravenous magnesium sulfate. Profound hypotension occurred in two women when nifedipine was added to magnesium sulfate and

methyldopa. However, a retrospective study found no significant increase in neuromuscular weakness in women treated with both magnesium sulfate and nifedipine compared with magnesium sulfate and no antihypertensive, and the incidence of hypotension was actually lower.

Clinical evidence

(a) Hypotension

Two women with pre-eclampsia, unsuccessfully treated with methyldopa and magnesium sulfate, experienced severe hypotension when a single 10-mg oral dose of **nifedipine** was added.¹ In contrast, a study in 10 women with severe pre-eclampsia receiving magnesium sulfate found that oral **nifedipine** 10 mg followed by 20 mg every 20 minutes, caused a steady decrease in mean arterial pressure and severe hypotension was not observed.² Moreover, in a retrospective study, the incidence of hypotension in 162 women given **nifedipine** and magnesium sulfate was lower than in 183 receiving magnesium sulfate and no antihypertensive (41.4% versus 53%).³ For further details of this study, see (b) below.

(b) Neuromuscular blockade and hypocalcaemia

A report describes symptomatic hypocalcaemia (serum calcium levels 5.4 mg/dL) in a woman at 33 weeks gestation after she received magnesium sulfate plus **nifedipine**.⁴ However, this report also describes this effect in a patient taking magnesium sulfate alone. Both women experienced bilateral hand contractures and were successfully treated with calcium gluconate.⁴

A pregnant woman at 32 weeks gestation was effectively treated for premature uterine contractions with **nifedipine**, 60 mg orally over 3 hours, and later 20 mg every 8 hours. When contractions began again 12 hours later she was given magnesium sulfate 500 mg intravenously. She developed jerky movements of the extremities, complained of difficulty in swallowing, paradoxical respirations and an inability to lift her head from the pillow. The magnesium was stopped and the muscle weakness disappeared over the next 25 minutes.⁵

A woman at 28 weeks gestation with mild pre-eclampsia was started on an infusion of magnesium sulfate 2 g/hour. Her plasma magnesium levels were found to be 2.75 mmol/L. No untoward reactions developed when she took a 20-mg dose of **nifedipine**, but 30 minutes after taking a second dose [by implication 3 to 4 hours later] she complained of flushing and sweating and had difficulty in lifting her head and limbs. Shortly afterwards almost complete muscular paralysis developed. The magnesium sulfate was stopped and a dramatic improvement followed within 15 minutes of a 1-g intravenous injection of calcium gluconate.⁶

In contrast, a retrospective analysis found no increased risk of serious magnesium-related maternal adverse effects in 162 women with pre-eclampsia who were also treated with **nifedipine** compared with 32 women receiving another antihypertensive or 183 who received no antihypertensive. The women receiving **nifedipine** had more severe pre-eclampsia and a longer magnesium sulfate infusion. However, the incidence of neuromuscular weakness was 53.1% in these women compared with 53.1% in those receiving another antihypertensive and 44.8% in those receiving no antihypertensive. These differences were not statistically significant. Moreover, the incidence of maternal hypotension was lower in those receiving **nifedipine** than in those receiving no antihypertensive (see (a) above).³

Mechanism

The probable reason for neuromuscular effects is that both drugs can seriously reduce the amount of calcium ions needed for normal muscular contraction. Nifedipine inhibits the inflow of extracellular calcium across cell membranes. Magnesium probably acts in the same way, and also reduces intracellular calcium by activating adenylyl cyclase and increasing cAMP. In addition magnesium stimulates calcium-dependent ATPase which promotes calcium uptake by the sarcoplasmic reticulum. The result is muscular paralysis, which is reversed by giving large amounts of calcium. Magnesium sulfate is also known to have neuromuscular blocking activity. Both drugs can also cause hypotension, which could be additive.

Importance and management

Direct information on the neuromuscular effects and hypotensive effects of the combination of nifedipine and magnesium seems to be limited. Al-

though a few cases of possible additive effects have been reported, one large retrospective study did not find an increase in risk of neuromuscular effects or of hypotension with combined use. Nevertheless, at least one manufacturer of nifedipine advises particular caution when it is used in combination with intravenous magnesium sulfate in pregnant women.⁷ The same interaction would be expected to occur with other calcium-channel blockers.

Calcium-channel blockers + Nitrates

Enhanced hypotensive effects may occur when calcium-channel blockers are given with nitrates. The manufacturers of amlodipine say that long-acting nitrates and sublingual glyceryl trinitrate have been given safely with amlodipine.¹ Increased hypotensive effects and faintness due to additive vasodilating effects have been noted when diltiazem has been given with nitrate derivatives. In patients treated with calcium-channel blockers, the dosage of concurrent nitrate derivatives should be increased gradually.²

2. Tildiem Retard (Diltiazem hydrochloride). Sanofi-Aventis. UK Summary of product characteristics, April 2004.

Calcium-channel blockers + Phenobarbital

Limited evidence suggests that phenobarbital greatly reduces the levels and/or increases the clearance of felodipine, nifedipine, nimodipine, and verapamil. Other calcium-channel blockers are expected to be similarly affected.

Clinical evidence

(a) Felodipine

After taking felodipine 10 mg daily for 4 days, 10 epileptics (including one who was taking phenobarbital) had markedly reduced plasma felodipine levels (peak levels of 1.6 nanomol/L compared with 8.9 nanomol/L in 12 control subjects). The felodipine bioavailability was reduced to 6.6%.¹

(b) Nifedipine

After taking phenobarbital 100 mg daily for 2 weeks the clearance of a single 20-mg dose of nifedipine in a 'cocktail' also containing sparteine, mephenytoin and antipyrine was increased almost threefold in 15 healthy subjects. The nifedipine AUC was reduced by about 60%.²

(c) Nimodipine

A study in 8 epileptic patients receiving long-term antiepileptic treatment (including 4 who were taking phenobarbital and 2 who were taking phenobarbital with carbamazepine) found that the AUC of a single 60-mg oral dose of nimodipine was only about 15% of that obtained from a group of healthy subjects.³

(d) Verapamil

A study in 7 healthy subjects found phenobarbital 100 mg daily for 3 weeks increased the clearance of verapamil 80 mg every 6 hours four-fold and reduced the bioavailability fivefold.⁴

Mechanism

Phenobarbital is an enzyme inducer which can increase the metabolism of the calcium-channel blockers by the cytochrome P450 isoenzyme CYP3A4 in the liver, resulting in lower serum levels.

Importance and management

Phenobarbital markedly reduces felodipine, nifedipine and verapamil levels. A considerable increase in the dosage of these calcium-channel blockers will probably be needed in patients taking phenobarbital. Nimodipine effects are also markedly reduced by phenobarbital and the manufacturer contraindicates concurrent use.⁵ There is no direct information of interactions with other calcium-channel blockers, but as they are largely metabolised in the same way (see 'calcium-channel blockers', (p.860)) they would all be expected to interact similarly.

Calcium-channel blockers + Protease inhibitors

Symptomatic orthostasis occurred in a patient taking nelfinavir or ritonavir/indinavir and nifedipine. Another patient had similar symptoms when nelfinavir was added to felodipine therapy. Atazanavir markedly increased diltiazem bioavailability with an increase in cardiac effects in healthy subjects. Similarly, ritonavir/indinavir caused a modest to marked increase in diltiazem levels, and a 1.9-fold increase in amlodipine levels. Based on this evidence, raised calcium-channel blocker levels are predicted when any calcium-channel blocker is given with a protease inhibitor, especially ritonavir. Caution is required.

Clinical evidence

(a) Amlodipine

Ritonavir/indinavir 100/800 mg twice daily given with amlodipine 5 mg daily for 7 days increased the median AUC of amlodipine by 1.9-fold in 13 healthy subjects. Amlodipine had no effect on the steady-state AUCs of the protease inhibitors.¹

(b) Diltiazem

1. **Atazanavir.** A study in healthy subjects found that atazanavir 400 mg once daily given with diltiazem 180 mg once daily resulted in a two- to threefold increase in the bioavailability of diltiazem and its metabolite desacetyl-diltiazem. The pharmacokinetics of atazanavir were not affected by diltiazem. There was an increase in the maximum PR interval with combined use compared to that found with atazanavir alone.^{2,3}

2. **Ritonavir with Indinavir.** Ritonavir/indinavir 100/800 mg twice daily given with diltiazem 120 mg daily for 7 days modestly increased the median AUC of diltiazem by 27% (not statistically significant) in 13 healthy subjects. However, two of the subjects had a fourfold increase in the AUC of diltiazem, and the desacetyl-diltiazem AUC increased by 102%. Diltiazem had no effect on the steady-state AUCs of the protease inhibitors.¹

(c) Felodipine

A woman taking metoprolol 50 mg daily and felodipine 5 mg daily for hypertension developed bilateral leg oedema, orthostatic hypotension, and other symptoms including dizziness and fatigue, 3 days after starting HAART following a needle-stick injury. The antiretroviral therapy included zidovudine, lamivudine, and **nelfinavir** 2 g daily. Antihypertensive treatment was stopped and the adverse effects abated within 3 days. The patient was then successfully switched to a diuretic-based regimen without recurrence of oedema.⁴

(d) Nifedipine

A 51-year-old HIV positive man with coronary artery disease, hypertension and osteoarthritis, and taking atenolol, was started on extended-

release nifedipine 60 mg daily. When his blood pressure control improved he was started on zidovudine 300 mg, lamivudine 150 mg, and **nelfinavir** 1.25 g all twice daily. Within 3 days of starting the antiretroviral therapy he experienced dizziness, weakness and hypotension and developed complete heart block with a junctional escape rhythm. His ECG returned to normal within 24 hours of stopping the antiretroviral therapy, but he developed orthostatic symptoms within 2 days of restarting **nelfinavir**. He later tolerated a regimen consisting of stavudine, didanosine and efavirenz without any episodes of dizziness, hypotension or bradycardia. However, when he was given zidovudine, abacavir, **ritonavir**, and **indinavir**, he experienced hypotension, decreased heart rate, weakness and fatigue. His symptoms were controlled by modifying his antihypertensive therapy, including discontinuation of atenolol and reduction of the dose of nifedipine to 30 mg daily.⁵

Mechanism

Protease inhibitors, particularly ritonavir (see 'Antivirals', (p.772)), are potent inhibitors of cytochrome P450 isoenzyme CYP3A4, by which all the calcium-channel blockers are extensively metabolised. It appears that some protease inhibitors can cause a clinically relevant increase in calcium-channel blocker levels. In addition, verapamil, diltiazem and nifedipine can also inhibit CYP3A4, and might therefore theoretically reduce the metabolism of the protease inhibitors. However, the effect might depend on which is the more potent inhibitor, since, in the studies above, diltiazem did not affect atazanavir, indinavir or ritonavir levels.

Importance and management

Although information is limited, these pharmacokinetic interactions are predictable, and potentially serious. To date, clinically relevant increases in calcium-channel blocker levels or effects have been shown for nelfinavir with nifedipine or felodipine, indinavir/ritonavir with amlodipine, diltiazem or nifedipine, and atazanavir with diltiazem. Caution would be required with any of these combinations, anticipating the need to use lower doses of the calcium-channel blocker. The manufacturers specifically recommend that if diltiazem is given with **atazanavir** the initial dose of diltiazem should be reduced by 50% with subsequent dose titration and ECG monitoring.^{2,3} They also note that **verapamil** levels may be raised and therefore advise caution.^{2,3} Similarly, the manufacturers of nifedipine say that blood pressure monitoring is required and a reduction in nifedipine dose may be necessary if it is given with HIV-protease inhibitors.^{6,7} However, some UK manufacturers (e.g. felodipine,⁸ **lercanidipine**,⁹ **nimodipine**¹⁰) recommend avoiding the concurrent use of ritonavir and other protease inhibitors if possible.

Until more is known, caution is warranted with any combination of a calcium-channel blocker and a protease inhibitor.

Calcium-channel blockers + Proton pump inhibitors

The clearance of both nifedipine and omeprazole is modestly reduced by their concurrent use, but these changes seem unlikely to be of clinical importance. Pantoprazole does not affect the pharmacokinetics of nifedipine.

Clinical evidence, mechanism, importance and management

(a) Omeprazole

After taking omeprazole 20 mg daily for 7 days the clearance of **nifedipine** was reduced 21% in 10 healthy subjects. The same subjects had a

14% reduction in the clearance of a 40-mg intravenous dose of omeprazole after 5 days of treatment with **nifedipine** 10 mg three times daily.¹ In a related study, the same group of workers found that omeprazole 20 mg daily for 8 days increased the AUC of a single 10-mg dose of **nifedipine** by 26%, but no changes in blood pressures or heart rates were seen.² None of these changes is large and they seem not to be of clinical importance.

(b) Pantoprazole

In an open, randomised, crossover study, 24 healthy subjects were given pantoprazole 40 mg daily for 10 days, with sustained-release **nifedipine** 20 mg twice daily from day 6 to 10. The pharmacokinetics of the **nifedipine** were unchanged by the pantoprazole.³ No special precautions would seem to be necessary if pantoprazole and **nifedipine** are given concurrently.

Calcium-channel blockers + Quinupristin/Dalfopristin

Quinupristin/dalfopristin modestly increased the AUC of nifedipine. Other calcium-channel blockers are predicted to be similarly affected.

Clinical evidence, mechanism, importance and management

The manufacturers note that the AUC of repeated-dose **nifedipine** was increased 1.4-fold by quinupristin/dalfopristin, and the maximum level was increased by 1.18-fold.¹ This is probably because quinupristin/dalfopristin inhibits the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of **nifedipine**.² Although the clinical relevance of these increases have not been assessed, the manufacturers advise blood pressure monitoring and, if necessary, a reduction of **nifedipine** dosage during concurrent use.^{1,3} It is predicted that other calcium-channel blockers (e.g. **verapamil**, **diltiazem**) will also have their levels raised by quinupristin/dalfopristin.²

Calcium-channel blockers + Rifampicin (Rifampin)

Rifampicin markedly reduces the plasma levels of diltiazem, nifedipine, nilvadipine, verapamil and possibly reduces those of barnidipine, isradipine, lercanidipine, manidipine, nicardipine, nimodipine, and nisoldipine. They may become therapeutically ineffective unless the dose of the calcium-channel blocker is raised. Rifapentine and rifabutin would also be expected to reduce the levels of the calcium-channel blockers.

Clinical evidence

(a) Barnidipine and Manidipine

A brief report states that elderly patients with hypertension well-controlled with calcium-channel blockers including barnidipine or manidipine had blood pressure rises when rifampicin was added. Increased dosages or additional antihypertensives were needed to control the blood pressures, and reduced doses were required when the rifampicin was withdrawn.¹

(b) Diltiazem

A study in 12 subjects found that the peak serum level following a single 120-mg oral dose of diltiazem alone was 186 nanograms/mL, but after taking rifampicin 600 mg daily for 8 days maximum serum diltiazem levels were less than 8 nanograms/mL.² One patient with angina controlled with diltiazem 120 mg daily began to feel chest pain at rest one month af-

ter starting rifampicin and isoniazid. Nifedipine was also not effective in this man while he was taking rifampicin.³

(c) Nifedipine

A woman with hypertension well controlled with nifedipine 40 mg twice daily, had a blood pressure rise from under 160/90 mmHg to 200/110 mmHg within 2 weeks of starting to take antitubercular treatment, which included rifampicin 450 mg daily. When the rifampicin was stopped and then restarted, the blood pressure fell and then rose again. The peak nifedipine plasma levels and the AUC fell by about 60% in the presence of rifampicin.⁴ Another patient had anginal attacks refractory to both diltiazem and nifedipine while taking rifampicin, but which were controlled by nifedipine when the rifampicin was stopped. Restarting rifampicin reduced nifedipine levels (peak plasma levels and AUCs roughly halved) and increased the number of anginal attacks.⁵ Yet another patient taking nifedipine had a loss of blood pressure control when given rifampicin.⁵

Six healthy subjects were given nifedipine 20 micrograms/kg intravenously and nifedipine 20 mg orally on separate days before and after taking rifampicin 600 mg daily for 7 days. The pharmacokinetics of the intravenous nifedipine were not significantly changed by the rifampicin, but the oral clearance increased from 1.5 to 20.9 L/minute and the bioavailability fell from 41.2 to 5.3%.⁶ A pharmacokinetic study in 6 healthy subjects found that when a single 10-mg oral dose of nifedipine was taken 8 hours after a single 1.2-g dose of rifampicin its bioavailability was reduced to 36%, its half-life was more than halved and its clearance increased threefold.⁷

(d) Nilvadipine

A study in 5 healthy normotensive subjects found that rifampicin 450 mg daily for 6 days reduced the peak plasma level and AUC of a single 4-mg dose of nilvadipine by about 20-fold and 30-fold, respectively. The hypotensive effect and reflex tachycardia associated with nilvadipine alone in these subjects was also abolished by rifampicin.⁸

(e) Nisoldipine

There is some evidence that nisoldipine is ineffective in reducing blood pressure in the presence of rifampicin.^{1,4}

(f) Verapamil

The observation that a patient whose raised blood pressure was not reduced by verapamil while on antitubercular drugs, prompted a study in 4 other patients.⁹ No verapamil could be detected in the plasma of 3 patients who took a single 40-mg dose of verapamil with rifampicin 450 to 600 mg daily, isoniazid 5 mg/kg daily, and ethambutol 15 mg/kg daily. A maximum verapamil level of 20 nanograms/mL was found in the fourth patient. Six other subjects not taking antitubercular drugs had a maximum verapamil plasma concentration of 35 nanograms/mL.⁹ Similar results have been reported by the same authors in another study.¹⁰

Supraventricular tachycardia was inadequately controlled in a patient taking rifampicin 600 mg daily and isoniazid 300 mg daily, despite a verapamil dose of 480 mg every 6 hours. Substitution of the rifampicin by ethambutol resulted in a fourfold rise in serum verapamil levels.¹¹ A later study in 6 healthy subjects found that after taking rifampicin 600 mg daily for 2 weeks the oral bioavailability of verapamil was reduced from 26 to 2%, and the effects of verapamil on the ECG were abolished.¹² Yet another study in elderly patients similarly found that rifampicin 600 mg daily markedly increased the clearance of verapamil 120 mg twice daily. The effects of verapamil on AV conduction were almost abolished.¹³

Mechanism

Rifampicin reduces the effectiveness of nifedipine and verapamil to a greater extent after oral than after intravenous use. The evidence suggests that rifampicin increases the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of calcium-channel blockers in the gastrointestinal wall,^{6,13,14} thereby reducing their oral bioavailability. Rifabutin and rifapentine are also inducers of CYP3A4, although to a lesser extent than rifampicin, and would therefore also be expected to reduce the levels of the calcium-channel blockers.

Importance and management

The interactions between diltiazem, nifedipine, or verapamil and rifampicin are established and of clinical importance. There is some evidence that barnidipine, manidipine, nilvadipine, and nisoldipine interact with rifampicin and the manufacturers of a number of other calcium-channel blockers.

nel blockers warn of similar interactions. Monitor the effects closely if rifampicin is given with any calcium-channel blocker, being alert for the need to make a marked increase in their dosage. However, note that some manufacturers of nifedipine,¹⁵ and nisoldipine¹⁶ contraindicate their use with rifampicin. Although the manufacturers of **nimodipine**¹⁷ do not strictly contraindicate concurrent use they say that both drugs should not be given together. **Rifabutin** and **rifapentine** would also be expected to reduce levels of calcium-channel blockers, although perhaps to a lesser extent than rifampicin. However, there does not appear to be any data to prove this.

Calcium-channel blockers + St John's wort (*Hypericum perforatum*)

St John's wort significantly reduces the bioavailability of verapamil.

Clinical evidence, mechanism, importance and management

In a study, racemic **verapamil** 24 mg was given as a jejunal perfusion over 100 minutes to 8 healthy subjects both before and after treatment with St John's wort tablets (*Movina*; containing 3 to 6% hyperforin) 300 mg three times daily for 14 days. St John's wort did not affect jejunal permeability or the absorption of either **R-** or **S-verapamil**. The AUCs of **R-** and **S-verapamil** were decreased by 78% and 80%, respectively, and the peak plasma levels were decreased by 76% and 78%, respectively. The terminal half-life was not changed significantly. The AUC for **R-verapamil** was sixfold higher than that of **S-verapamil** and St John's wort did not change this ratio.¹

It appears that St John's wort decreased the bioavailability of both **R-** and **S-verapamil** by inducing their metabolism by the cytochrome P450 isoenzyme CYP3A4 in the gut. An effect on P-glycoprotein-mediated transport is not likely, as intestinal permeability was not significantly altered.¹ The clinical importance of this interaction is not known but it may be prudent to avoid concurrent use. There appears to be no information about other calcium-channel blockers, but as they are also affected by other CYP3A4 enzyme inducers, it would seem prudent to monitor concurrent use carefully. More study is required.

1. Tannergren C, Engman H, Knutson L, Hedeland M, Bondesson U, Lennernäs H. St John's wort decreases the bioavailability of **R-** and **S-verapamil** through induction of first-pass metabolism. *Clin Pharmacol Ther* (2004) 75, 298–309.

Calcium-channel blockers + Sulfinpyrazone

The clearance of verapamil is markedly increased by sulfinpyrazone.

Clinical evidence, mechanism, importance and management

A study in 8 healthy subjects found that sulfinpyrazone 800 mg daily for a week, increased the clearance of a single oral dose of **verapamil** by about threefold, possibly due to an increase in its liver metabolism.¹ The clinical importance of this is uncertain, but be alert for reduced **verapamil** effects. It seems probable that the dosage may need to be increased.

1. Wing LMH, Miners JO, Lillywhite KJ. Verapamil disposition—effects of sulfinpyrazone and cimetidine. *Br J Clin Pharmacol* (1985) 19, 385–91.

Calcium-channel blockers + Terbinafine

A study in 12 healthy subjects found that terbinafine 250 mg did not alter the pharmacokinetics of nifedipine 30 mg (as Procardia XL).¹

1. Cramer JA, Robbins B, Barbeito R, Bedman TC, Dreisbach A, Meligeni JA. Lamisil®: interaction study with a sustained release nifedipine formulation. *Pharm Res* (1996) 13 (9 Suppl), S436.

Calcium-channel blockers + Valproate

Nimodipine and possibly nifedipine levels are raised by valproate.

Clinical evidence, mechanism, importance and management

Eight epileptic patients who had been taking valproate alone for at least 4 months were given a single 60-mg dose of **nimodipine**. The AUC of **nimodipine** was about 50% higher than in the control group.¹ The **nimodipine** dosage may need to be reduced if it is given with valproate.

One of the UK manufacturers of **nifedipine** notes that there is a theoretical possibility that levels of **nifedipine** may be increased in the presence of valproate.² The US manufacturer recommends blood pressure monitoring during concurrent use and also suggests that a reduction in the dose of **nifedipine** should be considered.³

3. Adalat CC (Nifedipine). Bayer HealthCare. US Prescribing information, August 2005.

Calcium-channel blockers + Vancomycin

An isolated case report suggests that the hypotensive effects of the rapid infusion of vancomycin may occur more readily in those who are already vasodilated with nifedipine, but it seems likely that the effects seen were due to the rapid infusion alone.

Clinical evidence, mechanism, importance and management

A man with severe systemic sclerosis was hospitalised for Raynaud's phenomenon and dental extraction. After being started on **nifedipine** 40 mg daily, he was given intravenous vancomycin 1 g in 200 mL of dextrose 5% over 30 minutes. After 20 minutes he experienced a severe headache and was found to have a marked macular erythema on the upper trunk, head, neck and arms. His blood pressure fell to 100/60 mmHg and his pulse rate was 90 bpm. He recovered spontaneously.¹ The authors of the report acknowledge the possibility of 'red-man syndrome' caused by the vancomycin, and suggest that it may occur more readily in those already vasodilated with **nifedipine**. However, given that this is an isolated report, and the vancomycin was given over 3 times faster than the recommended rate, it seems likely that this is purely an adverse effect of vancomycin.

1. Daly BM, Sharkey I. Nifedipine and vancomycin-associated red man syndrome. *Drug Intell Clin Pharm* (1986) 20, 986.

Calcium-channel blockers + X-ray contrast media

The hypotensive effects of an intravenous bolus of an ionic X-ray contrast medium can be increased by the presence of calcium-channel blockers. No interaction or only a small interaction appears to occur with non-ionic contrast media.

Clinical evidence, mechanism, importance and management

It is well recognised that ionic X-ray contrast media used for ventriculography reduce the systemic blood pressure due to peripheral vasodilation. They also have a direct depressant effect on the heart muscle. A comparative study of the haemodynamic response of 65 patients found that the hypotensive effect of a bolus dose of an ionic agent (0.5 mL/kg of **meglumine amidotrizoate** and **sodium amidotrizoate** with edetate sodium or disodium) was increased by the concurrent use of **nifedipine** or **diltiazem**. Haemodynamic effects occurred earlier (3.1 seconds instead of 12.9 seconds), were more profound (a fall in systolic pressure of 48.4 instead of 36.9 mmHg) and more prolonged (62 seconds instead of 36 seconds).¹ A similar interaction was seen in *dogs* given **verapamil**.² No interaction or only a minimal interaction was seen in the patients and *dogs* when non-ionic contrast media (**iopamidol** or **iohexol**) were used instead.^{1,2} The clinical relevance of these findings is uncertain. Note that cal-

cium-channel blockers have been tried to prevent the nephrotoxicity of contrast media.

1. Morris DL, Wisneski JA, Gertz EW, Wexman M, Axelrod R, Langberg JJ. Potentiation by nifedipine and diltiazem of the hypotensive response after contrast angiography. *J Am Coll Cardiol* (1985) 6, 785–91.
2. Higgins CB, Kuber M, Slutsky RA. Interaction between verapamil and contrast media in coronary arteriography: comparison of standard ionic and new nonionic media. *Circulation* (1983) 68, 628–35.

Calcium-channel blockers + Zidovudine

Animal studies suggest that nimodipine may increase the bioavailability of zidovudine.

Clinical evidence, mechanism, importance and management

Studies in *animals* have shown that the AUC of zidovudine is increased and its volume of distribution and clearance rate decreased when it is given with **nimodipine**.¹ The clinical relevance of the interaction is not known, but as the adverse effects of zidovudine are dose related, the manufacturer of **nimodipine** suggests that the possibility of this interaction should be borne in mind in patients given both drugs.²

2. Nimotop (Nimodipine). Bayer plc. UK Summary of product characteristics, August 2005.

Cardiovascular drugs, miscellaneous

The drugs dealt with in this section include the centrally acting drugs (clonidine, methyldopa), inotropes and vasopressors (adrenaline, phenylephrine), adrenergic neurone blockers (guanethidine), some vasodilator antihypertensives (hydralazine, diazoxide), nitrates (glyceryl trinitrate), potassium channel activators (nicorandil), peripheral vasodilators (pentoxifylline), calcium sensitisers (levosimendan), endothelin antagonists (bosentan) and newer drugs used in the management of angina (ivabradine and ranolazine).

(a) Miscellaneous antihypertensives

The combination of two antihypertensive drugs often results in an increased antihypertensive action, likewise the combination of drugs which may have hypotension as an adverse effect, can lead to an unexpected increase in hypotension. Examples of this type of interaction are discussed in the monograph 'Antihypertensives + Other drugs that affect blood pressure', p.880. Some drugs are known to antagonise the effect of antihypertensives, and these are also generally discussed in this monograph.

(b) Sympathomimetics

Many of the inotropes and vasopressors have actions on the sympathetic nervous system. Noradrenaline (norepinephrine) is the principal neurotransmitter involved in the final link between nerve endings of the sympathetic nervous system and the adrenergic receptors of the organs or tissues innervated. The effects of stimulating this system can be reproduced or mimicked by exogenous noradrenaline and by a number of other drugs that also stimulate these receptors. The drugs that behave in this way are described as 'sympathomimetics' and act either directly, like noradrenaline, on the adrenergic receptors, or indirectly by releasing stored noradrenaline from the nerve endings. Some drugs do both. This is very simply illustrated in 'Figure 24.1', (below).

The adrenergic receptors of the sympathetic system are not identical but can be subdivided into two main types, namely alpha and beta receptors, which can then be further subdivided. The sympathomimetics are categorised in 'Table 24.1', (p.879), and a brief summary of the principal effects of stimulation of these receptors is listed below:

- Alpha₁ (vasoconstriction, increased blood pressure and sometimes reflex bradycardia; contraction of smooth muscle; mydriasis in the eye)
- Alpha₂ (role in feedback inhibition of neurotransmitter release; inhibition of insulin release)
- Beta₁ (increased rate and force of contraction of the heart)
- Beta₂ (vasodilatation and bronchodilation; uterine relaxation and decreased gastrointestinal motility; release of insulin)

A third distinct group of receptors, which occur primarily within the CNS and may be affected by some sympathomimetics, are the dopamine receptors.

It is therefore possible to broadly categorise the sympathomimetics into groups according to their activity.

Given these wide ranging actions on a number of different receptors the group 'sympathomimetics' is clearly a very diverse collection of drugs with a wide range of uses. One should not, therefore, extrapolate the inter-

actions seen with one drug to any other without fully taking into account their differences. For this reason, where possible, this term has been avoided and drugs have been grouped by therapeutic use. This section is generally concerned with the interactions of sympathomimetics that have predominately cardiovascular actions (mainly through stimulation of alpha₁ and/or beta₁ receptors). Those used as decongestants (through stimulation of alpha receptors with or without beta activity) are mainly discussed in the Miscellaneous drugs section but some of these drugs are also given intravenously for their pressor actions, in which case their interactions are discussed here. Interactions involving beta agonists, such as salbutamol, which selectively stimulate the beta₂ receptors in bronchi causing bronchodilation, are mainly covered in 'Respiratory drugs', (p.1158) and interactions involving dopaminergics, such as levodopa, are dealt with in 'Antiparkinsonian and related drugs', (p.672).

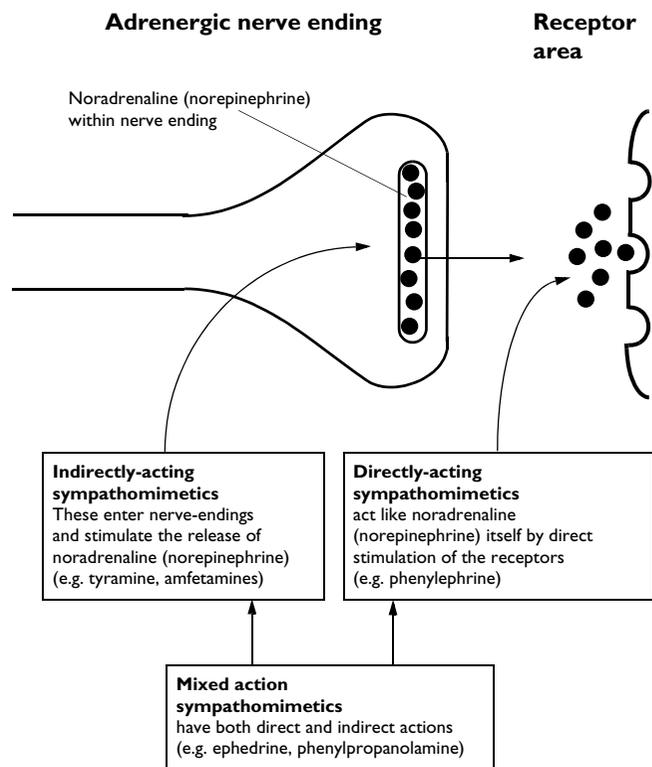

Fig. 24.1 A very simple illustration of the modes of action of indirectly-acting, directly-acting and mixed action sympathomimetics at adrenergic neurones.

Table 24.1 A categorisation of some sympathomimetic drugs

<i>Drug</i>	<i>Receptors stimulated</i>
Direct stimulators of alpha and beta receptors	
Adrenaline (Epinephrine)	Beta more marked than alpha
Mainly direct stimulators of alpha receptors	
Phenylephrine	Predominantly alpha
Metaraminol	Predominantly alpha
Methoxamine	Predominantly alpha
Noradrenaline (Norepinephrine)	Predominantly alpha
Mainly direct stimulators of beta-1 receptors	
Dobutamine	Predominantly beta-1, some beta-2 and alpha
Dopamine	Predominantly beta-1, some alpha
Direct stimulators of beta-1 and beta-2 receptors (beta-agonist bronchodilators)	
Bambuterol	Predominantly beta-2
Fenoterol	Predominantly beta-2
Formoterol	Predominantly beta-2
Isoetharine	Predominantly beta-2
Isoprenaline (Isoproterenol)	Beta-1 and beta-2
Orciprenaline	Predominantly beta-2
Pirbuterol	Predominantly beta-2
Reproterol	Predominantly beta-2
Rimiterol	Predominantly beta-2
Ritodrine	Predominantly beta-2
Salbutamol (Albuterol)	Predominantly beta-2
Salmeterol	Predominantly beta-2
Terbutaline	Predominantly beta-2
Tulobuterol	Predominantly beta-2
Direct and indirect stimulators of alpha and beta receptors	
Ephedrine	Alpha and beta
Etefedrine	Alpha and beta
Phenylpropanolamine	Alpha and beta
Pseudoephedrine	Alpha and beta
Mainly indirect stimulators of alpha and beta receptors	
Amfetamine (Amphetamine)	Alpha and beta – also central stimulant
Mephentermine	Alpha and beta – also central stimulant
Methylphenidate	Alpha and beta – also central stimulant
Tyramine	Alpha and beta

Antihypertensives + Hormonal contraceptives

Combined oral contraceptives are associated with increased blood pressure and may antagonise the efficacy of antihypertensive drugs. However, the effects are far greater with the high-dose contraceptives that were used historically, and the risks appear to be smaller with the newer low-dose contraceptives.

Clinical evidence, mechanism, importance and management

Early after the introduction of **combined oral contraceptives** it was realised that they can cause increases in blood pressure and clinical hypertension.^{1,2} One study,³ from the 1970s, in 83 women found that the average rise in blood pressure was 9.2/5 mmHg, and that it was about twice as likely to occur as in those not on the pill. Additionally, cases were noted where antihypertensives (at that time, commonly **guanethidine** and/or **methyl-dopa**) were not that effective in women with hypertension on combined oral contraceptives.^{2,4} Although modern combined oral contraceptives are lower dose, they are still associated with a small increased risk of elevated blood pressure.⁵ A UK study found that **combined oral contraceptives** were associated with a 2.6/1.8 mmHg rise in blood pressure, whereas **progestogen-only oral contraceptives** did not affect blood pressure.⁵ Furthermore, in a study in 24 postmenopausal women with hypertension taking **enalapril** 10 mg twice daily the use of enalapril with **drospirenone/estradiol** 3/1 mg (12 women) produced a significant decrease in blood pressure of 9/5 mmHg after 14 days of treatment, when compared with the placebo group (12 patients). No serious adverse effects were reported.⁶ Note that drospirenone is an analogue of spironolactone, and shares some of its effects, including its blood pressure-lowering effects.

This is only a very brief review of this subject, but the risks of hypertension with combined hormonal contraceptives appear to be modest. Nevertheless, they need to be considered in the context of other possible cardiovascular risk factors. Where possible, blood pressure should be monitored before and during contraceptive use.

Antihypertensives + Other drugs that affect blood pressure

The hypotensive effect of antihypertensives can be enhanced by other antihypertensives, as would be expected. Although ‘first-dose hypotension’ (dizziness, lightheadedness, fainting) can occur with some combinations, the additive effects are usually clinically useful. Perhaps of more concern is the use of antihypertensives with drugs that have hypotension as an adverse effect, where the effects may not be anticipated. Some drugs antagonise the blood pressure-lowering effects of the antihypertensives and should therefore be used with caution.

Clinical evidence, mechanism, importance and management

(a) Antihypertensive drugs

Enhanced hypotensive effects should be expected when using two antihypertensives together and it is now widely acknowledged that most people require more than one antihypertensive to control blood pressure.¹ In the US, more than two-thirds of patients receive two or more antihypertensives in order to reach the desired target blood pressure. Not only does this improve blood pressure control, but adverse effects can also be reduced as

lower doses of each drug can be used.²

Therefore many antihypertensive combinations produce additive effects that are exploited clinically. ‘Calcium-channel blockers and diuretics’, (p.867) are often used together for additional blood pressure lowering in patients with hypertension. Although there are only a few reports describing these additive interactions, they are highly probable, and caution is advised when using two antihypertensives together. The most common symptoms seen in hypotensive patients are dizziness, fatigue, headache, nausea, confusion, general weakness, lightheadedness, faintness and possible loss of consciousness.

However, in some cases combining two or more antihypertensives has led to severe, first-dose hypotension, see ‘Alpha blockers + ACE inhibitors’, p.84. Further, life-threatening bradycardia, asystole and sinus arrest can occur when antihypertensives that cause cardiodepression are given together (see ‘beta blockers and diltiazem’, (p.840)).

In contrast, a sharp and serious rise in blood pressure (rebound hypertension) can occur following the sudden withdrawal of clonidine, and this can be exacerbated in the presence of a beta blocker (see ‘clonidine’, (p.882)). In some cases fatalities have occurred. ‘Table 24.2’, (p.881) lists antihypertensive combinations that have been implicated in adverse events.

(b) Drugs with significant hypotensive adverse effects

Caution must also be used when combining two or more drugs that, although not primarily indicated for hypertension, may have hypotensive adverse effects. In fact, it is these drugs, rather than drugs commonly given for their hypotensive effects that may cause more of a problem, as the effects are less likely to be deliberately sought. These drugs are listed in ‘Table 24.3’, (p.881) with cross-references to the individual monographs that discuss the reports of adverse effects from these combinations.

(c) Drugs that antagonise hypotensive effects

When using antihypertensive drugs it is important to consider the implications of using drugs that antagonise their effects. The NSAIDs are the prime example of this. Drugs that are thought to antagonise the effects of antihypertensives are listed in ‘Table 24.4’, (p.881), with cross-references to the individual monographs that discuss the reports of adverse effects from these combinations.

Antihypertensives + Phenylpropanolamine

A single dose of a sustained-release preparation of phenylpropanolamine and brompheniramine was found to cause a minor and clinically insignificant rise in the blood pressures of patients on various antihypertensives.

Clinical evidence, mechanism, importance and management

A randomised, double-blind, crossover study in 13 patients with hypertension controlled with **unnamed diuretics** (7), **ACE inhibitors** (6), **beta blockers** (5), **calcium-channel blockers** (1) and a **centrally acting alpha-agonist** (1) found that a single dose of *Dimetapp Extentabs* (phenylpropanolamine 75 mg with brompheniramine 12 mg) caused only a minor rise in blood pressure of 1.7/0.9 mmHg over 4 hours.¹ This sustained-release preparation in this dosage has therefore no clinically important effect on blood pressure, but (as the authors point out), these results do not necessarily apply to different doses and immediate-release preparations. A marked rise in blood pressure was seen in one patient taking **methyl-dopa** and **oxprenolol** when given phenylpropanolamine, see ‘Methyl-dopa + Sympathomimetics; Indirectly-acting’, p.898. Consider also ‘Beta blockers + Phenylpropanolamine’, p.851.

Table 24.2 Antihypertensive + Antihypertensive drug interactions

Drugs	Additive antihypertensive interactions
ACE inhibitors	Alpha blockers Beta blockers Calcium-channel blockers Clonidine Diuretics
Adrenergic neurone blockers (e.g. guanethidine)	Minoxidil + Guanethidine
Alpha blockers	ACE inhibitors Beta blockers Calcium-channel blockers Diuretics
Angiotensin II receptor antagonists	Beta blockers Calcium-channel blockers Diuretics
Beta blockers	ACE inhibitors Alpha blockers Angiotensin II receptor antagonists Calcium-channel blockers; Dihydropyridines Calcium-channel blockers; Diltiazem Calcium-channel blockers; Verapamil Clonidine Ketanserin Vasodilators
Calcium-channel blockers	ACE inhibitors Alpha blockers Angiotensin II receptor antagonists Beta blockers + Dihydropyridines Beta blockers + Diltiazem Beta blockers + Verapamil Calcium-channel blockers Diuretics Glyceryl trinitrate (Nitroglycerin) Nitrates
Centrally acting antihypertensives (e.g. clonidine, moxonidine)	ACE inhibitors + Clonidine Clonidine + Beta blockers Moxonidine + Miscellaneous
Diazoxide	Vasodilators
Diuretics	ACE inhibitors Alpha blockers Angiotensin II receptor antagonists Calcium-channel blockers
Nicorandil	Vasodilators
Nitrates	Calcium-channel blockers Calcium-channel blockers; Nifedipine Sodium nitroprusside + Miscellaneous
Rauwolfia alkaloids	—
Vasodilators (e.g. hydralazine)	Beta blockers + Hydralazine Diazoxide + Hydralazine Guanethidine + Minoxidil Nicorandil + Vasodilators

Table 24.3 Antihypertensive drug interactions involving drugs with significant hypotensive properties or adverse effects

Drugs	Additive antihypertensive interactions
Alcohol	Alcohol + Antihypertensives
Anaesthetics	General anaesthetics + Antihypertensives Local anaesthetics + Antihypertensives MAOIs Timolol
Antipsychotics	ACE inhibitors Beta blockers Clonidine Clozapine + Antihypertensives Guanethidine + Antipsychotics Methyldopa
Dopamine agonists (e.g. apomorphine, bromocriptine etc.)	Apomorphine + Miscellaneous Pergolide + ACE inhibitors
Levodopa	Guanethidine Methyldopa
Moxisylyte	Moxisylyte + Miscellaneous
Phosphodiesterase type-5 inhibitors	Alpha blockers Antihypertensives Nitrates
Procarbazine	Procarbazine + Miscellaneous
Tizanidine	Tizanidine + Antihypertensives
Other drugs suggested to cause hypotension but where no reports of adverse interaction found	Aldesleukin Alprostadiol MAOIs

Table 24.4 Antihypertensive drugs and drugs antagonising their effect

Drugs	Antagonising antihypertensive interactions
Amfetamines	Guanethidine + Amfetamines and related drugs
High-dose aspirin	ACE inhibitors + Aspirin
Carbenoxolone	Carbenoxolone + Antihypertensives
Hormonal contraceptives	Antihypertensives + Hormonal contraceptives
Epoetin	ACE inhibitors or Angiotensin II receptor antagonists + Epoetin
NSAIDs	ACE inhibitors + NSAIDs Alpha blockers + NSAIDs Angiotensin II receptor antagonists + Aspirin or NSAIDs Beta blockers + Aspirin or NSAIDs Calcium-channel blockers + Aspirin or NSAIDs Guanethidine + NSAIDs Hydralazine + NSAIDs Thiazide and related diuretics + NSAIDs
Phenylpropanolamine	Antihypertensives + Phenylpropanolamine Beta blockers + Phenylpropanolamine
Other drugs suggested to antagonise the effects of antihypertensives	Corticosteroids

Bosentan + Azoles

Ketoconazole increases bosentan levels by twofold: fluconazole is predicted to have a greater effect.

Clinical evidence, mechanism, importance and management

In a randomised crossover study, 10 healthy subjects were given bosentan 62.5 mg twice daily for 11 doses, either alone, or with **ketoconazole** 200 mg daily. The maximum plasma level of bosentan was increased 2.1-fold, and the AUC was increased 2.3-fold (range 1.4- to 4-fold) by **ketoconazole**. This interaction probably occurs because bosentan is metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a known, potent inhibitor.¹

Other potent CYP3A4 inhibitors (e.g. **itraconazole**) are expected to interact similarly to **ketoconazole**.² However, because **fluconazole** (a moderate inhibitor of CYP3A4) also inhibits CYP2C9, another enzyme involved in the metabolism of bosentan, it is anticipated that it could cause even larger increases in bosentan levels.

The clinical significance of raised the bosentan levels is unclear. Bosentan has been tolerated in single-doses of up to 2.4 g in healthy subjects, although elevations in liver transaminases have been seen during long-term, high-dose treatment.¹ Even so, the manufacturers do not recommend the combination of **fluconazole** with bosentan because of the risk of liver toxicity.² Similarly using **ketoconazole** or **itraconazole** in combination with a CYP2C9 inhibitor (the manufacturers name **voriconazole**) and bosentan is also not recommended.² Other drugs that inhibit CYP2C9 are listed in 'Table 1.3', (p.6).

Until more is known, it may be prudent to carefully monitor liver function when the combination is used. The manufacturers suggest that no dosage adjustment is likely to be required when **ketoconazole** is used with bosentan.²

2. Tracleer (Bosentan monohydrate). Actelion Pharmaceuticals UK. UK Summary of product characteristics, October 2006.

Bosentan + Food

In a study in 16 healthy subjects the pharmacokinetics of bosentan were not significantly changed by the presence of food. Bosentan may therefore be given without regard to meal times.¹

Bosentan + Miscellaneous

The pharmacokinetics of bosentan were not significantly altered when it was taken with losartan or nimodipine.

Clinical evidence, mechanism, importance and management

(a) Losartan

A study in healthy subjects found that the pharmacokinetics of bosentan 125 mg twice daily were unaffected by the concurrent use of losartan 100 mg once daily for 9 doses.¹

(b) Nimodipine

In a study of 6 patients with subarachnoid haemorrhage, the pharmacokinetics of a single 500-mg intravenous dose of bosentan were not affected by the concurrent use of nimodipine (dose not specified).²

Clonidine + Antipsychotics

The hypotensive adverse effects of the phenothiazines, and possibly haloperidol may be additive with the antihypertensive effects of clonidine. Patients may feel faint and dizzy if they stand up quickly.

Clinical evidence

One report describes a patient who experienced dizziness and hypotension (systolic blood pressure 76 mmHg) about an hour after being given **chlorpromazine** 100 mg, clonidine 100 micrograms and **furosemide** 40 mg. Another patient also experienced hypotension 2 hours after being given clonidine 100 micrograms and a 1-mg intramuscular dose of **haloperidol**.¹

There is also an isolated and unexplained case of a psychotic patient taking **fluphenazine decanoate** who began to exhibit delirium, agitation, disorientation, short-term memory loss, confusion and clouded consciousness within 10 days of starting to take clonidine 200 micrograms daily. These symptoms disappeared when the clonidine was stopped and returned when it was re-started. He had previously uneventfully taken **haloperidol** with clonidine.²

Mechanism

Simple addition of the hypotensive effects of both drugs seems to be the explanation for the increased hypotension and orthostasis. However, note that in contrast to the case report above, *animal* studies have shown that chlorpromazine *reduces* the antihypertensive effect of clonidine.³

Importance and management

The increased hypotension and orthostasis that can occur if phenothiazines are used with antihypertensive drugs such as clonidine is established. Note that, of the phenothiazines, **levomepromazine** is particularly associated with postural hypotension. One report suggests that haloperidol may interact similarly. Monitor, particularly during the initial stages of concurrent use, and warn patients that if they feel faint and dizzy they should lie down, and that they should remain lying down until symptoms abate completely. Dosage adjustment may be necessary.

The manufacturers of clonidine note that a reduced antihypertensive effect may occur with antipsychotics with alpha-blocking properties (e.g. chlorpromazine), as well as mentioning the risk of orthostatic hypotension.⁴ Consider also 'Clonidine + Tricyclic and related antidepressants', p.884. Although antagonism of the antihypertensive effect of clonidine has been seen in *animals* given chlorpromazine, there appear to be no clinical reports.

Clonidine + Beta blockers

The use of clonidine with beta blockers can be therapeutically valuable, but a sharp and serious rise in blood pressure ('rebound hypertension') can follow the sudden withdrawal of clonidine, which may be worsened by the presence of a beta blocker. Isolated cases of marked bradycardia and hypotension have been seen in patients given clonidine with esmolol. There are also two reports describing paradoxical hypertension with the combination of clonidine and beta blockers.

Clinical evidence

(a) Exacerbation of the clonidine-withdrawal hypertensive rebound

A woman with a blood pressure of 180/140 mmHg was taking clonidine and **timolol**. When the clonidine was stopped in error, she developed a violent throbbing headache and became progressively confused, ataxic and

semicomatose, and had a grand mal convulsion. Her blood pressure was found to have risen to over 300/185 mmHg.¹

A number of other reports describe similar cases of hypertensive rebound (a sudden and serious rise in blood pressure) within 24 to 72 hours of stopping the clonidine, apparently worsened by the presence of **propranolol**.^{2,6} The symptoms resemble those of pheochromocytoma, and include tremor, apprehension, flushing, nausea, vomiting, severe headache, and a serious rise in blood pressure. One patient died from a cerebellar haemorrhage.⁵

(b) Bradycardia and hypotension

A man anaesthetised with thiopental and diamorphine, with oxygen, nitrous oxide, enflurane and atracurium, was given clonidine 50 micrograms to control hypertension. After 15 minutes he became tachycardic with a heart rate of up to 170 bpm. **Esmolol** 75 mg was given by slow infusion, whereupon his heart rate fell to 20 bpm. He responded to atropine 1.2 mg, adrenaline (epinephrine) 1 mg and calcium chloride 10 mL with a stable heart rate of 110 bpm.⁷ Of 32 patients receiving **esmolol** during surgery in a clinical study, one patient developed marked hypotension and bradycardia, which responded to ephedrine 10 mg. It was noted that this patient had been receiving clonidine.⁸ A subset of 5 patients involved in a study investigating the use of clonidine with **propranolol** and minoxidil had a reduction in blood pressure when clonidine (0.2 to 0.4 mg daily) was added. After the discontinuation of **propranolol**, blood pressure returned to that seen before clonidine was added, indicating that **propranolol** and clonidine have additive hypotensive actions.⁹ Similarly, **atenolol** and clonidine have been shown to have additive hypotensive effects.^{10,11}

(c) Antagonism of the hypotensive effects

The combination of **sotalol** 160 mg daily and clonidine 450 micrograms daily caused a marked rise in blood pressure in 6 of 10 patients, compared with either clonidine alone (3 patients) or **sotalol** alone (3 patients). Two of the 10 had blood pressures that were lower than with either drug alone, and the remaining 2 patients had no appreciable change in blood pressure.¹² Two cases of hypertension involving clonidine with **propranolol** have also been described,¹³ and in some studies the combination of clonidine and **nadolol**¹¹ or **propranolol**¹⁰ has been no more effective than either drug alone.

(d) Peripheral vascular disorders

The manufacturer of clonidine notes that the concurrent use of a beta blocker may possibly potentiate peripheral vascular disorders.¹⁴ This is based on the known pharmacology of the drugs,¹⁵ and no specific cases appear to have been reported.

Mechanism

The normal additive hypotensive effects of these drugs result from the two acting in concert at different but complementary sites in the cardiovascular system. Just why antagonism sometimes occurs is unexplained. The hypertensive rebound following clonidine withdrawal is thought to be due to an increase in the levels of circulating catecholamines. With the beta (vasodilator) effects blocked by a beta blocker, the alpha (vasoconstrictor) effects of the catecholamines are unopposed and the hypertension is further exaggerated.

Importance and management

It is well-known that beta blockers seriously worsen the rebound hypertension following clonidine withdrawal. Control this adverse effect by stopping the beta blocker several days before starting a gradual withdrawal of clonidine.¹⁶ A successful alternative is to replace the clonidine and the beta blocker with labetalol,¹⁷ which is both an alpha and a beta blocker: The blood catecholamine levels still rise markedly (20-fold) and the patient may experience tremor, nausea, apprehension and palpitations, but no serious blood pressure rise or headaches appear to occur.¹⁷ The dosage of labetalol will need to be titrated to effect, with regular checks on the blood pressure over 2 to 3 days. If a hypertensive episode develops, control it with an alpha-blocking drug such as phentolamine.² Diazoxide is also said to be effective.¹⁵ Re-introduction of oral or intravenous clonidine should also stabilise the situation. It is clearly important to emphasise to patients taking clonidine and beta blockers that they should not stop taking these drugs without seeking medical advice.

Clonidine and atenolol (a cardio-selective beta blocker) have additive hypotensive effects and smaller doses of clonidine can be given, which decreases its troublesome adverse effects (sedation and dry mouth). In contrast, limited evidence suggests that propranolol or nadolol (non-selective beta blockers) the blood pressure reductions were the same as with either drug alone, although this has not been confirmed in other studies. The weight of evidence suggests that paradoxical hypertension is rare.^{12,13}

Clonidine + Bupropion

Bupropion 100 mg three times daily for 9 days did not reduce the hypotensive effect of a single 300-microgram dose of oral clonidine in 8 healthy subjects.¹

1. Cubeddu LX, Cloutier G, Gross K, Grippo R, Tanner L, Lerea L, Shakarjian M, Knowlton G, Harden TK, Arendshorst W and Rogers JF. Bupropion does not antagonize cardiovascular actions of clonidine in normal subjects and spontaneously hypertensive rats. *Clin Pharmacol Ther* (1984) 35, 576-84.

Clonidine and related drugs + CNS depressants

Increased sedation may occur if alcohol or other CNS depressants are taken with clonidine, guanfacine or guanabenz.

Clinical evidence, mechanism, importance and management

Sedation is a common adverse effect of clonidine and other central alpha-adrenoceptor agonists such as **guanfacine** and **guanabenz**, particularly during the initial stages of treatment.¹⁻³ Patients starting treatment with these drugs should be warned that their tolerance to **alcohol** and other CNS depressant drugs may be diminished. Patients who are affected should not drive or operate machinery. Consider also 'Moxonidine + Miscellaneous', p.899.

Clonidine + Hormonal contraceptives

The sedative effects of intravenous clonidine have been increased by a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

A study¹ in a group of 10 women found that the sedative effects of a single 1.3-microgram/kg dose of intravenous clonidine were increased by a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 30 micrograms/150 or 250 micrograms). The clinical importance of this is uncertain. Consider also 'Antihypertensives + Hormonal contraceptives', p.880.

Clonidine + Naloxone

A study in *animals* suggesting naloxone blocked the antihypertensive effects of clonidine prompted a placebo-controlled study in 6 patients with hypertension. Each patient received a single oral dose of clonidine 300 micrograms during an infusion of either naloxone 6 micrograms/kg per hour for 8 hours. Supine and standing blood pressure and heart rate were monitored. Naloxone was not found to affect the hypotensive or bradycardic effect of clonidine.¹

1. Rogers JF, Cubeddu LX. Naloxone does not antagonize the antihypertensive effect of clonidine in essential hypertension. *Clin Pharmacol Ther* (1983) 34, 68–73.

Clonidine + Prazosin

There is some evidence to suggest that prazosin can reduce the antihypertensive effects of clonidine, whereas some other evidence suggests that this does not occur.

Clinical evidence, mechanism, importance and management

The hypotensive effect of a 150-microgram intravenous dose of clonidine was reduced by 47% in 18 patients with essential hypertension after they took prazosin (mean dose 11 mg three times daily for 4 days).¹ A later crossover study by the same research group in 17 patients with essential hypertension (mean blood pressures 170/103 mmHg) found that clonidine 300 micrograms daily for 4 days reduced the mean blood pressure by 38/18 mmHg and prazosin 6 mg daily for 3 days reduced the mean blood pressure by 10/4 mmHg. However, when prazosin and clonidine were given together the mean blood pressure was only reduced to a similar extent as prazosin alone (12/6 mmHg).² Similarly, some earlier studies had suggested that the combination of clonidine and prazosin produced only a modest,³ or no additive antihypertensive effect.⁴ Conversely, other studies using the combination have not reported a reduced antihypertensive effect.^{5,6} In the presence of prazosin the rebound hypertension following clonidine withdrawal was said to be moderate (a rise from 145/85 to 169/104 mmHg).⁶

Clonidine is an α_2 agonist, whereas prazosin is an α_1 blocker. Consequently, it has been postulated that the drugs may be partially antagonistic when given together, and the authors of the first study cite a number of *animal* studies to support this.¹ Although not conclusive, it seems possible that concurrent use may not always be favourable. Monitor the effects.

Clonidine + Rifampicin (Rifampin)

Rifampicin does not interact with clonidine.

