Preface

The aim of *Stockley's Drug Interactions* is to inform busy doctors, pharmacists, surgeons, nurses and other healthcare professionals, of the facts about drug interactions, without their having to do the time-consuming literature searches and full assessment of the papers for themselves. These therefore are the practical questions which this book attempts to answer:

- Are the drugs and substances in question known to interact or is the interaction only theoretical and speculative?
- If they do interact, how serious is it?
- Has it been described many times or only once?
- Are all patients affected or only a few?
- Is it best to avoid these two substances altogether or can the interaction be accommodated in some way?
- And what alternative and safer drugs can be used instead?

To précis the mass of literature into a concise and easy-to-read form, the text has been organised into a series of individual monographs, all with a common format. If you need some insight into the general philosophy underlying the way all this information is handled in this publication, you should have a look at the section, 'Before using this book. . . '.

There have been several changes for the 8th edition. All of the existing monographs have, as with each edition, been reviewed, revalidated and updated, and many new ones have been added, making a total in excess of 3100 monographs. Many new monographs on herbal interactions have been added, although good quality human studies remain sparse. A new chapter has been added to cover the growing number of interactions about anorectics, and the chapter on sympathomimetics has been removed, with the information redistributed according to the therapeutic use of the drugs in question, to give a better indication of precisely which drugs from this disparate group are likely to interact. We have continued to add information provided by regulatory bodies outside of the UK, which further enhances the international flavour of the publication.

This edition has also seen the growth in our editorial team, with two practising clinical pharmacists recruited to help us ensure we maintain the practical nature of the information given. This has also allowed us to develop our product range, with the publication of the first *Stockley's Drug Interactions Pocket Companion*, which we have developed for delivery on PDA.

As always, the Editorial team have had assistance from many other people in developing this publication, and the Editor gratefully acknowledges the assistance and guidance that they have provided. The Martindale team continue to be a great source of advice and support, and particular thanks is due to the editor, Sean Sweetman. Thanks are also due to John Wilson and Tamsin Cousins, who handle the various aspects of producing our publications in print. We are also grateful for the support of both Paul Weller and Charles Fry. Ivan Stockley remains an important part of the publication, taking a keen interest in the development of new products, and as ever, we find his advice invaluable.

Stockley's Drug Interactions continues to be available on the Pharmaceutical Press platform, MedicinesComplete, as well as being available on other platforms, both in English and Spanish. With the further development of the integratable Alerts product and the new PDA, we remain indebted to Julie McGlashan, Michael Evans, Elizabeth King, and all those involved in the development of these products, for their advice and support. For more details about these digital products please visit: www.pharmpress.com/Stockley

As ever, we have had feedback from pharmacists and doctors about the content of the publication, which is always valuable, especially in ensuring the publication meets the needs of the users. We are particularly grateful to those who have taken the time to answer our questions about specific aspects of practice. Anyone who wishes to contact the Stockley team can do so at the following address: stockley@rpsgb.org

London, September 2007

Abbreviations

ACE—angiotensin-converting enzyme	ITU—intensive therapy unit
ADP—adenosine diphosphate	IU—International Units
AIDS—acquired immunodeficiency syndrome	IUD—intra-uterine device
ALL—acute lymphoblastic leukaemia	kg—kilogram(s)
ALT—alanine aminotransferase	l—litre
am— <i>ante meridiem</i> (before noon)	lbs—pound(s) avoirdupois
AML—acute myeloid leukaemia	LDL—low-density lipoprotein
aPTT—activated partial thromboplastin time	LFT—liver function test
AST—aspartate aminotransferase	LH—luteinising hormone
AUC—area under the time–concentration curve	LMWH—low-molecular-weight heparin
AUC _{0–12} —area under the time–concentration curve measured over 0 to 12 hours	MAC—minimum alveolar concentration
AV—atrioventricular	MAOI—monoamine oxidase inhibitor
BNF—British National Formulary	MAOI-A—monoamine oxidase inhibitor, type A
BP—blood pressure	MAOI-B—monoamine oxidase inhibitor, type B
BP—British Pharmacopoeia	MCA—Medicines Control Agency (UK) (now MHRA)
BPC—British Pharmaceutical Codex	MHRA—Medicines and Healthcare products Regulatory Agency (UK)
BPH—benign prostatic hyperplasia	MIC—minimum inhibitory concentration
bpm—beats per minute	mEq—milliequivalent(s)
BUN—blood urea nitrogen	mg—milligram(s)
CAPD—continuous ambulatory peritoneal dialysis	mL—millilitre(s)
CDC—Centers for Disease Control (USA)	mmHg—millimetre(s) of mercury
CNS—central nervous system	mmol—millimole
COPD—chronic obstructive pulmonary disease	mol—mole
CPR—cardiopulmonary resuscitation	MRSA—methicillin resistant <i>Staphylococcus aureus</i>
CSF—cerebrospinal fluid	NICE—National Institute for Health and Clinical Excellence (UK) (formerly the National Institute for Clinical Excellence)
CSM—Committee on Safety of Medicines (UK) (now subsumed within the Commission on Human Medicines)	nM—nanomole
DNA—deoxyribonucleic acid	nmol—nanomole
ECG—electrocardiogram	NNRTI—non-nucleoside reverse transcriptase inhibitor
ECT—electroconvulsive therapy	NRTI—nucleoside reverse transcriptase inhibitor
ED ₅₀ —the dose at which 50% of subjects respond	NSAID—non-steroidal anti-inflammatory drug
EEG—electroencephalogram	PABA—para-amino benzoic acid
e.g.— <i>exempli gratia</i> (for example)	PCP—pneumocystis pneumonia
EMA—The European Agency for the Evaluation of Medicinal Products	pH—the negative logarithm of the hydrogen ion concentration
FDA—Food and Drug Administration (USA)	pm— <i>post meridiem</i> (after noon)
FEF _{25–75} —maximum expiratory flow over the middle 50% of the vital capacity	pO ₂ —plasma partial pressure (concentration) of oxygen
FEV ₁ —forced expiratory volume in one second	PPI—proton pump inhibitor
FSH—follicle stimulating hormone	ppm—parts per million
ft—foot (feet)	PTT—partial thromboplastin time
FVC—forced vital capacity	PUD—peptic ulcer disease
GGT—gamma glutamyl transpeptidase	RIMA—reversible inhibitor of monoamine oxidase type A
g—gram(s)	RNA—ribonucleic acid
h—hour(s)	<i>sic</i> —written exactly as it appears in the original
HAART—highly active antiretroviral therapy	SNRI—serotonin and noradrenaline reuptake inhibitor
HCV—hepatitis C virus	SSRI—selective serotonin reuptake inhibitor
HIV—human immunodeficiency virus	STD—sexually transmitted disease
HRT—hormone replacement therapy	SVT—supraventricular tachycardia
<i>ibid</i> — <i>ibidem</i> , in the same place (journal or book)	TPN—total parenteral nutrition
i.e.— <i>id est</i> (that is)	TSH—thyroid-stimulating hormone
INR—international normalised ratio	UK—United Kingdom
	US and USA—United States of America
	USP—The United States Pharmacopoeia
	UTI—urinary tract infection

Before using this book . . .

. . . you should read this short explanatory section so that you know how the drug interaction data have been set out here, and why – as well as the basic philosophy that has been followed in presenting it.

The monographs

This publication has over 3100 monographs with a common format, which are subdivided into sections like these:

- An abstract or summary for quick reading.
- **Clinical evidence**, detailing one, two or more illustrative examples of the interaction, followed by most or all of other supportive clinical evidence currently available.
- **Mechanism**, in brief.
- **Importance and management**, a short discussion designed to aid rapid clinical decision making. For example:
 - Is the interaction established or not?
 - What is its incidence?
 - How important is it?
 - How can it be managed?
 - And what, if any, are the non-interacting alternatives?
- **References**, a list of all of the relevant references. The length of the references list gives a very fair indication of the extent of the documentation. A long list indicates a well documented interaction, whereas a short list indicates poor documentation.

Some of the monographs have been compressed into fewer subsections instead of the more usual five, simply where information is limited or where there is little need to be more expansive.

The monographs do not carry the drug interaction Hazard/Severity ratings as used in the electronic *Stockley Interactions Alerts* because of the difficulties of applying them to monographs that cover multiple pairs of drug–drug interactions, but what is written in each monograph should speak for itself.

Quality of information on interactions

The data on interactions are of widely varying quality and reliability. The best come from clinical studies carried out on large numbers of patients under scrupulously controlled conditions. The worst are anecdotal, uncontrolled, or based solely on *animal* studies. Sometimes they are no more than speculative and theoretical scaremongering guesswork, halloed by repeated quotation until they become virtually set in stone.

The aim has been to filter out as much useless noise as possible, so wherever possible ‘secondary’ references are avoided, and ‘primary’ references which are available in good medical and scientific libraries are used instead – although sometimes unpublished, good quality, in-house reports on drug company files have been used where the drug company

has kindly allowed access to the information. Product literature (the Summary of Product Characteristics in the UK and the Prescribing Information in the US) rather than the research reports that lie behind them are also cited because they are the only source of published information about new drugs.

The quality of drug company literature is very variable. Some of it is excellent, helpful and very reliable, but regrettably a growing proportion contains a welter of speculative and self-protective statements, probably driven more by the company's medico-legal policy than anything else, and the nervousness of drug regulatory authorities. It is almost unbelievable (but true all the same) that drug companies that are scrupulous in the way they do their research, come out with statements about possible interactions that are little more than guesswork.

When drawing your own conclusions

The human population is a total mixture, unlike selected batches of laboratory animals (same age, weight, sex, and strain etc.). For this reason human beings do not respond uniformly to one or more drugs. Our genetic make up, ethnic background, sex, renal and hepatic functions, diseases and nutritional states, ages and other factors (the route of administration, for example) all contribute towards the heterogeneity of our responses. This means that the outcome of giving one or more drugs to any individual for the first time is never totally predictable because it is a new and unique ‘experiment’. Even so, some idea of the probable outcome of using a drug or a pair of drugs can be based on what has been seen in other patients: the more extensive the data, the firmer the predictions.

The most difficult decisions concern isolated cases of interaction, many of which only achieved prominence because they were serious. Do you ignore them as ‘idiosyncratic’ or do you, from that moment onwards, contraindicate the use of the two drugs totally?

There is no simple ‘yes’ or ‘no’ answer to these questions, but one simple rule-of-thumb is that isolated cases of interaction with old and very well-tried pairs of drugs are unlikely to be of general importance, whereas those with new drugs may possibly be the tip of an emerging iceberg and should therefore initially be taken much more seriously until more is known. The delicate balance between these two has then to be set against the actual severity of the reaction reported and weighed up against how essential it is to use the drug combination in question.

When deciding the possible first-time use of any two drugs in any particular patient, you need to put what is currently known about these drugs against the particular profile of your patient. Read the monograph. Consider the facts and conclusions, and then set the whole against the backdrop of your patient's unique condition (age, disease, general condition, and so forth) so that what you eventually decide to do is well thought out and soundly based. We do not usually have the luxury of knowing absolutely all the facts, so that an initial conservative approach is often the safest.

General considerations and an outline survey of some basic interaction mechanisms

A. What is a drug interaction?

An interaction is said to occur when the effects of one drug are changed by the presence of another drug, herbal medicine, food, drink or by some environmental chemical agent. Much more colourful and informal definitions by patients are that it is “. . . when medicines fight each other. . .”, or “. . . when medicines fizz together in the stomach . . .”, or “. . . what happens when one medicine falls out with another. . .”

The outcome can be harmful if the interaction causes an increase in the toxicity of the drug. For example, there is a considerable increase in risk of severe muscle damage if patients on statins start taking azole antifungals (see ‘Statins + Azoles’, p.1093). Patients taking monoamine oxidase inhibitor antidepressants (MAOIs) may experience an acute and potentially life-threatening hypertensive crisis if they eat tyramine-rich foods such as ‘cheese’, (p.1153).

A reduction in efficacy due to an interaction can sometimes be just as harmful as an increase: patients taking warfarin who are given rifampicin need more warfarin to maintain adequate and protective anticoagulation (see ‘Coumarins + Antibacterials; Rifamycins’, p.375), while patients taking ‘tetracyclines’, (p.347) or ‘quinolones’, (p.332) need to avoid antacids and milky foods (or separate their ingestion) because the effects of these antibacterials can be reduced or even abolished if admixture occurs in the gut.

These unwanted and unsought-for interactions are adverse and undesirable but there are other interactions that can be beneficial and valuable, such as the deliberate co-prescription of antihypertensive drugs and diuretics in order to achieve antihypertensive effects possibly not obtainable with either drug alone. The mechanisms of both types of interaction, whether adverse or beneficial, are often very similar, but the adverse interactions are the focus of this publication.

Definitions of a drug interaction are not rigidly adhered to in this publication because the subject inevitably overlaps into other areas of adverse reactions with drugs. So you will find in these pages some ‘interactions’ where one drug does not actually affect another at all, but the adverse outcome is the simple additive effects of two drugs with similar effects (for example the combined effects of two or more CNS depressants, or two drugs which affect the QT interval). Sometimes the term ‘drug interaction’ is used for the physico-chemical reactions that occur if drugs are mixed in intravenous fluids, causing precipitation or inactivation. The long-established and less ambiguous term is ‘pharmaceutical incompatibilities’. Incompatibilities are not covered by this publication.

B. What is the incidence of drug interactions?

The more drugs a patient takes the greater the likelihood that an adverse reaction will occur. One hospital study found that the rate was 7% in those taking 6 to 10 drugs but 40% in those taking 16 to 20 drugs, which represents a disproportionate increase.¹ A possible explanation is that the drugs were interacting.

Some of the early studies on the frequency of interactions uncritically compared the drugs that had been prescribed with lists of possible drug interactions, without appreciating that many interactions may be clinically trivial or simply theoretical. As a result, an unrealistically high incidence was suggested. Most of the later studies have avoided this error by looking at only potentially clinically important interactions, and incidences of up to 8.8% have been reported.²⁻⁴ Even so, not all of these studies took into

account the distinction that must be made between the incidence of potential interactions and the incidence of those where clinical problems actually arise. The simple fact is that some patients experience quite serious reactions while taking interacting drugs, while others appear not to be affected at all.

A screening of 2 422 patients over a total of 25 005 days revealed that 113 (4.7%) were taking combinations of drugs that could interact, but evidence of interactions was observed in only seven patients, representing only 0.3%.² In another hospital study of 44 patients over a 5-day period taking 10 to 17 drugs, 77 potential drug interactions were identified, but only one probable and four possible adverse reactions (6.4%) were detected.⁵ A further study among patients taking anticonvulsant drugs found that 6% of the cases of toxicity were due to drug interactions.⁶ These figures are low compared with those of a hospital survey that monitored 927 patients who had received 1004 potentially interacting drug combinations. Changes in drug dosage were made in 44% of these cases.⁷ A review of these and other studies found that the reported incidence rates ranged from 2.2 to 70.3%, and the percentage of patients actually experiencing problems was less than 11.1%. Another review found a 37% incidence of interactions among 639 elderly patients.⁸ Yet another review of 236 geriatric patients found an 88% incidence of clinically significant interactions, and a 22% incidence of potentially serious and life-threatening interactions.⁹ A 4.1% incidence of drug interactions on prescriptions presented to community pharmacists in the USA was found in a further survey,¹⁰ whereas the incidence was only 2.9% in another American study,¹¹ and just 1.9% in a Swedish study.¹² An Australian study found that about 10% of hospital admissions were drug-related, of which 4.4% were due to drug interactions.¹³ A very high incidence (47 to 50%) of potential drug interactions was found in a study carried out in an Emergency Department in the US.¹⁴ One French study found that 16% of the prescriptions for a group of patients taking antihypertensive drugs were contraindicated or unsuitable,¹⁵ whereas another study on a group of geriatrics found only a 1% incidence.¹⁶ The incidence of problems would be expected to be higher in the elderly because ageing affects the functioning of the kidneys and liver.^{17,18}

These discordant figures need to be put into the context of the under-reporting of adverse reactions of any kind by medical professionals, for reasons that may include pressure of work or the fear of litigation. Both doctors and patients may not recognise adverse reactions and interactions, and some patients simply stop taking their drugs without saying why. None of these studies give a clear answer to the question of how frequently drug interactions occur, but even if the incidence is as low as some of the studies suggest, it still represents a very considerable number of patients who appear to be at risk when one thinks of the large numbers of drugs prescribed and taken every day.

C. How seriously should interactions be regarded and handled?

It would be very easy to conclude after browsing through this publication that it is extremely risky to treat patients with more than one drug at a time, but this would be an over-reaction. The figures quoted in the previous section illustrate that many drugs known to interact in some patients, simply fail to do so in others. This partially explains why some quite important drug interactions remained virtually unnoticed for many years, a good example of this being the increase in serum digoxin levels seen with quinidine (see 'Digitalis glycosides + Quinidine', p.936).

Examples of this kind suggest that patients apparently tolerate adverse interactions remarkably well, and that many experienced physicians accommodate the effects (such as rises or falls in serum drug levels) without consciously recognising that what they are seeing is the result of an interaction.

One of the reasons it is often difficult to detect an interaction is that, as already mentioned, patient variability is considerable. We now know many of the predisposing and protective factors that determine whether or not an interaction occurs but in practice it is still very difficult to predict what will happen when an individual patient is given two potentially interacting drugs. An easy solution to this practical problem is to choose a non-interacting alternative, but if none is available, it is frequently possible to give interacting drugs together if appropriate precautions are taken. If the effects of the interaction are well-monitored they can often be allowed for, often simply by adjusting the dosages. Many interactions are dose-related so that if the dosage of the causative drug is reduced, the effects on the other drug will be reduced accordingly. Thus a non-prescription dosage of cimetidine may fail to inhibit the metabolism of phenytoin, whereas a larger dose may clearly increase phenytoin levels (see 'Phenytoin + H₂-receptor antagonists', p.559).

The dosage of the affected drug may also be critical. For example, isoniazid causes the levels of phenytoin to rise, particularly in those individuals who are slow acetylators of isoniazid, and levels may become toxic. If the serum phenytoin levels are monitored and its dosage reduced appropriately, the concentrations can be kept within the therapeutic range (see 'Phenytoin + Antimycobacterials', p.550). Some interactions can be accommodated by using another member of the same group of drugs. For example, the serum levels of doxycycline can become subtherapeutic if phenytoin, barbiturates or carbamazepine are given, but other 'tetracyclines' (p.346) do not seem to be affected. Erythromycin causes serum lovastatin levels to rise because it inhibits its metabolism, but does not affect pravastatin levels because these two statins are metabolised in different ways (see 'Statins', (p.1086)). It is therefore clearly important not to uncritically extrapolate the interactions seen with one drug to all members of the same group.

It is interesting to note in this context that a study in two hospitals in Maryland, USA, found that when interacting drugs were given with warfarin (but not theophylline) the length of hospital stay increased by a little over 3 days, with a rise in general costs because of the need to do more tests to get the balance right.¹ So it may be easier, quicker and cheaper to use a non-interacting alternative drug (always provided that its price is not markedly greater).

The variability in patient response has led to some extreme responses among prescribers. Some clinicians have become over-anxious about interactions so that their patients are denied useful drugs that they might rea-

Table I.1 Some drug absorption interactions

Drug affected	Interacting drugs	Effect of interaction
Digoxin	Metoclopramide Proprantheline	Reduced digoxin absorption Increased digoxin absorption (due to changes in gut motility)
Digoxin Levothyroxine Warfarin	Colestyramine	Reduced absorption due to binding/complexation with colestyramine
Ketoconazole	Antacids H ₂ -receptor antagonists Proton pump inhibitors	Reduced ketoconazole absorption due to reduced dissolution
Penicillamine	Antacids (containing Al ³⁺ and/or Mg ²⁺), iron compounds, food	Formation of less soluble penicillamine chelates resulting in reduced absorption of penicillamine
Methotrexate	Neomycin	Neomycin-induced malabsorption state
Quinolones	Antacids (containing Al ³⁺ and/or Mg ²⁺), milk, Zn ²⁺ (?), Fe ²⁺	Formation of poorly absorbed complexes
Tetracyclines	Antacids (containing Al ³⁺ , Ca ²⁺ , Mg ²⁺ , and/or Bi ²⁺), milk, Zn ²⁺ , Fe ²⁺	Formation of poorly soluble chelates resulting in reduced antibacterial absorption (see Fig. I.1, p.3)

sonably be given if appropriate precautions are taken. This attitude is exacerbated by some of the more alarmist lists and charts of interactions, which fail to make a distinction between interactions that are very well documented and well established, and those that have only been encountered in a single patient, and which in the final analysis are probably totally idiosyncratic. 'One swallow does not make a summer', nor does a serious reaction in a single patient mean that the drugs in question should never again be given to anyone else.

At the other extreme, there are some health professionals who, possibly because they have personally encountered few interactions, fail to consider drug interactions, so that some of their patients are potentially put at risk. An example of this is the fact that cisapride continued to be prescribed with known interacting drugs, even after the rare risk of fatal torsade de pointes arrhythmias, which can cause sudden death, was well established² (see 'Cisapride + Miscellaneous', p.963). The responsible position lies between these two extremes, because a very substantial number of interacting drugs can be given together safely, if the appropriate precautions are taken. There are relatively few pairs of drugs that should always be avoided.

D. Mechanisms of drug interaction

Some drugs interact together in totally unique ways, but as the many examples in this publication amply illustrate, there are certain mechanisms of interaction that are encountered time and time again. Some of these common mechanisms are discussed here in greater detail than space will allow in the individual monographs, so that only the briefest reference need be made there.

Mechanisms that are unusual or peculiar to particular pairs of drugs are detailed within the monographs. Very many drugs that interact do so, not by a single mechanism, but often by two or more mechanisms acting in concert, although for clarity most of the mechanisms are dealt with here as though they occur in isolation. For convenience, the mechanisms of interactions can be subdivided into those that involve the pharmacokinetics of a drug, and those that are pharmacodynamic.

I. Pharmacokinetic interactions

Pharmacokinetic interactions are those that can affect the processes by which drugs are absorbed, distributed, metabolised and excreted (the so-called ADME interactions).

I.1. Drug absorption interactions

Most drugs are given orally for absorption through the mucous membranes of the gastrointestinal tract, and the majority of interactions that go on within the gut result in reduced rather than increased absorption. A clear distinction must be made between those that decrease the *rate* of absorption and those that alter the *total amount* absorbed. For drugs that are given long-term, in multiple doses (e.g. the oral anticoagulants) the rate of absorption is usually unimportant, provided the total amount of drug absorbed is not markedly altered. On the other hand for drugs that are given as single doses, intended to be absorbed rapidly (e.g. hypnotics or analgesics), where a rapidly achieved high concentration is needed, a reduction in the rate of absorption may result in failure to achieve an adequate effect. 'Table 1.1', (p.2) lists some of the drug interactions that result from changes in absorption.

(a) Effects of changes in gastrointestinal pH

The passage of drugs through mucous membranes by simple passive diffusion depends upon the extent to which they exist in the non-ionised lipid-soluble form. Absorption is therefore governed by the pKa of the drug, its lipid-solubility, the pH of the contents of the gut and various other parameters relating to the pharmaceutical formulation of the drug. Thus the absorption of salicylic acid by the stomach is much greater at low pH than at high. On theoretical grounds it might be expected that alterations in gastric pH caused by drugs such as the H₂-receptor antagonists would have a marked effect on absorption, but in practice the outcome is often uncertain because a number of other mechanisms may also come into play, such as chelation, adsorption and changes in gut motility, which can considerably affect what actually happens. However, in some cases the effect can be significant. Rises in pH due to 'proton pump inhibitors', (p.218), 'H₂-receptor antagonists', (p.217) can markedly reduce the absorption of ketoconazole.

(b) Adsorption, chelation and other complexing mechanisms

Activated charcoal is intended to act as an adsorbing agent within the gut for the treatment of drug overdose or to remove other toxic materials, but inevitably it can affect the absorption of drugs given in therapeutic doses. Antacids can also adsorb a large number of drugs, but often other mechanisms of interaction are also involved. For example, the tetracycline antibacterials can chelate with a number of divalent and trivalent metallic ions, such as calcium, aluminium, bismuth and iron, to form complexes that are both poorly absorbed and have reduced antibacterial effects (see 'Figure 1.1', (below)).

These metallic ions are found in dairy products and antacids. Separating the dosages by 2 to 3 hours goes some way towards reducing the effects of this type of interaction. The marked reduction in the bioavailability of penicillamine caused by some antacids seems also to be due to chelation, although adsorption may have some part to play. Colestyramine, an anionic exchange resin intended to bind bile acids and cholesterol metabolites in the gut, binds to a considerable number of drugs (e.g. digoxin, warfarin, levothyroxine), thereby reducing their absorption. 'Table 1.1', (p.2) lists some drugs that chelate, complex or adsorb other drugs.

(c) Changes in gastrointestinal motility

Since most drugs are largely absorbed in the upper part of the small intestine, drugs that alter the rate at which the stomach empties can affect absorption. Propantheline, for example, delays gastric emptying and reduces 'paracetamol (acetaminophen)' absorption, (p.192), whereas 'metoclopramide', (p.191), has the opposite effect. However, the total amount of drug absorbed remains unaltered. Propantheline also increases the absorption of 'hydrochlorothiazide', (p.959). Drugs with antimuscarinic effects decrease the motility of the gut, thus the tricyclic antidepressants can increase the absorption of 'dicoumarol', (p.457), probably because they

increase the time available for dissolution and absorption but in the case of 'levodopa', (p.690), they may reduce the absorption, possibly because the exposure time to intestinal mucosal metabolism is increased. The same reduced levodopa absorption has also been seen with 'homatropine', (p.682). These examples illustrate that what actually happens is sometimes very unpredictable because the final outcome may be the result of several different mechanisms.

(d) Induction or inhibition of drug transporter proteins

The oral bioavailability of some drugs is limited by the action of drug transporter proteins, which eject drugs that have diffused across the gut lining back into the gut. At present, the most well characterised drug transporter is 'P-glycoprotein', (p.8). Digoxin is a substrate of P-glycoprotein, and drugs that induce this protein, such as rifampicin, may reduce the bioavailability of 'digoxin', (p.938).

(e) Malabsorption caused by drugs

Neomycin causes a malabsorption syndrome, similar to that seen with non-tropical sprue. The effect is to impair the absorption of a number of drugs including 'digoxin', (p.906) and 'methotrexate', (p.642).

I.2. Drug distribution interactions

(a) Protein-binding interactions

Following absorption, drugs are rapidly distributed around the body by the circulation. Some drugs are totally dissolved in the plasma water, but many others are transported with some proportion of their molecules in solution and the rest bound to plasma proteins, particularly the albumins. The extent of this binding varies enormously but some drugs are extremely highly bound. For example, dicoumarol has only four out of every 1000 molecules remaining unbound at serum concentrations of 0.5 mg%. Drugs can also become bound to albumin in the interstitial fluid, and some, such as digoxin, can bind to the heart muscle tissue.

The binding of drugs to the plasma proteins is reversible, an equilibrium being established between those molecules that are bound and those that are not. Only the unbound molecules remain free and pharmacologically active, while those that are bound form a circulating but pharmacologically inactive reservoir which, in the case of drugs with a low-extraction ratio, is temporarily protected from metabolism and excretion. As the free molecules become metabolised, some of the bound molecules become unbound and pass into solution to exert their normal pharmacological actions, before they, in their turn are metabolised and excreted.

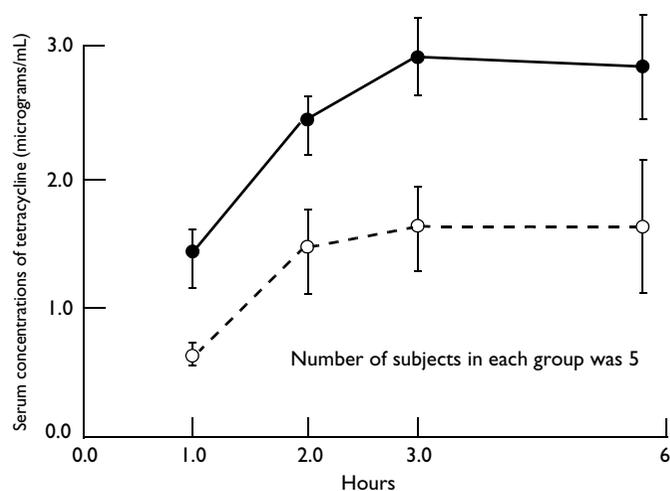

Fig. 1.1 A drug chelation interaction. Tetracycline forms a less-soluble chelate with iron if the two drugs are allowed to mix within the gut. This reduces the absorption and depresses the serum levels and the antibacterial effects (after Neuvonen PJ, *BMJ* (1970) 4, 532, with permission). The same interaction can occur with other ions such as Al³⁺, Ca²⁺, Mg²⁺, Bi²⁺ and Zn²⁺.

Depending on the concentrations and their relative affinities for the binding sites, one drug may successfully compete with another and displace it from the sites it is already occupying. The displaced (and now active) drug molecules pass into the plasma water where their concentration rises. So for example, a drug that reduces the binding from 99 to 95% would increase the unbound concentration of free and active drug from 1 to 5% (a fivefold increase). This displacement is only likely to raise the number of free and active molecules significantly if the majority of the drug is within the plasma rather than the tissues, so that only drugs with a low apparent volume of distribution (V_d) will be affected. Examples include the sulphonylureas, such as tolbutamide (96% bound, V_d 10 litres), oral anticoagulants, such as warfarin (99% bound, V_d 9 litres), and phenytoin (90% bound, V_d 35 litres). However, another important factor is clearance. Clinically important protein-binding interactions are unlikely if only a small proportion of the drug is eliminated during a single-passage through the eliminating organ (low-extraction ratio drugs), since any increase in free fraction will be effectively cleared. Most drugs that are extensively bound to plasma proteins and subject to displacement reactions (e.g. warfarin, sulphonylureas, phenytoin, methotrexate, and valproate) have low-extraction ratios, and drug exposure is therefore independent of protein-binding.

An example of displacement of this kind happens when patients stabilised on warfarin are given cloral hydrate because its major metabolite, trichloroacetic acid, is a highly bound compound that successfully displaces warfarin. This effect is only very short-lived because the now free and active warfarin molecules become exposed to metabolism as the blood flows through the liver, and the amount of drug rapidly falls. This transient increase in free warfarin levels is unlikely to change the anticoagulant effect of warfarin because the clotting factor complexes that are produced when warfarin is taken have a very long half-life, and thus take a long time to reach a new steady state. Normally no change in the warfarin dosage is needed (see 'Coumarins + Cloral and derivatives', p.396).

In vitro many commonly used drugs are capable of being displaced by others but in the body the effects seem almost always to be buffered so effectively that the outcome is not normally clinically important. It would therefore seem that the importance of this interaction mechanism has been grossly over-emphasised.¹⁻³ It is difficult to find an example of a clinically important interaction due to this mechanism alone. It has been suggested that this interaction mechanism is likely to be important only for drugs given intravenously that have a high-extraction ratio, a short pharmacokinetic-pharmacodynamic half-life and a narrow therapeutic index. Lidocaine has been given as an example of a drug fitting these criteria.³ Some drug interactions that were originally assumed to be due to changes in protein binding have subsequently been shown to have other interaction mechanisms involved. For example, inhibition of metabolism has subsequently been shown to be important in the interactions between 'warfarin and phenylbutazone', (p.434), and 'tolbutamide and sulphonamide', (p.506).

However, knowledge of altered protein binding is important in therapeutic drug monitoring. Suppose for example a patient taking phenytoin was given a drug that displaced phenytoin from its binding sites. The amount of free phenytoin would rise but this would be quickly eliminated by metabolism and excretion thereby keeping the amount of free active phenytoin the same. However, the total amount of phenytoin would now be reduced. Therefore if phenytoin was monitored using an assay looking at total phenytoin levels it may appear that the phenytoin is subtherapeutic and that the dose may therefore need increasing. However, as the amount of free active phenytoin is unchanged this would not be necessary and may even be dangerous.

Basic drugs as well as acidic drugs can be highly protein bound, but clinically important displacement interactions do not seem to have been described. The reasons seem to be that the binding sites within the plasma are different from those occupied by acidic drugs (alpha-1-acid glycoprotein rather than albumin) and, in addition, basic drugs have a large V_d with only a small proportion of the total amount of drug being within the plasma.

(b) Induction or inhibition of drug transporter proteins

It is increasingly being recognised that distribution of drugs into the brain, and some other organs such as the testes, is limited by the action of drug transporter proteins such as P-glycoprotein. These proteins actively transport drugs out of cells when they have passively diffused in. Drugs that are inhibitors of these transporters could therefore increase the uptake of drug

Table 1.2 Drugs affecting or metabolised by the cytochrome P450 isoenzyme CYP1A2

Inhibitors	Cimetidine	Ipriflavone
	Fluoroquinolones	Mexiletine
	Ciprofloxacin	Rofecoxib
	Enoxacin	Tacrine

1.3. Drug metabolism (biotransformation) interactions

Although a few drugs are cleared from the body simply by being excreted unchanged in the urine, most are chemically altered within the body to less lipid-soluble compounds, which are more easily excreted by the kidneys. If this were not so, many drugs would persist in the body and continue to exert their effects for a long time. This chemical change is called 'metabolism', 'biotransformation', 'biochemical degradation' or sometimes 'detoxification'. Some drug metabolism goes on in the serum, the kidneys, the skin and the intestines, but the greatest proportion is carried out by enzymes that are found in the membranes of the endoplasmic reticulum of the liver cells. If liver is homogenised and then centrifuged, the reticulum breaks up into small sacs called microsomes which carry the enzymes, and it is for this reason that the metabolising enzymes of the liver are frequently referred to as the 'liver microsomal enzymes'.

We metabolise drugs by two major types of reaction. The first, so-called phase I reactions (involving oxidation, reduction or hydrolysis), turn drugs into more polar compounds, while phase II reactions involve coupling drugs with some other substance (e.g. glucuronic acid, known as glucuronidation) to make usually inactive compounds.

The majority of phase I oxidation reactions are carried out by the haem-containing enzyme cytochrome P450. Cytochrome P450 is not a single entity, but is in fact a very large family of related isoenzymes, about 30 of which have been found in human liver tissue. However, in practice, only a few specific subfamilies seem to be responsible for most (about 90%) of the metabolism of the commonly used drugs. The most important isoenzymes are: CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1 and CYP3A4. Other enzymes involved in phase I metabolism include monoamine oxidases and epoxide hydrolases.

Less is known about the enzymes responsible for phase II conjugation reactions. However, UDP-glucuronyltransferases (UGT), methyltransferases, and N-acetyltransferases (NAT) are examples.

Although metabolism is very important in the body removing drugs, it is increasingly recognised that drugs can be adsorbed, distributed, or eliminated by transporters, the most well understood at present being 'P-glycoprotein', (p.8).

(a) Changes in first-pass metabolism

(i) Changes in blood flow through the liver

After absorption in the intestine, the portal circulation takes drugs directly to the liver before they are distributed by the blood flow around the rest of the body. A number of highly lipid-soluble drugs undergo substantial biotransformation during this first-pass through the gut wall and liver and there is some evidence that some drugs can have a marked effect on the extent of first pass metabolism by altering the blood flow through the liver. However, there are few clinically relevant examples of this, and many can be explained by other mechanisms, usually altered hepatic metabolism (see (ii) below). One possible example is the increase in rate of absorption of dofetilide with 'verapamil', (p.256), which has resulted in an increased incidence of torsade de pointes.

Another is the increase in bioavailability of high-extraction beta blockers with 'hydralazine', (p.847), possibly caused by altered hepatic blood flow, or altered metabolism.

(ii) Inhibition or induction of first-pass metabolism

The gut wall contains metabolising enzymes, principally the cytochrome P450 isoenzymes. In addition to the altered metabolism caused by changes in hepatic blood flow (see (i) above) there is evidence that some drugs can have a marked effect on the extent of first-pass metabolism by inhibiting or inducing the cytochrome P450 isoenzymes in the gut wall or in the liver. An example is the effect of grapefruit juice, which seems to inhibit the cytochrome P450 isoenzyme CYP3A4, mainly in the gut, and therefore reduces the metabolism of oral calcium-channel blockers. Although altering the amount of drug 'absorbed', these interactions are usually considered drug metabolism interactions. The effect of grapefruit on the metabolism of other drugs is discussed further under 'Drug-food interactions', (p.11).

(b) Enzyme induction

When barbiturates were widely used as hypnotics it was found necessary to keep increasing the dosage as time went by to achieve the same hypnotic effect, the reason being that the barbiturates increase the activity of the microsomal enzymes so that extent of metabolism and excretion increases. This phenomenon of enzyme stimulation or 'induction' not only accounts for the need for an increased barbiturate dose but if another drug that is metabolised by the same range of enzymes is also present, its enzymatic metabolism is similarly increased and larger doses are needed to maintain the same therapeutic effect. However, note that not all enzyme-inducing drugs induce their own metabolism (a process known as auto-induction). The metabolic pathway that is most commonly induced is phase I oxidation mediated by the cytochrome P450 isoenzymes. The main drugs responsible for induction of the most clinically important cytochrome P450 isoenzymes are listed in 'Table 1.2', (p.4), 'Table 1.3', (p.6), 'Table 1.4', (p.6). 'Figure 1.2', (see below) shows the reduction in trough cyclosporin levels when it is given with the enzyme inducer, St John's wort. 'St John's

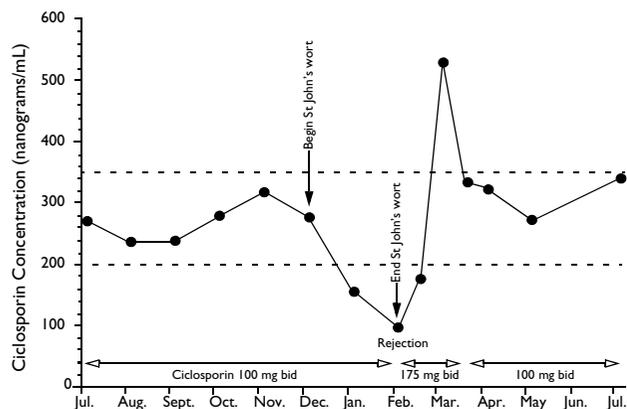

Fig. 1.2 An enzyme induction interaction. Chronology of cyclosporin trough concentrations (—●—) in a patient self-medicating with St John's wort. ----- = desired cyclosporin therapeutic range (after Barone GW, Gurley BJ, Ketel BL, Lightfoot ML, Abul-Ezz SR. Drug interaction between St. John's Wort and Cyclosporine. *Ann Pharmacother* (2000) 34: 1013–16, with permission).

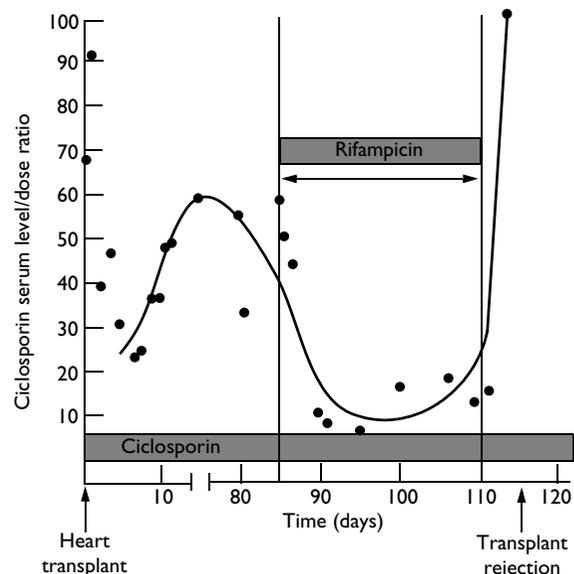

Fig. 1.3 An enzyme induction interaction. Rifampicin (600 mg daily plus isoniazid) increased the metabolism of cyclosporin in this patient, thereby reducing the trough serum levels. He subsequently died because his heart transplant was rejected (after *Transplant Proc.* 16, Van Buren D, Wideman CA, Ried M, Gibbons S, Van Buren CT, Jarowenko M, Flechner SM, Frazier OH, Cooley DA, Kahan BD. The antagonistic effect of rifampicin upon cyclosporine bioavailability. 1642–5, Copyright Elsevier (1984)).

wort', (p.1037), induces the metabolism of cyclosporin by induction of CYP3A4 and possibly also P-glycoprotein. 'Figure 1.3', (see above) shows the effects of another enzyme inducer, rifampicin (rifampin) on the serum levels of 'cyclosporin', (p.1022), presumably via its effects on CYP3A4. Phase II glucuronidation can also be induced. An example is when rifampicin induces the glucuronidation of 'zidovudine', (p.792).

The extent of the enzyme induction depends on the drug and its dosage, but it may take days or even 2 to 3 weeks to develop fully, and may persist for a similar length of time when the enzyme inducer is stopped. This means that enzyme induction interactions are delayed in onset and slow to resolve. Enzyme induction is a common mechanism of interaction and is not confined to drugs; it is also caused by the chlorinated hydrocarbon insecticides such as dicophane and lindane, and smoking tobacco.

If one drug reduces the effects of another by enzyme induction, it may be possible to accommodate the interaction simply by raising the dosage of the drug affected, but this requires good monitoring, and there are obvious hazards if the inducing drug is eventually stopped without remembering to reduce the dosage again. The raised drug dosage may be an overdose when the drug metabolism has returned to normal.

(c) Enzyme inhibition

More common than enzyme induction is the inhibition of enzymes. This results in the reduced metabolism of an affected drug, so that it may begin to accumulate within the body, the effect usually being essentially the same as when the dosage is increased. Unlike enzyme induction, which may take several days or even weeks to develop fully, enzyme inhibition can occur within 2 to 3 days, resulting in the rapid development of toxicity. The metabolic pathway that is most commonly inhibited is phase I oxidation by the cytochrome P450 isoenzymes. The main drugs responsible for inhibition of the most clinically important cytochrome P450 isoenzymes are listed in 'Table 1.2', (p.4), 'Table 1.3', (p.6), 'Table 1.4', (p.6). For example a marked increase occurred in the plasma levels of a single dose of sildenafil after ritonavir had also been taken for 7 days, probably because ritonavir inhibits the metabolism of sildenafil by CYP3A4 (see 'Phosphodiesterase type-5 inhibitors + Protease inhibitors', p.1273).

An example of inhibition of phase I hydrolytic metabolism, is the inhibition of epoxide hydrolase by valpromide, which increases the levels of 'carbamazepine', (p.537). Phase II conjugative metabolism can also be inhibited. Examples are the inhibition of carbamazepine glucuronidation by

Table I.3 Drugs affecting or metabolised by the CYP2 family of cytochrome P450 isoenzymes

'sodium valproate', (p.537), and the inhibition of methyltransferase by aminosaliclates causing raised levels of 'azathioprine', (p.665).

The clinical significance of many enzyme inhibition interactions depends on the extent to which the serum levels of the drug rise. If the serum levels remain within the therapeutic range the interaction may not be clinically important.

(d) Genetic factors in drug metabolism

An increased understanding of genetics has shown that some of the cytochrome P450 isoenzymes are subject to 'genetic polymorphism', which simply means that some of the population have a variant of the isoenzyme with different (usually poor) activity. The best known example is CYP2D6, for which a small proportion of the population have the variant with low activity and are described as being poor or slow metabolisers (about 5 to 10% in white Caucasians, 0 to 2% in Asians and black people). Which group any particular individual falls into is genetically determined. The majority who possess the isoenzyme are called 'fast or extensive metabolisers'. It is possible to find out which group any particular individual falls into by looking at the way a single dose of a test or 'probe' drug is metabolised. This varying ability to metabolise certain drugs may explain why some patients develop toxicity when given an interacting drug while others remain symptom free. CYP2D6, CYP2C9 and CYP2C19 also show polymorphism, whereas CYP3A4 does not, although there is still some broad variation in the population without there being distinct groups. The effects of CYP2C19 polymorphism are discussed in more detail in 'Gastrointestinal drugs', (p.960). At present, genotyping of cytochrome P450 isoenzymes is primarily a research tool and is not used clinically. In the future, it may become standard clinical practice and may be used to individualise drug therapy.¹

(e) Cytochrome P450 isoenzymes and predicting drug interactions

It is interesting to know which particular isoenzyme is responsible for the metabolism of drugs because by doing *in vitro* tests with human liver enzymes it is often possible to explain why and how some drugs interact. For example, ciclosporin is metabolised by CYP3A4, and we know that rifampicin (rifampin) is a potent inducer of this isoenzyme, whereas ketoconazole inhibits its activity, so that it comes as no surprise that rifampicin reduces the effects of ciclosporin and ketoconazole increases it.

What is very much more important than retrospectively finding out why two drugs interact, is the knowledge such *in vitro* tests can provide about forecasting which other drugs may possibly also interact. This may reduce the numbers of expensive clinical studies in subjects and patients and avoids waiting until significant drug interactions are observed in clinical use. A lot of effort is being put into this area of drug development.²⁻⁶ However, at present such prediction is, like weather forecasting, still a somewhat hit-and-miss business because we do not know all of the factors that may modify or interfere with metabolism. It is far too simplistic to think that we have all the answers just because we know which liver isoenzymes are concerned with the metabolism of a particular drug, but it is a very good start.

'Table 1.2', (p.4), 'Table 1.3', (p.6), 'Table 1.4', (p.6) are lists of drugs that are inhibitors, inducers, or substrates of the clinically important cytochrome P450 isoenzymes, and each drug has a cross reference to a monograph describing a drug interaction thought to occur via that mechanism. If a new drug is shown to be an inducer, or an inhibitor, and/or a substrate of a given isoenzyme, these tables could be used to predict likely drug interactions. However, what may happen *in vitro* may not necessarily work in clinical practice because all of the many variables which can come into play are not known (such as how much of the enzyme is available, the concentration of the drug at the site of metabolism, and the affinity of the drug for the enzyme). Remember too that some drugs can be metabolised by more than one cytochrome P450 isoenzyme (meaning that this other isoenzyme may be able to 'pick up' more metabolism to compensate for the inhibited pathway); some drugs (and their metabolites) can both induce a particular isoenzyme and be metabolised by it; and some drugs (or their metabolites) can inhibit a particular isoenzyme but not be metabolised by it. With so many factors possibly impinging on the outcome of giving two or more drugs together, it is very easy to lose sight of one of the factors (or not even know about it) so that the sum of 2 plus 2 may not turn out to be the 4 that you have predicted.

For example, ritonavir and other protease inhibitors are well known potent inhibitors of CYP3A4, and in clinical use increase the levels of many

drugs that are substrates of this isoenzyme. Methadone is a substrate of CYP3A4, and some *in vitro* data show that ritonavir (predictably) increased methadone levels. However, unexpectedly, in clinical use the protease inhibitors seem to decrease methadone levels, by a yet unknown mechanism (see, 'Opioids; Methadone + Protease inhibitors', p.182).

Another factor complicating the understanding of metabolic drug interactions is the finding that there is a large overlap between the inhibitors/inducers and substrates of P-glycoprotein (a 'drug transporter protein', (p.8)) and those of CYP3A4. Therefore, both mechanisms may be involved in many of the drug interactions previously thought to be due to effects on CYP3A4.

1.4. Drug excretion interactions

With the exception of the inhalation anaesthetics, most drugs are excreted either in the bile or in the urine. Blood entering the kidneys along the renal arteries is, first of all, delivered to the glomeruli of the tubules where molecules small enough to pass through the pores of the glomerular membrane (e.g. water, salts, some drugs) are filtered through into the lumen of the tubules. Larger molecules, such as plasma proteins, and blood cells are retained within the blood. The blood flow then passes to the remaining parts of the kidney tubules where active energy-using transport systems are able to remove drugs and their metabolites from the blood and secrete them into the tubular filtrate. The renal tubular cells additionally possess active and passive transport systems for the reabsorption of drugs. Interference by drugs with renal tubular fluid pH, with active transport systems and with blood flow to the kidney can alter the excretion of other drugs.

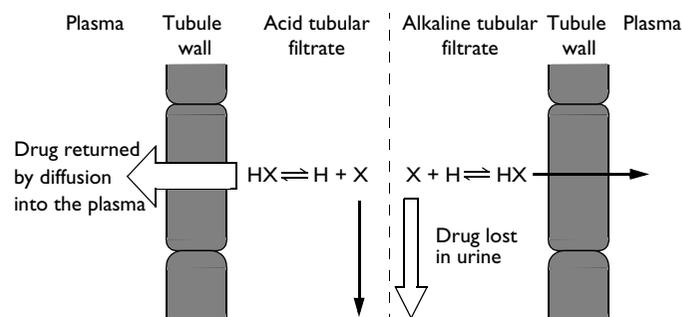

Fig. 1.4 An excretion interaction. If the tubular filtrate is acidified, most of the molecules of weakly acid drugs (HX) exist in an un-ionised lipid-soluble form and are able to return through the lipid membranes of the tubule cells by simple diffusion. Thus they are retained. In alkaline urine most of the drug molecules exist in an ionised non-lipid soluble form (X). In this form the molecules are unable to diffuse freely through these membranes and are therefore lost in the urine.

(a) Changes in urinary pH

As with drug absorption in the gut, passive reabsorption of drugs depends upon the extent to which the drug exists in the non-ionised lipid-soluble form, which in its turn depends on its pKa and the pH of the urine. Only the non-ionised form is lipid-soluble and able to diffuse back through the lipid membranes of the tubule cells. Thus at high pH values (alkaline), weakly acid drugs (pKa 3 to 7.5) largely exist as ionised lipid-insoluble molecules, which are unable to diffuse into the tubule cells and will there-

fore remain in the urine and be removed from the body. The converse will be true for weak bases with pKa values of 7.5 to 10.5. Thus pH changes that increase the amount in the ionised form (alkaline urine for acidic drugs, acid urine for basic drugs) increase the loss of the drug, whereas moving the pH in the opposite direction will increase their retention. 'Figure 1.4', (p.7) illustrates the situation with a weakly acidic drug. The clinical significance of this interaction mechanism is small, because although a very large number of drugs are either weak acids or bases, almost all are largely metabolised by the liver to inactive compounds and few are excreted in the urine unchanged. In practice therefore only a handful of drugs seem to be affected by changes in urinary pH (possible exceptions include changes in the excretion of 'quinidine', (p.277) or 'analgesic-dose aspirin', (p.135), due to alterations in urinary pH caused by antacids, and the increase in the clearance of 'methotrexate', (p.654), with urinary alkalinisers). In cases of overdose, deliberate manipulation of urinary pH has been used to increase the removal of drugs such as methotrexate and salicylates.

Table 1.5 Examples of interactions probably due to changes in renal transport

Drug affected	Interacting drug	Result of interaction
Cephalosporins Dapsone Methotrexate Penicillins Quinolones	Probenecid	Serum levels of drug affected raised; possibility of toxicity with some drugs
Methotrexate	Salicylates and some other NSAIDs	Methotrexate serum levels raised; serious methotrexate toxicity possible

(b) Changes in active renal tubular excretion

Drugs that use the same active transport systems in the renal tubules can compete with one another for excretion. For example, probenecid reduces the excretion of penicillin and other drugs. With the increasing understanding of drug transporter proteins in the kidneys, it is now known that probenecid inhibits the renal secretion of many other anionic drugs by organic anion transporters (OATs).¹ Probenecid possibly also inhibits some of the ABC transporters in the kidneys. The ABC transporter, P-glycoprotein, is also present in the kidneys, and drugs that alter this may alter renal drug elimination. See, 'Drug transporter proteins', (p.8), for further discussion. Some examples of drugs that possibly interact by alterations in renal transport are given in 'Table 1.5', (see above).

(c) Changes in renal blood flow

The flow of blood through the kidney is partially controlled by the production of renal vasodilatory prostaglandins. If the synthesis of these prostaglandins is inhibited the renal excretion of some drugs may be reduced. An interaction where this is the suggested mechanism is the rise in serum lithium seen with some NSAIDs, see 'Lithium + NSAIDs', p.1125.

(d) Biliary excretion and the entero-hepatic shunt

(i) Enterohepatic recirculation

A number of drugs are excreted in the bile, either unchanged or conjugated (e.g. as the glucuronide) to make them more water soluble. Some of the conjugates are metabolised to the parent compound by the gut flora and are then reabsorbed. This recycling process prolongs the stay of the drug within the body, but if the gut flora are diminished by the presence of an antibacterial, the drug is not recycled and is lost more quickly. This may possibly explain the rare failure of the oral contraceptives that can be brought about by the concurrent use of penicillins or tetracyclines, but see Mechanism in 'Hormonal contraceptives + Antibacterials; Penicillins', p.981. Antimicrobial-induced reductions in gut bacteria may reduce the activation of 'sulfasalazine', (p.973).

(ii) Drug transporters

Increasing research shows that numerous drug transporter proteins (both from the ABC family and SLC family, see 'Drug transporter proteins', (see below)) are involved in the hepatic extraction and secretion of drugs into the bile.² The relevance of many of these to drug interactions is still

unclear, but the bile salt export pump (ABCB11) is known to be inhibited by a variety of drugs including ciclosporin, glibenclamide, and bosentan. Inhibition of this pump may increase the risk of cholestasis, and the manufacturer of bosentan says that they should be avoided in patients taking bosentan (see 'glibenclamide', (p.515) and 'ciclosporin', (p.1026)).

1.5. Drug transporter proteins

Drugs and endogenous substances are known to cross biological membranes, not just by passive diffusion, but by carrier-mediated processes, often known as transporters. Significant advances in the identification of various transporters have been made, although the contribution of many of these to drug interactions in particular, is still unclear.^{1,2} The most well known is P-glycoprotein, which is a product of the MDR1 gene (ABCB1 gene) and a member of the ATP-binding cassette (ABC) family of efflux transporters.¹ Its involvement in drug interactions is discussed in (a) below.

Another ABC transporter is sister P-glycoprotein, otherwise called the bile salt export pump (BSEP or ABCB11).¹ It has been suggested that inhibition of this pump may increase the risk of cholestasis, see Drug transporters under 'Drug excretion interactions', (p.7).

Other transporters that are involved in some drug interactions are the organic anion transporters (OATs), organic anion-transporting polypeptides (OATPs) and organic cation transporters (OCTs), which are members of the solute carrier superfamily (SLC) of transporters.¹ The best known example of an OAT inhibitor is probenecid, which affects the renal excretion of a number of drugs, see Changes in active kidney tubule excretion under 'Drug excretion interactions', (p.7).

Table 1.6 Some possible inhibitors and inducers of P-glycoprotein shown to alter the levels of P-glycoprotein substrates in clinical studies¹

Inhibitors	Inducers
Atorvastatin	Ketoconazole
Clarithromycin	Propafenone
Dipyridamole	Quinidine
Erythromycin	Valspodar
Itraconazole	Verapamil
	Rifampicin
	St John's wort (<i>Hypericum perforatum</i>)

1. Mizuno N, Niwa T, Yotsumoto Y, Sugiyama Y. Impact of drug transporter studies on drug discovery and development. *Pharmacol Rev* (2003) 55, 425–61.

(a) P-glycoprotein interactions

More and more evidence is accumulating to show that some drug interactions occur because they interfere with the activity of P-glycoprotein. This is an efflux pump found in the membranes of certain cells, which can push metabolites and drugs out of the cells and have an impact on the extent of drug absorption (via the intestine), distribution (to the brain, testis, or placenta) and elimination (in the urine and bile). So, for example, the P-glycoprotein in the cells of the gut lining can eject some already-absorbed drug molecules back into the intestine resulting in a reduction in the total amount of drug absorbed. In this way P-glycoprotein acts as a barrier to absorption. The activity of P-glycoprotein in the endothelial cells of the blood-brain barrier can also eject certain drugs from the brain, limiting CNS penetration and effects.

The pumping actions of P-glycoprotein can be induced or inhibited by some drugs. So for example, the induction (or stimulation) of the activity of P-glycoprotein by rifampicin (rifampin) within the lining cells of the gut causes digoxin to be ejected into the gut more vigorously. This results in a fall in the plasma levels of digoxin (see 'Digitalis glycosides + Rifamycins', p.938). In contrast, verapamil appears to inhibit the activity of P-glycoprotein, and is well known to increase digoxin levels (see 'Digitalis glycosides + Calcium-channel blockers; Verapamil', p.916). Ketoconazole also has P-glycoprotein inhibitory effects, and has been shown to increase CSF levels of ritonavir, possibly by preventing the efflux of ritonavir from the CNS (see 'Protease inhibitors + Azoles; Ketoconazole',

p.814). Thus the induction or inhibition of P-glycoprotein can have an impact on the pharmacokinetics of some drugs. Note that there is evidence that P-glycoprotein inhibition may have a greater impact on drug distribution (e.g. into the brain) than on drug absorption (e.g. plasma levels).²

There is an overlap between CYP3A4 and P-glycoprotein inhibitors, inducers and substrates. Therefore, both mechanisms may be involved in many of the drug interactions traditionally thought to be due to changes in CYP3A4. 'Table 1.6', (p.8) lists some possible P-glycoprotein inhibitors and inducers. Many drugs that are substrates for CYP3A4 (see 'Table 1.4', (p.6)) are also substrates for P-glycoprotein. Digoxin and talinolol are examples of the few drugs that are substrates for P-glycoprotein but not CYP3A4.

P-glycoprotein is also expressed in some cancer cells (where it was first identified). This has led to the development of specific P-glycoprotein inhibitors, such as valspodar, with the aim of improving the penetration of cytotoxic drugs into cancer cells.

2. Pharmacodynamic interactions

Pharmacodynamic interactions are those where the effects of one drug are changed by the presence of another drug at its site of action. Sometimes the drugs directly compete for particular receptors (e.g. beta₂ agonists, such as salbutamol, and beta blockers, such as propranolol) but often the reaction is more indirect and involves interference with physiological mechanisms. These interactions are much less easy to classify neatly than those of a pharmacokinetic type.

2.1. Additive or synergistic interactions

If two drugs that have the same pharmacological effect are given together the effects can be additive. For example, alcohol depresses the CNS and, if taken in moderate amounts with normal therapeutic doses of any of a large number of drugs (e.g. anxiolytics, hypnotics, etc.), may cause excessive drowsiness. Strictly speaking (as pointed out earlier) these are not interactions within the definition given in 'What is a drug interaction?', (p.1). Nevertheless, it is convenient to consider them within the broad context of the clinical outcome of giving two drugs together.

Additive effects can occur with both the main effects of the drugs as well as their adverse effects, thus an additive 'interaction' can occur with antimuscarinic antiparkinson drugs (main effect) or butyrophenones (adverse effect) that can result in serious antimuscarinic toxicity (see 'Antipsychotics + Antimuscarinics', p.708).

Sometimes the additive effects are solely toxic (e.g. additive ototoxicity, nephrotoxicity, bone marrow depression, QT interval prolongation). Examples of these reactions are listed in 'Table 1.7', (see below). It is common to use the terms 'additive', 'summation', 'synergy' or 'potentiation' to describe what happens if two or more drugs behave like this. These words have precise pharmacological definitions but they are often used rather loosely as synonyms because in practice it is often very difficult to know the extent of the increased activity, that is to say whether the effects are greater or smaller than the sum of the individual effects.

The serotonin syndrome

In the 1950s a serious and life-threatening toxic reaction was reported in patients taking iproniazid (an MAOI) when they were given 'pethidine (meperidine)', (p.1140). The reasons were then not understood and even now we do not have the full picture. What happened is thought to have been due to over-stimulation of the 5-HT_{1A} and 5-HT_{2A} receptors and possibly other serotonin receptors in the central nervous system (in the brain stem and spinal cord in particular) due to the combined effects of these two drugs. It can occur exceptionally after taking only one drug, which causes over-stimulation of these 5-HT receptors, but much more usually it develops when two or more drugs (so-called serotonergic or serotomimetic drugs) act in concert. The characteristic symptoms (now known as the serotonin syndrome) fall into three main areas, namely altered mental status (agitation, confusion, mania), autonomic dysfunction (diaphoresis, diarrhoea, fever, shivering) and neuromuscular abnormalities (hyperreflexia,

incoordination, myoclonus, tremor). These are the 'Sternbach diagnostic criteria' named after Dr Harvey Sternbach who drew up this list of clinical features and who suggested that at least three of them need to be seen before classifying this toxic reaction as the serotonin syndrome rather than the neuroleptic malignant syndrome.¹

The syndrome can develop shortly after one serotonergic drug is added to another, or even if one is replaced by another without allowing a long enough washout period in between, and the problem usually resolves within about 24 hours if both drugs are withdrawn and supportive measures given. Non-specific serotonin antagonists (cyproheptadine, chlorpromazine, methysergide) have also been used for treatment. Most patients recover uneventfully, but there have been a few fatalities.

Table 1.7 Additive, synergistic or summation interactions

Drugs	Result of interaction
Antipsychotics + Antimuscarinics	Increased antimuscarinic effects; heat stroke in hot and humid conditions, adynamic ileus, toxic psychoses
Antihypertensives + Drugs that cause hypotension (e.g. Phenothiazines, Sildenafil)	Increased antihypertensive effects; orthostasis
Beta-agonist bronchodilators + Potassium-depleting drugs	Hypokalaemia
CNS depressants + CNS depressants Alcohol + Antihistamines Benzodiazepines + Anaesthetics, general Opioids + Benzodiazepines	Impaired psychomotor skills, reduced alertness, drowsiness, stupor, respiratory depression, coma, death
Drugs that prolong the QT interval + Other drugs that prolong the QT interval Amiodarone + Disopyramide	Additive prolongation of QT interval, increased risk of torsade de pointes
Methotrexate + Co-trimoxazole	Bone marrow megaloblastosis due to folic acid antagonism
Nephrotoxic drugs + Nephrotoxic drugs (e.g. Aminoglycosides, Ciclosporin, Cisplatin, Vancomycin)	Increased nephrotoxicity
Neuromuscular blockers + Drugs with neuromuscular blocking effects (e.g. Aminoglycosides)	Increased neuromuscular blockade; delayed recovery, prolonged apnoea
Potassium supplements + Potassium-sparing drugs (e.g. ACE inhibitors, Angiotensin II receptor antagonists, Potassium-sparing diuretics)	Hyperkalaemia

Following the first report of this syndrome, many other cases have been described involving 'tryptophan and MAOIs', (p.1151), the 'tricyclic anti-depressants and MAOIs', (p.1149), and, more recently, the 'SSRIs', (p.1142) but other serotonergic drugs have also been involved and the list continues to grow.

It is still not at all clear why many patients can take two, or sometimes several serotonergic drugs together without problems, while a very small number develop this serious toxic reaction, but it certainly suggests that there are as yet other factors involved that have yet to be identified. The full story is likely to be much more complex than just the simple additive effects of two drugs.

1. Sternbach H. The serotonin syndrome. *Am J Psychiatry* (1991) 148, 705–13.

2.2. Antagonistic or opposing interactions

In contrast to additive interactions, there are some pairs of drugs with activities that are opposed to one another. For example the coumarins can prolong the blood clotting time by competitively inhibiting the effects of dietary vitamin K. If the intake of vitamin K is increased, the effects of the

oral anticoagulant are opposed and the prothrombin time can return to normal, thereby cancelling out the therapeutic benefits of anticoagulant treatment (see 'Coumarins and related drugs + Vitamin K substances', p.458). Other examples of this type of interaction are listed in 'Table 1.8', (see below).

Drug affected	Interacting drugs	Results of interaction
ACE inhibitors or Loop diuretics	NSAIDs	Antihypertensive effects opposed
Anticoagulants	Vitamin K	Anticoagulant effects opposed
Antidiabetics	Glucocorticoids	Blood glucose-lowering effects opposed
Antineoplastics	Megestrol	Antineoplastic effects possibly opposed
Levodopa	Antipsychotics (those with dopamine antagonist effects)	Antiparkinsonian effects opposed
Levodopa	Tacrine	Antiparkinsonian effects opposed

2.3. Drug or neurotransmitter uptake interactions

A number of drugs with actions that occur at adrenergic neurones can be prevented from reaching those sites of action by the presence of other

drugs. The tricyclic antidepressants prevent the re-uptake of noradrenaline (norepinephrine) into peripheral adrenergic neurones. Thus patients taking tricyclics and given parenteral noradrenaline have a markedly increased response (hypertension, tachycardia); see 'Tricyclic antidepressants + Intotropes and Vasopressors', p.1237. Similarly, the uptake of guanethidine (and related drugs guanoclor, betanidine, debrisoquine, etc.) is blocked by 'chlorpromazine, haloperidol, tiotixene', (p.887), a number of 'amfetamine-like drugs', (p.886) and the 'tricyclic antidepressants', (p.888) so that the antihypertensive effect is prevented. The antihypertensive effects of clonidine are also prevented by the tricyclic antidepressants, one possible reason being that the uptake of clonidine within the CNS is blocked (see 'Clonidine + Tricyclic and related antidepressants', p.884). Some of these interactions at adrenergic neurones are illustrated in 'Figure 1.5', (see below).

E. Drug-herb interactions

The market for herbal medicines and supplements in the Western world has markedly increased in recent years, and, not surprisingly, reports of interactions with 'conventional' drugs have arisen. The most well known and documented example is the interaction of St John's wort (*Hypericum perforatum*) with a variety of drugs, see below. There have also been isolated reports of other herbal drug interactions, attributable to various mechanisms, including additive pharmacological effects.

Based on these reports, there are a growing number of reviews of herbal medicine interactions, which seek to predict likely interactions based on the, often hypothesised, actions of various herbs. Many of these predictions seem tenuous at best.

Rather than add to the volume of predicted interactions, at present, *Stockley's Drug Interactions* includes only those interactions for which there are published reports.

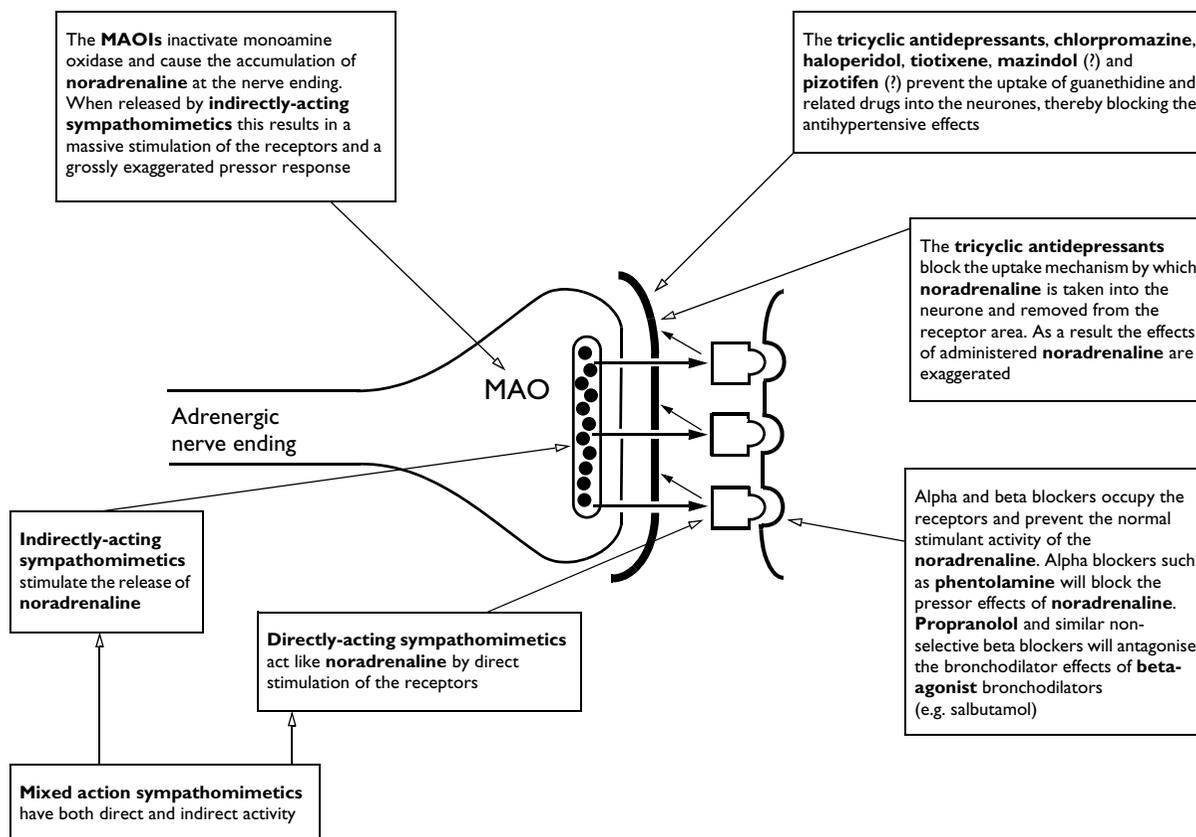

Fig. 1.5 Interactions at adrenergic neurones. A highly simplified composite diagram of an adrenergic neurone (molecules of noradrenaline (norepinephrine) indicated as (●) contained in a single vesicle at the nerve-ending) to illustrate in outline some of the different sites where drugs can interact. More details of these interactions are to be found in individual monographs.