Clinical evidence, mechanism, importance and management

In 6 subjects taking clonidine 200 micrograms twice daily the use of rifampicin 600 mg twice daily for 7 days did not affect the elimination kinetics of clonidine, or its effects on pulse rate or blood pressure.¹ No special precautions would seem necessary on concurrent use.

Clonidine + Tricyclic and related antidepressants

The tricyclic antidepressants, clomipramine, desipramine and imipramine, reduce or abolish the antihypertensive effects of clonidine. Other tricyclics are expected to behave similarly. A hypertensive crisis developed in a woman taking clonidine who was also given imipramine, and severe pain occurred in a man taking amitriptyline and diamorphine when he was given intrathecal clonidine. Conversely, the tetracyclics, maprotiline and mianserin do not appear to alter the antihypertensive effects of clonidine. An isolated case report describes a hypertensive crisis in a patient taking mirtazapine and clonidine. Hypotension occurred in a boy taking clonidine and trazodone.

Clinical evidence*(a) Tetracyclic and related antidepressants*

Maprotiline 100 mg in 4 divided doses over 22 hours did not alter the effect of a single dose of clonidine on blood pressure or heart rate in 8 healthy subjects.¹ **Mianserin** 20 mg three times daily for 2 weeks had no effect on the control of blood pressure in 5 patients receiving clonidine.^{2,3} Similarly, **mianserin** pretreatment did not significantly alter the hypotensive action of a single dose of clonidine in healthy subjects.^{2,4} In contrast, an isolated report describes hypertensive urgency in a man with end-stage renal disease taking clonidine, metoprolol and losartan when **mirtazapine** (a **mianserin** analogue) was added for depression.⁵

(b) Trazodone

A 12-year-old boy taking clonidine 100 micrograms three times daily and dexamfetamine 15 mg twice daily was prescribed trazodone 50 mg at bedtime. After a few weeks his trazodone dosage was increased to 100 mg at bedtime. Within 45 minutes of taking his first increased dose he had a hypotensive episode with bradycardia and sedation. The trazodone dose was reduced back to 50 mg, but the drug was discontinued 2 weeks later because of low blood pressure.⁶

(c) Tricyclic antidepressants

Desipramine 75 mg daily for 2 weeks caused the lying and standing blood pressures of 4 out of 5 hypertensive patients taking clonidine 600 to 1800 micrograms daily (with chlortalidone or hydrochlorothiazide) to rise by 22/15 mmHg and 12/10 mmHg respectively.⁷

This interaction has been seen in other patients taking **clomipramine**, **desipramine** and **imipramine**.^{8–11} In one study, the antihypertensive effects of a single intravenous dose of clonidine were reduced by about 50% in 6 patients given **desipramine** for 3 weeks.¹² Similarly the blood pressure lowering effect of a single 300-microgram dose of clonidine was reduced by 40 to 50% in 8 healthy subjects when it was given on day 9 of treatment with **imipramine** 25 mg three times daily.¹³ An elderly woman taking clonidine 200 micrograms daily developed severe frontal headache, dizziness, chest and neck pain and tachycardia of 120 bpm with hypertension (230/124–130 mmHg) on the second day of taking **imipramine** 50 mg for incontinence.¹⁴

Rebound hypertension and tachycardia seen on the withdrawal of clonidine, may have been made worse by the presence of **amitriptyline** in a 73-year-old woman.¹⁵

A man with severe pain, well controlled with **amitriptyline**, sodium valproate and intrathecal boluses of diamorphine, experienced severe pain within 5 minutes of an intrathecal test dose of clonidine 75 micrograms.¹⁶

Mechanism

Not understood. One idea is that the tricyclics desensitise or block central α_2 -receptors.¹⁷ This would explain the interaction with mirtazapine (a

mianserin analogue), which also has alpha-blocking properties.⁵ However, mianserin (also an alpha-blocker) did not interact.² Another idea is that tricyclics block noradrenaline uptake. However, maprotiline, which also blocks noradrenaline uptake, did not interact.¹ Trazodone, which also has alpha-blocking properties was predicted to inhibit the effect of clonidine based on a study in *animals* where it antagonised the hypotensive effect of clonidine when given centrally (note this effect was not seen when it was administered intravenously).¹⁸ The case of hypotension described could be explained by the hypotensive effect of trazodone alone, but may have been compounded by the hypotensive effect of clonidine.

Importance and management

The interaction between clonidine and the tricyclics is established and clinically important. The incidence is uncertain but it is not seen in all patients.⁷ Avoid concurrent use unless the effects can be monitored. Increasing the dosage of clonidine may possibly be effective. The clonidine dosage was apparently successfully titrated in 10 out of 11 hypertensive patients already on amitriptyline or imipramine.¹⁹ Only clomipramine, desipramine and imipramine have been implicated so far, but other tricyclics would be expected to behave similarly (amitriptyline, **nortriptyline** and **protriptyline** have been shown to interact in *animals*).²⁰ The tetracyclic antidepressants maprotiline and mianserin do not generally appear to interact with clonidine. The isolated case of hypotension with trazodone is of unknown general importance.

Diazoxide + Hydralazine

Severe hypotension, in some cases fatal, has followed the use of high doses of intravenous diazoxide, given before or after hydralazine.

Clinical evidence

A previously normotensive 25-year-old woman had a blood pressure of 250/150 mmHg during the 34th week of pregnancy, which failed to respond to intravenous magnesium sulfate 4 g. Her blood pressure fell transiently to 170/120 mmHg when she was given hydralazine 15 mg intravenously. One hour later intravenous diazoxide 5 mg/kg resulted in a blood pressure fall to 60/0 mmHg. Despite large doses of noradrenaline (norepinephrine), the hypotension persisted and the woman died.¹

Other cases of severe hypotension in patients given high doses of intravenous diazoxide and intravenous or oral hydralazine are described in this¹ and other studies and reports.^{2–4} In some instances the patients had also received other antihypertensives such as methyldopa¹ or reserpine.^{1,4} At least three of the cases had a fatal outcome.⁴

Mechanism

Not fully understood. The (vasodilatory) hypotensive effects of the two drugs are additive, and it would seem that in some instances the normal compensatory responses of the cardiovascular system to maintain an adequate blood pressure reach their limit. This can occur with intravenous diazoxide alone.²

Importance and management

The concurrent use of intravenous diazoxide and hydralazine should be undertaken extremely cautiously with thorough monitoring. Note that the doses of diazoxide used in the above reports were frequently higher than those currently recommended for hypertensive crises.⁵ In addition, there are now many more options available for the treatment of very severe hypertension, and the BNF in the UK considers intravenous diazoxide to be one of the less suitable choices.⁵ Moreover, diazoxide was frequently associated with clinically important hypotension when used in pregnancy, and is not considered a good choice in this situation.⁶

Diazoxide + Other drugs with hyperglycaemic activity

The risk of hyperglycaemia is increased if diazoxide is given with other drugs with hyperglycaemic activity (e.g. the thiazides, chlorpromazine, corticosteroids, combined oral contraceptives).

Clinical evidence, mechanism, importance and management

An isolated report¹ describes a child receiving long-term treatment for hypoglycaemia with diazoxide 8 mg/kg daily in divided doses and **benzoflumethiazide** 1.25 mg daily, who developed a diabetic pre-coma and severe hyperglycaemia after taking a single 30-mg dose of **chlorpromazine**. The reason for this reaction is not understood but one idea is that all three drugs had additive hyperglycaemic effects. Enhanced hyperglycaemia has been seen in other patients given diazoxide with **trichlormethiazide**.² Caution is clearly needed to ensure that the hyperglycaemic effects do not become excessive. The manufacturers of diazoxide also mention that the risk of hyperglycaemia may be increased by **corticosteroids** or oestrogen-progestogen combinations (e.g. **combined oral contraceptives**).³

Glyceryl trinitrate (Nitroglycerin) + Antimuscarinics

Drugs with antimuscarinic effects, such as the tricyclic antidepressants and disopyramide, depress salivation and many patients complain of having a dry mouth. In theory sublingual glyceryl trinitrate tablets will dissolve less readily under the tongue in these patients, thereby reducing their absorption and

effects. However, no formal studies seem to have been done to confirm that this actually happens. 'Table 18.1', (p.672), and 'Table 18.2', (p.674) list drugs that have antimuscarinic effects. A possible alternative is to use a glyceryl trinitrate spray in patients who suffer from dry mouth.

Glyceryl trinitrate (Nitroglycerin) + Aspirin

Some limited evidence suggests that analgesic doses of aspirin can increase the serum levels of glyceryl trinitrate given sublingually, possibly resulting in an increase in its adverse effects such as hypotension and headache. Paradoxically, long-term aspirin use appears to reduce the effects of intravenous glyceryl trinitrate used for vasodilatation in patients following coronary artery bypass surgery.

Clinical evidence

(a) Glyceryl trinitrate (sublingual) effects increased

When aspirin 1 g was given to 7 healthy subjects followed one hour later by 800 micrograms of glyceryl trinitrate sublingual spray, the mean plasma glyceryl trinitrate levels 30 minutes after administration were increased by 54% (from 0.24 to 0.37 nanograms/mL). The haemodynamic effects of the glyceryl trinitrate (including heart rate and reduced diastolic blood pressure) were enhanced. Some changes were seen when aspirin 500 mg was given every 2 days (described as an anti-aggregant dose) but the effects were not statistically significant.^{1,2}

(b) Glyceryl trinitrate (sublingual) effects unchanged

A study in 40 healthy subjects who were given 650 mg aspirin or placebo, followed after 1 to 2 hours by sublingual glyceryl trinitrate 432 micrograms found no significant alterations in the peak haemodynamic response, nor the area under the time-pressure and time-pulse curves. There was a transient pressor response, which occurred 1 minute after glyceryl trinitrate was given: this was blunted by aspirin. Taken alone, this change was significant, but when the overall pattern of changes during the 30 minute study was considered, the differences were not significant.³

(c) Glyceryl trinitrate (intravenous) effects reduced

A study in patients following coronary artery bypass surgery found that those who had been taking aspirin 150 or 300 mg daily (33 patients) for at least 3 months, needed more glyceryl trinitrate to control blood pressure during the recovery period than those who had not taken aspirin (33 patients). To achieve the blood pressure criteria required, the aspirin-group needed an 8.2 microgram/minute infusion of glyceryl trinitrate. The dose remained relatively high at 3.3 micrograms/minute even after 8 hours, whereas the non-aspirin group needed only 5.5 micrograms/minute, which was reduced to 1.9 micrograms/minute after 8 hours.⁴

Mechanism

Not understood. Prostaglandin-synthetase inhibitors such as aspirin can, to some extent, suppress the vasodilator effects of glyceryl trinitrate by blocking prostaglandin release. However, it seems that a much greater pharmacodynamic interaction also occurs, in which aspirin reduces the flow of blood through the liver, so that the metabolism of the glyceryl trinitrate is reduced, thus increasing its levels, and therefore its effects.

Importance and management

A confusing and unexplained situation. It seems possible that patients taking sublingual glyceryl trinitrate may experience an exaggeration of its adverse effects such as hypotension and headaches if they are taking analgesic doses of aspirin. Also be aware that long-term aspirin use may reduce the vasodilatory effects of intravenous glyceryl trinitrate. The antiplatelet effects of aspirin and glyceryl trinitrate appear to be additive.⁵

Glyceryl trinitrate (Nitroglycerin) + Nifedipine

The effect of sublingual glyceryl trinitrate was not altered by pretreatment with nifedipine in two studies. Nifedipine and intravenous glyceryl trinitrate had additive vasodilator effects in one study, but the preliminary results of another study found that patients undergoing coronary artery bypass surgery and taking nifedipine 20 mg twice daily required more intravenous glyceryl trinitrate than those taking nifedipine 10 mg twice daily or those not taking nifedipine.

Clinical evidence, mechanism, importance and management

(a) Sublingual glyceryl trinitrate

In 9 patients with stable chronic angina, there was no significant haemodynamic interaction between sublingual glyceryl trinitrate and a single-dose of nifedipine, or nifedipine three times daily for 5 days.¹ In another study in healthy subjects, the venodilatory effect of sublingual glyceryl trinitrate was not altered by pretreatment with nifedipine 10 mg.² No special precautions are required during concurrent use.

(b) Intravenous glyceryl trinitrate

In 7 patients with severe congestive heart failure, a single-dose of oral nifedipine increased stroke volume, with a peak effect at 30 minutes. The addition of intravenous glyceryl trinitrate at 2 hours further increased stroke volume and increased the cardiac index.³ Therefore the addition of glyceryl trinitrate enhanced the vasodilator action of nifedipine. Conversely, in the preliminary findings of a comparative study of 3 groups of patients undergoing coronary bypass graft surgery, those taking nifedipine 20 mg twice daily needed initial doses of intravenous glyceryl trinitrate (to reduce cardiac workload, maintain graft patency and control blood pressure) that were about 40% higher than those in the other 2 groups; one taking nifedipine 10 mg twice daily for hypertension, and the other a control group of normotensive patients. Moreover, these higher doses had little effect on the initial mean systolic blood pressure of half of the group taking nifedipine 20 mg twice daily, and they needed an additional infusion of nitroprusside.⁴ It was suggested that since glyceryl trinitrate is converted to nitric oxide to elicit its vasodilator effect, it is possible that the nifedipine inhibits the enzymic production of the nitrous oxide. This appears to be the only study to suggest a negative interaction, and the clinical relevance of its findings is unclear. Note that this study was non-randomised, and there may have been other important differences between the patients in each group that would account for the effects seen.

Guanethidine + Amfetamines and related drugs

The antihypertensive effects of guanethidine can be reduced or abolished by drugs including dexamfetamine, ephedrine, metamfetamine and methylphenidate. The blood pressure may even rise higher than before treatment with the antihypertensive.

Clinical evidence

When 16 hypertensive patients taking guanethidine 25 to 35 mg daily were given single-doses of dexamfetamine 10 mg orally, ephedrine 90 mg orally, metamfetamine 30 mg intramuscularly or methylphenidate 20 mg orally, the hypotensive effects of the guanethidine were com-

pletely abolished, and in some instances the blood pressures rose higher than before treatment with the guanethidine.¹ Another report describes the same interaction between guanethidine and **dexamfetamine**.²

Mechanism

These drugs are all indirectly-acting sympathomimetic amines, which not only prevent guanethidine-like drugs from entering the adrenergic neurones of the sympathetic nervous system, but also displace the antihypertensive drug already there.³ As a result the blood pressure lowering effects are lost. In addition these amines release noradrenaline (norepinephrine) from the neurones, which raises the blood pressure. Thus the antihypertensive effects are not only opposed, but the pressure may even be raised higher than before treatment.³⁻⁸

Importance and management

Well documented, well established, and clinically important interactions. Other drugs, such as **phenylpropanolamine**, which is also an indirectly-acting sympathomimetic, are likely to interact similarly. Patients taking guanethidine should avoid indirectly-acting sympathomimetics, see 'Table 24.1', (p.879) for a list. Warn them against the temptation to use proprietary non-prescription nasal decongestants containing any of these amines to relieve the nasal stuffiness commonly associated with the use of guanethidine and related drugs. The same precautions apply to the sympathomimetics used as appetite suppressants. However, one brief report stated that **diethylpropion** has been used with guanethidine without any adverse events.⁹ Note that guanethidine increases the hypertensive effects of 'directly-acting sympathomimetics', (p.891).

Guanethidine + Antipsychotics

Large doses of chlorpromazine may reduce or even abolish the antihypertensive effects of guanethidine, although in some patients the inherent hypotensive effects of the chlorpromazine may possibly predominate. Case reports suggest that haloperidol and tiotixene may interact similarly. Molindone is reported not to interact with guanethidine, and a single-dose of prochlorperazine also did not interact with guanethidine.

Clinical evidence

Two severely hypertensive patients, with stable blood pressure while taking guanethidine 80 mg daily, were given **chlorpromazine** 200 to 300 mg daily. The diastolic blood pressure of one rose over 10 days from 94 to 112 mmHg and continued to rise to 116 mmHg, even when the **chlorpromazine** was withdrawn. The diastolic pressure of the other rose from 105 to 127 mmHg, and then to 150 mmHg, again, even after the **chlorpromazine** had been withdrawn.¹ Other reports similarly describe marked rises in blood pressure in patients taking guanethidine with **chlorpromazine** 100 to 400 mg daily.²⁻⁴

Three hypertensive patients taking guanethidine 60 to 150 mg daily had increases in their blood pressure when **haloperidol** 6 to 9 mg daily was added. The blood pressure rose from 132/95 to 149/99 mmHg in the first patient; from 125/84 to 148/100 mmHg in the second patient; and from 138/91 to 154/100 mmHg in the third patient. **Tiotixene** 60 mg daily was later given to one of the patients and the blood pressure rose from 126/87 to 156/110 mmHg.² These results have been reported elsewhere.^{3,4}

However, a single 25-mg dose of **prochlorperazine** did not significantly antagonise the effect of guanethidine 15 to 20 mg daily in 5 patients.⁵ In another study in 7 patients taking guanethidine 50 to 95 mg daily, the addition of **molindone** 30 to 120 mg daily had no effect on blood pressure.⁶

Mechanism

Chlorpromazine prevents the entry of guanethidine into the adrenergic neurones of the sympathetic nervous system resulting in a loss of its blood pressure-lowering effects. The other interacting antipsychotics probably have similar effects. This is essentially the same mechanism of interaction as that seen with the 'tricyclic antidepressants', (p.888).

Importance and management

Direct information is limited but the interaction between guanethidine and chlorpromazine is established and can be clinically important. It may take several days to develop. Not all patients may react to the same extent.^{2,7} Monitor concurrent use and raise the guanethidine dosage if necessary. It is uncertain how much chlorpromazine is needed before a significant effect occurs, but the smallest dose of chlorpromazine used in the studies was 100 mg with 90 mg guanethidine, which raised the blood pressure by 40/23 mmHg.² The inherent hypotensive effects of the chlorpromazine may possibly reduce the effects of this interaction. Other antipsychotics (particularly the phenothiazines) might be expected to interact similarly and this has been seen with tiotixene and haloperidol. The effects should be monitored. However, molindone is reported not to interact, and a single-dose of prochlorperazine did not interact.

Guanethidine + Levodopa

When two patients taking guanethidine were given levodopa it was possible to reduce the guanethidine dosage in one and to stop adjunctive diuretics in the other.

Clinical evidence, mechanism, importance and management

A brief report describes a patient taking guanethidine and a diuretic who, when given levodopa (dose not stated), required a reduction in his daily dose of guanethidine, from 60 to 20 mg. Another patient similarly treated was able to discontinue the diuretic.¹ The suggested reason is that the hypotensive adverse effects of the levodopa are additive with the effects of the guanethidine. Direct information seems to be limited to this report but it would be wise to confirm that excessive hypotension does not develop if levodopa is added to treatment with guanethidine.

1. Hunter KR, Stern GM, Laurence DR. Use of levodopa with other drugs. *Lancet* (1970) ii, 1283-5.

Guanethidine + MAOIs

The antihypertensive effects of guanethidine can be reduced by nialamide, and probably therefore other similar MAOIs.

Clinical evidence, mechanism, importance and management

Four out of 5 hypertensive patients taking guanethidine 25 to 35 mg daily had a rise in blood pressure from 140/85 to 165/100 mmHg six hours after being given a single 50-mg dose of **nialamide**.¹ The reason is not understood but one idea is that MAOIs possibly oppose the guanethidine-induced loss of noradrenaline from sympathetic neurones. In *animal* studies, effective antagonism of guanethidine was shown by those MAOIs that also possess sympathomimetic effects (**phenelzine** and **tranylcyp-**

promine), but not by **iproniazid** or **nialamide**,² and the antagonism was weaker than that seen with some other sympathomimetics.³

Direct clinical information seems to be limited to the single dose study,¹ but it would be prudent to monitor the effects if any MAOI is given to patients taking any guanethidine-like drug. The manufacturers of guanethidine actually contraindicate the use of MAOIs because of the possibility of the release of large quantities of catecholamines and the risk of hypertensive crisis. They recommend that at least 14 days should elapse between stopping an MAOI and starting guanethidine.⁴

Guanethidine + NSAIDs

Phenylbutazone and kebuzone reduce the antihypertensive effects of guanethidine.

Clinical evidence, mechanism, importance and management

When 20 patients taking guanethidine 75 mg daily were given **phenylbutazone** or **kebuzone** 750 mg daily the mean systolic blood pressure rose by 20 mmHg (from 169 to 189 mmHg).¹ This rise represents about a 35% reduction in the antihypertensive effect of guanethidine. The mechanism of this interaction is uncertain but it is probably due to salt and water retention caused by these pyrazolone compounds. Direct evidence seems to be limited to this report. Patients taking guanethidine should be monitored if **phenylbutazone** or **kebuzone** is given concurrently. There does not appear to be any information on guanethidine and other NSAIDs, but indometacin in particular is well known to reduce the efficacy of other classes of antihypertensives, see for example 'ACE inhibitors + NSAIDs', p.28.

1. Polak F. Die hemmende Wirkung von Phenylbutazon auf die durch einige Antihypertonika hervorgerufene Blutdrucksenkung bei Hypertonikern. *Z Gesamte Inn Med* (1967) 22, 375–6.

Guanethidine + Tricyclic and related antidepressants

The antihypertensive effects of guanethidine are reduced or abolished by amitriptyline, desipramine, imipramine, nortriptyline and protriptyline. Doxepin in doses of 300 mg or more daily interacts similarly, but in smaller doses appears not to do so, although one case is reported with doxepin 100 mg daily. A few case reports suggest that maprotiline and mianserin do not interact with guanethidine.

Clinical evidence

(a) Tricyclic antidepressants

Five hypertensive patients taking guanethidine sulfate 50 to 150 mg daily had a mean arterial blood pressure rise of 27 mmHg when they were also given **desipramine** 50 or 75 mg or **protriptyline** 20 mg daily for 1 to 9 days. The full antihypertensive effects of the guanethidine were not established until 5 days after the antidepressants were withdrawn.¹

The same interaction has been described in other reports, with guanethidine and **desipramine**,^{2,3} **imipramine**,⁴ **amitriptyline**,^{5–7} **protriptyline**³ or **nortriptyline**.⁸ The interaction may take several days to develop fully and can last an average of 5 days after discontinuation of the tricyclic.² Some studies, and clinical experience suggests that **doxepin** does not begin to interact until doses of about 200 to 250 mg daily are used, then at 300 mg or more daily it interacts to the same extent as other tricyclics.^{9–13} However, in one case excessive hypertension occurred in a man taking guanethidine and **doxepin** 100 mg daily.¹⁴

(b) Tetracyclic antidepressants

Maprotiline 25 mg three times daily caused no appreciable change in blood pressure in two patients taking guanethidine.⁷ Similarly, in a study in two patients, **mianserin** 20 mg three times daily for 2 days did not alter the antihypertensive efficacy of guanethidine.¹⁵

Mechanism

The guanethidine-like drugs exert their hypotensive actions by entering the adrenergic nerve endings associated with blood vessels using the noradrenaline uptake mechanism. The tricyclics successfully compete for the same mechanism so that the antihypertensives fail to reach their site of action, and as a result, the blood pressure rises once again.¹⁶ The differences in the rate of development, duration and extent of the interactions reflect the pharmacokinetic differences between the various tricyclics, as well as individual differences between patients.

Importance and management

A very well documented and well established interaction of clinical importance. Not every combination of guanethidine and tricyclic antidepressant has been studied but all are expected to interact similarly. Concurrent use should be avoided unless the effects are very closely monitored and the interaction balanced by raising the dosage of the antihypertensive. Note that the use of guanethidine and related adrenergic neurone blockers has largely been superseded by other antihypertensive drug classes.

Guanfacine + Phenobarbital or Phenytoin

In two patients, the concurrent use of phenobarbital or phenytoin increased the metabolism of guanfacine.

Clinical evidence, mechanism, importance and management

When a hypertensive patient with chronic renal failure who was taking guanfacine 4 mg daily, was given phenobarbital 10 mg daily the antihypertensive effects of guanfacine were noted to be reduced and its dose was progressively raised over about 18 months to 12 mg daily. Phenobarbital was eventually stopped. Single measurements of the pharmacokinetics of guanfacine, both when the patient was taking phenobarbital, and 2 months after cessation of phenobarbital, showed that the half-life of guanfacine increased fourfold when the phenobarbital was stopped.¹ The manufacturer also reports a similar case with phenytoin and guanfacine.² Phenobarbital and phenytoin probably induce the metabolism of guanfacine. Patients taking these drugs are likely to need more frequent doses of guanfacine.

2. Guanfacine hydrochloride. Watson Laboratories Inc. US Prescribing information, April 2003.

Guanfacine + Tricyclic antidepressants

A single report describes a reduced antihypertensive response to guanfacine in a patient given amitriptyline and later imipramine. The sedative effects of guanfacine and tricyclics are predicted to be additive.

Clinical evidence

A 38-year-old woman with stable hypertension, taking guanfacine 2 mg daily, had a rise in her mean blood pressure from 138/89 mmHg to 150/100 mmHg while taking **amitriptyline** 75 mg daily for 14 days. The pressure fell again when the **amitriptyline** was stopped. A month later her blood pressure rose to 142/98 mmHg after she had taken **imipramine** 50 mg daily for two days, and fell again when it was stopped.¹

Mechanism

Uncertain. A possible reason is that, like clonidine (another alpha-2 agonist), the uptake of guanfacine into neurones within the brain is blocked by tricyclic antidepressants, thereby reducing its effects.

Importance and management

Direct information is limited to this report, but it is supported by *animal studies*² and consistent with the way another alpha-2 agonist interacts with tricyclic antidepressants (see 'Clonidine + Tricyclic and related antidepressants', p.884). Be alert for this interaction in any patient given guanfacine and any tricyclic antidepressant. **Guanabenz** is another alpha-2 agonist that might interact similarly, but as yet there is no direct clinical evidence that it does so. Note that the sedative effects of guanfacine or **guanabenz** and tricyclics would be predicted to be additive.

Hydralazine + Adrenaline (Epinephrine)

The manufacturers note that patients taking hydralazine who develop hypotension while undergoing surgery should not be treated with adrenaline (epinephrine).¹ This is because hydralazine frequently causes tachycardia,² and adrenaline would enhance this.¹

1. Apresoline (Hydralazine hydrochloride). Amdipharm. UK Summary of product characteristics, March 2005.
2. Lin M-S, McNay JL, Shepherd AMM, Musgrave GE, Keeton TK. Increased plasma norepinephrine accompanies persistent tachycardia after hydralazine. *Hypertension* (1983) 5, 257–63.

Hydralazine + Food

The effect of food on hydralazine absorption is uncertain: food increased the AUC of hydralazine in two studies, had no effect in one study, and decreased it in three others. In other studies, a bolus dose of enteral feed decreased the AUC of hydralazine, but an enteral feed infusion had no effect.

Clinical evidence, mechanism, importance and management

Food *enhanced* the bioavailability of a single 50-mg dose of hydralazine in healthy subjects by two to threefold in one study.¹ Similar findings were reported by the same research group with conventional hydralazine tablets, but not slow-release tablets.² In contrast, others found that food had no effect on the AUC of hydralazine in healthy subjects.³ Furthermore, other studies have found that food decreases the AUC of hydralazine by 46% when it is given as oral solution,⁴ by 44% after conventional tablets,⁵ and by 29% (not significant) after a slow-release preparation.⁵ A reduction in the antihypertensive effect of hydralazine was noted in the first of these studies,⁴ but no significant alteration in antihypertensive effect was seen in the second.⁵ Similarly, another study reported a decrease in the AUC of hydralazine of 55% when it was given with a meal, and 62% when it was

given with a bolus dose of **enteral feed**, but no significant change when it was given during an **enteral feed infusion**.⁶

The widely different findings of these studies may be related to the problems in analysing hydralazine and its metabolites, all of which are unstable. All these studies were single-dose, and no studies have adequately assessed the possible clinical importance of any pharmacokinetic changes in long-term clinical use. Note that the bioavailability of hydralazine varies widely between individuals depending on their acetylator status. No recommendations can be made as to whether or not hydralazine should be taken at a set time in relation to meals.

Hydralazine + NSAIDs

Oral indometacin abolished the hypotensive effects of intravenous hydralazine in one study, but no effect was found in another. In patients with pulmonary hypertension, intravenous indometacin reduced the effects of intravenous hydralazine, and in patients with hypertension, intravenous diclofenac reduced the effects of intravenous dihydralazine.

Clinical evidence, mechanism, importance and management

In 9 healthy subjects, oral **indometacin** 50 mg every 6 hours for 4 doses abolished the hypotensive response to intravenous hydralazine 150 micrograms/kg, and the subjects only responded when given another dose of hydralazine 30 minutes later.¹ A study in 7 patients with pulmonary hypertension given **indometacin** 50 mg and hydralazine 350 micrograms/kg, both intravenously, either alone, or concurrently, also found that the effects of hydralazine (reduction in systemic arterial pressure, heart rate, cardiac index) were reduced by **indometacin**.² In contrast, another study in 9 healthy subjects³ found that oral **indometacin** 25 mg four times daily for 2.5 days did not affect the hypotensive response to a single 200-microgram/kg intravenous dose of hydralazine.

Thus it is not clear if **indometacin** interacts with intravenous hydralazine, and it is uncertain if an interaction occurs when hydralazine is given orally.

On the other hand, a single-dose study in 4 hypertensive subjects found that the actions of intravenous **dihydralazine** (effects on blood pressure, urinary excretion, heart rate and sodium clearance) were reduced by intravenous **diclofenac**.⁴

NSAIDs can cause increases in blood pressure due to their effects on sodium and water retention. Various NSAIDs have been reported to reduce the efficacy of other antihypertensive drug classes, for example see 'ACE inhibitors + NSAIDs', p.28. It would therefore be prudent to monitor concurrent use of hydralazine and NSAIDs.

Inotropes and Vasopressors + Antimuscarinics

The hypertensive and other serious adverse effects of intravenous phenylephrine and phenylephrine absorbed from eye drops can be markedly increased by intravenous or intramuscular atropine.

Clinical evidence

A brief report describes 7 cases of pseudo-phaeochromocytoma, with severe rises in blood pressure and tachycardia, which occurred in young adults and children when they underwent eye operations and were given phenylephrine 10% eye drops and atropine. Only two of them had any pre-existing cardiovascular illness (moderate hypertension). All were under general anaesthesia with propofol, phenoperidine and vecuronium, and premedicated with intramuscular atropine, and some were later given more intravenous atropine to control the bradycardia, which occurred as a result of stretching the oculomotor muscles. The total atropine doses were less than 10 micrograms/kg in adults and 20 micrograms/kg in children. At least 0.4 mL of phenylephrine 10% was used. In three cases left ventricular failure and pulmonary oedema occurred, which needed monitoring in intensive care. The authors say that no further cardiovascular adverse events were observed during similar procedures when steps were taken to reduce the amount of phenylephrine used and absorbed (see Importance and Management, below).¹ Prior to this case report, a number of cases of cardiovascular adverse effects (severe hypertension, cardiac arrhythmias, myocardial infarction) had been reported for phenylephrine eye drops (usually 10%), or as a subconjunctival injection, and many of these patients had also received antimuscarinics (atropine, cyclopentolate, homatropine, hyoscine, tropicamide),²⁻⁶ although the contribution, if any, of these antimuscarinics to the adverse effects is unknown.

In a study, 6 healthy subjects were given an intravenous phenylephrine infusion at incremental rates before and after being given three intravenous doses of atropine (20, 10, and 10 micrograms/kg) at 90, 120 and 150 minutes. It was found that phenylephrine 420 nanograms/kg per minute raised the diastolic and systolic blood pressures by 4 mmHg before using atropine, and 17 mmHg after atropine was given. For safety reasons the increases in blood pressure were limited to 30 mmHg above the baseline.⁷

Mechanism

Phenylephrine causes vasoconstriction, which can raise the blood pressure. Normally this would be limited by a baroreflex mediated by the vagus nerve, but if this cholinergic mechanism is blocked by atropine or other antimuscarinics, the rise in blood pressure is largely uncontrolled. Severe hypertension may occur, and other adverse cardiac events such as acute cardiac failure may follow.

Importance and management

A surprisingly large amount of phenylephrine can be absorbed from eye drops, and the potential cardiovascular adverse effects of this are well documented. The reports cited here suggest that these risks are clearly increased by the systemic use of atropine. The authors of one of the reports¹ found that the systemic absorption of phenylephrine can be reduced by using lower concentrations of phenylephrine, swabbing to minimise the amount that drains into the nasolachrymal duct to the nasal mucosa where rapid absorption occurs, and reducing the drop size by using a thin-walled cannula. Others have demonstrated that a cannula reduced the dose of phenylephrine given by two-thirds without loss of efficacy.⁸ Other suggestions for reducing systemic absorption of phenylephrine are punctal plugging, nasolachrymal duct compression, and lid closure after instillation of the eye drop.⁸ Note that phenylephrine eye drops are contraindicated in those with cardiovascular disease.⁹ Note also that topical phenylephrine is commonly used with a topical antimuscarinic to enhance mydriasis.

Inotropes and Vasopressors + Calcium compounds

Calcium chloride infusions reduce the cardiotoxic effects of adrenaline (epinephrine) and dobutamine, but not those of amrinone.

Clinical evidence, mechanism, importance and management

In a double-blind, randomised, crossover study in 12 patients following coronary artery bypass grafting, calcium chloride (10 mg/kg bolus followed by 2 mg/kg per hour infusion) was found to attenuate the effects of adrenaline (epinephrine) 10 and 30 nanograms/kg per minute, given for 8 minutes each. Adrenaline alone produced a significant increase in the cardiac index, but following the calcium infusion adrenaline had no significant effect and the maximal adrenaline-induced increase in cardiac index was reduced by 70%. Adrenaline 30 nanograms/kg per minute alone increased mean arterial blood pressure from 87 to 95 mmHg; calcium chloride also raised blood pressure from 85 to 93 mmHg. After calcium was given, adrenaline had no further significant effect on blood pressure.¹

Some of these workers also studied the mode of action of dobutamine in 22 patients recovering from coronary artery bypass surgery.² It was found that an infusion of calcium chloride (1 mg/kg per minute initially, then 0.25 mg/kg per minute) reduced the increase in cardiac output produced by an infusion of dobutamine 2.5 to 5 micrograms/kg per minute by 30%. In a group of 24 similar patients the cardiotoxic actions of amrinone (a phosphodiesterase inhibitor) were unaffected by the calcium infusion.²

Just how the calcium alters the effects of adrenaline and dobutamine is not known, but since they are both beta-receptor agonists a reasonable suggestion is that calcium interferes with the signal transduction through the beta-adrenergic receptor complex. The clinical importance of these findings is uncertain.

Inotropes and Vasopressors + Cimetidine

An exaggerated hypertensive response to dobutamine occurred during anaesthetic induction in a patient taking cimetidine. Another case report describes supraventricular tachycardia, which occurred when a patient receiving dobutamine and dopamine was given cimetidine.

Clinical evidence, mechanism, importance and management

A patient about to undergo coronary artery bypass grafting was anaesthetised with midazolam, fentanyl, vecuronium and oxygen. When a 5 microgram/kg per minute infusion of dobutamine was given the patient developed unexpectedly marked hypertension of 210/100 mmHg. The infusion was stopped and over the next 15 minutes the blood pressure fell to 90/50 mmHg. A new infusion had the same hypertensive effect, and the patient's blood pressure was subsequently controlled at 120/80 mmHg with dobutamine 1 microgram/kg per minute.¹ The authors of the report suggest that this exaggerated response to dobutamine may have been due to cimetidine 1 g daily, which the patient was also taking. They postulate that the cimetidine may possibly have inhibited the metabolism and clearance of the dobutamine by the liver, thereby increasing its effects.¹

A post-operative patient receiving dopamine and dobutamine infusions developed a supraventricular tachycardia 30 seconds after an intravenous injection of cimetidine. Similar episodes of tachycardia occurred on rechallenge with both drugs, but not when each drug was given separately.²

These are isolated cases and the general importance is not known but it seems likely to be small.

Inotropes and Vasopressors + Clonidine

Experimental studies in patients show that pretreatment with clonidine decreases the blood pressure response to small doses of dopamine; does not affect the blood pressure response to noradrenaline (norepinephrine); and can increase the blood pressure responses to dobutamine, ephedrine, isoprenaline (isoproterenol) and phenylephrine.

Clinical evidence

In a study in 70 patients undergoing elective surgery, 35 patients were given clonidine 5 micrograms/kg 90 minutes before the induction of anaesthesia and 35 patients were used as a control group. While under anaesthesia, and when haemodynamically stable for at least 10 minutes, all patients were given a 10-minute infusion of **dopamine** 3 or 5 micrograms/kg per minute or **dobutamine** 0.5, 1, or 3 micrograms/kg per minute.¹ Clonidine attenuated the response to the 5 micrograms/kg per minute dose of **dopamine** (blood pressure rise 19/10 mmHg in the control group but only 4/0 mmHg in the clonidine group). However, **dopamine** 3 micrograms/kg per minute did not significantly affect blood pressure in either the control group or the clonidine group. Conversely, clonidine enhanced the response to **dobutamine** at all 3 doses. The study had to be stopped after 2 minutes in the clonidine group receiving the highest dose of **dobutamine** as the rise in blood pressure exceeded the study limits (rise 45/24 mmHg compared with 16/7 mmHg in the control group).¹ In a study of the same design, 20 clonidine-treated patients and 20 controls were given a bolus infusion of **phenylephrine** 3 micrograms/kg or **isoprenaline (isoproterenol)** 0.02 micrograms/kg. Those who received clonidine had a greater and more prolonged increase in arterial pressure and heart rate with **phenylephrine** (10 minutes compared with 2 to 3 minutes) and increase in heart rate (but not arterial pressure) with **isoprenaline (isoproterenol)**.²

In another similar study, 77 patients (38 premedicated with clonidine 5 micrograms/kg and famotidine 20 mg, 90 minutes before anaesthetic induction, and a control group of 39 given only famotidine) were given **noradrenaline (norepinephrine)** 0.5 micrograms/kg or **phenylephrine** 2 micrograms/kg. It was found that the overall response to **noradrenaline (norepinephrine)** was not significantly affected by clonidine, although 2 to 4 minutes after administration the mean arterial blood pressure was raised in the clonidine group. The blood pressure rise in response to **phenylephrine** was found to be augmented. There were no significant differences between the groups in terms of the incidence of hypertension, arrhythmias or bradycardia.³ Similar results have been reported with phenylephrine in other studies (see below). The same group of workers repeated this study using two doses of **ephedrine** 100 micrograms/kg as the vasopressor. Clonidine prolonged the response to **ephedrine** by 2 minutes and increased the rise in blood pressure (rise in mean blood pressure in response to **ephedrine** at 3 minutes of 12.7 mmHg with clonidine, compared with 6.6 mmHg without clonidine). The rise in blood pressure was greater in both groups after a second dose of **ephedrine** was given but the effect in the clonidine group was still greater (rise in mean blood pressure in response to **ephedrine** at 4 minutes of 15 mmHg with clonidine compared with 9.4 mmHg without clonidine).⁴

Further study by these same workers, using enflurane and nitrous oxide/oxygen for anaesthesia, found that the mean maximum blood pressure increases in a group of patients premedicated with clonidine and given intravenous **phenylephrine** 2 micrograms/kg were 26% and 32%, for awake and anaesthetised subjects, respectively. This was greater than the blood pressure rises seen in a group not given clonidine, which were 13% and 18%, for awake and anaesthetised subjects, respectively.⁵

Similar additional effects on blood pressure were found in patients given intravenous **ephedrine** 100 micrograms/kg after pretreatment with clonidine.⁶

Mechanism

Not understood, although clonidine is an α_2 agonist, which blocks the release of noradrenaline (norepinephrine) from the nerve endings, and most suggested mechanisms consider noradrenaline release to be involved in some way.

Importance and management

An interaction is established, although the exact outcome of the concurrent use of clonidine and these sympathomimetic vasopressors is not clear. It has been suggested that the effects may be different at different doses of dopamine.⁵ The authors of the one report,³ studying phenylephrine and noradrenaline (norepinephrine) with clonidine, suggested that the increase in pressor response was unlikely to be clinically significant.

Be aware that dobutamine, ephedrine, and phenylephrine may have a greater than expected effect if clonidine has been taken. Some of these drugs may also be used as nasal decongestants (e.g. ephedrine, and phenylephrine). The outcome of the concurrent use of clonidine in these circumstances is unclear, but a rise in blood pressure seems possible. However, note that these products are usually cautioned in patients with hypertension.

Inotropes and Vasopressors + Ergometrine (Ergonovine)

An isolated report attributes the development of gangrene and subsequently fatal septicaemia to the use of dopamine following the use of ergometrine. A similar case has been reported with ergometrine and noradrenaline (norepinephrine).

Clinical evidence, mechanism, importance and management

One patient developed gangrene of the hands and feet after being given an infusion of **dopamine** (10 micrograms/kg per minute, later doubled) started approximately 2 hours after the use of ergometrine (two 400 microgram doses).¹ This would seem to have resulted from the additive peripheral vasoconstrictor effects of both drugs, which reduced the circulation to such an extent that gangrene and then fatal septicaemia developed. Note that gangrene has been reported with the use of both drugs alone, and it is recommended that peripheral tissue perfusion should be monitored in elderly patients or patients with a history of peripheral vascular disease receiving **dopamine**.² This would also seem to be a prudent precaution in those who have previously received ergometrine.

A similar case report describes a pregnant woman (24-week gestation) with severe burns who received ergometrine to treat post-partum bleeding after spontaneous abortion and **noradrenaline (norepinephrine)** to treat hypotensive septic shock. The combination of these two vasoconstrictors is thought to have contributed to ischaemia of the fingers, resulting in loss of some digits.³ In the rare circumstances when it may be necessary to use both of these drugs, close attention should be paid to peripheral tissue perfusion.

Inotropes and Vasopressors + Guanethidine

The pressor effects of noradrenaline (norepinephrine), phenylephrine, and metaraminol can be increased in the presence of guanethidine. These drugs can also be used as eye drops, and in this situation their mydriatic effects are similarly enhanced and prolonged by guanethidine.

Clinical evidence

(a) Blood pressure response

A study in 6 normotensive subjects given guanethidine 200 mg on the first day of the study and 100 mg daily for the next 2 days, found that their mean arterial blood pressure in response to a range of doses of **noradrenaline (norepinephrine)**, was increased by 6 to 18% (a 6 to 20 mmHg increase). Moreover, cardiac arrhythmias appeared at lower doses of **noradrenaline** and with greater frequency than in the absence of guanethidine, and were more serious in nature.¹

In another report, a patient taking guanethidine 20 mg daily was given intramuscular **metaraminol** 10 mg, which rapidly caused the blood pressure to rise to 220/130 mmHg accompanied by severe headache and extreme angina.² An increase in blood pressure from 165/90 to 170/110 mmHg was also seen in a patient taking guanethidine who, prior to surgery, was given **phenylephrine** eye drops.³

(b) Mydriatic response

The mydriasis due to **phenylephrine** given as a 10% eye drop solution was prolonged for up to 10 hours in a patient taking guanethidine for hypertension.⁴ This enhanced mydriatic response has been described in another study using guanethidine eye drops with **adrenaline (epinephrine)**, **phenylephrine** or **methoxamine** eye drops.⁵

Mechanism

By preventing the release of noradrenaline from adrenergic neurones, guanethidine and other adrenergic neurone blockers cause a temporary 'drug-induced sympathectomy', which is also accompanied by hypersensitivity of the receptors. This results in the increased response to the stimulation of the receptors by directly-acting sympathomimetics such as noradrenaline and phenylephrine.

Importance and management

An established, well-documented and potentially serious interaction. Since the pressor effects can be grossly exaggerated, dosages of directly-acting sympathomimetics (alpha-agonists) should be reduced appropriately. In addition it should be remembered that the incidence and severity of cardiac arrhythmias is increased.¹ Considerable care is required. Direct evidence seems to be limited to noradrenaline (norepinephrine), phenylephrine, metaraminol, and methoxamine. **Dopamine** also possess direct sympathomimetic activity and may be expected to interact similarly. If as a result of this interaction the blood pressure becomes grossly elevated, it can be controlled by giving an alpha-adrenergic blocker such as phentolamine.⁶ Phenylephrine is contained in a number of non-prescription cough and cold preparations, which may contain 12 mg in a dose. A single dose of this size is only likely to cause a moderate blood pressure rise. However, this requires confirmation, particularly since the non-prescription products may be taken up to 4 times daily for up to 7 days, and higher doses may be available in some countries.

An exaggerated pressor response is clearly much more potentially serious than enhanced and prolonged mydriasis, but the latter is also possible and undesirable. The same precautions apply about using smaller amounts of the sympathomimetic drugs. Note that many indirectly-acting sympathomimetics can antagonise the blood pressure lowering effect of guanethidine, see 'Guanethidine + Amfetamines and related drugs', p.886. The sympathomimetics are classified in 'Table 24.1', (p.879).

Inotropes and Vasopressors + Lithium

The pressor effects of noradrenaline (norepinephrine) and phenylephrine are slightly reduced by lithium carbonate.

Clinical evidence, mechanism, importance and management

A study in 8 patients with 'manic depression' found that after taking lithium carbonate for 7 to 10 days (serum level range 0.72 to 1.62 mmol/L) the dosage of a **noradrenaline (norepinephrine)** infusion had to be increased by 1.8 micrograms in 7 patients to maintain a blood pressure increase of 25 mmHg. This equated to a 22% reduction in the pressor effect of **noradrenaline (norepinephrine)**.¹ Another study in 17 depressed patients with serum lithium levels in the range 0.8 to 1.2 mmol/L found that 12% more **noradrenaline (norepinephrine)** and 31% more **phenylephrine** was needed to raise the blood pressure by 30 mmHg.² The reasons for this interaction are not known.

These decreases in the pressor response to **noradrenaline (norepinephrine)** and to **phenylephrine** in the presence of lithium carbonate are both relatively small and it seems unlikely that they will present any problems in practice.

- Ghose K. Assessment of peripheral adrenergic activity and its interactions with drugs in man. *Eur J Clin Pharmacol* (1980) 17, 233-8.

Inotropes and Vasopressors + Reserpine

The effects of adrenaline (epinephrine), noradrenaline (norepinephrine) and other directly-acting sympathomimetics are slightly increased in the presence of reserpine.

Clinical evidence

Pretreatment with **phenylephrine** 10% eye drops caused a blood pressure increase of 30/12 mmHg in 11 patients taking reserpine, whereas no significant increase in blood pressure occurred in 176 patients who were given **phenylephrine** eye drops and who were not taking reserpine.¹ After 7 healthy subjects took reserpine 0.25 to 1 mg daily for 2 weeks the increase in the blood pressure response to **noradrenaline (norepinephrine)** was increased by 20 to 40%.² A man taking reserpine who became hypotensive while undergoing surgery failed to respond to an intravenous injection of ephedrine, but did so after 30 minutes treatment with **noradrenaline**, presumably because the stores of **noradrenaline** at adrenergic neurones had become replenished.³ The mydriatic effects of **ephedrine** have also been shown to be antagonised by pretreatment with reserpine.⁴ However, in contrast, one report claimed that ephedrine 25 mg given orally or intramuscularly, once or twice daily, proved to be an effective treatment for reserpine-induced hypotension and bradycardia in schizophrenic patients.⁵

Studies in dogs have demonstrated that **adrenaline (epinephrine)**, **noradrenaline (norepinephrine)** and **phenylephrine** (all sympathomimetics with direct actions) remain effective vasopressors after treatment with reserpine, and their actions are enhanced to some extent.⁶⁻⁸ **Metaraminol** has also been successfully used to raise blood pressure in reserpine-treated patients.⁹

Mechanism

The rauwolfia alkaloids (e.g. reserpine) cause adrenergic neurones to lose their stores of noradrenaline (norepinephrine), so that they can no longer stimulate adrenergic receptors and transmission ceases. Indirectly-acting sympathomimetics, which work by stimulating the release of stored noradrenaline, may therefore be expected to become ineffective. In contrast, the effects of directly-acting sympathomimetics should remain unchanged. However, their effects may be enhanced (as described above) because when the receptors are deprived of stimulation by noradrenaline for any length of time they can become supersensitive. Drugs with mixed direct and indirect actions, such as ephedrine, should fall somewhere between the two, although the reports cited seem to indicate that ephedrine has predominantly indirect activity.^{3,4}

Importance and management

These are established interactions, but the paucity of clinical information suggests that in practice they do not present many problems, perhaps because the effects of these vasopressors are so closely monitored, and titrated to effect. If a pressor drug is required, a directly-acting drug such as noradrenaline (norepinephrine) or phenylephrine may be expected to be effective. The receptors may show some supersensitivity so that a dosage

reduction may be required. 'Table 24.1', (p.879) gives a classification of the sympathomimetics.

Inotropes and Vasopressors; Dobutamine + Dipyridamole

The addition of dipyridamole to dobutamine for echocardiography can cause potentially hazardous hypotension.

Clinical evidence, mechanism, importance and management

Ten patients with a low probability of coronary artery disease underwent dobutamine echocardiography. Five were given dobutamine alone, while the other 5 were given a low intravenous dose of dipyridamole with the maximal dose of dobutamine, to see whether the sensitivity of the test could be improved. Four of the patients given both drugs experienced severe hypotension while no hypotension was seen in the control group. The conclusion was reached that this combination of drugs can be hazardous and should not be used in patients suspected of coronary heart disease.¹ Note that, although both of these drugs are commonly used in stress echocardiography, they are not given together.

1. Shaheen J, Rosenmann D, Tzivoni D. Severe hypotension induced by combination of dobutamine and dipyridamole. *Isr J Med Sci* (1996) 32, 1105–7.

Inotropes and Vasopressors; Dopamine + Phenytoin

Some limited evidence suggests that patients needing dopamine to support their blood pressure can become severely hypotensive if they are also given intravenous phenytoin.

Clinical evidence, mechanism, importance and management

Five critically ill patients treated with a number of different drugs, were given dopamine to maintain an adequate blood pressure. When seizures developed they were given intravenous phenytoin at an infusion rate of 5 to 25 mg/minute. Their previously stable blood pressures then fell rapidly, one patient became bradycardic, and two patients died from cardiac arrest. A similar reaction was found in *dogs* made hypovolaemic and hypotensive by bleeding, and then given dopamine followed by a phenytoin infusion.¹ However, another study in *dogs* was unable to find evidence of this serious adverse interaction,² and no evidence of marked hypotension occurred when a patient with cardiogenic shock was given a phenytoin infusion while receiving dopamine and dobutamine.³

The documentation of this adverse interaction therefore appears to be limited to this single report. However, intravenous phenytoin is known to cause hypotension if it is given rapidly, particularly in gravely ill patients. Blood pressure is doubtless being monitored in patients receiving dopamine, and should be measured when phenytoin is given intravenously. However, more frequent monitoring may be necessary initially, as this interaction develops rapidly.

Inotropes and Vasopressors; Dopamine + Selegiline

A case report describes a hypertensive reaction attributed to the concurrent use of dopamine and selegiline.

Clinical evidence, mechanism, importance and management

A 75-year-old man, who was taking selegiline 5 mg twice daily for Parkinson's disease, was given intravenous dopamine 3.5 micrograms/kg per minute because of a decline in blood pressure and urine output following a serious road traffic accident. Twenty minutes after the infusion was started his blood pressure had hardly changed, but 30 minutes later it had risen from 108/33 to 228/50 mmHg. The dopamine infusion was discontinued and the blood pressure decreased to 121/40 mmHg over the next 30 minutes. The dopamine infusion was reinstated twice more at lower doses (1.03 and 0.9 micrograms/kg per minute), but each time similar reactions occurred. The exaggerated vasopressor response was thought to be due to inhibition of dopamine metabolism by selegiline.¹

The authors of the report¹ and the manufacturers of selegiline recommend that dopamine should be used cautiously,² and only after careful risk-benefit assessment,³ in patients who are currently taking selegiline or who have taken selegiline in the 2 weeks prior to dopamine therapy. In addition, the manufacturers of dopamine warn that in patients who have received MAOIs within the previous 2 to 3 weeks, the initial dose of dopamine should be no greater than 10% of the usual dose.⁴

Inotropes and Vasopressors; Dopamine + Tolazoline

Acute and eventually fatal hypotension occurred in a patient given dopamine and tolazoline.

Clinical evidence

A patient receiving ventilatory support following surgery was given dopamine on the third postoperative day. Pulmonary arterial pressure had been steadily rising since the surgery, so on day 4 he was given a slow 2-mg/kg bolus injection of tolazoline. Systemic arterial pressure immediately fell to 50/30 mmHg so the dopamine infusion was increased but, contrary to the expected effect, the arterial pressure then fell even further to 38/15 mmHg. The dopamine was stopped and ephedrine, methoxamine and fresh frozen plasma were given. Two hours later his blood pressure was 70/40 mmHg. Two further attempts were made to give dopamine, but the arterial pressure fell to 40/15 mmHg on the first occasion, and to 38/20 mmHg on the second, which resulted in a fatal cardiac arrest.¹

Mechanism

Not fully understood. Dopamine has both alpha (vasoconstrictor) and beta (vasodilator) activity. With the alpha effects on the systemic circulation competitively blocked by the tolazoline, its vasodilatory actions would predominate, resulting in paradoxical hypotension.

Importance and management

Information is limited but this interaction would appear to be established. The authors of this report warn that an infusion of dopamine should not be considered for several hours after even a small single dose of tolazoline has been given. They point out that impaired renal function often accompanies severe respiratory failure, which may significantly prolong the effects of tolazoline.

Ivabradine + CYP3A4 inducers

The metabolism of ivabradine may be increased by CYP3A4 inducers including barbiturates, phenytoin, rifampicin, and St John's wort.

Clinical evidence, mechanism, importance and management

St John's wort (*Hypericum perforatum*) reduced the AUC of ivabradine 10 mg twice daily by half.¹ St John's wort is a known inducer of the cytochrome P450 isoenzyme CYP3A4, by which ivabradine is metabolised. Concurrent use therefore decreases ivabradine levels, and as a result probably reduces its effects (although this does not appear to have been studied) increase the metabolism of ivabradine, which results in a reduction in its plasma levels.¹ The manufacturers suggest that the use of St John's wort should be restricted in patients taking ivabradine. They also advise that patients taking other CYP3A4 inducers (they specifically name **barbiturates, phenytoin, and rifampicin**) may need dosage increases of ivabradine.¹ Monitor concurrent use for ivabradine efficacy and adjust the dose as necessary. Remember to re-adjust the dose of ivabradine if concurrent use of these drugs is stopped.

1. Procoralan (Ivabradine hydrochloride) Servier Laboratories Ltd. UK Summary of product characteristics, March 2007.

Ivabradine + CYP3A4 inhibitors

Ivabradine is metabolised by CYP3A4 and its levels may therefore be increased significantly in the presence of inhibitors of this isoenzyme, such as some azoles, diltiazem, some macrolides, nefazodone, protease inhibitors, or verapamil.

Clinical evidence

A study found that ketoconazole 200 mg daily or josamycin 1 g twice daily increased ivabradine plasma levels by seven to eightfold. Studies in healthy subjects given diltiazem or verapamil have resulted in an increase in the AUC of ivabradine of two to threefold, and an additional heart rate reduction of 5 bpm.¹

Mechanism

Ivabradine is a substrate of the cytochrome P450 isoenzyme CYP3A4, and its metabolism is reduced by inhibitors of CYP3A4, resulting in increased plasma levels and increased therapeutic effects.¹

Importance and management

The manufacturers contraindicate the use of potent inhibitors of CYP3A4 with ivabradine, (they specifically mention **clarithromycin, oral erythromycin, itraconazole, josamycin, ketoconazole, nefazodone, nelfinavir, ritonavir, and telithromycin**). The manufacturers suggest that if moderate inhibitors of CYP3A4 are given (they name **fluconazole**) ivabradine may be used, but at a lower starting dose of 2.5 mg, with consideration of heart rate monitoring.¹ Diltiazem and verapamil are also moderate inhibitors of CYP3A4, but their use is not recommended because of their effects on heart rate. Note that clinically relevant inhibitors of CYP3A4 are listed in 'Table 1.4', (p.6).