To aid collection of data in this area, health professionals should routinely ask patients about their use of herbal medicines and supplements, and report any unexpected responses to treatment.

An additional problem in interpreting these interactions, is that the interacting constituent of the herb is usually not known and is therefore not standardised for. It could vary widely between different products, and batches of the same product.

St John's wort

An increasing number of reports have implicated St John's wort (*Hypericum perforatum*) in drug interactions. Evidence has shown that the herb can induce the cytochrome P450 isoenzyme CYP3A4, and can also induce 'P-glycoprotein', (p.8). Hence St John's wort decreases the levels of 'ciclosporin', (p.1037) and 'digoxin', (p.927), respectively. Other less certain evidence suggests that CYP2E1 and CYP1A2 may also be induced. St John's wort has serotonergic properties, and this has resulted in a pharmacodynamic interaction with the 'SSRIs', (p.1224), namely the development of the serotonin syndrome. St John's wort contains many possible constituents that could be responsible for its pharmacological effects. The major active constituents are currently considered to be hyperforin (a phloroglucinol) and hypericin (a naphthodianthrone). Hypericin is the only constituent that is standardised for, and then only in some St John's wort preparations.

F. Drug-food interactions

It is well established that food can cause clinically important changes in drug absorption through effects on gastrointestinal motility or by drug binding, see 'Drug absorption interactions', (p.3). In addition, it is well known that tyramine (present in some foodstuffs) may reach toxic concentrations in patients taking 'MAOIs', (p.1153). With the growth in understanding of drug metabolism mechanisms, it has been increasingly recognised that some foods can alter drug metabolism. Currently, grapefruit juice causes the most clinically relevant of these interactions, see (b) below.

(a) Cruciferous vegetables and charcoal-broiled meats

Cruciferous vegetables, such as brussels sprouts, cabbage, and broccoli, contain substances that are inducers of the cytochrome P450 isoenzyme CYP1A2. Chemicals formed by 'burning' meats additionally have these

properties. These foods do not appear to cause any clinically important drug interactions in their own right, but their consumption may add another variable to drug interaction studies, so complicating interpretation. In drug interaction studies where alteration of CYP1A2 is a predicted mechanism, it may be better for patients to avoid these foods during the study.

(b) Grapefruit juice

By chance, grapefruit juice was chosen to mask the taste of alcohol in a study of the effect of alcohol on felodipine, which led to the discovery that grapefruit juice itself markedly increased felodipine levels, see 'Calcium-channel blockers + Grapefruit juice', p.869. In general, grapefruit juice inhibits intestinal CYP3A4, and only slightly affects hepatic CYP3A4. This is demonstrated by the fact that intravenous preparations of drugs that are metabolised by CYP3A4 are not much affected, whereas oral preparations of the same drugs are. These interactions result in increased drug levels.

Some drugs that are not metabolised by CYP3A4 show decreased levels with grapefruit juice, such as 'fexofenadine', (p.588). The probable reason for this is that grapefruit juice is an inhibitor of some drug transporters (see 'Drug transporter proteins', (p.8)), and possibly affects organic anion-transporting polypeptides (OATPs), although inhibition of P-glycoprotein has also been suggested.

The active constituent of grapefruit juice is uncertain. Grapefruit contains naringin, which degrades during processing to naringenin, a substance known to inhibit CYP3A4. Because of this, it has been assumed that whole grapefruit will not interact, but that processed grapefruit juice will. However, subsequently some reports have implicated the whole fruit. Other possible active constituents in the whole fruit include bergamottin and dihydroxybergamottin.

G. Conclusions

It is now quite impossible to remember all the known clinically important interactions and how they occur, which is why this reference publication has been produced, but there are some broad general principles that need little memorising:

- Be on the alert with any drugs that have a narrow therapeutic window or where it is necessary to keep serum levels at or above a suitable level (e.g. anticoagulants, antidiabetic drugs, antiepileptics, antihypertensives, anti-infectives, antineoplastic cytotoxics, digitalis glycosides, immunosuppressants, etc.).
- Remember some of those drugs that are key enzyme inducers (e.g. phenytoin, barbiturates, rifampicin, etc) or enzyme inhibitors (e.g. azole antifungals, HIV-protease inhibitors, erythromycin, SSRIs).
- Think about the basic pharmacology of the drugs under consideration so that obvious problems (additive CNS depression for example) are not overlooked, and try to think what might happen if drugs that affect the same receptors are used together. And don't forget that many drugs affect more than one type of receptor.
- Keep in mind that the elderly are at risk because of reduced liver and renal function on which drug clearance depends.

2

ACE inhibitors and Angiotensin II receptor antagonists

ACE inhibitors (angiotensin-converting enzyme inhibitors) prevent the production of angiotensin II from angiotensin I. The angiotensin II receptor antagonists are more selective, and target the angiotensin II type I (AT₁) receptor, which is responsible for the pressor actions of angiotensin II.

Angiotensin II is involved in the renin-angiotensin-aldosterone system, which regulates blood pressure, sodium and water homeostasis by the kidneys, and cardiovascular function. Angiotensin II stimulates the synthesis and secretion of aldosterone and raises blood pressure via a direct vasoconstrictor effect.

Angiotensin converting enzyme (ACE) is identical to bradykinase, so ACE inhibitors may additionally reduce the degradation of bradykinin and affect enzymes involved in the production of prostaglandins.

Many of the interactions of the ACE inhibitors and angiotensin II receptor antagonists involve drugs that affect blood pressure. Consequently in most cases the result is either an increase in the hypotensive effect (e.g. 'alcohol', (p.48)) or a decrease in the hypotensive effect (e.g. 'indometacin', (p.28)).

In addition, due to their effects on aldosterone, the ACE inhibitors and angiotensin II antagonists may increase potassium concentrations and can therefore have additive hyperkalaemic effects with other drugs that cause elevated potassium levels. Furthermore, drugs that affect renal function may potentiate the adverse effects of ACE inhibitors and angiotensin II antagonists on the kidneys.

Most ACE inhibitor and angiotensin II receptor antagonist interactions are pharmacodynamic, that is, interactions that result in an alteration in drug effects rather than drug disposition, so in most cases interactions of individual drugs will be applicable to the group. *In vitro* experiments suggest that the role of cytochrome P450 isoenzymes in the metabolism and

interactions of the angiotensin II receptor antagonists (candesartan, eprosartan, irbesartan, losartan and valsartan) is small, although losartan, irbesartan, and to a minor extent, candesartan, are metabolised by CYP2C9. Only losartan and irbesartan were considered to have a theoretical potential for pharmacokinetic drug interactions involving the CYP2C9 enzyme.¹ See 'Angiotensin II receptor antagonists + Azoles', p.35. The ACE inhibitors do not appear to undergo interactions via cytochrome P450 isoenzymes.

'Table 2.1', (see below) lists the ACE inhibitors and the angiotensin II receptor antagonists. Although most of the interactions of the ACE inhibitors or angiotensin II receptor antagonists are covered in this section, if the ACE inhibitor or angiotensin II receptor antagonist is the affecting drug, the interaction is dealt with elsewhere.

1. Taavitsainen P, Kiukaanniemi K, Pelkonen O. In vitro inhibition screening of human hepatic P₄₅₀ enzymes by five angiotensin-II receptor antagonists. *Eur J Clin Pharmacol* (2000) 56, 135-40.

Table 2.1 ACE inhibitors and Angiotensin II receptor antagonists

Group	Drugs
ACE inhibitors	Benazepril, Captopril, Cilazapril, Delapril, Enalapril, Fosinopril, Imidapril, Lisinopril, Moexipril, Perindopril, Quinapril, Ramipril, Spirapril, Temocapril, Trandolapril, Zofenopril
Angiotensin II receptor antagonists	Candesartan, Eprosartan, Irbesartan, Losartan, Olmesartan, Telmisartan, Valsartan

ACE inhibitors + Allopurinol

Three cases of Stevens-Johnson syndrome (one fatal) and two cases of hypersensitivity have been attributed to the use of captopril with allopurinol. Anaphylaxis and myocardial infarction occurred in one man taking enalapril when given allopurinol. The combination of ACE inhibitors and allopurinol may increase the risk of leucopenia and serious infection, especially in renal impairment.

Clinical evidence

An elderly man with hypertension, chronic renal failure, congestive heart failure and mild polyarthritis receiving multiple drug treatment, which included **captopril** 25 mg twice daily and diuretics, developed fatal Stevens-Johnson syndrome about 5 weeks after starting to take allopurinol 100 mg twice daily.¹ The authors of the report noted that the manufacturer of **captopril** was aware of two other patients who developed the syndrome 3 to 5 weeks after allopurinol was started.¹ Another report describes fever, arthralgia and myalgia in a diabetic man with chronic renal failure who was also given **captopril** and allopurinol. He improved when the **captopril** was withdrawn.² Exfoliative facial dermatitis occurred in a patient with renal failure who was taking **captopril** and allopurinol.³ A man taking **enalapril** had an acute anaphylactic reaction with severe coronary spasm, culminating in myocardial infarction, within 20 minutes of taking allopurinol 100 mg. He recovered and continued to take **enalapril** without allopurinol.⁴

The UK manufacturer of **captopril** also warns that neutropenia and agranulocytosis, resulting in serious infection, have occurred in patients taking **captopril** and other ACE inhibitors, and that concurrent treatment with allopurinol may be a complicating factor, especially in those with renal impairment.⁵ However, the US manufacturer notes that, while renal impairment and a relatively high dose of **captopril** markedly increases the risk of neutropenia, no association between allopurinol and **captopril** and neutropenia has appeared in US reports.⁶

No significant pharmacokinetic changes were seen in 12 healthy subjects given allopurinol and **captopril** alone and in combination.⁷

Mechanism

Not understood. It is uncertain whether these are interactions because allopurinol alone can cause severe hypersensitivity reactions, particularly in the presence of renal failure and in conjunction with diuretic use. Captopril can also induce a hypersensitivity reaction.

Importance and management

These interactions are not clearly established, and the reaction appears to be rare and unpredictable. All that can be constructively said is that patients taking both drugs should be very closely monitored for any signs of hypersensitivity (e.g. skin reactions) or low white cell count (sore throat, fever), especially if they have renal impairment. The UK manufacturer of captopril recommends that differential white blood cell counts should be performed before adding allopurinol, then every 2 weeks during the first 3 months of treatment, and periodically thereafter.⁵ Similar caution and advice is given by the UK manufacturers of several other ACE inhibitors. For other possible interactions with ACE inhibitors that might result in an increased risk of leucopenia see also 'ACE inhibitors + Azathioprine', p.18 and 'ACE inhibitors + Procainamide', p.33.

ACE inhibitors + Angiotensin II receptor antagonists

The combined use of ACE inhibitors and angiotensin II receptor antagonists increases the risk of hypotension, renal impairment and hyperkalaemia in patients with heart failure.

Clinical evidence, mechanism, importance and management

Both ACE inhibitors and angiotensin II receptor antagonists can have adverse renal effects and can cause hyperkalaemia. These effects might be expected to be additive when they are used together. In one randomised clinical study in patients with heart failure taking ACE inhibitors, the addition of **candesartan** resulted in higher rates of withdrawals than placebo for renal impairment (increase in creatinine 7.8% versus 4.1%) and hyperkalaemia (3.4% versus 0.7%).¹ In another double-blind study in patients with heart failure, the combination of **valsartan** and captopril resulted in a higher incidence of adverse events leading to a dose reduction or a discontinuation of study treatment than either drug alone. For hypotension, treatment was discontinued in 90 (1.9%) of patients in the combined group, 70 (1.4%) of patients in the valsartan group, and 41 (0.8%) of patients in the captopril group. For renal causes the corresponding figures were 61 (1.3%), 53 (1.1%) and 40 (0.8%) of patients, respectively, and for hyperkalaemia the figures were 12 (0.2%), 7 (0.1%) and 4 (0.1%) of patients, respectively.²

Monitor renal function and serum potassium carefully when combination therapy is used.

ACE inhibitors + Antacids

An aluminium/magnesium hydroxide antacid reduced the bioavailability of captopril by 40%, but this did not seem to be clinically important. The bioavailability of fosinopril was reduced by about one-third by *Mylanta*. An antacid did not affect ramipril pharmacokinetics.

Clinical evidence

In 10 healthy subjects an antacid containing **aluminium/magnesium hydroxide** and **magnesium carbonate** reduced the AUC of a single 50-mg dose of **captopril** by about 40%, when compared with the fasting state. However, this did not alter the extent of the reduction in blood pressure.¹

Another study found that *Mylanta* [**aluminium/magnesium hydroxide** and **simeticone**²] reduced the bioavailability of **fosinopril** 20 mg by about one-third.³

It is briefly noted in a review that antacid use did not affect the pharmacokinetics of ramiprilat, the active metabolite of **ramipril**.⁴

Mechanism

The mechanism of this interaction is uncertain, but is unlikely to be due to elevated gastric pH since cimetidine did not have a similar effect.³

Importance and management

Note that greater decreases in **captopril** bioavailability (caused by 'food', (p.26)) were found not to be clinically relevant, therefore, it is unlikely the change seen with antacids will be clinically important.

However, with **fosinopril**, the manufacturers^{2,5} suggest separating administration of antacids by at least 2 hours.

The UK manufacturers of **quinapril**⁶ and **trandolapril**⁷ also warn that antacids may reduce the bioavailability of ACE inhibitors, quite possibly

based on the way these named ACE inhibitors interact, but there seems to be no evidence of a clinically significant interaction in practice.

ACE inhibitors + Antipsychotics

Marked postural hypotension occurred in a patient given chlorpromazine and captopril. The hypotensive adverse effects of antipsychotics such as the phenothiazines may be additive with the effects of ACE inhibitors.

Clinical evidence, mechanism, importance and management

A patient fainted and developed marked postural hypotension (standing blood pressure 66/48 mmHg) when given **captopril** 6.25 mg twice daily and **chlorpromazine** 200 mg three times daily. He had previously taken **chlorpromazine** with nadolol, prazosin and hydrochlorothiazide without any problems, although his blood pressure was poorly controlled on these drugs. Since the patient's blood pressure was quite elevated when taking **chlorpromazine** or **captopril** alone, there appeared to be a synergistic hypotensive effect between the two drugs.¹

The manufacturers of several ACE inhibitors warn that ACE inhibitors may enhance the hypotensive effects of certain antipsychotics, and that postural hypotension may occur. Some of these warnings are based, not unreasonably, on the adverse reactions seen with other ACE inhibitors or antihypertensives, but not necessarily on direct observations.² If postural hypotension occurs warn patients to lay down and elevate their legs if they feel faint or dizzy, and, when recovered, to get up slowly. Dosage adjustments may be necessary to accommodate this interaction.

ACE inhibitors + Aprotinin

Aprotinin suppressed the hypotensive action of captopril and enalapril in rats.

Clinical evidence, mechanism, importance and management

A study in spontaneously hypertensive *rats* found that aprotinin suppressed the hypotensive responses of **captopril** and **enalapril**.¹ Aprotinin is a proteolytic enzyme inhibitor that has many actions including antagonism of the kallikrein-kinin system, which in turn affects bradykinins and renin. It would therefore be expected to have complex interactions with the ACE inhibitors,² which also affect these proteins. However, there does not appear to be any evidence to suggest that this theoretical interaction is of clinical relevance.

ACE inhibitors + Aspirin

The antihypertensive efficacy of captopril and enalapril may be reduced by high-dose aspirin in about 50% of patients. Low-dose aspirin (less than or equal to 100 mg daily) appears to have little effect. It is unclear whether aspirin attenuates the benefits of ACE

inhibitors in heart failure. The likelihood of an interaction may depend on disease state and its severity.

Renal failure has been reported in a patient taking captopril and aspirin.

Clinical evidence

A. Effects on blood pressure

(a) Captopril

Aspirin 600 mg every 6 hours for 5 doses did not significantly alter the blood pressure response to a single 25 to 100-mg dose of captopril in 8 patients with essential hypertension. However, the prostaglandin response to captopril was blocked in 4 of the 8, and in these patients, the blood pressure response to captopril was blunted.¹ In another study, aspirin 75 mg daily did not alter the antihypertensive effects of captopril 25 mg twice daily in 15 patients with hypertension.²

(b) Enalapril

Two groups of 26 patients, one with mild to moderate hypertension taking enalapril 20 mg twice daily and the other with severe primary hypertension taking enalapril 20 mg twice daily (with nifedipine 30 mg and atenolol 50 mg daily), were given test doses of aspirin 100 and 300 mg daily for 5 days. The 100-mg dose of aspirin did not alter the efficacy of the antihypertensive drugs, but the 300-mg dose reduced the antihypertensive efficacy in about half the patients in both groups. In these patients, the antihypertensive effects were diminished by 63% in those with mild to moderate hypertension and by 91% in those with severe hypertension.³ In contrast, another study in 7 patients with hypertension taking enalapril (mean daily dose 12.9 mg) found that aspirin 81 mg or 325 mg daily for 2 weeks did not have any significant effect on blood pressure.⁴ A further study in 18 patients also found that aspirin 100 mg daily for 2 weeks did not alter the antihypertensive effect of enalapril 20 or 40 mg daily.⁵

(c) Unspecified ACE inhibitors

In a randomised study, the use of low-dose aspirin 100 mg daily for 3 months did not alter blood pressure control in patients taking calcium-channel blockers or ACE inhibitors, when compared with placebo.⁶ Similarly, in a re-analysis of data from the Hypertension Optimal Treatment (HOT) study, long-term low-dose aspirin 75 mg daily did not interfere with the blood pressure-lowering effects of the antihypertensive drugs studied, when compared with placebo. Of 18 790 treated hypertensive patients, about 82% received a calcium-channel blocker, usually felodipine alone or in combination, and 41% received an ACE inhibitor, usually in combination with felodipine.⁷

B. Effects in coronary artery disease and heart failure

Various pharmacological studies have looked at the *short-term* effects of the combination of ACE inhibitors and aspirin on haemodynamic parameters. In one study in 40 patients with decompensated heart failure, aspirin 300 mg given on the first day and 100 mg daily thereafter antagonised the short-term haemodynamic effects of **captopril** 50 mg given every 8 hours for 4 days. The **captopril**-induced increase in cardiac index and the reduction in peripheral vascular resistance and pulmonary wedge pressure were all abolished.⁸ In another study, in 15 patients with chronic heart failure receiving treatment with ACE inhibitors (mainly **enalapril** 10 mg twice daily), aspirin in doses as low as 75 mg impaired vasodilatation induced by arachidonic acid.⁹ In yet another study, aspirin 325 mg daily worsened pulmonary diffusion capacity and made the ventilatory response to exercise less effective in patients taking **enalapril** 10 mg twice daily, but did not exert this effect in the absence of ACE inhibitors.¹⁰ However, results from studies are inconsistent. In a review,¹¹ five of 7 studies reported aspirin did not alter the haemodynamic effects of ACE inhibitors whereas the remaining two did. In one of these studies showing an adverse interaction between aspirin and **enalapril**, **ticlopidine** did not interact with **enalapril**.¹²

A number of large clinical studies of ACE inhibitors, mostly post-myocardial infarction, have been re-examined to see if there was a difference in outcome between those receiving aspirin at baseline, and those not. The results are summarised in 'Table 2.2', (p.15). However, in addition to the problems of retrospective analysis of non-randomised parameters, the studies vary in the initiation and duration of aspirin and ACE inhibitor treatment and the length of follow-up, the degree of heart failure or ischaemia, the prognosis of the patients, and the final end point (whether compared with placebo or with the benefits of aspirin or ACE inhibitors). The conclusions are therefore conflicting, and, although two meta-analyses of

Table 2.2 Sub-group analyses of clinical studies assessing the interaction between aspirin and ACE inhibitors

<i>Study and patients</i>	<i>Aspirin dose</i>	<i>ACE inhibitor</i>	<i>Follow-up</i>	<i>Finding</i>	<i>Refs</i>
Evidence of an interaction					
SOLVD 6512 patients treated for heart failure or prevention of heart failure	Not reported	Enalapril	37 to 41 months	Combined treatment associated with reduced benefits compared with enalapril alone.	1
CONSENSUS II 6090 patients with acute MI	Not reported	Enalapril	6 months	Effect of enalapril less favourable in those taking aspirin at baseline.	2
GUSTO-I 31622 post-MI patients without heart failure	Not reported	Not reported	11 months (starting 30 days post MI)	Combined use associated with higher mortality than aspirin alone (mortality rates 3.3 vs 1.6%).	3
EPILOG 2619 patients undergoing coronary angioplasty	325 mg daily	Not reported	12 months	Combined use associated with higher mortality than aspirin alone (mortality rates 3.7 vs 1.2%).	3
AIRE 1986 patients after acute MI, with heart failure	Not reported	Ramipril 2.5 to 5 mg twice daily started 3 to 10 days after MI	15 months (average)	Trend towards greater benefit of ramipril in those not receiving aspirin.	4
No evidence of an interaction					
BIP Secondary prevention of MI in 1197 patients with coronary artery disease	250 mg daily	Captopril or enalapril	5 years (average)	Lower death rate in those on combined therapy than those on ACE inhibitor alone (19 vs 27%).	5
SAVE 2231 patients with left ventricular dysfunction after MI	Not reported	Captopril 75 to 150 mg daily	42 months (average)	Trend towards greater benefits of captopril when taken with aspirin.	6
HOPE Prevention of cardiovascular events in 9297 patients without left ventricular dysfunction or heart failure	Not reported	Ramipril 10 mg daily	About 4.5 years	Benefits of ramipril not affected by aspirin.	7
CATS Early treatment of acute MI in 298 patients	80 to 100 mg daily	Captopril	1 year	Benefits of captopril not affected by aspirin. Better prognosis in those on aspirin.	8
ISIS-4 Early treatment of acute MI in 58050 patients	Not reported	Captopril 100 mg daily	At 5 weeks and 1 year	Benefits of captopril not affected by aspirin.	9
Meta analysis of AIRE, SAVE, SOLVD and TRACE 12763 patients with left ventricular dysfunction or heart failure with or without MI	Not reported	Captopril, enalapril, ramipril,trandolapril	35 months (average)	Benefits of ACE inhibitors observed even if aspirin given.	10
Meta analysis of CCS-I, CONSENSUS II, GISSI-3, and ISIS-4 Early treatment of MI in 96712 patients	160 to 325 mg daily	Captopril, enalapril, lisinopril	30 days	ACE inhibitor reduced 30-day mortality from 15.1 to 13.8%. ACE inhibitor plus aspirin reduced 30-day mortality from 6.7 to 6.3%.	11
TRACE 1749 patients with left ventricular dysfunction after acute MI	Not reported	Trandolapril 1 to 4 mg daily	24 to 50 months	Trend towards greater benefit of trandolapril in those receiving aspirin (mortality of 45% with ACE inhibitor, and 34% with ACE inhibitor plus aspirin).	12
SMILE 1556 patients with acute MI	Not reported	Zofenopril 7.5 mg increasing to 30 mg twice daily for 6 weeks	At 6 weeks and 1 year	Benefits of zofenopril not significantly affected by aspirin.	13

these studies found no interaction, an editorial¹³ disputes the findings of one of these analyses.¹⁴ In addition to these sub-group analyses, there have been a number of retrospective cohort studies. A retrospective study involving 576 patients with heart failure requiring hospitalisation, showed a trend towards an increased incidence of early readmissions (within 30 days after discharge) for heart failure among subjects treated with ACE inhibitors and aspirin, compared with those treated with ACE inhibitors without aspirin (16% versus 10%). In patients without coronary artery disease the increase in readmissions was statistically significant (23% versus 10%).¹⁵ However, long-term survival in heart failure was not affected by the use of aspirin with ACE inhibitors. Furthermore, among patients with coronary artery disease there was a trend towards improvement in mortality in patients treated with the combination, compared with ACE inhibitor without aspirin (40% versus 56%).¹⁶ Similarly, a lack of adverse interaction was found in a retrospective study involving 14 129 elderly patients who survived a hospitalisation for acute myocardial infarction. However, the added benefit of the combination over patients who received either aspirin or ACE inhibitors alone was not statistically significant.¹⁷ Similarly, in another cohort of patients discharged after first hospitalisation for heart failure, there was no increase in mortality rates or readmission rates in those taking aspirin and ACE inhibitors.¹⁸ In another retrospective analysis in patients with stable left ventricular systolic dysfunction, no decrease in survival was seen in patients receiving ACE inhibitors, when comparing those also receiving aspirin (mean dose 183 mg daily, 74% 200 mg or

less) and those not.¹⁹ Conversely, another study found that, compared to patients not taking aspirin, the use of high-dose aspirin (325 mg daily or more) with an ACE inhibitor was associated with a small but statistically significant 3% increase in the risk of death, whereas low-dose aspirin (160 mg daily or less) was not.²⁰

C. Effects on renal function

Acute renal failure developed in a woman taking **captopril** when she started to take aspirin for arthritis. Renal function improved when both were stopped.²¹ However, in a re-analysis of data from the Hypertension Optimal Treatment (HOT) study, long-term low-dose aspirin 75 mg daily had no effect on changes in serum creatinine, estimated creatinine clearance or the number of patients developing renal impairment, when compared with placebo. Of 18 790 treated hypertensive patients, 41% received an ACE inhibitor.⁷

D. Pharmacokinetic studies

A single-dose study in 12 healthy subjects found that the pharmacokinetics of **benazepril** 20 mg and aspirin 325 mg were not affected by concurrent use.²²

Mechanism

Some, but not all the evidence suggests that prostaglandins may be involved in the hypotensive action of ACE inhibitors, and that aspirin, by inhibiting prostaglandin synthesis, may partially antagonise the effect of ACE inhibitors on blood pressure. This effect appears to depend on the

dose of aspirin and may also be dependent on sodium status and plasma renin, and therefore it does not occur in all patients.

The beneficial effects of ACE inhibitors in heart failure and ischaemic heart disease are thought to be due, in part, to the inhibition of the breakdown of kinins, which are important regulators of prostaglandin and nitric oxide synthesis. Such inhibition promotes vasodilatation and afterload reduction. Aspirin may block these beneficial effects by inhibiting cyclo-oxygenase (COX) and thus prostaglandin synthesis, causing vasoconstriction, decreased cardiac output and worsening heart failure.^{11,23}

Importance and management

Low-dose aspirin (less than or equal to 100 mg daily) does not alter the **antihypertensive efficacy** of captopril and enalapril. No special precautions would therefore seem to be required with ACE inhibitors and these low doses of aspirin. A high dose of aspirin (2.4 g daily) has been reported to interact in 50% of patients in a single study. Aspirin 300 mg daily has been reported to interact in about 50% of patients in another study, whereas 325 mg daily did not interact in further study. Thus, at present, it appears that if an ACE inhibitor is used with aspirin in doses higher than 300 mg daily, blood pressure should be monitored more closely, and the ACE inhibitor dosage raised if necessary. Intermittent use of aspirin should be considered as a possible cause of erratic control of blood pressure in patients on ACE inhibitors.

Both ACE inhibitors and aspirin are often taken by patients with **coronary artery disease**, and ACE inhibitors are used in **chronic heart failure**, which is often associated with coronary heart disease. The information about a possible interaction between ACE inhibitors and aspirin in heart failure is conflicting. This may be due to much of the clinical data being obtained from retrospective non-randomised analyses.²³ It may also be a factor of different disease states. For example, an interaction may be less likely to be experienced in patients with heart failure of ischaemic aetiology than those with non-ischaemic causes, because of the added benefits of aspirin in ischaemic heart disease.²⁴ The available data, and its implications, have been extensively reviewed and commented on.^{11,13,23-32} Some commentators have advised that, if possible, aspirin should be avoided in patients requiring long-term treatment for heart failure, particularly if heart failure is severe.^{13,27} Others suggest avoiding aspirin in heart failure unless there are clear indications, such as atherosclerosis.^{11,23,28,29} The use of lower doses of aspirin (80 to 100 mg daily rather than greater than or equal to 325 mg daily) in those with heart failure taking ACE inhibitors has also been suggested.^{24,25,28} US guidelines from 2005 on chronic heart failure³³ state that, "Many physicians believe the data justify prescribing aspirin and ACE inhibitors together when there is an indication for use of aspirin," while recognising that not all physicians agree. The guidelines say that further study is needed. European guidelines state that there is little evidence to support using ACE inhibitors and aspirin together in heart failure. The guidelines say aspirin can be used as prophylaxis after prior myocardial infarction, but that it should be avoided in patients with recurrent hospitalisation for worsening heart failure.³⁴ NICE guidelines in the UK make no comment about the combination of ACE inhibitors and aspirin. They say that all patients with heart failure due to left ventricular systolic dysfunction should be considered for treatment with an ACE inhibitor, and that aspirin (75 to 150 mg once daily) should be prescribed for patients with the combination of heart failure and atherosclerotic arterial disease (including coronary heart disease).³⁵ Data from ongoing randomised studies may provide further insight. Until these are available, combined low-dose aspirin and ACE inhibitors may continue to be used where there is a clear indication for both.

An increased risk of deterioration in **renal function** or **acute renal failure** appears to occur rarely with the combination of aspirin and ACE inhibitors. The routine monitoring of renal function, which is advised with ACE inhibitors, should be sufficient to detect any interaction.

ACE inhibitors + Azathioprine

Anaemia has been seen in patients given azathioprine with enalapril or captopril. Leucopenia occasionally occurs when captopril is given with azathioprine.

Clinical evidence

(a) Anaemia

Nine out of 11 kidney transplant patients taking ACE inhibitors (**enalapril** or **captopril**) had a fall in their haematocrit from 34% to 27%, and a fall in their haemoglobin from 11.6 g/dL to 9.5 g/dL when ciclosporin was replaced by azathioprine. Two patients were switched back to ciclosporin, and had a prompt rise in their haematocrit. Another 10 patients taking both drugs similarly developed a degree of anaemia, when compared with 10 others not taking an ACE inhibitor (haematocrit of 33% compared with 41%, and a haemoglobin of 11.5 g/dL compared with 13.9 g/dL).¹ A later study by the same group of workers (again in patients taking **enalapril** or **captopril**) confirmed these findings: however, no pharmacokinetic interaction was found between **enalapril** and azathioprine.²

(b) Leucopenia

A patient whose white cell count fell sharply when taking both **captopril** 50 mg daily and azathioprine 150 mg daily, did not develop leucopenia when each drug was given separately.³ Another patient who was given **captopril** (increased to 475 mg daily [sic] then reduced to 100 mg daily) immediately after discontinuing azathioprine, developed leucopenia. She was later successfully treated with **captopril** 4 to 6 mg daily [sic].⁴ Other patients have similarly shown leucopenia when given both drugs;^{5,6} in one case this did not recur when the patient was rechallenged with **captopril** alone (at a lower dose).⁶

Mechanism

The anaemia appears to be due to suppression of erythropoietin by the ACE inhibitors, and azathioprine may cause patients to be more susceptible to this effect.² The cause of the leucopenia is unknown. It may just be due to the additive effects of both drugs.

Importance and management

Anaemia caused by captopril and enalapril has been seen in kidney transplant patients and in dialysis patients (see 'ACE inhibitors and Angiotensin II receptor antagonists + Epoetin', p.25). The evidence that this effect can be potentiated by azathioprine is limited, but it would be prudent to monitor well if these drugs are used together.

The evidence that the concurrent use of ACE inhibitors and azathioprine increases the risk of leucopenia is also limited. However, the UK manufacturer of captopril recommends that captopril should be used with extreme caution in patients receiving **immunosuppressants**, especially if there is renal impairment. They advise that in such patients differential white blood cell counts should be performed before starting captopril, then every 2 weeks in the first 3 months of treatment, and periodically thereafter.⁷ The UK manufacturers of a number of other ACE inhibitors also state in their prescribing information that the use of ACE inhibitors with **cytostatic** or **immunosuppressive drugs** may lead to an increased risk of leucopenia. For other potential interactions with ACE inhibitors that might lead to an increased risk of leucopenia, see also 'ACE inhibitors + Allopurinol', p.13, and 'ACE inhibitors + Procainamide', p.33.

ACE inhibitors + Beta blockers

The combination of an ACE inhibitor with a beta blocker is in established clinical use. Enhanced blood pressure-lowering effects occur, as would be expected. Although not all combinations have been studied, no clinically significant pharmacokinetic interactions appear to occur between the ACE inhibitors and beta blockers.

Clinical evidence

(a) Atenolol

In a double-blind, crossover study in hypertensive subjects, the combination of atenolol 50 mg once daily and **enalapril** 20 mg once daily increased the hypotensive effect of either drug alone, but the effect was 30 to 50% less than additive.¹

(b) Bisoprolol

In a single-dose, placebo-controlled, crossover study in 16 healthy men, bisoprolol 5 mg given with **imidapril** 10 mg did not significantly influence the pharmacokinetics of its active metabolite imidaprilat, and the pharmacodynamic effects, including blood pressure and heart rate reductions, were mainly additive.²

(c) Propranolol

Propranolol 80 mg three times daily did not affect the pharmacokinetics of a single 20-mg dose of **quinapril** in 10 healthy subjects.³ The pharmacokinetics of **ramipril** 5 mg daily were unaffected by propranolol 40 mg twice daily.⁴ Similarly, the manufacturer of **fosinopril** reports that the bioavailability of fosinoprilat, its active metabolite, was not altered by propranolol.^{5,6} Another study found no significant pharmacokinetic interaction between **cilazapril** 2.5 mg daily and propranolol 120 mg daily in healthy subjects, but the reductions in blood pressure were about doubled and long-lasting in healthy subjects and in patients with hypertension.^{7,8}

Mechanism, importance and management

Both ACE inhibitors and beta blockers lower blood pressure by different mechanisms, and therefore the enhanced blood pressure-lowering effects of the combination would be expected. No pharmacokinetic interactions have been demonstrated. The combination of an ACE inhibitor and a beta blocker is clinically useful in a number of cardiovascular disorders.

ACE inhibitors + Calcium-channel blockers

The combination of an ACE inhibitor and a dihydropyridine calcium-channel blocker is in established clinical use for hypertension, and, although only certain combinations have been studied, no clinically significant pharmacokinetic interactions appear to

occur between the dihydropyridine-type calcium-channel blockers and ACE inhibitors.

Clinical evidence

(a) Amlodipine

A study in 12 healthy subjects indicated that there was no pharmacokinetic interaction between single doses of amlodipine 5 mg and **benazepril** 10 mg.¹

(b) Felodipine

No pharmacokinetic interaction occurred between single doses of felodipine 10 mg and **ramipril** 5 mg in healthy subjects. The blood pressure-lowering effect of the combination was greater, and **ramipril** attenuated the reflex tachycardia caused by felodipine.²

(c) Manidipine

In a single-dose crossover study in 18 healthy subjects, the concurrent use of manidipine 10 mg and **delapril** 30 mg did not significantly alter the pharmacokinetics of either drug or their main metabolites.³

(d) Nicardipine

In a study in 12 patients with hypertension taking **enalapril** 20 mg daily, the addition of nicardipine 30 mg three times daily for 2 weeks did not alter the pharmacokinetics of **enalapril**.⁴ The manufacturer of **spirapril** briefly noted in a review that the concurrent use of spirapril and nicardipine increased **spirapril** plasma levels by about 25% and those of its active metabolite, spiraprilat, by about 45%. The bioavailability of nicardipine was reduced by 30%. It was assumed that the interaction took place at the absorption site. However, the changes were not considered clinically relevant.⁵

(e) Nifedipine

No evidence of either a pharmacokinetic or adverse pharmacodynamic interaction was seen in 12 healthy subjects given single doses of nifedipine retard 20 mg and **lisinopril** 20 mg; the effects on blood pressure were additive.⁶ Similarly, there was no pharmacokinetic interaction between single doses of slow-release nifedipine 20 mg and **benazepril** 10 mg in healthy subjects; the effects on blood pressure were additive and the tachycardic effect of nifedipine was attenuated by benazepril.⁷ The manufacturer of **fosinopril** notes that the bioavailability of fosinoprilat, the active metabolite, was not altered by nifedipine.^{8,9} Similarly, the manufacturer of **moexipril** notes that no clinically important pharmacokinetic interaction occurred with nifedipine in healthy subjects.¹⁰

(f) Nilvadipine

In a single-dose, placebo-controlled, crossover study in 16 healthy subjects, no pharmacokinetic interaction occurred between nilvadipine 8 mg and **imidapril** 10 mg, and the pharmacodynamic effects, including the reduction in blood pressure and the decrease in total peripheral resistance, were mostly additive.¹¹

Mechanism

No pharmacokinetic interactions are expected. Enhanced blood pressure-lowering effects occur, as would be expected.

Importance and management

No important pharmacokinetic interactions have been demonstrated. The combination of an ACE inhibitor and a dihydropyridine calcium-channel blocker is clinically useful in the treatment of hypertension. A number of products combining an ACE inhibitor with a calcium-channel blocker are available. It is generally advised that these combination products are only used in patients who have already been stabilised on the individual components in the same proportions.

ACE inhibitors + Capsaicin

An isolated report describes a woman taking an ACE inhibitor who developed a cough each time she used a topical cream containing capsaicin.

Clinical evidence, mechanism, importance and management

A 53-year-old woman who had been taking an unnamed ACE inhibitor for several years, complained of cough each time she applied *Axsain*, a cream containing capsaicin 0.075%, to her lower extremities. Whether this reaction would have occurred without the ACE inhibitor was not determined,¹ but cough is a recognised adverse effect of ACE inhibitors and pre-treatment with an ACE inhibitor has been shown to enhance the cough caused by inhaled capsaicin.¹ This potential interaction is probably of little general clinical importance.

1. Hakas JF. Topical capsaicin induces cough in patient receiving ACE inhibitor. *Ann Allergy* (1990) 65, 322.

ACE inhibitors + Clonidine

Potential of the antihypertensive effect of clonidine by ACE inhibitors can be clinically useful.¹ However, limited evidence suggests that the effects of captopril may be delayed when patients are switched from clonidine.² Note that sudden withdrawal of clonidine may cause rebound hypertension.

ACE inhibitors + Colloids

Acute hypotension has been seen in a few patients taking enalapril when they were given a rapid infusion of albumin-containing stable plasma protein solution (SPPS). Another case occurred in an infant taking captopril when given albumin 4%. A few other cases have been described with gelatin-type colloids in patients taking ACE inhibitors (cilazapril, enalapril, lisinopril).

Clinical evidence

(a) Albumin

A woman taking **enalapril** 10 mg in the morning, underwent surgery for groin lymph node resection under spinal and general anaesthesia. When she was given a rapid infusion of 500 mL of the albumin solution, **stable plasma protein solution (SPPS, Commonwealth Serum Laboratories, Melbourne, Australia)**, her pulse rose to 90 to 100 bpm and systolic blood pressure fell from 100 to 60 mmHg and a red flush was noted on all exposed skin. The blood pressure was controlled at 90 to 95 mmHg with metaraminol 4.5 mg, given over 10 minutes. When the **SPPS** was finished, the blood pressure and pulse rate spontaneously stabilised.¹ **SPPS** is a 5% plasma protein solution prepared by the cold ethanol fractionation process and pasteurisation from human plasma (volunteer donors). It contains sodium octanoate as a stabiliser.¹ Two very similar cases have been recorded in patients taking **enalapril** when given **SPPS**.^{2,3} The manufacturer of **SPPS** notes that **captopril** has also been involved in this hypotensive interaction.⁴

A 20-month-old infant taking **captopril** was haemodynamically stable for 35 minutes after induction of anaesthesia while awaiting a donor kidney, but then developed hypotension after a bolus dose of 20 mL of albumin 4% (*Albumex*) was given. This was reversed with dopamine infusion.⁵

(b) Gelatin-based colloids

A report describes 3 cases of severe hypotension in patients taking ACE inhibitors (**lisinopril**, **enalapril**) while undergoing joint replacement surgery, and after they had been given a gelatin-based plasma expander (*Gelofusin*), which contains 4% succinylated gelatin in saline. The hypotension was resistant to ephedrine and methoxamine, and responded to adrenaline or dobutamine, which was required for 24 hours and 3 days in two cases. Anaphylactoid reactions were excluded as a cause of the hypotension.⁶ In another similar case, a patient taking **cilazapril** developed hypotension refractory to sodium chloride 0.9% after induction of anaesthesia, and this worsened when a gelatin-type colloid (*Gelafundina*) was given.⁷

Mechanism

Not fully established, but it is believed that SPPS contains low levels of pre-kallikrein activator, which stimulates the production of bradykinin, which can cause vasodilatation and hypotension. Normally the bradykinin is destroyed by kininase II (ACE), but this is delayed by the ACE inhibitor so that the hypotensive effects are exaggerated and prolonged.^{3,8} In the case with albumin 4%, a sample of the albumin used was analysed, and it was found to contain less prekallikrein activating factor than maximum permissible levels.⁵ It was suggested that the infusion of gelatin-based colloids somehow resulted in raised plasma kinin levels associated with inhibition of ACE.⁶

Importance and management

The interaction with SPPS would appear to be established and of clinical importance, and would apply to all ACE inhibitors. The author of one report suggested that if rapid expansion of intravascular volume is needed in patients taking ACE inhibitors, an artificial colloid might be a safer choice than SPPS.¹ The manufacturer of SPPS also recommended using an alternative plasma volume expander, including other albumin solutions.⁴ It should be noted that following these reports SPPS was withdrawn from the Australasian market.⁹ However, note that a case has also occurred with albumin 4%, and cases have also been attributed to synthetic colloid solutions containing gelatin. It may be that this is just an unpredictable effect of colloids in patients taking ACE inhibitors. See also 'Anaesthetics, general + Antihypertensives', p.94, for discussion of the marked hypotension sometimes seen during induction of anaesthesia in patients taking ACE inhibitors.

ACE inhibitors + Co-trimoxazole or Trimethoprim

Two reports describe serious hyperkalaemia, apparently caused by the use of trimethoprim with enalapril or quinapril in association with renal impairment.

Clinical evidence

A 40-year-old woman with a lung transplant (taking ciclosporin, azathioprine, prednisolone, **enalapril**, gentamicin inhalation, salbutamol and acetylcysteine) developed life-threatening hyperkalaemia of 6.8 mmol/L

when she was treated with high-dose co-trimoxazole 120 mg/kg daily for suspected *Pneumocystis pneumonia*. The co-trimoxazole (sulfamethoxazole/trimethoprim) and **enalapril** were stopped and she was treated with sodium chloride 0.9%, mannitol and furosemide. After 12 hours her serum potassium had decreased to 4.6 mmol/L and she began to recover over a period of a week, but she then developed fatal septic shock with multi-organ failure.¹

In another case, an elderly man treated with **quinapril** 20 mg daily for essential hypertension was found to have hyperkalaemia (serum potassium 7 to 7.4 mmol/L) and azotaemia after 20 days of treatment with co-trimoxazole for mild acute pyelonephritis. Co-trimoxazole and **quinapril** were stopped, and nifedipine was given to control blood pressure. After treatment with dextrose, insulin, sodium polystyrene sulfonate and calcium gluconate, the azotaemia and hyperkalaemia resolved over 36 hours.²

Mechanism

Hyperkalaemia has been reported in patients receiving co-trimoxazole alone.³ This is attributed to the trimethoprim component, which can have a potassium-sparing effect on the distal part of the kidney tubules. ACE inhibitors reduce aldosterone synthesis, which results in reduced renal loss of potassium. The interaction is probably due to the additive effects of these two mechanisms, compounded by impaired renal function.^{1,2}

Importance and management

Clinical examples of this interaction seem to be few, but the possibility of hyperkalaemia with either trimethoprim or ACE inhibitors alone, particularly with other factors such as renal impairment, is well documented. Thus it may be prudent to monitor potassium levels if this combination is used. It has been suggested that trimethoprim should probably be avoided in elderly patients with chronic renal impairment taking ACE inhibitors, and that patients with AIDS taking an ACE inhibitor for associated nephropathy should probably discontinue this treatment during treatment with high-dose co-trimoxazole.²

ACE inhibitors + Dialysis or Transfusion membranes

An anaphylactoid reaction can occur in patients taking ACE inhibitors within a few minutes of starting haemodialysis using high-flux polyacrylonitrile membranes ('AN 69'). Anaphylactoid reactions have also been reported in patients taking ACE inhibitors undergoing low-density lipoprotein apheresis. In addition, hypotensive reactions associated with blood transfusions through leucoreduction filters have occurred in patients taking ACE inhibitors.

Clinical evidence, mechanism, importance and management

(a) High-flux dialysis

In a retrospective study, 9 of 236 haemodialysis patients treated with **high-flux polyacrylonitrile membranes ('AN 69')** were found to have had anaphylactoid reactions (severe hypotension, flushing, swelling of face and/or tongue, and dyspnoea) within 5 minutes of starting haemodialysis. Treatment with an ACE inhibitor had been recently started in all 9 patients (7 **enalapril**, 1 **captopril**, 1 **lisinopril**). The anaphylactoid reactions disappeared in all 6 patients who discontinued the ACE inhibitor. Two other patients were given a filter rinsing procedure (the 'Bioprime' rinse method) and a new dialysis membrane, and in the final patient further anaphylactoid reactions were prevented by cellulose-triacetate haemofiltration while the ACE inhibitor was continued.¹ Similar reactions have been reported elsewhere and are thought to be bradykinin mediated.^{2,3} The CSM in the UK has advised that the combination of ACE inhibitors and such membranes should be avoided, either by substituting an alternative membrane or an alternative antihypertensive drug.⁴

(b) Lipoprotein apheresis

Anaphylactoid reactions occurred in 2 patients taking ACE inhibitors during removal of low-density lipoproteins (LDL apheresis) with dextran sulfate adsorption.⁵ Further reactions were reported in 6 patients taking either **captopril** or **enalapril** and dextran sulfate apheresis. When the interval between the last dose of the ACE inhibitor and the apheresis was prolonged to 12 to 30 hours no further adverse reactions occurred.⁶ However, other workers found lengthening the interval to be ineffective in one patient.⁷ The manufacturer of **enalapril** suggests temporarily withholding the ACE inhibitor before each apheresis,⁸ but other manufacturers of ACE inhibitors recommend using a different class of antihypertensive drug^{9,10} or changing the method of lipoprotein reduction.^{9,11}

(c) Transfusion reactions

A report describes 8 patients receiving ACE inhibitors and blood transfusions through bedside **leucoreduction filters** who experienced severe hypotensive reactions. The reactions were attributed to bradykinin generation during blood filtration and prevention of bradykinin breakdown due to the ACE inhibitors. Six of the patients tolerated subsequent transfusions, but 3 had discontinued their medication the day before the planned transfusion and one received washed (plasma-depleted) components. One patient experienced a second reaction, but then received washed red cells and had no reaction.¹²

ACE inhibitors + Diuretics; Loop, Thiazide and related

The combination of captopril or other ACE inhibitors with loop or thiazide diuretics is normally safe and effective, but ‘first dose hypotension’ (dizziness, lightheadedness, fainting) can occur, particularly if the dose of diuretic is high, and often in association with various predisposing conditions. Renal impairment, and even acute renal failure, have been reported. Diuretic-induced hypokalaemia may still occur when ACE inhibitors are used with these potassium-depleting diuretics.

Clinical evidence

(a) First dose hypotensive reaction

The concurrent use of **captopril** or other ACE inhibitors and loop or thiazide diuretics is normally safe and effective, but some patients experience ‘first dose hypotension’ (i.e. dizziness, lightheadedness, fainting) after taking the first one or two doses of the ACE inhibitor. This appears to be associated with, and exaggerated by, certain conditions (such as heart failure, renovascular hypertension, haemodialysis, high levels of renin and angiotensin, low-sodium diet, dehydration, diarrhoea or vomiting) and/or hypovolaemia and sodium depletion caused by diuretics, particularly in high doses. A study describes one woman whose blood pressure of 290/150 mmHg failed to respond to a 10-mg intravenous dose of **furosemide**. After 30 minutes she was given **captopril** 50 mg orally and within 45 minutes her blood pressure fell to 135/60 mmHg, and she required an infusion of saline to maintain her blood pressure.¹ In another study, a

man developed severe postural hypotension shortly after **furosemide** was added to **captopril** treatment.²

Starting with a low dose of the ACE inhibitor reduces the risk of first-dose hypotension. In a study in 8 patients with hypertension, treated with a diuretic (mainly **furosemide** or **hydrochlorothiazide**) for at least 4 weeks, **captopril** was started in small increasing doses from 6.25 mg. Symptomatic postural hypotension was seen in 2 of the 8 patients, but was only mild and transient.³

Hypotension is more common in patients with heart failure who are receiving large doses of diuretics. In a study in 124 patients with severe heart failure, all receiving **furosemide** (mean dose 170 mg daily; range 80 to 500 mg daily) and 90 also receiving the potassium-sparing diuretic spironolactone, the addition of **captopril** caused transient symptomatic hypotension in 44% of subjects. The **captopril** dose had to be reduced, and in 8 patients it was later discontinued. In addition, four patients developed symptomatic hypotension after 1 to 2 months of treatment, and **captopril** was also discontinued in these patients.⁴

There is some evidence that in patients with heart failure the incidence of marked orthostatic hypotension requiring treatment discontinuation in the first 36 hours was lower with **perindopril** 2 mg once daily than **captopril** 6.25 mg three times daily (6 of 357 cases versus 16 of 368 cases, respectively).⁵

(b) Hypokalaemia

In one study, the reduction in plasma potassium was greater with **hydrochlorothiazide** 25 mg daily than with **hydrochlorothiazide** combined with **cilazapril** 2.5 mg daily, showing that cilazapril reduced the potassium-depleting effect of **hydrochlorothiazide**.⁶ In one analysis, 7 of 21 patients taking potassium-depleting diuretics given ACE inhibitors for heart failure developed hypokalaemia. This was corrected by potassium supplementation in 2 cases, an increase in the ACE inhibitor dose in 3 cases, and the use of a potassium-sparing diuretic in the remaining 2 cases.⁷ In another report, a woman taking **furosemide** 80 to 120 mg daily remained hypokalaemic despite also taking **ramipril** 10 mg daily and spironolactone 50 to 200 mg daily.⁸ However, note that the addition of ‘spironolactone’, (p.23) to ACE inhibitors and loop or thiazide diuretics has generally resulted in an increased incidence of hyperkalaemia.

(c) Hyponatraemia

An isolated report describes a patient who developed severe hyponatraemia 3 days after **bendroflumethiazide** 10 mg daily was added to treatment with **enalapril** 20 mg daily and atenolol 100 mg daily. However, on 2 other occasions she only developed mild hyponatraemia when given **bendroflumethiazide** alone.⁹ An earlier study reported changes in sodium balance due to **captopril** in all 6 patients with renovascular hypertension and in 11 of 12 patients with essential hypertension; sodium loss occurred in 12 of the 18 patients.¹

(d) Impairment of renal function

The risk of ACE inhibitor-induced renal impairment in patients with or without renovascular disease can be potentiated by diuretics.^{10–13} In an analysis of 74 patients who had been treated with **captopril** or **lisinopril**, reversible acute renal failure was more common in those who were also treated with a diuretic (**furosemide** and/or **hydrochlorothiazide**) than those who were not (11 of 33 patients compared with 1 of 41 patients).¹² Similarly, in a prescription-event monitoring study, **enalapril** was associated with raised creatinine or urea in 75 patients and it was thought to have contributed to the deterioration in renal function and subsequent deaths in 10 of these patients. However, 9 of these 10 were also receiving loop or thiazide diuretics, sometimes in high doses.¹⁴ Retrospective analysis of a controlled study in patients with hypertensive nephrosclerosis identified 8 of 34 patients who developed reversible renal impairment when treated with **enalapril** and various other antihypertensives including a diuretic (**furosemide** or **hydrochlorothiazide**). In contrast, 23 patients treated with placebo and various other antihypertensives did not develop renal impairment. Subsequently, **enalapril** was tolerated by 7 of the 8 patients without deterioration in renal function and 6 of these patients later received diuretics.¹⁵ One patient was again treated with **enalapril** with recurrence of renal impairment, but discontinuation of the diuretics (**furosemide**, **hydrochlorothiazide**, and triamterene) led to an improvement in renal function despite the continuation of **enalapril**.¹⁶

Renal impairment in patients taking ACE inhibitors and diuretics has also been described in patients with heart failure. A patient with congestive heart failure and pre-existing moderate renal impairment developed

acute non-oliguric renal failure while taking **enalapril** 20 mg daily and **furosemide** 60 to 80 mg daily, which resolved when the sodium balance was restored.¹⁷ In a study involving 90 patients with severe congestive heart failure who were receiving **furosemide** and spironolactone, a decline in renal function occurred in 18 patients during the first month after initiation of **captopril** treatment; mean serum creatinine levels rose from 220 to 300 micromol/L. All the patients were receiving high daily doses of **furosemide** and all had renal impairment before receiving the first dose of **captopril**.⁴

Acute, fatal, renal failure developed in 2 patients with cardiac failure within 4 weeks of being treated with **enalapril** and **furosemide**, and in 2 similar patients renal impairment developed over a longer period.¹⁸ Reversible renal failure developed in a patient with congestive heart failure when **captopril** and **metolazone** were given.¹⁹

(e) Pharmacokinetic and diuresis studies

1. **Furosemide**. A study in healthy subjects given single doses of **enalapril** and **furosemide** found no evidence of any pharmacokinetic interaction between these drugs.²⁰ Another study in hypertensive patients found that **captopril** did not affect the urinary excretion of **furosemide**, nor its subsequent diuretic effects.²¹ However, a further study in healthy subjects showed that, although **captopril** did not alter urinary excretion of **furosemide**, it did reduce diuresis.²² Yet another study in healthy subjects found that **captopril** reduced the urinary excretion of **furosemide**, and reduced the diuretic response during the first 20 minutes to approximately 50%, and the natriuretic response to almost 30%, whereas **enalapril** and **ramipril** did not significantly alter the diuretic effects of **furosemide**.²³ In one single-dose study in healthy subjects the concurrent use of **benazepril** and **furosemide** reduced the urinary excretion of **furosemide** by 10 to 20%, whereas **benazepril** pharmacokinetics were unaffected.²⁴ **Lisinopril** did not alter plasma levels or urinary excretion of **furosemide** in one study, nor did it alter urinary electrolyte excretion.²⁵ Similarly, **furosemide** did not affect the pharmacokinetics of **lisinopril** either in single-dose or multiple-dose regimens.²⁶

2. **Hydrochlorothiazide**. In a single-dose, randomised, crossover study in 19 elderly patients the pharmacokinetics of **enalapril** 10 mg were unaffected by hydrochlorothiazide 25 mg. However, there was a significant reduction in renal clearance and a significant increase in the AUC of its metabolite, enalaprilat, resulting in higher serum levels of the active drug. This acute interaction was not thought to be clinically significant for long-term use.²⁷ No pharmacokinetic interaction occurred between **cilazapril** and hydrochlorothiazide in healthy subjects or patients with hypertension.⁶ Similarly, no significant pharmacokinetic interaction occurred between **imidapril** and hydrochlorothiazide in healthy subjects²⁸ and neither **captopril** nor **ramipril** altered the diuresis induced by hydrochlorothiazide.²³ The manufacturer of **spirapril** briefly noted in a review that there was no clinically relevant pharmacokinetic interaction between **spirapril** and hydrochlorothiazide.²⁹ Furthermore no pharmacokinetic interaction was found when **spirapril** and hydrochlorothiazide were given together as a bi-layer tablet.³⁰ There was no clinically important pharmacokinetic interaction when **moexipril** was given with hydrochlorothiazide in a single-dose study in healthy subjects.³¹

Mechanism

The first dose hypotension interaction is not fully understood. One suggestion is that if considerable amounts of salt and water have already been lost as a result of using a diuretic, the resultant depletion in the fluid volume (hypovolaemia) transiently exaggerates the hypotensive effects of the ACE inhibitor.

The cases of hypokalaemia are simply a result of the potassium-depleting effects of the diuretics outweighing the potassium-conserving effects of the ACE inhibitor. The converse can also occur.

Thiazides can cause hyponatraemia, but this enhanced effect may have been due to an alteration in renal haemodynamics caused by the ACE inhibitor; sustained angiotensin-converting enzyme blockade can produce natriuresis.¹

Marked decreases in blood pressure may affect renal function, and in addition, the renin-angiotensin system plays an important role in the maintenance of the glomerular filtration rate when renal artery pressure is

diminished.¹¹ However, diuretic-induced sodium depletion may also be an important factor in the renal impairment sometimes observed with ACE inhibitors.

Importance and management

The 'first dose hypotension' interaction between ACE inhibitors and diuretics is well established. The BNF in the UK notes that the risk is higher when the dose of diuretic is greater than **furosemide** 80 mg daily or equivalent,³² and suggest that, in patients taking these doses of diuretics, consideration should be given to temporarily stopping the diuretic or reducing its dosage a few days before the ACE inhibitor is added. If this is not considered clinically appropriate, the first dose of the ACE inhibitor should be given under close supervision. In all patients taking diuretics, therapy with ACE inhibitors should be started with a very low dose, even in patients at low risk (e.g. those with uncomplicated essential hypertension on low-dose thiazides). To be on the safe side, all patients should be given a simple warning about what can happen and what to do when they first start concurrent use. The immediate problem (dizziness, lightheadedness, faintness), if it occurs, can usually be solved by the patient lying down. Taking the first dose of the ACE inhibitor just before bedtime is also preferable. Any marked hypotension is normally transient, but if problems persist it may be necessary temporarily to reduce the diuretic dosage. There is usually no need to avoid the combination just because an initially large hypotensive response has occurred.

A number of products combining an ACE inhibitor with a thiazide diuretic are available for the treatment of hypertension. These products should be used only in those patients who have been stabilised on the individual components in the same proportions.

The use of ACE inhibitors in patients taking potassium-depleting diuretics does not always prevent **hypokalaemia** developing. Serum potassium should be monitored.

There is only an isolated report of **hyponatraemia**, but be aware that ACE inhibitors may affect the natriuresis caused by diuretics.

The cases of **renal impairment** cited emphasise the need to monitor renal function in patients on ACE inhibitors and diuretics. If increases in blood urea and creatinine occur, a dosage reduction and/or discontinuation of the diuretic and/or ACE inhibitor may be required. In a statement, the American Heart Association comments that acute renal failure complicating ACE inhibitor therapy is almost always reversible and repletion of extracellular fluid volume and discontinuation of diuretic therapy is the most effective approach. In addition, withdrawal of interacting drugs, supportive management of fluid and electrolytes, and temporary dialysis, where indicated, are the mainstays of therapy.¹³ Combined use of ACE inhibitors, diuretics and NSAIDs may be particularly associated with an increased risk of renal failure, see 'ACE inhibitors + NSAIDs', p.28.

The possibility of undiagnosed renal artery stenosis should also be considered.

None of the **pharmacokinetic** changes observed appear to be clinically significant.

ACE inhibitors + Diuretics; Potassium-sparing

Combining ACE inhibitors with potassium-sparing diuretics (e.g. amiloride), including the aldosterone antagonists (epplerenone, spironolactone) can result in clinically relevant or severe hyperkalaemia, particularly if other important risk factors are present.

Clinical evidence

(a) Amiloride

The serum potassium levels of two patients taking furosemide and unnamed potassium-sparing diuretics and potassium supplements rose by 18% and 24%, respectively, when they were given **captopril** 37.5 to 75 mg daily. The rises occurred within one or two days. No clinical signs or symptoms of hyperkalaemia were seen, but one of the patients had an increase in serum potassium to above the upper limits of normal.¹ In a post-marketing survey, 2 patients who had **enalapril**-associated renal impairment and died were also receiving amiloride and furosemide; one was also taking potassium supplements.² Four diabetic patients, with some renal impairment, developed life-threatening hyperkalaemia with severe cardiac arrhythmias and deterioration of renal function, within 8 to 18 days of having an amiloride/hydrochlorothiazide diuretic added to their **enalapril** treatment. Two suffered cardiac arrest and both died. Potassium levels were between 9.4 and 11 mmol/L. A fifth diabetic patient with normal renal function developed hyperkalaemia soon after receiving amiloride/hydrochlorothiazide and **captopril** in combination.³ A further case of hyperkalaemia and cardiac arrest was associated with **enalapril** and furosemide/amiloride.⁴ In a brief report, the manufacturers of **enalapril** noted that, of 47 serious cases of hyperkalaemia, 25 patients were taking one or more (unnamed) potassium-sparing drugs.⁵

However, a retrospective comparison of 35 patients treated for congestive heart failure found no differences in the serum potassium levels of 16 patients taking furosemide, amiloride and **enalapril**, when compared with

another group of 19 patients taking furosemide and amiloride alone. Patients were excluded from the comparison if they had significant renal impairment or were taking other drugs likely to affect serum potassium.⁶

(b) Eplerenone

In the large Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS)⁷ the rate of serious hyperkalaemia (defined as serum potassium 6 mmol/L or greater) was 5.5% in patients randomised to eplerenone 25 mg to 50 mg daily (mean 43 mg daily⁸) compared with 3.9% in those receiving placebo: this represented a 1.4-fold increase. More eplerenone recipients required hospitalisation for serious hyperkalaemia than placebo recipients (12 versus 3). The risk of serious hyperkalaemia was increased in those with a baseline creatinine clearance of less than 50 mL/minute (10.1% in the eplerenone group and 5.9% in the placebo group). Eplerenone reduced the risk of serious hypokalaemia (defined as serum potassium 3.5 mmol/L or less) by 1.6-fold (8.4% versus 13.1%). About 86% of patients in this study were also receiving an ACE inhibitor or an angiotensin II receptor antagonist, and about 60% were receiving a (loop⁸) diuretic.⁷ However, the US manufacturer states that the rate of maximum potassium levels greater than 5.5 mmol/L were similar in EPHESUS regardless of the use of ACE inhibitor or angiotensin II receptor antagonist.⁸ Nevertheless, they mention another study in diabetics with microalbuminuria, where a higher dose of eplerenone 200 mg combined with **enalapril** 10 mg increased the frequency of hyperkalaemia (defined as serum potassium greater than 5.5 mmol/L) from 17% with enalapril alone to 38% with the combination: this represented a 2.2-fold increase.⁸

(c) Spironolactone

Twenty-five of 262 patients treated with ACE-inhibitors and spironolactone, and admitted to hospital for medical emergencies, were found to have serious hyperkalaemia (defined as serum potassium levels greater than 6 mmol/L: 11 patients had levels of at least 8 mmol/L). These 25 patients were elderly (mean age 74 years) and being treated for hypertension, heart failure, diabetic nephropathy, proteinuria, or nephrotic syndrome; 22 had associated renal impairment and 12 had signs of volume depletion. Combined treatment had been started an average of 25 weeks before the admission. The ACE inhibitors involved were **enalapril**, **captopril**, **lisinopril** or **perindopril**, and the average dose of spironolactone used was 57 mg daily; 10 patients were also receiving a loop or thiazide diuretic. Nineteen patients had ECG changes associated with hyperkalaemia; 2 of them died, another 2 required temporary pacing for third-degree heart block, and 2 others survived after sustained ventricular tachycardia and fibrillation. Of the 19 patients, 17 required at least one haemodialysis session and 12 were admitted to intensive care.⁹ Other authors reported a higher 36% incidence of hyperkalaemia (serum potassium levels greater than 5 mmol/L) in 42 patients hospitalised for heart failure and prescribed spironolactone. It was suggested that this may be due to the excessively large doses of spironolactone prescribed,¹⁰ although the specific doses were not mentioned.

Similar risk factors were found in an analysis of 44 patients with congestive heart failure who were taking spironolactone and ACE inhibitors or angiotensin II receptor antagonists, and were admitted for treatment of life-threatening hyperkalaemia. Their mean age was 76 years, the mean dose of spironolactone was 88 mg daily (range 25 to 200 mg daily) and 40 patients also received loop diuretics. In addition, 35 patients had type II diabetes. Haemodialysis was given to 37 patients, but in 6 patients renal function did not recover and 2 patients developed fatal complications.¹¹ A number of other cases of serious hyperkalaemia have been described in patients taking ACE inhibitors (**captopril**, **enalapril**, **lisinopril**), spironolactone, and loop (furosemide or bumetanide) or thiazide (hydroflumethiazide) diuretics.^{2,12–16} Many of the patients were elderly and were receiving spironolactone 50 to 100 mg daily,^{2,12,15} but one diabetic patient with moderate renal impairment was receiving just 25 mg of spironolactone daily.¹⁴ In one report, the 4 cases had associated **enalapril**-induced deterioration in renal function and died.² Another patient died from complete heart block.¹²

One of the factors that affects the incidence of hyperkalaemia appears to be the dose of spironolactone. In a preliminary investigation for the Randomised Aldactone Evaluation Study (RALES), 214 patients with congestive heart failure taking an ACE inhibitor and a loop diuretic with or without digitalis, were randomised to receive placebo or various doses of spironolactone for 12 weeks. The incidence of hyperkalaemia (defined as serum potassium level of 5.5 mmol/L or greater) was 5% for the placebo group, whereas it was 5%, 13%, 20%, and 24% when spironolactone was

given in single daily doses of 12.5, 25, 50, or 75 mg, respectively.¹⁷ The main RALES study involving 1663 patients showed a 30% reduction in the risk of mortality in patients with severe heart failure when they were given spironolactone in addition to treatment including an ACE inhibitor, a loop diuretic and in most cases digoxin. During the first year of follow-up, the median creatinine concentration in the spironolactone group increased by about 4 to 9 micromol/L and the median potassium level increased by 0.03 mmol/L, but there was a low incidence of serious hyperkalaemia (2% in the spironolactone group compared with 1% in the placebo group). However, the dose of spironolactone was fairly low (mean dose 26 mg daily; range 25 mg every other day to 50 mg daily depending on serum potassium levels and response). In addition, patients with a serum creatinine of more than 221 micromol/L or a serum potassium of more than 5 mmol/L were excluded.¹⁸ In a Canadian population-based time-series analysis, the increase in use of spironolactone for heart failure in patients taking ACE inhibitors after publication of the RALES study was found to be associated with 50 additional hospitalisations for hyperkalaemia for every 1000 additional prescriptions for spironolactone, and there was a 6.7-fold increase in numbers of patients dying from hyperkalaemia. The authors say that spironolactone-related hyperkalaemia is a much greater problem in every day practice than in the setting of a clinical study, and give a number of reasons for this including, less frequent monitoring of potassium levels, presence of conditions predisposing to hyperkalaemia, failure to detect subsequent development of renal impairment, inappropriately high doses of spironolactone, increase in dietary potassium intake, and use of spironolactone in heart failure with causes not included in the RALES study.¹⁹ In another study, use of spironolactone with ACE inhibitors in patients with class IV chronic heart failure was associated with a 14.6 odds ratio for developing hyperkalaemia when compared with ACE inhibitors alone. Predictors for hyperkalaemia included increases in creatinine following treatment, and diabetes.²⁰

(d) Triamterene

A retrospective analysis found that **captopril**, given to 6 patients on **Dyazide** (hydrochlorothiazide/triamterene), had not increased the potassium levels.²¹

Mechanism

ACE inhibitors reduce the levels of aldosterone, which results in the retention of potassium. This would be expected to be additive with the potassium-retaining effects of amiloride and triamterene and aldosterone antagonists such as spironolactone and eplerenone, leading to hyperkalaemia, but usually only if other risk factors are present (see *Importance and management* below).