1. Procoralan (Ivabradine hydrochloride) Servier Laboratories Ltd. UK Summary of product characteristics, March 2007.

Ivabradine + Drugs that prolong the QT interval

The manufacturers advise that ivabradine should not be taken with drugs that prolong the QT interval. Bradycardia is a pharmacological effect of ivabradine, and QT prolongation may be exacerbated by heart rate reductions.¹ For a list of drugs known to affect the QT interval see 'Table 9.2', (p.257).

1. Procoralan (Ivabradine hydrochloride). Servier Laboratories Ltd. UK Summary of product characteristics, March 2007.

Ivabradine + Grapefruit juice

Grapefruit juice inhibits the metabolism of ivabradine.

Clinical evidence, mechanism, importance and management

Grapefruit juice increases the exposure to ivabradine exposure twofold. This interaction probably occur because grapefruit inhibits the cytochrome P450 isoenzyme CYP3A4 in the intestine, by which ivabradine is metabolised. This leads to increased levels, which increases the risks of adverse effects such as profound bradycardia. The manufacturers recommend that the intake of grapefruit juice by patients also taking ivabradine is restricted.¹ However, note that they contraindicate the use of other drugs that increase ivabradine levels by a similar amount, and so it would seem that concurrent use is best avoided.

1. Procoralan (Ivabradine hydrochloride) Servier Laboratories Ltd. UK Summary of product characteristics, March 2007.

Ivabradine + Miscellaneous

The manufacturers say that in specific drug-drug interaction studies, ivabradine was not found to interact with proton pump inhibitors (omeprazole, lansoprazole), sildenafil, statins (simvastatin), dihydropyridine calcium-channel blockers (amlodipine, lacidipine), digoxin and warfarin. During clinical studies, ivabradine was taken with ACE inhibitors, angiotensin II receptor antagonists, diuretics, short and long acting nitrates, statins, fibrates, proton pump inhibitors, oral antidiabetics, aspirin and other antiplatelet drugs, and there was no evidence of safety concerns.¹

Ketanserin + Beta blockers

There is no pharmacokinetic interaction between ketanserin and propranolol, but additive hypotensive effects may occur. Very marked acute hypotension has been seen in two patients taking atenolol when they were first given ketanserin.

Clinical evidence, mechanism, importance and management

A study in 6 patients and 2 healthy subjects given ketanserin 40 mg twice daily for 3 weeks found that **propranolol** 80 mg twice daily for 6 days did not significantly alter the steady-state plasma levels of ketanserin.¹ Another study in healthy subjects, using single doses of both drugs, found that neither drug affected the pharmacokinetics of the other.² In a third study, **propranolol** 80 mg twice daily had no effect on the pharmacokinetics of a single 10-mg intravenous dose of ketanserin. However, ketanserin 40 mg twice daily modestly decreased the clearance of a single 160-mg dose of **propranolol** by 29% and increased its maximum serum level by 38%, although neither of these changes were statistically significant.³ The hypotensive effects of ketanserin were slightly increased by **propranolol** in the first study,¹ and additive hypotensive effects were seen in another study in patients with essential hypertension.⁴

Acute hypotension is reported to have occurred in two patients taking **atenolol** within an hour of taking a 40-mg oral dose of ketanserin. One of them briefly lost consciousness.⁵

The concurrent use of ketanserin and beta blockers can be valuable and uneventful, but a few patients may experience marked hypotensive effects when first given ketanserin. Patients should be warned.

Ketanserin + Diuretics

Sudden deaths, probably from cardiac arrhythmias, were markedly increased in patients taking potassium-depleting diuretics and high doses of ketanserin. No interaction occurred with low doses of ketanserin in those with normal potassium levels. Potassium-sparing diuretics do not interact in this way.

Clinical evidence

A large multi-national study¹ in 3899 patients found that a harmful and potentially fatal interaction could occur in those given ketanserin 40 mg three times daily and **potassium-depleting diuretics**. Of 249 patients taking both drugs, 35 died (16 suddenly) compared with only 15 (5 suddenly) of 260 patients taking a placebo and **potassium-depleting diuretics**. No significant increase in the number of deaths occurred in those taking ketanserin and **potassium-sparing diuretics**.

It was found that the corrected QT interval was prolonged as follows: ketanserin alone 18 milliseconds, ketanserin with **potassium-sparing diuretics** 24 milliseconds, ketanserin with **potassium-depleting diuretics** 30 milliseconds. Preliminary results of a later study in 33 patients using a smaller dose of ketanserin (20 mg twice daily) with **potassium-depleting diuretics (furosemide, thiazides)** found no evidence of a prolonged QTc interval in patients with normal potassium levels.² The pharmacokinetics of a single 20-mg dose of ketanserin were not altered by single 25-mg doses of **hydrochlorothiazide**.³

Mechanism

Potassium-depleting diuretics may cause hypokalaemia, which increases the risk of QT-prolongation and torsade de pointes arrhythmia, which can result in sudden death. Ketanserin also prolongs the QT interval in a dose-related way, and its effects would be expected to be additive with that of diuretic-induced hypokalaemia. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Importance and management

The use of potassium-depleting diuretics (see 'Table 26.1', (p.944)) with ketanserin 40 mg three times daily should be avoided. Lower doses of ketanserin (20 mg twice daily) have less effect on the QT interval, and can probably be used cautiously with potassium-depleting diuretics, as long as serum potassium levels are maintained. Potassium-sparing diuretics do not interact.

Ketanserin + Miscellaneous

Ketanserin should not be given with certain antiarrhythmics, nifedipine, or tricyclic antidepressants because of the risk of potentially fatal cardiac arrhythmias. Drowsiness and dizziness are common adverse effects, which may possibly be additive with the effects of other CNS depressants.

Clinical evidence, mechanism, importance and management

Ketanserin has weak class III antiarrhythmic activity and can prolong the QTc interval. For safety reasons it has therefore been advised that it should be avoided in patients with existing QTc prolongation, atrioventricular or sinoauricular block of higher degree, or severe bradycardia of less than 50 bpm.¹ For the same reason the concurrent use of drugs that affect repolarisation (**class Ia, Ic and III arrhythmics**) or those that cause conduction disturbances (**naftidrofuryl, tricyclic antidepressants**) should be avoided.¹ See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257, and 'Ketanserin + Diuretics', above.

Dizziness and drowsiness are common adverse effects of ketanserin and

therefore it seems likely that these will be additive with other **CNS depressants** and **alcohol**, which may possibly make driving more hazardous, but this needs confirmation.

1. Distler A. Clinical aspects during therapy with the serotonin antagonist ketanserin. *Clin Physiol Biochem* (1990) 8 (Suppl 3), 64–80.

Ketanserin + Nifedipine

Two patients experienced an increase in cardiac arrhythmias when they were given ketanserin with nifedipine.

Clinical evidence, mechanism, importance and management

A study in 20 subjects aged 60 years or more, with normal or slightly raised blood pressures, found that the concurrent use of ketanserin and nifedipine for a week did not, on average, affect their blood pressures, heart rates, or QT intervals, but two of the subjects monitored over 24 hours showed a marked increase in the frequency of ectopic beats, couplets and ventricular tachycardia.¹ The reasons are not understood. The authors of this study say that their findings do not exclude the possibility that the concurrent use of these two drugs might therefore increase arrhythmia in some elderly patients.¹ Concurrent use should be monitored.

Levosimendan + Miscellaneous

Orthostatic hypotension occurred when levosimendan was given with isosorbide mononitrate. The haemodynamic effects of levosimendan were not significantly altered by captopril, carvedilol or other unnamed beta blockers, or felodipine. Levosimendan does not alter the effects of warfarin. Itraconazole does not alter the pharmacokinetics of levosimendan. Levosimendan appears not to interact adversely with alcohol.

Clinical evidence, mechanism, importance and management

(a) Alcohol

A double-blind, randomised, crossover study in 12 healthy subjects given oral alcohol 0.8 g/kg with intravenous levosimendan 1 mg found no clinically significant pharmacokinetic or pharmacodynamic interactions.¹

(b) Beta blockers

In 12 healthy subjects carvedilol 25 mg twice daily for 7 to 9 days did not alter the effects of a single 2-mg intravenous dose of levosimendan on cardiac contractility. In addition, the heart rate and diastolic blood pressure responses were not altered, but the systolic blood pressure response was blunted.² In a study to compare levosimendan with dobutamine in patients with severe, low-output heart failure, 33 of the 102 patients receiving levosimendan were also given unnamed beta blockers. The use of a beta blocker was shown not to reduce the haemodynamic effects of levosimendan. The authors say this suggests that there may be a place for levosimendan in the management of exacerbations of heart failure not controlled by beta blockers.³

(c) Captopril

Captopril, in doses of up to 50 mg twice daily, did not change the haemodynamic effects of a single 1- or 2-mg intravenous dose of levosimendan in 24 patients with heart failure. No additional decrease in blood pressure was observed.⁴ No special precautions appear to be required if levosimendan is given to patients taking captopril.

(d) Felodipine

A study of the use of oral levosimendan 500 micrograms four times daily and felodipine 5 mg once daily in 24 men with coronary heart disease found that concurrent use was well tolerated. The felodipine did not antagonise the positive inotropic effects of the levosimendan and had no effect on exercise capacity. Both drugs increased the heart rate during exercise, and there was a slight additional effect with the combination (5 to 8 bpm

for levosimendan alone versus 6 to 10 bpm for the combination).⁵ There would appear to be no reason for avoiding concurrent use.

(e) *Isosorbide mononitrate*

In 12 healthy subjects at rest giving an infusion of levosimendan (12 micrograms/kg over 10 minutes, then 0.2 micrograms/kg/minute for 110 minutes) with a single 20-mg oral dose of isosorbide mononitrate had no additional effects on haemodynamic parameters (heart rate, blood pressure, leg blood flow, cardiac output). However, during an orthostatic test, the circulatory response of the combination was significantly potentiated, and three subjects were unable to remain standing for the stipulated time.⁶ Care is therefore required when levosimendan and isosorbide mononitrate, or similar drugs, are used concurrently.

(f) *Itraconazole*

A study in 12 healthy subjects found that the pharmacokinetics of a single 2-mg oral dose of levosimendan were unchanged by itraconazole 200 mg daily for 5 days, and there was no change in heart rates or ECGs (including the QTc interval). It was concluded that because itraconazole, a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, does not interact significantly with levosimendan, interactions with other CYP3A4 inhibitors are unlikely.⁷

(g) *Warfarin*

In an open, randomised, crossover study, 10 healthy subjects were given a single 25-mg oral dose of warfarin both before and on day 4 of a 9-day course of oral levosimendan 500 micrograms four times daily. No clinically relevant changes in the anticoagulant effects of the warfarin were seen, and levosimendan alone had no effect on blood coagulation. In addition, there was no important pharmacokinetic interaction between warfarin and levosimendan. No interactions would therefore be expected if both drugs are used concurrently.⁸

Methyldopa + Barbiturates

Methyldopa plasma levels are not altered by the use of phenobarbital.

Clinical evidence, mechanism, importance and management

Indirect evidence from one study in hypertensive subjects suggested that phenobarbital could reduce methyldopa levels,¹ but later work, which directly measured the plasma levels of methyldopa, did not find any evidence of a pharmacokinetic interaction.^{2,3}

3. Kristensen M, Jørgensen M, Hansen T. Barbiturates and methyldopa metabolism. *BMJ* (1973) 1, 49.

Methyldopa + Bile-acid binding resins

Colestyramine and colestipol are reported to have no important effect on the absorption of methyldopa.¹

1. Hunninghake DB, King S. Effect of colestyramine and colestipol on the absorption of methyldopa and hydrochlorothiazide. *Pharmacologist* (1978) 20, 220.

Methyldopa + Cephalosporins

Pustular eruptions developed in two women taking methyldopa and cefradine or cefazolin. The use of methyldopa may have been coincidental.

Clinical evidence, mechanism, importance and management

A 74-year-old black woman taking methyldopa and insulin developed pruritus on her arms and legs within 2 hours of starting to take **cefradine** 250 mg every 6 hours. **Cefradine** was stopped after 7 doses. Over the next 2 days, fever and a widespread pustular eruption developed.¹ Another 65-year-old black woman taking methyldopa and furosemide experienced severe pruritus within 8 hours of starting to receive intravenous **cefazolin sodium** 1 g every 12 hours. Over the next 2 days superficial and coalescing pustules appeared on her trunk, arms and legs.² The authors of the first report attributed the reaction to **cefradine**.¹ The authors of the second report note that the concurrent use of methyldopa may or may not have been a contributing factor in both reports.² There seem to be no other reports of this reaction.

Methyldopa + Disulfiram

An isolated report describes a patient with hypertension, which was unresponsive to methyldopa in the presence of disulfiram.

Clinical evidence, mechanism, importance and management

An alcoholic patient taking disulfiram did not respond to moderate to high doses of intravenous methyldopa, given to control his hypertension, but responded to oral low-dose clonidine. The suggested reason for this lack of response to methyldopa is that disulfiram blocks the activity of dopamine beta-hydroxylase, the enzyme responsible for the conversion of the methyldopa to its active form.¹ The general importance of this apparent interaction is uncertain.

1. McCord RW, LaCorte WS. Hypertension refractory to methyldopa in a disulfiram-treated patient. *Clin Res* (1984) 32, 923A.

Methyldopa + Haloperidol

Two cases of marked CNS adverse effects have been attributed to the use of methyldopa and haloperidol. Another patient became irritable and aggressive. In a small pilot study, the combination of methyldopa and haloperidol lowered blood pressure, and symptomatic hypotension occurred in one patient. The combination also caused marked sedation.

Clinical evidence

Two patients who had been taking methyldopa 1 to 1.5 g daily for hypertension, without problems, developed a dementia syndrome (cognitive disabilities, loss of memory, disorientation, etc.) within 3 days of starting to take haloperidol 6 to 8 mg daily for anxiety. The symptoms totally cleared within 72 hours of stopping the haloperidol.¹ Another patient treated with haloperidol for schizophrénia, and methyldopa for hypertension, became very irritable and aggressive. When the methyldopa was replaced with hydrochlorothiazide, the patient's behaviour improved dramatically.²

In a pilot study of the therapeutic potential of using haloperidol 10 mg daily with methyl dopa 500 mg daily for 4 weeks, in the treatment of schizophrenia, the supine diastolic blood pressure decreased significantly from 65 to 59.5 mmHg. Six of the 10 patients complained of dizziness, and one patient needed a reduction in the drug doses because of transient hypotension. Somnolence occurred in 8 of the 10 patients.³

Mechanism

The hypotensive effects of methyl dopa and haloperidol might be expected to be additive. The CNS effects are not understood, although methyl dopa can cause sedation, depression and dementia, and haloperidol can cause drowsiness, dizziness and depression.

Importance and management

Concurrent use need not be avoided, but it would be prudent to be on the alert for excessive sedation, excessive reductions in blood pressure or the development of other unexpected CNS adverse effects, particularly in the initial stages of concurrent use.

3. Chouinard G, Pinard G, Serrano M, Tetreault L. Potentiation of haloperidol by α -methyl dopa in the treatment of schizophrenic patients. *Curr Ther Res* (1973) 15, 473–83.

Methyl dopa + Iron compounds

The antihypertensive effects of methyl dopa can be reduced by ferrous sulfate. Ferrous gluconate appears to interact similarly.

Clinical evidence

Ferrous sulfate 325 mg three times daily was given to 5 hypertensive patients who had been taking methyl dopa 250 mg to 1.5 g daily for more than a year. After 2 weeks the blood pressures of all of them had risen, and the systolic pressures of 3 of them had risen by more than 15 mmHg. Four had diastolic blood pressure rises, two of them exceeding 10 mmHg.¹ The renal excretion of unmetabolised methyl dopa was reduced by 88% and 79% when methyl dopa was given with **ferrous sulfate** and **ferrous gluconate**, respectively.¹ A further study found that if the **ferrous sulfate** was given 2 hours before, 1 hour before or with the methyl dopa, its bioavailability was reduced by 42%, 55%, and 83%, respectively.²

Mechanism

It appears that methyl dopa chelates or complexes with the iron in the gut, reducing its absorption by about 50%.^{1,3,4} The increase in the metabolic sulfonation of the methyl dopa also seems to have a part to play.

Importance and management

Information is limited, but this interaction appears to be established and clinically important. Monitor the effects of concurrent use and increase the methyl dopa dosage as necessary. Separating the dosages by up to 2 hours apparently only partially reduces the effects of this interaction. Ferrous gluconate appears to interact like ferrous sulfate, and all iron compounds would be expected to interact similarly.

4. Greene RJ, Hall AD, Hider RC. The interaction of orally administered iron with levodopa and methyl dopa therapy. *J Pharm Pharmacol* (1990) 42, 502–4.

Methyl dopa + Oxazepam

A single, unsubstantiated case report suggests that blood pressure control with methyl dopa may possibly be made more difficult in the presence of oxazepam.

Clinical evidence, mechanism, importance and management

A 54-year-old woman with insomnia and essential hypertension had unexplained variability in blood pressure while taking methyl dopa 750 mg three times daily and a thiazide diuretic. Within a week of stopping oxazepam 60 mg at night, she developed grand mal convulsions and hypertension (190/90 mmHg standing, 240/140 mmHg lying). Her hypertension was then successfully controlled by switching to atenolol and prazosin. The authors of this report suggest that short-acting benzodiazepines such as oxazepam can cause transient hypotension after a dose, but that *hypertension* may occur on withdrawal. These effects may complicate the management of hypertension.¹ The general importance of this possible interaction is not established, but it seems likely to be limited.

1. Stokes GS. Can short-acting benzodiazepines exacerbate essential hypertension? *Cardiovasc Rev Rep* (1989) 10, 60–1.

Methyl dopa + Phenothiazines

The hypotensive adverse effects of chlorpromazine and other phenothiazines may be additive with the antihypertensive effects of methyl dopa. Patients may feel faint and dizzy if they stand up quickly. An isolated report describes paradoxical hypertension in a patient given methyl dopa and trifluoperazine.

Clinical evidence

In one study, 8 normotensive patients given methyl dopa 500 mg to 1 g daily with **chlorpromazine** 200 to 400 mg daily for schizophrenia experienced orthostatic dizziness and had reductions in their standing systolic blood pressure.¹ In contrast, an isolated report describes a paradoxical *rise* in blood pressure in a patient with systemic lupus erythematosus and renal failure when methyl dopa and **trifluoperazine** were given. When the **trifluoperazine** was stopped, the blood pressure fell.²

Mechanism

Simple addition of the hypotensive effects of both drugs seems to be the explanation for the increased hypotension and orthostasis. The suggested explanation for the hypertensive interaction with methyl dopa and trifluoperazine is that the phenothiazine blocked the reuptake of the 'false transmitter' (alpha-methyl noradrenaline) that is produced during when methyl dopa is given.²

Importance and management

The increased hypotension and orthostasis that can occur if chlorpromazine or other phenothiazines are used with antihypertensive drugs such as methyl dopa is established. Note that, of the phenothiazines, **levomepromazine** is particularly associated with postural hypotension. Warn patients that they may feel faint and dizzy particularly during the initial stages of concurrent use, and that if this occurs they should lie down, and that they should remain lying down until symptoms abate completely. Dosage adjustments may be necessary.

The manufacturers of methyl dopa note that a reduced antihypertensive effect may occur with phenothiazines, as well as mentioning the risk of additive hypotensive effects³

Methyl dopa + Phenoxybenzamine

An isolated case report describes a patient who had undergone bilateral lumbar sympathectomy who developed total urinary incontinence when taking methyl dopa and phenoxybenzamine.

Clinical evidence, mechanism, importance and management

A woman who had previously had bilateral lumbar sympathectomy for Raynaud's disease developed total urinary incontinence when given methyl dopa 500 mg to 1.5 g with phenoxybenzamine 12.5 mg daily, but not when she was taking either drug alone. This would seem to be the outcome

of the additive effects of the sympathectomy and the two drugs on the sympathetic control of the bladder sphincters.¹ Stress incontinence has previously been described with these drugs. The general importance of this interaction is probably small.

1. Fernandez PG, Sahni S, Galway BA, Granter S, McDonald J. Urinary incontinence due to interaction of phenoxybenzamine and α -methyl-dopa. *Can Med Assoc J* (1981) 124, 174.

Methyldopa + Sympathomimetics; Indirectly-acting

Indirectly-acting sympathomimetics might be expected to cause a blood pressure rise in patients taking methyldopa, and an isolated case report describes such a reaction in a patient who took phenylpropanolamine, but in practice this interaction normally seems to be of little or no general practical importance. The mydriatic effects of ephedrine are reported to be reduced by methyldopa.

Clinical evidence, mechanism, importance and management

In a study in 5 hypertensive subjects taking methyldopa 2 to 3 g daily, the pressor (rise in blood pressure) effects of **tyramine** were doubled.¹ In another study the pressor effect of **tyramine** was 50/16 mmHg, compared with 18/10 mmHg before methyldopa treatment.²

A man with renal hypertension, whose blood pressure was well controlled with methyldopa 250 mg twice daily and oxprenolol 160 mg three times daily, had a rise in blood pressure from under 140/80 mmHg to 200/150 mmHg within 2 days of starting to take two tablets of **Triogesic (phenylpropanolamine 12.5 mg and paracetamol 500 mg)** three times daily. His blood pressure fell when the **Triogesic** was withdrawn.³

The reason for this is uncertain. One suggestion is that the methyldopa causes the replacement of noradrenaline at adrenergic nerve endings by methylnoradrenaline, which has weaker pressor (alpha) activity but greater vasodilator (beta) activity. With the vasodilator activity blocked by the oxprenolol, the vasoconstrictor (pressor) activity of the **phenylpropanolamine** would be unopposed and exaggerated. Alternatively it could have been that he was unusually sensitive to the pressor effects of **phenylpropanolamine**.

Despite the information derived from the studies outlined above^{1,2} and the single report cited, there seems to be nothing else in the literature to suggest that indirectly-acting sympathomimetics normally cause an adverse reaction with methyldopa. One report briefly mentions that the antihypertensive effects of various drugs, including methyldopa, were not affected by **diethylpropion**.⁴

In 9 patients with untreated hypertension, the normal mydriatic effects of **ephedrine** were reduced by 54% after they started treatment with methyldopa 500 mg to 1.5 g daily.⁵

Methyldopa + Tricyclic and related antidepressants

The antihypertensive effects of methyldopa are not normally adversely affected by desipramine, but an isolated report describes hypertension, tachycardia, tremor and agitation in a man taking methyldopa and amitriptyline. The tetracyclic mianserin does not appear not to interact significantly.

Clinical evidence

A man with hypertension, taking methyldopa 250 mg three times daily and a thiazide diuretic, experienced tremor, agitation, tachycardia (148 bpm) and hypertension (a rise from under 150/90 mmHg to 170/110 mmHg) within 10 days of starting to take **amitriptyline** 25 mg three times daily. A week after stopping all treatment his pulse rate was 100 bpm and his blood pressure 160/90 mmHg.¹ In contrast, a double-blind, crossover study in 5 subjects (one with mild hypertension) found that **desipramine** 25 mg three times daily for 3 days had no significant effect on the hypotensive effects of a single 750-mg dose of methyldopa.² Another study in 3 hypertensive patients taking methyldopa 2.5 to 3 g daily found that **desipramine** 75 mg daily for 5 to 6 days did not antagonise the action of methyldopa. In fact, the blood pressure fell slightly.³ **Mianserin** 20 mg three times daily for 2 weeks had no effect on the control of blood pressure in 6 patients receiving methyldopa, although 2 patients developed symptomatic hypotension after the first dose of **mianserin**.^{4,5}

Mechanism

Not understood. Antagonism of the antihypertensive actions of methyldopa by tricyclic antidepressants is seen in *animals* and it seems to occur within the brain.^{6,7}

Importance and management

Normally no adverse interaction occurs, nevertheless it would seem prudent to monitor the effects of concurrent use if amitriptyline or any other tricyclic antidepressant is given to patients taking methyldopa. Note that methyldopa sometimes induces depression, and so it is generally considered contraindicated in depressed patients.

Minoxidil + Glibenclamide (Glyburide)

There is some evidence that a 5-mg dose of glibenclamide, but not a 2.5-mg dose, may reduce the hypotensive effect of minoxidil.

Clinical evidence, mechanism, importance and management

A single-dose study in 9 healthy subjects found that glibenclamide 2.5 mg did not alter the hypotensive effect of oral minoxidil 5 mg. However, in a further 4 subjects a 5-mg dose of glibenclamide appeared to cause some loss in the hypotensive effect of minoxidil, but this was not statistically significant. The authors therefore suggested that this interaction may be dose-related. The suggested reason for these effects is that these two drugs have opposing effects on the potassium channels of the smooth muscle of blood vessels.¹ In this study, subjects were pre-treated with propranolol to prevent reflex tachycardia when given minoxidil, which is how minoxidil is used clinically.¹ What is not yet clear is whether any interaction occurs between minoxidil and glibenclamide in a clinical setting.

1. Stein CM, Brown N, Carlson MG, Campbell P, Wood AJJ. Coadministration of glyburide and minoxidil, drugs with opposing effects on potassium channels. *Clin Pharmacol Ther* (1997) 61, 662–8.

Minoxidil + Miscellaneous

The manufacturer notes that excessive blood pressure reductions may occur if minoxidil is used in patients taking guanethidine, because of the adrenergic blocking effects of guanethidine.^{1,2} If ex-

cessive hypotension occurs with minoxidil, this should *not* be treated with adrenaline (epinephrine) or noradrenaline (norepinephrine), because this may result in excessive tachycardia.¹

1. Loniten Tablets (Minoxidil). Pharmacia Ltd. UK Summary of product characteristics, July 2007.
2. Minoxidil. Watson Pharmaceuticals, Inc. US Prescribing information, October 2002.

Minoxidil; Topical + Miscellaneous

A study in 19 healthy subjects found that the absorption of topical minoxidil was increased by almost threefold by the use of topical tretinoin 0.05% applied 1 hour before the minoxidil.¹ The manufacturers note that topical drugs that alter the stratum corneum barrier, such as tretinoin or dithranol, could result in increased absorption of minoxidil if applied concurrently. They suggest that, theoretically, one possible effect of minoxidil absorption would be potentiation of orthostatic hypotension caused by vasodilator drugs.² The exact drugs are not stated but this caution would be expected to cover drugs such as the nitrates and hydralazine.

2. Regaine for Men Gel (Minoxidil). Pfizer Consumer Healthcare. UK Summary of product characteristics, August 2005.

Moxonidine + Miscellaneous

On theoretical grounds the manufacturers of moxonidine advise withdrawing beta blockers before withdrawing moxonidine. They also advise avoiding alcohol and tricyclic antidepressants during the use of moxonidine. Moxonidine alone can cause sedation, and increases the sedative effects of lorazepam, therefore care is needed with other benzodiazepines, hypnotics and sedatives. No clinically significant pharmacokinetic interactions occur with moxonidine and digoxin, glibenclamide (glyburide), hydrochlorothiazide, moclobemide, or quinidine.

Clinical evidence, mechanism, importance and management

(a) Benzodiazepines and other sedatives and hypnotics

The cognitive function of 24 healthy subjects was not impaired by moxonidine 400 micrograms daily, but the presence of moxonidine was found to increase the cognitive impairment caused by lorazepam 1 mg daily.¹ For this reason the manufacturers warn that the sedative effects of the benzodiazepines may possibly be enhanced by moxonidine.² Sedation and dizziness may occur with moxonidine, which the manufacturers suggest may be additive with the effects of sedatives and hypnotics.² They also advise the avoidance of alcohol.²

(b) Beta blockers

The presence of a beta blocker can exacerbate the rebound hypertension that follows the withdrawal of clonidine (see 'Clonidine + Beta blockers', p.882). Moxonidine is reported to have less affinity for central alpha-receptors than clonidine, and no such rebound hypertension has actually been seen when moxonidine is withdrawn. However, to be on the safe side the manufacturers advise that any beta blocker should be stopped first, followed by the moxonidine a few days later.^{2,3}

(c) Digoxin

No clinically relevant pharmacokinetic interaction was seen at steady state between moxonidine 200 micrograms twice daily and digoxin 200 micrograms daily in 15 healthy subjects.⁴

(d) Glibenclamide (Glyburide)

Glibenclamide 2.5 mg daily had no effect on the steady-state pharmacokinetics of moxonidine 200 micrograms twice daily in 18 healthy subjects. There was a minor 12% decrease in the AUC of glibenclamide, and a 14% increase in clearance, but these changes are unlikely to be of any clinical relevance.⁵

(e) Hydrochlorothiazide

No clinically relevant pharmacokinetic interaction was seen at steady state between moxonidine 200 micrograms twice daily and hydrochlorothiazide 25 mg twice daily.⁶ A double-blind, placebo-controlled study showed that when moxonidine 400 micrograms daily was given with hydrochlorothiazide 25 mg daily an increased blood pressure lowering effect was seen, compared to either drug alone. A mean reduction of 27/16 mmHg was noted with the combination, compared to 13/9, 20/12, and 22/13 mmHg for placebo, moxonidine and hydrochlorothiazide, respectively.⁷

(f) Moclobemide

A study found no pharmacokinetic interaction occurred when healthy subjects were given moxonidine 400 micrograms daily and a single 300-mg dose of moclobemide. Moxonidine alone or with moclobemide did not significantly affect cognitive function.¹

(g) Quinidine

In a single-dose study in 6 healthy subjects, quinidine sulfate 400 mg, given one hour before moxonidine 200 micrograms, caused a minor 11% increase in the AUC of moxonidine and decreased its clearance by 10%. These small changes are unlikely to be of any clinical relevance.⁸

(h) Tricyclic antidepressants

The manufacturers of moxonidine advise avoiding tricyclic antidepressants, because of the lack of clinical experience of combined use.² Presumably, this is because moxonidine is related to clonidine, and tricyclics may antagonise the blood pressure-lowering effects of clonidine, see 'Clonidine + Tricyclic and related antidepressants', p.884. Tricyclics can also cause postural hypotension and sedation, both of which could potentially be additive with the effects of moxonidine. If the combination is used, it would be prudent to carefully monitor blood pressure and sedation.

Nicorandil + Miscellaneous

Neither cimetidine nor rifampicin had any clinically relevant effect on the pharmacokinetics of nicorandil. Nicorandil did not alter the anticoagulant effects of acenocoumarol. Although *animal* studies suggest antagonism of effects, a study in patients found no pharmacodynamic interaction between nicorandil and glibenclamide. Nicorandil may potentiate the hypotensive effects of other vasodilators, tricyclic antidepressants and alcohol.

Clinical evidence, mechanism, importance and management

(a) Acenocoumarol

Nicorandil 10 mg twice daily for 4 days then 20 mg twice daily for 7 days did not alter the INR in 11 patients stabilised on acenocoumarol.¹

(b) Cimetidine

Cimetidine 400 mg twice daily for 7 days had no effect on the pharmacokinetics of nicorandil 20 mg twice daily for 7 days, except that the nicorandil AUC showed a minor 10% increase, which is not clinically important.¹

(c) Glibenclamide

Studies in *animals* have indicated that there may be antagonism between nicorandil and glibenclamide. However, in a study, 8 patients with diabetes and angina (taking glibenclamide), and 11 similar patients not receiving glibenclamide, were given nicorandil 15 mg daily for more than 8 weeks. In contrast to the findings in the *animal* studies, glibenclamide

did not cause inhibition of the anti-anginal effects of nicorandil, nor was there any disturbance of diabetic control.²

(d) Miscellaneous drugs

Combined data from clinical studies in 1152 patients using nicorandil found no evidence of increased adverse effects or an increased number of withdrawals in patients taking unnamed **beta blockers** (210 patients), **calcium-channel blockers** (117), **long-acting nitrates** (130), **bepridil** (18), **diltiazem** (91), **verapamil** (9), **amiodarone** (23) or **molsidomine** (30). It has also been reported that unnamed **antihypertensives**, **antidiabetic** or **lipid-regulating drugs** do not appear to interact adversely with nicorandil.³ No adverse ECG effects have been seen (including QT or ST segment modifications) with nicorandil.³ However, the manufacturers suggest that nicorandil may possibly potentiate the blood pressure-lowering effects of other **vasodilators**, **tricyclic antidepressants** or **alcohol**.⁴ For mention that phosphodiesterase inhibitors (e.g. **sildenafil**, **tadalafil**, **ildenafil**) should not be used with nicorandil, see 'Phosphodiesterase type-5 inhibitors + Nitrates', p.1272.

(e) Rifampicin

Rifampicin 600 mg daily for 5 days had no effect on the pharmacokinetics of nicorandil 20 mg twice daily for 5 days, except that the elimination half-life showed a minor 17% decrease, which is not clinically important.¹

Pentoxifylline + Cimetidine

Cimetidine increases plasma pentoxifylline levels to a moderate extent, which may increase the incidence of adverse effects.

Clinical evidence, mechanism, importance and management

A study in 10 healthy subjects found that the mean steady-state plasma levels of controlled-release pentoxifylline 400 mg every 8 hours were raised by about 27% when cimetidine 300 mg four times daily for 7 days was added.¹ Adverse effects such as headache, nausea, and vomiting were said to be more common and bothersome while taking the cimetidine.¹

The reason for this interaction is not known. However, cimetidine is known to inhibit the metabolism of 'theophylline', (p.1181), to which pentoxifylline is structurally related.

The findings of this study suggest that this interaction may be clinically relevant. If cimetidine is required in a patient taking pentoxifylline, monitor for adverse effects, and decrease the pentoxifylline dose if problems occur.

1. Mauro VF, Mauro LS, Hageman JH. Alteration of pentoxifylline pharmacokinetics by cimetidine. *J Clin Pharmacol* (1988) 28, 649–54.

Pentoxifylline + Ciprofloxacin

Evidence from one study suggests that ciprofloxacin increases the serum levels of pentoxifylline, and may increase the incidence of adverse effects. In some clinical studies ciprofloxacin has been used to boost the levels of pentoxifylline.

Clinical evidence

Because patients taking pentoxifylline and ciprofloxacin often complained of headache, the possibility of a pharmacokinetic interaction was studied in 6 healthy subjects. The study showed that ciprofloxacin 500 mg daily for 3 days increased the peak serum levels of a single 400-mg dose of pentoxifylline by almost 60% (from 114.5 to 179.5 nanograms/mL), and increased the AUC by 15%. All 6 subjects complained of a frontal headache.¹

Mechanism

The evidence suggests that ciprofloxacin inhibits the metabolism of the pentoxifylline (a xanthine derivative) by the liver. Compare 'Theophylline + Quinolones', p.1192.

Importance and management

Information on this interaction and its clinical relevance is limited. The author of the pharmacokinetic study suggests that, if the drugs need to be used together, the dosage of pentoxifylline should be halved.¹ In the absence of other information, if a short-course of ciprofloxacin is required in a patient taking pentoxifylline, this may be a sensible precaution. Alternatively, because the increase in AUC was minor, it may be sufficient to recommend a reduction in pentoxifylline dose only in those who experience adverse effects (e.g. nausea, headache). Note that ciprofloxacin has been used to boost pentoxifylline levels in studies investigating the possible therapeutic value of pentoxifylline's ability to inhibit various cytokines. For example, ciprofloxacin 500 mg twice daily was used with pentoxifylline 800 mg three times daily for up to one year in patients with myelodysplastic syndrome.²

Patients with myelodysplastic syndromes benefit from palliative therapy with amifostine, pentoxifylline, and ciprofloxacin with or without dexamethasone. *Blood* (2000) 95, 1580–87.

Perhexiline + SSRIs

Case reports describe an increase in perhexiline serum levels resulting in toxicity when citalopram, fluoxetine or paroxetine were given.

Clinical evidence, mechanism, importance and management

An 86-year-old woman taking perhexiline was admitted to hospital because of ataxia, falls, lethargy, nausea, and an inability to cope at home. She had started to take **paroxetine** 20 mg daily 5 weeks earlier. Her serum perhexiline levels were 2.02 mg/L, compared with the normal range of 0.15 to 0.6 mg/L.¹ Perhexiline toxicity was also seen in two other elderly women, following the use of **paroxetine** in one case, and **fluoxetine** in the other. The perhexiline serum levels fell when both drugs were stopped, but in one case the fall was very slow.² Another case report describes toxicity and raised perhexiline levels in an elderly man shortly after he started taking **citalopram**.³

The reason for the rise in perhexiline levels is not known, but it seems likely that these SSRIs can inhibit its metabolism, probably via the cytochrome P450 isoenzyme CYP2D6. The general importance of these interactions is also not known, but it would now be prudent to monitor the outcome of concurrent use for perhexiline toxicity and consider monitoring perhexiline serum levels where possible. The perhexiline dosage may need to be reduced. More study is needed.

3. Nyfort-Hansen K. Perhexiline toxicity related to citalopram use. *Med J Aust* (2002) 176, 560–61.

Ranolazine + Miscellaneous

The concurrent use of ranolazine and moderate or potent inhibitors of CYP3A4, such as some azoles, diltiazem, grapefruit juice, macrolides, protease inhibitors, or verapamil will result in increased levels of ranolazine, and can predispose the patient to adverse effects including QT interval prolongation. Cimetidine and paroxetine do not interact to a clinically significant extent. Ranolazine may increase levels of ciclosporin, digoxin or simvastatin.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inhibitors

Moderate inhibitors of CYP3A4 (e.g. diltiazem and verapamil) cause a two- to threefold rise in ranolazine levels, and ketoconazole, a potent inhibitor of CYP3A4 causes an even greater rise (see below). Raised ranolazine levels can cause clinically significant QT prolongation. The manufacturer of ranolazine therefore contraindicates its use with these and other potent or moderately potent CYP3A4 inhibitors. They specifically name **grapefruit juice** and **grapefruit-containing products, macrolides and protease inhibitors**.¹

A list of clinically relevant CYP3A4 inhibitors is given in 'Table 1.4', (p.6).

1. *Diltiazem*. In a placebo-controlled study in 12 healthy subjects diltiazem 60 mg three times daily was given to 12 healthy subjects for 7 days, with ranolazine 240 mg three times daily on days 4 to 7. Ranolazine did not alter the pharmacokinetics of diltiazem, but diltiazem increased the AUC and maximum plasma level of ranolazine by 85% and twofold, respectively. A further study using modified-release diltiazem 180 mg, 240 mg, and 360 mg once daily, and a slow-release preparation of ranolazine 1 g twice daily, resulted in increases in the AUC of ranolazine of 52%, 93%, and 139%, respectively.²

2. *Ketoconazole*. In a double-blind, randomised study, healthy subjects were given slow-release ranolazine 375 mg twice daily for 9 days, with ketoconazole 200 mg twice daily on days 5 to 9. The same study was repeated with ranolazine 1 g twice daily. It was found that ketoconazole increased the AUC, levels (mean, peak and trough) and half-life of ranolazine by 2.5- to 4.5-fold. The most common adverse events were headaches, dizziness and nausea. In some patients the higher dose of ranolazine with ketoconazole resulted in intolerable adverse events.²

3. *Verapamil*. Plasma levels of ranolazine 750 mg twice daily are reported to be increased twofold by concurrent verapamil 120 mg three times daily.¹

(b) Ciclosporin

Ranolazine inhibits P-glycoprotein, and has been shown to raise digoxin levels (see below), presumably by this mechanism. However, it is also a substrate of P-glycoprotein. The manufacturers of ranolazine therefore advise caution if it is given to patients taking ciclosporin, which is also a P-glycoprotein inhibitor [and substrate].¹ Until more is known it would seem prudent to increase the frequency of ciclosporin and ranolazine monitoring if both drugs are given.

(c) CYP3A4 substrates

In an open-label study, simvastatin 80 mg daily was given with ranolazine 1 g twice daily for 4 days. Simvastatin had no effect on the pharmacokinetics of ranolazine, but ranolazine increased the maximum plasma levels of simvastatin and its active metabolites by about twofold and increased its AUC by 40 to 60%.²

These changes may be clinically significant in some patients. If simvastatin is given to a patient taking ranolazine, it would seem prudent to start at the lowest dose and titrate cautiously. If ranolazine is given to patients already taking simvastatin consider reducing the dose of simvastatin (particularly with high simvastatin doses). All patients taking statins should be warned about the symptoms of myopathy and told to report muscle pain or weakness. It would be prudent to reinforce this advice if they are given ranolazine.

(d) Digoxin

A study in healthy subjects given ranolazine 1 g twice daily and digoxin 125 micrograms found that ranolazine increased the plasma levels of digoxin by about 1.5-fold. Plasma levels of ranolazine were not significantly affected by concurrent digoxin.¹ Ranolazine probably raises digoxin levels by inhibiting P-glycoprotein. It would seem prudent to monitor digoxin levels if ranolazine is started, anticipating the need to reduce the digoxin dose.

(e) Paroxetine

Paroxetine has been reported to increase the average steady state plasma concentrations of ranolazine 1.2-fold.¹ Ranolazine is metabolised by the cytochrome P450 isoenzymes CYP2D6, which paroxetine inhibits. However, as CYP2D6 is not the main route of metabolism, only very modest effects are seen, and no dosage adjustment is necessary.¹

(f) Ritonavir

Ranolazine and ritonavir are both substrates for and inhibitors of P-glycoprotein. The manufacturers of ranolazine advise caution if ranolazine is given to patients taking ritonavir.¹

1. Ranexa (Ranolazine). CV Therapeutics, Inc. US Prescribing Information, February 2006
2. Jerling M, Huan B-L, Leung K, Chu N, Abdallah H, Hussein Z. Studies to investigate the pharmacokinetic interactions between ranolazine and ketoconazole, diltiazem or simvastatin during combined administration in healthy subjects. *J Clin Pharmacol.* (2005) 45, 422-33.

Sodium nitroprusside + Miscellaneous

Smaller doses of sodium nitroprusside might be required in patients receiving antihypertensive drugs. There is a risk of severe hypotension if phosphodiesterase inhibitors (e.g. sildenafil, tadalafil and vardenafil) are used with sodium nitroprusside.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives

The manufacturer notes that smaller doses of sodium nitroprusside might be required in patients receiving antihypertensive drugs. In any event the required dose varies considerably between patients and so should be titrated to effect. When used for controlled hypotension during anaesthesia, the hypotensive effect of other drugs, particularly anaesthetics, should be remembered.¹ They name **halothane** and **enflurane**.

(b) Phosphodiesterase inhibitors

The use of phosphodiesterase inhibitors (e.g. **sildenafil**, **tadalafil** and **vardenafil**) with sodium nitroprusside is contraindicated by the manufacturers, due to the risk of severe hypotension. See also 'Phosphodiesterase type-5 inhibitors + Nitrates', p.1272. A case report describes the therapeutic use of **sildenafil** to enhance the hypotensive effect of sodium nitroprusside and other antihypertensives in a patient with a hypertensive crisis.²

1. Sodium Nitroprusside. Mayne Pharma plc. UK Summary of product characteristics, May 2005.
2. Bahadur MM, Aggarwal VD, Mali M, Thamba A. Novel therapeutic option in hypertensive crisis: sildenafil augments nitroprusside-induced hypotension. *Nephrol Dial Transplant* (2005) 20, 1254-6.

Tirilazad mesilate + Miscellaneous

Phenobarbital and phenytoin reduce the serum levels of tirilazad mesilate whereas ketoconazole increases them. Finasteride inhibits the metabolism of tirilazad to its active metabolite. No pharmacokinetic interaction appears to occur between cimetidine or nimodipine and tirilazad.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

A study in 16 healthy men found that cimetidine 300 mg every 6 hours for 4 days had no effect on the pharmacokinetics of a single 2-mg/kg dose of tirilazad mesilate, given by infusion over 10 minutes on day 2, nor on U-89678, its active metabolite.¹ No special precautions would seem necessary if cimetidine is given with tirilazad mesilate.

(b) Finasteride

In a study, 8 healthy men were given finasteride 5 mg daily for 10 days, with tirilazad mesilate 10 mg/kg orally or 2 mg/kg intravenously on day 7. Finasteride increased the AUCs of intravenous and oral tirilazad by 21% and 29%, respectively. Oral finasteride reduced the AUCs of the active metabolite (U-89678) by 92% when tirilazad was given intravenously and by 75% when tirilazad was given orally. Although the metabolism of tirilazad to U-89678 was inhibited there was only a moderate effect on the overall clearance of tirilazad and the interaction was considered unlikely to be of clinical significance.²

(c) Ketoconazole

Tirilazad mesilate, 10 mg/kg orally or 2 mg/kg intravenously, was given to 12 healthy men and women, either alone or on day 4 of a 7-day regimen of ketoconazole 200 mg daily. The ketoconazole more than doubled the absolute bioavailability of the oral tirilazad mesilate (from 8.7% to 20.9%), apparently because its metabolism by the cytochrome P450 isoen-

zyme CYP3A in the gut wall and during the first pass through the liver was inhibited.³ The clinical importance of this interaction awaits assessment.

(d) Nimodipine

In a single-dose study in 12 healthy men, there was no pharmacokinetic or pharmacodynamic interaction between intravenous tirilazad mesilate 2 mg/kg and oral nimodipine 60 mg.⁴ No special precautions would seem necessary if nimodipine is given with tirilazad mesilate

(e) Phenobarbital

The pharmacokinetics of tirilazad mesilate (1.5 mg/kg as 10 minute intravenous infusions every 6 hours for 29 doses) were studied in 15 healthy subjects before and after they took phenobarbital 100 mg daily for 8 days. The phenobarbital increased the clearance of the tirilazad by 25% in the male subjects and 29% in the female, and the AUC of the active metabolite of tirilazad (U-89678) was reduced by 51% in the males and 69% in the females. The reason is thought to be that the phenobarbital acts as an enzyme inducer, which increases the metabolism of the tirilazad.⁵ The clinical importance of these reductions awaits assessment, but be alert for evidence of reduced effects if both drugs are given. It is doubtful if the full enzyme-inducing effects of the phenobarbital would have been reached in this study after only one week, so anticipate a greater effect if it is given for a longer period.

(f) Phenytoin

After taking phenytoin 200 mg every 8 hours for 11 doses then 100 mg every 8 hours for 5 doses, the AUC₀₋₆ of tirilazad mesilate was reduced by 35% in 12 healthy subjects. The AUC of the active metabolite, U-89678, was reduced by 87%.⁶ Another report by the same group of workers⁷ found that phenytoin every 8 hours for 7 days (9 doses of 200 mg followed by 13 doses of 100 mg) reduced the clearance of tirilazad by 92% and of U-89678 by 93%. In another report the authors noted that phenytoin increased the metabolism of tirilazad and its metabolite in men and women to similar extents.⁸ The clinical importance of these reductions is still to be assessed, but be alert for any evidence of reduced tirilazad effects if both drugs are given.

Tolazoline + H₂-receptor antagonists

Cimetidine and ranitidine can reduce or abolish the effects of tolazoline used as a pulmonary vasodilator in children.

Clinical evidence

A newborn infant with persistent foetal circulation was given a continuous infusion of tolazoline to reduce pulmonary hypertension. The oxygenation improved but gastrointestinal bleeding occurred. When **cimetidine** was given, the condition of the child deteriorated with a decrease in oxygen saturation and arterial pO₂ values.¹ A second case report describes a similar outcome in a 2-day-old neonate, who had an initial improvement with tolazoline alone, but then developed worsening hypoxaemia when cimetidine was given.²

These reports are similar to another, in which the tolazoline-induced reduction in pulmonary arterial pressure in a child was reversed when **cimetidine** was given, for acute gastrointestinal haemorrhage.³ Another study in 12 children found that intravenous **ranitidine** 3 mg/kg abolished the tolazoline-induced reduction in pulmonary and systemic vascular.⁴

Mechanism

Tolazoline dilates the pulmonary vascular system by stimulating both H₁- and H₂-receptors. Cimetidine and ranitidine block H₂-receptors so that at least part of the effects of tolazoline are abolished. It has been suggested that this interaction is confined to children.³

Importance and management

An established interaction. Cimetidine and ranitidine are not suitable drugs for prophylaxis of the gastrointestinal adverse effects of tolazoline in children. Other H₂-receptor antagonists would be expected to behave similarly.

Digitalis glycosides

Plant extracts containing cardiac glycosides have been in use for thousands of years. The ancient Egyptians were familiar with squill (a source of **proscillaridin**), as were the Romans who used it as a heart tonic and diuretic. The foxglove was mentioned in the writings of Welsh physicians in the thirteenth century and features in 'An Account of the Foxglove and some of its Medical Uses', published by William Withering in 1785, in which he described its application in the treatment of 'dropsy' or the oedema that results from heart failure.

The most commonly used cardiac glycosides are those obtained from the members of the foxglove family, *Digitalis purpurea* and *Digitalis lanata*. The leaves of *D. lanata* are the source of a number of purified glycosides including **digoxin**, **digitoxin**, **acetyldigoxin**, **acetyldigitoxin**, **lanatoside C**, **deslanoside**, of gitalin (an amorphous mixture largely composed of digitoxin and digoxin), and of powdered whole leaf **digitalis lanata leaf**. *D. purpurea* is the source of **digitoxin**, **digitalis leaf**, and the standardised preparation **digitalin**. **Metildigoxin** is a semi-synthetic digitalis glycoside. Occasionally ouabain or strophanthin-K (also of plant origin) are used for particular situations, while for a number of years the Russians have exploited cardiac glycosides from lily of the valley (**convallaria**). Bufalin is a related cardioactive compound obtained from toads, and is found in a number of Chinese medicines.

Digitalisation

The cardiac glycosides have two main actions and two main applications. They reduce conductivity within the atrioventricular (AV) node, hence are used for treating supraventricular tachycardias (especially atrial fibrillation), and they have a positive inotropic effect (i.e. increase the force of contraction), hence are used for congestive heart failure, although this use has declined.

Because the most commonly used glycosides are derived from digitalis, the achievement of the desired therapeutic serum concentration of any cardiac glycoside is usually referred to as digitalisation. Treatment may be started with a large loading dose so that the therapeutic concentrations are achieved reasonably quickly, but once these have been reached the amount is reduced to a maintenance dose. This has to be done carefully because

there is a relatively narrow gap between therapeutic and toxic serum concentrations. Normal therapeutic levels are about one-third of those that are fatal, and serious toxic arrhythmias begin at about two-thirds of the fatal levels. The normal range for digoxin levels is 0.8 to 2 nanograms/mL (or 1.02 to 2.56 nanomol/L). To convert nanograms/mL to nanomol/L multiply by 1.28, or to convert nanomol/L to nanograms/mL multiply by 0.781. Note that micrograms/L is the same as nanograms/mL.

If a patient is over-digitalised, signs of toxicity will occur, which may include loss of appetite, nausea and vomiting, and bradycardia. These symptoms are often used as clinical indicators of toxicity, and a pulse rate of less than 60 bpm is usually considered to be an indication of over-treatment. Note that paroxysmal atrial tachycardia with AV block and junctional tachycardia can also occur as a result of digitalis toxicity. Other symptoms include visual disturbances, headache, drowsiness and occasionally diarrhoea. Death may result from cardiac arrhythmias. Patients treated for cardiac arrhythmias can therefore demonstrate arrhythmias when they are both under- as well as over-digitalised.

Interactions of the cardiac glycosides

The pharmacological actions of these glycosides are very similar, but their rates and degree of absorption, metabolism and clearance are different. For example, digoxin is mainly renally cleared whereas digitoxin undergoes a degree of metabolism by the liver. It is therefore most important not to extrapolate an interaction seen with one glycoside and apply it uncritically to any other. Because the therapeutic ratio of the cardiac glycosides is low, a quite small change in serum levels may lead to inadequate digitalisation or to toxicity. For this reason interactions that have a relatively modest effect on serum levels may sometimes have serious consequences.

Many interactions between digoxin and other drugs are mediated by P-glycoprotein. Drugs that inhibit the activity of P-glycoprotein in the renal tubules may reduce the elimination of digoxin in the urine and this may result in toxic serum levels. Further, the induction or inhibition of P-glycoprotein in the gut may affect the oral absorption of digoxin. See also 'Drug transporter proteins', (p.8).

Digitalis glycosides + ACE inhibitors

Most ACE inhibitors do not interact with digoxin to a clinically relevant extent. Some studies have found that serum digoxin levels rise by about 20% or more if captopril is used, but others have found no significant changes. It has been suggested that any interaction is likely to occur only in those patients who have pre-existing renal impairment. Digitoxin and captopril appear not to interact.

Clinical evidence

(a) Digitoxin and Captopril

A study in 12 healthy subjects given digitoxin 70 micrograms daily for up to 58 days found no evidence that the addition of captopril 25 mg daily had a relevant effect on the pharmacokinetics of digitoxin, or its effects on the heart.¹

(b) Digoxin and Captopril

The serum digoxin levels of 16 patients with severe chronic congestive heart failure rose by 21%, from 1.1 to 1.3 nanograms/mL, while taking captopril (average dose 93.7 mg daily). Serum digoxin levels were above the therapeutic range at 2 nanograms/mL on 3 out of 63 occasions, but no toxicity was seen. All patients had impaired renal function and were being treated with diuretics.^{2,3} Another study⁴ found an approximate 30% rise in serum digoxin levels in patients with congestive heart failure class II and a further study⁵ found an approximate 60% rise in peak serum digoxin levels in patients with congestive heart failure class IV. Conversely, another study in 31 patients with stable congestive heart failure, given captopril 25 mg three times daily, found no significant changes in serum digoxin levels over a 6-month period.⁶ Two other studies in healthy subjects⁷ and patients with congestive heart failure⁸ also found no evidence of an interaction.

(c) Digoxin and Other ACE inhibitors

In general no significant interactions have been seen between ACE inhibitors and digoxin.

- **Cilazapril** 5 mg for 14 days did not alter the trough plasma digoxin levels in healthy subjects.⁹
- **Enalapril** 20 mg daily for 30 days had no significant effect on the pharmacokinetics of digoxin 250 micrograms daily in 7 patients with congestive heart failure.¹⁰
- **Imidapril** 10 mg daily had no effect on the serum digoxin levels of 12 healthy subjects, but slight reductions in levels of the active form imidaprilat and in ACE inhibition of about 15% were seen, which were of uncertain clinical relevance.¹¹
- **Lisinopril** 5 mg daily for 4 weeks had no significant effect on the serum digoxin levels of 9 patients.¹² This confirms the findings of a single-dose study.¹³
- **Moexipril** has been reported, by the manufacturer, to have had no important pharmacokinetic interaction with digoxin in healthy subjects.¹⁴ They also have clinical studies that show no evidence of clinically important adverse interactions when moexipril was used with digoxin.¹⁵
- **Perindopril** 2 to 4 mg daily for a month had no effect on the steady-state serum digoxin levels of 10 patients with mild chronic heart failure.¹⁶
- **Quinapril** is also reported not to alter the steady-state levels of digoxin in healthy subjects,¹⁷ and patients with congestive heart failure.¹⁸
- **Ramipril** 5 mg daily for 14 days had no effect on the serum digoxin levels of 12 healthy subjects.¹⁹
- **Spirapril** 12 to 48 mg daily did not significantly affect the pharmacokinetics nor the steady-state serum levels of digoxin in 15 healthy subjects taking digoxin 250 micrograms twice daily.²⁰
- **Trandolapril** has been shown to have no significant pharmacokinetic interaction with digoxin in healthy subjects.²¹ The manufacturers also note that, in patients with left ventricular dysfunction after myocardial infarction, no clinical interactions have been found between trandolapril and digoxin.^{22,23}

Mechanism

Not fully understood. It has been suggested that an interaction is only likely to occur in those who have renal impairment because the glomerular filtration rate of these patients may be maintained by the vasoconstrictor action of angiotensin II on the post-glomerular blood vessels, which would be impaired by ACE inhibition. As a result some of the loss of digoxin through the tubules is reduced.⁷

Importance and management

The overall picture is that no clinically important adverse interaction occurs between digoxin and ACE inhibitors in patients with normal renal function, and that serum digoxin monitoring is only needed in those who have a high risk of reversible ACE inhibitor induced renal failure (e.g. patients with congestive heart failure during chronic diuretic treatment, with bilateral renal artery stenosis or unilateral renal artery stenosis in a solitary kidney);⁷ however, note these latter two conditions are contraindications to the use of ACE inhibitors. The critical factor does not seem to be the particular ACE inhibitor used but the existence of abnormal renal function or conditions that increase the risk of renal impairment. This needs confirmation.