Importance and management

Hyperkalaemia with ACE inhibitors and potassium-sparing diuretics, and particularly the aldosterone antagonist spironolactone, is well documented and well established. If it occurs it can be serious and potentially life threatening. Its incidence depends on the presence of other risk factors, and clinically important hyperkalaemia usually only appears to develop if one or more of these are also present, particularly renal impairment. Other risk factors in patients with heart failure include advanced age¹⁵ and diabetes^{11,22} (hyperkalaemia has been found to be relatively common in both non-insulin-dependent and insulin-dependent diabetics).²³ In addition, doses of spironolactone greater than 25 mg daily increase the risk of hyperkalaemia.

Because ACE inhibitors have potassium-sparing effects, potassium-sparing diuretics such as amiloride and triamterene should normally not be given concurrently. If, however, the use of both drugs is thought to be appropriate the serum potassium levels should be closely monitored so that any problems can be quickly identified. Note that the concurrent use of a potassium-depleting diuretic (a 'loop or thiazide diuretic', (p.21)) with the potassium-sparing diuretic may not necessarily prevent the development of hyperkalaemia. The combination of an ACE inhibitor and spironolactone can be beneficial in some types of heart failure, but close monitoring of serum potassium and renal function is needed, especially with any changes in treatment or the patient's clinical condition. The combination should be avoided in patients with renal impairment with a glomerular filtration rate of less than 30 mL/min.²² In addition, the dose of spironolactone should not exceed 25 mg daily.²² Similarly, the UK manufacturer of

eplerenone says that caution is required when it is given with ACE inhibitors, especially in renal impairment, and that potassium levels and renal function should be monitored.²⁴

ACE inhibitors + Dopamine agonists

A single report describes severe hypotension when a patient taking lisinopril was given pergolide. Dopamine agonists are well known to be associated with hypotensive reactions during the first few days of treatment.

Clinical evidence

A man successfully treated for hypertension with **lisinopril** 10 mg daily experienced a severe hypotensive reaction within four hours of taking a single 50-microgram dose of **pergolide** for periodic leg movements during sleep. He needed hospitalisation and treatment with intravenous fluids.¹

Mechanism

All dopamine agonists can cause hypotensive reactions during the first few days of treatment. It is not clear whether this patient was extremely sensitive to the pergolide or whether what occurred was due to an interaction. However, it is not unreasonable to assume that the hypotensive effects of dopamine agonists and antihypertensives might be additive.

Importance and management

Postural hypotension on starting dopamine agonists is a well recognised adverse effect, but this appears to be the only report that this might be of more concern in patients taking antihypertensives. The manufacturers of pergolide recommend caution when it is given with antihypertensives be-

cause of the risk of postural and/or sustained hypotension. The authors of the case report suggest that in patients taking antihypertensives the initial dose of pergolide should be 25 micrograms.¹ It would seem prudent to exercise extra caution with the initial use of pergolide and other dopamine agonists in patients treated with antihypertensives.

ACE inhibitors and Angiotensin II receptor antagonists + Epoetin

Epoetin may cause hypertension and thereby reduce the effects of antihypertensive drugs. An additive hyperkalaemic effect is theoretically possible with ACE inhibitors or angiotensin II receptor antagonists and epoetin. It is not entirely clear whether captopril, enalapril, fosinopril or other ACE inhibitors affect the efficacy of epoetin or not, but any interaction may take many months to develop.

Clinical evidence

(A) Antihypertensive effects

The most frequent adverse effect of epoetin is an increase in blood pressure, so it is important to control any existing hypertension before epoetin is started (the manufacturers contraindicate epoetin in uncontrolled hypertension). Blood pressure should be monitored before and during epoetin treatment, and if necessary antihypertensive drug treatment should be started or increased if the pressure rises.¹⁻³

(B) Epoetin efficacy

(a) Decreased epoetin effects

In a retrospective analysis of 43 haemodialysis patients given epoetin regularly for about 10 months, the dose of epoetin was not significantly different between patients taking **captopril** (20 patients) and a control group (23 patients) who did not receive any ACE inhibitors (116.7 versus 98.3 units/kg per week, respectively). However, the haemoglobin and haematocrit values were significantly less at 6.2 mmol/L and 29.3%, respectively, in the **captopril** group than the values of 7.1 mmol/L and 33.3% in the control group.⁴ Another retrospective study of 40 dialysis patients found that the 20 patients taking an ACE inhibitor (**captopril** 12.5 to 75 mg daily, **enalapril** 2.5 to 5 mg daily or **fosinopril** 10 to 20 mg daily) had some evidence of increased epoetin requirements after 1 year, when compared with the control group. However, this was not significant until 15 months when the cumulative epoetin dosage requirements were about doubled (12 092 versus 6 449 units/kg).⁵ Similarly, a prospective study with a 12-month follow-up period found that 20 patients receiving **enalapril** 5 to 20 mg daily required significantly higher doses of epoetin compared with 20 patients receiving nifedipine or 20 patients receiving no antihypertensive therapy.⁶ Higher epoetin requirements with ACE inhibitors were also reported in a small study in peritoneal dialysis patients.⁷ Furthermore, another prospective study found that 15 patients in whom ACE inhibitors (**enalapril**, **captopril**, or **perindopril**) were withdrawn and replaced with amlodipine, felodipine or doxazosin, had an increase in their mean haematocrit level and a decrease in their mean epoetin dose requirement.⁸

(b) No interaction

A retrospective review of 14 haemodialysis patients receiving epoetin, compared the haematocrit and dosage of epoetin for 16 weeks before, and 16 weeks after, starting ACE inhibitors (8 taking **captopril**, mean dose 35 mg daily and 6 taking **enalapril**, mean dose 7.85 mg daily). This study failed to find any evidence of a clinically significant interaction when ACE inhibitors were added.⁹ Another study involving 17 chronic haemodialysis patients found that ACE inhibitors (5 taking **captopril** and 12 taking **enalapril**) for 3 and 12 months did not increase the epoetin dose requirements or reduce the haematocrits.¹⁰ However, given the results of the study⁵ reported in (a) above, it is possible that these studies were not continued for long enough to detect an effect. Another study in 14 haemodialysis patients found no difference in epoetin requirements between patients receiving **losartan** 25 mg daily or placebo,¹¹ but again the **losartan**

was only given for 3 months. A further study (length not specified) in 604 dialysis patients also found that the use of ACE inhibitors or angiotensin II receptor blockers was not associated with epoetin resistance.¹²

(c) ACE inhibitors compared with Angiotensin II receptor antagonists

In one retrospective analysis of dialysis patients, 18 of 24 receiving **losartan** had decreases in haemoglobin, and 14 of these were using epoetin. A three to fourfold increase in the epoetin dose was required in these patients to restore the haemoglobin levels.¹³ This study suggests that angiotensin II receptor antagonists can behave similarly to ACE inhibitors. However, in a prospective study in 25 patients who had been undergoing haemodialysis for more than one year, 12 patients were given **temocapril** 2 mg daily and 13 patients received **losartan** 25 to 50 mg daily for 12 months. **Temocapril** significantly decreased haemoglobin levels from 9.8 to 9.1 g/dL at 3 months and reached a minimum of 9 g/dL at 6 months; haemoglobin levels recovered to 9.7 g/dL at the end of the study by increasing the dosage of epoetin. In contrast, no change was found in haemoglobin values in the patients receiving **losartan**. The dosage of epoetin was gradually increased from 76 to 121 units/kg per week in the **temocapril** group, but in the **losartan** group the epoetin dose was not significantly increased (94 versus 101 units/kg per week).¹⁴ Similar results were found in a study with **captopril** and **losartan**.¹⁵

(C) Hyperkalaemia

The manufacturers of epoetin comment that increased potassium levels have been reported in a few patients with chronic renal failure receiving epoetin, and that serum potassium levels should be monitored regularly.¹⁻³ An additive hyperkalaemic effect is therefore theoretically possible with patients also receiving ACE inhibitors or angiotensin II receptor antagonists.

Mechanism

(A) Epoetin can cause hypertension, possibly associated with haemodynamic changes produced by the increase in haematocrit.¹⁶

(B) It has been argued that ACE inhibitors might possibly reduce the efficacy of epoetin in haemodialysis patients for several reasons. Firstly, because patients with chronic renal failure have a reduction in their haematocrit when given ACE inhibitors, secondly because ACE inhibitors reduce polycythaemia following renal transplantation, and thirdly because ACE inhibitors reduce the plasma levels of endogenous erythropoietin.^{4,9,17} Many other factors have also been proposed.¹⁸

(C) Drugs that block angiotensin II cause reduced levels of aldosterone, which results in the retention of potassium. This would be expected to be additive with other drugs that cause hyperkalaemia.

Importance and management

Blood pressure should be routinely monitored in patients using epoetin, and this monitoring would seem sufficient to detect any interaction that affects the blood pressure-lowering effects of the ACE inhibitors. The dose of ACE inhibitor may need to be increased, but if blood pressure rises cannot be controlled, a transient interruption of epoetin therapy is recommended. Similarly, serum electrolytes, including potassium, should be routinely monitored in patients using epoetin. If potassium levels rise, consider ceasing epoetin until the level is corrected.^{1,2}

The overall picture of the effect of ACE inhibitors on epoetin resistance is unclear, and it would seem that an interaction, if it happens, takes a long time to develop. There is even less evidence regarding any interaction with angiotensin II antagonists. As epoetin dosage is governed by response, no immediate intervention is generally necessary. More long-term study is needed.

ACE inhibitors + Food

Food has little or no effect on the absorption of cilazapril, enalapril, fosinopril, lisinopril, quinapril, ramipril, spirapril, and trandolapril. Although food may reduce the absorption of captopril, this does not appear to be clinically important. Food reduced the absorption of imidapril and moexipril, and reduced the conversion of perindopril to perindoprilat, but the clinical relevance of these effects has not been assessed.

Clinical evidence, mechanism, importance and management

(a) No interaction

Although food reduced the AUC of **captopril** 25 to 100 mg by up to 56%^{1–4} this had no effect on the maximum decrease in blood pressure.^{1,3,4} One study in 10 healthy subjects reported a one-hour delay in the maximum hypotensive effect.¹ Another study, in 10 hypertensive patients, found that the extent and duration of the antihypertensive efficacy of **captopril** 50 mg twice daily for one month was not affected by whether it was taken before or after food.⁵ However, decreasing the dose of an ACE inhibitor might reduce the duration of the hypotensive effect and it has been suggested that these results should be confirmed with lower doses of **captopril**.⁵

Other single-dose studies have shown that food had no statistically significant effect on the pharmacokinetics of **lisinopril**,⁶ or **enalapril**, and its active metabolite, **enalaprilat**.⁷ Similarly, food had minimal effects on the pharmacokinetics of **cilazapril** (AUC decreased by only 14%).⁸ Food caused small, but statistically significant increases in the time to reach maximum plasma levels of **quinapril** and its active metabolite. However, as the increase was less than 30 minutes this is not expected to alter the therapeutic effect.⁹ Likewise, the manufacturers of **spirapril** briefly mention in a review that food delayed its absorption by 1 hour, it did not affect the bioavailability of **spirapril** or **spiraprilat**, its active metabolite.¹⁰ Other manufacturers state that food had no effect on the absorption of **fosinopril**,^{11,12} **ramipril**,^{13,14} or **trandolapril**.^{15,16}

(b) Possible interaction

In one study, food reduced the AUC of the active metabolite of **moexipril** (**moexiprilat**) by 40 to 50%.^{17,18} Food did not reduce **moexipril**-induced ACE-inhibition and therefore the reduced bioavailability was not expected to be clinically relevant.¹⁹ However, the US manufacturers suggest taking **moexipril** one hour before food.¹⁸

Although food did not significantly affect the pharmacokinetics of a single 4-mg dose of **perindopril**, the AUC of its active metabolite **perindoprilat** was reduced by 44%.²⁰ The blood pressure-lowering effects were not assessed, but it seems possible that they would not be affected (see **captopril**, above). Nevertheless, the UK manufacturer recommends that **perindopril** should be taken in the morning before a meal.²¹

The UK manufacturer of **imidapril** states that a fat-rich meal significantly reduces the absorption of **imidapril**, and recommends that the drug be taken at the same time each day, about 15 minutes before a meal.²²

ACE inhibitors + Garlic

In a single report, a patient taking lisinopril developed marked hypotension and became faint after taking garlic capsules.

Clinical evidence, mechanism, importance and management

A man whose blood pressure was 135/90 mmHg while taking **lisinopril** 15 mg daily began to take garlic 4 mg daily (*Boots odourless garlic oil capsules*). After 3 days he became faint on standing and was found to have a blood pressure of 90/60 mmHg. Stopping the garlic restored his blood pressure to 135/90 mmHg within a week. The garlic on its own did not lower his blood pressure. The reasons for this interaction are not known, although garlic has been reported to cause vasodilatation and blood pressure reduction.¹ This seems to be the first and only report of this reaction, so its general importance is small. There seems to be nothing documented about garlic and any of the other ACE inhibitors.

1. McCoubrie M. Doctors as patients: lisinopril and garlic. *Br J Gen Pract* (1996) 46, 107.

ACE inhibitors + Gold

Peripheral vasodilatation has occurred when some patients receiving gold were given ACE inhibitors.

Clinical evidence, mechanism, importance and management

A report describes 4 patients receiving long-term gold for rheumatoid arthritis who developed nitritoid reactions (adverse effects associated with **sodium aurothiomalate** treatment, consisting of facial flushing, nausea, dizziness, and occasionally, hypotension, as a result of peripheral vasodilatation). These reactions occurred soon after starting treatment with an ACE inhibitor (**captopril**, **enalapril**, or **lisinopril**). All the patients had been receiving a monthly injection of **sodium aurothiomalate** 50 mg for at least 2 years and none had ever had such a reaction before. The reactions were controlled by changing treatment to aurothioglucose (1 patient),

discontinuing the ACE inhibitor (2), or reducing the dose of **sodium aurothiomalate** to 25 mg (1).¹ There appear to be few reports of this interaction, possibly because the nitritoid reaction is an established adverse effect of gold. However, a possible interaction should be borne in mind if a patient experiences these reactions and is also taking an ACE inhibitor.

ACE inhibitors + H₂-receptor antagonists

In general, no clinically significant interactions appear to occur between the H₂-receptor antagonists (including cimetidine) and the ACE inhibitors. However, note that cimetidine modestly reduces the bioavailability of temocapril.

Clinical evidence, mechanism, importance and management

Cimetidine did not appear to alter the pharmacokinetics or pharmacological effects of **captopril**¹ or **enalapril**,² or the pharmacokinetics of **fosinopril**³ or **quinapril**⁴ in studies in healthy subjects. The manufacturers of **cilazapril** say that no clinically significant interaction occurred with H₂-receptor antagonists (not specifically named)⁵ and the manufacturers of **moexipril**,^{6,7} **ramipril**,⁸ and **trandolapril**⁹ say that no important pharmacokinetic interaction occurred with **cimetidine**. The manufacturers of **spirapril** briefly note in a review that **cimetidine** did not alter the plasma concentrations of **spirapril** or its active metabolite spiraprilat.¹⁰ None of these pairs of drugs appears to interact to a clinically relevant extent, and no special precautions appear to be necessary.

Preliminary findings suggest that **cimetidine** 400 mg twice daily had no effect on the metabolism of **temocapril** 20 mg daily in 18 healthy subjects, but the AUC was reduced by 26% on the fifth day of concurrent use.¹¹ The clinical relevance of this is uncertain, but changes of this magnitude with other ACE inhibitors have often not been clinically relevant.

ACE inhibitors and Angiotensin II receptor antagonists + Heparins

Heparin may increase the risk of hyperkalaemia with ACE inhibitors or angiotensin II receptor antagonists.

Clinical evidence, mechanism, importance and management

An extensive review of the literature found that heparin (both **unfractionated** and **low-molecular-weight heparins**) and **heparinoids** inhibit the secretion of aldosterone, which can cause hyperkalaemia.¹ The CSM in the UK suggests that plasma-potassium levels should be measured in all patients with risk factors (including those taking potassium-sparing drugs) before starting heparin, and monitored regularly thereafter, particularly if heparin is to be continued for more than 7 days.² Note that ACE inhibitors and angiotensin II receptor antagonists are potassium sparing, via their ef-

fects on aldosterone. Some workers¹ have suggested that the monitoring interval should probably be no greater than 4 days in patients at a relatively high risk of hyperkalaemia. Other risk factors include renal impairment, diabetes mellitus, pre-existing acidosis or raised plasma potassium.²

If hyperkalaemia occurs, the offending drugs should be stopped (although this may not be practical in the case of heparin). When the hyperkalaemia has been corrected (by whatever medical intervention is deemed appropriate) the drugs can cautiously be reintroduced.

ACE inhibitors + Insect allergen extracts

There are a few case reports of severe anaphylactoid reactions in patients receiving ACE inhibitors during desensitisation with bee or wasp venom. Extra caution is required, and some suggest temporarily withholding the ACE inhibitor before each venom injection.

Clinical evidence

A report describes 2 cases of anaphylactoid reactions during **wasp venom immunotherapy** in patients taking **enalapril**. In one patient, generalised pruritus and severe hypotension occurred within a few minutes of the first **venom** injection. Desensitisation was achieved after the **enalapril** was stopped, and then the immunotherapy was maintained by discontinuing the **enalapril** 24 hours before the monthly **venom** injection. However, on one occasion, when the **enalapril** had not been stopped, the patient experienced a severe anaphylactoid reaction 30 minutes after the **venom** injection. In the other patient an anaphylactoid reaction occurred after the second dose of **venom**. The ACE inhibitor was replaced with nifedipine so that **venom immunotherapy** could be continued.¹

In another report, a 43-year-old man who had been taking ACE inhibitors for 2 years (**lisinopril** 40 mg daily for the previous 5 months) had a hypotensive reaction to an insect sting. After skin testing, he received venom immunotherapy. About 4 months later, he had a severe anaphylactic reaction 5 minutes after being given a maintenance dose of **wasp venom** and **mixed vespid venom**. The ACE inhibitor was replaced with a calcium-channel blocker, and he subsequently tolerated full-strength venom immunotherapy injections.²

Mechanism

ACE inhibitors might potentiate the hypotension associated with anaphylactic reactions by inhibiting the breakdown of bradykinin and decreasing concentrations of the vasoconstrictor angiotensin II.³ It has also been suggested that similar reactions may occur after an insect sting.³ This is supported by a case report that describes a woman who had generalised angioedema in response to bee stings on at least three occasions while taking captopril and then cilazapril, but experienced only localised swelling before and after treatment with an ACE inhibitor.⁴

Importance and management

On the basis of these few reports, it cannot be said with certainty that an interaction occurs; however, it is possible that ACE inhibitors could exacerbate the response to insect venom immunotherapy. Because of the potential severity of the reaction, extra caution should be taken in patients taking ACE inhibitors and undergoing desensitising treatment with **Hymenoptera** (bee or wasp) **venom**. Some authors^{1–3} and manufacturers advise temporarily withholding the ACE inhibitor before each desensitisation (24 hours was sufficient in one case), while others suggest temporary substitution of a different antihypertensive e.g. a calcium-channel blocker. Note that some evidence suggests that anaphylactic shock in patients taking beta blockers may be resistant to treatment with adrenaline (epinephrine), see 'Beta blockers + Inotropes and Vasopressors', p.848. Therefore beta blockers are probably not a suitable alternative.

ACE inhibitors + Interleukin-3

Marked hypotension occurred when three patients taking ACE inhibitors were given interleukin-3.

Clinical evidence, mechanism, importance and management

Twenty-six patients with ovarian or small-cell undifferentiated cancers were treated with chemotherapy followed by recombinant human interleukin-3. Three of the 26 were taking ACE inhibitors (not named) and all three developed marked hypotension (WHO toxicity grade 2 or 3) within 1 to 4 hours of the first interleukin-3 injection. Their blood pressures returned to normal while continuing the interleukin-3 when the ACE inhibitors were stopped. When the interleukin-3 was stopped, they once again needed the ACE inhibitors to control their blood pressure. None of the other 23 patients had hypotension, except one who did so during a period of neutropenic fever.¹ The authors of the report suggest (and present some supporting evidence) that the drugs act synergistically to generate large amounts of nitric oxide in the blood vessel walls. This relaxes the smooth muscle in the blood vessel walls causing vasodilatation and consequent hypotension.¹ Information seems to be limited to this single report, but it would be prudent to monitor blood pressure even more closely in patients receiving interleukin-3 while taking ACE inhibitors.

- Dercksen MW, Hoekman K, Visser JJ, ten Bokkel Huinink WW, Pinedo HM, Wagstaff J. Hypotension induced by interleukin-3 in patients on angiotensin-converting enzyme inhibitors. *Lancet* (1995) 345, 448.

ACE inhibitors + Iron compounds

Serious systemic reactions occurred when three patients taking enalapril were given infusions of ferric sodium gluconate; however, there was no increase in the incidence of such adverse reactions in patients taking ACE inhibitors in a very large clinical study. Oral ferrous sulfate may decrease the absorption of captopril, but this is probably of little clinical importance.

Clinical evidence

(a) Intravenous iron

A man with iron-deficiency anaemia taking furosemide and digoxin was given 125 mg of **ferric sodium gluconate** (*Ferlixit*)¹ intravenously in 100 mL of saline daily. Four days later, **enalapril** 5 mg daily was started. After the infusion of only a few drops of his next dose of **ferric sodium gluconate**, he developed diffuse erythema, abdominal cramps, hypotension, nausea and vomiting. He recovered after being given hydrocortisone 200 mg. Three days later, in the absence of the **enalapril**, he restarted the iron infusions for a further 10 days without problems, and was later treated uneventfully with the **enalapril**.² Two other patients taking **enalapril** reacted similarly when given intravenous infusions of **ferric sodium gluconate**. Neither was given any more intravenous iron and later had no problems while taking **enalapril** alone. During the same 13-month period in which these three cases occurred, 15 other patients, who were not taking ACE inhibitors, also received intravenous iron therapy with no adverse reactions.² In contrast, an interim report of a randomised, crossover study involving 1117 dialysis patients given a placebo or a single intravenous dose of 125 mg of **ferric sodium gluconate complex** (*Ferrlecit*) in sucrose, found no evidence of any significant difference in the incidence of immediate allergic reactions or other adverse reactions to the iron in the 308 patients also taking ACE inhibitors.³ The findings of the full study, which included 707 patients taking ACE inhibitors, were the same.⁴ Similarly, the longer-term follow-up of patients from this study who continued to receive intravenous **ferric sodium gluconate complex**, found that there was no difference in the incidence or severity of adverse events in the 372 patients taking ACE inhibitors, when compared with the 949 patients who were not.⁵

(b) Oral iron

A double-blind study in 7 healthy subjects, given single 300-mg doses of **ferrous sulfate** or placebo with **captopril** 25 mg, found that the AUC of unconjugated plasma **captopril** (the active form) was reduced by 37% although the maximum plasma levels were not substantially changed. The AUC of total plasma **captopril** was increased by 43%, although this was not statistically significant. There were no significant differences in blood pressure between treatment and placebo groups.⁶

Mechanism

(a) Uncertain. Intravenous iron may cause a variety of systemic reactions including fever, myalgia, arthralgia, hypotension, and nausea and vomiting, which are believed to be due to the release of various inflammatory mediators such as bradykinin, caused by iron-catalysed toxic free radicals. The authors of the report suggest that ACE inhibitors like enalapril decrease the breakdown of kinins so that the toxic effects of the iron become exaggerated.²

(b) Reduced levels of unconjugated captopril in the plasma are probably due to reduced absorption resulting from a chemical interaction between ferric ions and captopril in the gastrointestinal tract.⁶

Importance and management

(a) The interaction with intravenous iron is not firmly established because up to 25% of all patients given iron by this route develop a variety of systemic reactions, ranging from mild to serious anaphylactoid reactions. In addition, information from the large clinical study indicates that there is no increased risk in patients taking ACE inhibitors. This suggests that no extra precautions are required if intravenous iron is given to patients taking any ACE inhibitor.

(b) There is limited evidence that oral iron may reduce the absorption of captopril. The clinical relevance of this is unknown, but probably small. Information about the effect of oral iron on other ACE inhibitors is lacking.

ACE inhibitors + Moracizine

Moracizine causes some moderate alterations in the pharmacokinetics of free captopril, but these are unlikely to be clinically important.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 19 healthy subjects were given moracizine 250 mg or **captopril** 50 mg, both every 8 hours, either alone or together, for 22 doses. When taken together the pharmacokinetics of the moracizine and total **captopril** remained unchanged, but the maximum blood levels of the free **captopril** and its AUC decreased by 32% and 14%, respectively. The half-life of the free **captopril** was reduced by 44%.¹ These modest changes are unlikely to be clinically relevant.

- Pieniaszek HJ, Shum L, Widner P, Garner DM, Benedek IH. Pharmacokinetic interaction of moricizine and captopril in healthy volunteers. *J Clin Pharmacol* (1993) 33, 1005.

ACE inhibitors + NSAIDs

There is evidence that most NSAIDs can increase blood pressure in patients taking antihypertensives, including ACE inhibitors, although some studies have not found the increase to be clinically relevant. Some variation between drugs possibly occurs, with in-

dometacin appearing to have the most significant effect. The combination of an NSAID and an ACE inhibitor can increase the risk of renal impairment and hyperkalaemia.

Clinical evidence

(A) Effects on blood pressure

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients taking **antihypertensives**, and the findings of these are summarised in 'Table 23.2', (p.862). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both coxibs and non-selective NSAIDs. In two meta-analyses,^{1,2} the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between them, with the exception of the comparison between **indometacin** and **sulindac** in one analysis.² Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,¹ the effect was said to be greatest for **piroxicam**, **indometacin**, and **ibuprofen**, intermediate for **naproxen**, and least for **sulindac** and **flurbiprofen**. In the other meta-analysis,² the effect was said to be greatest for **indometacin** and **naproxen**, intermediate for **piroxicam**, and least for **ibuprofen** and **sulindac**. An attempt was also made to evaluate the effect by **antihypertensive**.¹ The mean effect was greatest for beta blockers, intermediate for vasodilators (this group included ACE inhibitors and calcium-channel blockers), and least for diuretics. However, the differences between the groups were not significant.

The findings of individual studies that have studied the effects of specific NSAIDs on ACE inhibitors are outlined in the subsections below.

(a) Celecoxib

In a double-blind study in hypertensive patients taking **lisinopril** 10 to 40 mg daily, celecoxib did not have a clinically or statistically significant effect on blood pressure. The 24-hour blood pressure increased by 2.6/1.5 mmHg in 91 patients taking celecoxib 200 mg twice daily for 4 weeks compared with 1/0.3 mmHg in 87 patients taking placebo.³ In another large study in 810 elderly patients with osteoarthritis and controlled hypertension given either celecoxib 200 mg or rofecoxib 25 mg daily for 6 weeks, approximately 40% of the patients randomised to the celecoxib group were receiving ACE inhibitors. Systolic blood pressure increased by a clinically significant amount (greater than 20 mmHg) in 11% of patients receiving celecoxib,⁴ while in another study, only 4 of 87 (4.6%) of hypertensive patients taking ACE inhibitors had clinically significant increases in blood pressure after taking celecoxib 200 mg twice daily for 4 weeks.⁵ A further study in 25 hypertensive patients with osteoarthritis taking **trandolapril** (with or without hydrochlorothiazide) found that the 24-hour blood pressure was not significantly increased by celecoxib 200 mg daily, but, at its peak activity, celecoxib increased blood pressure by about 5/4 mmHg.⁶ In another randomised study, 16% of 138 patients given celecoxib 200 mg daily developed hypertension within 6 weeks (defined as a 24-hour systolic blood pressure greater than 135 mmHg). These patients had well-controlled hypertension at baseline; 83% were receiving an ACE inhibitor and 64% an additional antihypertensive.⁷ The proportion of patients who developed hypertension was similar to that with naproxen (19%) and less than that with rofecoxib (30%).

(b) Ibuprofen

In 90 patients taking ACE inhibitors, giving ibuprofen for 4 weeks resulted in clinically significant increases in blood pressure in 15 of the patients. For the group as a whole, diastolic blood pressure was increased by 3.5 mmHg.⁵ In one single-dose study, ibuprofen 800 mg or indometacin 50 mg abolished the hypotensive effect of **captopril** 50 mg in 8 healthy subjects when they took a high sodium diet, but not when they took a low sodium diet.⁸ A case report describes attenuation of the antihypertensive effects of **captopril** by ibuprofen in an elderly woman.⁹ However, two studies in African women found that ibuprofen 800 mg three times daily for one month did not alter the antihypertensive effect of either **fosinopril** 10 to 40 mg daily or **lisinopril** 10 to 40 mg daily (given with hydrochlorothiazide 25 mg daily).^{10,11} It was thought that the diuretic might have enhanced salt depletion and renin stimulation making the antihypertensive action of the combination less prostaglandin dependent.¹⁰

(c) Indometacin

1. **Captopril**. In a randomised, double-blind study, 105 patients with hypertension were given captopril 25 to 50 mg twice daily for 6 weeks, which reduced their blood pressure by a mean of 8.6/5.6 mmHg. Indometacin 75 mg once daily was then added for one week, which caused a rise in blood pressure in the group as a whole of 4.6/2.7 mmHg (an attenuation of the effect of captopril of about 50%). Clear attenuation was seen in 67% of the patients, and occurred regardless of baseline blood pressure.¹² This same interaction has been described in numerous earlier studies, in both patients with hypertension and healthy subjects, given indometacin.^{8,13-20} A man whose blood pressure was well controlled with captopril 75 mg daily had a rise in his blood pressure from 145/80 to 220/120 mmHg when he started using indometacin suppositories 200 mg daily.²¹ In contrast, a randomised, placebo-controlled, crossover study in 11 patients found that indometacin 50 mg twice daily did not alter the antihypertensive efficacy of captopril 50 mg twice daily.²²

2. **Enalapril**. In 9 patients with hypertension indometacin 50 mg twice daily for 1 week significantly reduced the antihypertensive effect of enalapril 20 to 40 mg once daily by about 18 to 22%.²³ In another study in 18 patients, indometacin 25 mg three times daily attenuated the antihypertensive effect of enalapril 20 to 40 mg daily. The reduction in hypotensive effect was about 42% when assessed by 24-hour ambulatory blood-pressure monitoring (9.4/4.1 mmHg increase in blood pressure with indometacin), and 12 to 23% when assessed by clinic blood pressure monitoring.²⁴ Similar results were found in other studies.²⁵⁻²⁸ A further study in 10 normotensive subjects receiving a fixed sodium intake and enalapril 20 mg daily, with or without indometacin 50 mg twice daily for one week, found that indometacin reduced the natriuretic response to the ACE inhibitor.²⁹ A single case report describes a patient taking enalapril 10 mg daily whose hypertension was not controlled when indometacin 100 mg daily in divided doses was added.³⁰ However, other studies found indometacin did not significantly alter the blood pressure response to enalapril.^{19,22,31}

3. **Lisinopril**. In a placebo-controlled, crossover study, indometacin 50 mg twice daily for 2 weeks produced mean blood pressure increases of 5.5/3.2 mmHg in 56 patients taking lisinopril 10 to 20 mg daily.³² Similarly, results of an earlier study suggested that indometacin increased the blood pressure of 9 patients taking lisinopril.²⁶ In contrast in a placebo-controlled study in 16 patients, indometacin 50 mg twice daily for 4 weeks was found to have little effect on the antihypertensive efficacy of lisinopril 40 mg daily.³³

4. **Other ACE inhibitors**. A placebo-controlled, randomised, crossover study in 16 hypertensive patients found that indometacin 50 mg twice daily reduced the blood pressure-lowering effects of **cilazapril** 2.5 mg daily. The reduction was greater when **cilazapril** was added to indometacin than when indometacin was added to **cilazapril** (approximately 60% versus 30% reduction in hypotensive effect measured 3 hours after the morning dose).³⁴ The antihypertensive effects of **perindopril** 4 to 8 mg daily were also found to be reduced by about 30% by indometacin 50 mg twice daily in 10 hypertensive patients.³⁵ A brief mention is made in a review that the pharmacodynamics of **ramipril** were unaffected by indometacin (dosage not stated) given to healthy subjects for 3 days.³⁶ Indometacin 25 mg three times daily did not alter the hypotensive effects of **trandolapril** 2 mg daily in 17 hypertensive patients.³⁷

(d) Naproxen

In a randomised study, 19% of 130 patients given naproxen 500 mg twice daily developed hypertension within 6 weeks (defined as a 24-hour systolic blood pressure greater than 135 mmHg). These patients had well-controlled hypertension at baseline; 83% were receiving an ACE inhibitor and 66% an additional antihypertensive.⁷ The proportion of patients who developed hypertension was similar to that with celecoxib (16%) and less than that with rofecoxib (30%).

(e) Rofecoxib

The manufacturer of rofecoxib noted that in patients with mild-to-moderate hypertension, rofecoxib 25 mg daily, taken with **benazepril** 10 to 40 mg daily, for four weeks, was associated with a small attenuation of the antihypertensive effect (average increase in mean arterial pressure of 2.8 mmHg).³⁸ Similarly, a case report describes a patient taking **lisinopril** 10 mg daily whose blood pressure rose from 127/78 to 143/89 mmHg when he was given rofecoxib 25 mg daily. His blood pressure was controlled by increasing the dose of **lisinopril** to 20 mg daily.³⁹

In another study in 810 elderly patients with osteoarthritis and controlled hypertension given either celecoxib 200 mg or rofecoxib 25 mg daily for

6 weeks, approximately 29% of the patients randomised to the rofecoxib group were receiving ACE inhibitors. Systolic blood pressure increased by a clinically significant amount (greater than 20 mmHg) in 17% of the patients receiving rofecoxib.⁴ In another similar randomised study, 30% of 138 patients given rofecoxib 25 mg daily developed hypertension within 6 weeks (defined as a 24-hour systolic blood pressure greater than 135 mmHg). These patients had well-controlled hypertension at baseline; 84% were receiving an ACE inhibitor and 62% an additional antihypertensive.⁷ The proportion of patients who developed hypertension was greater than with celecoxib (16%) or naproxen (19%).

(f) *Sulindac*

In one study, sulindac 200 mg twice daily given to patients taking **captopril** 100 to 200 mg twice daily caused only a small rise in blood pressure (from 132/92 to 137/95 mmHg).¹⁵ Sulindac 150 mg twice daily did not attenuate the blood pressure response to **captopril** when it was substituted for ibuprofen in an elderly woman.⁹ Similarly, sulindac 200 mg twice daily did not blunt the antihypertensive effect of **enalapril** in 9 patients with hypertension.³¹ Two studies in black women also found that sulindac 200 mg twice daily for one month did not alter the antihypertensive effect of **fosinopril** 10 to 40 mg daily or **lisinopril** 10 to 40 mg daily (given with hydrochlorothiazide 25 mg daily).^{10,11}

(g) *Other NSAIDs*

A single 8-mg dose of **lornoxiam** was found to have no effect on the systolic blood pressure of 6 hypertensive patients taking **enalapril**, but a small rise in diastolic pressure (from 88.2 to 93.3 mmHg) occurred after 2 hours.²⁵ In 29 patients with hypertension **oxaprozin** 1.2 g daily for 3 weeks did not affect the pharmacodynamics of **enalapril** 10 to 40 mg daily.⁴⁰

Twenty-five hypertensive patients with osteoarthritis taking **trandolapril** 2 to 4 mg daily (with or without hydrochlorothiazide) had an increase in blood pressure of about 3/4 mmHg when they were given **diclofenac** 75 mg twice daily.⁶ However, **diclofenac** 75 mg twice daily for one month did not alter the antihypertensive effect of **lisinopril** 10 to 40 mg daily (given with hydrochlorothiazide).¹¹

A study found that only 5 of 91 (5.5%) hypertensive patients stabilised on ACE inhibitors had clinically significant increases in blood pressure when they were given **nabumetone** 1 g twice daily for 4 weeks.⁵ A study in 17 black women found that **nabumetone** 1 g twice daily for one month did not alter the antihypertensive effect of **fosinopril** 10 to 40 mg daily (given with hydrochlorothiazide).¹⁰

(B) Effects on renal function

In a retrospective analysis, 3 of 162 patients who had been taking ACE inhibitors and NSAIDs developed reversible renal failure, compared with none of 166 patients taking ACE inhibitors alone and none of 2116 patients taking NSAIDs alone. One patient was taking **naproxen** or **sal-salate** and had a progressive decline in renal function over 19 months after **captopril** was started. Another man taking unnamed NSAIDs developed reversible renal failure 4 days after starting to take **captopril**.⁴¹ In another similar analysis, in patients aged over 75 years, 2 out of 12 patients given an ACE inhibitor and an NSAID developed acute renal failure (1 died) and a further 4 showed deterioration in renal function. All of these 6 patients were also taking 'diuretics', (p.21), but of the 6 with unaffected renal function, only two were taking diuretics.⁴² A randomised, crossover study in 17 black patients receiving **fosinopril** with hydrochlorothiazide and NSAIDs for a month, found that acute renal failure (a decrease in glomerular filtration rate of greater than or equal to 25%) occurred in 4 of the 17 patients when receiving **ibuprofen**, 1 of 17 receiving **sulindac** and 0 of 17 receiving **nabumetone**.¹⁰ In a multivariate analysis, significant renal impairment was associated with use of two or more of ACE inhibitors or angiotensin II receptor antagonists with NSAIDs or diuretics.⁴³ In a case-control study, recently starting an NSAID was associated with a 2.2-fold increased risk of hospitalisation for renal impairment in patients taking ACE inhibitors.⁴⁴ In 2002, 28 of 129 reports to the Australian Adverse Drug Reactions Advisory Committee of acute renal failure were associated with the combined use of ACE inhibitors (or angiotensin II receptor antagonists), diuretics, and NSAIDs (including coxibs), and these cases had a fatality rate of 10%. In patients taking this triple combination, renal failure appeared to be precipitated by mild stress such as diarrhoea or dehydration. In other patients, the addition of a third drug (usually an NSAID) to a stable combination of the other two, resulted in acute renal failure.⁴⁵

In contrast, another retrospective analysis found no evidence that the adverse effects of ACE inhibitors on renal function were greater in those tak-

ing NSAIDs.⁴⁶ A further study in 17 hypertensive patients with normal baseline renal function, found that **indometacin** 25 mg three times daily did not adversely affect renal function when it was given with **trandolapril** 2 mg daily for 3 weeks.⁴⁷

(C) Hyperkalaemia

Hyperkalaemia, resulting in marked bradycardia, was attributed to the use of **loxoprofen** in an elderly woman taking **imidapril**.⁴⁸ A 77-year-old woman with mild hypertension and normal renal function taking **enalapril** 2.5 mg daily arrested and died 5 days after starting treatment with **rofecoxib** for leg pain. Her potassium was found to be 8.8 mmol/L. Infection and dehydration could have contributed to the hyperkalaemia in this patient.⁴⁹

(D) Pharmacokinetic studies

The manufacturer of **spirapril** briefly noted in a review that there was no relevant pharmacokinetic interaction between **spirapril** and **diclofenac**.⁵⁰ **Oxaprozin** 1.2 g daily for 3 weeks did not affect the pharmacokinetics of **enalapril** 10 to 40 mg daily in 29 patients with hypertension.⁴⁰ A brief mention is made in a review that, in healthy subjects, the pharmacokinetics of **ramipril** were unaffected by **indometacin** [dosage not stated] given for 3 days.³⁶

Mechanism

Some, but not all the evidence suggests that prostaglandins may be involved in the hypotensive action of ACE inhibitors, and that NSAIDs, by inhibiting prostaglandin synthesis, may partially antagonise the effect of ACE inhibitors. Another suggestion is that NSAIDs promote sodium retention and so blunt the blood pressure lowering effects of several classes of antihypertensive drugs, including ACE inhibitors. This interaction may be dependent on sodium status and on plasma renin, and so drugs that affect sodium status e.g. diuretics may possibly influence the effect. Therefore, the interaction does not occur in all patients. It may also depend on the NSAID, with indometacin being frequently implicated, and sulindac less so, as well as on the dosing frequency.⁶

Both NSAIDs and ACE inhibitors alone can cause renal impairment. In patients whose kidneys are underperfused, they may cause further deterioration in renal function when used together.⁵¹ Impaired renal function is a risk factor for hyperkalaemia with ACE inhibitors.

Importance and management

The interaction between indometacin and ACE inhibitors is well established, with several studies showing that indometacin can reduce the **blood pressure-lowering** effect of a number of ACE inhibitors. The interaction may not occur in all patients. If indometacin is required in a patient taking any ACE inhibitor, it would be prudent to monitor blood pressure. In a few small comparative studies, indometacin has been shown to have less effect on the calcium-channel blockers amlodipine, felodipine, and nifedipine, than on enalapril.^{24,27,28} See also, 'Calcium-channel blockers + Aspirin or NSAIDs', p.861. Therefore, a calcium-channel blocker may sometimes be an alternative to an ACE inhibitor in a patient requiring indometacin.

Limited information suggests that sulindac has little or no effect on ACE inhibitors, and may therefore be less likely to cause a problem, but further study is needed. The coxibs appear to have similar (celecoxib) or greater (rofecoxib) effects on ACE inhibitors than conventional NSAIDs (naproxen).

Although information about other NSAIDs is limited, the mechanism suggests that all of them are likely to interact similarly. Until more is known, it may be prudent to increase blood pressure monitoring when any NSAID is added or discontinued in a patient taking any ACE inhibitor, and intermittent use of NSAIDs should be considered as a possible cause of erratic control of blood pressure. In addition, sodium status and therefore diuretic use may affect any interaction. However, some consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.⁵² While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inadequate control of blood pressure, other reasons may be more likely than any effect of concurrent NSAIDs.⁵² Further study is needed. For the effects of NSAIDs on other antihypertensive drug classes see 'beta blockers', (p.835), 'calcium-channel blockers', (p.861) and 'thiazide diuretics', (p.956).

There is an increased risk of **deterioration in renal function** or acute re-

nal failure with the combination of NSAIDs and ACE inhibitors, especially if poor renal perfusion is present. Renal function should be monitored periodically in patients taking ACE inhibitors with NSAIDs, particularly in volume depleted patients. In a statement, the American Heart Association comments that acute renal failure complicating ACE inhibitor therapy is almost always reversible and repletion of extracellular fluid volume and discontinuation of diuretic therapy is the best approach. In addition, withdrawal of interacting drugs, supportive management of fluid and electrolytes, and temporary dialysis, where indicated, are the mainstays of therapy.⁵³ The Australian Adverse Drug Reactions Advisory Committee consider that the triple combination of ACE inhibitors, 'diuretics', (p.21) and NSAIDs (including coxibs) should be avoided if possible, and that great care should be taken when giving ACE inhibitors and NSAIDs to patients with renal impairment.⁴⁵ Deterioration in renal function increases the risk of hyperkalaemia.

ACE inhibitors and other antihypertensives + Orlistat

In a handful of cases, patients taking enalapril and/or losartan and other antihypertensive drugs (amlodipine, atenolol, hydrochlorothiazide) had marked increases in blood pressure, hypertensive crises and, in one case, intracranial haemorrhage, within 7 to 60 days of starting orlistat.

Clinical evidence

The Argentinian System of Pharmacovigilance identified the following 3 cases of a possible interaction of orlistat with antihypertensives. An obese man whose hypertension was controlled at 120/80 mmHg with daily doses of **losartan** 100 mg, **atenolol** 100 mg, and **hydrochlorothiazide** 12.5 mg developed a hypertensive crisis (BP 260/140 mmHg) 7 days after starting to take orlistat 120 mg three times daily. The orlistat was stopped and the crisis was controlled. When later rechallenged with orlistat, his diastolic blood pressure rose to 100 to 110 mmHg after 5 days, but the systolic blood pressure increased only slightly. His blood pressure returned to baseline values 3 days after stopping the orlistat.¹ Two other patients reacted similarly. One whose blood pressure was controlled at 130/85 mmHg with **enalapril** 20 mg daily and **losartan** 50 mg daily developed an intracranial haemorrhage and hypertension (BP 160/100 mmHg) with occasional systolic peaks of around 200 mmHg one week after starting orlistat 120 mg three times daily. The other patient who was taking **enalapril** 20 mg daily and **amlodipine** 5 mg daily began to develop hypertensive peaks (BP 180/120 mmHg) 60 days after starting orlistat 120 mg twice daily. The hypertension responded to a change to **losartan** with **hydrochlorothiazide**, but 20 days later new hypertensive peaks developed (BP 180/110 to 120 mmHg). When the orlistat was withdrawn, the hypertension was controlled within 48 hours.¹

The Uppsala Adverse Drug Reaction database has two reports of aggravated hypertension in women taking antihypertensives and orlistat.¹ Hypertension has also been reported in previously normotensive individuals taking orlistat, which, in one case, responded to stopping orlistat.^{2,3}

However, the manufacturer has found no evidence of an association between orlistat and hypertension. In clinical studies, orlistat use was associated with a small reduction in blood pressure compared with placebo, which was as a result of weight reduction. Moreover, the incidence of hypertension of new onset and hypertensive crisis did not differ between orlistat and placebo (1.2% versus 1.3%, and 0% versus 0.1%, respectively).⁴ In studies in healthy subjects, orlistat had no effect on steady-state **losartan** pharmacokinetics,⁵ and no clinically significant effect on the pharmacokinetics of single-dose **captopril**, **atenolol**, **furosemide** or **nifedipine**.⁶

Mechanism

Not understood. Suggestions include a decrease in the absorption of the drugs due to accelerated gastrointestinal transit, increased defaecation, diarrhoea, or an increase in the amount of fat in the chyme.¹ An explanation for the difference between the clinical cases and pharmacokinetic studies may be that the latter tended to be single-dose studies and in healthy subjects only. Alternatively, these cases could just be idiosyncratic and not related to orlistat treatment.

Importance and management

The interactions between the antihypertensives and orlistat seem to be confined to the reports cited here, and their general significance is unclear. Given that the manufacturers report that specific drug interaction studies have not found any evidence of an interaction, the incidence seems likely to be small.

ACE inhibitors + Potassium compounds

ACE inhibitors maintain serum potassium levels. Hyperkalaemia is therefore a possibility if potassium supplements or potassium-containing salt substitutes are given, particularly in those patients where other risk factors are present, such as decreased renal function.

Clinical evidence

(a) Potassium levels increased by concurrent use

1. **Potassium supplements.** The serum potassium levels of a patient taking a potassium supplement rose by 66% when **captopril** was added, with signs of a deterioration in renal function. Four others taking potassium supplements and furosemide (2 also taking unnamed potassium-sparing diuretics) had rises in their potassium levels of only 8 to 24% when given **captopril**. The rises occurred within 1 or 2 days. No clinical signs or symptoms of hyperkalaemia were seen, but 3 of the 5 patients had rises to above the upper limits of normal.¹ A post-marketing survey identified 10 patients in whom **enalapril** appeared to have been associated with renal impairment and death. Eight of them were also taking potassium supplements and/or potassium-sparing diuretics, and hyperkalaemia appeared to have been the immediate cause of death in two of them.² In a review of 47 patients treated with **enalapril** for heart failure, and who experienced serious hyperkalaemia, 8 had also received potassium supplements.³ In another survey of 53 patients taking ACE inhibitors who had hyperkalaemia in the absence of significant renal impairment, less than 5% were taking a potassium supplement, but 30% were using a potassium-containing **salt substitute** (see 2. below).⁴

2. **Dietary potassium.** Two patients with renal impairment, one taking **lisinopril** and the other **enalapril**, developed marked hyperkalaemia shortly after starting to take 'Lo salt' (a salt substitute containing 34.6 g potassium in every 100 g). One developed a life-threatening arrhythmia.⁵ A similar report describes a man taking **captopril** who developed hyperkalaemia and collapsed 2 weeks after starting to use a **salt substitute** containing potassium.⁶ In a further report, severe hyperkalaemia occurred in a patient on a very-low-calorie diet with a protein supplement who was taking **lisinopril** 10 mg daily. The protein supplement contained 48 mmol of potassium and salad topped with lemon juice and potassium chloride salt added at least another 72 mmol daily.⁷ In 53 patients taking ACE inhibitors who had hyperkalaemia in the absence of significant renal impairment, 30% were using a **salt substitute**, and 72% were eating a moderate-to-high potassium diet, consisting of 2 or more servings of a potassium-rich food daily.⁴ Hyperkalaemia and acute renal failure has also been reported in a diabetic patient taking **lisinopril** 20 mg twice daily following the use of a potassium-based water softener.⁸

(b) Potassium levels unaltered by concurrent use

A retrospective analysis of 14 patients without renal impairment taking potassium supplements and either furosemide or hydrochlorothiazide, found that the levels of serum potassium, during a 4-year period, had not significantly increased after the addition of **captopril**.⁹ Another study in 6 healthy subjects found that intravenous potassium chloride caused virtually the same rise in serum potassium levels in those given **enalapril** as in those given a placebo.¹⁰

Mechanism

The potassium-retaining effects of ACE inhibitors (due to reduced aldosterone levels) are additive with an increased intake of potassium, particularly when there are other contributory factors such as poor renal function or diabetes.

Importance and management

The documentation of this interaction appears to be limited, but it is well established. In practice, a clinically relevant rise in potassium levels usually occurs only if other factors are also present, the most important of which is impaired renal function. In general, because ACE inhibitors have potassium-sparing effects, potassium supplements should not routinely be given concurrently. If a supplement is needed, serum potassium should be closely monitored. This is especially important where other possible contributory risk factors are known to be present.

Other sources of dietary potassium should also be borne in mind. Patients with heart disease and hypertension are often told to reduce their salt (sodium) intake. One way of doing this is to use potassium-containing salt substitutes. However, it appears that there is some risk associated with excess use of these substitutes, especially in patients taking ACE inhibitors.

ACE inhibitors + Probenecid

Probenecid decreases the renal clearance of captopril, but this is probably not clinically important. Probenecid decreases the renal clearance of enalapril, and raises its serum levels.

Clinical evidence, mechanism, importance and management

Steady-state levels of unchanged and total **captopril**, given by intravenous infusion, were slightly increased (14% and 36%, respectively) by the use of probenecid in 4 healthy subjects. Renal clearance of unchanged **captopril** decreased by 44%, but total clearance was reduced by only 19%.¹ These moderate changes are unlikely to be clinically important.

In 12 healthy subjects probenecid 1 g twice daily for 5 days increased the AUC of a single 20-mg oral dose of **enalapril** and its active metabolite, enalaprilat by about 50%. The renal clearance of **enalapril** decreased by 73%.² A moderate increase in the hypotensive effects might be expected, but there do not appear to be any reports of adverse effects.

ACE inhibitors + Procaïnamide

The combination of captopril or other ACE inhibitors and procainamide possibly increases the risk of leucopenia. No pharmacokinetic interaction occurs between captopril and procainamide.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects the concurrent use of **captopril** 50 mg twice daily and procainamide 250 mg every 3 hours did not affect the pharmacokinetics of either drug.¹ The US manufacturer of **captopril** notes that in patients with heart failure who developed neutropenia, about 50% had a serum creatinine of 1.6 mg/dL or greater, and more than 75% were also receiving procainamide.² Similarly, the UK manufacturer of **captopril** notes that neutropenia or agranulocytosis and serious infection have occurred in patients taking **captopril**, and that concurrent treatment with procainamide may be a complicating factor. They recommend that the combination should be used with caution, especially in patients with impaired renal function. They suggest that differential white blood cell counts should be performed before concurrent use, then every 2 weeks in the first 3 months of treatment and periodically thereafter.³ The UK manufacturers of a number of other ACE inhibitors suggest that concurrent use of ACE inhibitors and procainamide may lead to an increased risk of leucopenia. For reports of other possible interactions with ACE inhibitors that might result in an increased risk of leucopenia see also 'ACE inhibitors + Allopurinol', p.13 and 'ACE inhibitors + Azathioprine', p.18.

ACE inhibitors + Rifampicin (Rifampin)

An isolated report describes a rise in blood pressure in one hypertensive patient, which was attributed to an interaction between enalapril and rifampicin. Rifampicin may reduce the plasma levels of the active metabolites of imidapril and spirapril.

Clinical evidence

A man taking **enalapril** and a variety of other drugs (warfarin, acebutolol, bendroflumethiazide, dipyridamole, metoclopramide and *Gaviscon*) developed a fever. He was given streptomycin, oxytetracycline and rifampicin, because of a probable *Brucella abortus* infection, whereupon his blood pressure rose from 164/104 to 180/115 mmHg over the next 5 to 6 days. It was suspected that an interaction with the rifampicin was possibly responsible. Subsequent studies in the same patient showed that rifampicin, reduced the AUC_{0–7} of enalaprilat, the active metabolite of **enalapril**, by 31%, although the AUC of **enalapril** was unchanged.¹ There is also the hint of this interaction in another report, where **enalapril** failed to control blood pressure in a patient taking rifampicin.²

The manufacturer of **spirapril** briefly noted in a review that the use of rifampicin with **spirapril** modestly decreased plasma levels of **spirapril**

and its active metabolite, spiraprilat.³ The manufacturer of **imidapril** notes that rifampicin reduced plasma levels of imidaprilat, the active metabolite of **imidapril**.⁴

Mechanism

The mechanism of this interaction is not clear, because rifampicin is a potent liver enzyme inducer, which might have been expected to cause the production of more, rather than less, of the active metabolites of these ACE inhibitors. However, the authors of one of the reports postulated that the rifampicin might have increased the loss of the enalaprilat in the urine,¹ and others suggested that rifampicin stimulates the elimination of spiraprilat non-specifically.³

Importance and management

The general importance of these interactions is uncertain. The isolated reports with enalapril suggest minor clinical relevance. The manufacturers of spirapril did not consider the modest pharmacokinetic changes to be clinically relevant.³ However, the manufacturers of imidapril state that rifampicin might reduce the antihypertensive efficacy of imidapril,⁴ but this awaits clinical assessment.

4. Tanatril (Imidapril). Trinity Pharmaceuticals Ltd. UK Summary of product characteristics, May 2003.

ACE inhibitors + Sevelamer

Sevelamer did not alter the pharmacokinetics of enalapril.

Clinical evidence, mechanism, importance and management

The concurrent use of a single 2.418-g dose of sevelamer hydrochloride (equivalent to 6 capsules) and did not alter the AUC of a single 20-mg dose of **enalapril** or its active metabolite, enalaprilat, in 28 healthy subjects.¹ Thus it appears that sevelamer does not bind to **enalapril** within the gut to reduce its absorption.

1. Burke SK, Amin NS, Incerti C, Plone MA, Lee JW. Sevelamer hydrochloride (Renagel®), a phosphate-binding polymer, does not alter the pharmacokinetics of two commonly used antihypertensives in healthy volunteers. *J Clin Pharmacol* (2001) 41, 199–205.

ACE inhibitors + Sibutramine

Sibutramine had only a minimal effect on blood pressure control with ACE inhibitors.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind study over 52 weeks in 220 obese, hypertensive patients, whose hypertension was well controlled with an ACE inhibitor (**benazepril**, **enalapril** or **lisinopril**) with or without a thiazide diuretic, two-thirds of the patients were also given sibutramine and one-third were given placebo. Sibutramine 20 mg daily caused small increases in mean blood pressure compared with placebo (133.1/85.5 mmHg compared with 130.4/82.8 mmHg, at 52 weeks, respectively), but overall, hypertension remained well controlled.¹

Sibutramine is safe and effective for weight loss in obese patients whose hypertension is well controlled with angiotensin-converting enzyme inhibitors. *J Hum Hypertens* (2002) 16, 5–11.

Angiotensin II receptor antagonists + Antacids

Antacids slightly reduce irbesartan and olmesartan absorption, but this is not clinically relevant.

Clinical evidence, mechanism, importance and management

In a single-dose, crossover study in 18 healthy subjects, 10 mL of an antacid containing **aluminium/magnesium hydroxides** (*Unimaalox*) given with, or 2 hours before, a single 300-mg dose of **irbesartan** had little effect on irbesartan pharmacokinetics. The only difference was that the AUC was reduced by 10% when the antacid was given 2 hours before irbesartan, when compared with irbesartan alone. However, this change is not considered to be clinically relevant.¹

The steady-state AUC of **olmesartan** 20 mg daily was 12% lower when it was given 15 minutes after a daily dose of an **aluminium/magnesium hydroxide** antacid, when compared with **olmesartan** alone, but this was not considered to be clinically significant.²

Angiotensin II receptor antagonists + Aspirin or NSAIDs

Indometacin may attenuate the antihypertensive effect of losartan, valsartan, or other angiotensin II receptor antagonists. However, low-dose aspirin does not appear to alter the antihypertensive effect of losartan. No clinically relevant pharmacokinetic interactions occur between telmisartan and ibuprofen or paracetamol (acetaminophen), or between valsartan and indometacin. The combination of an NSAID and angiotensin II receptor antagonist can increase the risk of renal impairment and hyperkalaemia.

Clinical evidence

(A) Effects on blood pressure

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with **antihypertensives**, and the findings of these are summarised in 'Table 23.2', (p.862). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg.

(a) Aspirin

A double-blind, placebo-controlled study in 10 patients with hypertension taking **losartan** (mean daily dose 47.5 mg) found that neither aspirin 81 mg nor 325 mg daily for 2 weeks had any significant effect on blood pressure.¹

(b) Indometacin

In a study in 111 patients with hypertension, **losartan** 50 mg once daily for 6 weeks reduced their blood pressure by a mean of 7.9/5.3 mmHg. Indometacin 75 mg once daily was then added for one week and this caused a rise in blood pressure in the group as a whole of 3.8/2.2 mmHg (reduction of about 45% in the effect of **losartan**). A rise in ambulatory diastolic blood pressure was seen in 69% of the **losartan**-treated patients during indometacin use.² In contrast, a much smaller study in 10 patients with essential hypertension taking **losartan** found that indometacin 50 mg twice daily for one week caused sodium and fluid retention, but did not significantly attenuate the antihypertensive effects of **losartan**.³

In a placebo-controlled, crossover study in 56 hypertensive patients whose blood pressure was adequately controlled by **valsartan** 80 to 160 mg daily, the addition of indometacin 50 mg twice daily for 2 weeks produced an increase in mean blood pressure of 2.1/1.9 mmHg.⁴ A study in normotensive subjects given a fixed sodium intake and **valsartan** 80 mg daily, with or without indometacin 50 mg twice daily for one week, demonstrated that indometacin reduced the natriuretic response to the angiotensin receptor blockade.⁵

(B) Effects on renal function

In 2002, 28 of 129 reports to the Australian Adverse Drug Reactions Advisory Committee of acute renal failure were associated with the combined use of ACE inhibitors or angiotensin II receptor antagonists,

diuretics, and NSAIDs (including coxibs), and these cases had a fatality rate of 10%. In patients taking this triple combination, renal failure appeared to be precipitated by mild stress such as diarrhoea or dehydration. In other patients, the addition of a third drug (usually an NSAID) to a stable combination of the other two, resulted in acute renal failure.⁶ In a multivariate analysis, significant renal impairment was associated with the use of two or more of an ACE inhibitor or angiotensin II receptor antagonist, and NSAIDs or diuretics.⁷

(C) Pharmacokinetic studies

(a) Ibuprofen

In a crossover study in 12 healthy subjects, **telmisartan** 120 mg daily had no effect on the pharmacokinetics of ibuprofen 400 mg three times a day for 7 days. Similarly, the pharmacokinetics of **telmisartan** were unaffected by the concurrent use of ibuprofen, when compared with previous studies of **telmisartan** alone.⁸

(b) Indometacin

In 12 healthy subjects the pharmacokinetics of single oral doses of **valsartan** 160 mg or indometacin 100 mg were not significantly changed when the drugs were given together, although the pharmacokinetics of **valsartan** showed wide variations between subjects.⁹

(c) Paracetamol (Acetaminophen)

Telmisartan 120 mg had no effect on the pharmacokinetics of paracetamol 1 g in a single-dose study in 12 healthy subjects. The pharmacokinetics of **telmisartan** were also unaffected by paracetamol, when compared with previous studies of **telmisartan** alone.⁸

Mechanism

Some evidence suggests that prostaglandins may be partially involved in the hypotensive action of angiotensin II receptor antagonists, and that NSAIDs, by inhibiting prostaglandin synthesis, may antagonise their effects. However, a non-specific mechanism such as sodium retention may also be involved, as indometacin has been shown to reduce the hypotensive effect of other classes of antihypertensive drugs.^{4,5} Both NSAIDs and angiotensin II receptor antagonists alone can cause renal impairment. In patients whose kidneys are underperfused, they may cause further deterioration in renal function when used together. Renal impairment increases the risk of hyperkalaemia.

Importance and management

As with other antihypertensives, the **antihypertensive effect** of angiotensin II receptor antagonists may be attenuated by NSAIDs such as indometacin. Patients taking losartan or valsartan or other angiotensin II receptor antagonists, who require indometacin and probably other NSAIDs, should be monitored for alterations in blood pressure control. See also 'ACE inhibitors + NSAIDs', p.28. Low-dose aspirin is unlikely to alter the blood pressure-lowering effect of angiotensin II receptor antagonists. However, for a discussion of the controversy as to whether low-dose aspirin might attenuate the benefits of ACE inhibitors in patients with heart failure, see 'ACE inhibitors + Aspirin', p.14.

Poor renal perfusion may increase the risk of **renal failure** if angiotensin II receptor antagonists are given with NSAIDs and so regular hydration of the patient and monitoring of renal function is recommended.¹⁰ The Australian Adverse Drug Reactions Advisory Committee consider that the triple combination of angiotensin II receptor antagonists or ACE inhibitors with diuretics and NSAIDs (including coxibs) should be avoided if possible.⁶ See also 'ACE inhibitors + NSAIDs', p.28.

Angiotensin II receptor antagonists + Azoles

Fluconazole reduces the conversion of losartan to its active metabolite and decreases the metabolism of irbesartan, but the clinical relevance of these changes is uncertain. Fluconazole does not appear to influence the pharmacokinetics of eprosartan; candesartan and valsartan. Itraconazole does not significantly affect the pharmacokinetics or antihypertensive effects of losartan, and ketoconazole does not affect the pharmacokinetics of eprosartan or losartan.

Clinical evidence, mechanism, importance and management

(a) Fluconazole

In a study of 32 healthy subjects, half were given **losartan** 100 mg daily and half were given **eprosartan** 300 mg twice daily for 20 days. Fluconazole 200 mg daily was given to both groups on days 11 to 20. Fluconazole increased the AUC and maximum plasma levels of **losartan** by 69% and 31%, respectively, and reduced those of E-3174, the active metabolite of **losartan**, by 41% and 54%, respectively. However, fluconazole had no significant effect on the pharmacokinetics of **eprosartan**.¹ In a randomised, crossover study, 11 healthy subjects were given a single 50-mg dose of **losartan** after 4 days of fluconazole (400 mg on day 1 and 200 mg daily on days 2 to 4). The AUC of **losartan** was increased by 27% while its maximum plasma level was reduced by 23%. The AUC and the maximum plasma levels of E-3174 were reduced by 47% and 77%, respectively. However, no significant changes in the hypotensive effect of **losartan** were noted.² It is thought that fluconazole inhibits the conversion of **losartan** to its active metabolite mainly by inhibiting the cytochrome P450 isoenzyme CYP2C9,¹⁻⁴ although other isoenzymes may play a minor role. The lack of pharmacodynamic changes suggests that this pharmacokinetic interaction may not be clinically important, but the possibility of a decreased therapeutic effect should be kept in mind.²

A study in 15 healthy subjects given **irbesartan** 150 mg daily for 20 days found that the steady-state AUC and maximum blood levels were increased by about 55% and 18%, respectively, by fluconazole 200 mg daily on days 11 to 20. **Irbesartan** is primarily metabolised by CYP2C9,⁴ and these increased levels probably occur as a result of CYP2C9 inhibition by fluconazole.⁵ These modest increases were considered unlikely to be clinically relevant and a dosage reduction would not generally be required.⁶ Other angiotensin II receptor antagonists would not be expected to interact, see the ‘introduction’, (p.12), to this section.

(b) Itraconazole

In 11 healthy subjects the pharmacokinetics and hypotensive effects of a single 50-mg dose of **losartan** and its active metabolite, E-3174, were not significantly affected by itraconazole 200 mg daily for 4 days.² Inhibition of the cytochrome P450 isoenzyme CYP3A4 alone (caused by itraconazole) does not appear to prevent the conversion of **losartan** to E-3174. No special precautions would appear to be needed if these drugs are used concurrently.

(c) Ketoconazole

A placebo-controlled, crossover study in 11 healthy subjects given a single 30-mg intravenous dose of **losartan**, found that ketoconazole 400 mg daily for 4 days did not affect the conversion of **losartan** to its active metabolite, E-3174, or the plasma clearance of **losartan**.⁷ Inhibition of the cytochrome P450 isoenzyme CYP3A4 alone (caused by ketoconazole) does not appear to prevent the conversion of **losartan** to E-3174.

The plasma clearance of a 20-mg intravenous dose of E-3174 was also unaffected by pretreatment with ketoconazole.⁷ Similar results were found

in a study involving 27 healthy subjects. Ketoconazole 200 mg daily for 5 days was found to have no effect on the pharmacokinetics of **eprosartan** or **losartan** and its active metabolite.⁸ No special precautions would appear to be needed if these drugs are used concurrently.

Angiotensin II receptor antagonists + Beta blockers

There appears to be no clinically significant pharmacokinetic interaction between atenolol and valsartan, and concurrent use enhances the hypotensive effects. The combination of angiotensin II receptor antagonists and beta blockers is in established clinical use.

Clinical evidence, mechanism, importance and management

In a single-dose, crossover study in 12 healthy subjects, the pharmacokinetics of **valsartan** 160 mg and **atenolol** 100 mg were not significantly altered by concurrent use. The combination had some additive effects on resting blood pressure.¹

Although pharmacokinetic information is apparently limited to this drug pair, no significant adverse interaction would be expected between angiotensin II receptor antagonists and beta blockers, and the combination is clinically useful in a number of cardiovascular disorders.

1. Czendlik CH, Sioufi A, Preiswerk G, Howald H. Pharmacokinetic and pharmacodynamic interaction of single doses of valsartan and atenolol. *Eur J Clin Pharmacol* (1997) 52, 451–9.