No interaction apparently occurs between digitoxin and captopril in healthy subjects, but this needs confirmation in patients.

Digitalis glycosides + Acipimox

One study suggests that acipimox does not interact with digoxin.

Clinical evidence, mechanism, importance and management

In 6 elderly patients acipimox 250 mg three times daily for a week was found to have no significant effect on plasma digoxin levels, clinical con-

dition, ECGs, plasma urea or electrolyte levels.¹ No special precautions during concurrent use would seem necessary.

1. Chijioko PC, Pearson RM, Benedetti S. Lack of acipimox-digoxin interaction in patient volunteers. *Hum Exp Toxicol* (1992) 11, 357–9.

Digitalis glycosides + Allopurinol

Allopurinol does not appear to affect serum digoxin levels.

Clinical evidence, mechanism, importance and management

No significant changes in the serum **digoxin** levels of 5 healthy subjects occurred over a 7-day period while they were taking allopurinol 300 mg daily.¹ No additional precautions would appear to be necessary on concurrent use.

1. Havelund T, Abildtrup N, Birkebaek N, Breddam E, Rosager AM. Allopurinols effekt på koncentrationen af digoksin i serum. *Ugeskr Laeger* (1984) 146, 1209–11.

Digitalis glycosides + Alpha blockers

A rapid and marked rise in serum digoxin levels occurred in one study when prazosin was also given. Alfuzosin, doxazosin, tamsulosin and terazosin appear not to interact with digoxin.

Clinical evidence, mechanism, importance and management

(a) Alfuzosin

The manufacturers of alfuzosin report that no pharmacodynamic or pharmacokinetic interaction was observed in healthy subjects given alfuzosin 10 mg [daily] with **digoxin** 250 micrograms daily for 7 days.^{1,2}

(b) Doxazosin

Doxazosin is highly bound to plasma proteins (98%), but the manufacturer notes that *in vitro* data in human plasma indicated that doxazosin did not affect the protein binding of **digoxin**.^{3,4} Although there appears to be no clinical evidence of an interaction between **digoxin** and doxazosin, an *in vitro* study found that doxazosin inhibited the P-glycoprotein-mediated transcellular transport of **digoxin**, suggesting that an interaction is possible, as **digoxin** renal transport may be inhibited.⁵ More study is needed.

(c) Prazosin

In 20 patients prazosin 2.5 mg twice daily increased the mean steady-state plasma **digoxin** level by 43% from 0.94 to 1.34 nanograms/mL after one day, and by 60% from 0.94 to 1.51 nanograms/mL after 3 days, although the individual response varied from an increase to a decrease, or no effect. Three days after the prazosin was stopped, by which time it would be totally cleared from the body, the serum **digoxin** concentrations had fallen to their previous levels.⁶ The reason for this response is not understood. There do not appear to be any other reports in the literature, and the manufacturer notes that, in clinical experience, prazosin has been given with **digoxin** (and 'digitalis') without any adverse drug interaction.⁷ However, bear this interaction in mind in case of an unexpected response to treatment.

(d) Tamsulosin

A placebo-controlled study in 10 healthy subjects found that tamsulosin 800 micrograms daily had no effect on the pharmacokinetics of a single 500-microgram intravenous dose of **digoxin**. The most frequently reported adverse effect was dizziness and the safety profile was considered acceptable.⁸ The manufacturers note that dosage adjustments are not necessary when tamsulosin is given with **digoxin**.⁹

(e) Terazosin

The manufacturer of terazosin states that terazosin has been given with cardiac glycosides without evidence of an interaction.¹⁰

Digitalis glycosides + Alpha-glucosidase inhibitors

Some but not all studies have found that digoxin plasma levels can be markedly reduced by acarbose. Miglitol modestly reduced digoxin levels in healthy subjects, but no change was seen in diabetic patients. Voglibose does not appear to interact adversely with digoxin.

Clinical evidence, mechanism, importance and management

(a) Acarbose

A woman taking **digoxin** 250 micrograms daily, insulin, nifedipine, isosorbide dinitrate, clorazepate and nabumetone had subtherapeutic plasma **digoxin** levels of 0.48 to 0.64 nanograms/mL while taking acarbose, even when her **digoxin** dosage was raised by adding 125 micrograms on two days of the week. Later, in the absence of acarbose and with the original **digoxin** dosage, her plasma levels were 1.9 nanograms/mL.^{1,2} Two other patients similarly had markedly reduced plasma **digoxin** levels while taking acarbose. When the acarbose was stopped, the plasma **digoxin** levels rose from 0.23 to 1.6 nanograms/mL and from 0.56 to 1.9 nanograms/mL, respectively.³ Another patient with heart failure and type 2 diabetes taking **digoxin** and voglibose, was found to have subtherapeutic levels of **digoxin** when his treatment was changed from voglibose (see below) to acarbose. The serum levels unexpectedly remained subtherapeutic for at least a month when treatment was switched back to voglibose.⁴

A pharmacokinetic study in 7 healthy subjects, using either a 200-mg dose of acarbose or pretreatment with acarbose 100 mg doses three times daily, similarly found that the serum levels and AUC of a single 500-microgram dose of **digoxin** were reduced. Maximum **digoxin** serum levels were reduced by about 30 to 40% and the AUC was reduced by about 40%.⁵ The reasons for this interaction are not understood but a reduction in the absorption of the **digoxin** from the gut has been suggested.⁵ These reports contrast with other studies that found no significant interaction between single-dose **digoxin** and acarbose at therapeutic doses in healthy subjects.^{6,7} Just why there is an inconsistency between these reports is not understood but it would clearly be prudent to consider monitoring **digoxin** levels if both drugs are used, being alert for any evidence of reduced levels.

(b) Miglitol

The manufacturer notes that in a study in healthy subjects, miglitol 50 mg or 100 mg three times daily reduced the average plasma concentrations of **digoxin** by 19% and 28%, respectively. However, in diabetic patients receiving treatment with **digoxin**, plasma **digoxin** levels were not altered by the concurrent use of miglitol 100 mg three times daily for 14 days.⁸ It would seem prudent to monitor digoxin levels if both drugs are used together.

(c) Voglibose

A randomised, crossover study in 8 healthy subjects taking **digoxin** 250 micrograms daily after breakfast for 8 days found that voglibose 200 micrograms three times daily had no effect on the pharmacokinetics of the **digoxin**.⁹ For mention of a patient whose **digoxin** levels became subtherapeutic when acarbose was substituted for voglibose, see above. There would therefore appear to be no reason for avoiding concurrent use. No special precautions are needed.

Digitalis glycosides + Aminoglutethimide

The clearance of digitoxin is markedly increased by aminoglutethimide and a reduction in its effects would be expected.

Clinical evidence, mechanism, importance and management

The clearance of **digitoxin** was increased by a mean of 109% in 5 patients who took aminoglutethimide (250 mg four times a day in four, and 125 mg twice daily in one).^{1,2} The likely reason is that aminoglutethimide increases the metabolism of the **digitoxin** by the liver.

This increase in clearance would be expected to be clinically important, but this does not appear to have been assessed. Check that patients do not become under-digitalised during concurrent treatment. No interaction would be expected with **digoxin** because it is largely excreted unchanged in the urine and therefore metabolism by the liver has little part to play in its clearance.

Digitalis glycosides + Aminoglycosides

Serum levels of digoxin can be reduced by the concurrent use of oral neomycin and increased by intramuscular gentamicin.

Clinical evidence

(a) Gentamicin

In a study in 12 patients with congestive heart failure taking **digoxin** 250 micrograms daily, the addition of gentamicin 80 mg intramuscularly twice daily for 7 days was found to increase serum **digoxin** levels by 129%. In a further 12 patients with congestive heart failure and diabetes, the same dosage of gentamicin increased **digoxin** levels more than two-fold to 2 nanograms/mL. However, no symptoms of **digoxin** toxicity were seen. It should be noted that serum creatinine levels were higher in both groups than those in healthy controls even before receiving gentamicin, and were further increased after gentamicin.¹

An earlier study similarly found that gentamicin prolonged the half-life of **digoxin** and increased serum levels from 1.9 to 2.8 nanograms/mL.²

(b) Neomycin

Neomycin 1 to 3 g orally was found to reduce and delay the absorption of a single 500-microgram dose of **digoxin** in healthy subjects.³ The AUC was reduced by 41 to 51%. Absorption was affected even when the neomycin was given 3 to 6 hours before the **digoxin**. In a steady-state study, neomycin 2 g given with **digoxin** 250 to 500 micrograms daily reduced the serum level of **digoxin** by 8 to 49% (mean 28.2%).³

Mechanism

Gentamicin impairs renal function, so decreasing digoxin clearance.² Higher digoxin levels and serum creatinine levels in diabetic compared with non-diabetic patients may be due to differences in renal function,¹ with concurrent gentamicin causing further renal function impairment and even higher digoxin levels. The reduction in digoxin toxicity is not fully understood but changes in ionic transport may be involved. The inhibition

by gentamicin of Na⁺/K⁺ ATPase, which acts as a specific receptor for digoxin, may also be a factor.¹

Neomycin can cause a general but reversible malabsorption syndrome, which affects the absorption of several drugs. The extent of this is probably offset in some patients, because the neomycin also reduces the breakdown of digoxin by the bacteria in the gut.⁴

Importance and management

Information is limited, but patients should be monitored for increased digoxin effects if gentamicin is given, especially those with diabetes or any other patient with impaired renal function. Initially, checking pulse rate is probably adequate. There seems to be no information about other parenteral aminoglycosides.

Patients should be monitored for reduced digoxin effects if neomycin is given and suitable dosage adjustments made if necessary. Separating the dosages of the two drugs does not prevent this interaction. Other aminoglycosides that can be given orally such as **kanamycin** and **paromomycin** might possibly interact similarly to neomycin, but this requires confirmation.

Digitalis glycosides + 5-Aminosalicylates

Serum digoxin levels can be reduced by sulfasalazine. The manufacturers of balsalazide suggest that it may interact similarly.

Clinical evidence, mechanism, importance and management

The observation that a patient taking **sulfasalazine** 8 g daily had low serum **digoxin** levels, prompted a crossover study in 10 healthy subjects. In this study a single 500-microgram dose of **digoxin** syrup was given alone, and after 6 days of treatment with **sulfasalazine** 2 to 6 g daily. **Digoxin** absorption was reduced, ranging from 0 to 50% depending on the dosage of **sulfasalazine** used.¹ Serum **digoxin** levels were reduced accordingly.¹ The reasons for this effect are not understood. This seems to be the only report of this interaction. Concurrent use need not be avoided, but it would be prudent to check for under-digitalisation, initially by checking symptoms and pulse rate, and then taking **digoxin** levels if an interaction is suspected. In the one patient examined, separating the dosages appeared not to prevent this interaction.¹

Although no interaction involving **digoxin** and **balsalazide** has been reported, based on the information with sulfasalazine, the manufacturers of **balsalazide** recommend that plasma levels of **digoxin** should be monitored in digitalised patients starting **balsalazide**.²

Digitalis glycosides + Aminosalicic acid

Aminosalicic acid causes a small reduction in digoxin levels in healthy subjects but the importance of this in patients is uncertain.

Clinical evidence, mechanism, importance and management

In one study in 10 healthy subjects, the bioavailability of a single 750-microgram dose of **digoxin**, using urinary excretion as a measure, was reduced by 20% by aminosalicic acid 2 g four times daily for 2 weeks.¹ This seems to be just another aspect of the general malabsorption caused by aminosalicic acid. The importance of this interaction in patients is not known (it is probably small) but it would be prudent to monitor concurrent use.

- Brown DD, Juhl RP, Warner SL. Decreased bioavailability of digoxin due to hypocholesterolemic interventions. *Circulation* (1978) 58, 164–72.

Digitalis glycosides + Amiodarone

Digoxin levels can be approximately doubled by amiodarone. Some individuals may show even greater increases. The same interaction also appears to occur with digitoxin.

Clinical evidence

(a) Acetyldigoxin

Torsade de pointes developed in one patient 3 days after the amiodarone dose was increased to 600 mg daily, and beta-acetyldigoxin 100 micrograms and bisoprolol 1.25 mg daily were added, for persistent atrial fibrillation. Serum levels of digoxin and amiodarone were normal. Withdrawal of all medications and treatment with intravenous magnesium resolved the arrhythmias. It has been suggested that the bradycardia caused by treatment with these three drugs may have placed the patient at risk of such arrhythmias.¹ Cases of proarrhythmic effects of amiodarone with digoxin have also been reported, see *Digoxin*, below.

(b) Digitoxin

Two elderly patients (aged 77 and 78) taking digitoxin 100 micrograms daily were given loading doses of amiodarone followed by maintenance doses of 200 to 400 mg daily. Within 2 months in one case, and 4 months in the other, they were hospitalised because of bradycardia, dyspnoea, nausea and malaise. One of them had total AV block (38 bpm). The serum digitoxin levels of both of them were found to be elevated (54 and 45 nanograms/mL, respectively) well above the therapeutic range of 9 to 30 nanograms/mL. Serum amiodarone and desethylamiodarone levels were normal. Both patients recovered when the digitoxin was stopped.²

(c) Digoxin

The observation that patients taking digoxin developed digoxin toxicity when given amiodarone³ prompted a study of this interaction. Seven patients receiving maintenance digoxin had a mean rise in their plasma digoxin levels of 69%, from 1.17 to 1.98 nanograms/mL, when they were given amiodarone 200 mg three times daily. Two other patients similarly treated also showed this interaction.³

Numerous studies in patients have confirmed this interaction with reported increases in serum digoxin levels of 75%,⁴ 90%,⁵ 95%⁶ and 104%.⁷ The occasional patient may show three- to fourfold increases, whereas others may show little or no change.^{5,8} Children seem particularly sensitive, with threefold, and even as much as ninefold rises.⁹ Other reports confirm that the digoxin levels are markedly increased or roughly doubled, and toxicity can occur.^{8,10-19} In contrast, one group of workers state that they observed no change in serum digoxin levels in 5 patients given amiodarone.^{20,21}

There is also some evidence that, in the treatment of resistant atrial tachyarrhythmias, the risk of arrhythmias may be increased by the concurrent use of digoxin and amiodarone,^{18,22} and another study found that combined use had an unfavourable effect on survival in patients with atrial fibrillation and sinus rhythm.²³

A review of prescribing in an Australian hospital revealed 42 patients who had received amiodarone with digoxin (both long-term (16), either drug recently started (21), or both drugs recently started (5)). Of 31 patients who had digoxin levels monitored, 12 required a change in dose of the digoxin, and in 3, digoxin was stopped.²⁴ It is unclear whether this was purely on the basis of serum levels, or whether patients experienced adverse effects.

Mechanism

Not fully understood. Amiodarone reduces both the renal and non-renal excretion of digoxin.²⁵ *In vitro* studies have found that amiodarone (and possibly desethylamiodarone) inhibit P-glycoprotein-mediated transcellular transport of digoxin. This suggests that any interaction may occur, at least in part, by inhibiting digoxin renal tubular secretion.^{26,27} Other possible mechanisms that have been suggested include changes in thyroid function,²⁸ protein-binding displacement^{29,30} or increased absorption.³¹

It is thought that amiodarone can also inhibit the metabolism of digitoxin by the liver, which would explain why its serum levels are increased.²

Importance and management

The pharmacokinetic interaction between digoxin and amiodarone is well documented, well established and of considerable clinical importance. It occurs in most patients. It is clearly evident after a few days and develops over the course of 1 to 4 weeks.⁶ If no account is taken of this interaction the patient may develop digitalis toxicity. Reduce the digoxin dosage by between one-third to one-half when amiodarone is added,^{3,4,13,31} with further adjustment of the dosage after a week or two, and possibly a month or more,¹³ depending on digoxin levels. Particular care is needed in children, who may show much larger rises in digoxin levels than adults. Amiodarone has a long half-life so that the effects of this interaction will persist for several weeks after its withdrawal.¹⁷ A synergistic effect on heart rate and atrioventricular conduction is also possible, which may result in the development of new arrhythmias. Also note that some authors suggest that concurrent use may possibly worsen the prognosis in some patients.^{22,23}

Far less is known about the interaction between digitoxin and amiodarone but the limited evidence available suggests that all of the precautions appropriate for digoxin should be used for digitoxin as well. Note that the interaction may possibly take months to develop.

Digitalis glycosides + Angiotensin II receptor antagonists

Candesartan, eprosartan, irbesartan, losartan, and valsartan do not appear to affect the pharmacokinetics of digoxin, but telmisartan may cause a rise in serum digoxin levels.

Clinical evidence

(a) Candesartan

There was no pharmacokinetic interaction between candesartan 16 mg daily and **digoxin** given as a loading dose of 750 micrograms then 250 micrograms daily in 12 healthy subjects.¹

(b) Eprosartan

A study in 12 healthy men given a single 600-microgram dose of **digoxin** found that eprosartan 200 mg every 12 hours for 4 days had no significant effect on the pharmacokinetics of **digoxin**.²

(c) Irbesartan

A study in 10 healthy subjects taking **digoxin** for 2 weeks found no changes in the AUC or maximum serum levels of **digoxin**, when, during the second week, they also took irbesartan 150 mg daily.³

(d) Losartan

In 13 healthy subjects the pharmacokinetics of a single 500-microgram oral or intravenous dose of **digoxin** were not affected by losartan 50 mg daily for a week.⁴

(e) Telmisartan

A study in 12 healthy subjects given a 500-microgram loading dose of **digoxin** followed by 250 micrograms daily found that the maximum serum concentration, the trough serum concentration and the AUC were increased by 50%, 13%, and 22%, respectively, when telmisartan 120 mg daily was given for 7 days.⁵ No clinically relevant changes in vital signs or ECGs were noted.

(f) Valsartan

There was no adverse interaction between a single 160-mg dose of valsartan and **digoxin** 250 micrograms in a study in 12 healthy subjects.⁶

Mechanism

It has been suggested that telmisartan may have caused digoxin to be more rapidly absorbed.⁵ An *in vitro* study found that candesartan and losartan do not appear to inhibit P-glycoprotein-mediated transcellular transport. Therefore interactions resulting in reduced digoxin renal excretion are unlikely.⁷

Importance and management

No special precautions seem to be necessary when digoxin is used with candesartan, eprosartan, irbesartan, losartan, or valsartan. However, note that information for eprosartan, losartan, and valsartan is from single-dose studies, although the authors of the eprosartan study consider that a clinically relevant interaction with multiple doses of digoxin is unlikely.² The small increase in trough serum digoxin level with telmisartan suggests that the dose of digoxin need not automatically be reduced when telmisartan is started, but consideration should be given to monitoring digoxin effects (e.g. monitor for bradycardia) and take digoxin levels if necessary.

Digitalis glycosides + Antacids

Although some studies suggest that antacids can reduce the bioavailability of digoxin and digitoxin, there is other evidence suggesting that no clinically relevant interactions occur.

Clinical evidence

(a) Digoxin

1. *Evidence of an interaction.* A study in 10 healthy subjects given digoxin 750 micrograms with 60 mL of either 4% **aluminium hydroxide gel**, 8% **magnesium hydroxide gel** or **magnesium trisilicate** found that the cumulative 6-day urinary excretion, expressed as a percentage of the original dose, was 40% for control; 31% for **aluminium hydroxide**; 27% for **magnesium hydroxide**; and 29% for **magnesium trisilicate**.¹

Other studies describe reductions in digoxin absorption of 11% with **aluminium hydroxide**, 15% with **bismuth carbonate** and **light magnesium carbonate**, and 99.5% with **magnesium trisilicate**.²

When digoxin was given with 30 mL of an **aluminium/magnesium hydroxide** antacid and mexiletine, the digoxin AUC was approximately halved. As 'mexiletine', (p.931) does not appear to interact with digoxin the interaction was attributed to the antacid.³

2. *Evidence of no interaction.* A study in 4 patients chronically treated with digoxin 250 to 500 micrograms daily, found that the concurrent use of either 10 mL of **aluminium hydroxide mixture BP** or **magnesium trisilicate mixture BP**, three times daily, did not reduce the bioavailability of the digoxin and none of the patients showed any reduction in the control of their symptoms.⁴

Other bioavailability studies have not found a significant interaction between digoxin capsules and **aluminium/magnesium hydroxide**.⁵

(b) Other cardiac glycosides

In vitro studies with **digitoxin** suggest that it might possibly interact like digoxin, and be absorbed by various antacids,⁶ but **lanatoside C** probably does not interact.⁷ Bioavailability studies have not found a significant interaction between **beta-acetyldigoxin** and **aluminium/magnesium hydroxide**.⁸

A study in 10 patients with heart failure showed that their steady-state serum **digitoxin** levels were slightly, but not significantly raised (from 13.6 to 15.1 nanograms/mL) while taking 20 mL of **aluminium/magnesium hydroxide gel** three or four times daily, separated from the **digitoxin** dosage by at least 1 to 2 hours.⁹

Mechanism

Not established. One suggestion is that the digoxin can become adsorbed onto the antacids and therefore unavailable for absorption.^{1,6} This is probably also true for digitoxin. However, some results are not consistent with this idea.

Importance and management

The interactions between digoxin or digitoxin and antacids are only moderately well documented, and the evidence is inconsistent. No clearly clinically relevant interactions have been reported. Separating the dosages by 1 to 2 hours to minimise admixture is effective with many other drugs that interact in the gut, and seems to work with digitoxin. However, unless further information becomes available it seems unlikely that separating administration is necessary, although it may be worth bearing in mind if, on rare occasions, a patient experiences an interaction.

Digitalis glycosides + Anticholinesterases; Centrally acting

There is no pharmacokinetic interaction between digoxin and tacrine or donepezil. The bradycardic effects of anticholinesterases and digoxin may possibly be additive.

Clinical evidence, mechanism, importance and management

A single-dose study in 12 healthy subjects found that the pharmacokinetics of **donepezil** 5 mg and **digoxin** 250 micrograms were not affected by concurrent use and no clinically relevant changes in cardiac conduction parameters occurred.¹

In one study in healthy subjects given a single 500-microgram dose of **digoxin**, the pharmacokinetics of the **digoxin** were unchanged by **tacrine** 20 mg every 6 hours.² Although no special precautions would seem necessary on a pharmacokinetic basis, check to see that the combined bradycardic effects of **digoxin** and **tacrine** do not become excessive.

Similarly, the manufacturers of **galantamine**³ say that no pharmacokinetic interactions have been seen with **digoxin**, but caution about the possibility of a pharmacodynamic interaction that may result in bradycardia. The manufacturers of **rivastigmine**⁴ say that the combination has no pharmacokinetic interaction, nor does it interfere with cardiac conduction. It would however seem prudent to monitor heart rate if any of these combinations are used.

Digitalis glycosides + Antiepileptics; Miscellaneous

There is little evidence to suggest that carbamazepine interacts with digoxin, and topiramate causes only a small reduction in digoxin serum levels. Levetiracetam and tiagabine do not appear to interact with digoxin.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine

In an early clinical study, bradycardia seen in 3 patients taking **digitalis** and carbamazepine was tentatively attributed to their concurrent use.¹ There appear to be no other reports to confirm or refute this.

(b) Levetiracetam

In a placebo-controlled study, 11 healthy subjects were given an initial loading dose of **digoxin** 500 micrograms followed by 250 micrograms daily with levetiracetam 1 g twice daily for one week. Levetiracetam did not significantly affect the pharmacokinetics or pharmacodynamics of **digoxin**, and the pharmacokinetics of levetiracetam were not significantly altered by **digoxin**.² No additional precautions seem necessary on concurrent use.

(c) Tiagabine

In a crossover study, 13 healthy subjects were given a loading dose of **digoxin** 500 micrograms twice daily for one day then 250 micrograms daily for 8 days, either alone or with tiagabine 4 mg three times daily for 9 days. It was found that the pharmacokinetics of **digoxin** were not significantly altered by tiagabine.³

(d) Topiramate

Topiramate 100 mg twice daily for 9 days caused a small reduction in the serum **digoxin** levels of 12 healthy subjects. The maximum serum levels

and the AUC were reduced by 15.8% and 12%, respectively, and the oral **digoxin** clearance was increased by 13%.^{4,6} The manufacturers suggest good monitoring of **digoxin** if topiramate is added or withdrawn,⁵ but changes in the pharmacokinetics of **digoxin** of this magnitude seem unlikely to be clinically relevant in most patients.

Digitalis glycosides + Antiepileptics; Phenytoin

Phenytoin reduces the serum levels of digoxin and digitoxin. Cases of bradycardia have been seen in digitalised patients given phenytoin. Phenytoin was formerly used for the treatment of digitalis-induced cardiac arrhythmias, but sudden cardiac arrest has been reported.

Clinical evidence

(a) Bradycardia and cardiac arrest

A patient with suspected digitalis-induced cardiac arrhythmias developed bradycardia, then became asystolic and died, following an intravenous injection of phenytoin.¹ The discussion of this case briefly mentions a further 6 fatalities in patients similarly treated.¹ A patient with Down's syndrome and mitral valve insufficiency taking **digoxin** 250 micrograms daily developed bradycardia of 34 bpm and complete heart block when his phenytoin dose was increased from 200 to 300 mg daily.²

(b) Reduced digoxin levels

A study in 6 healthy subjects given **beta-acetyldigoxin** 400 micrograms daily found that the half-life of digoxin was reduced by 30% (from 33.9 to 23.7 hours) and the AUC was reduced by 23% after they took phenytoin 200 mg twice daily for a week. Total digoxin clearance increased by 27% (from 258.6 to 328.3 mL/minute).³

(c) Reduced digitoxin levels

The plasma digitoxin levels of a man were reduced on three occasions when he was given phenytoin. On the third occasion, while taking digitoxin 200 micrograms daily, the addition of phenytoin 900 mg daily caused a 60% fall in digitoxin levels (from 25 to 10 nanograms/mL) over a 7 to 10 day period.⁴

Mechanism

Phenytoin has a stabilising effect on the myocardial cells so that the toxic threshold of digoxin at which arrhythmias occur is raised. However, the bradycardic effects of the digitalis glycoside are not opposed and the lethal dose is unaltered, so that the cardiac arrest reported would appear to be the result of excessive bradycardia. It seems possible that the fall in plasma digitoxin levels may be due to a phenytoin-induced increase in the metabolism of the digitoxin by the liver.⁵

Importance and management

Phenytoin was formerly used for treating digitalis-induced arrhythmias, but this use now appears to be obsolete. Intravenous phenytoin should not be used in patients with a high degree of heart block or marked bradycardia because of the risk that cardiac arrest may occur. Information about the effects of phenytoin on digitalis glycoside levels seems to be confined to these single reports, but it may be prudent to check that patients who are taking digitoxin (and possibly digoxin), and are subsequently given phenytoin, do not become under-digitalised.

Digitalis glycosides + Antineoplastics

Treatment with radiation and/or antineoplastic cytotoxics can damage the lining of the intestine so that digoxin (given as tablets) is much less readily absorbed. This appears to be resolved by giving the digoxin in liquid or liquid-in-capsule form, or by substituting digitoxin.

Clinical evidence

A study in 13 patients with various forms of neoplastic disease showed that radiation therapy and/or various high-dose cytotoxic regimens (including **carmustine**, **cyclophosphamide**, **melphalan**, **cytarabine** and **methotrexate**) reduced the absorption of **digoxin** from tablets (*Lanoxin*) by almost 46%, but the reduction was not significant (15%) when the **digoxin** was given as capsules (*Lanoxicaps*).¹

Other studies confirm that a 50% reduction in serum **digoxin** levels (using **beta-acetyldigoxin**) occurred in patients given **cyclophosphamide**, **vincristine**, **procarbazine** and prednisone (COPP); **cyclophosphamide**, **vincristine** and prednisone (COP); **cyclophosphamide**, **vincristine**, **cytarabine** and prednisone (COAP); and **doxorubicin**, **bleomycin** and prednisone (ABP). These effects disappeared about a week after cytotoxic therapy finished.² Radiation has a smaller effect.³ **Digitoxin** absorption does not seem to be affected by antineoplastics.⁴

Mechanism

The reduced absorption is thought to result from damage to the intestinal epithelium caused by the antineoplastic cytotoxics.⁵

Importance and management

The interaction appears to be established. Patients taking digoxin and receiving treatment with antineoplastic cytotoxics should be monitored for signs of under-digitalisation. The problem can be overcome by replacing digoxin tablets with digoxin in liquid form or in solution inside a capsule. The effects of the interaction are short-lived so that a downward readjustment may be necessary about a week after treatment is withdrawn. An alternative is to use digitoxin, which does not appear to be affected.

Digitalis glycosides + Aprepitant

Aprepitant does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A placebo-controlled, randomised, study in 11 healthy subjects found that the pharmacokinetics of **digoxin** 250 micrograms daily were not affected by aprepitant (125 mg given on day 7 and 80 mg given daily on days 8 to 11). *In vitro* evidence indicates that aprepitant is a substrate and weak inhibitor of P-glycoprotein. However, at the doses used for the prevention of chemotherapy-induced nausea and vomiting, it appears unlikely to interact with P-glycoprotein substrates such as **digoxin**.¹

- Feuring M, Lee Y, Orlowski LH, Michiels N, De Smet M, Majumdar AK, Petty KJ, Goldberg MR, Murphy MG, Gottesdiener KM, Hesney M, Brackett LE, Wehling M. Lack of effect of aprepitant on digoxin pharmacokinetics in healthy subjects. *J Clin Pharmacol* (2003) 43, 912–17.

Digitalis glycosides + Argatroban

No significant pharmacokinetic interaction occurs between digoxin and argatroban.

Clinical evidence, mechanism, importance and management

A placebo-controlled, crossover study in 12 healthy subjects found that the pharmacokinetics of steady-state **digoxin** 375 micrograms daily were not affected by an infusion of argatroban 2 micrograms/kg per minute for 120 hours. Steady-state argatroban levels were obtained within 3 hours and maintained throughout the infusion. Dosage adjustments should not be necessary during concurrent use.¹

Digitalis glycosides + Aspirin

Aspirin may cause a moderate rise in serum digoxin levels, but no interaction of clinical relevance seems to occur.

Clinical evidence, mechanism, importance and management

Although aspirin can double the serum concentrations of **digoxin** in dogs, a study in 8 healthy subjects found no interaction, even when high doses of aspirin (975 mg three times daily) were given.¹ However, in another study in 9 healthy subjects given aspirin 1.5 g daily for 10 days, the serum **digoxin** levels were increased by 31%.² A further study found a 49% increase in **digoxin** levels when it was given with aspirin 1.5 g daily.³ Bearing in mind that both drugs have been in use for a very considerable number of years, the lack of reports in the literature describing problems suggests that no clinically important interaction normally occurs.

Digitalis glycosides + Azoles; Itraconazole

Itraconazole causes a marked increase in serum digoxin levels. Toxicity may occur unless the digoxin dosage is suitably reduced. Theoretically, itraconazole might also oppose the positive inotropic effects of digoxin.

Clinical evidence

In a placebo-controlled, crossover study, 10 healthy subjects taking **digoxin** 250 micrograms daily were given itraconazole 200 mg daily for 10 days. The serum **digoxin** levels increased by about 80% (from 1 to 1.8 nanograms/mL). New steady-state **digoxin** levels were not fully achieved during the 10-day period with itraconazole, so greater rises might occur on longer use.¹ A study in 3 patients with congestive heart failure taking **digoxin** found that itraconazole decreased **digoxin** clearance by 50% and increased **digoxin** levels, and ECG changes (premature ventricular contractions, AV block and ST depression) occurred.²

A 68-year-old man taking **digoxin** 250 micrograms twice daily and ibuprofen developed nausea and fatigue (interpreted later as **digoxin** toxicity) after starting itraconazole 400 mg daily for an infected elbow. The symptoms disappeared when both the itraconazole and ibuprofen were stopped, but returned when the itraconazole was restarted. After 7 days his heart rate had fallen, from 60 to 40 bpm, and his **digoxin** level had doubled, from 1.6 to 3.2 nanograms/mL. He was later satisfactorily restabilised on a quarter of the **digoxin** dosage while taking the same dose of itraconazole.³ Several other patients developed **digoxin** toxicity (a sixfold increase in one case) within 3 to 13 days of starting to take itraconazole,^{4–10} and after 4 weeks in one case.¹¹ A possible case of **digoxin** toxicity has also occurred with itraconazole pulse therapy.¹² Two cases of **digoxin** toxicity

have been reported when itraconazole was given to renal transplant patients, but other factors may have contributed to the high levels of **digoxin** in these 2 patients.¹³

Mechanism

Itraconazole inhibits P-glycoprotein, which transports digoxin out of kidney tubule cells into the urine,¹⁴⁻¹⁷ and therefore digoxin urinary clearance is reduced and serum levels are increased.^{5,10}

Importance and management

An established and clinically important pharmacokinetic interaction. Monitor the effects of digoxin (e.g. bradycardia, nausea, vomiting) if itraconazole is started, anticipating the need to reduce the digoxin dosage. Halving the dose was suggested in one study.² Two of the patients cited above were restabilised with a quarter of the digoxin dosage^{3,4} and another with about one-third of the original digoxin dose⁵ while taking itraconazole. More recent findings suggest that itraconazole may possess significant negative inotropic properties, and the CSM in the UK suggest that it should be used with caution in patients at risk of heart failure.¹⁸ This suggests that itraconazole might oppose the pharmacological effects of digoxin.

Digitalis glycosides + Azoles; Posaconazole

The UK manufacturer of posaconazole advises that digoxin levels should be monitored when initiating or discontinuing treatment with posaconazole, in the light of the rise in digoxin levels when given with other azoles.¹ See 'itraconazole', (p.910).

- Noxafil (Posaconazole). Schering-Plough Ltd. UK Summary of product characteristics, October 2006.

Digitalis glycosides + Azoles; Voriconazole

Voriconazole did not affect the steady-state pharmacokinetics of digoxin in a study in healthy patients. One study briefly mentions increased digoxin levels in two patients receiving voriconazole.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in healthy subjects given a **digoxin** loading dose over 2 days, then **digoxin** 250 micrograms daily for 20 days, found

that voriconazole 200 mg twice daily for the last 12 days had no significant effect on the steady-state pharmacokinetics of **digoxin**.¹ Unlike 'itraconazole', (p.910), voriconazole appears not to alter the P-glycoprotein-mediated transport of **digoxin**.

However, a clinical study in severely ill patients with invasive mycosis briefly mentions that two patients receiving voriconazole developed high trough **digoxin** levels, which required the **digoxin** to be withdrawn. One patient was symptomatic with an arrhythmia and ECG changes.²

Digitalis glycosides + Barbiturates

Blood levels of digitoxin can be halved by phenobarbital and its effects may be expected to be reduced accordingly. However, another study found that phenobarbital did not affect digitoxin, digoxin or acetyldigitoxin pharmacokinetics.

Clinical evidence

Phenobarbital 60 mg three times daily for 12 weeks, halved the steady-state plasma levels of **digitoxin** 100 micrograms daily.¹ In associated studies the half-life of **digitoxin** decreased from 7.8 to 4.5 days during **phenobarbital** treatment.¹ In another study² the rate of conversion of **digitoxin** to digoxin increased from 4% to 27% in one patient who took **phenobarbital** 96 mg daily for 13 days.

In contrast, a study in groups of 10 healthy subjects given either **digitoxin** 400 micrograms, **digoxin** 1 mg or **acetyldigitoxin** 800 micrograms daily did not find any changes in the serum concentrations of any of these digitalis glycosides when **phenobarbital** 100 mg was given three times daily for 7 to 9 days.³

Mechanism

Phenobarbital and other barbiturates are well-known potent liver enzyme inducers which, it would seem, can increase the metabolism and conversion of digitoxin to digoxin.^{1,2} The lack of interaction in one study may possibly have been because the barbiturate was taken for a relatively short time.³

Importance and management

An established interaction, although its clinical importance is somewhat uncertain because there seem to be few reports of the effects of using digitoxin with phenobarbital, or of problems in practice. Nevertheless, patients taking both drugs should be monitored for possible underdigitalisation and the dosage of digitoxin increased if necessary. It seems likely that digoxin will not be affected by the barbiturates because it is largely excreted unchanged in the urine. Other barbiturates would be expected to behave like phenobarbital.

Digitalis glycosides + Benzodiazepines and related drugs

Digoxin toxicity occurred in two elderly patients and rises in serum digoxin levels have been seen in others when they were given alprazolam. A reduction in the urinary clearance of digoxin has been described during the use of diazepam. No pharmacokinetic interaction seems to occur with digoxin and eszopiclone, zaleplon, or zolpidem.

Clinical evidence*(a) Benzodiazepines*

1. *Alprazolam*. An elderly woman taking **digoxin**, maprotiline, isosorbide dinitrate, furosemide and potassium chloride showed signs of **digoxin** toxicity during the second week of taking alprazolam 1 mg daily. Her serum **digoxin** levels were later found to have risen almost 300%, from 1.6 to 4.3 nanograms/mL, and her apparent **digoxin** clearance had fallen from 126.3 to 49.8 L/day.¹ A later study in 12 patients confirmed that **digoxin** levels can be significantly raised by alprazolam, particularly in those over 65 years old. One elderly man developed clinical **digoxin** toxicity.² In contrast, a study in 8 healthy subjects found no changes in the clearance of **digoxin** after they took alprazolam 1.5 mg daily.³

2. *Diazepam*. The observation that 3 patients developed raised **digoxin** levels while also taking diazepam prompted a further study in 7 healthy subjects.⁴ After taking diazepam 5 mg with a single 500-microgram dose of **digoxin**, and diazepam 5 mg every 12 hours thereafter, all of them had a substantial reduction in the urinary excretion of **digoxin** and 5 of them had a moderate increase in the **digoxin** half-life. No further details were given.⁴

3. *Metaclozepam*. No statistically significant interaction was seen in 9 patients taking **beta-acetyldigoxin** when they were given metaclozepam.⁵

(b) Non-benzodiazepine hypnotics

1. *Eszopiclone*. In a study in 12 healthy subjects, a 3-mg single dose of eszopiclone did not alter the pharmacokinetics of **digoxin**, given for 7 days.⁶

2. *Zaleplon*. Zaleplon 10 mg daily given to 20 healthy subjects for 5 days had no significant effects on the steady-state pharmacokinetics of **digoxin** 375 micrograms daily. There were no significant differences in QTc or PR intervals.⁷

3. *Zolpidem*. No significant pharmacokinetic interaction occurs between zolpidem and **digoxin**.⁸

Mechanism

Uncertain. The suggestion is that diazepam may possibly alter the extent of the protein binding of digoxin within the plasma, which may have some influence on the renal tubular excretion,⁴ but see comments on protein binding interactions in 'Drug distribution interactions', (p.3). The reason for the interaction between digoxin and alprazolam is not understood.

Importance and management

The interaction between digoxin and alprazolam is established and clinically important. Monitor the effects of digoxin (e.g. bradycardia) in any patient if alprazolam is added, and reduce the digoxin dosage as necessary. What is known suggests that toxicity is more likely in the elderly. Other benzodiazepines and digoxin have been used for a considerable time but there seem to be no other reports of adverse interactions. The newer non-benzodiazepine hypnotics, eszopiclone, zaleplon and zolpidem do not appear to affect the pharmacokinetics of digoxin.

Digitalis glycosides + Beta-agonist bronchodilators

Oral salbutamol (albuterol) causes a small reduction in serum digoxin levels. Beta agonists can cause hypokalaemia, which could lead to the development of digitalis toxicity.

Clinical evidence, mechanism, importance and management

A study in 10 healthy subjects who had taken **digoxin** 500 micrograms daily for 10 days¹ found that, 3 hours after taking oral **salbutamol** (albuterol) 3 to 4 mg, their serum **digoxin** levels had fallen by 0.23 nanograms/mL and their serum potassium levels had fallen by 0.58 mmol/L. A follow-up study suggested that the **digoxin** distribution to skeletal muscle may have been increased.²

Note that all beta₂ agonists can cause a fall in serum potassium, which could possibly affect the response of patients to **digoxin**. The clinical importance of these changes is uncertain but concurrent use should be monitored. Consider monitoring potassium levels if the effects of **digoxin** seem excessive.

2. Edner M, Jogestrand T, Dahlqvist R. Effect of salbutamol on digoxin pharmacokinetics. *Eur J Clin Pharmacol* (1992) 42, 197–201.

Digitalis glycosides + Beta blockers

In general there appears to be no pharmacokinetic interaction between digoxin and beta blockers, although talinolol and carvedilol appear to increase the bioavailability of digoxin. Pharmacodynamic interactions, resulting in additive bradycardia, are possible. A few cases of excessive bradycardia have been reported when propranolol was used to control digitalis-induced arrhythmias.

Clinical evidence*(a) Pharmacokinetic interactions*

1. *Carvedilol*. A 12-year-old boy with dilated cardiomyopathy taking **digoxin** 250 micrograms in the morning and 125 micrograms in the evening was subsequently given carvedilol 70 micrograms/kg twice daily. Several days later he became anorexic and started vomiting and his **digoxin** serum level was found to have increased from 1.6 to 2.3 nanograms/mL up to 4.2 nanograms/mL. **Digoxin** was stopped and subsequently restarted at half the original dose.¹ In one study, 8 children aged 2 weeks to 8 years were given **digoxin** for ventricular failure secondary to congenital heart disease. When they were also given carvedilol 0.06 to 1.06 mg/kg daily the clearance of **digoxin** was approximately halved and 2 children experienced **digoxin** toxicity.¹

A single-dose study in healthy adults given carvedilol 25 mg found that maximum plasma levels of a 500-microgram dose of **digoxin** were increased by 0.97 nanograms/mL (60%) and the AUC was increased by about 20%, but the clinical effects of these changes were considered likely to be small.² No significant pharmacokinetic interaction was found in other single-dose studies in adults given carvedilol and **digoxin**,³ or carvedilol and intravenous **digoxin**.⁵

In a multiple-dose study in adult patients with hypertension, carvedilol raised the maximum serum levels and AUC of **digoxin** 250 micrograms daily by 32% and 14%, respectively, after 2 weeks of treatment. Again, these changes were considered unlikely to be clinically significant.⁴ In another study in 12 male and 12 female patients taking **digoxin** 62.5 to 250 micrograms daily for heart failure, the addition of carvedilol 6.25 mg twice daily for 7 days increased the maximum concentration and the AUC₀₋₁₆ of **digoxin** by 37% and 56%, respectively, in the men, but no significant changes to the pharmacokinetics of **digoxin** were noted in the women.⁵

2. *Talinolol*. In healthy subjects talinolol 100 mg orally substantially increased the bioavailability of a single 500-microgram dose of **digoxin**. The AUC₀₋₇₂ and the maximum serum levels of **digoxin** were increased by 23% and 45%, respectively.⁶ Conversely, intravenous talinolol 30 mg had no effect on **digoxin** pharmacokinetics.⁶

3. *Miscellaneous*. A single dose of intravenous **esmolol** did not affect the pharmacokinetics of multiple-dose **digoxin**, except that a small increase was seen in the AUC₀₋₆ of **digoxin**.⁷ The pharmacokinetics of multiple-dose **digoxin** have been shown to be unaffected by **acebutolol**,⁸ **bevantolol** 200 mg daily,⁹ **bisoprolol** 10 mg daily,¹⁰ **nebivolol** 10 mg daily,¹¹ or **sotalol** 80 to 320 mg daily.¹²

(b) Pharmacodynamic interactions

Increased bradycardia is expected to occur with combinations of **digoxin** and beta blockers, but reports of this becoming a problem seem rare. One report notes marked bradycardia of 35 to 50 bpm in a 91-year-old patient taking **digoxin** and using **timolol** 0.25% eye drops.¹³ Bradycardia persisted on withdrawal of **digoxin**, and improved only after discontinuation of the timolol as well. Two cases, where **propranolol** 10 mg orally was used to treat arrhythmias associated with **digoxin** toxicity, are reported.¹⁴ The first patient (who had heart failure) became bradycardic, asystolic and then died, while the second patient became bradycardic (30 bpm) but recovered after being given atropine. A further fatality was reported when intravenous **propranolol** was used.¹⁵ In a placebo-controlled study of the use of **sotalol** in digitalised patients with chronic atrial fibrillation, 2 of 24 **sotalol** recipients were withdrawn due to bradycardia compared with none of 10 given placebo. However, the combination was still considered valuable.¹² In a prospective analysis of adverse drug reactions leading to hospital admission over a 4-year period, 83 patients were identified who had been admitted with bradycardia. Of these, 62 were taking **digitalis glycosides**, and 14 were also taking a beta blocker.¹⁶

In healthy subjects, the pharmacodynamics of **digoxin** were unaffected by **bevantolol**,⁹ and **esmolol**,⁷ with no significant changes in heart rate or blood pressure occurring.

Mechanism

In most cases where the situation has had an adverse outcome the interaction seems to be due to the additive effects on the slowing of the heart.

It has been suggested that the pharmacokinetic interaction with talinolol is due to competition with digoxin for *intestinal* P-glycoprotein, although this needs confirmation.⁶ It would seem possible that this mechanism also accounts for the interaction between digoxin and carvedilol, and an *in vitro* study found that carvedilol (but not atenolol or metoprolol) inhibits P-glycoprotein-mediated transcellular transport of digoxin,¹⁷ which may mean *renal* tubular secretion of digoxin is inhibited. It is conceivable that P-glycoprotein inhibition by carvedilol enhances the intestinal absorption of digoxin and also decreases its renal excretion. This may explain why the interaction is possibly more significant in children, as they have a higher renal clearance rate of digoxin than adults.¹ Women have lower P-glycoprotein activity in the gut than men, which may account for the gender differences seen with the interaction of carvedilol and digoxin.⁵

It has also been suggested that the interaction between digoxin and talinolol may be dosage form dependent. More study is needed.

Importance and management

Concurrent use appears, on the whole, beneficial, but the potential for additive bradycardia should be borne in mind. Use of beta blockers in cases of digoxin toxicity should be undertaken with great care. In addition, it may be prudent to monitor digoxin levels with talinolol, and also with carvedilol, particularly in children. It has been suggested that the dose of digoxin should be reduced by at least 25% in children given carvedilol, with further adjustments as required.¹

Digitalis glycosides + Beta-lactam antibacterials

No interaction normally occurs between digoxin and amoxicillin, cefazolin, cefuroxime, flucloxacillin, phenoxymethylpenicillin or ticarcillin/clavulanic acid. No pharmacokinetic interaction occurs between ampicillin and digoxin. In contrast, one early study found that cefradine increased serum levels of digoxin.

Clinical evidence

Ampicillin 500 mg four times daily for 5 days had no significant effect on the pharmacokinetics of a single 1-mg dose of **digitoxin** in 6 healthy subjects.¹ No significant changes in **digoxin** serum concentrations were found in 16 elderly patients given **amoxicillin** (2 patients also took erythromycin and one **flucloxacillin**), and 2 patients who took **flucloxacillin** and **phenoxymethylpenicillin**. However, a few patients complained of some 'toxic' symptoms (nausea, vomiting, anorexia, headache, fatigue, blurred vision, confusion), which the authors of the report attributed to the underlying illness or the antibacterials rather than to an interaction.² There was no significant change in digoxin pharmacokinetics in 15 patients given **ticarcillin/clavulanic acid** 1 g/200 mg intramuscularly every 12 hours for one week.³ There was no reduction in the excretion of **digoxin** metabolites from the gut (see Mechanism) in 3 patients taking **cefazolin**, and a reduction occurred in only 1 of 10 patients taking penicillins (**ampicillin** 6, **oxacillin** 3, **penicillin** 1).⁴

A case-control study using data from healthcare databases in Ontario from 1994 to 2000 identified 1051 patients who had been admitted to hospital with **digoxin** toxicity. Of these, 5 patients (0.5%) had been exposed to **cefuroxime** in the preceding 3 weeks when compared with 0.3% of controls, suggesting that digoxin toxicity was not significantly related to **cefuroxime** exposure.⁵

In an early study, **cefradine** prolonged the half-life of **digoxin** and increased serum levels from 1.8 to 2.6 nanograms/mL. This effect was considered to occur as a result of reduced renal clearance.⁶

Mechanism

Up to 10% of patients receiving oral digoxin excrete it in substantial amounts in the faeces and urine as inactive metabolites (digoxin reduction products or DRPs). This metabolism seems to be due to gut flora,⁷ in particular *Eubacterium lentum*, which is anaerobic and Gram positive. It was suggested that inhibition of digoxin metabolism by gut flora was responsible for any interaction, but doubt has been thrown on this theory, see *Mechanism* in 'Digitalis glycosides + Macrolides', (p.929).

Importance and management

The silence of the literature on adverse interactions between digoxin and beta-lactam antibacterials, and the limited evidence for a plausible mechanism suggest that interactions are unlikely.

Digitalis glycosides + Bosentan

Bosentan does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In 18 healthy subjects bosentan 500 mg twice daily for a week did not significantly affect the steady-state peak or trough levels of **digoxin** 375 micrograms daily. There was a small reduction of about 12% in the AUC of **digoxin**, although this was not considered to be clinically relevant. There were no changes in ECG recordings and vital signs.¹

The results suggest that bosentan does not interact with **digoxin**, and that concurrent use need not be avoided. However, the authors note that further studies over the longer term, and in patients with renal impairment may be necessary to confirm this.

1. Weber C, Banken L, Birnboeck H, Nave S, Schulz R. The effect of bosentan on the pharmacokinetics of digoxin in healthy male subjects. *Br J Clin Pharmacol* (1999) 47, 701–6.

Digitalis glycosides + Calcium-channel blockers

Concurrent use can be valuable. Felodipine, gallopamil, lacidipine, nicardipine and nisoldipine cause small but normally clinically unimportant increases in digoxin levels, while amlodipine, isradipine and nimodipine appear not to interact. The situation with nitrendipine is uncertain but it possibly causes only a small rise in digoxin levels.

Clinical evidence

(a) Amlodipine

Amlodipine 5 mg daily had no significant effect on the serum levels or renal clearance of **digoxin** 375 micrograms daily given to 21 healthy subjects.¹

(b) Bepridil

In 12 healthy subjects bepridil 300 mg daily for a week raised the serum levels of **digoxin** 375 micrograms daily by 34% (from 0.93 to 1.25 nanograms/mL).² Five of them had mild to moderate headache, nausea and dizziness for 1 to 3 days shortly after concurrent use was started. The bradycardic effects of the two drugs were found to be additive, while the negative inotropic effects of the bepridil and the positive inotropism of the increased serum **digoxin** levels were almost balanced.²

In another study in 23 subjects given **digoxin** 250 micrograms and bepridil 300 mg daily for 14 days, peak plasma **digoxin** levels rose by 48% (from 1.49 to 2.2 nanograms/mL) and the AUC rose by 21%.³

(c) Felodipine

Felodipine 10 mg twice daily for 8 weeks raised the serum **digoxin** levels in 11 patients by 15%, which was not clinically significant.⁴ In another study, 14 patients were given felodipine 10 mg daily for a week. Plain tablets raised the steady-state **digoxin** serum levels by 11%, but extended-release tablets had no significant effect.⁵ A third study found that, when taking felodipine, peak plasma **digoxin** levels were transiently raised by about 40% one hour after intake, but that **digoxin** AUCs were not significantly increased.⁶

(d) Gallopamil

Gallopamil 50 mg three times daily for 2 weeks raised the serum levels of **digoxin** 375 micrograms daily by 16% (from 0.58 to 0.67 nanograms/mL) in 12 healthy subjects.⁷

(e) Isradipine

Isradipine (given as 2.5 mg every 12 hours for 2 days, 5 mg every 12 hours for 2 days and then 5 mg three times daily for 10 days) did not interact significantly with a single 1-mg intravenous dose of **digoxin** given to 24 healthy subjects.⁸ A similar study by the same group found that the same dosage regimen of isradipine given with oral **digoxin** 250 micrograms twice daily caused a small increase in peak serum **digoxin** levels but no changes in its steady-state levels or AUC.⁹

(f) Lacidipine

In 12 healthy subjects, a single 4-mg oral dose of lacidipine did not affect the AUC or minimum serum levels of **digoxin** 250 micrograms daily for 7 days, but the maximum serum levels of **digoxin** were increased by 34%. These changes were not considered to be clinically significant.¹⁰

(g) Lercanidipine

The maximum serum levels of **digoxin** rose by 33% in healthy subjects also given lercanidipine. However, there was no evidence of a pharmacokinetic interaction in patients given **metildigoxin** with lercanidipine.¹¹

(h) Nicardipine

In 10 patients given nicardipine 20 mg three times daily for 14 days the plasma levels of **digoxin** 130 to 250 micrograms daily were increased by 15%, but this was not statistically significant.¹² Another 20 patients with congestive heart failure also had no significant changes in steady-state serum **digoxin** levels while taking nicardipine 30 mg three times daily for 5 days.¹³ Yet another study in 9 patients confirmed the absence of an interaction.¹⁴

(i) Nimodipine

Nimodipine 30 mg twice daily caused no change in the pharmacokinetics or haemodynamic effects of **beta-acetyldigoxin** in 12 healthy subjects.¹⁵

(j) Nisoldipine

In 10 patients with heart failure nisoldipine 20 mg daily increased the plasma trough **digoxin** levels by about 15%.^{16,17} Nisoldipine 10 mg twice daily caused no changes in the pharmacokinetics or haemodynamic effects of **digoxin** in 8 healthy subjects.¹⁵

(k) Nitrendipine

A study in 8 healthy subjects who had been taking **digoxin** 250 micrograms twice daily for 2 weeks, showed that nitrendipine 10 mg daily caused a slight but insignificant rise in plasma **digoxin** levels. Nitrendipine 20 mg daily increased the AUC of **digoxin** by 15%, its maximum plasma levels rose from 1.34 to 2.1 nanograms/mL, and its clearance fell by 13%. One subject dropped out of the study because of dizziness, nausea and vomiting, palpitations, insomnia and nervousness.^{18,19}

Another study found that plasma **digoxin** levels were approximately doubled when nitrendipine was given,²⁰ but other studies in healthy subjects and patients found that nitrendipine 20 mg twice daily caused no changes in the pharmacokinetics or haemodynamic effects of **digoxin**,^{15,21} or **beta-acetyldigoxin**.²²

Mechanism

Where an interaction occurs it is probably due to changes in the renal excretion of the digoxin. An *in vitro* study found that several calcium-channel blockers including bepridil, nicardipine, and to a lesser extent nisoldipine (as well as barnidipine, benidipine, efonidipine, manidipine, nilvadipine, and verapamil) inhibited P-glycoprotein-mediated transcellular transport of digoxin. This suggests that any interaction may occur, at least in part, by affecting digoxin renal tubular excretion. Nitrendipine (and also diltiazem and nifedipine) only weakly inhibited the transcellular transport of digoxin.²³

Importance and management

The extent of the information varies from drug to drug, but the concurrent use of digoxin and calcium-channel blockers can be therapeutically valuable. Monitor the effects of digoxin (e.g. bradycardia) in patients given digoxin and bepridil or lercanidipine, and consider measuring levels if the effects of digoxin seem excessive. Reduce the digoxin dosage as necessary. The other calcium-channel blockers listed here either cause only minimal increases in digoxin levels, which are unlikely to be clinically important in most patients, or do not interact at all. The situation with nitrendipine needs clarification. For the interactions of digoxin with other calcium-channel blockers see 'diltiazem', (p.915), 'nifedipine', (p.915), and 'verapamil', (p.916).

Digitalis glycosides + Calcium-channel blockers; Diltiazem

Serum digoxin levels are reported to be unchanged by diltiazem in a number of studies but others describe increases ranging from 20 to 85%. Serum digitoxin levels have also been reported to rise in some patients, but only by about 20%. There is a risk of additive bradycardia when cardiac glycosides are given with diltiazem.

Clinical evidence

(a) Digitoxin

Five out of 10 patients taking digitoxin had a 6 to 31% (mean 21%) rise in plasma digitoxin levels while taking diltiazem 180 mg daily for 4 to 6 weeks.¹

(b) Digoxin

1. *Evidence of no interaction.* Diltiazem 30 or 60 mg four times daily had no significant effect on the serum levels of digoxin 250 micrograms daily in 9 patients with cardiac diseases.² Two similar studies in 12 patients³ and 8 healthy subjects,⁴ taking digoxin with diltiazem 120 to 360 mg daily confirmed the absence of an interaction. Two further studies in healthy subjects,^{5,6} found that diltiazem 120 mg daily did not affect the pharmacokinetics of a single 1-mg intravenous dose of digoxin.

2. *Evidence of an interaction.* A study in 17 Japanese patients (some with rheumatic valvular disease) taking either digoxin or metildigoxin found that diltiazem 60 mg three times daily for 2 weeks increased their serum digoxin levels measured at 24 hours by 36% and 51%, respectively.⁷ Another study in 8 patients with chronic heart failure secondary to ischaemic disease, taking digoxin 250 micrograms daily, found that diltiazem 60 mg three times daily increased the digoxin AUC and mean steady-state serum levels by about 50%, its peak serum level by 37% and elimination half-life by 29%. Diltiazem had no significant effects on haemodynamic parameters.⁸

Other studies in Western patients^{9,10} and healthy subjects^{11–14} have shown rises of 20 to 85% in plasma digoxin levels during diltiazem use. In one case report a 143% increase was seen.¹⁵ The authors of two of these studies noted that the effect was highly individual with some subjects showing no increase and some a large increase.^{10,12} There is also a case report of raised serum **digoxin** levels and toxicity in a man taking digoxin when given diltiazem with or without nifedipine.¹⁶

Mechanism

Not understood. In those individuals showing a pharmacokinetic interaction, falls in total digoxin clearance of about 25% have been described.^{8,10,11,17,18} Although several calcium-channel blockers may inhibit the P-glycoprotein-mediated renal clearance of digoxin, the results of an *in vitro* study¹⁹ suggest that this may not occur with diltiazem.

A synergistic effect on heart rate and atrioventricular conduction is also possible.

Importance and management

A thoroughly investigated and well documented pharmacokinetic interaction but there is no clear explanation for the inconsistent results. All patients taking digoxin given diltiazem should be well monitored for signs of over-digitalisation (e.g. bradycardia) with digoxin levels measured as necessary. Dosage reductions may be necessary. Those most at risk are patients with digoxin levels near the top end of the range. Similar precautions would appear to be necessary with digitoxin, although the documentation of this interaction is very limited and the expected rise in levels only small. The potential for additive bradycardia and heart block should be borne in mind when using diltiazem with any digitalis glycoside.

Digitalis glycosides + Calcium-channel blockers; Nifedipine

Serum digoxin levels are normally unchanged or increased only to a small extent by nifedipine. However, one unexplained and conflicting study indicated that a 45% rise could occur. Digitoxin appears not to interact.

Clinical evidence

(a) Digoxin

A study in 18 subjects showed that nifedipine 40 to 60 mg daily had no significant effect on their steady-state plasma digoxin levels over a 6-week period.¹ This study has also been published elsewhere.²

(b) Digoxin

1. *Serum digoxin levels unchanged.* Studies in 25 patients³⁻⁵ and 28 healthy subjects⁶⁻⁸ showed that serum digoxin levels were not significantly altered by nifedipine 30 to 60 mg daily. Similarly no significant changes in the pharmacokinetics of a single intravenous dose of digoxin were found in 6 patients⁹ or 16 healthy subjects^{10,11} taking nifedipine 40 to 90 mg daily. Furthermore, no changes in the pharmacokinetics of nifedipine were seen.¹⁰

2. *Serum digoxin levels increased.* In 12 healthy subjects nifedipine 30 mg increased the plasma levels of digoxin 375 micrograms daily by 45% (from 0.505 to 0.734 nanograms/mL) over 14 days.¹² In a study in 7 healthy subjects, nifedipine 15 to 60 mg daily increased the levels of digoxin 250 micrograms twice daily by a modest 15%.¹³ These studies have been reported elsewhere.^{14,15}

Nifedipine 20 mg twice daily increased the steady-state serum digoxin levels of 9 patients by 15% (from 0.87 to 1.04 nanograms/mL).¹⁶ A 61% increase in serum digoxin levels was found in a study involving nifedipine in daily doses of 30 mg.¹⁷

Mechanism

Not understood. Changes and lack of changes in both the renal and non-renal excretion of digoxin have been reported. A retrospective analysis of pharmacokinetic data suggests that clearance of digoxin may be reduced by 10% in patients also taking nifedipine.¹⁸ Although several calcium-channel blockers may inhibit the P-glycoprotein mediated renal clearance of digoxin, the results of an *in vitro* study¹⁹ suggest that this may not occur with nifedipine.

Importance and management

The pharmacokinetic interaction of digoxin and nifedipine is well documented but the findings are inconsistent. The weight of evidence appears to be that serum digoxin levels are normally unchanged or only modestly increased by nifedipine. Concurrent use appears normally to be safe and effective.²⁰ One report suggests that nifedipine has some attenuating effect on the digoxin-induced inotropism.²¹ Another points out that under some circumstances (renal impairment or pre-existing digoxin overdosage) some risk of an undesirable interaction still exists.¹³ If undesirable bradycardia occurs in a patient taking digoxin and nifedipine consider measuring digoxin levels, and adjust the dose accordingly. Nifedipine appears not to interact with digoxin to a clinically significant extent.

Digitalis glycosides + Calcium-channel blockers; Verapamil

Serum digoxin levels are increased by about 40% by verapamil 160 mg daily, and by about 70% by verapamil 240 mg daily. Digoxin toxicity may develop if the dosage is not reduced. Deaths have occurred. Verapamil causes a rise of about 35% in digoxin levels. There is a risk of additive bradycardia and conduction disturbances when cardiac glycosides are given with verapamil.

Clinical evidence

(a) Digoxin

Eight out of 10 patients had a mean 35% rise (range 14 to 97%) in plasma digoxin levels over a 4 to 6 week period while taking verapamil 240 mg daily, in three divided doses. In 2 patients (and 3 other healthy subjects given a single dose of digoxin) the pharmacokinetics of digoxin were not affected by verapamil.^{1,2}

(b) Digoxin

After 2 weeks of treatment with verapamil 240 mg daily, in three divided doses, the mean serum digoxin levels of 49 patients with chronic atrial fibrillation had risen by 72%. The rise was seen in most patients, and it occurred largely within the first 7 days. A rise of about 40% has been seen with verapamil 160 mg daily.^{3,4}

Reports in a total of 21 healthy subjects,^{5,6} and 54 patients⁷⁻⁹ describe rises in serum digoxin levels of 22 to 147% when verapamil 240 to 360 mg daily was added to digoxin. Similar rises are reported elsewhere.^{4,10-12}

A rise in digoxin levels of about 50% was seen in chronic haemodialysis patients given verapamil 120 to 240 mg daily.¹³ Nine healthy subjects had a 53% rise in their digoxin levels while taking verapamil 240 mg three times daily for two weeks.⁵ Toxicity¹⁴ and a fatality¹⁵ occurred in patients whose digoxin levels became markedly increased by verapamil. Both asystole and sinus arrest have been described.^{16,17} A single-dose study indicated that cirrhosis magnifies the extent of this interaction.¹⁸

Mechanism

The rise in serum digoxin levels is due to reductions in renal and especially extra-renal (biliary) clearance; a diminution in the volume of distribution also takes place.^{4,9,10,19} It has been suggested that P-glycoprotein may be involved.²⁰ An *in vitro* study found that verapamil can inhibit the P-glycoprotein-mediated transcellular transport of digoxin,²¹ which suggests that any interaction may occur, at least in part, by inhibiting the renal tubular excretion of digoxin. Impaired extra-renal excretion is suggested as the reason for the rise in serum digoxin levels.¹

The increased plasma levels of digoxin caused by verapamil are reported to increase both inotropism²² and toxic effects.²³ Verapamil may enhance the digoxin-induced elevation of intracellular sodium, which may increase the risk of arrhythmias.^{23,24} A synergistic effect on heart rate and atrioventricular conduction is also possible.

Importance and management

The pharmacokinetic interaction between digoxin and verapamil is well documented, well established and it occurs in most patients.^{10,25} Serum digoxin levels should be well monitored and downward dosage adjustments made to avoid digoxin toxicity (deaths have occurred¹⁵). An initial 33 to 50% dosage reduction has been recommended.^{26,27} The interaction develops within 2 to 7 days, approaching or reaching a maximum within 14 days or so.^{3,8} The magnitude of the rise in serum digoxin is dose-dependent²⁸ with a significant increase if the verapamil dosage is increased from 160 to 240 mg daily,³ but with no further significant increase if the dose is raised any higher.⁶ The mean rise with verapamil 160 mg daily is about 40%, and with 240 mg or more is about 60 to 80%,

but the response is variable. Some patients may show rises of up to 150% while others show only a modest increase. One study found that although the rise in serum digoxin levels was 60% within a week, this had lessened to about 30% five weeks later.¹⁰ Regular monitoring and dosage adjustments would seem to be necessary. Note that the potential for additive bradycardia and heart block should also be borne in mind.

The documentation of the digitoxin and verapamil interaction is limited, but the interaction appears to be established. Downward dosage adjustment may be necessary, particularly in some patients.¹

Digitalis glycosides + Chinese herbal medicines

Bufalin can interfere with the assay of cardiac glycosides. Danshen appears not to interact with digoxin, but it can falsify the results of serum immunoassay methods. Digoxin toxicity in an elderly man was attributed to the use of a herbal laxative containing kanzo (liquorice).

Clinical evidence, mechanism, importance and management

(a) Bufalin (Chan Su, Kyushin, and Lu-Shen-Wan)

Bufalin, a cardioactive substance of amphibian origin and Chinese medicines such as Chan Su, Lu-Shen-Wan and Kyushin that contain bufalin can interfere with some immunoassay methods of **digitoxin** and **digoxin**, particularly the fluorescence polarisation immunoassay.^{1–3} The digoxin-like immunoreactivity of Kyushin was found to be equivalent to varying amounts of **digoxin** because of differences in the cross-reactivity of the

antibody used in different immunoassays.³ A chemiluminescent assay for **digitoxin**^{2,4} and **digoxin**² did not cross-react with bufalin.

Bufalin and an extract of Chan Su displaced **digitoxin** from protein-binding sites *in vitro*.⁴ Whether this would result in elevated free **digitoxin** levels and toxicity *in vivo* is not known. However, this is probably unlikely, since *in vivo* the free drug would be available for metabolism (see 'protein-binding interactions', (p.3)).

Another possibility, given the similarities between bufalin and cardiac glycosides, is that toxicity could result from additive cardiac effects. Cases of cardiotoxicity following the ingestion of bufalin (or toads) alone have been reported. In one case, the symptoms seen were very similar to those of **digoxin** toxicity, with nausea, vomiting, blurred vision, mental confusion, cardiopulmonary arrest and severe bradyarrhythmia. Assay for digoxin was positive (2.1 nanograms/mL) when measured by the fluorescence energy transfer immunoassay. The patient had ingested a bowl of toad soup (*Bufo melanostictus* Schneider) shortly before his symptoms developed.⁵

(b) Danshen

Danshen appears not to have been reported to affect serum **digoxin** levels, but it can falsify laboratory measurements. A study found that a fluorescent polarization immunoassay method (Abbott Laboratories) for **digoxin** gave falsely high readings in the presence of danshen, whereas a micro-particle enzyme immunoassay (Abbott Laboratories) gave falsely low readings. These false readings could be eliminated by monitoring the free (i.e. unbound) **digoxin** concentrations⁶ or by choosing assay systems that are unaffected by the presence of danshen (said to be the Roche and Beckman systems¹ or an enzyme linked chemiluminescent immunosorbent digoxin assay by Bayer HealthCare⁷).

(c) Kanzo (Liquorice)

An 84-year-old man taking **digoxin** 125 micrograms daily and furosemide complained of loss of appetite, fatigue and oedema of the lower extremities 5 days after starting to take a Chinese herbal laxative containing liquorice (kanzo) 400 mg and rhubarb (daio) 1.6 g three times daily. It was suggested that heart failure occurred because of **digoxin** toxicity induced by liquorice-associated electrolyte imbalance, which may also have been exacerbated by the age of the patient, the diuretic and his existing cardiovascular disease.⁸

Digitalis glycosides + Chloroquine or Hydroxychloroquine

The levels of digoxin were found to be increased by over 70% in two elderly patients when they were given hydroxychloroquine. A similar increase has been seen with chloroquine in dogs.

Clinical evidence, mechanism, importance and management

Two women aged 65 and 68 who had been taking **digoxin** 250 micrograms daily for 2 to 3 years for arrhythmias were given hydroxychloroquine 250 mg twice daily for rheumatoid arthritis. When the hydroxychloroquine was withdrawn the plasma **digoxin** levels of both women fell by 70 to 75% (from 2.3 to 0.5 nanograms/mL and from 2.4 to 0.7 nanograms/mL, respectively). Neither showed any evidence of toxic

ty during concurrent use, and one of them claimed that the regularity of her heart rhythm had been improved.¹ The reason for this apparent interaction is not understood and its general significance is uncertain.

No interaction between digoxin and chloroquine has been described clinically, but increases in peak serum **digoxin** levels of about 77% have been seen in *dogs*.²

Digitalis glycosides + Cibenzoline (Cifenline)

Cibenzoline did not affect plasma digoxin levels.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects taking **digoxin** 250 to 375 micrograms daily showed that cibenzoline 160 mg twice daily for 7 days had no effect on the pharmacokinetics of **digoxin**.¹ An *in vitro* study found that cibenzoline only slightly inhibited the P-glycoprotein-mediated transcellular transport of **digoxin** and therefore inhibition of the renal tubular secretion of **digoxin** is unlikely.²

Digitalis glycosides + Ciclosporin

Ciclosporin causes a marked rise in serum digoxin levels in some patients.

Clinical evidence

Digoxin toxicity developed in 4 patients when they were given ciclosporin before cardiac transplantation. In the two cases described in detail, ciclosporin 10 mg/kg daily was added to **digoxin** 375 micrograms daily. Fourfold rises in **digoxin** levels, from 1.2 to 4.5 nanograms/mL and from 2 to 8.3 nanograms/mL, were seen within 2 to 3 days. This was accompanied by rises in serum creatinine levels from 110 to 120 micromol/L and from 84 to 181 micromol/L respectively, which were considered insufficient to explain the rise in **digoxin** levels. As a consequence of these findings, the same authors conducted a study in 4 patients given ciclosporin and **digoxin**. Two patients developed acute renal failure. In the other 2 patients, the volume of distribution of **digoxin** was decreased by 69% and 72%, while the clearance was reduced by 47% and 58%.¹ In a further 7 patients, **digoxin** pharmacokinetics were assessed before cardiac transplantation, then after transplantation during maintenance ciclosporin therapy.² The total body clearance of **digoxin** remained unchanged, which appeared to be at odds with the earlier results.¹ It was suggested that haemodynamic improvements brought about by successful cardiac transplantation may have counterbalanced any inhibitory effect ciclosporin had on renal clearance.²

Mechanism

Not fully understood. The authors of the studies concluded that ciclosporin has no specific inhibitory effect on the renal elimination of digoxin, but that it causes a non-specific reduction in renal function after acute administration, which reduces digoxin elimination.² Conversely, another study in *animals* suggested that ciclosporin can reduce the secretion of digoxin by the kidney tubular cells by inhibiting P-glycoprotein.³

Importance and management

Information seems limited to the studies cited. Nevertheless, the effects of concurrent use should be monitored very closely, and the digoxin dosage should be adjusted as necessary.

Digitalis glycosides + Colesevelam

The absorption of a single dose of digoxin is not affected by colesevelam.

Clinical evidence, mechanism, importance and management

A single-dose study in which 26 healthy subjects were given **digoxin** 250 micrograms with or without **colesevelam** 4.5 g, followed by a standard meal, found that **colesevelam** did not significantly affect the absorption of **digoxin**.¹ Because the bile-acid binding resins 'colestyramine', (p.919) and 'colestipol', (below) may interact with digoxin it was suggested that **colesevelam** could also interact, although this appears not to be the case.

1. Donovan JM, Stypinski D, Stiles MR, Olson TA, Burke SK. Drug interactions with colesevelam hydrochloride, a novel, potent lipid-lowering agent. *Cardiovasc Drugs Ther* (2000) 14, 681–90.

Digitalis glycosides + Colestipol

Colestipol appears not to interfere with the absorption of either digoxin or digitoxin if it is given at least 1.5 hours after the digitalis glycoside.

Clinical evidence

(a) Digitalis glycoside levels reduced

Four patients with **digitoxin** toxicity were given colestipol 10 g at once and 5 g every 6 to 8 hours thereafter to reduce their **digitoxin** serum levels. The average **digitoxin** half-life fell to 2.75 days compared with an untreated control patient in whom the **digitoxin** half-life was 9.3 days. In another patient with **digoxin** toxicity who was similarly treated, the **digoxin** half-life was 16 hours compared with 1.8 to 2 days in two other control patients.¹

(b) Digitalis glycoside levels unaffected

Ten patients receiving long-term treatment with either **digoxin** 125 to 250 micrograms daily or **digitoxin** 100 to 200 micrograms daily were given colestipol 15 g daily or a placebo, taken 1.5 hour after the digitalis. Their serum digitalis levels were not significantly altered over a 1-year period by the colestipol.²

A comparative study in 11 patients with plasma **digitoxin** levels greater than 40 nanograms/mL found that when the **digitoxin** was stopped and colestipol 5 g four times daily was given before meals, the **digitoxin** half-life (6.3 days) was unaffected, when compared with 11 other patients not given colestipol (6.8 days).³

Mechanism

Colestipol is an ion-exchange resin, which can bind to digitalis glycosides.¹ In cases of toxicity colestipol may possibly reduce serum digitalis levels because under these circumstances the excretion of digitalis in the bile increases and more becomes available for binding in the gut.²

Importance and management

This interaction is not well established. Giving either digoxin or digitoxin 1.5 hours before colestipol appears to avoid any possible interaction in the gut.² It is usually recommended that other drugs are given 1 hour before or 4 hours after colestipol.

Digitalis glycosides + Colestyramine

The levels of both digoxin and digitoxin can be reduced by colestyramine, but the clinical importance of this is uncertain. Minimise the possible effects of this interaction by separating administration.

Clinical evidence

(a) Digitalis glycoside levels reduced

A study in 12 healthy subjects given **digoxin** 750 micrograms showed that the cumulative 6-day recovery of **digoxin** from the urine was reduced by almost 20% (from 40.5 to 33.1%) when colestyramine 4 g was given.¹ Two patients with congestive heart failure and toxic serum levels of **digoxin** of 3 and 4 nanograms/mL were given colestyramine 4 g every 4 hours for 4 doses. The levels of **digoxin** fell to therapeutic levels within 13 to 24 hours.²

Other reports describe a fall in serum **digoxin** levels during the concurrent use of colestyramine³⁻⁵ and an increase in the loss of **digoxin** and its metabolites in the faeces during long-term use.⁶ Another study showed that giving **digoxin** as a solution in a capsule reduced the effects of this interaction.⁵ Other studies have found that colestyramine reduces the half-life of **digitoxin** by 35 to 40%.^{7,8}

(b) Digitalis glycoside levels unaffected

Ten patients receiving long-term treatment with either **digoxin** 125 to 250 micrograms daily or **digitoxin** 100 to 200 micrograms daily were given colestyramine 12 g daily or a placebo taken 1.5 hour after the digitalis. Their plasma digitalis levels were not significantly altered by the colestyramine over a 1-year period.⁹ The half-life of **digitoxin** is reported to have remained unchanged when colestyramine was given.¹⁰ One study suggested that **metildigoxin** may be minimally affected by colestyramine.¹¹

Mechanism

Not totally understood. Colestyramine appears to bind with digitoxin in the gut, thereby reducing its bioavailability and interfering with enterohepatic recirculation so that its half-life is shortened. Digoxin may interact similarly.²

Importance and management

The overall picture is far from clear. Some interaction seems possible but the extent to which it impairs the treatment of patients receiving these glycosides is uncertain. Be alert for any evidence of under-digitalisation if digoxin or, more particularly, digitoxin is given with colestyramine. The studies suggest that colestyramine should not be given less than 1.5 to 2 hours after the digitalis to minimise the possibility of an interaction.⁹ Note that the standard recommendation is to give other drugs 1 hour before or 4 to 6 hours after colestyramine.

Digitalis glycosides + Co-trimoxazole or Trimethoprim

Serum digoxin levels can be modestly increased by about 22% by trimethoprim, although some individuals may show a much greater rise.

Clinical evidence

(a) Elderly patients

After taking trimethoprim 200 mg twice daily for 14 days the mean serum **digoxin** levels in 9 elderly patients (aged 62 to 92) had risen by an average of 22%, from 0.9 to 1.2 nanograms/mL. One patient had a 75% rise. A 34% increase in mean serum creatinine was also seen. When the trimethoprim was withdrawn, the serum **digoxin** levels returned to their previous value.^{1,2}

(b) Young healthy adult subjects

Trimethoprim 200 mg twice daily for 10 days did not affect the total body clearance of a single 1-mg intravenous dose of **digoxin** in 6 young healthy subjects (aged 24 to 31). Renal clearance was reduced, but this was compensated for by an increase in extra-renal clearance.²

Mechanism

It is suggested that trimethoprim reduces the renal excretion of digoxin.^{1,2} The paradoxical finding between the elderly patients and the young healthy subjects may be the age difference, probably as the elderly patients may not be able to accommodate an increase in extra-renal digoxin clearance.

Importance and management

Information seems to be limited to the information cited. Although the serum digoxin rise in the elderly was modest, it would seem prudent to monitor the effects because some individuals can apparently experience a marked rise. Reduce the digoxin dosage if necessary. Trimethoprim is contained in co-trimoxazole but it is not known whether prophylactic doses of co-trimoxazole (160 mg trimethoprim a day, from 960 mg co-trimoxazole) will interact to a clinically significant degree. An interaction would seem likely with high-dose co-trimoxazole regimens and care with any co-trimoxazole regimen is needed in the elderly.

Digitalis glycosides + Danaparoid

No clinically significant interaction appears to occur between digoxin and danaparoid.

Clinical evidence, mechanism, importance and management

In a study, 6 healthy subjects were given digoxin 250 micrograms daily for 8 days, with a single 3250 anti-Xa-unit-bolus dose of danaparoid during day 7. The AUC of digoxin was slightly decreased, although this did not appear to be clinically significant. Digoxin did not alter the effects of danaparoid on clotting tests (including aPTT).¹

Digitalis glycosides + Darifenacin or Solifenacin

Darifenacin increased digoxin exposure by a modest 16%, which would usually not be clinically important. Solifenacin did not alter the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management*(a) Darifenacin*

The manufacturer notes that the concurrent use of **digoxin** 250 micrograms and darifenacin 30 mg daily increased **digoxin** exposure at steady state by a modest 16%. This small increase would generally not be clinically relevant.¹

(b) Solifenacin

In a crossover study in 24 healthy subjects, solifenacin 10 mg daily for 10 days had no effect on the pharmacokinetics of **digoxin** 125 micrograms daily.²

This study suggests that no pharmacokinetic interaction occurs, and that no **digoxin** dose adjustment would be expected to be needed on concurrent use.

Digitalis glycosides + Dexmedetomidine

An isolated report describes bradycardia when an infant receiving digoxin was given dexmedetomidine.

Clinical evidence, mechanism, importance and management

A 5-week-old infant with an atrioventricular septal defect, taking **digoxin** 10 micrograms twice daily and furosemide for mild congestive heart failure, developed respiratory failure requiring intubation and mechanical ventilation. She was given dexmedetomidine for sedation and received a loading dose of 0.5 micrograms/kg over 15 minutes, followed by an infusion of 0.44 micrograms/kg per hour. During the loading dose period her heart rate decreased from 133 to 116 bpm. Throughout the next 13 hours the rate continued to decrease to about 90 bpm, with episodes of sinus bradycardia (heart rate around 50 bpm). Within 1 hour of discontinuing dexmedetomidine, the heart rate increased to its baseline value and no further episodes of bradycardia were observed. The reasons for the interaction are not known, but caution is advised if dexmedetomidine is used for sedation in patients receiving **digoxin**.¹

1. Berkenbosch JW, Tobias JD. Development of bradycardia during sedation with dexmedetomidine in an infant concurrently receiving digoxin. *Pediatr Crit Care Med* (2003) 4, 203–5.

Digitalis glycosides + Dietary fibre and Laxatives

Bisacodyl reduces serum digoxin levels to a small extent. Large amounts of dietary fibre, guar gum and bulk-forming laxatives containing ispaghula or psyllium appear to have no significant effect on the absorption of digoxin. Single-dose studies show that macrogol 4000, a laxative polymer, reduces the serum levels of digoxin.

Clinical evidence*(a) Bisacodyl*

Bisacodyl reduced the mean serum **digoxin** levels of 11 healthy subjects by about 12%. When the bisacodyl was taken 2 hours before the **digoxin**, serum **digoxin** levels were slightly raised, but not to a statistically significant extent.¹

(b) Fibre

The serum **digoxin** levels of 12 patients taking **digoxin** 125 to 250 micrograms daily 15 to 30 minutes before breakfast were unchanged over a 10-day period when they were given a diet supplemented each day with 22 g of dietary fibre. The fibre was given in this way to simulate the conditions that might be encountered clinically (for example to reduce the symptoms of diverticular disease).²

Wheat bran 7.5 g twice daily caused a small 10% reduction in the plasma **digoxin** levels of 14 geriatric patients after 2 weeks, but there was no significant change after 4 weeks.³ Bran fibre 11 g caused a 6 to 7% reduction in the absorption and the steady-state serum levels of **digoxin** in 16 healthy subjects.⁴ The cumulative urinary recovery of a single oral dose of

digoxin in healthy subjects was reduced almost 20% by 5 g of fibre, whereas 0.75 g of fibre had no effect.⁵

(c) Guar gum

In 10 healthy subjects *Guarem* (95% guar gum) 5 g reduced the peak serum levels of a single 500-microgram oral dose of **digoxin** by 21% and the AUC₀₋₆ was reduced by 16%, but the amount excreted in the urine over 24 hours was only minimally reduced.⁶ Guar gum 18 g with a test meal did not affect steady-state plasma **digoxin** levels in 11 healthy subjects given **digoxin** 1 mg on day 1, then 750 micrograms on day 2, then 500 micrograms daily for 3 days.⁷

(d) Ispaghula or psyllium

An ispaghula preparation (*Vi-Siblin S*) was found to have no significant effect on serum **digoxin** levels of 16 geriatric patients.³ The same lack of effect was seen in another study in 15 patients given 3.6 g of a psyllium preparation (*Metamucil*) three times a day.⁸

(e) Macrogol 4000

A randomised, crossover study in 18 healthy subjects found that 20 g of macrogol 4000 daily over an 8-day period reduced the maximum serum levels of a single 500-microgram dose of **digoxin** by 40%, and reduced the AUC by 30%. Heart rate and the PR interval were unchanged.⁹ More study is needed to assess the effects of this interaction on steady-state **digoxin** levels.

Mechanism

Not established. Digoxin can bind to some extent to fibre within the gut.¹⁰ However, *in vitro* studies (with bran, carrageenan, pectin, sodium pectinate, xylan and carboxymethylcellulose) have shown that most of the binding is reversible.¹¹

Importance and management

Information seems to be limited to these reports. The reduction in serum digoxin levels caused by bisacodyl is small, and not expected to be of clinical importance, and apparently preventable by giving the bisacodyl 2 hours before the digoxin. Neither dietary fibre (bran), guar gum nor the two bulk-forming laxatives (*Vi-Siblin* and *Metamucil*) have a clinically important effect on serum digoxin levels. No special precautions would appear to be necessary. The importance of the interaction between digoxin and macrogol 4000 awaits further assessment, but on the available evidence it would be prudent to be alert for the need to increase the digoxin dosage.

Digitalis glycosides + Dihydroergocryptine

Dihydroergocryptine appears not to interact with digoxin.

Clinical evidence, mechanism, importance and management

In a randomised study in 12 healthy subjects dihydroergocryptine 20 mg did not affect the pharmacokinetics of a single 500-microgram dose of **digoxin**. No clinically significant changes were seen in the ability of the heart to initiate and conduct impulses, or repolarise. The slight drop in blood pressure during the first 2 to 4 hours after **digoxin** was more pro-

nounced in the presence of dihydroergocryptine, but there was no evidence of impaired orthostatic blood pressure control.¹ No special precautions would seem necessary during concurrent use.

Digitalis glycosides + Dipyridamole

Dipyridamole may cause a minor increase in the absorption of digoxin.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that dipyridamole 150 mg twice daily for 5 doses increased the AUC_{0–4} and the AUC_{0–24} of a single 500-microgram oral dose of **digoxin** by 20% and 13%, respectively. This was attributed to an increase in **digoxin** absorption possibly mediated by intestinal P-glycoprotein inhibition.¹ *In vitro* studies^{1,2} found that dipyridamole inhibits P-glycoprotein-mediated transport of **digoxin**, but in one study this was only at higher levels than those achieved clinically.² Therefore these minor changes are not fully explained. The changes in **digoxin** pharmacokinetics in the presence of dipyridamole are probably not clinically significant.

Digitalis glycosides + Disopyramide or Procainamide

Neither disopyramide nor procainamide normally cause a significant change in serum digoxin levels. A single report describes toxicity in a patient taking digitoxin and disopyramide.

Clinical evidence, mechanism, importance and management

(a) Disopyramide

A number of studies have clearly shown that disopyramide causes only a very small increase or no increase at all in the serum levels of **digoxin**.^{1–6} A small but insignificant reduction in heart rate has been seen⁷ but the weight of evidence suggests that no adverse interaction occurs if **digoxin** and disopyramide are used together. However, a very brief report describes toxicity and serious arrhythmia in one patient given **digitoxin** and disopyramide.⁸

(b) Procainamide

A study in patients who had been taking **digoxin** for at least 7 days showed that procainamide did not affect their serum **digoxin** levels.² However, it should be noted that the manufacturers of procainamide say that, in digitalis toxicity, procainamide may further depress conduction, which may result in ventricular asystole or fibrillation.⁹

Digitalis glycosides + Diuretics; Potassium-depleting

The potassium loss caused by potassium-depleting diuretics increases the toxicity of the digitalis glycosides.

Clinical evidence

(a) Evidence suggesting an interaction

A comparative study¹ of the medical records of 418 patients taking digitalis over the period 1950 to 1952, and of 679 patients over the period 1964 to 1966, showed that the incidence of digitalis toxicity had more than doubled. Of the earlier group 8.6% developed toxicity (58% taking diuretics, mainly of the **organomercurial type**) compared with 17.2% of the latter group (81% taking diuretics, mainly **chlorothiazides, furosemide, etacrynic acid, chlortalidone**). It was concluded that the increased toxicity was related to the increased usage of potassium-depleting diuretics.

A retrospective study of over 400 patients taking **digoxin** showed that almost one in five had some toxic reactions attributable to the use of the glycoside. Of these, 16% had demonstrable hypokalaemia (defined as serum potassium less than 3.5 mmol/L). Almost half of the patients who showed toxicity were taking potassium-depleting diuretics, notably **hydrochlorothiazide** or **furosemide**.² Similar results were found in other studies^{3–9} in a considerable number of patients. There are other reports not listed here. In addition there is also some evidence that **furosemide** may raise serum **digoxin** levels,¹⁰ although two other studies found no evidence that **furosemide** affects the urinary excretion of **digoxin**.^{11,12}

(b) Evidence suggesting no interaction

A retrospective study of patients who developed digitalis toxicity showed that the likelihood of its development in those with potassium levels below 3.5 mmol/L was no greater than those with normal potassium levels.¹³

Two other studies in a total of almost 200 patients failed to detect any association between the development of digitalis toxicity and the use of diuretics or changes in potassium levels.^{14,15}

A pharmacokinetic study in 6 patients found that single 50-mg and 100-mg doses of cicletanine had no effect on the plasma levels of **digoxin** 125 to 250 micrograms daily.¹⁶

Mechanism

Not fully understood. The cardiac glycosides inhibit sodium-potassium ATP-ase, which is concerned with the transport of sodium and potassium ions across the membranes of the myocardial cells. This is associated with an increase in the availability of calcium ions concerned with the contraction of the cells. Potassium loss caused by these diuretics exacerbates the potassium loss from the myocardial cells, thereby increasing the activity and the toxicity of the digitalis. Some loss of magnesium may also have a part to play. The mechanism of this interaction is still being debated.

Importance and management

A direct link between the use of these potassium-depleting diuretics and the development of digitalis toxicity is not established beyond doubt, but concurrent use can result in digitalis toxicity. It is therefore important that potassium levels remain within the accepted normal range during digitalis treatment. Potassium levels should be routinely monitored when diuretics are given and it may be prudent to recheck levels if patients develop symptoms of digitalis toxicity. See 'Table 26.1', (p.944) for a list of potassium-depleting diuretics.

Digitalis glycosides + Diuretics; Potassium-sparing

Serum digoxin levels may be increased by 25% by spironolactone, but because spironolactone or its metabolite, canrenone, can interfere with some digoxin assay methods, the evaluation of this interaction is difficult. Eplerenone may also cause a minor increase in digoxin levels. Amiloride has little effect on digoxin levels in healthy subjects, but it may reduce its inotropic effects. In patients with renal impairment it possibly raises plasma digoxin levels. The effects of digitoxin are reported to be both increased and decreased by spironolactone.

Clinical evidence

(a) Digitoxin

A study in 6 healthy subjects who had been taking digitoxin 100 or 150 micrograms daily for 30 days showed that **spironolactone** 300 mg daily increased the digitoxin half-life by one-third (from 142 to 192 hours).¹

In contrast, other studies have found that the digitoxin half-life was reduced (from 256 to 205 hours) by **spironolactone**.²

(b) Digoxin

1. **Amiloride**. In 6 healthy subjects amiloride 5 mg twice daily for 8 days almost doubled the renal clearance of digoxin from 1.3 to 2.4 mL/kg per minute, but reduced the extra-renal clearance from 2.1 to 0.1 mL/kg per minute. The balance of the two effects was to cause a small fall in total clearance and a small rise in plasma digoxin levels.³ The positive inotropic effects of digoxin were reduced, but whether this is clinically important is uncertain. In contrast, a later study in 8 healthy subjects found that a single 75-mg [sic] oral dose of amiloride given 3 hours before an infusion of digoxin did not reduce the inotropic effects of digoxin.⁴

2. **Eplerenone**. The UK manufacturer of eplerenone states that the AUC of digoxin increased by 16% (90% confidence interval: 4% to 30%) when it was given with eplerenone.⁵

3. **Spironolactone**. The plasma digoxin levels of 9 patients were increased by about 20% (from 0.8 to 1 nanograms/mL) when they were given spironolactone 100 mg daily. One patient had a three to fourfold rise in digoxin levels.⁶

The clearance of a single 750-microgram intravenous dose of digoxin was reduced by about 25% in 4 patients and 4 healthy subjects following 5 days of treatment with spironolactone 100 mg twice daily.⁷ A marked fall in serum digoxin levels occurred in an elderly patient when spironolactone was withdrawn,⁸ but the accuracy of the assay method used is uncertain (see *Importance and management* below). One study found that no clinically important reduction in digoxin clearance occurred when *Acetazolamide* (spironolactone-hydrochlorothiazide) was also given.⁹

Mechanism

Not fully understood. Spironolactone inhibits the excretion of digoxin by the kidney (by 13%) but does not affect its biliary clearance.¹⁰ *Animal* studies have suggested that spironolactone may induce P-glycoprotein expression, resulting in reduced intestinal absorption of substrates such as digoxin.¹¹ Spironolactone probably also causes a reduction in the volume of distribution of digoxin.

It has been suggested that amiloride may have increased the production of aldosterone, which suppressed the positive inotropic effects of digoxin.³ Studies in patients with congestive heart failure are needed.

Importance and management

The pharmacokinetic interaction between digoxin and spironolactone appears to be established. What is known suggests that a rise in digoxin levels of up to 25% is likely to occur, although much greater increases can apparently occur in some patients.⁶ Monitor concurrent use carefully for signs of over-digitalisation. Note that spironolactone or its metabolite, canrenone, can interfere with some digoxin assay methods.¹² In one report, radioimmunoassay (RIA) and affinity-column-mediated immunoassay (ACMIA) were particularly affected by spironolactone and its metabolites.¹³ Conversely, falsely low digoxin readings with the AxSym MEIA assay method led to digoxin overdose and toxicity in one patient.¹⁴ This means that monitoring is difficult unless the digoxin assay method is known to be reliable. Measurement of free digoxin levels or use of a chemiluminescent assay (CLIA) or turbidometric immunoassay for digoxin has been reported to mostly eliminate interference from spironolactone, potassium canrenoate and canrenone.^{15,16}

Eplerenone also appears to cause a small increase in digoxin levels. The UK manufacturers recommend that caution is warranted when digoxin is dosed near the upper limit of therapeutic range.⁵ However, the US manufacturer states that the pharmacokinetic interaction is not clinically significant.¹⁷

The situation with digitoxin and spironolactone is confusing because the reports are contradictory and the outcome uncertain. Concurrent use should be well monitored.

Patients with poor renal function would be expected to have a rise in digoxin levels when given amiloride (due to the increased reliance on renal clearance) but the clinical importance of this awaits confirmation.

Digitalis glycosides + Dofetilide

Dofetilide does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 13 subjects, dofetilide 250 micrograms twice daily for 5 days had no effect on the steady-state pharmacokinetics of **digoxin**, given at a dose of 250 micrograms daily after a loading dose.¹

1. Kleinermans D, Nichols DJ, Dalrymple I. Effect of dofetilide on the pharmacokinetics of digoxin. *Am J Cardiol* (2001) 87, 248–50.

Digitalis glycosides + Drugs that affect calcium

The effects of digitalis glycosides might be increased by rises in blood calcium levels, and the use of intravenous calcium may result in the development of potentially life-threatening digitalis-induced cardiac arrhythmias. Teriparatide appears not to affect the calcium-mediated pharmacodynamics of digoxin.

Clinical evidence

(a) Calcium

Two patients developed cardiac arrhythmias and died after being given digitalis intramuscularly and either calcium chloride or calcium gluconate intravenously. No absolutely certain causative relationship was established.¹

There is some evidence that increases or decreases in blood calcium levels can increase or decrease, respectively, the effects of digitalis. A patient with congestive heart failure and atrial fibrillation was resistant to the actions of digoxin serum levels of 1.5 to 3 nanograms/mL until his serum calcium levels were raised from 1.68 to about 2.13 mmol/L by oral calcium and vitamin D.²

(b) Other drugs affecting calcium

1. *Disodium edetate*. Disodium edetate,³⁻⁵ which lowers blood calcium levels, has been used successfully in the treatment of digitalis toxicity, although less toxic drugs are generally preferred.

2. *Teriparatide*. A placebo-controlled study in 15 healthy subjects given digoxin 500 micrograms daily, adjusted to maintain steady-state serum levels in the range 1 to 2 nanograms/mL, found that a single 20-microgram subcutaneous dose of teriparatide on day 15 or 16 did not alter the calcium-mediated effects of digoxin (systolic time interval), or heart rate. Serum calcium increased slightly, with a maximum increase of 0.05 mmol/L.⁶

Mechanism

The actions of the cardiac glycosides (even now not fully understood) are closely tied up with movement of calcium ions into heart muscle cells. Increased concentrations of calcium outside these cells increase the inflow of calcium and this enhances the activity of the glycosides. This can lead to effective over-digitalisation and even potentially life-threatening arrhythmias. Conversely, a drop in calcium levels can attenuate the activity of the glycosides. However, the clinical relevance of these changes in calcium is not fully established.

Importance and management

The report of deaths associated with digitalis and calcium compounds (published in 1936) seems to be the only direct clinical evidence of a serious adverse interaction, although there is plenty of less direct evidence that an interaction is possible. Intravenous calcium should be avoided in patients receiving cardiac glycosides. If that is not possible, it has been suggested⁷ that it should be given slowly or only in small amounts in order to avoid transient serum calcium levels higher than 7.5 mmol/L, but it seems likely that very large doses of calcium would be required to reach this level, even transiently.

The very slight increases in calcium observed with teriparatide were considered insufficient to increase cardiac sensitivity to digoxin at therapeutic dosage.⁶ Nevertheless, the manufacturer of teriparatide still advises caution in patients taking digitalis, because of the possibility for transiently raised calcium levels.^{8,9}

Digitalis glycosides + Drugs that reduce potassium levels

A number of drugs, including amphotericin B, carbenoxolone, and corticosteroids, cause potassium loss, which could lead to the development of digitalis toxicity.

Clinical evidence, mechanism, importance and management

Among the well-recognised adverse effects of amphotericin B is hypokalaemia, which can be severe. Although there seem to be no reports of adverse interactions, it would be logical to expect that digitalis toxicity could develop in patients given both drugs if the potassium levels fall. Amiloride has been successfully used to counteract the potassium loss caused by amphotericin B.¹

The adverse effects of carbenoxolone include an increase in blood pressure (both systolic and diastolic), fluid retention and reduced serum potassium levels. The incidence of these adverse effects is said in some reports to be as high as 50%; others quote lower figures. Hypertension and fluid retention occur early in carbenoxolone treatment, whereas the hypokalaemia develops later and may occur in the absence of the other two adverse effects.²⁻⁵ Carbenoxolone is therefore unsuitable for patients with congestive heart failure, or those taking digitalis glycosides, unless measures to avoid hypokalaemia are taken.

Systemic corticosteroids can increase the loss of potassium, particularly those that are naturally occurring (cortisone, deoxycortone, hydrocortisone) whereas the synthetic derivatives (betamethasone, dexamethasone, methylprednisolone, prednisolone, prednisone, triamcinolone) have much less mineralocorticoid activity. There is therefore the possibility of potassium depletion, particularly when corticosteroids are used long-term, which may increase the risk of digitalis toxicity. These corticosteroids also cause sodium and water retention, resulting in oedema and hypertension, which can lead to cardiac failure in some individuals.

It is therefore important to monitor the use of digoxin and any of these drugs well. Potassium levels should be routinely monitored in any patient taking amphotericin B, but it is particularly important in those taking digoxin. With other drugs where potassium monitoring is not routine, it would seem prudent to watch for signs of digoxin toxicity (e.g. bradycardia) and consider measuring potassium levels. No problems of this kind would be expected with corticosteroids used topically or by inhalation, because the amounts absorbed are likely to be relatively small.

Digitalis glycosides + Edrophonium

Excessive bradycardia and AV-block may occur if patients taking digitalis glycosides are given edrophonium.

Clinical evidence, mechanism, importance and management

The rapid intravenous injection of edrophonium 10 mg has been used in the differentiation of cardiac arrhythmias, but in one study, 4 of 10 digitalised patients given edrophonium developed atrial tachycardia with AV block. The effect was transient; recovery of baseline ECGs occurred 15 to 20 minutes after administration.¹ Nevertheless, the authors recommended that edrophonium should not be given to patients with atrial flutter or tachycardia who are taking digitalis glycosides. This recommendation is reinforced by the case of an elderly woman² who developed bradycardia, AV block and asystole following concurrent use. She recovered after being given atropine 1 mg.

2. Gould L, Zahir M, Gomprecht RF. Cardiac arrest during edrophonium administration. *Am Heart J* (1971) 81, 437-8.

Digitalis glycosides + Enoximone

Studies in patients receiving long-term treatment with digitalis glycosides (digoxin or digitoxin) showed that *oral* enoximone 100 mg three times daily for a week had no significant effect on the plasma levels of either of these digitalis glycosides.^{1,2} Cardiac function was improved.

Digitalis glycosides + Etanercept

No clinically significant interaction appears to occur between digoxin and etanercept.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given an oral loading dose of **digoxin** 500 micrograms twice daily on day one followed by 250 micrograms daily found that subcutaneous etanercept 25 mg twice weekly did not significantly affect the pharmacokinetics of **digoxin**. The maximum serum levels and AUC of etanercept were 4.2% and 12.5% lower, respectively, during concurrent use but this was not considered to be clinically significant. The combination was well tolerated and there were no changes in ECG parameters.¹ No special precautions therefore seem necessary if both drugs are given.

1. Zhou H, Parks V, Patat A, Le Coz F, Simcoe D, Korth-Bradley J. Absence of a clinically relevant interaction between etanercept and digoxin. *J Clin Pharmacol* (2004) 44, 1244–51.

Digitalis glycosides + Exenatide

Exenatide delayed the time to peak plasma digoxin levels, but this change is not expected to be clinically relevant.

Clinical evidence, mechanism, importance and management

To determine the effects of exenatide on the pharmacokinetics of **digoxin**, 21 healthy subjects were given a loading dose of **digoxin** 500 micrograms twice daily on day one, then 250 micrograms daily for 11 days, with subcutaneous exenatide 10 micrograms twice daily on days 8 to 12. The median time to maximum concentration of **digoxin** was increased from 1.5 hours to 4 hours, and there was a reduction of 17% in its maximum plasma levels. There was no change in AUC and trough **digoxin** levels, and the renal clearance of **digoxin** was not altered. It is thought that the changes in **digoxin** pharmacokinetics occurred as a result of altered gastric emptying caused by exenatide.¹

Nevertheless, the changes in **digoxin** pharmacokinetics are unlikely to be clinically relevant, and no **digoxin** dose adjustment is likely to be required on concurrent use.

1. Kothare AP, Soon DKW, Linnebjerg H, Park S, Chan C, Yeo A, Lim M, Mace KF, Wise SD. Effect of Exenatide on the steady-state pharmacokinetics of digoxin. *J Clin Pharmacol* (2005) 45, 1032–7.

Digitalis glycosides + Ezetimibe

In a study in 12 healthy subjects ezetimibe 10 mg daily for 7 days did not alter the pharmacokinetics of a single 500-microgram dose of digoxin. In addition, ezetimibe did not alter the ECG effects of digoxin.¹

1. Kosoglou T, Statkevick P, Johnson-Levonos AO, Paolini JF, Bergman AJ, Alton KB. Ezetimibe. A review of its metabolism, pharmacokinetics and drug interactions. *Clin Pharmacokinet* (2005) 44, 467–94.

Digitalis glycosides + Fenoldopam

Oral fenoldopam appears to cause a small and clinically unimportant reduction in serum digoxin levels in most patients, but more marked changes may occur in a few individuals.

Clinical evidence, mechanism, importance and management

Ten patients with congestive heart failure receiving **digoxin** long-term (doses not stated) were additionally given *oral* fenoldopam 100 mg three times daily for 9 days. The mean AUC and steady-state **digoxin** levels were reduced by about 20%. In two patients, the steady-state serum levels of **digoxin** fell by 48%, from 1.36 to 0.71 nanograms/mL, and 68%, from 1.93 to 0.61 nanograms/mL, respectively, and in a further patient, rose by 45% (from 1.03 to 1.49 nanograms/mL).¹ Most patients appear therefore not to show marked changes in serum **digoxin** levels, but a few individuals may possibly need some dosage adjustment. Monitor the effects of concurrent use.

1. Strocchi E, Tartagni F, Malini PL, Valtancoli G, Ambrosioni E, Pasinelli F, Riva E, Fuccella LM. Interaction study of fenoldopam-digoxin in congestive heart failure. *Eur J Clin Pharmacol* (1989) 37, 395–7.

Digitalis glycosides + Finasteride

Finasteride does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In a randomised study, 17 healthy subjects were given a single 400-microgram dose of **digoxin** while taking finasteride 5 mg daily for 10 days. Finasteride had no significant effect on the pharmacokinetics of **digoxin**.¹ No adverse effects are expected on concurrent use.

1. Gregoire S, Williams R, Gormely G, Lin E. Effect of finasteride (MK-906) on the disposition of digoxin. *J Clin Pharmacol* (1990) 30, 847.

Digitalis glycosides + Flecainide

Plasma digoxin levels are unaltered or only modestly increased by the use of flecainide, but this is not likely to be important in most patients.

Clinical evidence

The plasma **digoxin** levels of 10 patients with congestive heart failure were unchanged when they took flecainide 100 to 200 mg twice daily for 7 days. A similar lack of interaction was also seen in 4 patients who took both drugs over a 4-week period.¹

In contrast, a study in 15 healthy subjects found that flecainide 200 mg twice daily increased the trough and peak plasma levels of **digoxin** 250 micrograms by 24% and 13%, respectively.² The changes observed in vital signs were not clinically significant. Based on the results of a single-dose study the steady-state **digoxin** levels were predicted to rise by about 15% during the use of flecainide 200 mg twice daily.³

Mechanism

Uncertain. It is suggested that any changes may be due to alterations in the volume of distribution.³

Importance and management

Documentation is limited but what is known suggests that either no interaction occurs, or any changes are small and unlikely to be clinically relevant in most patients. However, the UK manufacturers of flecainide recommend that digoxin plasma levels should be measured not less than 6 hours after any digoxin dose, before or after the administration of flecainide.⁴ The US manufacturers do not advise any additional monitoring.⁵ The authors of one of the reports² suggest that patients with high drug

levels, atrioventricular nodal dysfunction, or both, should be monitored during concurrent treatment.

Digitalis glycosides + Fondaparinux

No significant interaction appears to occur between digoxin and fondaparinux.

Clinical evidence, mechanism, importance and management

A phase I randomised study in 24 healthy subjects found that the pharmacokinetics of oral **digoxin** 250 micrograms twice daily for one day then 250 micrograms daily for 6 days was unaffected by subcutaneous fondaparinux 10 mg daily. The pharmacokinetics of fondaparinux were not affected by **digoxin**. The combination was well tolerated and no clinically significant changes in vital signs and ECGs were observed.¹ No additional precautions therefore seem necessary on concurrent use.

- Mant T, Fournié P, Ollier C, Donat F, Necciari J. Absence of interaction of fondaparinux sodium with digoxin in healthy volunteers. *Clin Pharmacokinet* (2002), 41 (Suppl 2), 39–45.

Digitalis glycosides + Grapefruit juice

Plasma digoxin levels are generally unaltered or only modestly increased by grapefruit juice, but in some individuals significant changes may occur.

Clinical evidence

A crossover study in 12 healthy subjects found that when they were given either grapefruit juice 220 mL or water, 30 minutes before and 3.5, 7.5, and 11.5 hours after a single 500-microgram dose of **digoxin** (taken with 50 mL of grapefruit juice or water respectively), the 0 to 4-hour and 0 to 24-hour **digoxin** AUCs were increased by about 10%. The maximum plasma levels and renal clearance of **digoxin** were not significantly affected. However, in 2 subjects taking grapefruit juice, the ECGs taken 90 minutes after **digoxin** ingestion revealed an asymptomatic first-degree atrioventricular block. Plasma levels in these subjects had increased by 50% to 2.4 and 2.8 nanograms/mL, respectively.¹ Another study found that grapefruit juice decreased the rate but not the extent of absorption of **digoxin** and had no effect on AUC or renal clearance, but there was significant inter-individual variability.²

Mechanism

The modest increases in digoxin levels may be due to increased intestinal absorption of digoxin, possibly due to inhibition of P-glycoprotein-mediated digoxin transport by grapefruit juice, although this mechanism has been questioned.¹ *In vitro*, pomelo (*Citrus grandis*) and grapefruit juices inhibited P-glycoprotein transport of digoxin.³

Importance and management

Although grapefruit juice appears to have little effect on digoxin bioavailability, it is possible that in some individuals the interaction could be of clinical significance.² Bear this interaction in mind in the case of an unexpected response to digoxin. More study is needed.

Digitalis glycosides + Guanadrel

Guanadrel did not affect the pharmacokinetics of a single dose of digoxin.

Clinical evidence, mechanism, importance and management

In 13 healthy subjects guanadrel 10 mg orally every 12 hours for 8 days did not affect the pharmacokinetics of a single intravenous dose of **digoxin** given on day 5. One subject experienced a 10-minute episode of asymptomatic second-degree heart block (Wenckebach) 3 hours after the dose of **digoxin**, but the reason for this effect was not clear.¹ There seem to be no reports of adverse interactions between the digitalis glycosides and any of the guanethidine-like antihypertensive drugs.

- Wright CE, Andreadis NA. Digoxin pharmacokinetics when administered concurrently with guanadrel sulfate. *Drug Intell Clin Pharm* (1986) 20, 465.

Digitalis glycosides + H₂-receptor antagonists

Small changes in serum digoxin levels, both rises and falls, have been seen in patients also given cimetidine, but these do not appear to be of clinical importance. Ranitidine does not appear to interact with metildigoxin.

Clinical evidence, mechanism, importance and management

While taking **cimetidine** 300 mg every 6 or 12 hours the steady-state serum **digoxin** levels of 11 patients with congestive heart failure fell, on average, by 25% (from 2 to 1.5 nanograms/mL), but none of them showed any ECG changes or signs that their condition had worsened.¹ Four other patients with stable congestive heart failure had no significant changes in the pharmacokinetics of **digoxin** 125 to 250 micrograms daily when they were given **cimetidine** 300 mg every 6 hours.² Three single-dose studies in a total of 19 healthy subjects, and 6 patients with duodenal ulcers³ found that **cimetidine** 600 mg to 1.2 g daily had no significant effect on the absorption⁴ or the pharmacokinetics^{3,5} of **digoxin**. Another study found a small increase in **digoxin** levels in healthy subjects, but only a small statistically insignificant rise in the steady-state levels of 11 patients given **cimetidine** 400 mg four times daily.⁶ Six patients with chronic congestive heart failure given **metildigoxin** had no changes in their serum **digoxin** levels when they were given **ranitidine** 150 mg twice daily for a week.⁷

No interaction of clinical importance with either of these H₂-receptor antagonists has been established and no special precautions would seem to be necessary.

Digitalis glycosides + Herbal medicines; Cimicifuga

A standardised black cohosh extract (Cimicifuga) did not alter the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A study in 16 healthy subjects who were given a single 400-microgram dose of **digoxin** before and on the last day of a 14-day course of a standardised black cohosh (*Cimicifuga racemosa*) extract 20 mg twice daily, found no statistically significant changes in the pharmacokinetics of **digoxin**. The product used was standardised to 2.5% triterpene glycosides.¹

Digoxin is a substrate of P-glycoprotein, and this study was conducted

to see if black cohosh had any clinically relevant effect on P-glycoprotein.¹ The findings indicated that black cohosh does not cause clinically relevant changes in digoxin pharmacokinetics, and no alteration in **digoxin** levels would therefore be expected on concurrent use. For mention of a case of digoxin-like toxicity attributed to a herbal preparation, containing amongst other ingredients, black cohosh, see 'Digitalis glycosides + Herbal medicines; Digoxin-like', below.

1. Gurley BJ, Barone GW, Williams DK, Carrier J, Breen P, Yates CR, Song P-f, Hubbard MA, Tong Y, Cheboyina S. Effect of milk thistle (*Silybum marianum*) and black cohosh (*Cimicifuga racemosa*) supplementation on digoxin pharmacokinetics in humans. *Drug Metab Dispos* (2006) 34, 69–74.

Digitalis glycosides + Herbal medicines; Digoxin-like

Many herbal remedies contain cardiac glycosides, which could in theory have additive effects with digoxin or digitoxin, or interfere with their assays. However, there appear to be few such interactions reported.