Angiotensin II receptor antagonists + Calcium-channel blockers

No significant pharmacokinetic interactions occur between nifedipine and candesartan or irbesartan, or between amlodipine and telmisartan or valsartan. Calcium-channel blockers have been given safely with eprosartan or irbesartan.

Clinical evidence, mechanism, importance and management

(a) Amlodipine

In a study in 12 healthy subjects, **telmisartan** 120 mg daily had no clinically relevant effect on the pharmacokinetics of amlodipine 10 mg daily for 9 days, and there was no evidence of any marked effect of amlodipine on the pharmacokinetics of **telmisartan**. Although there were no serious adverse effects, mild to moderate adverse events (most commonly headache) occurred slightly more frequently with the combination, compared with amlodipine alone (19 events versus 12 events).¹

In 12 healthy subjects the pharmacokinetics of single oral doses of **valsartan** 160 mg and amlodipine 5 mg were not significantly altered on concurrent use, although the pharmacokinetics of **valsartan** showed wide variations between subjects.²

No special precautions would therefore appear to be necessary if any of these drugs are given together, although be aware that an increase in adverse effects may occur.

(b) Nifedipine

In 12 healthy subjects nifedipine 30 mg daily did not significantly affect the pharmacokinetics of **candesartan** 16 mg daily.³

In vitro studies indicated that nifedipine inhibited the oxidation of **irbesartan**, which was mediated by the cytochrome P450 isoenzyme CYP2C9.⁴ However, a randomised, crossover study in 11 healthy subjects given **irbesartan** 300 mg daily alone or with nifedipine 30 mg daily for 4 days, found that nifedipine did not alter the pharmacokinetics of **irbesartan**.⁴ The manufacturer says that **irbesartan** has been safely given with antihypertensives such as long-acting calcium-channel blockers.⁵ Similarly the manufacturer of **eprosartan** notes that it has been safely given with calcium-channel blockers (such as sustained-release nifedipine).⁶

Angiotensin II receptor antagonists + Diuretics; Loop, Thiazide and related

Symptomatic hypotension may occur when an angiotensin II receptor antagonist is started in patients taking high-dose diuretics. Potassium levels may be either increased, decreased or not affected. No clinically relevant pharmacokinetic interactions appear to occur between candesartan, eprosartan, irbesartan, losartan, telmisartan or valsartan and hydrochlorothiazide, although the bioavailability of hydrochlorothiazide may be modestly reduced. Similarly, there is no clinically significant pharmacokinetic interaction between valsartan and furosemide.

Clinical evidence, mechanism, importance and management

(a) Hypotension

Angiotensin II receptor antagonists and thiazide or related diuretics have useful additive effects in the control of hypertension and are generally well tolerated. For example, in one double-blind, placebo-controlled study in 604 patients with hypertension, **losartan** 50 mg given with **hydrochlorothiazide** 12.5 mg once daily produced an additive reduction in trough sitting systolic and diastolic blood pressure, and the incidence of dizziness and headache was not significantly different from placebo.¹ However, symptomatic hypotension, especially after the first dose, may occur when angiotensin II receptor antagonists are started in patients with heart failure or those with hypertension who also have sodium and/or volume depletion, such as those taking **high-dose diuretics**. It is recommended that any volume and/or sodium depletion should be corrected before the angiotensin II receptor antagonist is given. In some situations it may be appropriate to reduce the dose of the diuretic and/or use a lower starting dose of the angiotensin II receptor antagonist.

A similar problem occurs with the ACE inhibitors, see 'ACE inhibitors + Diuretics; Loop, Thiazide and related', p.21.

(b) Pharmacokinetic studies

The changes in **furosemide** and **hydrochlorothiazide** pharmacokinetics appear to be of no practical importance, and the combination with an angiotensin II receptor antagonist can produce a significant and useful additional reduction in blood pressure. Details of these studies are given below.

1. **Furosemide**. In 12 healthy subjects the relative bioavailability of furosemide 40 mg was reduced by about 26% when it was given with **valsartan** 160 mg. However, this pharmacokinetic interaction had no influence on the diuretic effect of furosemide. Simultaneous use of **valsartan** and furosemide did not modify the pharmacokinetics of **valsartan**.²

2. **Hydrochlorothiazide**. In 18 healthy subjects the concurrent use of hydrochlorothiazide 25 mg daily and **candesartan** 12 mg daily for 7 days increased the AUC and maximum serum levels of **candesartan** by 18% and 23%, respectively, and reduced the AUC of hydrochlorothiazide by 14%, but these changes were not considered to be clinically relevant.³ **Eprosartan** 800 mg also decreased the AUC of hydrochlorothiazide 25 mg by about 20% in 18 healthy subjects, but again this was not considered to be clinically important. In addition, hydrochlorothiazide had no effect on **eprosartan** pharmacokinetics.⁴ Similarly, in a study of 12 patients with mild or moderate hypertension given **losartan** 50 mg alone or with hydrochlorothiazide 12.5 mg daily for 7 days, the AUC of hydrochlorothiazide was decreased by 17% during concurrent use (not clinically significant) while the pharmacokinetics of **losartan** were unchanged.⁵ A single-dose study in 12 healthy subjects found that **valsartan** 160 mg reduced the systemic availability of hydrochlorothiazide 25 mg (AUC decreased by 31%), but the mean amount of hydrochlorothiazide excreted in the urine did not seem to change significantly. The pharmacokinetics of **valsartan** were not significantly affected by hydrochlorothiazide.⁶

In a randomised, crossover study in 13 healthy subjects, **telmisartan** 160 mg daily was given with hydrochlorothiazide 25 mg daily for 7 days. There was no difference in AUC and maximum plasma concentrations of either drug compared with when they were given alone.⁷ Similarly, no pharmacokinetic interactions were found between **irbesartan** and hydrochlorothiazide.⁸

(c) Serum potassium levels

Angiotensin receptor II antagonists are potassium sparing, whereas loop and thiazide diuretics are potassium depleting. Giving an angiotensin receptor II antagonist with a diuretic could result in an increase, a decrease, or no change to the potassium levels, although logically adding an angiotensin II receptor antagonist to established treatment with a diuretic would seem more likely to raise potassium, and vice versa. Serum potassium should be routinely monitored when angiotensin II antagonists are used in patients with heart failure, renal impairment, or in the elderly.

Angiotensin II receptor antagonists + Diuretics; Potassium-sparing

There is an increased risk of hyperkalaemia if angiotensin II receptor antagonists are given with potassium-sparing diuretics (such as amiloride and the aldosterone antagonists, eplerenone and spironolactone), particularly if other risk factors are also present.

Clinical evidence

Life-threatening hyperkalaemia occurred in 6 patients with congestive heart failure who were taking **spironolactone** and an angiotensin II receptor antagonist (**candesartan**, **losartan** or **telmisartan**). Analysis of these patients, together with another 38 similar patients who had received ACE

inhibitors, identified certain conditions that may lead to the development of severe hyperkalaemia in such patients. These were advanced age, dose of **spironolactone** greater than 25 mg, reduced renal function and type II diabetes.¹

Mechanism

Angiotensin II receptor antagonists reduce the levels of aldosterone, which results in the retention of potassium. This would be expected to be additive with the potassium-retaining effects of amiloride, triamterene, spironolactone and eplerenone, leading to hyperkalaemia, but usually only if other risk factors are present.

Importance and management

Concurrent use of potassium-sparing diuretics (namely **amiloride**, **triamterene** and the aldosterone antagonists **eplerenone** and **spironolactone**) may increase serum potassium. There is a greater risk of hyperkalaemia if renal impairment and/or heart failure or diabetes are present. Because angiotensin II receptor antagonists have potassium-sparing effects, amiloride and triamterene should not normally be given concurrently. Aldosterone antagonists such as spironolactone may be useful in heart failure, but the combined use of angiotensin II receptor antagonists requires increased monitoring of serum potassium. Note that the combination should be avoided in patients with a glomerular filtration rate of less than 30 mL/minute.² In addition, the dose of spironolactone should not exceed 25 mg daily.² Similarly, the UK manufacturer of eplerenone says that caution is required when it is combined with angiotensin II receptor antagonists, especially in renal impairment, and that potassium levels and renal function should be monitored.³

Angiotensin II receptor antagonists + Food

Food slightly increases the AUC of eprosartan and losartan, slightly reduces the AUC of telmisartan, and modestly reduces the AUC of valsartan. However, none of these changes is likely to be clinically important. Food has no effect on the AUC of candesartan, irbesartan or olmesartan.

Clinical evidence, mechanism, importance and management

(a) Candesartan

Food does not affect the bioavailability of candesartan,^{1,2} and the manufacturer states that it may be given with or without food.

(b) Eprosartan

Food delays eprosartan absorption, and slightly increases its AUC and maximum serum concentrations by up to 25%. The UK manufacturer recommends that eprosartan is given with food,³ but the US manufacturer suggests that the change in absorption is not clinically significant, and that eprosartan may be taken with or without food.⁴

(c) Irbesartan

In a study in 16 healthy men, a **high-fat breakfast** had no clinically relevant effects on the bioavailability of a single 300-mg dose of irbesartan,⁵ therefore it may be taken with or without food.

(d) Losartan

In a crossover study in healthy subjects, the AUC and maximum levels of a single 100-mg dose of losartan, given 30 minutes before a **high-fat breakfast** was increased by 17% and 35%, respectively, when compared to the fasted state. Food caused a less than 10% decrease in AUC and maximum level of the losartan metabolite, E-3174.⁶ These minor changes are unlikely to be clinically significant, and the manufacturer says that losartan may be given with or without food.^{7,8}

(e) Olmesartan

Food does not affect the bioavailability of olmesartan,^{9,10} and the manufacturer states that it may be given with or without food.

(f) Telmisartan

Food slightly reduces the AUC of telmisartan by about 6 to 20% depending on dose,^{11,12} but this would not be expected to cause a reduction in therapeutic efficacy,¹¹ and telmisartan may be taken with or without food.¹²

(g) Valsartan

Food modestly decreased the AUC of valsartan by 40%,¹³ but the manufacturer states that it may be taken with or without food.^{13,14}

Angiotensin II receptor antagonists + H₂-receptor antagonists

Cimetidine may cause a small rise in plasma concentrations of valsartan, but this is unlikely to be clinically significant. Cimetidine did not significantly affect the pharmacokinetics and blood pressure-lowering effect of losartan, and ranitidine did not significantly alter the pharmacokinetics of eprosartan.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

1. **Losartan.** In a randomised, crossover study in 8 healthy subjects when losartan 100 mg was given after cimetidine 400 mg four times daily for 6 days, the pharmacokinetics and pharmacodynamics of losartan and its active metabolite, E-3174, were not changed to a clinically relevant extent, although there was a minor increase of 18% in the AUC of losartan.¹ No special precautions are needed if these drugs are used concurrently.

2. **Valsartan.** In a single-dose, crossover study, cimetidine 800 mg, given one hour before valsartan 160 mg, increased the initial rate of absorption of valsartan (attributed to a raised gastric pH) resulting in a roughly 50% increase in its maximum plasma concentration. However, the AUC was only slightly increased and there were large inter-subject variations in the pharmacokinetics of valsartan.² The changes in valsartan pharmacokinetics seen with cimetidine are unlikely to be clinically relevant.

(b) Ranitidine

A single 400-mg dose of **eprosartan** was given to 17 healthy subjects, both alone and after ranitidine 150 mg twice daily for 3 days. The ranitidine caused some slight, but statistically insignificant, changes in the pharmacokinetics of the **eprosartan** (maximum plasma concentration and AUC reduced by about 7% and 11%, respectively).³

Angiotensin II receptor antagonists + Mannitol

A report describes mannitol-induced acute renal failure in a diabetic patient taking losartan.

Clinical evidence, mechanism, importance and management

A man with diabetic nephropathy taking **losartan** 25 mg twice daily for hypertension developed acute renal failure after being given a total of 420 g of intravenous mannitol over 4 days for haemorrhagic glaucoma. The patient recovered after the mannitol and **losartan** were discontinued, and after receiving haemodialysis.¹ It is not fully understood why this combination caused acute renal failure, but it may result in a marked decrease in glomerular filtration rate. Caution is recommended.¹ For comment on the potentiation of ACE inhibitor-induced renal damage by diuretics, see 'ACE inhibitors + Diuretics; Loop, Thiazide and related', p.21.

- Matsumura M. Mannitol-induced toxicity in a diabetic patient receiving losartan. *Am J Med* (2001) 110, 331.

Angiotensin II receptor antagonists + Potassium compounds

There may be a risk of hyperkalaemia if angiotensin II receptor antagonists are given with potassium supplements or potassium-containing salt substitutes, particularly in those patients where other risk factors are present, such as decreased renal function, heart failure, or diabetes.

Clinical evidence, mechanism, importance and management

Angiotensin II receptor antagonists are potassium-sparing, via their effects on aldosterone, and their potential to cause clinically important hyperkalaemia is well established. The incidence of hyperkalaemia varies depending on the clinical indication and other disease conditions, being lowest in essential hypertension, and highest in heart failure, diabetes, and renal impairment. For example, the incidence of hyperkalaemia in clinical studies in patients with hypertension was 0.9% with **eprosartan**^{1,2} and 1.5% with **losartan**;³ in type II diabetic patients with nephropathy, the incidence was 9.9% with **losartan**³ and 18.6% with **irbesartan**;⁴ and in those with heart failure the incidence was 6.3% with **candesartan**.⁵

The concurrent use of potassium-containing supplements or **salt substitutes** and angiotensin II receptor antagonists is likely to further increase serum potassium. Therefore potassium supplements are generally unlikely to be needed in patients taking angiotensin II receptor antagonists, particularly if they have other risk factors for hyperkalaemia, and it may be prudent for such patients to be told to avoid using potassium-containing **salt substitutes**. If concurrent use is considered necessary, potassium levels should be closely monitored. For reports of hyperkalaemia associated with ACE inhibitors and *dietary* potassium, see 'ACE inhibitors + Potassium compounds', p.32.

Angiotensin II receptor antagonists + Rifampicin (Rifampin)

Rifampicin increases the metabolism of losartan and its active metabolite, E-3174, which may result in reduced antihypertensive effects.

Clinical evidence, mechanism, importance and management

Ten healthy subjects were given **losartan** 50 mg daily for a week and then, after a 6-day washout period, **losartan** 50 mg daily with rifampicin 300 mg twice daily for a week. It was found that rifampicin reduced the AUC of **losartan** by 36%, reduced its half-life from 2 to 0.9 hours, and increased its clearance by 60%. The AUC of the active metabolite, E3174, was reduced by 41% and its half-life was reduced from 5.1 to 2.5 hours. Diastolic blood pressure was significantly reduced by **losartan** alone, but not by the combination.¹ The presumed reason for this interaction is that rifampicin (a recognised enzyme inducer) increases the metabolism of **losartan** to its active metabolite by the cytochrome P450 isoenzyme CYP2C9.

The clinical importance of this interaction still awaits assessment, but it would seem likely that the antihypertensive effects of **losartan** would be reduced by rifampicin. If both drugs are used, be alert for the need to increase the **losartan** dosage. More study is needed. There seems to be no information regarding other angiotensin II receptor antagonists, but note that **irbesartan**, and to a limited extent **candesartan**, are also metabolised by CYP2C9 (see the 'introduction', (p.12)).

- Williamson KM, Patterson JH, McQueen RH, Adams KF, Pieper JA. Effects of erythromycin or rifampin on losartan pharmacokinetics in healthy volunteers. *Clin Pharmacol Ther* (1998) 63, 316–23.

Angiotensin II receptor antagonists; Losartan + AST-120

AST-120 does not appear to have an important effect on the pharmacokinetics of losartan.

Clinical evidence, mechanism, importance and management

When a single 100-mg dose of losartan was given 30 minutes before a high-fat breakfast, with AST-120 3 g three times daily for 48 hours started 30 minutes after the breakfast, the AUC of losartan was not significantly altered, although there was a minor 12.3% decrease in the maximum losartan level. Similarly, various other schedules (losartan with breakfast, then AST-120 started 30 minutes later, or AST-120 started 30 minutes after breakfast, then losartan given 30 minutes after that), did not significantly alter the AUC of losartan, when compared with losartan given 30 minutes before breakfast. However, there were minor to modest increases in the AUC of losartan (of up to 37%) when these schedules were compared with losartan given in the fasting state, which was attributed to the effect of food.¹

AST-120 is a predominantly carbon-based oral absorbent, and might therefore interfere with absorption of other drugs.

Data from this pharmacokinetic study indicate that AST-120 has minimal effects on the pharmacokinetics of losartan. The authors suggest that giving AST-120 one hour after losartan may be preferred.¹

- Marier JF, Guilbaud R, Kambhampati SR, Mathew P, Moberly J, Lee J, Salazar DE. The effect of AST-120 on the single-dose pharmacokinetics of losartan and losartan acid (E-3174) in healthy subjects. *J Clin Pharmacol* (2006) 46, 310–20.

Angiotensin II receptor antagonists; Losartan + Erythromycin

The pharmacokinetics and blood pressure-lowering effect of losartan do not seem to be affected by erythromycin.

Clinical evidence, mechanism, importance and management

When 10 healthy subjects were given **losartan** 50 mg daily for a week and then, after a 6-day washout period, **losartan** 50 mg daily with erythromycin 500 mg four times daily for a week, it was found that erythromycin had no significant effect on the pharmacokinetics of **losartan** or its active metabolite, E-3174. In addition, erythromycin did not alter the blood pressure-lowering effect of **losartan**.¹ Inhibition of the cytochrome P450

isoenzyme CYP3A4 alone does not appear to prevent the conversion of **losartan** to E-3174. There would therefore appear to be no reason to take any special precautions if both drugs are used concurrently.

1. Williamson KM, Patterson JH, McQueen RH, Adams KF, Pieper JA. Effects of erythromycin or rifampin on losartan pharmacokinetics in healthy volunteers. *Clin Pharmacol Ther* (1998) 63, 316–23.

Angiotensin II receptor antagonists; Losartan + Grapefruit juice

Grapefruit juice has a minor effect on the pharmacokinetics of losartan and its active metabolite, E-3174, which is unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

In a study in 9 healthy subjects, grapefruit juice approximately doubled the time for a single 50-mg dose of **losartan** to be detected in the serum (from 0.6 to 1.3 hours) and reduced the AUC of its active metabolite, E-3174, by 21%. **Losartan** is partly metabolised by the cytochrome P450 isoenzyme CYP3A4 and transported by P-glycoprotein, both of which can be affected by grapefruit juice. This may explain the minor changes seen.¹ However, this interaction is unlikely to be clinically relevant.

1. Zaidenstein R, Soback S, Gips M, Avni B, Dishy V, Weissgarten Y, Golik A, Scapa E. Effect of grapefruit juice on the pharmacokinetics of losartan and its active metabolite E3174 in healthy volunteers. *Ther Drug Monit* (2001) 23, 369–73.

Angiotensin II receptor antagonists; Losartan + Phenobarbital

Phenobarbital minimally alters the levels of losartan and its active metabolite.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study 15 healthy subjects were given phenobarbital 100 mg daily for 16 days with a single 100-mg dose of **losartan**. Phenobarbital slightly reduced the AUC of **losartan** and its active metabolite,

E-3174, by about 20%, but this was not considered to be clinically significant.¹

1. Goldberg MR, Lo MW, Deutsch PJ, Wilson SE, McWilliams EJ, McCrea JB. Phenobarbital minimally alters plasma concentrations of losartan and its active metabolite E-3174. *Clin Pharmacol Ther* (1996) 59, 268–74.

Angiotensin II receptor antagonists; Losartan + Phenytoin

Phenytoin inhibited the metabolism of losartan to its active metabolite, E-3174, but the clinical relevance of the changes seen are unknown.

Clinical evidence, mechanism, importance and management

The concurrent use of phenytoin and losartan for 10 days reduced the AUC of the active metabolite of losartan, E-3174, by 63%, but did not significantly alter the AUC of losartan. The pharmacokinetics of phenytoin were not affected by losartan. In this crossover study in 16 healthy subjects, phenytoin was given at a dose of 4 mg/kg rounded to the nearest 100 mg, not to exceed 400 mg daily, and the dose was adjusted on the fourth day, if necessary, based on serum phenytoin levels. The losartan dose was 50 mg daily. Phenytoin did not alter the effect of losartan on blood pressure. The effect of phenytoin appeared to be CYP2C9 genotype-specific, with increases in losartan AUC seen in the 14 subjects who were extensive metabolisers of CYP2C9, and decreases in the 2 subjects who were poor metabolisers.¹

Both phenytoin and losartan are substrates for the cytochrome P450 isoenzyme CYP2C9. It appears that phenytoin had an inhibitory effect on losartan metabolism. The conversion of losartan to E3174 represents about 5 to 15% of the clearance of an oral losartan dose,¹ but E3174 is much more active than losartan.

The clinical importance of this interaction still awaits assessment. Until more is known, if phenytoin is added to established losartan therapy, it may be prudent to initially monitor blood pressure more closely. More study is needed.

3

Alcohol

For social and historical reasons alcohol is usually bought from a store or in a bar or restaurant, rather than from a pharmacy, because it is considered to be a drink and not a drug. However, pharmacologically it has much in common with medicinal drugs that depress the central nervous system. Objective tests show that as blood-alcohol levels rise, the ability to perform a number of skills gradually deteriorates as the brain becomes progressively disorganised. The myth that alcohol is a stimulant has arisen because at parties and social occasions it helps people to lose some of their inhibitions and it allows them to relax and unwind. Professor JH Gaddum put it amusingly and succinctly when, describing the early effects of moderate amounts of alcohol, he wrote that “logical thought is difficult but after dinner speeches easy.” The expansiveness and loquaciousness that are socially acceptable can lead on, with increasing amounts of alcohol, to unrestrained behaviour in normally well-controlled individuals, through to drunkenness, unconsciousness, and finally death from respiratory failure. These effects are all a reflection of the progressive and deepening depression of the CNS.

‘Table 3.1’, (p.41) gives an indication in very broad terms of the reactions of men and women to different amounts and concentrations of alcohol.

On the whole women have a higher proportion of fat in which alcohol is not very soluble, their body fluids represent a smaller proportion of their total body mass, and their first-pass metabolism of alcohol is less than men because they have less alcohol dehydrogenase in their stomach walls. Consequently if a man and woman of the same weight matched each other, drink for drink, the woman would finish up with a blood alcohol level about 50% higher than the man. The values shown assume that the drinkers regularly drink, have had a meal and weigh between 9 and 11 stones (55 to 70 kg). Higher blood-alcohol levels would occur if alcohol was drunk on an empty stomach and lower values in much heavier individuals. The liver metabolises about one unit per hour so the values will fall with time.

Since alcohol impairs the skills needed to drive safely, almost all national and state authorities have imposed maximum legal blood alcohol limits (see ‘Table 3.2’, (p.41)). In a number of countries this has been set at

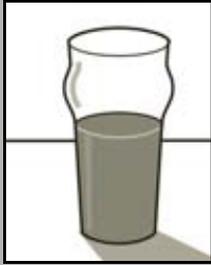

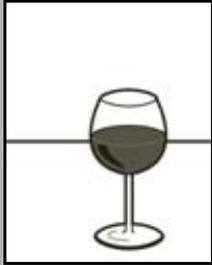

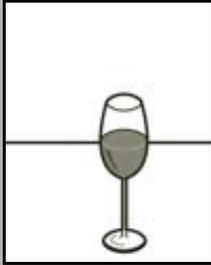

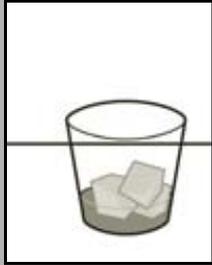

80 mg/100 mL (35 micrograms per 100 mL in the breath) but impairment is clearly detectable at lower concentrations, for which reason some countries have imposed much lower legal limits.

Alcohol can interact with many drugs both by pharmacokinetic and/or pharmacodynamic mechanisms. The quantity and frequency of alcohol consumption can affect the bioavailability of alcohol and other drugs. Several hepatic enzymes are important in the metabolism of alcohol; primarily alcohol dehydrogenases convert alcohol into acetaldehyde, but other enzymes, in particular the cytochrome P450 isoenzyme CYP2E1, are also involved, especially in moderate to heavy alcohol consumption. Enzyme induction of CYP2E1 (and possibly other isoenzymes) occurs after prolonged heavy alcohol intake, and this can result in an increased metabolic rate and lower blood levels of drugs metabolised via this system. Conversely, short term binge drinking is likely to cause inhibition of this enzyme group by direct competition for binding sites and therefore decrease the metabolism of other drugs.

Probably the most common drug interaction of all occurs if alcohol is drunk by those taking other drugs that have CNS depressant activity, the result being even further CNS depression. Blood-alcohol levels well within the legal driving limit may, in the presence of other CNS depressants, be equivalent to blood-alcohol levels at or above the legal limit in terms of worsened driving and other skills. This can occur with some antihistamines, antidepressants, anxiolytics, hypnotics, opioid analgesics, and others. This section contains a number of monographs that describe the results of formal studies of alcohol combined with a number of recognised CNS depressants, but there are still many other drugs that await study of this kind, and which undoubtedly represent a real hazard.

A less common interaction that can occur between alcohol and some drugs, chemical agents, and fungi, is the flushing (*Antabuse*) reaction. This is exploited in the case of disulfiram (*Antabuse*) as a drink deterrent (see ‘Alcohol + Disulfiram’, p.61), but it can occur unexpectedly with some other drugs, such as some antifungals and cephalosporins, chlorpropamide and metronidazole, and can be both unpleasant and possibly frightening, but it is not usually dangerous.

Table 3.1 Reactions to different concentrations of alcohol in the blood

Amounts of alcohol drunk		Blood-alcohol levels mg% (mg per 100 mL)	Reactions to different % of alcohol in the blood		
Man 11 stones (70 kg)	Woman 9 stones (55 kg)				
2 units	1 unit	25 to 30	Sense of well-being enhanced. Reaction times reduced		
4 units	2 units	50 to 60	Mild loss of inhibition, judgement impaired, increased risk of accidents at home, at work and on the road; no overt signs of drunkenness		
5 units	3 units	75 to 80	Physical co-ordination reduced, more marked loss of inhibition; noticeably under the influence; at the maximum legal limit for driving in some countries		
7 units	4 units	100 or more	Clumsiness, loss of physical control, tendency to extreme responses; definite intoxication		
10 units	6 units	150	Slurred speech, possible loss of memory the following day, probably drunk and disorderly		
24 units	14 units	360	Dead drunk, sleepiness, possible loss of consciousness		
33 units	20 units	500	Coma and possibly death		
1 unit	= half a pint (300 mL medium strength beer)	= glass of wine (100 mL)	= single sherry or martini (50 mL)	= single spirit (25 mL)	
					
alcohol 3 to 4%		alcohol 11%		alcohol 17 to 20%	
					
				alcohol 37 to 40%	

After *Which?* October 1984, page 447 and others.

Table 3.2 Maximum legally allowable blood alcohol limits when driving in various countries

80 mg%	Belize, Canada,* Cape Verde, Central African Republic, Ghana, Guatemala, Ireland, Kenya, Luxembourg, Malaysia, Malta, Mexico, New Zealand,* Nicaragua, Niger, Paraguay, Seychelles, Singapore, Suriname, Switzerland, Uganda, United Kingdom, United States of America,* Uruguay, Zambia
70 mg%	Bolivia, Ecuador, Honduras
60 mg%	Brazil, Sri Lanka
52 mg%	Republic of Korea
50 mg%	Argentina, Australia,* Austria, Belarus, Benin, Bosnia & Herzegovina, Bulgaria, Cambodia, Croatia, Denmark, El Salvador, Finland, France, French Polynesia, Germany, Greece, Guinea-Bissau, Iceland, Israel, Italy, Kyrgyzstan, Mauritius, Micronesia (Federated States of), Namibia, Netherlands, Peru, Philippines, Portugal, Slovenia, South Africa, Spain, Thailand, The former Yugoslav Republic of Macedonia, Turkey, United Republic of Tanzania, Venezuela
49 mg%	Chile, Costa Rica, Latvia
40 mg%	Lithuania
35 mg%	Jamaica
33 mg%	Turkmenistan
30 mg%	Georgia, India, Japan, Republic of Moldova
20 mg%	Estonia, Mongolia, Norway, Poland, Sweden
10 mg%	Guyana, Palau
0 mg%	Armenia, Azerbaijan, Colombia, Czech Republic, Equatorial Guinea, Eritrea, Gambia, Guinea, Hungary, Islamic Republic of Iran, Jordan, Kazakhstan, Malawi, Nepal, Nigeria, Panama, Romania, Russian Federation, Slovakia
No legislation	China, Comoros, Congo (Brazzaville), Dominican Republic, Ethiopia, Lao People's Democratic Republic, Togo, Ukraine

Note: For easy comparison the legally allowable blood alcohol limits have all been expressed as mg%. Thus: blood alcohol levels of 80 mg% = 80 mg of alcohol in 100 mL blood = 0.8 g/L.

*Variations occur within these countries e.g. in Australia no alcohol is allowed for drivers of heavy, dangerous goods, public transport vehicles; learners and drivers under 25 years of age for first three years of driving.

Adapted from the WHO Global Status Report: Alcohol policy, Geneva, 2004.

Alcohol + Alpha blockers

The plasma levels of both indoramin and alcohol may be raised by concurrent use. The combination of alcohol and indoramin has been reported to increase drowsiness, which may possibly increase the risks when driving or using machinery. Prazosin appears to enhance the hypotensive effects of alcohol.

Clinical evidence

(a) Indoramin

When 10 healthy subjects were given a single 50-mg oral dose of indoramin together with alcohol 0.5 g/kg in 600 mL of alcohol-free lager, the AUC of indoramin was increased by 25% and the peak plasma levels were raised by 58%.^{1,2} When the subjects were given a single 175-microgram/kg intravenous dose of indoramin together with the same oral dose of alcohol, a 26% rise in blood-alcohol levels occurred during the first 1.25 hours after dosing, but no change in indoramin pharmacokinetics were seen. The combination of alcohol and indoramin caused more sedation than either drug alone.²

(b) Prazosin

A study in 10 Japanese hypertensive patients found that alcohol 1 mL/kg decreased blood pressure for several hours. Treatment with prazosin 1 mg three times daily caused a significant reduction in blood pressure and enhanced alcohol-induced hypotension.³ These effects may be restricted to Oriental/Asian patients because the alcohol flush syndrome, caused by accumulation of vasodilative acetaldehyde due to a genetic alteration in aldehyde dehydrogenase, is rare in whites and blacks.³ The clinical significance is uncertain as the dose of prazosin in the study was relatively small and the dose of alcohol was relatively large, therefore these findings may not apply to more moderate drinking or higher doses of prazosin.

Mechanism

Uncertain. Increased absorption of indoramin from the gut or reduced liver metabolism may be responsible for the raised indoramin serum levels. The increase in sedation would appear to be due to the additive sedative effects of the two drugs.

Importance and management

Information is limited but the interaction between indoramin and alcohol appears to be established. The clinical importance of the raised levels of both drugs is uncertain. However since indoramin sometimes causes drowsiness when it is first given, there is the possibility that alertness will be reduced, which could increase the risks of driving or handling machinery. Patients should be warned. Prazosin appears to enhance the hypotensive effect of alcohol, see also, 'Alcohol + Antihypertensives', p.48.

Alcohol + Amfetamines

Dexamfetamine can reduce the deleterious effects of alcohol to some extent, but some impairment still occurs making it unsafe to drive. Another report suggests the combination of metamfetamine and alcohol produces an increase in perceived total intoxication, and may also increase cardiac adverse effects.

Clinical evidence

In 12 healthy subjects alcohol 0.85 g/kg (2 mL/kg of 100 proof vodka in orange juice) worsened the performance of a SEDI task (Simulator Evaluation of Drug Impairment).¹ This task is believed to parallel the skills needed to drive safely, and involves tests of attention, memory, recognition, decision making and reaction times. When the subjects were also given dexamfetamine 90 or 180 micrograms/kg, there was a dose-related improvement in the performance of the SEDI task, but the subjective as-

essment of intoxication was unchanged. Blood alcohol levels reached a maximum of about 100 mg% at approximately one hour. The bioavailability of the alcohol was slightly increased.¹

Earlier reports using different testing methods found that in some tests dexamfetamine modified the effects of alcohol,^{2,3} but the total picture was complex. Other reports found no antagonism.^{4,5} Another study found that in stress situations, where relief of fatigue or boredom alone will not produce improved performance, dexamfetamine failed to improve attentive motor performance impaired by alcohol.⁶ A later study found that, while the combination of alcohol and metamfetamine diminished the subjective feelings of alcohol intoxication, there was actually an increase in feelings of total intoxication.⁷ The combination of alcohol and metamfetamine may increase cardiac toxicity.⁷

Mechanism

Not understood. Although alcohol is a CNS depressant and the amfetamines are CNS stimulants, there is no simple antagonism between the two.³

Importance and management

Clear-cut conclusions cannot be drawn from the evidence presented in the reported studies. There is some evidence that the effects of alcohol are modified or reduced, but driving skills appear to remain impaired to some extent. There is also evidence of an increased risk of adverse cardiac effects. The increase in perceived total intoxication noted in one report has been suggested as a possible reason for the popularity of the illicit use of the combination.⁷ Consider also 'Alcohol + Ecstasy', p.62.

Alcohol + Aminosalicic acid

Alcohol can abolish the lipid-lowering effects of aminosalicic acid.

Clinical evidence, mechanism, importance and management

The effectiveness of PAS-C (purified aminosalicic acid recrystallised in vitamin C) and diet on the treatment of hyperlipidaemia types IIa and IIb was studied in a group of 63 subjects. It was noted that when 3 of the subjects drank unstated amounts of alcohol (beer or cocktails), the effects of the PAS-C on lowering serum cholesterol, triglyceride and LDL-cholesterol levels were completely abolished.¹ The reasons are not understood.