Clinical evidence, mechanism, importance and management

(a) Additive effects possible

A 26-year-old woman developed severe and unexplained chest pain, and was later noted to have a heart rate of 39 bpm and a blood pressure of 59/36 mmHg, but these rose to normal with conservative management. She was found to have a **digoxin** level of 0.9 nanograms/mL and was diagnosed as having **digoxin** toxicity, despite not taking any prescribed **digoxin**. The digoxin-like cardiac glycosides were thought to have come from an unnamed herbal remedy for stress, which contained **black cohosh root** (*Cimicifuga racemosa*), **cayenne pepper fruit** (*Capsicum annuum*), **hops flowers** (*Humulus lupulus*), **skullcap herb** (*Scutellaria lateriflora*), **valerian root** (*Valeriana officinalis*) and **wood betony herb** (*Pedicularis canadensis*).¹ All of these had previously been shown to contain small amounts of digoxin-like compounds, which were only partially detected by **digoxin** antibody immunoassays.^{1,2} In this previous *in vitro* study, 46 commercially packaged herb teas and 78 teas prepared from herbs were assayed for digoxin-like factors by their cross-reactivity with **digoxin** antibody or inhibition of ouabain binding, and these values were used to give approximate equivalent daily doses of **digoxin**. Three packaged teas (**Breathe Easy**, **blackcurrant**, and **jasmine**) and 3 herbs (**pleurisy root**, **chaparral**, **peppermint**) were found to contain greater than 30 micrograms of **digoxin** equivalents per cup and were postulated to provide a therapeutic daily dose of **digoxin** if 5 cups a day were drunk.² However, note that some common teas sampled in this study (e.g. English Breakfast, Earl Grey) contained over 20 micrograms of **digoxin** equivalents per cup, and tea drinking has not been associated with adverse cardiovascular risk.³ Therefore the interpretation of the findings of this study is unclear.

Theoretical interactions with herbal remedies are not always translated into practice, and there do not appear to be any cases of herbals interacting with **digoxin** because of their cardiac glycoside content. See also 'Digitalis glycosides + Chinese herbal medicines', p.917.

(b) Effects on digoxin assays

A 68-year-old woman who was given a loading dose of **digitoxin** 750 micrograms then 100 micrograms on the second day was found to have markedly elevated levels of **digitoxin** (greater than 100 nanograms/mL), but no clinical signs of toxicity. Two days before admission she had ingested 90 drops of **Uzara**, a preparation from *Xysmalobium undulatum*, which contains weak cardiac glycosides. Later investigations in 4 healthy subjects given 30 drops of **Uzara** confirmed that assays for **digitoxin** (CEDIA digitoxin test, Roche Diagnostics, Germany) and **digoxin** (Tina-quant digoxin test, Roche Diagnostics, Germany) were markedly elevated by **Uzara** to levels well above usual therapeutic concentrations, but that there were no clinically relevant changes in heart rate and blood pressure.⁴

In an *in vitro* study, **plantain** (*Plantago major*) extract from capsules, liquid extract, or dry leaf did not affect the results of **digoxin** assays when using fluorescence polarization immunoassay or microparticle enzyme immunoassay.⁵ Note that contamination of plantain with *Digitalis lanata* has been reported.⁶

See also 'Digitalis glycosides + Chinese herbal medicines', p.917 and 'Digitalis glycosides + Herbal medicines; Ginseng', below for other herbals that can affect the results of **digoxin** assays.

Digitalis glycosides + Herbal medicines; Ginkgo biloba

A study in 8 healthy subjects found that ginkgo biloba leaf extract 80 mg three times daily had no significant effects on the pharmacokinetics of a single 500-microgram dose of digoxin.¹

1. Mauro VF, Mauro LS, Kleshinski JF, Khuder SA, Wang Y, Erhardt PW. Impact of Ginkgo biloba on the pharmacokinetics of digoxin. *Am J Ther* (2003) 10, 247–51.

Digitalis glycosides + Herbal medicines; Ginseng

A man taking digoxin developed grossly elevated serum digoxin levels, without symptoms of toxicity, while taking Siberian ginseng. This was eventually attributed to an effect of ginseng on the digoxin assay. Both Chinese and Siberian ginseng may interfere with some digoxin assays.

Clinical evidence, mechanism, importance and management

A 74-year-old man who had been taking **digoxin** for many years (serum levels normally in the range 0.9 to 2.2 nanograms/mL) was found, during a routine check, to have **digoxin** levels of 5.2 nanograms/mL, but without evidence of toxicity or bradycardia or any other ECG changes.¹ The levels remained high even when the **digoxin** was stopped. It turned out he had also been taking **Siberian ginseng** capsules. When the ginseng was stopped, the **digoxin** levels returned to the usual range, and **digoxin** was resumed. Later rechallenge with the ginseng caused a rise in his serum **digoxin** levels. No digoxin or digitoxin contamination was found in the capsules, and the authors of the report also rejected the idea that the eleutherosides (chemically related to cardiac glycosides) in ginseng might have been converted *in vivo* into **digoxin**, or that the renal elimination of **digoxin** might have been impaired, since the patient showed no signs of toxicity. One possible explanation is that the ginseng affected the accuracy of the **digoxin** assay so that it gave false results.¹

Asian or Chinese ginseng (*Panax ginseng*) and **Siberian ginseng** (*Eleutherococcus senticosus*) have both been found to interfere with some **digoxin** assays including fluorescence polarisation immunoassay (FPIA) and microparticle enzyme immunoassay (MEIA).²

Whether serum digoxin levels are actually affected is uncertain. Nevertheless it may be sensible to ask about ginseng use when interpreting **digoxin** levels.

Digitalis glycosides + Herbal medicines; Goldenseal (Hydrastis)

A standardised goldenseal root extract did not alter the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A study in 20 healthy subjects given a single 500-microgram dose of **digoxin** before and on the last day of treatment with standardised **goldenseal root extract** (*Hydrastis canadensis*) 1070 mg three times daily for 14 days, found a 14% increase in the maximum **digoxin** plasma levels, but no other changes in the pharmacokinetics of **digoxin**. The product was standardised for isoquinoline alkaloid content.¹

It was suggested that constituents of goldenseal may alter **digoxin** pharmacokinetics by affecting P-glycoprotein, since goldenseal alkaloids are modulators of P-glycoprotein *in vitro*. However, the clinical study showed that goldenseal does not cause clinically relevant changes in **digoxin** pharmacokinetics. Therefore no changes in **digoxin** levels would be anticipated on concurrent use, the caveat being that, as with all herbals, these results may not be applicable to all goldenseal products.¹

Digitalis glycosides + Herbal medicines; Hawthorn (*Crataegus*)

A standardised extract of hawthorn (*Crataegus*) did not have any clinically relevant effect on digoxin levels.

Clinical evidence, mechanism, importance and management

In a crossover study in 8 healthy subjects, a standardised extract of hawthorn leaves and flowers (*Crataegus oxyacantha*) 450 mg twice daily for 21 days had no effect on the steady-state pharmacokinetics of **digoxin**. The biggest difference was a non-significant 23% reduction in the **digoxin** trough level. There were no changes in ECG or blood pressure from baseline values for either **digoxin** alone or combined with hawthorn.¹

It was suggested that flavonol constituents of hawthorn might induce P-glycoprotein and therefore decrease **digoxin** levels,¹ similar to 'St John's wort', (below).

This study suggests that, at the most, hawthorn might cause a minor decrease in **digoxin** levels, and no adjustment of the **digoxin** dose is therefore likely to be needed on concurrent use. Although no pharmacodynamic effects were seen, the possibility that hawthorn's cardioactive constituents might increase the effect of **digoxin** on cardiac contractility cannot be ruled out.¹

Digitalis glycosides + Herbal medicines; Kava

A standardised kava extract did not alter the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A study in 20 healthy subjects given a single 500-microgram dose of **digoxin** before and on the last day of treatment with a standardised kava rhizome (*Piper methysticum*) extract 1227 mg three times daily for 14 days, found no changes in the pharmacokinetics of **digoxin**. The product used was standardised for kavalactone content.¹

It was suggested that kava may alter **digoxin** pharmacokinetics by affecting P-glycoprotein, since kavalactones are modulators of P-glycoprotein *in vitro*. However, the clinical study showed that kava does not cause clinically relevant changes in **digoxin** pharmacokinetics. Therefore no changes in **digoxin** levels would be anticipated on concurrent use, the caveat being that, as with all herbals, these results may not be applicable to all kava products.¹

1. Gurley BJ, Swain A, Barone GW, Williams DK, Breen P, Yates CR, Stuart LB, Hubbard MA, Tong Y, Cheboyina S. Effect of goldenseal (*Hydrastis canadensis*) and kava kava (*Piper methysticum*) supplementation on digoxin pharmacokinetics in humans. *Drug Metab Dispos* (2007) 35, 240–5.

Digitalis glycosides + Herbal medicines; Milk thistle

A standardised milk thistle extract did not alter the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A study in 16 healthy subjects who were given a single 400-microgram dose of **digoxin** before and on the last day of a 14-day course of a standardised milk thistle (*Silybum marianum*) extract 300 mg three times daily, found no statistically significant changes in the pharmacokinetics of **digoxin**. There was a trend towards a minor 10% reduction in the AUC of **digoxin**, but this did not reach statistical significance. The extract used was standardised to contain 80% silymarin.¹

It was suggested that milk thistle may alter **digoxin** pharmacokinetics by affecting P-glycoprotein, since silymarin is a modulator of P-glycoprotein *in vitro*. However, the clinical study showed that milk thistle does not cause clinically relevant changes in **digoxin** pharmacokinetics. Therefore no changes in **digoxin** levels would be anticipated on concurrent use, the caveat being that, as with all herbals, these results may not be applicable to all milk thistle products.¹

Digitalis glycosides + Herbal medicines; St John's wort (*Hypericum perforatum*)

Digoxin toxicity occurred in a patient taking digoxin when he stopped taking St John's wort. There is good evidence that some preparations of St John's wort can reduce the levels of digoxin by about one-quarter to one-third.

Clinical evidence

An 80-year-old man taking long-term **digoxin** and St John's wort herbal tea (2 litres daily) developed symptoms of **digoxin** toxicity (nodal bradycardia of 36 bpm and bigeminy) when he stopped taking the herbal tea.¹

In a study 13 healthy subjects were given **digoxin** for 5 days until steady-state had been achieved, and then St John's wort extract (LI 160, Lichtwer Pharma) 300 mg three times daily for a further 10 days. The AUC and trough level of **digoxin** decreased by 28% and 37%, respectively. When compared with a parallel group of 12 subjects taking digoxin and placebo, the St John's wort group had 26.3% lower maximum plasma **digoxin** levels, 33.3% lower trough **digoxin** levels and a 25% lower AUC.²

In a further randomised placebo-controlled study, 93 healthy subjects were given **digoxin** alone for 7 days and then with one of ten St John's wort preparations for 14 days. The extract used in the earlier study (LI 160, Jarsin 300, Lichtwer Pharma) 300 mg three times daily similarly reduced the **digoxin** AUC, peak and trough plasma levels by 25%, 37%, and 19%, respectively. Comparable results were found with hypericum powder containing similar amounts of hyperforin (about 21 mg daily), while hypericum powder with half the hyperforin content (about 10 mg daily) reduced the AUC, peak and trough plasma levels by about 18%, 21%, and 13%, respectively. Some St John's wort products, including tea, juice, oil extract, and powder with low-dose hyperforin (all 5 mg daily or less), did not significantly affect the pharmacokinetics of **digoxin**.³ Similarly, a further study in 28 healthy subjects found no statistically significant change in **digoxin** pharmacokinetics when another low-hyperforin (about 3.5 mg daily) St John's wort extract (*Esbericum*) 120 mg was given twice daily for 11 days to patients who had received a digoxin loading dose of 750 micrograms daily for 2 days before starting St John's wort, and then received digoxin 250 micrograms daily each day during the study.⁴

Mechanism

St John's wort has been shown to increase the activity of the P-glycoprotein drug transporter protein in the intestines, which reduces the absorption of digoxin.^{2,5}

Importance and management

Information seems to be limited to these reports, but the interaction would appear to be established. The extent of the interaction may depend on the St John's wort preparation involved and dose used and seems to be correlated with the dose of hyperforin.^{3,4} See also 'Drug-herb interactions', (p.10). Reductions in serum digoxin levels of the size seen with LI 160 could diminish the control of arrhythmias or heart failure. Digoxin serum levels should therefore be well monitored if St John's wort is either started or stopped and appropriate dosage adjustments made if necessary. The recommendation of the CSM in the UK is that St John's wort should not be used by patients taking digoxin.⁶

Digitalis glycosides + HRT

Post hoc analysis of one study found an increased rate of cardiovascular adverse events in women using digitalis and also taking HRT.

Clinical evidence, mechanism, importance and management

Retrospective analysis of data from a large randomised, placebo-controlled study of HRT (conjugated estrogens/medroxyprogesterone 0.625/2.5 mg daily) in women with coronary heart disease was conducted to see if there were any subgroups of patients who responded differently. Use of digitalis was associated with a fivefold excess rate of cardiovascular events in the first year in women receiving HRT, when compared with the control group. A lower 1.5-fold excess rate was seen over the whole duration of the study (average 4.1 years). Possible mechanisms could be a drug-drug interaction or a drug-disease (HRT with congestive heart failure) interaction.¹

However, it is impossible to say whether this represents a true effect, because the number of positive sub-group analyses in this study was the same as the number predicted by chance alone. Confirmatory evidence is required.¹

Digitalis glycosides + Kaolin-pectin

Plasma digoxin levels can be reduced by kaolin-pectin, but the reduction is small and probably of minimal clinical importance.

Clinical evidence

The concurrent use of kaolin-pectin suspension and digoxin reduced the peak plasma digoxin levels of 7 patients by 36%, while the AUC₀₋₂₄ was reduced by 15%. Conversely, when two doses of kaolin-pectin were taken, the first 2 hours before and the other 2 hours after the digoxin, no significant changes were seen.¹

Two single-dose studies have found 42% and 62% reductions in the bioavailability of digoxin caused by kaolin-pectin.^{2,3} Another study found an interaction with digoxin tablets but not with digoxin capsules.⁴

Mechanism

Not understood. The digoxin may possibly become adsorbed onto the kaolin so that less is available for absorption. Another possibility is that the kaolin reduces the motility of the gut, which normally increases mixing and brings the digoxin into contact with the absorbing surface.

Importance and management

Steady-state studies reflect the every-day situation much more closely than single-dose studies, and the one cited above¹ indicates that the total reduction in digoxin absorption is small (15%). This is unlikely to be of clinical importance. However, if an interaction does occur the effects can seemingly be minimised by separating the dosages by 2 hours.

4. Allen MD, Greenblatt DJ, Hartz JS, Smith TW. Effect of magnesium aluminum hydroxide and kaolin-pectin on absorption of digoxin from tablets and capsules. *J Clin Pharmacol* (1981) 21, 26–30.

Digitalis glycosides + Ketanserin

Ketanserin does not appear to affect the pharmacokinetics of either digoxin or digitoxin.

Clinical evidence, mechanism, importance and management

Ketanserin 40 mg twice daily did not cause any significant changes in the pharmacokinetics of single doses of either digoxin 1.25 mg or digitoxin 1 mg in healthy subjects, and it was concluded that ketanserin is unlikely to alter serum concentrations of either digitalis glycoside during clinical use.¹

1. Ochs HR, Verburg-Ochs B, Höller M, Greenblatt DJ. Effect of ketanserin on the kinetics of digoxin and digitoxin. *J Cardiovasc Pharmacol* (1985) 7, 205–7.

Digitalis glycosides + Lanthanum

Lanthanum did not significantly affect the pharmacokinetics of digoxin in a single-dose study.

Clinical evidence, mechanism, importance and management

In a crossover study, 14 healthy subjects were given lanthanum 1 g for 3 doses on one day, followed by a fourth dose the next day. A single 500-microgram dose of digoxin was given 30 minutes after the fourth dose of lanthanum. The digoxin half-life was increased during concurrent treatment from 11.4 to 14.8 hours but this was not considered to be clinically significant. Other pharmacokinetic parameters were not significantly affected.¹ Further multiple dose studies are needed to confirm this lack of interaction in patients.

1. Fiddler G. Fosrenol™ (lanthanum carbonate) does not affect the pharmacokinetics of concomitant treatment with digoxin. *J Am Soc Nephrol* (2002) 13, 749A.

Digitalis glycosides + Lithium

No pharmacokinetic interaction occurs between digoxin and lithium but the addition of digoxin to lithium possibly has a detrimental short-term effect on the control of mania. An isolated report describes severe bradycardia in one patient given both drugs.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects taking lithium carbonate sufficient to achieve mean steady-state serum levels of 0.76 mmol/L (range 0.4 to 1 mmol/L) showed that the pharmacokinetics of a 750-microgram intravenous dose of digoxin were unchanged by lithium, and that there were no significant effects on sodium pump activity or electrolyte concentrations.¹ However an experimental 7-day study in patients with manic-depressive psychoses found that there was a greater improvement in those given lithium with placebo than those given lithium with digoxin. This may be a reflection of changes in Na-K ATP-ase.² An isolated report describes tremor, confusion and severe nodal bradycardia in a patient given both drugs. The bradycardia worsened (30 bpm) even after both drugs were stopped.³ The clinical

significance of all of these findings is uncertain. Note that one UK manufacturer of **digoxin**⁴ lists lithium as a drug that may increase sensitivity to **digoxin** because it may cause hypokalaemia or intracellular potassium deficiency, consider also 'drugs that lower potassium', (p.923).

Digitalis glycosides + Macrolides

Clarithromycin markedly increases digoxin levels, and numerous cases of digoxin toxicity have been reported. Increases in serum digoxin levels also occur with telithromycin. Cases of rapid and marked two to fourfold increase in serum digoxin levels have also been reported for azithromycin, erythromycin, josamycin and roxithromycin. A similar case has been seen with digitoxin and azithromycin.

Clinical evidence

A. Digitoxin

A man with congestive heart failure taking digitoxin 70 micrograms daily for 5 days of each week, with enalapril and furosemide, was admitted to hospital with nausea and bradycardia of 26 bpm 4 days after starting a 3-day course of **azithromycin** (dosage not stated). His serum digitoxin levels were found to be raised from his usual baseline range of 9.9 to 19 nanograms/mL up to 34 nanograms/mL. His renal function was normal. Another patient treated with intravenous digitoxin 250 micrograms once daily had a marked rise from his steady-state digitoxin range of 11 to 15 nanograms/mL after being given **azithromycin** 500 mg daily for 3 days. The digitoxin was withdrawn one day later, but even so the levels climbed to a peak of 32 nanograms/mL after a further 3 days, and remained in the toxic range for yet another 3 days.¹

B. Digoxin

(a) Azithromycin

A 31-month-old boy with Down's syndrome and tetralogy of Fallot (a congenital heart defect resulting in reduced blood flow to the lungs) was discharged from hospital after repair of his heart defect. He was taking digoxin 60 micrograms twice daily, furosemide, and potassium chloride. Eight days later, when readmitted with symptoms of heart failure, intermittent fever and wheezing, he was given azithromycin (10 mg/kg on day 1, then 5 mg/kg daily for 4 days). Three days later his steady-state serum digoxin levels had risen from 1.79 to 2.37 nanograms/mL and he experienced anorexia, nausea, and second degree atrioventricular block. All the symptoms resolved when the digoxin was withdrawn. Digoxin was restarted at 50 micrograms twice daily after the azithromycin course was completed and steady-state digoxin levels of 1.42 nanograms/mL were noted.²

The manufacturers of azithromycin said that, as of October 2000, there were 230 cases of the concurrent use of azithromycin and digoxin on their database. Of these, 78 cases had adverse events indicating possible digoxin toxicity. However on review, 21 cases were clearly excluded. Of the remaining cases, only 13 provided digoxin levels, and of these, high serum digoxin concentrations were reported in 6, but generally insufficient data made interpretation difficult.³ The manufacturers concluded that the possibility that a patient may experience an increase in digoxin levels while taking azithromycin cannot be entirely excluded.³

(b) Clarithromycin

A woman receiving treatment with warfarin, heparin, carbamazepine and digoxin was admitted to hospital with syncope, vomiting and an irregular heart rhythm shortly after starting clarithromycin 1 g daily. Her serum digoxin levels were found to be raised. The clarithromycin was decreased, the carbamazepine and digoxin stopped, and she was treated with digoxin-specific antibody fragments (*Digibind*) and intravenous fluids. Her serum digoxin levels fell again and the digitalis toxicity disappeared.⁴

In 1995, the manufacturers of clarithromycin had a few other cases on their records of raised digoxin levels in patients following treatment with clarithromycin⁴ and there are many other case reports of this interaction in

the literature,⁵⁻¹⁹ including a case series of 6 patients with end stage renal disease.²⁰

A subsequent randomised, placebo-controlled study in 12 healthy subjects confirmed that clarithromycin 250 mg twice daily for 3 days increased the AUC of a single 750-microgram oral dose of digoxin by 70%. The non-glomerular renal clearance of digoxin was reduced by 40%.²¹ Intravenous digoxin was much less affected.^{21,22} In two further studies in which clarithromycin (500 mg twice daily for 7 days) was used as a positive control, a 57% and 35% increase in the AUC of digoxin was seen.^{23,24}

Two studies that prospectively measured digoxin levels in patients before and during clarithromycin therapy found an important increase in all patients of 70%,²⁵ and from a range of 1 to 1.6 nanograms/mL up to 2.3 to greater than 4 nanograms/mL.²⁶ In one of these studies, there was a significant correlation between the dose of clarithromycin and the increase in digoxin serum levels.²⁵

A case-control study using data from healthcare databases in Ontario from 1994 to 2000 identified 1051 patients who had been admitted to hospital with digoxin toxicity. Of these, 55 patients (5.2%) had been exposed to clarithromycin in the preceding 3 weeks, when compared with just 0.5% of controls, showing about a tenfold increase in risk.²⁷

(c) Erythromycin

An elderly woman with a prosthetic heart valve being treated for left ventricular dysfunction with warfarin, furosemide, hydralazine, isosorbide dinitrate and digoxin, was given erythromycin. She took only four 250-mg doses. Four days later her serum digoxin levels were found to have risen to 2.6 nanograms/mL from a normal steady-state range of 1.4 to 1.7 nanograms/mL, and she showed evidence of digitalis toxicity.²⁸ Another four similar cases have also been reported.²⁹⁻³¹

A study in a man who was resistant to digoxin found that erythromycin 1 g daily increased the AUC of digoxin by 300%.³² A neonate given oral digoxin 5 micrograms/kg daily developed digoxin toxicity two days after erythromycin (10 mg three times daily, then 17 mg three times daily) was given. Digoxin levels rose from 1.8 to 16 nanograms/mL.³³

(d) Josamycin

A case report describes a premature neonate receiving digoxin who had a 50% increase in digoxin levels from 2 to 2.95 nanograms/mL, resulting in bradycardia, and sinoatrial block after being given josamycin for 4 days. This was treated with antidigitalis Fab fragments.³⁴

(e) Rokitamycin

Rokitamycin did not affect serum digoxin levels in a study in 10 subjects.³⁵

(f) Roxithromycin

A 76-year-old woman taking digoxin and a number of other drugs (enalapril, isosorbide mononitrate, furosemide, diltiazem, glyceryl trinitrate, slow-release potassium, prednisolone, omeprazole, calcitriol) developed signs of digoxin toxicity (nausea, vomiting, first degree heart block) within 4 days of starting to take roxithromycin 150 mg twice daily. Her serum digoxin levels were raised by about fourfold.³⁶

(g) Telithromycin

A study in 26 healthy subjects given digoxin 500 micrograms twice daily on the first day followed by 250 micrograms twice daily found that telithromycin 800 mg daily increased the digoxin AUC by 37% and the maximum blood levels by 74%. Trough plasma levels were increased by 21% and remained within the therapeutic range. No signs of digoxin toxicity were observed on ECGs.³⁷

A 58-year-old woman taking digoxin 250 micrograms daily developed syncope and malaise after a 5-day course of telithromycin 800 mg daily. Her digoxin levels were 55% higher than her normal baseline level, and there were ECG changes.³⁸

Mechanism

It was originally thought that this interaction was due to the effect of the antibacterials on gut flora. Up to 10% of patients receiving oral digoxin excrete it in substantial amounts in the faeces and urine as inactive metabolites (digoxin reduction products or DRPs). This metabolism seems to be the responsibility of the gut flora,²⁹ in particular *Eubacterium lentum*, which is anaerobic and Gram positive.^{31,39} In the presence of antibacterials that inhibit this organism, much more digoxin becomes available for absorption, which results in a marked rise in serum levels. At the same time the inactive metabolites derived from the gut disappear.^{29,40} However, it is

worth noting that most classes of antibacterials do not appear to interact with digoxin despite inhibiting *E. lentum in vitro*.³⁹ See 'Digitalis glycosides + Beta-lactam antibacterials', p.913. In addition, more recent data showing that digoxin levels are affected by clarithromycin in all, or the majority, of patients or subjects throw doubt on this theory.

A more plausible explanation for the interaction between digoxin and clarithromycin, and probably also erythromycin, is that the antibacterials inhibit the intestinal^{22,41} or renal^{14,25} P-glycoprotein transport of digoxin, which would increase the oral bioavailability and reduce the nonglomerular renal clearance respectively. Both mechanisms may be important.²¹

Further, the increased gastric emptying due to erythromycin may also increase the bioavailability of digoxin⁴² or digitoxin.³⁹

Importance and management

The pharmacokinetic interaction between oral digoxin and clarithromycin is established, and likely to occur in the majority of patients. Digoxin toxicity has been commonly reported. Monitor all patients well for signs of increased digoxin effects when clarithromycin is first given, reducing the digoxin dosage as necessary. Intravenous digoxin is unlikely to be affected to a clinically relevant extent. Telithromycin appears to interact similarly to clarithromycin, and similar advice applies.

Information about azithromycin and erythromycin is limited to a relatively small number of patients, and there is only one report of an interaction between digoxin and josamycin or digoxin and roxithromycin. Until more is known, it would be prudent to monitor all patients well for signs of increased digoxin effects when any of these macrolide antibacterials is first given, reducing the digoxin dosage as necessary. In addition, remember that azithromycin has a long serum half-life (60 hours), which means that it can continue to interact for several days after it has been withdrawn. Rokitamycin appears not to interact.

Digitalis glycosides + Medroxyprogesterone acetate or Megestrol

Doses of medroxyprogesterone acetate or megestrol used for malignant disease do not appear to interact with digitoxin to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

Steady-state **digitoxin** levels were monitored in 3 patients before and after 5 weeks of treatment with oral medroxyprogesterone acetate 500 mg twice daily or megestrol 160 mg daily. Only small and clinically irrelevant changes in **digitoxin** levels and clearance were seen.¹ For the possible effect of HRT including medroxyprogesterone on digitalis, see 'Digitalis glycosides + HRT', p.928.

Digitalis glycosides + Methyldopa

Methyldopa does not appear to affect serum digoxin levels, but marked bradycardia has been seen in two elderly women given both drugs.

Clinical evidence

Methyldopa 250 mg daily had no effect on the steady-state serum levels of **digoxin** 250 micrograms daily in 8 healthy subjects.¹

However, two elderly women with hypertension and left ventricular failure developed marked bradycardia when they were given **digoxin** with methyldopa 750 mg or 3.75 g daily but not when they were given **digoxin** alone. Average heart rates were 50 and 48 bpm while minimum heart rates were 32 and 38 bpm, respectively. They were subsequently discharged taking **digoxin** and hydralazine with heart rates within the normal range.²

Mechanism

Uncertain. Both digoxin and methyldopa³ can cause some bradycardia, but these effects seem to have been more than simply the sum of the individual drug effects on the autonomic nervous system.²

Importance and management

Information is limited but it would seem that concurrent use need not be avoided, but be aware that on rare occasions undesirable bradycardia has occurred.

Digitalis glycosides + Metoclopramide

The serum levels of digoxin may be reduced by about one-third if metoclopramide is given with slowly dissolving forms of digoxin. No interaction is likely with digoxin in liquid form or in fast-dissolving preparations.

Clinical evidence

A study in 11 patients taking slowly dissolving **digoxin** tablets (*Orion*) found that metoclopramide 10 mg three times a day for 10 days reduced the serum **digoxin** levels by 36%, from 0.72 to 0.46 nanograms/mL.¹ The **digoxin** concentrations rose to their former levels when the metoclopramide was withdrawn.

Another study in healthy subjects found metoclopramide 10 mg three times daily caused a 19% reduction in the AUC of **digoxin** and a 27% reduction in peak serum **digoxin** levels (**digoxin** formulation not stated).² Yet another study in healthy subjects clearly showed that metoclopramide decreased the absorption of **digoxin** from tablets (*Lanoxin*) but not capsules (*Lanoxicaps*).³

Mechanism

It would seem^{4–6} that the metoclopramide increases the motility of the gut to such an extent that full dissolution and absorption of some digoxin formulations does not occur.

Importance and management

Information is very limited, but the interaction seems to be established. It is not likely to occur with solid form, fast-dissolving digoxin preparations (e.g. liquid-filled capsules) or digoxin in liquid form, but only with those preparations which are slowly dissolving (i.e. some tablet formulations). A reduction in digoxin levels of one-third could result in under-digitalisation. There seems to be no information about **digitoxin**.

Digitalis glycosides + Mexiletine

Serum digoxin levels are not significantly altered by mexiletine.

Clinical evidence, mechanism, importance and management

Mexiletine 200 mg every 8 hours for 4 days slightly reduced the serum levels of **digoxin** 250 micrograms daily from 0.32 to 0.27 nanograms/mL in 10 healthy subjects.¹ Two other studies in a total of 17 patients^{2,3} confirmed that mexiletine does not significantly affect serum **digoxin** levels.

3. Day T, Hunt D. Interaction between mexiletine and digoxin. *Med J Aust* (1983) 2, 630.

Digitalis glycosides + Mizolastine

Mizolastine can cause a small but clinically irrelevant rise in serum digoxin levels.

Clinical evidence, mechanism, importance and management

A placebo-controlled, crossover study in 12 healthy subjects found that mizolastine 10 mg daily for a week caused a 17% increase in the maximum serum levels of **digoxin** 250 micrograms daily. The **digoxin** AUC and half-life were unchanged and the haemodynamic parameters measured (blood pressure, ECG) were unaltered.¹ No special precautions would seem necessary during concurrent use.

1. Chaufour S, Le Coz F, Denolle T, Dubruc C, Cimarosti I, Deschamps C, Ulliac N, Delhotal-Landes B, Rosenzweig P. Lack of effect of mizolastine on the safety and pharmacokinetics of digoxin administered orally in repeated doses to healthy volunteers. *Int J Clin Pharmacol Ther* (1998) 36, 286–91.

Digitalis glycosides + Moclobemide

Moclobemide had no clinically relevant effect on the pharmacokinetics of beta-acetyldigoxin.

Clinical evidence, mechanism, importance and management

A study in 14 patients with decompensated heart failure given an individualised dose of **beta-acetyldigoxin** for 2 weeks found that moclobemide 100 mg three times daily given for 8 days caused a non-significant 14% reduction (from 0.99 to 0.85 nanograms/mL) in plasma **beta-acetyldigoxin** levels. No adverse effects attributable to an interaction were seen.¹ No special precautions appear to be required during concurrent use of acetyldigoxin and moclobemide.

1. Amrein R, Güntert TW, Dingemans J, Lorscheid T, Stabl M, Schmid-Burgk W. Interactions of moclobemide with concomitantly administered medication: evidence from pharmacological and clinical studies. *Psychopharmacology (Berl)* (1992) 106, S24–S31.

Digitalis glycosides + Montelukast

Montelukast does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In a randomised study in 11 healthy subjects montelukast 10 mg was given for 12 days with a single 500-microgram dose of digoxin on day 7. It was found that the pharmacokinetic profile of the digoxin was unchanged by the montelukast.¹ No special precautions are needed if both drugs are used concurrently.

1. Depre M, Van Hecken A, Verbesselt R, Wynants K, De Lelepeire I, Freeman A, Holland S, Shahane A, Gertz B, De Schepper PJ. Effect of multiple doses of montelukast, a CysLT1 receptor agonist, on digoxin pharmacokinetics in healthy volunteers. *J Clin Pharmacol* (1999) 39, 941–4.

Digitalis glycosides + Moracizine

Moracizine does not significantly increase serum digoxin levels in patients with normal renal function. However, some adverse conduction effects have been seen.

Clinical evidence

Thirteen patients taking **digoxin** 125 to 250 micrograms daily showed a non-significant rise in their serum **digoxin** levels of 10 to 15% when they were given moracizine 10 mg/kg daily in three divided doses for 2 weeks. Nine patients taking **digoxin** and moracizine for 1 to 6 months had no significant changes in their serum **digoxin** levels.¹

No changes in the pharmacokinetics of **digoxin** were seen in a single-dose study of intravenous **digoxin** and moracizine in 9 healthy subjects² or in a study in patients receiving maintenance treatment with **digoxin** over a 13-day period. However, cardiac arrhythmias (AV junctional rhythm and heart block) were seen, which resolved when the moracizine was stopped.³

Mechanism

Not established. There does not appear to be a pharmacokinetic interaction between moracizine and digoxin. Concurrent use can cause a significant increase in the PR interval and QRS duration, which can result in AV block.⁴

Importance and management

Although no clinically important changes in serum digoxin levels appear to occur during concurrent use, the occurrence of arrhythmias in a few patients indicates that good monitoring is advisable. It has been pointed out that the additive effects of both drugs on intranodal and intraventricular conduction may be excessive in some patients with heart disease.⁴ More study is needed.

4. Siddoway LA, Schwartz SL, Barbey JT, Woosley RL. Clinical pharmacokinetics of moricizine. *Am J Cardiol* (1990) 65, 21D–25D.

Digitalis glycosides + Nateglinide or Repaglinide

The pharmacokinetics of nateglinide and digoxin are not altered when they are given together. Repaglinide does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

(a) Nateglinide

A crossover study in 12 healthy subjects found that when a single 1-mg dose of **digoxin** was given with the first dose of nateglinide 120 mg three times daily for 2 days, there were no changes in the pharmacokinetics of **digoxin**, nor were the pharmacokinetics of nateglinide altered by the **digoxin**.¹

(b) Repaglinide

A crossover, multiple-dose study in 14 healthy subjects found that repaglinide 2 mg three times daily before meals had no effect on the pharmacokinetics of **digoxin** 250 micrograms daily. Concurrent use was well tolerated.²

1. Zhou H, Walter YH, Smith H, Devineni D, McLeod JF. Nateglinide, a new mealtime glucose regulator. Lack of pharmacokinetic interaction with digoxin in healthy volunteers. *Clin Drug Invest* (2000) 19, 465–71.
2. Hatorp V, Thomsen MS. Drug interaction studies with repaglinide: repaglinide on digoxin or theophylline pharmacokinetics and cimetidine on repaglinide pharmacokinetics. *J Clin Pharmacol* (2000) 40, 184–92.

Digitalis glycosides + Nefazodone

Nefazodone causes a moderate increase in serum digoxin levels but this is of uncertain clinical importance. Digoxin does not appear to affect the pharmacokinetics of nefazodone.

Clinical evidence

Eighteen healthy subjects were given **digoxin** 200 micrograms daily for 8 days, then nefazodone 200 mg twice daily for 8 days, and then both drugs together for 8 days. Nefazodone increased the AUC of **digoxin** by 15%, and increased the peak and trough serum levels of **digoxin** by 29% and 27%, respectively. However, no clinically significant changes in ECG measurements occurred (PR, QRS and QT intervals), nor was the heart rate nor any other vital sign altered. The pharmacokinetics of the nefazodone were unchanged.¹

Mechanism

Not understood.

Importance and management

This interaction appears to be established, but its clinical importance is uncertain. The increase in the AUC of digoxin is modest, and would not generally be expected to be clinically significant, although some effect may be seen in patients with digoxin levels at the higher end of the therapeutic range. It may be prudent to monitor for symptoms of digoxin excess (e.g. bradycardia) and take digoxin levels if necessary.

1. Dockens RC, Greene DS, Barbhaya RH. Assessment of pharmacokinetic and pharmacodynamic drug interactions between nefazodone and digoxin in healthy male volunteers. *J Clin Pharmacol* (1996) 36, 160–7.

Digitalis glycosides + Neuromuscular blockers

Serious cardiac arrhythmias can develop in patients receiving digitalis glycosides who are given suxamethonium (succinylcholine) or pancuronium.

Clinical evidence

Eight out of 17 digitalised patients (anaesthetised with thiamylal and then maintained with nitrous oxide and oxygen) developed serious ventricular arrhythmias following the intravenous injection of **suxamethonium (succinylcholine)** 40 to 100 mg. Four out of the 8 patients reverted to their previous rhythm when they were given tubocurarine 15 to 30 mg, with one patient returning to a regular nodal rhythm from ventricular tachycardia.¹

Of the other 9 patients, 3 had immediate and definite ST-T wave changes, and the remaining 6 had no demonstrable changes.¹ There are other reports of this interaction,^{2–4} including one that describes sinus tachycardia and atrial flutter in 6 out of 18 patients taking **digoxin** after they were given **pancuronium**.⁴

Mechanism

Not understood. One possibility is that the suxamethonium may cause the rapid removal of potassium from the myocardial cells. Another idea is that it affects catecholamine-releasing cholinergic receptors.

Importance and management

Information is limited but the interaction appears to be established. Suxamethonium should be used with great caution in patients taking digitalis glycosides. Similarly, caution would seem appropriate with pancuronium.

4. Bartolone RS, Rao TLK. Dysrhythmias following muscle relaxant administration in patients receiving digitalis. *Anesthesiology* (1983) 58, 567–9.

Digitalis glycosides + NSAIDs

Diclofenac and indometacin can cause potentially toxic rises in digitalis glycoside levels, while azapropazone, fenbufen and tiaprofenic acid raise levels to a lesser degree. Two studies found that ibuprofen raised serum digoxin levels, whereas another found no evidence of an interaction. Isoxicam, ketoprofen, lornoxicam, meloxicam, nimesulide, piroxicam, and rofecoxib do not appear to interact significantly with digoxin. In contrast, phenylbutazone appears to lower plasma digitalis glycoside levels. NSAIDs can cause a deterioration in renal function, which could result in digoxin toxicity.

Clinical evidence

(a) Azapropazone

In 8 arthritic patients azapropazone 900 mg daily did not significantly alter the AUC of a single 500-microgram intravenous dose of **digitoxin**, but its mean half-life was increased by about 10%. Two of the patients showed individual half-life increases of almost one-third.¹

(b) Diclofenac

A study in 7 healthy subjects found that diclofenac 100 mg daily for 10 days increased the serum levels of **digoxin** by 29%.² Another study in 6 healthy subjects similarly found that diclofenac 50 mg three times daily raised the serum **digoxin** levels by about one-third.³ **Digitoxin** 100 micrograms had no effect on the plasma levels of diclofenac 50 mg twice daily in 8 subjects; **digitoxin** levels were not reported.⁴

(c) Etoricoxib

A study in healthy subjects given **digoxin** found that the addition of etoricoxib 120 mg daily for 10 days did not alter the steady-state AUC of **digoxin** or its renal elimination, but the maximum serum **digoxin** levels were increased by about 33%.⁵ This change is unlikely to be clinically relevant in most patients but it might possibly affect a very small number whose **digoxin** levels are already high.

(d) Fenbufen

Fenbufen 900 mg daily was found to cause an insignificant rise in the serum levels of **digoxin**.⁶

(e) Ibuprofen

The serum **digoxin** levels of 12 patients were reported to have risen by about 60% after they were given at least 1.6 g of ibuprofen daily for a week. However, after a month the **digoxin** levels had returned to their former amount.⁷ These findings may be unreliable because half of the patients were not satisfactorily compliant with treatment. Another study found that ibuprofen 1.2 g daily for 10 days raised the serum **digoxin** levels of 9 healthy subjects by 25%.² Yet another study found that ibuprofen 600 mg three times daily for 10 days had no effect on steady-state serum **digoxin** levels of 8 patients.⁸

(f) Indometacin

1. *Neonates.* A study in 11 premature neonates (gestational age 25 to 33 weeks) given **digoxin** showed that when they were given indometacin (mean total dose of 320 micrograms/kg over 12 to 24 hours) for patent ductus arteriosus, their mean serum **digoxin** levels rose on average by 40%. The **digoxin** was stopped in 5 of them because serum levels were potentially toxic.⁹ This confirms the observation of digitalis toxicity in 3 similarly treated premature neonates,¹⁰ and of toxic serum **digoxin** levels in another neonate.¹¹ A further report describes very high **digoxin** levels (8.2 nanograms/mL) without symptoms of toxicity in a full-term neonate given indometacin.¹²

2. *Adults.* Indometacin 50 mg three times daily for 10 days increased steady-state **digoxin** levels of 10 patients by about 40% (from 0.57 to 0.8 nanograms/mL), with a range of 0 to 100%.⁸ Indometacin 150 mg daily for 10 days increased the serum **digoxin** levels of 9 healthy subjects by 25%.² In yet another study, a 60% increase in digoxin levels was seen with indometacin 150 mg daily.¹³ This contrasts with the results of single-dose studies in 2 groups of 6 healthy adult subjects^{14,15} who were given a 4-hour infusion of **digoxin**. Both studies suggested that no interaction occurs with indometacin.

(g) Isoxicam

Isoxicam 200 mg daily did not affect the steady-state plasma levels of 12 healthy subjects taking **beta-acetyldigoxin**.¹⁶ This confirms the findings of a previous study.¹⁷

(h) Ketoprofen

Ketoprofen 50 mg four times daily for 4 days had no effect on the serum **digoxin** levels of 12 patients.¹⁸

(i) Lornoxicam

In 12 healthy subjects the concurrent use of lornoxicam 4 mg twice daily for 14 days and **digoxin** 250 micrograms daily had only a small effect on the pharmacokinetics of each drug. The apparent clearance of the **digoxin** was decreased by 14% while the maximum serum level of the lornoxicam was decreased by 21% and its elimination half-life increased by 36%.¹⁹

(j) Meloxicam

Meloxicam 15 mg daily for 8 days had no effect on the pharmacokinetics of **digoxin** (given as **beta-acetyldigoxin**) in 12 healthy subjects.²⁰

(k) Nimesulide

Nimesulide 100 mg twice daily for 7 days had little effect on the pharmacokinetics of **digoxin** 250 micrograms daily in 9 patients with mild heart failure. No major change in their clinical condition occurred.²¹

(l) Phenylbutazone

Phenylbutazone 200 or 400 mg daily halved the plasma levels of **digitoxin** 100 micrograms daily in 6 patients, on two separate occasions. **Digitoxin** levels returned to their former values within roughly the same period of time after phenylbutazone was withdrawn.²² A similar response has been described elsewhere in one patient.²³ Six healthy subjects showed an a decrease of about 20% in their serum **digoxin** levels while taking phenylbutazone 200 mg three times daily for 4 days.³ In contrast, one study found no alteration in the levels of **digoxin** when it was given with phenylbutazone 600 mg daily.¹³

(m) Piroxicam

In 10 patients taking **digoxin** for mild heart failure, piroxicam 10 or 20 mg daily for 15 days had no effect on the steady-state **digoxin** levels, nor were consistent effects seen on the pharmacokinetics of **digoxin**.²⁴ Piroxicam 20 mg daily for 10 days was found to have no effect on serum **digoxin** levels in 6 healthy subjects.²

(n) Rofecoxib

Rofecoxib 75 mg once daily did not cause significant changes in the plasma pharmacokinetics or renal elimination of single 500-microgram doses of **digoxin** elixir.²⁵

(o) Tiaprofenic acid

Tiaprofenic acid 200 mg three times daily for 10 days caused a non-significant 15% rise, from 0.97 to 1.12 nanograms/mL, in the serum **digoxin** levels of 12 healthy subjects.²⁶

Mechanism

The reasons for the altered digoxin pharmacokinetics in some of the studies are not clear. However, in the studies in neonates, the elevated digoxin levels were clearly related to an indometacin-induced deterioration in renal function.^{9,11,12} It should be noted that all NSAIDs have the potential to cause renal impairment.

It is suggested that phenylbutazone lowers digitoxin levels by increasing its rate of metabolism by the liver.²²

Importance and management

The interaction between digoxin and **indometacin** seems established in neonates, but documentation is limited. It has been suggested that the digoxin dosage should be halved if indometacin is given to premature or full-term infants and the serum digoxin levels and urinary output monitored. Also be alert for moderate increases in serum digoxin levels in adults if indometacin is given. In adults it may be sufficient to monitor pulse rate (for bradycardia) and take digoxin levels if an interaction is suspected. The interaction between digoxin and **diclofenac** is less well established and its clinical importance is somewhat uncertain as the rises in digoxin levels were mostly modest. It would be prudent to monitor concurrent use (e.g. for bradycardia) and monitor digoxin levels as necessary. Adjust the digoxin dosage accordingly.

The importance of the interaction with azapropazone, etoricoxib, fenbufen and tiaprofenic acid is not known. In most cases changes to doses are unlikely to be necessary, but remain aware of the potential for an interaction. No special precautions would appear to be necessary with isoxicam, ketoprofen, meloxicam, piroxicam, and rofecoxib. More study is needed in most cases, but especially with ibuprofen, where the evidence is conflicting (although note that the one study reporting a significant interaction was poor).

The interaction with phenylbutazone appears to be in direct contrast to that with the other NSAIDs, but documentation is limited. The dosage of digoxin and digitoxin may possibly need to be increased to avoid underdigitalisation if phenylbutazone is added to established treatment. Monitor concurrent use well.

Digitalis glycosides + Orlistat

Orlistat appears not to interact with digoxin.

Clinical evidence, mechanism, importance and management

Orlistat 120 mg three times daily for 6 days was found to have no effect on the pharmacokinetics of a single 400-microgram oral dose of **digoxin** (in soft gelatin capsules) in 12 healthy subjects.¹ This suggests that an approximate 30% reduction in dietary fat absorption induced by orlistat should not change the efficacy of **digoxin** and that no special precautions will be needed in patients who are given both drugs.

Digitalis glycosides + Penicillamine

Serum digoxin levels can be reduced by penicillamine.

Clinical evidence

In 10 patients, penicillamine 1 g daily taken 2 hours after an oral dose of **digoxin**, reduced the serum **digoxin** levels measured 2, 4 and 6 hours later, by 13%, 20% and 39%, respectively. In 10 other patients similarly treated but given **digoxin** intravenously, the serum **digoxin** levels measured 4 and 6 hours later were reduced by 23% and 64%, respectively.¹ The same authors have also reported this interaction in children.²

Mechanism

Unknown.

Importance and management

Information seems to be limited to the reports cited. Patients taking digoxin should be checked for signs of under-digitalisation if penicillamine is added. Information about digitoxin appears to be lacking.

Digitalis glycosides + Pinaverium

Plasma digoxin levels are not affected by pinaverium in patients taking either beta-acetyldigoxin or metildigoxin.

Clinical evidence, mechanism, importance and management

A study in 25 patients, taking either **beta-acetyldigoxin** or **metildigoxin** for congestive heart failure, found that pinaverium 50 mg three times daily for 12 days had no significant effect on their plasma digoxin levels.¹ No special precautions seem necessary on concurrent use.

Digitalis glycosides + Pioglitazone or Rosiglitazone

Pioglitazone and rosiglitazone do not affect the pharmacokinetics of digoxin, but they may adversely affect cardiac function in patients with cardiac failure.

Clinical evidence

(a) Pioglitazone

In healthy subjects, pioglitazone did not alter the steady-state pharmacokinetics of **digoxin** 250 micrograms daily.^{1,2}

(b) Rosiglitazone

A study in healthy subjects found that rosiglitazone 8 mg once daily for 14 days had no effect on the steady-state pharmacokinetics of **digoxin** 375 micrograms daily. Concurrent use was safe and well tolerated (aside from one patient who withdrew because of a rash).³

Mechanism

Pioglitazone and rosiglitazone can cause fluid retention, which may cause or exacerbate heart failure.

Importance and management

No pharmacokinetic interaction occurs. However, the US manufacturers advise caution with the use of pioglitazone or rosiglitazone in those with a history of heart failure because it may cause fluid retention which could lead to a deterioration in cardiac function.^{1,4} For the same reason the UK manufacturers contraindicate use in heart failure.^{5,6} If **digoxin** or any other **digitalis glycoside** is being used to treat cardiac failure, the use of pioglitazone or rosiglitazone would not therefore be recommended. This is not a drug-drug interaction but a drug-disease interaction.

Digitalis glycosides + Probenecid

Probenecid has no clinically significant effect on plasma digoxin levels.

Clinical evidence, mechanism, importance and management

A study in 2 healthy subjects taking **digoxin** 250 micrograms daily showed that after taking *ColBenemid* (probenecid 500 mg with colchicine

500 micrograms) twice daily for 3 days, their plasma **digoxin** levels were slightly but not significantly raised (from 0.67 to 0.7 nanograms/mL, and from 0.6 to 0.67 nanograms/mL, respectively).¹ Another study in 6 healthy subjects found that probenecid 2 g daily for 8 days had no significant effect on the pharmacokinetics of **digoxin**.² No special precautions would seem necessary during concurrent use.

2. Hedman A, Angelin B, Arvidsson A, Dahlgvist R. No effect of probenecid on the renal and biliary clearances of digoxin in man. *Br J Clin Pharmacol* (1991) 32, 63–7.

Digitalis glycosides + Propafenone

Propafenone can increase serum digoxin levels by 30 to 90% or even more in children.

Clinical evidence

Propafenone (increasing over 6 days to 300 mg every 8 hours) increased the mean steady-state serum levels of **digoxin** 125 to 250 micrograms daily by 83% in 5 patients. Three patients continued to take both drugs for 6 months, at which point the **digoxin** levels were 63% higher. No digitalis toxicity was seen.¹ In another study, propafenone 600 mg daily in divided doses increased the steady-state serum **digoxin** levels of 10 patients by 90% (from 0.97 to 1.54 nanograms/mL), and two of them developed symptoms of toxicity (nausea, vomiting).² An even greater increase was seen in 3 children who showed rises in serum **digoxin** levels of 112 to 254% over 3 to 24 days when given propafenone 250 to 500 mg/m² daily.³ The mean AUC of **digoxin** increased by 13.8% in 27 patients receiving propafenone 10 mg/kg daily in divided doses. However, there was great inter-individual variability, with 22 patients showing an increase in AUC, and 5 a decrease. One patient experienced **digoxin** toxicity resulting in fatal ventricular fibrillation.⁴

Propafenone 450 mg daily increased the mean steady-state serum **digoxin** levels of 12 healthy subjects by about 35% (from 0.58 to 0.78 nanograms/mL), and the cardiac effects were increased accordingly.⁵ In a study in 6 subjects⁶ given a single 1-mg intravenous dose of **digoxin**, propafenone 150 or 300 mg every 8 hours increased the AUC of **digoxin** by 28% and decreased the total clearance of **digoxin** by 21.9%. A similar study with oral **digoxin** found a 25% increase in the AUC of **digoxin** when healthy subjects were given propafenone.⁷

Mechanism

Not understood. One suggestion is that propafenone increases the bioavailability of the digoxin.⁷ Another is that the volume of distribution and non-renal clearance of digoxin are changed by the propafenone.⁶ Conversely, others reported that propafenone decreased the renal clearance of digoxin.^{2,5} There is certainly some *in vitro* evidence that propafenone and its metabolite inhibit the P-glycoprotein transporter, which is concerned with digoxin secretion by the renal tubular cells.^{8,9}

Importance and management

A very well established interaction of clinical importance. Monitor the effects of concurrent use and reduce the digoxin dosage appropriately in order to avoid toxicity. Most patients appear to be affected and dosage reductions in the range 15 to 70% were found necessary in one of the studies cited.² The data available suggest that the extent of the rise may possibly depend on the propafenone serum concentration rather than on its dose.^{6,10}

Digitalis glycosides + Propantheline

Serum digoxin levels may be increased by at least one-third if propantheline is given with slow-dissolving forms of digoxin tablets. No clinically significant interaction is likely with digoxin given as a liquid or in soft-gelatin capsules or in the form of fast-dissolving tablets.

Clinical evidence

The serum **digoxin** levels of 9 out of 13 patients rose by 30%, from 1.02 to 1.33 nanograms/mL when they took a slow-dissolving formulation of **digoxin** tablets (*Orion*) with propantheline 15 mg three times daily for 10 days. The serum levels stayed the same in 3 patients and fell slightly in one. An associated study in 4 healthy subjects given **digoxin** in liquid form found that serum **digoxin** levels were unaffected by propantheline.¹

Another study by the same workers showed that propantheline increased the **digoxin** serum levels of a slow-dissolving tablet formulation (*Orion*) by 40%, but had no effect on serum **digoxin** levels with a fast-dissolving tablet formulation (*Lanoxin*).² In a further study, propantheline increased the AUC of **digoxin** from *Lanoxin* tablets by 24%, compared with a non-significant increase of 13% with digoxin in the form of a solution in a capsule (*Lanoxicaps*).³

Mechanism

Propantheline is an antimuscarinic, which reduces gut motility. This allows the slow-dissolving formulations of digoxin more time to pass into solution so that more is available for absorption.

Importance and management

An established interaction, but only of importance if slow-dissolving digoxin formulations are used. No interaction is likely with liquid or liquid-filled capsule forms of digoxin. With slow-dissolving forms of digoxin tablets it may be necessary to reduce the digoxin dosage. No interaction seems likely with **digoxin** because it is better absorbed from the gut than digoxin, but this requires confirmation.

Digitalis glycosides + Prostaglandins

Iloprost does not significantly alter digoxin pharmacokinetics. Epoprostenol caused a small decrease in digoxin clearance in the short-term, which is of uncertain clinical importance.

Clinical evidence, mechanism, importance and management

A 6-hour intravenous infusion of **iloprost** 2 nanograms/kg per minute was given to 12 patients taking **digoxin** 250 micrograms daily over a period of 20 days. The mean time to maximum serum **digoxin** levels was delayed by an hour, but overall the pharmacokinetics of the **digoxin** were unchanged.^{1,2} No special precautions would seem to be necessary on concurrent use.

The **digoxin** clearance of 14 patients with congestive heart failure was reduced by an estimated 15% by **epoprostenol** given for 3 days, but this effect was no longer apparent by the end of 12 weeks concurrent use. The clinical relevance of this awaits evaluation but it seems unlikely to be important. However, the authors of the report suggest that the possible short-term changes in patients with high trough-serum **digoxin** levels and those

prone to **digoxin** toxicity should be borne in mind when using the combination.³

Digitalis glycosides + Proton pump inhibitors

A small rise in serum digoxin levels may occur with omeprazole, pantoprazole or rabeprazole, but this is not thought to be clinically significant. One case of digoxin toxicity has been reported with omeprazole.

Clinical evidence

(a) Lansoprazole

A study in 47 patients regularly taking **digoxin** and either lansoprazole or omeprazole found that changing the proton pump inhibitor to an equivalent dose of rabeprazole did not significantly change the mean serum **digoxin** level, although 12 of the patients had increases of more than 15%.¹

(b) Omeprazole

In a study in healthy subjects, omeprazole 20 mg daily for 11 days caused only minor changes in the disposition of a single 1-mg oral dose of **digoxin**. On average the AUC was increased by 10%.² See also *Lansoprazole*, above. However, a 65-year-old woman showed signs of digoxin toxicity 3 months after starting to take omeprazole 20 mg daily. She was found to have a **digoxin** level of 3.9 nanograms/mL (previous level 1.1 nanograms/mL) and ECG changes, which resolved after the administration of **digoxin** immune fab. No changes in renal function were noted in this patient.³

(c) Pantoprazole

Beta-acetyldigoxin 200 micrograms twice daily was given to 18 healthy subjects, with and without pantoprazole 40 mg daily, for 5 days. The pantoprazole caused a 10% rise in the **digoxin** AUC and a 9% rise in the maximum **digoxin** serum levels, but both were considered to be clinically irrelevant. No changes in the **digoxin**-induced height reduction in the T-wave occurred.⁴

(d) Rabeprazole

A preliminary report, giving few details, states that rabeprazole increased the minimum **digoxin** levels by about 20%, and increased the AUC and maximum level.⁵ The US manufacturer states that rabeprazole increased the AUC and maximum level of **digoxin** by 19%, and 29%, respectively.⁶ However, these changes are thought to be within the normal variations of **digoxin** levels and so are not considered clinically significant.⁷ See also *Lansoprazole*, above.

Mechanism

The increase in digoxin levels with omeprazole may be the result of higher gastric pH which results in less digoxin hydrolysis and an increase in digoxin absorption.⁸ Non-selective digoxin assay methods may fail to detect an interaction, whereas selective HPLC assay methods and ECG studies provide evidence that the bioavailability of digoxin may be increased by omeprazole.⁸ An *in vitro* study found that omeprazole, pantoprazole and lansoprazole inhibit P-glycoprotein-mediated intestinal transport of digoxin.⁹

Importance and management

Although some studies suggest small changes in digoxin pharmacokinetics may occur these changes are usually small and unlikely to be clinically significant. No special precautions would therefore seem to be necessary if proton pump inhibitors and digoxin are given concurrently.

Digitalis glycosides + Quinidine

In most patients, on average, the serum levels of digoxin doubled within five days of starting quinidine. The digoxin dosage usually needs to be halved if toxicity is to be avoided. Digoxin levels are also increased but to a lesser extent and takes a longer period of time to develop.

Clinical evidence

(a) Digitoxin

Quinidine 750 mg daily increased the steady-state serum digitoxin levels of 8 healthy subjects by 45%, from 13.6 to 19.7 nanograms/mL, over 32 days.¹ Another study found a 31% increase in serum digitoxin levels over 10 days,² whereas yet another found a 115% increase after 70 days of treatment with 360 mg quinidine three times daily.³ A study in 5 healthy subjects found that quinidine reduced the total body clearance of digitoxin by 63%, resulting in raised serum digitoxin levels.⁴

(b) Digoxin

The observation that quinidine appeared to increase serum digoxin levels prompted a retrospective study of patient records, which revealed that 25 out of 27 patients taking digoxin had shown a significant rise in serum digoxin levels from 1.4 to 3.2 nanograms/mL when given quinidine. Of the patients who showed a rise, 16 showed typical signs of digoxin toxicity (nausea, vomiting, anorexia), which resolved in 10 of them when the digoxin dosage was reduced or withdrawn, and in 5 when the quinidine was withdrawn.⁵

This is one of the first reports published in 1978 (two other groups independently reported it at a similar time^{6,7}) that clearly describes this interaction, although hints of its existence can be found in papers published over the previous 50 years. Since then large numbers of research reports, both retrospective and prospective, and case studies have confirmed and established the incidence and magnitude of this interaction. It occurs in over 90% of patients and, on average, there is a 100% increase in serum digoxin levels, although there are pronounced inter-individual differences, and the increase is somewhat dependent on the quinidine dose. There are numerous reports and reviews of this interaction, only a selection of which are listed here. Two reviews published in 1982 and 1983 contain valuable bibliographies.^{8,9}

Mechanism

Quinidine reduces the renal excretion of digoxin by 40 to 50%, and it also appears to have some effects on non-renal clearance, which includes a reduction in digoxin excretion in the bile.¹⁰ There is also evidence that increases in the rate and extent of absorption of digoxin from the gut occur.¹¹ More recent studies show that the mechanism behind these effects on absorption and renal excretion is likely to be P-glycoprotein inhibition by quinidine.^{12–14} Digoxin also appears to cause a small reduction in the renal clearance of quinidine.¹⁵ Quinidine appears to increase digitoxin serum levels by reducing its non-renal clearance.

Importance and management

The interaction between digoxin and quinidine is very well-documented, well-established and of definite clinical importance. Since serum digoxin levels are usually roughly doubled (up to fivefold increases have been seen⁸) and over 90% of patients are affected, digitalis toxicity will develop unless the dosage of digoxin is reduced (approximately halved).^{5,8,16,17} A suggested rule-of-thumb is that if serum digoxin levels are no greater than 0.9 nanograms/mL the addition of quinidine is unlikely to cause toxic di-

gouxin levels (if serum potassium levels are normal) whereas with levels of 1 nanogram/mL or more, toxic concentrations may develop.¹⁸ Monitor the effects and readjust the dosage as necessary. Significant effects occur within a day of taking the quinidine and reach a maximum after about 3 to 6 days (quicker or slower in some patients), but digoxin levels will only stabilise when the quinidine has reached steady-state and that depends on whether a loading dose of quinidine is given. The effects are to some extent dose-related but the correlation is not good: less than 400 to 500 mg of quinidine daily has minimal effects, and increasing doses up to 1.2 g has greater effects.^{16,19} About 5 days are needed after withdrawing the quinidine before serum digoxin levels fall to their former levels. It has been recommended that patients with chronic renal failure should have their digoxin dosage reduced by as much as two-thirds.²⁰⁻²² An appropriate upward readjustment will be necessary if the quinidine is subsequently withdrawn.

Far less is known about the interaction between digitoxin and quinidine but similar precautions should be taken. It develops much more slowly.

Digitalis glycosides + Quinine

The digoxin levels of some but not all patients may rise by more than 60% if they are given quinine.

Clinical evidence

After taking quinine 300 mg four times daily for a day the steady-state digoxin levels of 4 subjects taking digoxin 250 micrograms daily rose by 63%, from 0.49 to 0.8 nanograms/mL. After taking the quinine for a further 3 days the digoxin levels rose a further 11% (to 0.86 nanograms/mL). Digoxin renal clearance fell by 20%.¹

Quinine sulfate 250 mg daily for 7 days increased the mean serum digoxin levels of 7 healthy subjects by 25%, from 0.64 to 0.8 nanograms/mL. When quinine sulfate 250 mg was given three times daily there was a further 8% rise. Considerable individual differences were seen; one subject had a 92% rise.² In contrast, 17 patients given quinine 750 mg daily had only a small and statistically insignificant rise in mean serum digoxin levels, from 0.8 to 0.91 nanograms/mL. Serum levels were virtually unaltered in 11 patients, decreased in two and markedly increased (amount not stat-

ed) in four.³ Another study found that quinine reduced the total clearance of digoxin by 26%.⁴

Mechanism

Not fully understood. A reduction in non-renal clearance is apparently largely responsible for the rise in serum digoxin levels with quinine.^{2,4,5} This is possibly due to changes in digoxin metabolism or in its biliary excretion.^{4,5}

Importance and management

An established interaction of clinical importance but only moderately documented. Monitor the effects of concurrent use (e.g. for bradycardia) and reduce the digoxin dosage where necessary. Some patients may have a substantial increase in serum digoxin levels whereas others will have only a small or moderate rise. There appear to be no case reports of digoxin toxicity arising from this interaction.

Digitalis glycosides + Quinolones

Levofloxacin, gemifloxacin, moxifloxacin and sparfloxacin do not affect the pharmacokinetics of digoxin. Similarly moxifloxacin does not interact with beta-acetyldigoxin. Gatifloxacin may cause small increases in digoxin levels, which are probably not clinically significant. The effects of garenoxacin are unclear.

Clinical evidence

(a) Garenoxacin

In a study designed to look at the effects of garenoxacin on gut flora, 16 healthy subjects were given digoxin 250 micrograms every 6 hours on day 1, then 250 micrograms daily to day 14, with garenoxacin 600 mg daily on days 8 to 14. Garenoxacin did not decrease (but may actually increase) the numbers of *E. lentum* in faeces (see 'Digitalis glycosides + Macrolides', p.929, for an explanation of the possible significance of these findings). Thus an interaction due to the effect of garenoxacin on intestinal microflora is unlikely.¹

(b) Gatifloxacin

The vital signs of 12 healthy subjects given gatifloxacin 400 mg daily for 7 days while taking digoxin 250 micrograms daily were not altered. The AUC and steady-state levels of digoxin were increased by 19% and 12% respectively. Dosage adjustments were not considered necessary.²

(c) Gemifloxacin

No clinically relevant pharmacokinetic changes were seen in a study in 14 healthy elderly subjects given gemifloxacin 320 mg daily for 7 days while taking digoxin (Lenoxin) 250 micrograms daily. No clinically important changes in vital signs or ECGs were found.³

(d) Levofloxacin

The pharmacokinetics of a single 400-microgram dose of digoxin (Lanoxicaps) were unchanged when 12 healthy subjects were given levofloxacin 500 mg twice daily for 6 days.⁴

(e) Moxifloxacin

In 14 healthy subjects, moxifloxacin 400 mg daily for 14 days did not cause any clinically relevant changes in the steady-state pharmacokinetics of digoxin 250 micrograms daily.⁵ No pharmacokinetic changes were seen in another study in 12 healthy subjects given a single 600-microgram dose of beta-acetyldigoxin with moxifloxacin 400 mg daily for 2 days.⁶

(f) Sparfloxacin

Sparfloxacin, 400 mg as a loading dose, followed by 200 mg daily for 9 days did not affect the pharmacokinetics of digoxin (Lanoxicaps) 300 micrograms daily in 24 healthy subjects.⁷

Mechanism, importance and management

Information about other digitalis glycosides and quinolones seems to be lacking, but bearing in mind their extensive use, this silence in the literature would suggest that no problems normally arise. Despite *in vitro* susceptibility of *E. lentum* to a range of antibacterials including some quinolones there is currently no information to suggest such an interaction occurs between the quinolones and digoxin.⁸ See 'Digitalis glycosides + Macrolides', p.929, for an explanation of the possible significance of *E. lentum*.

Digitalis glycosides + Rauwolfia alkaloids

Concurrent use of digitalis glycosides and rauwolfia alkaloids is usually uneventful, but the incidence of arrhythmias appears to be increased, particularly in those with atrial fibrillation. Excessive bradycardia and syncope have also been described.

Clinical evidence

Three patients taking **digoxin** and either **reserpine** or whole root **Rauwolfia serpentina** developed arrhythmias, namely atrial tachycardia with 4:1 Wenckebach irregular block, ventricular bigeminy and tachycardia, and atrial fibrillation. A large number of other patients received both drugs without problems.¹

The incidence of premature ventricular systoles was roughly doubled in patients taking **digoxin** and **rauwolfia** compared with a similar group taking **rauwolfia** alone.² **Reserpine** reduced the tolerated dose of **acetyl strophanthidin** in 15 patients with congestive heart failure; 8 out of 9 patients with atrial fibrillation developed ECG abnormalities, including complete heart block and ventricular ectopics, during acute digitalisation following **reserpine** use, compared with only one of 9 patients not taking **reserpine**.³

A man taking **digoxin** 250 and 375 micrograms on alternate days and **reserpine** 25 micrograms daily developed sinus bradycardia and carotid sinus supersensitivity. He was hospitalised because of syncope, which resolved when the **reserpine** was withdrawn.⁴

Mechanism

Not understood. A possible explanation is that because the rauwolfia alkaloids deplete the neurotransmitter from the sympathetic nerve supply to the heart, the parasympathetic vagal supply (i.e. heart slowing) has full rein. Digitalis also causes bradycardia which in the presence of the rauwolfia becomes excessive. In this situation the rate could become so slow that ectopic foci, which would normally be swamped by a faster, more normal beat, begin to fire, leading to the development of arrhythmias. Syncope could also result from the combination of bradycardia and the hypotensive effects of reserpine.

Importance and management

Some caution is advisable. One group of authors, despite having described the adverse reactions cited above,¹ conclude that time has proven the safety of the combination. However, they warn that arrhythmias must be anticipated. Particular risk of arrhythmias seems to occur in patients with

atrial fibrillation, and in digitalised patients given reserpine parenterally, because of the sudden release of catecholamines that takes place.⁴

Digitalis glycosides + Rifamycins

The serum levels of digitoxin can be halved by rifampicin (rifampin). Digoxin serum levels are modestly reduced by rifampicin.

Clinical evidence

(a) Digitoxin

A comparative study in 21 patients with tuberculosis and 19 healthy subjects taking digitoxin 100 micrograms daily found that the serum digitoxin levels of the patients taking **rifampicin (rifampin)** were about half of the levels in healthy subjects not taking **rifampicin** (18.4 nanograms/mL compared with 39.1 nanograms/mL).¹ The half-life of digitoxin was reduced from 8.2 to 4.5 days by the **rifampicin**. There are case reports confirming that **rifampicin** can markedly reduce serum digitoxin levels.^{2,3}

(b) Digoxin

A woman, hospitalised for endocarditis, taking digoxin 250 to 375 micrograms daily, furosemide, aspirin, isosorbide dinitrate and potassium chloride, had a marked fall of about 80% in her serum digoxin level when she was given **rifampicin** 600 mg daily. The serum digoxin returned to its former level over the 2 weeks following **rifampicin** withdrawal.⁴ She had only moderate renal impairment (serum creatinine 221 micromol/L).

Another report describes 2 patients undergoing renal dialysis whose digoxin dosage needed to be doubled while they were taking **rifampicin**, and similarly reduced when the **rifampicin** was withdrawn.⁵ This confirms an earlier report.⁶

A study in 8 healthy subjects found that the AUC and maximum plasma levels of a single 1-mg oral dose of digoxin were reduced by 30% and 52%, respectively, by **rifampicin** 600 mg daily for 10 days.⁷ In two further studies in which **rifampicin** 300 mg twice daily for 7 days was used as a positive control, the AUC of a single oral dose of digoxin was reduced by 16%, and the maximum levels were reduced by about 25%.^{8,9}

A 15% reduction in the AUC and maximum plasma levels of digoxin was seen when a single 1-mg intravenous dose of digoxin was given after pre-treatment with **rifampicin** 600 mg daily for 10 days.⁷ Similarly, a study in 8 healthy subjects who were given a single 1-mg intravenous dose of digoxin after 14 days of treatment with **rifampicin** 600 mg daily found an increased excretion of digoxin into the bile, and a 27% reduction in the AUC of digoxin.¹⁰

Mechanism

The interaction between digitoxin and rifampicin is almost certainly due to the increase in digitoxin metabolism caused by rifampicin, which is a potent enzyme inducer.¹ Digoxin is largely excreted unchanged in the urine and the interaction with rifampicin appears to be mainly due to induction of P-glycoprotein, resulting in reduced digoxin absorption from the intestine,^{7,10} and increased biliary excretion.¹⁰

Importance and management

The interaction between digitoxin and rifampicin is established and clinically important. Under-digitalisation may occur unless the digitoxin dosage is increased appropriately. Good monitoring is obviously advisable.

The pharmacokinetic interaction with digoxin is also established, but rifampicin causes only a minor to modest reduction in digoxin levels, and the few case reports suggest that these changes are generally not clinically relevant. However, it would be prudent to monitor the concurrent use of these drugs, being alert for the need to increase the digoxin dosage. It may

be that renal impairment increases the extent of this interaction, as several of the cases cited involved patients with some degree of renal impairment.

There does not seem to be any information regarding the other rifamycins, **rifabutin** (a weak enzyme inducer) and **rifapentine** (a moderate enzyme inducer). However, the UK manufacturers and the CSM in the UK warn that rifabutin may possibly reduce the effects of a number of drugs, including digitalis (but not digoxin).^{11,12}

Digitalis glycosides + Ritonavir

A woman had elevated serum digoxin levels and signs of toxicity after she was given ritonavir. Pharmacokinetic studies have shown that ritonavir causes modest to marked increases in single-dose digoxin levels.

Clinical evidence

A 61-year-old HIV-positive woman taking lamivudine, indinavir, stavudine, pentamidine, warfarin with **digoxin** 250 micrograms daily for atrial fibrillation, presented with increasing nausea and vomiting 3 days after starting to take ritonavir 200 mg twice daily. **Digoxin** levels about 5 and 27 hours after her last dose were 5.6 nanograms/mL and 2.1 nanograms/mL, respectively.¹

A study in 12 healthy subjects found that ritonavir 300 mg twice daily for 11 days significantly increased the AUC and volume of distribution of a single 500-microgram intravenous dose of **digoxin** by 86% and 77%, respectively. Non-renal and renal **digoxin** clearance were decreased by 48% and 35%, respectively, and its half-life increased by 156%.² Another study found that ritonavir 200 mg twice daily for 15 days increased the AUC of a single 400-microgram oral dose of **digoxin** by 22%, with 9 of 12 subjects having an increase. Non-renal but not renal clearance was reduced.³

Mechanism

Raised digoxin levels are possibly due to inhibition of the P-glycoprotein-mediated renal transport of digoxin by ritonavir.^{1–3}

Importance and management

A pharmacokinetic interaction between ritonavir and digoxin would appear to be established, although its extent is uncertain. The study with intravenous digoxin showed a marked effect, whereas the study with oral digoxin showed a much smaller effect. Nevertheless, given the case report, it would seem prudent to closely monitor patients taking digoxin when ritonavir is started or stopped. There do not appear to be any reports or studies of the interaction of digoxin with other protease inhibitors.

Digitalis glycosides + Ropinirole

Ropinirole does not significantly affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 10 patients with Parkinson's disease were given ropinirole (initially 250 micrograms increasing to 2 mg three times daily) in addition to their usual treatment with **digoxin** 125 or 250 micrograms daily. Although ropinirole decreased the **digoxin** AUC by 10%, and the maximum plasma concentration by 25%, the **digoxin** minimum plasma concentration was not significantly altered. The authors therefore concluded that no dosage adjustment would be needed on concurrent use.¹

1. Taylor A, Beerah A, Citerone D, Davy M, Fitzpatrick K, Lopez-Gil A, Stocchi F. The effect of steady-state ropinirole on plasma concentrations of digoxin in patients with Parkinson's disease. *Br J Clin Pharmacol* (1999) 47, 219–22.

Digitalis glycosides + Sevelamer

The pharmacokinetics of single doses of digoxin are not affected by sevelamer.

Clinical evidence, mechanism, importance and management

In a randomised study a single 1-mg oral dose of **digoxin** was given with or without sevelamer 2.4 g followed by a standard breakfast. Five further doses of sevelamer were given immediately before subsequent meals over the following 2 days. During this time, the pharmacokinetic profile of **digoxin** was not altered.¹

Sevelamer is a non-absorbed phosphate-binding polymer with bile-acid binding properties. Because the bile-acid binding resins 'colestyramine', (p.919) and 'colestipol', (p.918) may interact with **digoxin**, it was suggested that sevelamer could also interact, although this does not appear to be the case. This finding requires confirmation in long-term studies.

1. Burke S, Amin N, Incerti C, Plone M, Watson N. Sevelamer hydrochloride (Renagel®), a non-absorbed phosphate-binding polymer, does not interfere with digoxin or warfarin pharmacokinetics. *J Clin Pharmacol* (2001) 41, 193–8.

Digitalis glycosides + SSRIs

Citalopram, fluvoxamine, paroxetine, and sertraline appear not to affect the pharmacokinetics of digoxin. However, one case-control study found a small increased risk of digoxin toxicity after starting sertraline, paroxetine, fluoxetine or fluvoxamine, and two isolated reports describe increased serum digoxin levels attributed to the use of fluoxetine or paroxetine.

Clinical evidence

A study in 11 healthy subjects found that **citalopram** 40 mg once daily for 28 days did not have any significant effect on the pharmacokinetics of a single 1-mg dose of **digoxin** taken on day 21. No clinically significant ECG changes were observed.¹

After taking **fluvoxamine** 100 mg daily for 15 days, the pharmacokinetics of a single 1.25-mg intravenous dose of **digoxin** were unchanged in 8 healthy subjects.²

A study in healthy subjects found that **paroxetine** 30 mg daily had no effect on the pharmacokinetics of **digoxin** 250 micrograms daily. The pharmacokinetics of **paroxetine** were unaffected by **digoxin**.³

A placebo-controlled study in 19 healthy subjects found that **sertraline**, in an initial dose of 50 mg daily titrated to 200 mg daily, had no effect on the steady-state pharmacokinetics of **digoxin**, except for a decrease in time to maximum plasma levels.⁴

However, in a case-control study in 3144 patients who had been admitted to hospital with **digoxin** toxicity, these patients were significantly more likely than controls to have received a new prescription for **sertraline**, **fluoxetine**, **fluvoxamine**, or **paroxetine** in the 30 days prior to admission (adjusted odds ratios, 3, 2.9, 3 and 2.8, for the SSRIs, respectively). This was after adjusting for renal disease and other interacting drugs. Nevertheless, this increased risk was not statistically significantly different to that in patients taking tricyclics (1.5) or benzodiazepines (2.1), which the authors considered have no known basis for an interaction (see 'Digitalis glycosides + Benzodiazepines and related drugs', p.911). In addition, it was small compared with the 12-fold increased risk found by the same authors in a similar study⁵ of 'clarithromycin', (p.929).

An isolated report describes a 93-year-old woman with congestive heart failure who developed increased serum **digoxin** levels on two occasions when **fluoxetine** was added.⁶ Another case report describes **digoxin** toxicity in a 68-year-old woman with atrial fibrillation and depression, which was attributed to the addition of **paroxetine** 20 mg daily. Her **digoxin** levels reached 5.2 nanograms/mL.⁷

Mechanism

It has been suggested that paroxetine might inhibit P-glycoprotein leading to reduced renal excretion of digoxin.⁷ This suggestion has been criticised by other authors who propose that the increase in levels seen in the case with paroxetine may be due to hospital-induced compliance or renal impairment.^{8,9} Moreover, the case-control study found no evidence of a significantly different risk of digoxin toxicity between those SSRIs with greater P-glycoprotein inhibitory activity (sertraline and paroxetine) than those with less (fluoxetine, fluvoxamine).⁵

Importance and management

The pharmacokinetic studies show that it is unlikely that, in general, SSRIs will affect the steady-state serum levels of digoxin. The excess risk seen in the case-control study was considered to be small and related to detection bias or confounding by indication,⁵ although the findings do introduce a note of caution. Nevertheless, the fact that there are only isolated case reports of possible interactions with digoxin for such a widely used class of drugs suggests that problems are rarely encountered. No special precautions would seem to be necessary.

Digitalis glycosides + Statins

Atorvastatin, fluvastatin and simvastatin cause small but probably clinically unimportant increases in the serum levels of digoxin. Pravastatin and rosuvastatin appear to have no effect on digoxin pharmacokinetics.

Clinical evidence

(a) Atorvastatin

Digoxin 250 micrograms daily was given to 24 healthy subjects for 10 days, with atorvastatin 10 or 80 mg daily for a further 10 days. The mean steady-state **digoxin** levels were unaffected by atorvastatin 10 mg,

but atorvastatin 80 mg caused a 20% rise in maximum **digoxin** levels and a 15% rise in its AUC.¹

(b) Fluvastatin

In a crossover study in 18 patients, fluvastatin 40 mg caused no significant changes in the pharmacokinetics of **digoxin** 100 to 375 micrograms daily.² Another similar study in patients found changes of up to 15% in maximum plasma **digoxin** levels and clearance, but these were not considered to be clinically relevant.³

(c) Pravastatin

Pravastatin 20 mg daily for 9 days had no significant effect on the steady-state levels of **digoxin** 200 micrograms daily in 18 healthy subjects.⁴

(d) Rosuvastatin

In a randomised study, 18 healthy subjects were given rosuvastatin 40 mg daily or placebo for 12 days, with a single 500-microgram dose of **digoxin** on day 8. The absorption, renal excretion, AUC and maximum serum levels of **digoxin** were unaffected by rosuvastatin.⁵

(e) Simvastatin

Plasma **digoxin** levels can be slightly raised, by about 0.3 nanograms/mL, by simvastatin but this appears to be of little or no clinical importance.⁶

Mechanism

The small changes seen in digoxin levels are probably due to the inhibitory effects of these statins on P-glycoprotein. Pravastatin does not appear to inhibit P-glycoprotein.⁷

Importance and management

The small changes seen in the digoxin levels with statins seem unlikely to be clinically relevant in most patients.

Digitalis glycosides + Sucralfate

Sucralfate caused only a small reduction in the absorption of digoxin in one study, but an isolated report describes a marked reduction in one patient.

Clinical evidence

Sucralfate 1 g four times daily given to 12 healthy subjects for 2 days had no effect on most of the pharmacokinetics of a single 750-microgram dose of **digoxin**; however, the AUC was reduced by 19% and the amount of **digoxin** eliminated in the urine was reduced by 12%. **Digoxin** was also absorbed faster.¹ No interaction occurred when the **digoxin** was given 2 hours before the sucralfate.¹ One elderly patient is reported to have had subtherapeutic serum **digoxin** levels while taking sucralfate, even though the dosages were separated by 2 hours.²

Mechanism

Uncertain. One possibility is that the digoxin and sucralfate bind together in the gut, which reduces the digoxin absorption.

Importance and management

Information appears to be limited to the reports cited. The reduction in digoxin levels reported in the study is small and therefore normally unlikely

to be clinically relevant, but the unexplained and isolated case suggests that clinicians should at least be aware of the possibility of an interaction.

Digitalis glycosides + Surfactant excipients

Non-ionic surfactants used as pharmaceutical excipients such as polyoxyl castor oil (Cremophor) may slightly enhance the absorption of digoxin.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 12 healthy subjects found that **polyoxyl castor oil (Cremophor RH40)** 600 mg three times daily increased the AUC_{0–5} and peak plasma levels of a single 500-microgram oral dose of **digoxin** by about 22%. The absorption of **digoxin** was delayed. The pharmacodynamic effects of **digoxin** were not affected by **Cremophor**.

It was suggested that **Cremophor** increases **digoxin** plasma levels by inhibiting intestinal P-glycoprotein, or that the **Cremophor** prolongs the dissolution of **digoxin** tablets resulting in delayed absorption from the intestines.¹

Other surfactants inhibit P-glycoprotein mediated intestinal transport and an *in vitro* study found that the order of effectiveness for enhanced intestinal uptake of **digoxin** (starting with the most effective) was **Labrasol**, **Imwitor 742**, **Acconon E**, **Softigen 767**, **Cremophor EL**, **Miglyol**, **Solutol HS 15**, **Sucrose monolaurate**, **Polysorbate 20**, **TPGS**, **Polysorbate 80**.² See also 'Digitalis glycosides + Vitamin E substances', p.943.

Digitalis glycosides + Tegaserod

Tegaserod slightly reduces the AUC of digoxin, but this is unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given tegaserod 6 mg twice daily for 5 days found that the time to peak levels of a single 1-mg dose of **digoxin** on day 4 was reduced by 30 minutes, and the mean AUC and maximum plasma concentrations were slightly reduced by 11.9% and 15%, respectively.¹ These small changes are unlikely to be clinically relevant. Note that the manufacturer has discontinued marketing of tegaserod in the US because of a finding of an excess risk of serious cardiovascular ischaemic events.²

2. Dear Dr Letter. Novartis Pharmaceuticals Corp. March 30, 2007. Available at: http://www.zelnorm.com/Dr_Doctor_Letter.pdf (accessed 22/08/07).

Digitalis glycosides + Tetracycline

Limited early evidence suggested that tetracycline may cause a rise in serum digoxin levels.

Clinical evidence

A patient taking **digoxin** tablets 500 micrograms daily was given tetracycline 500 mg every 6 hours for 5 days. His urinary excretion of **digoxin** metabolites (see *Mechanism*, below) fell sharply within 2 days, and his steady-state serum **digoxin** levels rose by 43%.¹ Another subject had a marked fall in the excretion of **digoxin** metabolites from the gut after taking tetracycline.²

In one study, tetracycline prolonged the half-life of **digoxin** and increased serum levels from 1.7 to 2.9 nanograms/mL.³

Mechanism

Uncertain. Up to 10% of patients taking oral digoxin excrete it in substantial amounts in the faeces and urine as inactive metabolites (digoxin reduction products or DRPs). This metabolism seems to be performed by the gut flora,¹ in particular *Eubacterium lentum*, which is anaerobic and Gram positive.^{2,4} In the presence of some antibacterials, such as tetracycline, which can inhibit this organism, more digoxin becomes available for absorption, which results in a rise in serum levels. At the same time the inactive metabolites derived from the gut disappear.² However, this is not necessarily the full explanation, see also 'Digitalis glycosides + Macrolides', p.929.

Importance and management

The interaction between digoxin and tetracycline is not well established, the evidence is very limited, and its general clinical importance is uncertain. Bear this interaction in mind in case of an unexpected response to digoxin.

Digitalis glycosides + Thyroid hormones and Antithyroid drugs

Thyrotoxic patients are relatively resistant to the effects of digitalis glycosides and may need reduced doses as treatment with antithyroid drugs (carbimazole, thiamazole) progresses, whereas patients with hypothyroidism may need increased doses of digitalis glycosides as treatment with thyroid hormones progresses. Carbimazole has been shown to reduce serum digoxin in healthy subjects.

Clinical evidence

(a) Carbimazole

The observation of relatively low plasma **digoxin** levels in a patient taking carbimazole prompted a further study in 10 healthy subjects. In 9 out of the 10, steady-state peak serum **digoxin** levels were reduced by 23% (from 1.72 to 1.33 nanograms/mL) by a single 60-mg dose of carbimazole, but in the other subject the serum **digoxin** levels were increased. Other pharmacokinetic parameters were unaffected.

Carbimazole abolished the systolic blood pressure decrease seen in the first 3 hours with **digoxin**, and also reduced the duration of the **digoxin**-induced diastolic blood pressure fall from 12 to 6 hours. The changes in heart rates, cardiac output and stroke volumes were not statistically significant, but inter-individual differences were large.^{1–3}

(b) Thiamazole

A study in 12 patients with hyperthyroidism found that normalisation of serum T3 and T4 by thiamazole treatment did not produce significant changes in the pharmacokinetics of **digoxin**.⁴

Mechanism

One explanation for the changed response to digitalis with carbimazole is that there is a direct and altered response of the heart due to the raised or lowered thyroid hormone levels. Another is that changes in glomerular filtration rate associated with hypo- or hyperthyroidism result in increased or decreased serum digoxin, respectively.⁵ Why carbimazole *reduced* serum digoxin in healthy subjects (normal thyroid status) is not known.

Importance and management

As thyroid status is returned to normal by the use of drugs (antithyroid drugs or thyroid hormones), the dosage of the digitalis glycosides may need to be adjusted appropriately. Hyperthyroid patients may need to have their digitalis dosage gradually reduced as treatment proceeds (because initially they are relatively resistant to the effects of digitalis and start off needing higher doses). They are also relatively insensitive to the chrono-

tropic effects of digitalis.^{6,7} Hypothyroid patients on the other hand may need a gradually increasing dosage (because initially they are relatively sensitive to digitalis).^{5,6} In either of these situations it would be prudent to monitor serum digoxin levels and glomerular filtration rate as treatment continues. The reduction of serum digoxin by carbimazole in healthy subjects does not fit with the need to decrease digoxin doses when antithyroid drugs are used in patients. Further study is needed.

Digitalis glycosides + Ticlopidine

In 15 subjects ticlopidine 250 mg twice daily for 10 days reduced the peak serum levels and AUC of digoxin by about 10%.¹ This reduction is small and unlikely to be of clinical importance.

- Vargas R, Reitman M, Teitelbaum P, Ryan JR, McMahon FG, Jain AK, Ryan M, Regel G. Study of the effect of ticlopidine on digoxin blood levels. *Clin Pharmacol Ther* (1988) 43, 176.

Digitalis glycosides + Tiludronate

Tiludronate does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that **tiludronate**, 600 mg daily for 2 days then 400 mg daily for the next 10 days, caused no significant changes in the pharmacokinetics of **digoxin** 250 micrograms daily.¹ No special precautions appear to be needed.

- Sanofi Winthrop. Data on file, June 1996.

Digitalis glycosides + Trapidil

Trapidil does not alter serum digoxin levels.

Clinical evidence, mechanism, importance and management

Trapidil 400 mg daily for 8 days had no effect on the steady-state serum levels of **digoxin** 375 micrograms daily in 10 healthy subjects. It was noted that the positive chronotropic effect of trapidil opposed the negative chronotropic effect of **digoxin**, which should be remembered when using both drugs, but overall no adverse effects that would prevent concurrent use were noted.¹

- Szigoleit W, Weiss M, Fahr A, Scharfe S. Trapidil does not affect serum levels and cardiotoxic action of digoxin in healthy humans. *Jpn Circ J* (1987) 51, 1305–9.

Digitalis glycosides + Trazodone

A rise in serum digoxin levels, accompanied by toxicity in one instance, has been seen when two patients taking digoxin were given trazodone.

Clinical evidence, mechanism, importance and management

An elderly woman taking **digoxin** 125 micrograms daily (and also taking quinidine, clonidine and a triamterene/hydrochlorothiazide diuretic) complained of nausea and vomiting within about 2 weeks of starting to take

trazodone (initially 50 mg, increasing to 300 mg daily over 11 days). Her serum **digoxin** levels had risen more than threefold, from 0.8 to 2.8 nanograms/mL. The **digoxin** was stopped and then restarted at half the original dosage, which maintained therapeutic levels.¹ The patient had poor renal function, but this did not change significantly during this incident. Another case of raised **digoxin** levels, apparently caused by trazodone, has been reported.²

Direct information seems to be limited to these two reports, which is insufficient evidence to make any general recommendations; however, bear this interaction in mind in case of an unexpected response to **digoxin**.

- Rauch PK, Jenike MA. Digoxin toxicity possibly precipitated by trazodone. *Psychosomatics* (1984) 25, 334–5.
- Knapp JE. Mead Johnson Pharmaceutical Newsletter, 1983.

Digitalis glycosides + Trimetazidine

Trimetazidine does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

After taking trimetazidine 20 mg twice daily for at least 14 days the pharmacokinetics of a single 500-microgram dose of **digoxin** remained unchanged in 13 healthy subjects.¹ These results suggest that treatment with **digoxin** is unlikely to be altered in patients concurrently treated with trimetazidine.

- Edeki TI, Johnston A, Campbell DB, Ings RMJ, Brownsill R, Genissel P, Turner P. An examination of the possible pharmacokinetic interaction of trimetazidine with theophylline, digoxin and antipyrine. *Br J Clin Pharmacol* (1989) 26, 657P.

Digitalis glycosides + Trosipium

In a study in 40 healthy subjects trosipium 20 mg twice daily for 12 days did not affect the pharmacokinetics of a single 500-microgram dose of digoxin elixir given on day 7.¹

- Sandage B, Sabounjian L, Shipley J, Profy A, Lasseter K, Fox L, Harnett M. Predictive power of an in vitro system to assess drug interactions of an antimuscarinic medication: a comparison of in vitro and in vivo drug-drug interaction studies of trosipium chloride with digoxin. *J Clin Pharmacol* (2006) 46, 776–84.

Digitalis glycosides + Urapidil

Urapidil does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects urapidil 60 mg twice daily on days 5 to 8 had no significant effects on the serum levels of **digoxin** 250 micrograms twice daily on day one, then 250 micrograms daily on days 2 to 8. Blood pressures and pulse rates were not significantly changed.¹ No special precautions seem necessary if both drugs are given.

- Solleder P, Haerlin R, Wurst W, Klingmann I, Mosberg H. Effect of urapidil on steady-state serum digoxin concentration in healthy subjects. *Eur J Clin Pharmacol* (1989) 37, 193–4.

Digitalis glycosides + Valaciclovir

Valaciclovir appears not to interact with digoxin.

Clinical evidence, mechanism, importance and management

In a randomised study, 12 healthy subjects were given 1 g of oral valaciclovir alone, two 750-microgram doses of **digoxin** alone, valaciclovir 1 g after the second of two 750-microgram doses of **digoxin** given 12 hours apart, and finally valaciclovir 1 g three times daily for 8 days starting 12 hours before the first **digoxin** dose.¹

It was found that no clinically significant changes occurred in the pharmacokinetics of either drug and no ECG changes were seen and it was

therefore concluded that no dosage adjustments of either drug are needed if they are given concurrently.¹ Since valaciclovir is a prodrug of **aciclovir**, it also seems unlikely that an interaction will occur between **aciclovir** and **digoxin**. Information about **digitoxin** and other analogues of aciclovir seems to be lacking.

1. Soul-Lawton JH, Weatherley BC, Posner J, Layton G, Peck RW. Lack of interaction between valaciclovir, the L-valyl ester of aciclovir and digoxin. *Br J Clin Pharmacol* (1998) 45, 87–9.

Digitalis glycosides + Valsopodar

Valsopodar increases the AUC of digoxin two to threefold.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects were given **digoxin** 1 mg on day 1, followed by 125 micrograms daily for the next 10 days. Starting on day 7 they were also given a single 400-mg dose of valsopodar, followed by valsopodar 200 mg twice daily for the following 4 days. The steady-state **digoxin** AUC was increased by 76% after the first valsopodar dose, and by the end of valsopodar dosing it had increased by 211%. This was apparently due to a 73% reduction in **digoxin** renal clearance and a 58% reduction in non-renal clearance, probably because of reduced tubular secretion, reduced biliary elimination, and increased intestinal absorption caused by P-glycoprotein inhibition. No symptoms of digitalis toxicity were seen and there were no changes in vital signs or ECG parameters.¹

Information seems to be limited to this study in healthy subjects but it suggests that the **digoxin** dosage should be reduced if valsopodar is given. An initial 50% reduction has been suggested.

1. Kovarik JM, Rigaudy L, Guerret M, Gerbeau C, Rost K-L. Longitudinal assessment of a P-glycoprotein-mediated drug interaction of valsopodar on digoxin. *Clin Pharmacol Ther* (1999) 66, 391–400.

Digitalis glycosides + Vancomycin

In one early study, vancomycin prolonged the half-life of digoxin and increased its serum levels from 1.6 to 3 nanograms/mL. It was suggested that this effect might be as a result of reduced renal clearance.¹ This appears to be the only evidence of a possible interaction.

1. Halawa B. Interakcje digoksyny z cefradina (Sefril), tetracylina (Tetracyclinum), gentamycyna (Gentamycin) i wankomycyna (Vancocin). *Pol Tyg Lek* (1984) 39, 1717–20.

Digitalis glycosides + Vardenafil

Vardenafil does not appear to interact with digoxin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 19 healthy subjects were given **digoxin** 375 micrograms daily for 28 days, with vardenafil 20 mg once daily on alternate days from day 16 to day 28. The pharmacokinetics of **digoxin** were not significantly changed by vardenafil, and there was no alteration in vital signs, ECG readings and laboratory parameters (not stated). The incidence of mild to moderate headache rose slightly from 7 out of 19 with placebo to 13 out of 19 with **digoxin**.¹ There would appear to be no reason to monitor **digoxin** levels in patients given vardenafil.

1. Rohde G, Bauer R-J, Unger S, Ahr G, Wensing G. Vardenafil, a new selective PDE5 inhibitor, produces no interaction with digoxin. *Pharmacotherapy* (2001) 21, 1254.

Digitalis glycosides + Vasodilators

Sodium nitroprusside or hydralazine infusions can reduce serum digoxin levels, but the importance of this is uncertain. Isosorbide dinitrate did not alter digoxin pharmacokinetics in one study.

Clinical evidence, mechanism, importance and management

(a) Hydralazine or Sodium nitroprusside

An experimental study in 8 patients with congestive heart failure found that when they were given either **sodium nitroprusside** by infusion (7 to 425 micrograms/minute) or **hydralazine** by intravenous injection (5 mg every 10 to 20 minutes to a total dose of 10 to 60 mg) the total renal **digoxin** clearance was increased by about 50% by both drugs and the serum **digoxin** levels were decreased by 20% by the **nitroprusside** and 11% by the **hydralazine**.¹

It is not known whether these changes would be sustained during chronic concurrent use, or the extent to which the **digoxin** dosage might need to be increased. More study is needed to find out if this interaction is of practical importance.

(b) Isosorbide dinitrate

In a crossover study in 8 patients with chronic heart failure given **digoxin** 250 micrograms daily for 20 days with isosorbide dinitrate 10 mg three times daily for the last 10 days, there was no change in the mean steady-state concentration, AUC or half-life of digoxin.²

1. Cogan JJ, Humphreys MH, Carlson CJ, Benowitz NL, Rapaport E. Acute vasodilator therapy increases renal clearance of digoxin in patients with congestive heart failure. *Circulation* (1981) 64, 973–6.
2. Mahgoub AA, El-Medany AH, Abdulatif AS. A comparison between the effects of diltiazem and isosorbide dinitrate on digoxin pharmacodynamics and kinetics in the treatment of patients with chronic ischemic heart failure. *Saudi Med J* (2002) 23, 725–31.

Digitalis glycosides + Vitamin E substances

Alpha tocoferil acetate had no effect on digoxin pharmacokinetics, but vitamin E formulations with polyethylene glycol might.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, **alpha tocoferil acetate** 400 units twice daily for 15 days did not affect the pharmacokinetics of a single 500-microgram dose of **digoxin** given on day 15. This was in contrast to a formulation of vitamin E containing polyethylene glycol (**alpha tocoferil acid succinate**), which altered **digoxin** pharmacokinetics (amount not stated) without altering its ECG effects.

It was suggested that the effect of polyethylene glycol on **digoxin** was via P-glycoprotein inhibition,¹ see also 'Digitalis glycosides + Surfactant excipients', p.941.

1. Chan L, Humma LM, Schriever CA, Fahsingbauer BS, Dominguez CP, Baum CL. Vitamin E formulation affects digoxin absorption by inhibiting P-glycoprotein (P-GP) in humans. *Clin Pharmacol Ther* (2004) 75, P95.

Digitalis glycosides + Zileuton

Zileuton appears not to interact with digoxin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 12 healthy subjects were given zileuton 600 mg every 6 hours for 13 days, with **digoxin** 250 micrograms daily from days 1 to 11. The zileuton had no effect on the steady-state **digoxin** pharmacokinetics, although the time to reach maximum plasma levels was reduced from 1.43 to 0.95 hours. Concurrent use was well tolerated.¹ This evidence suggests that no special precautions are needed if these two drugs are used together.

1. Awani WM, Hussein Z, Cavanaugh JH, Granneman GR, Dube LM. Assessment of the pharmacokinetic interaction between zileuton and digoxin in humans. *Clin Pharmacokinetics* (1995) 29 (Suppl 2), 92–7.

26

Diuretics

The majority of the interactions of the diuretics appear to be pharmacodynamic in nature, that is, they appear to be due to the combined effects of the diuretic and the other interacting drug. Obvious examples of this would be hypotension caused by the use of a loop diuretic and a beta blocker, or hyperkalaemia caused by an ACE inhibitor and a potassium-sparing diuretic. Some commonly accepted interactions appear to be sparsely documented, most probably because they are perceived to be a predictable effect of using two drugs with similar actions together. 'Table 26.1', (below) lists the major diuretic drug groups classified by their effect

on potassium. Carbonic anhydrase inhibitors are included under potassium-depleting diuretics, but note that hypokalaemia caused by this type of drug is said to be transient and rarely clinically significant.

Eplerenone, a selective aldosterone antagonist similar to spironolactone, is metabolised by the cytochrome P450 isoenzyme CYP3A4 and is therefore affected by other drugs that are inhibitors or inducers of this enzyme.

The interactions covered in this section are mainly those in which the diuretic is affected. There are many other interactions throughout the publication where diuretics affect the actions of other drugs.

Table 26.1 Diuretics

<i>Group</i>	<i>Drugs</i>
Potassium-depleting diuretics	
Carbonic anhydrase inhibitors*	Acetazolamide, Diclofenamide (Dichlorphenamide), Methazolamide
Loop diuretics	Bumetanide, Etacrynic acid, Furosemide, Piretanide, Torasemide
Thiazides and related diuretics	Altizide, Bemetizide, Bendroflumethiazide, Benzthiazide, Butizide, Chlorothiazide, Chlortalidone, Clopamide, Cyclopenthiiazide, Cyclothiazide, Epitezide, Hydrochlorothiazide, Hydroflumethiazide, Indapamide, Mefruside, Methyclothiazide, Metolazone, Polythiazide, Teclothiazide, Trichlormethiazide, Xipamide
Potassium-sparing diuretics	
Aldosterone inhibitors	Eplerenone, Potassium canrenoate, Spironolactone
Other	Amiloride, Triamterene

*Note that hypokalaemia caused by this type of drug is said to be transient and rarely clinically significant

Acetazolamide + NSAIDs

A case of acute renal failure has been reported in a woman who underwent retinal surgery, which occurred after the postoperative use of a total of 2 g of acetazolamide, 80 g of mannitol and 700 mg of ketoprofen.¹ There appear to be no other similar case reports, but note that 'loop diuretics', (p.949) are known to increase the risk of NSAID-induced acute renal failure.

1. Truc C, Rigal E, Pernot A, Vaudelin G, Boulétreau P. Anti-inflammatoires non stéroïdiens et diurétiques: une association à risque néphrotoxique. *Ann Fr Anesth Reanim* (2000) 19, 675–7.

Acetazolamide + Sodium bicarbonate

Acetazolamide is associated with development of renal calculi and it is claimed that sodium bicarbonate, even on alternate days, potentiates the risk of calculus formation.¹

1. Rubenstein MA, Bucy JG. Acetazolamide-induced renal calculi. *J Urol (Baltimore)* (1975) 114, 610–12.

Acetazolamide + Timolol

The use of acetazolamide tablets with timolol eye drops resulted in severe mixed acidosis in a patient with chronic obstructive pulmonary disease.

Clinical evidence, mechanism, importance and management

An elderly man with severe chronic obstructive pulmonary disease was given oral acetazolamide 750 mg daily and timolol maleate 0.5% eye drops, one drop in each eye twice daily, as premedication to reduce ocular hypertension before surgery for glaucoma. Five days later he developed progressively worsening dyspnoea and he was found to have a severe, mixed acidosis.¹ This seems to have been caused by the additive effects of acetazolamide, which blocked the excretion of hydrogen ions in the kidney, and the bronchoconstrictor effects of the timolol, which was absorbed in sufficient amounts to exacerbate the airway obstruction in this patient, and thereby reduced the respiration. This isolated case emphasises the potential risks of using beta blockers, even as non-systemic preparations such as eye drops, in patients with obstructive pulmonary disease. The manufacturers of acetazolamide note that it should be used with caution in those with pulmonary obstruction or emphysema because of the increased risk of acidosis.² This is, in part, a drug-disease interaction.

1. Boada JE, Estopa R, Izquierdo J, Dorca J, Manresa F. Severe mixed acidosis by combined therapy with acetazolamide and timolol eyedrops. *Eur J Respir Dis* (1986) 68, 226–8.
2. Diamox (Acetazolamide). Wyeth Pharmaceuticals. UK Summary of product characteristics, February 2004.

Cyclothiazide/triamterene + Pravastatin

Reversible diabetes mellitus developed in a woman taking cyclothiazide/triamterene when she was also given pravastatin.

Clinical evidence, mechanism, importance and management

A 63-year-old woman who had been taking cyclothiazide/triamterene and acebutolol for 4 years, developed polyuria and polydipsia within 3 weeks of starting to take pravastatin 20 mg daily, which gradually worsened. After another 4 months she was hospitalised for hyperglycaemia, which was treated with insulin and later glibenclamide (glyburide). The cyclothiazide/triamterene and pravastatin were stopped and gradually the diabetic symptoms began to abate. Five weeks after admission she was discharged without the need for any antidiabetic treatment with the diabetes fully resolved.¹ The detailed reasons for this reaction are not understood, but it would seem that the pravastatin increased the hyperglycaemic potential of the thiazide diuretic to the point where frank diabetes developed. This is

an isolated case and there would seem to be little reason normally to avoid the concurrent use of these drugs.

1. Jonville-Bera A-P, Zakian A, Bera FJ, Carré P, Autret E. Possible pravastatin and diuretics-induced diabetes mellitus. *Ann Pharmacother* (1994) 28, 964–5.

Eplerenone + CYP3A4 inducers

St John's wort slightly decreased the AUC of eplerenone. The manufacturer recommends the avoidance of St John's wort and other stronger inducers of CYP3A4 such as rifampicin because of the possible risk of decreased eplerenone efficacy.

Clinical evidence, mechanism, importance and management

St John's wort (*Hypericum perforatum*) caused a slight 30% decrease in the AUC of a single 100-mg dose of eplerenone.^{1,2} Eplerenone is metabolised by the cytochrome P450 isoenzyme CYP3A4, and therefore inducers of this isoenzyme, such as St John's wort, would be expected to decrease its levels. In the UK, the manufacturer predicts that a more pronounced decrease in the AUC of eplerenone might occur with stronger CYP3A4 inducers, such as rifampicin (rifampin).¹ Because of the possibility of decreased efficacy, they do not recommend the concurrent use of potent CYP3A4 inducers with eplerenone, and they specifically name carbamazepine, phenytoin, phenobarbital, rifampicin, and St John's wort.¹ However, it is unlikely that the decrease seen with St John's wort is clinically relevant. Further study is needed of the other potential interactions to demonstrate their clinical significance.

2. Inspra (Eplerenone). Pfizer Inc. US Prescribing information, May 2005.

Eplerenone + CYP3A4 inhibitors

Ketoconazole markedly raises the AUC of eplerenone, and the manufacturer contraindicates concurrent use. Similarly, the concurrent use of other potent inhibitors of CYP3A4 should be avoided. Mild to moderate inhibitors of CYP3A4 (including diltiazem, fluconazole, saquinavir and verapamil) increase the AUC of eplerenone by up to almost threefold. Grapefruit juice had a small but unimportant effect.

Clinical evidence

(a) Azoles

Ketoconazole 200 mg twice daily for 7 days increased the AUC of a single 100-mg dose of eplerenone 5.4-fold in 18 healthy subjects,^{1,2} and fluconazole 200 mg daily for 7 days increased the AUC of eplerenone 2.2-fold in 18 healthy subjects.² The manufacturer predicts that itraconazole will have a similar effect to ketoconazole.³

(b) Calcium-channel blockers

In 24 healthy subjects the steady-state AUC of eplerenone 100 mg daily was increased by about twofold by verapamil 240 mg daily for 7 days.² Diltiazem has caused similar increases.³

(c) Grapefruit juice

Grapefruit juice caused only a small 25% increase in the AUC of eplerenone 100 mg.¹

(d) Macrolides

In 24 healthy subjects erythromycin 500 mg twice daily increased the steady-state AUC of eplerenone 100 mg daily by 2.9-fold.² The manufacturer predicts that clarithromycin,^{1,3} telithromycin,³ and troleandomycin¹ will have a greater effect. Eplerenone reduced the AUC of erythromycin by 14%, which was not considered clinically relevant.²

(e) Protease inhibitors

In 24 healthy subjects saquinavir 1.2 g three times daily increased the steady-state AUC of eplerenone 100 mg daily by 2.1-fold.² The manufacturer predicts that ritonavir and nelfinavir will have a greater effect.³

Eplerenone reduced the maximum level of **saquinavir** by 30%, and the AUC by 21%,² but the clinical relevance of this has not been assessed.

Mechanism

Eplerenone is metabolised by the cytochrome P450 isoenzyme CYP3A4, and therefore inhibitors of this isoenzyme will raise its levels.

Importance and management

These pharmacokinetic interactions are established. Although the clinical relevance has not been assessed, it is known that the risk of hyperkalaemia with eplerenone is related to its dose.³ Because the increase in the AUC of eplerenone with ketoconazole is so great, the manufacturers contraindicate this combination.^{1,3} They also contraindicate the concurrent use of other potent inhibitors of CYP3A4, and they list clarithromycin, itraconazole, **nefazodone**, nelfinavir, ritonavir,^{1,3} telithromycin³ and troleanomycin.¹

In the UK, the manufacturers recommend that the dose of eplerenone should not exceed 25 mg daily in patients taking mild to moderate CYP3A4 inhibitors such as **amiodarone**, diltiazem, erythromycin, fluconazole, saquinavir and verapamil.³ In the US, the manufacturer recommends that the starting dose for hypertension should be reduced to 25 mg daily for patients taking these drugs.¹ This seems a sensible precaution. However, note that in many cases erythromycin appears to be a more potent inhibitor of CYP3A4 than clarithromycin (and certainly the other moderate CYP3A4 inhibitors listed above), and so extra caution is probably warranted with this combination.

2. Cook CS, Berry LM, Burton E. Prediction of *in vivo* drug interactions with eplerenone in man from *in vitro* metabolic inhibition data. *Xenobiotica* (2004) 34, 215–28.
3. Inspra (Eplerenone). Pfizer Ltd. UK Summary of product characteristics, May 2006.

Eplerenone + Miscellaneous

Caution is recommended when eplerenone is used with alpha blockers, antipsychotics, amifostine, baclofen, corticosteroids, tetracosactide and tricyclic antidepressants. Lithium, ciclosporin, and tacrolimus should generally not be used with eplerenone. Antacids, cisapride, midazolam and simvastatin had no effect on eplerenone pharmacokinetics. Eplerenone had no important effect on cisapride, midazolam, warfarin or contraceptive steroid pharmacokinetics, but caused a slight increase in digoxin levels.

Clinical evidence, mechanism, importance and management

(a) Antacids

The manufacturer notes that **aluminium/magnesium**-containing antacids had no effect on the pharmacokinetics of eplerenone.¹

(b) Ciclosporin and Tacrolimus

No clinically significant pharmacokinetic interaction was noted when eplerenone was given with ciclosporin.^{1,2} Nevertheless, in the UK, the manufacturers state that ciclosporin and tacrolimus may impair renal function and increase the risk of hyperkalaemia. Therefore, they recommend that the concurrent use of either ciclosporin or tacrolimus with eplerenone should be avoided, or renal function and serum potassium should be closely monitored.³ See also 'Ciclosporin + Diuretics', p.1032 and 'Tacrolimus + Miscellaneous', p.1080.

(c) Cisapride

A pharmacokinetic study found no interaction between cisapride (a cytochrome P450 isoenzyme CYP3A4 substrate) and eplerenone.^{1,3}

(d) Combined hormonal contraceptives

Eplerenone 100 mg daily was given to 24 healthy subjects on days 1 to 11 of a 28-day cycle of a combined hormonal contraceptive (**ethinylestradiol/norethisterone** 35 micrograms/1 mg). There was no change in the **ethinylestradiol** AUC, but there was a small 17% increase in the **norethisterone** AUC, which is unlikely to be clinically relevant.^{1,2}

(e) Corticosteroids

The concurrent use of corticosteroids may reduce the antihypertensive effect of eplerenone as they may cause fluid and sodium retention.³

(f) Digoxin

The steady-state AUC of digoxin 200 micrograms daily increased by 16% when it was given to healthy subjects with eplerenone 100 mg daily.^{2,3} The UK manufacturers warn that caution may be warranted in patients with digoxin levels near the upper end of the therapeutic range.³ Note that changes of this size are within the usual expected variation in the AUC of digoxin.

(g) Drugs that may cause postural hypotension

The manufacturer suggests that there is a risk of increased hypotensive effects and/or postural hypotension if eplerenone is given with **alpha blockers** (e.g. prazosin), **tricyclic antidepressants**, **antipsychotics**, **amifostine** and **baclofen**. They suggest increased monitoring.³

(h) Lithium

No interaction study has been done with lithium and eplerenone.^{1,3} Serum lithium should be monitored frequently if eplerenone is given with lithium,^{1,3} although, in the UK, the manufacturers advise avoidance of the combination.³ This is because lithium toxicity has occurred with lithium and 'ACE inhibitors', (p.1112) or 'diuretics', (p.1122).

(i) Midazolam

A pharmacokinetic study has shown no pharmacokinetic interaction between midazolam (a cytochrome P450 isoenzyme CYP3A4 substrate) and eplerenone.^{1,3}

(j) Simvastatin

In 18 healthy subjects simvastatin 40 mg once daily had no effect on the pharmacokinetics of eplerenone 100 mg once daily. The maximum level of simvastatin was modestly decreased by 32%, and the AUC by 14%, but this was not considered to be clinically relevant.^{1,2}

(k) Tetracosactide

Tetracosactide can cause fluid and sodium retention and this may reduce the antihypertensive effect of eplerenone.³

(l) Warfarin

Eplerenone did not alter the pharmacokinetics of warfarin to a clinically significant extent.^{1,3} However, in the UK the manufacturer still recommends caution when the warfarin dose is near the upper limit of the therapeutic range.³

1. Inspra (Eplerenone). Pfizer Inc. US Prescribing information, May 2005.
2. Cook CS, Berry LM, Burton E. Prediction of *in vivo* drug interactions with eplerenone in man from *in vitro* metabolic inhibition data. *Xenobiotica* (2004) 34, 215–28.
3. Inspra (Eplerenone). Pfizer Ltd. UK Summary of product characteristics, May 2006.

Furosemide + Bile-acid binding resins

Colestyramine and colestipol markedly reduce the absorption and diuretic effects of furosemide.

Clinical evidence

In 6 healthy subjects **colestyramine** 8 g reduced the absorption of a single 40-mg dose of furosemide by 95%. The 4-hour diuretic response was reduced by 77% (urinary output reduced from 1510 to 350 mL). **Colestipol** 10 g reduced the furosemide absorption by 80% and the 4-hour diuretic response by 58% (urinary output reduced from 1510 to 630 mL).¹

Mechanism

Both colestyramine and colestipol are anionic exchange resins, which can bind with furosemide within the gut, thereby reducing its absorption and its effects.

Importance and management

An established interaction, although direct evidence seems to be limited to this study. The absorption of furosemide is relatively rapid so that giving it 2 to 3 hours before either the colestyramine or colestipol should be an effective way of overcoming this interaction. This needs confirmation. Note that it is normally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine and 1 hour before or 4 hours after colestipol.

1. Neuvonen PJ, Kivistö K, Hirvisalo EL. Effects of resins and activated charcoal on the absorption of digoxin, carbamazepine and frusemide. *Br J Clin Pharmacol* (1988) 25, 229–33.

Furosemide + Cloral hydrate

Intravenous injection of furosemide after treatment with cloral hydrate occasionally causes sweating, hot flushes, a variable blood pressure and tachycardia.

Clinical evidence

Six patients in a coronary care unit given an intravenous bolus of 40 to 120 mg of furosemide and who had received cloral hydrate during the previous 24 hours developed sweating, hot flushes, variable blood pressure, and tachycardia. The reaction was immediate and lasted for about 15 minutes. No special treatment was given. Furosemide had caused no problems when given before the cloral hydrate was started.¹

A retrospective study of hospital records revealed that, out of 43 patients who had received both cloral hydrate and furosemide, one patient developed this reaction and 2 others may have done so.² The interaction has also been described in an 8-year-old boy.³

Mechanism

Not understood. One suggestion is that furosemide displaces trichloroacetic acid (the metabolite of cloral hydrate) from its protein binding sites, which in its turn displaces levothyroxine or alters the serum pH so that the levels of free levothyroxine rise leading to a hypermetabolic state.¹

Importance and management

An established interaction, but information is limited to three reports. The incidence is uncertain but probably low. Concurrent use need not be avoided, but it would be prudent to give intravenous furosemide cautiously if cloral hydrate has been given recently. It seems possible that derivatives of cloral hydrate that break down in the body to release cloral hydrate (e.g. **dichloralphenazone**, **cloral betaine**) might interact similarly. There is no evidence that furosemide given orally or cloral hydrate given to patients already taking furosemide causes this reaction.²

3. Dean RP, Rudinsky BF, Kelleher MD. Interaction of chloral hydrate and intravenous furosemide in a child. *Clin Pharm* (1991) 10, 385–7.

Furosemide + Epoprostenol

An epoprostenol infusion did not significantly alter the pharmacokinetics of furosemide in a study modelling data from 23 patients with heart failure.¹ Note that the combination of loop diuretics with epoprostenol may lead to an enhanced hypotensive effect.

1. Carlton LD, Patterson JH, Mattson CN, Schmith VD. The effects of epoprostenol on drug disposition II: a pilot study of the pharmacokinetics of furosemide with and without epoprostenol in patients with congestive heart failure. *J Clin Pharmacol* (1996) 36, 257–64.

Furosemide + Germanium

An isolated case report describes a man who became resistant to furosemide after he took germanium.

Clinical evidence, mechanism, importance and management

A 63-year-old man was hospitalised for hypertension and oedema 10 days after adding ginseng containing germanium to his usual treatment with cyclophosphamide and furosemide. He gained almost 13 kg in weight. After treatment with intravenous furosemide he was discharged and again took ginseng with germanium. This time he gained 12 kg in weight over 14 days, despite an increase in the dose of furosemide from 80 to 240 mg twice daily. The weight gain and oedema again resolved when the ginseng and germanium was withdrawn and he was given intravenous furosemide. The authors suggest that germanium was responsible for this interaction.¹

This is an isolated report, and its general significance is unclear. However,

note that it has been said that the use of germanium should be discouraged due to its potential to cause renal toxicity.²

2. Sweetman SC, ed. Martindale: The complete drug reference. 35th ed. London: Pharmaceutical Press; 2007. p. 2097.

Furosemide + Paracetamol (Acetaminophen)

In 10 healthy women paracetamol 1 g four times daily for 2 days was found to have no effect on the diuresis or natriuresis in response to intravenous furosemide 20 mg.¹

1. Martin U, Prescott LF. The interaction of paracetamol with frusemide. *Br J Clin Pharmacol* (1994) 37, 464–7.

Furosemide + Phenytoin

The diuretic effects of furosemide can be reduced as much as 50% if phenytoin is also given.

Clinical evidence

The observation that dependent oedema in a group of epileptics was higher than expected, and that the response to diuretic treatment seemed to be reduced, prompted further study. In 30 patients taking **phenytoin** 200 to 400 mg daily with phenobarbital 60 to 180 mg daily the maximal diuresis in response to furosemide 20 or 40 mg occurred after 3 to 4 hours instead of the usual 2 hours, and the total diuresis was reduced by 32% for the 20-mg dose and 49% for the 40-mg dose. When intravenous furosemide 20 mg was given, the total diuresis was reduced by 50%. Some of the patients were also taking carbamazepine, pheneturide, ethosuximide, diazepam or chlordiazepoxide.¹

Another study in 5 healthy subjects given **phenytoin** 100 mg three times daily for 10 days found that the maximum serum levels of furosemide 20 mg, given orally or intravenously, were reduced by 50%.²

Mechanism

Not fully understood. One suggestion is that the phenytoin causes changes in the jejunal sodium pump activity, which reduces the absorption of the furosemide,² but this is not the whole story because an interaction also occurs when furosemide is given intravenously.¹ Another suggestion, based on *in vitro* evidence, is that the phenytoin generates a 'liquid membrane,' which blocks the transport of the furosemide to its active site.³

Importance and management

Information is limited but the interaction is established. A reduced diuretic response should be expected in the presence of phenytoin. A dosage increase may be needed.

Furosemide + Sevelamer

Sevelamer abolished the diuretic effect of furosemide in a haemodialysis patient.

Clinical evidence, mechanism, importance and management

A haemodialysis patient taking furosemide 250 mg twice daily found that her urine output reduced from 950 mL/day to zero when she started taking sevelamer 800 mg at breakfast and lunchtime, and 1.6 g with dinner. Urine output returned to the previous level within 24 hours of stopping the sevelamer. This effect also occurred on rechallenge. The dose times were adjusted so that she took furosemide 500 mg in the morning and sevelamer 1.6 g at lunch and dinner, and her urine output was unaffected and remained stable.¹

The authors suggest that furosemide became bound to sevelamer in the gut, and this prevented its absorption.

This appears to be the only case report of an interaction between these drugs so far; however, it is worth bearing this case in mind should a similar situation arise in other patients. Note that the manufacturers of sevelamer^{2,3} suggest that when giving any other oral drug for which a reduction in the bioavailability could have a clinically significant effect on safety or efficacy, the drug should be given at least 1 hour before or 3 hours after sevelamer.

3. Renagel Capsules (Sevelamer hydrochloride). Genzyme. US Prescribing information, April 2007.

Loop diuretics + Aspirin

Aspirin may reduce the diuretic effect of bumetanide or furosemide, and the venodilation produced by furosemide.

Clinical evidence

(a) Bumetanide

In 8 healthy subjects aspirin 640 mg four times daily reduced the 24-hour urinary output in response to bumetanide 1 mg by 18%.¹

(b) Furosemide

A study in 11 patients with chronic heart failure found that both aspirin 75 mg daily and aspirin 300 mg daily for 14 days reduced the venodilatory effects produced by a single 20-mg intravenous dose of furosemide (as measured by the forearm venous capacitance).² Six patients with cirrhosis and ascites had a reduced diuretic response to intravenous furosemide 40 mg when a single 450-mg dose of **lysine aspirin** was given before the injection.³

Mechanism

See 'Loop diuretics + NSAIDs', p.949.

Importance and management

The clinical significance of these interactions is unclear. Note that the European Society of Cardiology (ESC) and American College of Cardiology/American Heart Association (ACC/AHA) heart failure guidelines say that the prophylactic use of aspirin in patients with heart failure has not been proven unless the patient has underlying ischaemic heart disease^{4,5} and should be avoided in patients with recurrent hospital admissions for worsening heart failure.⁵

Loop diuretics + Food

Some studies suggest that food modestly reduces the bioavailability and diuretic effects of furosemide. However, other studies have found that the bioavailability of furosemide and its diuretic effect is not affected by food. Food does not appear to affect bumetanide bioavailability.

Clinical evidence

(a) Solutions or standard tablets

Ten healthy subjects were given **furosemide** 40 mg with and without a standard breakfast. The food reduced the peak plasma levels of **furosemide** by 55% and the bioavailability by about 30%.¹ The results were almost identical when 5 of the subjects were given a heavy meal.¹ The diuresis over 10 hours was reduced by 21% (from 2072 to 1640 mL) and over 24 hours by 15% (from 2668 to 2270 mL) by **furosemide** taken with breakfast.¹ A comparative study in healthy subjects found that the absorption of both **bumetanide** 2 mg (9 subjects) and **furosemide** 40 mg (8 subjects), given as *solutions*, was delayed, and peak plasma levels were reduced, by a standard breakfast.² However, although food reduced the oral bioavailability of **furosemide** by about one-third, from 76% to 43%, the bioavailability of **bumetanide** was not significantly reduced (75% with food and 84% fasting). Food delayed the absorption but did not significantly alter the bioavailability of **furosemide** as tablets or solutions in two other studies.^{3,4} In one of these studies, there was no difference in diuresis between fed and fasting subjects.⁴

(b) Sustained-release tablets

In a single-dose, crossover study in 28 subjects given two different controlled-release formulations of furosemide 60 mg, the absorption of one preparation (*Furix Retard*) was reduced by about 32% when it was given with breakfast, but the extent of absorption of the other formulation (*Lasix Retard*) was increased by about 18%. In the fasting phase of the study, the first formulation had a higher extent and rate of absorption than the second formulation. However, the differences in diuresis and total natriuresis between the formulations, and between the fed and fasted state, were minor.⁵

Mechanism

Not understood.

Importance and management

Information about the effect of food on **furosemide** absorption is somewhat contradictory. Of the four studies using solutions or standard tablets, just two found that the bioavailability of furosemide was modestly reduced by food (by about 30%) and the others found no effect. Moreover, the modest reduction in the AUC of furosemide did not result in a clinically relevant decrease in diuresis in the one study that assessed this. It would also seem that the absorption of controlled-release formulations of furosemide may be modestly affected by food, but this may lead to increased absorption depending on the preparation.⁵ The authors of this study noted that the amount of furosemide absorbed did not correlate with the extent of diuresis, and concluded that the urinary excretion profile of furosemide may be more important for producing diuresis than the amount of furosemide absorbed. It would seem that furosemide and **bumetanide** can be given to most patients without regard to meal times. Food does not affect the bioavailability of bumetanide given as solution.

Loop diuretics + H₂-receptor antagonists

Ranitidine and cimetidine may cause a moderate increase in the bioavailability of furosemide, but with no associated increase in diuretic effect. Cimetidine appears not to interact with torasemide.

Clinical evidence, mechanism, importance and management

(a) Furosemide

In a study in 6 healthy subjects, a single 400-mg dose of **cimetidine** increased the mean AUC of furosemide by one-third, although there was wide inter-patient variation. However, there were no changes in the diu-

retic effects of furosemide or in the pharmacokinetics of cimetidine, and an associated study using multiple doses of **cimetidine** over 5 days found no pharmacokinetic or pharmacodynamic interaction.¹ A similar study in patients with hepatic cirrhosis also found that **cimetidine** does not interact with furosemide.²

Eighteen healthy subjects were given oral furosemide 40 mg one hour after intravenous **ranitidine** 50 mg or saline. The **ranitidine** increased the AUC of furosemide by 28% and increased the maximum serum levels by 37%.³ The effects of furosemide could possibly be slightly increased by **ranitidine**, but the clinical importance of this is probably small. No special precautions seem necessary.

(b) Torasemide

In 11 healthy subjects **cimetidine** 300 mg four times daily for 3 days was found to have no effect on the pharmacokinetics of a single 10-mg oral dose of torasemide, nor were there any changes in the volume of urine or the excretion of sodium, potassium or chloride.⁴

Loop diuretics + NSAIDs

The antihypertensive and diuretic effects of the loop diuretics appear to be reduced by NSAIDs, including coxibs, although the extent of this interaction largely depends on individual NSAIDs. Diuretics increase the risk of NSAID-induced acute renal failure. The concurrent use of NSAIDs with loop diuretics may exacerbate congestive heart failure and increase the risk of hospitalisation.

Clinical evidence

A. Bumetanide

(a) Celecoxib and other Coxibs

A patient taking celecoxib with bumetanide developed a moderately raised serum creatinine. Another patient taking an ACE inhibitor, spironolactone and bumetanide developed severely raised serum creatinine, hyperkalaemia, and worsening of congestive heart failure shortly after starting celecoxib.¹ A similar case occurred in another patient taking bumetanide about 8 days after starting **rofecoxib**.¹

(b) Indometacin

In two studies, a single 100-mg dose of indometacin was found to reduce the bumetanide-induced output of urine, sodium and chloride (but not potassium) by about 25%.^{2–4} Diuresis was reduced by 42% and weight gain was noted.² There are other reports confirming this interaction between bumetanide and indometacin, including a clinical study,⁵ and a report of a patient who developed heart failure as a result of this interaction.⁶

(c) Sulindac

A study in 8 healthy subjects found that a single 300-mg dose of sulindac did not significantly reduce the diuretic response (measured by urinary volume, sodium, potassium and chloride) to a single 1-mg dose of bumetanide.⁷ However, another study in 9 healthy subjects found that pre-treatment with sulindac 200 mg twice daily for 5 days reduced the diuretic effect of a single 1-mg dose of bumetanide (mean urine flow rate after 2 hours reduced by 21% and cumulative sodium excretion at 3 hours reduced by 22%).⁸

(d) Tolfenamic acid

A study in 8 healthy subjects found that tolfenamic acid 300 mg reduced the diuretic response to a single 1-mg dose of bumetanide by 34% at 2 hours (measured by urinary volume, sodium, potassium and chloride).⁷

B. Furosemide

(a) Azapropazone

Ten healthy subjects had no change in their urinary excretion in response to furosemide 40 mg daily when they were also given azapropazone

600 mg twice daily. The furosemide did not antagonise the uricosuric effects of the azapropazone.⁹

(b) Celecoxib and other Coxibs

In a placebo-controlled study, 7 patients with cirrhosis and ascites were given a single 40-mg intravenous dose of furosemide before and after receiving celecoxib 200 mg twice daily for 5 doses. It was found that this short-term use of celecoxib did not reduce the natriuretic or diuretic effects of furosemide.¹⁰

Two patients with a history of chronic heart failure, taking furosemide 40 or 80 mg daily, developed acute renal failure when they started to take celecoxib 100 or 200 mg twice daily. Neither patient showed any sign of decompensated heart failure on admission (which can in itself cause renal failure) and both recovered on stopping the celecoxib and furosemide combination. One patient was also taking enalapril, and the combination of the enalapril with furosemide was restarted without any changes in renal function.¹¹ The same authors also described two other patients taking furosemide who developed renal failure when they started to take **rofecoxib**.¹¹ Other cases have occurred in patients taking furosemide, often with ACE inhibitors, after they started **rofecoxib**.¹

(c) Diclofenac

A study in patients with heart failure and cirrhosis found that diclofenac 150 mg daily reduced the furosemide-induced excretion of sodium by 38%, but the excretion of potassium was unaltered.¹²

(d) Diflunisal

A study in 12 healthy subjects found that diflunisal 500 mg twice daily reduced sodium excretion in response to furosemide by 59%, but potassium excretion remained unchanged.¹³ In patients with heart failure and cirrhosis taking furosemide, diflunisal 500 to 700 mg daily decreased the sodium excretion by 36% and the potassium excretion by 47%.¹² However, another study found no interaction between diflunisal and furosemide.¹⁴

(e) Flupirtine

A study in healthy subjects found that a single 200-mg dose of flupirtine did not affect the overall furosemide diuresis, but the diuretic effect was slightly delayed.¹⁵

(f) Flurbiprofen

A study in 7 healthy subjects found that the increase in renal osmolal clearance of a standard water load in response to furosemide 40 mg orally or 20 mg intravenously fell from 105% to 19% and from 140% to 70%, respectively, after flurbiprofen 100 mg was given.¹⁶ A single-dose study in 10 healthy subjects found that flurbiprofen 100 mg reduced the urinary volume, urinary sodium and urinary potassium, in response to oral furosemide 80 mg by 10%, 9%, and 12%, respectively.^{17,18}

(g) Ibuprofen

An elderly man with heart failure taking digoxin, isosorbide dinitrate and furosemide 80 mg daily, developed symptomatic congestive heart failure with ascites when given ibuprofen 400 mg three times daily. His serum urea and creatinine levels rose and no diuresis occurred, even when the furosemide dosage was doubled. Two days after withdrawing the ibuprofen, brisk diuresis took place, renal function returned to normal, and his condition improved steadily.¹⁹ Another elderly patient similarly had a poor response to furosemide (and later to metolazone as well) until he stopped taking ibuprofen 600 mg four times daily and at least two **aspirin** daily (for headache).²⁰ This was due to hyponatraemic hypovolaemia brought on by the drug combination.

In a small, placebo-controlled, crossover study in 8 healthy subjects, ibuprofen 400 mg and 800 mg three times daily for 3 days significantly reduced the glomerular filtration rate and the diuresis produced by a single 20-mg intravenous dose of furosemide, but did not alter sodium excretion.²¹

(h) Indometacin

A study in 4 healthy subjects and 6 patients with essential hypertension found that furosemide 80 mg three times daily reduced the mean blood pressure by 13 mmHg, but when indometacin 50 mg four times daily was also given the blood pressures returned to virtually pre-treatment levels. Moreover, the normal urinary sodium loss induced by the furosemide was significantly reduced.²²

A study in healthy subjects and patients with congestive heart failure given furosemide found that indometacin 100 mg reduced the urinary output by 53% and also reduced the excretion of sodium, potassium, and chloride by 64%, 49%, and 62%, respectively.²³ A study in 14 patients

with ascites secondary to liver cirrhosis found that indometacin 50 mg every 6 hours for 2 doses significantly reduced the urinary volume and the natriuretic response to furosemide, by 82% and 69%, respectively, but produced only a small, non-significant reduction in creatinine clearance.²⁴ Another study found that indometacin reduced the urinary output in response to furosemide by 20 to 30%.²⁵ There are other case reports and studies confirming the interaction between furosemide and indometacin.^{21,26-31}

(i) *Ketoprofen*

A study in 12 healthy subjects given furosemide 40 mg daily found that ketoprofen 100 mg twice daily reduced the 6-hour urine output by 67 mL, and the 24-hour urine output by 651 mL on the first day of treatment. However no significant differences were seen after 5 days of treatment.³²

(j) *Ketorolac*

Twelve healthy subjects were given oral ketorolac 30 mg four times daily, and then a single 30-mg intramuscular dose of ketorolac 30 minutes before a 40-mg intravenous dose of furosemide. No precise figures are given, but the maximum serum level of the furosemide, its diuretic effect, and the electrolyte loss were said to be significantly reduced by the ketorolac.³³ Another study in healthy elderly subjects found that when they were given oral ketorolac 120 mg, then, on the following day, intramuscular ketorolac 30 mg, followed 30 minutes later by furosemide 40 mg, the urinary output fell by 16% and the sodium output fell by 26% over the next 8 hours, when compared with furosemide alone.³⁴

(k) *Lornoxicam*

A study in 12 healthy subjects found that lornoxicam 4 mg significantly antagonised the diuretic and natriuretic effects of furosemide, but this was not quantified.³⁵

(l) *Meloxicam*

Meloxicam 15 mg daily for 3 days had no significant effect on the pharmacokinetics of furosemide 40 mg in 12 healthy subjects. The furosemide-induced diuresis was unchanged, and although the cumulative urinary electrolyte excretion was somewhat lower, but this was not considered to be clinically significant.³⁶ A similar study in patients with heart failure taking an ACE inhibitor also found no clinically significant pharmacokinetic or pharmacodynamic interaction between furosemide and meloxicam.³⁷

(m) *Metamizole sodium (Dipyrone)*

A study in 9 healthy subjects found that metamizole sodium 3 g daily for 3 days, reduced the clearance of intravenous furosemide 20 mg from 175 to 141 mL/minute but the diuretic effects of the furosemide were unchanged.³⁸

(n) *Mofebutazone*

A study in 10 healthy subjects found that mofebutazone 600 mg had no effect on the diuretic effects of furosemide 40 mg. The urinary volume and excretion of sodium, potassium and chloride were unchanged.³⁹

(o) *Naproxen*

Two elderly women with congestive heart failure did not respond to treatment with furosemide and digoxin until the naproxen they were taking was withdrawn.¹⁹ A single-dose study in patients with heart failure found that the volume of urine excreted in response to furosemide was reduced about 50% by naproxen.²⁵ In a placebo-controlled study, 6 patients with cirrhosis and ascites were given a single 40-mg intravenous dose of furosemide before and after naproxen 500 mg twice daily for 5 doses. It was found that this short-term use of naproxen reduced the glomerular filtration rate and the natriuretic and diuretic effects of furosemide.¹⁰

(p) *Nimesulide*

A study in 8 healthy subjects found that nimesulide 200 mg twice daily attenuated the effects of furosemide 40 mg twice daily. Subjects who had initially lost weight when taking furosemide regained weight, diuresis was slightly reduced, and the glomerular filtration rate was reduced.⁴⁰

(q) *Piroxicam*

A 96-year-old woman with congestive heart failure did not adequately respond to furosemide until the dosage of piroxicam she was taking was reduced from 20 to 10 mg daily.⁴¹

In one study in 9 hypertensive patients with a creatinine clearance of less than 60 mL/minute, who were taking furosemide, piroxicam 20 mg daily for 3 days produced a significant reduction in the natriuretic and kaliuretic effects of an additional single 40-mg dose of furosemide. However, in 13

other patients, with a creatinine clearance of greater than 60 mL/minute, who were taking a thiazide diuretic, piroxicam did not alter the effects of a single 40-mg dose of furosemide. In a third group of 8 healthy subjects, the same dose of piroxicam reduced the natriuretic effects, but not the kaliuretic effects, of a single 40-mg dose of furosemide.⁴²

(r) *Sulindac*

A study in 5 healthy subjects found that pre-treatment with two 150-mg doses of sulindac reduced the urinary volume and urinary sodium following an intravenous furosemide 80 mg by 25% and 37.5%, respectively. In patients with cirrhosis and ascites, sulindac 150 mg reduced the urinary volume, urinary sodium, and urinary potassium following an 80-mg intravenous dose of furosemide by 38%, 52%, and 8%, respectively.⁴³ In another placebo-controlled study in 15 healthy women, sulindac 200 mg twice daily for 5 days produced a similar but slightly smaller reduction in the natriuretic effect of a single 40-mg intravenous dose of furosemide, when compared with indometacin.³¹

(s) *Tenoxicam*

A study in 12 patients found that tenoxicam 20 to 40 mg daily had no significant effect on the urinary excretion of sodium or chloride due to furosemide 40 mg daily, and blood pressure, heart rate and body-weight also were not affected.⁴⁴

C. *Piretanide*

(a) *Indometacin*

A comparative study⁴⁵ into the pharmacological mechanisms underlying the way drugs interfere with the actions of loop diuretics found that indometacin 50 mg three times daily for 2 days reduced the peak fractional excretion of sodium in response to a single 6-mg dose of piretanide. The clinical importance of this change was not studied.

(b) *Piroxicam*

A comparative study into the pharmacological mechanisms underlying the way drugs interfere with the actions of loop diuretics found that piroxicam 20 mg twice daily for 2 days did not significantly affect the peak fractional excretion of sodium in response to a single 6-mg dose of piretanide.⁴⁵

D. *Toraseamide*

A study in healthy subjects suggested that indometacin did not affect the natriuretic effects of toraseamide,⁴⁶ but on the basis of later study the same workers suggest that pathological factors in patients may allow an interaction similar to that with furosemide and indometacin to occur.⁴⁷

Mechanism

Uncertain and complex. It is likely that a number of different mechanisms come into play. One probable mechanism involves the synthesis of renal prostaglandins, which occurs when the loop diuretics cause sodium excretion. If this synthesis is blocked by drugs such as the NSAIDs, then renal blood flow and diuresis will be altered.⁴⁸ NSAIDs cause fluid and salt retention, which would antagonise the effects produced by diuretics.

Importance and management

NSAIDs can cause renal impairment, particularly in patients in whom prostaglandins are playing an important role in maintaining renal function. Such patients include those taking diuretics, the elderly and those with concurrent conditions such as congestive heart failure and ascites. Hence the combination of diuretics and NSAIDs may increase the nephrotoxicity of NSAIDs.^{30,49-51}

The antihypertensive and diuretic effects of the loop diuretics are reduced by NSAIDs. This interaction is very well documented between furosemide and indometacin, and of clinical importance, whereas less is known about the interactions with other NSAIDs, although the interaction should be anticipated with all of them. Use of an alternative non-NSAID analgesic should always be considered if possible. However, in cases where concurrent use cannot be avoided, the loop diuretic dosage may need to be raised (according to clinical response), but the effects on renal function and electrolytes, as well as efficacy, should be closely monitored. Patients at greatest risk of an adverse interaction include the elderly and patients with cirrhosis, cardiac failure and/or renal impairment, and NSAIDs should usually be used with caution in these patient groups regardless of concurrent use of diuretics. Note that a retrospective analysis of records of patients taking diuretics (thiazides, loop and/or potassium-sparing) with NSAIDs found a twofold increase in the risk of hospitalisation for congestive heart failure on concurrent use. The most common

NSAIDs taken by this cohort of patients were diclofenac, ibuprofen, indometacin and naproxen.⁵²

Much less is known about the interactions of NSAIDs with **bumetanide**, and even less about **piretanide** and **torasemide**, but the evidence suggests that they probably interact in the same way as furosemide and indometacin. It would therefore seem prudent to be alert for interactions with any of the NSAIDs with which furosemide interacts. See also 'Loop diuretics + Aspirin', p.948, for a discussion of the interactions between aspirin and bumetanide or furosemide.

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with **antihypertensives**, including diuretics, and the findings of these are summarised in 'Table 23.2', (p.862).

Loop diuretics + Probenecid

Probenecid decreases the renal clearance of furosemide, but it appears not to alter its overall diuretic effect. Probenecid reduces the natriuretic effects of piretanide, but the clinical relevance of this is not known. Probenecid does not appear to significantly affect bumetanide diuresis.

Clinical evidence, mechanism, importance and management

(a) Bumetanide

Probenecid 1 g did not affect the response of 8 healthy subjects to 500 micrograms or 1 mg of intravenous bumetanide.¹ Another study reported a fall in natriuresis and in the clearance of bumetanide, but this was of minimal clinical importance.²

(b) Furosemide

The concurrent use of furosemide and probenecid has been closely studied to determine the renal pharmacological mechanisms of loop diuretics. One study in patients given furosemide 40 mg daily found that the addition of probenecid 500 mg twice daily for 3 days reduced their urinary excretion of sodium by about 36% (from 56.3 to 35.9 mmol daily).³ Other studies have also found some changes in overall diuresis (a fall,⁴ a rise,⁵ and no change^{6,7} in some studies), and a reduction of 35 to 80% in the renal clearance of furosemide.^{4,6-9} One study found that probenecid 1 g increased the half-life of furosemide by 70% and decreased its oral clearance by 65%.⁸ Similar results were found in another study.¹⁰ The clinical importance of these changes is uncertain, but probably small.

(c) Piretanide

A comparative study¹¹ into the pharmacological mechanisms underlying the way drugs interfere with the actions of loop diuretics found that probenecid 1 g reduced the peak fractional excretion of sodium produced by a 6-mg dose of oral piretanide by 65%. Another study confirmed that probenecid reduces the natriuretic effects of piretanide.¹² The clinical importance of these changes was not studied.

Potassium-sparing diuretics + H₂-receptor antagonists

Although minor interactions occasionally occur between potassium-sparing diuretics and the H₂-receptor antagonists, none of these have been shown to be of clinical significance. The combinations that have been studied are; amiloride or triamterene with cimetidine, and triamterene with ranitidine.

Clinical evidence, mechanism, importance and management

(a) Amiloride

A study in 8 healthy subjects given amiloride 5 mg daily found that **cimetidine** 400 mg twice daily for 12 days reduced the renal clearance of amiloride by 17% and reduced its urinary excretion from 65% to 53%. Amiloride also reduced the excretion of **cimetidine** from 43% to 32%, and the AUC was reduced by 14%.¹ No changes in the diuretic effects (urinary volume, sodium or potassium excretion) occurred. It seems that each drug reduces the gastrointestinal absorption of the other drug by as yet unidentified mechanisms. The overall plasma levels of the amiloride remain unchanged because the reduced absorption is offset by a reduction in its renal excretion. These mutual interactions do not seem to be clinically significant.

(b) Triamterene

A study in 6 healthy subjects given triamterene 100 mg daily for 4 days found that **cimetidine** 400 mg twice daily increased the AUC of triamterene by 22%, reduced its metabolism (hydroxylation) by 32%, and reduced its renal clearance by 28%. There also appeared to be a reduction in the absorption of triamterene. However, the loss of sodium in the urine was not significantly changed, and the potassium-sparing effects of triamterene were not altered.² Because the diuretic effects of triamterene are minimally changed, this interaction is unlikely to be clinically important.²

In 8 healthy subjects **ranitidine** 150 mg twice daily for 4 days roughly halved the absorption (as measured by renal clearance) of triamterene 100 mg daily. Its metabolism was also reduced, with the total effect being a 21% reduction in the AUC. As a result of the reduced plasma triamterene levels, the urinary sodium loss was reduced to some extent but potassium excretion remained unchanged.³ Overall the diuretic effects of triamterene were only mildly affected. Another study found that a 22% reduction in the AUC of triamterene is unlikely to result in a significant change in its diuretic effects.² No clinically significant interaction is anticipated.

Potassium-sparing diuretics + NSAIDs

The concurrent use of triamterene and indometacin has, in several cases, rapidly lead to acute renal failure. An isolated case of renal impairment with diclofenac has been reported in a patient taking triamterene plus a thiazide. A case of exercise-induced acute renal failure has also been reported in a patient taking ibu-

profen with triamterene plus a thiazide. **Indometacin reduced the diuretic effect of spironolactone.**

Clinical evidence

(a) Spironolactone with Indometacin

A study in healthy subjects found that indometacin 150 mg daily reduced the natriuretic effect of spironolactone 300 mg daily by 54%.¹

(b) Triamterene with Diclofenac

A patient receiving triamterene 100 mg plus trichlormethiazide 2 mg daily was given intramuscular diclofenac 75 mg before admission to hospital with breast pain. On admission serum creatinine was 91 micromol/L and after 2 days it had increased to 248 micromol/L, but it returned to normal over 2 weeks. Subsequent oral diclofenac produced no adverse effects. The observed deterioration in renal function was attributed to an interaction between triamterene and diclofenac.²

(c) Triamterene with Diflunisal

Diflunisal had no effects on the pharmacokinetics of triamterene in healthy subjects, but the plasma AUC of an active metabolite, *p*-hydroxy-triamterene was increased by more than fourfold.³

(d) Triamterene with Ibuprofen

A 37-year-old patient developed acute renal failure after strenuous exercise while taking hydrochlorothiazide/triamterene 50/75 mg daily and ibuprofen (800 mg 12 hours and 2 hours before the exercise, and 800 mg 24 hours after). A renal biopsy showed acute tubular necrosis.⁴

(e) Triamterene with Indometacin

A study in 4 healthy subjects found that indometacin 150 mg daily given with triamterene 200 mg daily over a 3-day period reduced the creatinine clearance in 2 subjects by 62% and 72%, respectively. Renal function returned to normal after a month. Indometacin alone caused an average 10% fall in creatinine clearance, but triamterene alone caused no consistent change in renal function. No adverse reactions were seen in 18 other subjects treated in the same way with indometacin and furosemide, hydrochlorothiazide or spironolactone.^{5,6} Five patients are reported to have rapidly developed acute renal failure after receiving indometacin and triamterene, either concurrently or sequentially.^{7–10}

Mechanism

Uncertain. One suggestion is that triamterene causes renal ischaemia, for which the kidney compensates by increasing prostaglandin (PGE₂) production, thereby preserving renal blood flow. Indometacin opposes this by inhibiting prostaglandin synthesis, so that the damaging effects of triamterene on the kidney continue unchecked. Increases in pharmacologically active metabolites of triamterene may occur due to competition for renal excretory pathways but the clinical significance is uncertain.

As prostaglandins may contribute to the natriuretic effects of spironolactone, the NSAIDs may exert their effects by blocking prostaglandin synthesis. See also 'Loop diuretics + NSAIDs', p.949.

Importance and management

Information is limited to these reports, but the interaction with **indometacin** is established. The incidence is uncertain. Since acute renal failure can apparently develop unpredictably and very rapidly it would seem prudent to use triamterene and indometacin cautiously, or avoid it altogether. The authors of the report with **diclofenac** suggest caution with the use of any NSAID with triamterene.² Strenuous exercise can reduce renal blood flow, and the author of the case report with **ibuprofen** notes that although renal failure secondary to this is rare, patients taking medication that also reduces renal blood flow are more at risk of this complication.⁴ A retrospective analysis of records of patients taking diuretics (thiazides, loop and/or potassium-sparing) and NSAIDs found a twofold increase in the risk of hospitalisation for congestive heart failure on concurrent use, although the relative risk (1.4) with potassium-sparing diuretics was less than that when combined with a thiazide (2.9). The most common NSAIDs taken by this cohort of patients were diclofenac, ibuprofen, indometacin and naproxen.¹¹ The European Society of Cardiology (ESC) Task Force and the joint American College of Cardiology/American Heart Association guidelines on the management of chronic heart failure both recommend that NSAIDs, including coxibs, should be avoided, if possible, with aldosterone antagonists (such as **eplerenone** or **spironolactone**),

as this increases the risk of developing hyperkalaemia and renal failure.^{12,13} For a discussion of the interaction of spironolactone with aspirin, see 'Spironolactone + Aspirin', p.954.

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with antihypertensives, including diuretics, and the findings of these are summarised in 'Table 23.2', (p.862).

Potassium-sparing diuretics + Potassium compounds

The concurrent use of spironolactone or triamterene and potassium supplements can result in severe and even life-threatening hyperkalaemia. Amiloride and eplerenone are expected to interact similarly. Potassium-containing salt substitutes can be as hazardous as potassium supplements.

Clinical evidence

In a retrospective analysis of hospitalised patients who had received spironolactone, hyperkalaemia had developed in 5.7% of patients taking spironolactone alone and in 15.4% of those also taking a potassium chloride supplement. The incidence was 42% in those with severe azotaemia given spironolactone and potassium chloride.¹ A retrospective survey of another group of 25 patients taking spironolactone and oral potassium chloride supplements found that half of them had developed hyperkalaemia.² Another patient developed severe hyperkalaemia and cardiotoxicity as a result of treatment with spironolactone and a potassium supplement.³ Three patients taking furosemide and spironolactone became hyperkalaemic^{4,5} because they took potassium-containing salt substitutes (*No Salt* in one case⁴). Two developed cardiac arrhythmias.⁵

The pacemaker of a patient failed because of hyperkalaemia caused by the concurrent use of triamterene/hydrochlorothiazide (*Dyazide*) and potassium chloride (*Slow-K*).⁶

Mechanism

The effects of these potassium-sparing diuretics and potassium compounds are additive, which can result in hyperkalaemia.

Importance and management

The interaction with spironolactone is established and of clinical importance. A case has also been reported with triamterene; amiloride and eplerenone would be expected to behave similarly. Avoid potassium

compounds in patients taking potassium-sparing diuretics except in cases of marked potassium depletion and where the effects can be closely monitored. Warn patients about the risks of salt substitutes containing potassium, which may increase the potassium intake by 50 to 60 mmol daily.⁵ The signs and symptoms of hyperkalaemia include muscular weakness, fatigue, paraesthesia, flaccid paralysis of the extremities, bradycardia, shock and ECG abnormalities, which may develop slowly and insidiously.

Potassium-sparing diuretics + Total parenteral nutrition

Metabolic acidosis occurred in two patients receiving total parenteral nutrition, which was attributed to the use of triamterene or amiloride.

Clinical evidence, mechanism, importance and management

Metabolic acidosis developed in two patients receiving total parenteral nutrition associated with the concurrent use of triamterene or amiloride. The cases were complicated by a number of pathological and other factors, but it was suggested that the major reason for the acidosis was because the diuretics prevented the kidneys from responding normally to the acid load. Caution is advised during concurrent use.¹

- Kushner RF, Sitrin MD. Metabolic acidosis. Development in two patients receiving a potassium-sparing diuretic and total parenteral nutrition. *Arch Intern Med* (1986) 146, 343–5.

Potassium-sparing/Thiazide diuretics + Trimethoprim

Excessively low sodium levels have been seen in a few patients taking hydrochlorothiazide with amiloride or triamterene when they were given trimethoprim or co-trimoxazole. Trimethoprim may cause hyperkalaemia and this may be additive with potassium-sparing diuretics, including the aldosterone antagonists.

Clinical evidence

A 75-year-old woman with multiple medical conditions taking methyl-dopa, levothyroxine and co-amiloride (hydrochlorothiazide with amiloride) developed nausea and anorexia, and was found to have hyponatraemia (plasma sodium 107 mmol/L), within 4 days of starting to take trimethoprim 200 mg twice daily. The problem resolved when the diuretics and trimethoprim were stopped. When re-challenged 4 months later with trimethoprim, hyponatraemia did not occur, but it developed rapidly when co-amiloride was also restarted.¹ The authors of this report say that they have seen several other patients who developed hyponatraemia within 4 to 12 days of starting trimethoprim or co-trimoxazole, all of whom were elderly and all but one of whom were taking a diuretic [un-named].¹

Another report describes hyponatraemia in two other patients after co-trimoxazole was added to treatment with co-amiloride or co-triamterezide (hydrochlorothiazide with triamterene).²

Mechanism

Not established. Thiazide diuretics combined with potassium-sparing diuretics are said to be particularly liable to cause hyponatraemia.³ Trimethoprim can also cause hyperkalaemia⁴, by blocking amiloride-sensitive sodium channels in the collecting duct (this produces a similar effect to that of a potassium-sparing diuretic). It seems likely that these adverse effects can be additive with the effects of other drugs.

Importance and management

Information is very limited but it would seem prudent to be on the alert for any signs of hyponatraemia (nausea, anorexia, etc.) in any patient taking potassium-sparing diuretics with thiazides and trimethoprim. Although there appears to have been no specific case reports of hyperkalaemia in patients taking trimethoprim with potassium-sparing diuretics (including the **aldosterone antagonists**), in theory the risk of hyperkalaemia would be increased by concurrent use. It may therefore be prudent to also monitor potassium levels. The UK manufacturers of eplerenone note that the concurrent use of trimethoprim increases the risk of hyperkalaemia and patients should be closely monitored.⁵

Spirolactone + Aspirin

The antihypertensive effects of spironolactone in patients with hypertension were unaffected by anti-inflammatory doses of aspirin in one small study, although there is evidence that these doses of aspirin reduce the spironolactone-induced loss of sodium in the urine.

Clinical evidence

(a) Effects on blood pressure

Five patients with low-renin essential hypertension, well-controlled for 4 months or more with spironolactone 100 to 300 mg daily, took part in a crossover study. Aspirin 2.4 to 4.8 g daily given over 6-week periods had no effect on blood pressure, serum electrolytes, body-weight, blood-urea-nitrogen or plasma renin activity.¹

(b) Effects on natriuresis

A study in 10 healthy subjects given single 25-, 50- and 100-mg doses of spironolactone, found that a single 600-mg dose of aspirin reduced the urinary excretion of sodium in response to spironolactone.² In a further study in 7 of these subjects, the effectiveness of the spironolactone was reduced by 70%, and the overnight sodium excretion was reduced by one-third when they were given spironolactone 25 mg four times daily for one week followed by a single 600-mg dose of aspirin.² Reductions in sodium excretion are described in other studies of this interaction.^{3,4} In one of these the sodium excretion brought about by spironolactone was completely abolished when aspirin was given 90 minutes after the spironolactone, but when the drugs were given in the reverse order the inhibition of sodium excretion, which was caused by aspirin, was not completely reversed by spironolactone.⁴

In another study in 7 patients with ascites due to liver cirrhosis, pre-treatment with two doses of aspirin 900 mg reduced the natriuretic effect of spironolactone 300 mg daily by 33%. However, there was no significant change in urinary output.⁵

Mechanism

Uncertain. There is evidence that the active secretion of canrenone (the active metabolite of spironolactone) is blocked by aspirin, but the significance of this is not entirely clear.³

Importance and management

An adequately but not extensively documented interaction. Despite the results of the studies showing a reduced natriuretic effect, the small study in hypertensive patients shows that the blood pressure-lowering effects of spironolactone might not be affected by anti-inflammatory doses of aspirin. In general, concurrent use need not be avoided, but if the diuretic response to spironolactone is less than expected consider this interaction as a cause.

None of these studies looked at the effects of low-dose aspirin on spironolactone. Nevertheless, it is likely that the proven protective cardi-

ovascular benefits of low-dose aspirin in patients with hypertension and/or coronary artery disease would usually outweigh the possible reduction in the efficacy of spironolactone. However, note that, when spironolactone is being used for congestive heart failure, the European Society of Cardiology (ESC) and American College of Cardiology/American Heart Association (ACC/AHA) heart failure guidelines say that the prophylactic use of aspirin in patients with heart failure has not been proven unless the patient has underlying ischaemic heart disease^{6,7} and should be avoided in patients with recurrent hospital admissions for worsening heart failure.⁷ See also 'Potassium-sparing diuretics + NSAIDs', p.952, for a discussion of the interactions of spironolactone with NSAIDs.

Spirolactone + Colestyramine

A few case reports have described hyperchloraemic metabolic acidosis, which was associated with the use of colestyramine and spironolactone.

Clinical evidence

Four case reports describe the development of hyperchloraemic metabolic acidosis in patients with liver cirrhosis taking colestyramine (up to about 25 g daily), who were also taking spironolactone 75 mg or 100 mg daily.^{1–4} One patient developed significant hyperkalaemia (potassium 8 mmol/L),⁴ and 2 patients developed mild renal impairment.^{1,3} One patient had recently recovered from a respiratory tract infection, which the authors suggested may have contributed to the acidosis.¹ Acidosis resolved when the colestyramine was stopped.

Mechanism

Bicarbonate has been shown to compete *in vitro* with bile acids for binding sites on the colestyramine resin.^{1,3} The chloride ions in the colestyramine resin may cause an anion exchange of not only the bile salts, as is the intention, but also bicarbonate in the small bowel. This removal of bicarbonate from the body can predispose to the development of a hyperchloraemic metabolic acidosis and hyperkalaemia. This might be exacerbated by the bicarbonate-losing and hyperkalaemic effects of spironolactone.^{1,4}

Importance and management

In healthy subjects with normal renal function, acidosis does not usually occur, as the kidneys correct it by increasing the excretion of chloride and production of bicarbonate.^{1–4} However, in patients with renal impairment, volume depletion (e.g. secondary to diuretics) or concurrent conditions that predispose to acidosis, this interaction may be significant. It has been suggested that electrolytes should be closely monitored when patients who are at risk of an interaction are taking colestyramine and spironolactone,¹ although note that the interaction appears to be rare.

Spironolactone + Dextropropoxyphene (Propoxyphene)

A single case report describes the development of gynaecomastia and a rash when a man taking spironolactone was given dextropropoxyphene.

Clinical evidence, mechanism, importance and management

A patient who had been taking spironolactone uneventfully for 4 years developed swollen, tender breasts and a rash on his chest and neck a fortnight after starting to take *Darvon Compound* (dextropropoxyphene, aspirin, phenacetin and caffeine). The problem disappeared when both drugs were withdrawn but the rash reappeared when the *Darvon Compound* alone was given and disappeared when it was withdrawn. No problems occurred when the spironolactone was given alone, but both the rash and the gynaecomastia recurred when the *Darvon Compound* was again added.¹ The reasons for this reaction are not understood. Gynaecomastia is a known adverse effect of spironolactone (incidence 1.2%), but the authors considered it unlikely that it should spontaneously develop after so many years of treatment. Consequently they attribute the reaction to an interaction with *Darvon Compound*, but say they cannot be sure which of the components is responsible. This is an isolated case, and would therefore not be expected to be of general relevance.

Spironolactone + Food

Food may increase the plasma levels of spironolactone, but this did not alter antihypertensive efficacy in one long-term study.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects food increased the AUC of canrenone (the major active metabolite of spironolactone) by about 30% after a single 100-mg dose of spironolactone, when compared to the fasted state.¹ However, the same research group later found that the steady-state canrenone levels did not differ when spironolactone 100 mg daily was taken at least 30 minutes before eating for 60 days, compared with immediately after eating for 60 days. Furthermore, in a crossover study in 10 hypertensive patients, the antihypertensive efficacy of spironolactone was not altered by food. They suggest that the difference is due to a more specific drug assay in the second study.² Other authors have also found that, in healthy subjects, food increased the AUC of a single dose of spironolactone by 71%, and also increased the AUC of three of its metabolites (including canrenone) by 32%, but they did not assess whether this altered the hypotensive effect.³ It appears from the long-term study, that food does not alter the antihypertensive efficacy of spironolactone. It has been recommended that spironolactone be taken with food to try and reduce the gastric irritant effects of the drug.²

Thiazide diuretics + Bile-acid binding resins

The absorption of hydrochlorothiazide (and probably chlorothiazide) can be reduced by more than one-third if colestipol is given concurrently. Colestyramine also reduces the absorption of hydrochlorothiazide by more than two-thirds.

Clinical evidence

In 6 healthy subjects the plasma levels of hydrochlorothiazide were reduced by about two-thirds by colestyramine 8 g, taken 2 minutes before and 6 and 12 hours after a single 75-mg oral dose of hydrochlorothiazide. Total urinary excretion of hydrochlorothiazide fell by 83%. In a parallel

study with colestipol 10 g, the blood levels of hydrochlorothiazide fell by about 14% and the total urinary excretion fell by 31%.¹ A further study found that giving the colestyramine 4 hours after the hydrochlorothiazide reduced the effects of the interaction but the absorption was still reduced by one-third.² In another study colestipol, given simultaneously or one hour after chlorothiazide, reduced the urinary excretion of chlorothiazide by 58% and 54%, respectively.³

Mechanism

Hydrochlorothiazide becomes bound to these non-absorbable anionic exchange resins within the gut, and less is available for absorption.

Importance and management

Established interactions of clinical importance. The best dosing schedule would appear to be to give hydrochlorothiazide 4 hours before colestyramine to minimise mixing in the gut. Even so, a one-third reduction in thiazide absorption occurs² and the possibility of this interaction should be considered in patients taking colestyramine or colestipol who have a reduced response to a thiazide diuretic. The optimum time-interval with colestipol has not been investigated but it would be reasonable to take similar precautions. Information about other thiazides is lacking although it seems likely that they will interact similarly. Note that it is normally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine and 1 hour before or 4 hours after colestipol.

Thiazide diuretics + Calcium and/or Vitamin D

Hypercalcaemia and possibly metabolic alkalosis can develop in patients who are given high doses of vitamin D and/or large amounts of calcium if they are also given diuretics such as the thiazides, which can reduce the urinary excretion of calcium. One case of hypercalcaemia has been reported in a patient using a high-strength topical tacalcitol with a thiazide diuretic.

Clinical evidence

(a) Calcium and vitamin D

An elderly woman taking hydrochlorothiazide 25 mg and triamterene 50 mg daily became confused, disorientated and dehydrated 6 months after starting to take vitamin D₂ 50 000 units and calcium 1.5 g daily (as calcium carbonate) for osteoporosis. Her serum calcium level had risen to about 3.5 mmol/L (normal range about 2 to 2.6 mmol/L).¹

A young woman with osteoporosis taking 3 mg of vitamin D₂ and calcium 2 g daily (as lactate) became hypercalcaemic 3 days after starting to take chlorothiazide 500 mg every 6 hours.²

(b) Calcium carbonate

A 47-year-old man was admitted to hospital complaining of dizziness and general weakness, which had begun 2 months previously. He was taking chlorothiazide 500 mg daily for hypertension, 'thyroid' 120 mg daily for hypothyroidism and calcium carbonate 7.5 to 10 g daily for heartburn. On examination he was found to have metabolic alkalosis with respiratory compensation, a total serum calcium concentration of 3.4 mmol/L (range given as 2.15 to 2.6 mmol/L) and an abnormal ECG. He was diagnosed as having the milk-alkali syndrome. Recovery was rapid when the thiazide and calcium carbonate were withdrawn and a sodium chloride infusion, furosemide and oral phosphates were given.³

An elderly woman with normal renal function taking hydrochlorothiazide 50 mg daily developed hypercalcaemia about 3 weeks after increasing her dose of calcium carbonate from 2.5 g daily to 7.5 g daily.⁴

In both cases the thiazide diuretic was thought to be implicated as the levels of calcium ingestion were in the region of the normally recommended doses.

(c) Oral vitamin D

In a group of 12 patients treated for hypoparathyroidism with vitamin D (dihydrotachysterol or ergocalciferol), 5 patients became hypercalcaemic.

mic when they took **bendroflumethiazide** or **methyclothiazide**.⁵ A significant rise in plasma calcium levels occurred in 7 patients given vitamin D and **methyclothiazide** or **chlorothiazide**, and hypercalcaemia developed in 3 of them.⁶ A study in 12 children taking **calcitriol** (31 nanograms/kg daily) found that the addition of **hydrochlorothiazide** (1 to 2 micrograms/kg daily) reduced the urinary excretion of calcium caused by the calcitriol.⁷ Another study in 7 patients with vitamin D-induced calciuria found that the addition of **hydrochlorothiazide** and **amiloride** reduced the urinary excretion of calcium due to the **calcitriol** to a greater extent than **hydrochlorothiazide** alone. Moreover, the addition of amiloride helped to prevent adverse effects associated with the use of **hydrochlorothiazide**, such as hypokalaemia and alkalosis.⁸

(d) Topical vitamin D analogues

A case of asymptomatic hypercalcaemia has been reported in a patient taking **trichlormethiazide** 6 mg daily and using 10 g of a high-strength topical **tacalcitol** ointment (20 micrograms/g) daily for psoriasis as part of a clinical study. His calcium level reached a peak of 3.55 mmol/L 28 days after starting the tacalcitol ointment and it fell back to within the normal range within 7 days of stopping the ointment.⁹

Mechanism

The thiazide diuretics (and triamterene) can cause calcium retention by reducing its urinary excretion. This, added to the increased intake of calcium, resulted in excessive calcium levels. Alkalosis (the milk-alkali syndrome, associated with hypercalcaemia, alkalosis, and renal impairment) may also occur in some individuals because the thiazide limits the excretion of bicarbonate.

Importance and management

An established interaction. The incidence is unknown but the reports cited^{5,6} suggest that it can be considerable if the intake of vitamin D and calcium are high. Concurrent use need not be avoided; thiazides have been used clinically to reduce vitamin-D induced hypercalciuria,^{7,8} but the serum calcium levels should be regularly monitored to ensure that they do not become excessive. Patients should be warned about the ingestion of very large amounts of calcium carbonate (readily available without prescription) if they are taking thiazide diuretics.

The case of hypercalcaemia with the use of a topical vitamin D analogue is rare and the strength of the preparation of tacalcitol used was fivefold higher than the current licensed preparation of 4 micrograms/g (*Curatoderm*). However, bear this case in mind should a patient taking thiazides with a topical vitamin D analogue develop hypercalcaemia.

Thiazide and related diuretics + NSAIDs

There is evidence that most NSAIDs can increase blood pressure in patients taking antihypertensives, including diuretics, although some studies have not found the increase to be clinically relevant. The concurrent use of NSAIDs with thiazide diuretics may exacerbate congestive heart failure and increase the risk of hospitalisation.

Clinical evidence

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure

in patients treated with **antihypertensives**, and the findings of these are summarised in 'Table 23.2', (p.862). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both coxibs and non-selective NSAIDs. In two meta-analyses,^{1,2} the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between **indometacin** and **sulindac** in one analysis.² Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,¹ the effect was greatest for **piroxicam**, **indometacin**, and **ibuprofen**, intermediate for **naproxen**, and least for **sulindac** and **flurbiprofen**. In the other meta-analysis,² the effect was greatest for **indometacin** and **naproxen**, intermediate for **piroxicam**, and least for **ibuprofen** and **sulindac**. An attempt was also made to evaluate the effect by **antihypertensive** in one analysis.¹ The mean effect was greatest for beta blockers, intermediate for vasodilators (includes ACE inhibitors and calcium-channel blockers), and least for **diuretics**. However, the differences between the groups were not significant.

The findings of individual clinical and pharmacological studies that have studied the effects of specific NSAIDs on diuretics are outlined in the subsections below and in 'Table 26.2', (p.957).

A. Bemetizide

Indometacin 100 mg was found to reduce the urinary excretion of sodium and chloride caused by bemetizide by 47% and 44%, respectively, in healthy subjects.³

B. Bendroflumethiazide

(a) Ibuprofen

In a randomised, placebo-controlled study, 7 hypertensive patients taking bendroflumethiazide 5 to 10 mg daily were also given ibuprofen 400 mg four times daily for 2 weeks. Although some small increases in blood pressure occurred, the diastolic blood pressure of all patients remained below 90 mmHg throughout the ibuprofen phase. Overall no statistically significant weight gain was noted, although 2 patients gained more than 2 kg.⁴

(b) Indometacin

A controlled study in 7 hypertensive patients taking bendroflumethiazide 5 to 10 mg daily found that indometacin 100 mg daily for 3 weeks raised their blood pressure by 13/9 mmHg when lying and by 16/9 mmHg when standing. Body-weight increased by 1.1 kg.⁵ Indometacin also attenuated the hypotensive effect of bendroflumethiazide in another study.⁶

(c) Sulindac

A brief report suggested that sulindac *enhanced* the hypotensive effects of bendroflumethiazide in 5 hypertensive patients.⁶

C. Hydrochlorothiazide

(a) Diclofenac

Diclofenac 25 mg three times daily was given to 8 patients with essential hypertension who were taking hydrochlorothiazide. Blood pressure was not significantly altered after the addition of diclofenac, but a weight gain of about 1 to 2 kg was noted, which was thought to have been caused by the sodium retaining effects of diclofenac.⁷ In another study, diclofenac 75 mg twice daily for one month did not alter the antihypertensive effect of the combination of hydrochlorothiazide 25 mg daily and lisinopril 10 to 40 mg daily.⁸

(b) Diflunisal

Diflunisal 375 mg twice daily caused the plasma levels of hydrochlorothiazide to rise by 25 to 30%, but this does not appear to be clinically significant.^{9,10} Diflunisal also has uricosuric activity, which counteracts the uric acid retention that occurs with hydrochlorothiazide.

(c) Ibuprofen

In two studies in patients taking hydrochlorothiazide, ibuprofen 400 or 600 mg three times daily for 4 weeks caused a small rise in systolic but not in diastolic blood pressure.^{7,11} However, a weight gain of about 1 to 2 kg was noted in one of the studies.⁷ Another study found that ibuprofen 400 mg three times daily had no effect on blood pressure controlled by triamterene with hydrochlorothiazide, although one patient had a marked fall in renal function.¹² Ibuprofen 800 mg four times daily for a week had little effect on blood pressure controlled with hydrochlorothiazide in yet another study.¹³ In two further studies, ibuprofen 800 mg three times daily for