There seems to be no evidence that alcohol affects the treatment of tuberculosis with aminosalicic acid.

Alcohol + Amisulpride

No pharmacokinetic interaction appears to occur between amisulpride and alcohol.

Clinical evidence, mechanism, importance and management

No significant pharmacokinetic interactions were seen in 18 healthy subjects given single 50- and 200-mg doses of amisulpride with alcohol 0.8 g/kg, nor were the detrimental effects of alcohol on performance

increased by amisulpride.¹ Nevertheless, the manufacturer advises that the central effects of alcohol may be enhanced by amisulpride, and so they do not recommend the combination.²

Alcohol + Antibacterials; Cephalosporins

Disulfiram-like reactions can occur in those who take cefamandole, cefmenoxime, cefoperazone, cefotetan, latamoxef (moxalactam) and possibly cefonicid, and drink alcohol. This is not a general reaction of the cephalosporins, but is confined to those with particular chemical structures.

Clinical evidence

A young man with cystic fibrosis was given **latamoxef** 2 g intravenously every 8 hours for pneumonia. After 3 days of treatment he drank, as was his custom, a can of **beer** with lunch. He rapidly became flushed with a florid macular eruption over his face and chest. This faded over the next 30 minutes but he complained of severe nausea and headache. Similarly, a patient taking **latamoxef** became flushed, diaphoretic and nauseated after drinking a cocktail of **vodka** and tomato juice.¹ This reaction has also been described in two subjects who drank alcohol while receiving **latamoxef**,² two of 10 subjects given **latamoxef** and alcohol,³ and a patient taking **latamoxef** given theophylline elixir containing alcohol 20%.⁴ It has also been seen in a patient taking **latamoxef** following the injection of alcohol into the para-aortic space for coeliac plexus block.⁵ The symptoms experienced by these patients have included flushing of the face, arms and neck, shortness of breath, headache, tachycardia, dizziness, hyper- and hypotension, and nausea and vomiting.

Similar reactions have been described in patients or subjects receiving **cefamandole**,^{6,7} **cefoperazone**,^{8–15} **cefmenoxime**,¹⁶ **cefonicid**¹⁷ and **cefotetan**,¹⁸ after drinking **wine**, **beer**, or other alcoholic drinks, or after the ingestion of an 8.5% alcoholic elixir.¹⁶

This disulfiram-like reaction is not a general reaction of all the cephalosporins. One study found no interaction in those taking **cefpriome** and alcohol,¹⁹ and in another **ceftizoxime** was reported not to interact with alcohol.²⁰ No interaction was seen with **cefonicid** and alcohol in one placebo-controlled study,²¹ however a case report describes a disulfiram-reaction in one patient taking the combination.¹⁷

Mechanism

These reactions appear to have the same pharmacological basis as the disulfiram/alcohol reaction (see 'Alcohol + Disulfiram', p.61). Three of these cephalosporins (latamoxef, cefamandole and cefoperazone) can raise blood acetaldehyde levels in *rats* when alcohol is given, but to a lesser extent than disulfiram.^{2,11,22} It appears that any reaction normally only occurs with cephalosporins that possess a methyltetrazolethiol group in the 3-position on the cephalosporin molecule,^{11,23} but it has also been seen with cefonicid, which possesses a methyl sulphonthiotetrazolic group instead.¹⁷ Some amine-containing cephalosporins (**cefalexin**, **cefadroxil** and **cefradine**) have also been reported to interact with acetaldehyde *in vitro*, but the clinical significance of this is unknown.²⁴

Importance and management

Established but unpredictable interactions of varying incidence. In studies, two out of 10 subjects given latamoxef and alcohol reacted,³ five out of 8 taking cefotetan reacted,¹⁸ and 8 out of 9 receiving cefoperazone reacted.^{14,15} The reaction appears normally to be more embarrassing or unpleasant and frightening than serious, with the symptoms subsiding spontaneously after a few hours. There is evidence that the severity varies; in one study cefoperazone was said to be worse than latamoxef, which in turn was said to be worse than **cefmetazole**.²⁵ Treatment is not usually needed but there are two reports^{4,6} of two elderly patients who needed treatment for hypotension, which was life-threatening in one case;⁴ plasma expanders and dopamine have been used as treatment.^{4,6}

Because the reaction is unpredictable, warn all patients taking these potentially interacting cephalosporins that it can occur during and up to 3 days after the course of treatment is over. Advise them to avoid alcohol. Those with renal or hepatic impairment in whom the drug clearance is prolonged should wait a week. It should not be forgotten that some foods and pharmaceuticals contain substantial amounts of alcohol, and a reaction with some topically applied products cannot be excluded (see 'Alcohol + Disulfiram', p.61).

A number of other cephalosporins are possible candidates for this reaction because they possess the methyltetrazolethiol group in the 3-position. These include, **ceforanide**, **cefotiam**, and **cefpiramide**,^{11,23} but there do not appear to be any reports of an interaction between alcohol and these drugs.

Alcohol + Antibacterials; Ciprofloxacin

Ciprofloxacin does not significantly affect the pharmacokinetics of alcohol or the psychomotor performance observed with alcohol alone. There is an isolated report of a cutaneous reaction to ciprofloxacin, which may have been precipitated by alcohol ingestion.

Clinical evidence, mechanism, importance and management

A 3-day course of ciprofloxacin 500 mg twice daily had no significant effect on the pharmacokinetics of a single 30-g oral dose of alcohol (75 mL of vodka) in 12 healthy subjects, nor was the performance of a number of psychomotor tests affected.¹

There is an isolated report of red blotches developing on the face and body of a tetraplegic patient receiving ciprofloxacin 250 mg twice daily, which developed within 10 minutes of drinking 2 cans of beer containing alcohol 4.7%. He did not feel unwell or drowsy and the blotches faded over a period of 30 minutes. Previous courses of ciprofloxacin had not produced any adverse effects and the same brand of alcohol caused no

problems in the absence of ciprofloxacin.² The general clinical importance of this report is unknown, but it seems likely to be small.

Alcohol + Antibacterials; Co-trimoxazole

A disulfiram-like reaction has been reported when two patients taking co-trimoxazole drank beer.

Clinical evidence, mechanism, importance and management

A 31-year-old man who had been taking prophylactic double-strength co-trimoxazole twice daily for 3 days experienced flushing, palpitations, dyspnoea, headache and nausea 10 to 20 minutes after drinking two 12-oz beers (about 340 mL each). Symptoms resolved gradually over 2 to 3 hours, but occurred again the next day when he drank 6 oz of beer. A similar experience occurred in another man taking double-strength co-trimoxazole after drinking three 12-oz beers. However, on the previous day, he had ingested 4 to 5 beers without a problem, even though he had taken co-trimoxazole.¹ The clinical and practical significance of these case reports is unknown as there do not appear to be any other reports of this interaction.

1. Heelon MW, White M. Disulfiram-cotrimoxazole reaction. *Pharmacotherapy* (1998) 18, 869–70.

Alcohol + Antibacterials; Erythromycin

Alcohol can cause a moderate reduction in the absorption of erythromycin ethylsuccinate. There is some evidence that intravenous erythromycin can raise blood-alcohol levels but the extent and the practical importance of this is unknown.

Clinical evidence, mechanism, importance and management

(a) Effects on alcohol

A study in 10 healthy subjects found that erythromycin base 500 mg three times daily did not alter the pharmacokinetics of oral alcohol 0.8 g/kg, and the subjects' perception of intoxication was unaltered.¹ In contrast, another study in 8 healthy subjects, primarily investigating the effects of intravenous erythromycin lactobionate 3 mg/kg on gastric emptying, found that when they were given a liquid meal of orange juice, alcohol 0.5 g/kg and lactulose 10 g immediately after a solid meal, the mean peak blood-alcohol levels were raised by about 40% and the AUC over the first hour was increased by 33%. After that the curve was virtually the same as that seen with a saline placebo. The authors suggest that the increased blood-alcohol levels are a result of erythromycin causing more rapid gastric emptying, so that the alcohol is exposed to metabolism by the gastric mucosa for a shorter time.²

What this means in terms of an increase in the effects of alcohol (e.g. on driving) is not known.

(b) Effects on erythromycin

When a single 500-mg dose of erythromycin ethylsuccinate was taken by 9 healthy subjects with two 150-mL alcoholic drinks (one immediately and the other 2.5 hours later) the erythromycin AUC was decreased by about 27% and its absorption was delayed. One subject had a 185% increase in absorption. The alcoholic drink was pisco sour, which contains lemon juice, sugar and pisco (a brandy-like liqueur). Blood alcohol levels achieved were about 50 mg%.³

The reason for the reduced absorption of erythromycin is not understood but it is suggested that the slight delay occurs because alcohol delays gastric emptying, so erythromycin reaches its absorption site in the duodenum a little later.³ The extent to which this reduced absorption might affect the control of an infection is uncertain but it seems likely to be small.

Alcohol + Antibacterials; Metronidazole

A disulfiram-like reaction has occurred when some patients taking oral metronidazole have drunk alcohol. There is one report of its occurrence when metronidazole was applied as a vaginal insert, and another when metronidazole was given intravenously. Some clinical studies have not confirmed the interaction, and its existence is disputed in some reports. The interaction is alleged to occur with all other 5-nitroimidazoles (e.g. tinidazole).

Clinical evidence

A man who had been in a drunken stupor for 3 days was given two metronidazole tablets (a total of 500 mg) one hour apart by his wife in the belief that they might sober him up. Twenty minutes after the first tablet he was awake and complaining that he had been given disulfiram (which he had taken some months before). Immediately after the second tablet, he took another drink and developed a classic disulfiram-like reaction with flushing of the face and neck, nausea and epigastric discomfort.¹ Other individual cases have been reported,² including a reaction with a metronidazole vaginal insert.³

In a test of the value of metronidazole 250 mg twice daily as a possible drink-deterrent, all 10 alcoholic patients studied experienced some disulfiram-like reactions of varying intensity (facial flushing, headaches, sensation of heat, fall in blood pressure, vomiting) when given alcohol.⁴ In another study in 60 alcoholic patients, given metronidazole 250 to 750 mg daily, most developed mild to moderate disulfiram-like reactions during an alcohol tolerance test.⁵ A lower incidence of this reaction, between 2 and 24%, has been reported.^{6–8}

Pharmaceutical preparations containing alcohol have also been implicated. A 2-year-old child became flushed and dyspnoeic when metronidazole was given with both *Stopayne* syrup and a phenobarbital syrup, both of which contained alcohol.⁹ Another reaction has been seen in a patient receiving intravenous metronidazole and a trimethoprim-sulfamethoxazole (co-trimoxazole) preparation containing alcohol 10%.¹⁰ A further patient who had just finished a 7-day course of metronidazole developed severe, prolonged nausea and vomiting postpartum: she had received a single 800-mg dose of prophylactic clindamycin intravenously before the birth and it was thought that the benzyl alcohol present in the clindamycin preparation could have caused the reaction. However, other factors such as intrathecal anaesthesia may have also contributed to the adverse effects.¹¹ For mention of other preparations containing alcohol, see 'Alcohol + Disulfiram', p.61.

An interaction has also been reported in association with metabolic acidosis in an intoxicated man 4 hours after he was given intravenous metronidazole as prophylaxis following injury.¹² A fatality occurred in a frail 31-year old woman, which was attributed to cardiac arrhythmia caused by acetaldehyde toxicity resulting from the alcohol/metronidazole interaction, linked to autonomic distress caused by a physical assault.¹³ Alcohol is also said to taste unpleasant^{1,4} or to be less pleasurable⁸ while taking metronidazole. Some drug abusers apparently exploit the reaction for 'kicks'.¹⁴

In contrast, a study in 207 patients with inflammatory bowel disease assessed (using a phone survey) the presence of adverse reactions to alcohol in patients taking chronic metronidazole and/or mercaptopurine or neither drug; all of the patients consumed less than 4 alcoholic beverages per day. There was a trend towards more adverse effects in both the metronidazole and mercaptopurine study groups, but no statistically significant interaction between alcohol and metronidazole was found.¹⁵ There are other reports, including two well-controlled studies, showing that metronidazole has no disulfiram-like effects.^{16–18}

Mechanism

Not understood. In the disulfiram reaction, the accumulation of acetaldehyde appears to be responsible for most of the symptoms (see 'Alcohol + Disulfiram', p.61). Some workers have reported an increase in acetaldehyde levels due to the metronidazole/alcohol interaction,¹³ but others have

reported no effect¹⁸ or a reduction in plasma acetaldehyde levels.¹⁹ Furthermore, some studies with metronidazole indicate a lack of a disulfiram-like reaction,^{16,17} and it has been suggested that if such a reaction does occur it may be by a mechanism other than the inhibition of hepatic acetaldehyde dehydrogenase.¹⁸ It appears that metronidazole, like disulfiram, can inhibit other enzymes related to alcohol metabolism including xanthine oxidase and alcohol dehydrogenase.^{20,21} Inhibition of xanthine oxidase may cause noradrenaline excess, and inhibition of alcohol dehydrogenase can lead to activation of microsomal enzyme oxidative pathways that generate ketones and lactate, which could produce acidosis.¹²

Importance and management

A reasonably well studied interaction, but it remains a controversial issue. The incidence is variously reported as between 0 and 100%, with more recent reports disputing its existence.^{18,19} Nevertheless because of the uncertainty, all patients given metronidazole should be warned about what may happen if they drink alcohol. The manufacturer recommends avoidance of alcohol when metronidazole is taken, and for at least 48 hours after it has been stopped.²² However, the authors of one report suggest a cautious trial of alcohol in patients that are starting and will be taking metronidazole on a chronic basis.¹⁵

The reaction, when it occurs, normally seems to be more unpleasant and possibly frightening than serious, and usually requires no treatment, although one report describes a serious reaction when intravenous metronidazole was given to an intoxicated man,¹² and one possible fatality has been reported.¹³ The risk of a reaction with metronidazole used intravaginally seems to be small because the absorption is low (about 20% compared with about 100% orally), but evidently it can happen, even if only rarely.³ Patients should be warned. It has been alleged that the disulfiram-like reaction with alcohol occurs with all of the related 5-nitroimidazoles,^{23,24} but there do not appear to be any published reports of it occurring with **nimorazole**, **ornidazole**, **secnidazole** or **tinidazole**. The manufacturer of **tinidazole** notes that, as with related compounds, there is a possibility of a disulfiram-like reaction with alcoholic beverages, and recommends that alcohol should be avoided until 72 hours after discontinuing tinidazole.²⁵

Alcohol + Antibacterials; Nitrofurantoin

There appears to be no good clinical evidence for an alleged interaction between alcohol and nitrofurantoin.

Clinical evidence, mechanism, importance and management

Despite claims in some books and reviews, an extensive literature search failed to find any experimental or clinical evidence for an alleged disulfiram-like reaction between alcohol and nitrofurantoin.¹ A study in healthy subjects failed to demonstrate any such interaction² and a survey of the reports in the manufacturer's database also failed to find good evidence for alcohol intolerance.³ It is concluded that this 'interaction' is erroneous.¹

Alcohol + Antibacterials; Penicillins

No adverse interaction normally occurs between alcohol and phenoxymethylpenicillin or amoxicillin.

Clinical evidence, mechanism, importance and management

A long-standing and very common belief among members of the general public (presumably derived from advice given by doctors and pharmacists) is that alcohol should be strictly avoided while taking any antibacterial. It has been claimed that alcohol increases the degradation of penicillin in the gut and reduces the amount available for absorption.¹ However, one study showed that the pharmacokinetics of **phenoxymethylpenicillin** (**penicillin V**) were unaffected by alcoholic drinks,² and another study found that alcohol delayed the absorption of **amoxicillin** but did not affect the total amount absorbed.³ An *in vitro* study did report that acetaldehyde, at concentrations occurring *in vivo* during alcohol metabolism, reacted with amine containing penicillins (**amoxicillin**, **ampicillin**, and **ciclacillin**), which theoretically could lead to decreased drug bioavailability and possibly adverse effects.⁴ However, there seems to be no clinical evidence to support claims of an adverse interaction.

Alcohol + Antibacterials; Tetracyclines

Doxycycline serum levels may fall below minimum therapeutic concentrations in alcoholic patients, but tetracycline is not affected. There is nothing to suggest that moderate amounts of alcohol have a clinically relevant effect on the serum levels of any tetracycline in non-alcoholic subjects.

Clinical evidence

(a) Alcoholic patients

A study into the effects of alcohol on **doxycycline** and **tetracycline** pharmacokinetics found that the half-life of **doxycycline** was 10.5 hours in 6 alcoholics (with normal liver function) compared with 14.7 hours in 6 healthy subjects. The serum **doxycycline** levels of 3 of the alcoholic patients fell below the generally accepted minimum inhibitory concentration at 24 hours. The half-life of **tetracycline** was the same in both groups. All of the subjects were given **doxycycline** 100 mg daily after a 200-mg loading dose, and **tetracycline** 500 mg twice daily after an initial 750-mg loading dose.¹

(b) Non-alcoholic patients

Single 500-mg doses of **tetracycline** were given to 9 healthy subjects with water or alcohol 2.7 g/kg. The alcohol caused a 33% rise in the maximum serum levels of **tetracycline** from 9.3 to 12.4 micrograms/mL, and a 50%

rise in the AUC of **tetracycline**.² The clinical relevance of this rise is unknown.

Another study in healthy subjects found that cheap red wine, but not whisky (both 1 g/kg) delayed the absorption of **doxycycline**, probably because of the presence of acetic acid, which slows gastric emptying. However, the total absorption was not affected. The authors concluded that acute intake of alcoholic beverages has no clinically relevant effects on the pharmacokinetics of **doxycycline**.³

Mechanism

Heavy drinkers can metabolise some drugs much more quickly than non-drinkers due to the enzyme-inducing effects of alcohol.⁴ The interaction with doxycycline would seem to be due to this effect, possibly allied with some reduction in absorption from the gut.

Importance and management

Information is limited, but the interaction between doxycycline and alcohol appears to be established and of clinical significance in alcoholics but not in non-alcoholic individuals. One possible solution to the problem of enzyme induction is to give alcoholic subjects double the dose of doxycycline.⁵ Alternatively tetracycline may be a suitable non-interacting alternative. There is nothing to suggest that moderate or even occasional heavy drinking has a clinically relevant effect on any of the tetracyclines in non-alcoholic subjects.

Alcohol + Antiepileptics

Moderate social drinking does not appear to affect the serum levels of carbamazepine, ethosuximide or phenytoin. Some small changes are seen in the serum levels of phenobarbital and sodium valproate, but no changes in the control of epilepsy seem to occur. No pharmacokinetic interaction was detected between tiagabine and alcohol, and tiagabine did not alter the cognitive effect of alcohol. The adverse effects of both alcohol and antiepileptics, such as enhanced sedation, may be additive.

Clinical evidence, mechanism, importance and management

A study in 29 non-drinking epileptics found that when they drank 1 to 3 glasses of an alcoholic beverage (1 to 3 units) over a 2-hour period, twice a week for 16 weeks the serum levels of **carbamazepine**, **ethosuximide** and **phenytoin** were unchanged, when compared with those from a control group of 23 epileptics given drinks without alcohol. There was a marginal change in **phenobarbital** levels, and some increase in serum **valproate** levels. However, this effect is hard to interpret as **valproate** levels are known to fluctuate and are hard to reproduce. Other antiepileptics used were **clonazepam**, **primidone** and **sultiame**, but too few patients used these for a valid statistical analysis to be carried out. Maximum blood-alcohol levels ranged from 5 to 33 mg%. More important than any changes that occurred in serum antiepileptic levels, was the finding that this social drinking had no effect on the frequency of tonic-clonic convulsions, partial complex seizures, or on the epileptic activity as measured by EEGs.¹ Another study in healthy subjects excluded any pharmacodynamic or pharmacokinetic interaction between **tiagabine** and alcohol. In this study, **tiagabine** 4 mg three times daily did not alter the effect of a single dose of alcohol as assessed in a range of cognitive tests.²

For the effect of chronic heavy drinking on the pharmacokinetics of carbamazepine or phenytoin, see 'carbamazepine', (p.46) and 'phenytoin', (p.47).

There are very few studies, but there seem to be no reasons for epileptics to avoid alcohol in moderate social amounts (1 or 2 drinks per occasion;

no more than 3 to 6 drinks per week).³ However, patients who drink moderate to heavy amounts of alcohol (3 to 4 drinks or more) should be warned that they are at increased risk of seizures, with the greatest risk occurring 7 to 48 hours after the last drink.³ The British Epilepsy Association comments that most people with epilepsy find they can have one or two units of alcohol, perhaps more, without increasing the chances of having a seizure, whereas other people find that even a small amount of alcohol triggers their seizures.⁴ Patients who drink heavily may also get alcohol withdrawal seizures and binge drinking has been associated with seizures even in non-epileptic people. They also say that anyone taking antiepileptics is likely to be more sensitive to the effects of alcohol and can exaggerate the adverse effects of the antiepileptics.⁴ Some antiepileptics such as **carbamazepine**, **clonazepam**, '**phenobarbital**', (p.52), **primidone**, and **topiramate** have sedative effects, which may be additive with those of alcohol.

Individuals need to decide what level of alcohol intake is appropriate for them, and be aware that a change in medication, or an increase in dose of antiepileptic, may make them more susceptible to the effects of alcohol. Patients should also be made aware that drinking alcohol when taking antiepileptics may reduce their ability to perform certain skilled tasks, such as driving.

Alcohol + Antiepileptics; Carbamazepine

Moderate social drinking does not affect the serum levels of carbamazepine. Heavy drinking may possibly increase the metabolism of carbamazepine, and this may be further increased in alcoholics who abstain from drinking alcohol.

Clinical evidence, mechanism, importance and management

(a) Heavy drinking and alcohol withdrawal

A study in 7 alcoholics who consumed a mean dose of 750 mL of spirits (240 g of alcohol) daily found that the early (0 to 4 hours) bioavailability of a single 400-mg dose of carbamazepine was not affected by 9 days of controlled alcohol withdrawal. However, over the 4 to 12-hour period, carbamazepine levels were higher and those of its epoxy metabolite lower in alcoholics following alcohol exposure, when compared with abstinence. This effect was thought to be due to the acute inhibition of carbamazepine metabolism by alcohol and/or accelerated carbamazepine metabolism in the abstinence phase. The absorption rate of carbamazepine in alcoholics appeared to be slower compared with 8 healthy subjects, probably due to alcoholism-induced chronic gastrointestinal changes although this did not significantly affect the maximum serum levels of alcohol. However, adverse effects occurred in all of the healthy subjects but in none of the alcoholics, possibly indicating that long-term alcohol exposure may make the patient less sensitive to acute carbamazepine exposure.¹

The long-term use of alcohol can cause induction of hepatic enzyme systems possibly resulting in increased metabolism and reduced plasma levels of carbamazepine. The risk of seizures may also increase on tapering or stopping alcohol because of an increase in metabolism and elimination caused by the relative lack of a competing substrate.²

(b) Moderate social drinking

Alcohol 25 g did not affect the bioavailability of carbamazepine in 8 healthy subjects.¹ A study in non-drinking epileptics (21 in the experimental alcohol group, 18 in the control group) found that the serum levels of carbamazepine were unchanged by moderate drinking (1 to 3 glasses of an alcoholic beverage, containing 9.85 g of alcohol, twice weekly), and there was no influence on tonic-clonic convulsions or partial complex seizures.³

For comment on moderate social drinking in epileptics and also the possible increased sedative effect of carbamazepine with alcohol, see 'Alcohol + Antiepileptics', above.

Alcohol + Antiepileptics; Phenytoin

Acute alcohol intake may possibly increase serum phenytoin levels, but moderate social drinking appears to have little clinical effect. However, chronic heavy drinking reduces serum phenytoin levels so that above-average doses of phenytoin may be needed to maintain adequate levels.

Clinical evidence

(a) Acute alcohol ingestion

In a study designed to test the effects of acute alcohol intoxication in epileptics, 25 patients were given a 12 oz (about 340 mL) drink of alcohol 25%. Blood-alcohol levels ranged from 39 to 284 mg%. All patients had signs of alcohol intoxication without any effect on seizure frequency.¹ The metabolism of a single dose of phenytoin was not affected in one study in healthy subjects by the acute ingestion of alcohol.² However, the manufacturers say that acute alcoholic intake may increase phenytoin serum levels.^{3,4}

(b) Heavy drinking

In a group of 15 drinkers (consuming a minimum of 200 g of ethanol daily for at least 3 months) phenytoin levels measured 24 hours after the last dose of phenytoin were approximately half those of 76 non-drinkers. The phenytoin half-life was reduced by 30%.⁵

Another study confirmed that alcoholics without liver disease have lower than usual plasma levels of phenytoin after taking standard doses while drinking.⁶ Two reports describe a chronic alcoholic who was resistant to large doses of phenytoin,⁷ and seizures, which developed in a man when an increase in his alcohol consumption appeared to cause a reduction in his serum phenytoin levels.⁸

(c) Moderate social drinking

A study in non-drinking epileptics (17 in the experimental group, 14 in the control group) found that the serum levels of phenytoin were unchanged by moderate drinking, and there was no influence on tonic-clonic convulsions or partial complex seizures. The experimental group drank 1 to 3 glasses of an alcoholic beverage (equivalent to a glass of beer containing 9.85 g of ethanol) over a 2-hour period, twice a week, for 16 weeks, and their maximum blood alcohol levels ranged from 5 to 33 mg%.⁹

Mechanism

Supported by *animal* data,¹⁰ the evidence suggests that repeated exposure to large amounts of alcohol induces liver microsomal enzymes so that the rate of metabolism and clearance of phenytoin is increased. Conversely, acute alcohol intake may decrease hepatic metabolism.¹¹

Importance and management

An established and clinically important interaction, although the documentation is limited. Heavy drinkers may need above-average doses of phenytoin to maintain adequate serum levels. However, be aware that patients with liver impairment usually need lower doses of phenytoin, so the picture may be more complicated. Moderate drinking appears to be safe in those taking phenytoin.^{1,9} Consider also 'Alcohol + Antiepileptics', p.46.

Alcohol + Antihistamines

Some antihistamines cause drowsiness, which can be increased by alcohol. The detrimental effects of alcohol on driving skills are considerably increased by the use of the older more sedative antihistamines and appear to be minimal or absent with the newer non-sedating antihistamines.

Clinical evidence

(a) Non-sedating antihistamines

A double-blind study found that **terfenadine** 60 to 240 mg alone did not affect psychomotor skills, nor did it affect the adverse effects of alcohol.¹ Another study had similar findings.² However, a later study found that **terfenadine** 240 mg slowed brake reaction times in the laboratory when given either alone or with alcohol.³ **Acrivastine** 4 and 8 mg, given with and without alcohol, was found in a study to behave like **terfenadine** (which interacts minimally or not at all).⁴ Other studies have shown that **astemizole** 10 to 30 mg daily,^{5–7} **desloratadine**,⁸ **ebastine** 20 mg,⁹ **fexofenadine** 120 to 240 mg,^{10,11} **levocabastine** 2 nasal puffs of 0.5 mg/mL,¹² **loratadine** 10 to 20 mg,^{2,13} and **mizolastine** 10 mg¹⁴ do not interact with alcohol. **Cetirizine** 10 mg did not appear to interact with alcohol in two studies^{14,15} but some slight additive effects were detected in other studies.^{13,16} Similarly, a single oral dose of **rupatadine** 10 mg did not interact with alcohol, but a 20-mg dose given with alcohol produced more cognitive and psychomotor impairment than alcohol alone.¹⁶

(b) Sedating antihistamines

The effects of alcohol (blood levels about 50 mg%) and antihistamines, alone or together, on the performance of tests designed to assess mental and motor performance were examined in 16 subjects. **Clemizole** 40 mg or **tripelenamine** 50 mg alone did not significantly affect the performance under the stress of delayed auditory feedback, neither did they potentiate the effect of alcohol.¹⁷ **Clemastine** in 3-mg doses had some additive detrimental effects with alcohol on co-ordination, whereas **clemastine** 1.5 mg and 1 mg did not.^{18,19} A study in 5 subjects showed that the detrimental effects of 100 mL of whiskey on the performance of driving tests on a racing car simulator (blood alcohol estimated as less than 80 mg%) were not increased by **cyclizine** 50 mg.²⁰ However 3 of the subjects experienced drowsiness after **cyclizine**, and other studies have shown that **cyclizine** alone causes drowsiness in the majority of subjects.²¹ Significant impairment of psychomotor performance was seen in healthy subjects given **chlorphenamine** 12 mg with alcohol 0.5 g/kg.⁵ A further study similarly found significant impairment in driving skills when chlorphenamine was given with alcohol, see (c) below. In 13 healthy subjects alcohol 0.75 g/kg given with **dexchlorpheniramine** 4 mg/70 kg significantly impaired the performance of a number of tests (standing steadiness, reaction time, manual dexterity, perception, etc.).²² A study in 17 subjects found that **mebhydrolin** 0.71 mg/kg enhanced the alcohol-induced deficits in the performance of a number of tests on perceptual, cognitive and motor functions.²³ No interaction was detected in one study of the combined effects of **pheniramine aminosalicylate** 50 mg or **cyproheptadine hydrochloride** 4 mg and alcohol 0.95 mL/kg.²⁴ **Triprolidine** 10 mg alone can significantly affect driving performance,² and marked deterioration in driving skills has been demonstrated with 10 mL of *Actifed Syrup* (**triprolidone** with pseudoephedrine) alone and with a double whiskey.²⁵

(c) Significantly-sedating antihistamines

Diphenhydramine in doses of 25 or 50 mg was shown to increase the detrimental effects of alcohol on the performance of choice reaction and co-ordination tests in subjects who had taken 0.5 g/kg of alcohol.¹⁸ The interaction between **diphenhydramine** in doses of 50, 75 or 100 mg and alcohol in doses of 0.5 to 0.75 g/kg has been confirmed in other reports.^{1,17,26–28} **Emedastine** in oral doses of 2 or 4 mg twice daily was found to be sedating and impair driving ability in 19 healthy subjects. The addition of alcohol increased this impairment.²⁹ A marked interaction can also occur with **hydroxyzine**^{11,16} or **promethazine**.³⁰ A very marked deterioration in driving skills was clearly demonstrated in a test of car drivers given 20 mL of *Beechams Night Nurse* (**promethazine** with dextrometh-

orphan), 10 mL of *Benylin* (diphenhydramine with dextromethorphan), or 30 mL of *Lemsip Night time flu medicine* (chlorphenamine with dextromethorphan). Very poor scores were seen when they were also given a double Scotch whiskey about 1.5 hours later.²⁵

Mechanism

When an interaction occurs it appears to be due to the combined or additive central nervous depressant effects of both the alcohol and the antihistamine. The 'highly-sedating antihistamines' are highly lipophilic and readily cross the blood-brain barrier; consequently they have considerable sedative effects that may persist into the next day. The 'sedating antihistamines' do not cross the blood-brain barrier so readily, and are therefore less sedating. Most of the non-sedating antihistamines, such as fexofenadine, do not appear to cross the blood-brain barrier.¹¹ The authors of one study found that the sedating effects of cetirizine and emedastine were more marked in women than in men, and they noted that they had also previously seen this with acrivastine, clemastine and mizolastine.²⁹ The reason for this is not established although it has been suggested that a smaller volume of distribution in women may result in higher plasma antihistamine levels.

Importance and management

An adverse interaction between alcohol and the **highly-sedating antihistamines** (see 'Table 15.1', (p.582)) is well established and clinically important. Marked drowsiness can occur with these antihistamines taken alone, which makes driving or handling other potentially dangerous machinery much more hazardous. This can be further worsened by alcohol. Patients should be strongly warned. Remember that some of these antihistamines are present in non-prescription products licensed as antiemetics and sedatives, and as components of cough, cold and influenza remedies (e.g. some preparations of *Benylin*, *Lemsip* or *Night Nurse*). Emedastine may also cause marked sedation when used orally, but it is usually given as eye drops.

The situation with some of the **sedating antihistamines** is less clear cut, and tests with some of them failed to detect an interaction with normal doses and moderate amounts of alcohol; however, it has been clearly seen with *Actifed Syrup* (containing triprolidine). It would therefore be prudent to issue some cautionary warning, particularly if the patient is likely to drive.

The **non-sedating antihistamines** seem to cause little or no drowsiness in most patients and the risks if taken alone or with alcohol appear to be minimal or absent. However, the incidence of sedation varies with the non-sedating antihistamine (e.g. sedation appears to be lower with fexofenadine and loratadine than with acrivastine or cetirizine)³¹ and with the individual (e.g. women may be more affected than men).²⁹ Therefore, patients should be advised to be alert to the possibility of drowsiness if they have not taken the drug before. Any drowsiness would be apparent after the first few doses. The patient information leaflets for acrivastine and cetirizine suggest avoidance of alcohol or excessive amounts of alcohol,³²⁻³⁴ and caution is advised with **levocetirizine**.³⁵

The possible interactions of alcohol with other antihistamines not cited here do not seem to have been formally studied, but increased drowsiness and increased driving risks would be expected with any that cause some sedation. Patients should be warned about drinking alcohol when taking sedative antihistamines. The risks with antihistamines given as eye drops or nasal spray (e.g. **azelastine**, **epinastine**) are probably minimal, but this needs confirmation.

Alcohol + Antihypertensives

Chronic moderate to heavy drinking raises the blood pressure and reduces, to some extent, the effectiveness of antihypertensive drugs. A few patients may experience postural hypotension, dizziness and fainting shortly after having drunk alcohol. Alpha blockers may enhance the hypotensive effect of alcohol in subjects susceptible to the alcohol flush syndrome.

Clinical evidence, mechanism, importance and management

(a) Hypertensive reaction

A study in 40 men with essential hypertension (taking **beta blockers, captopril, diuretics, methyldopa, prazosin or verapamil**) who were moderate to heavy drinkers, found that when they reduced their drinking over a 6-week period from an average of 450 mL of alcohol weekly (about 6 drinks daily) to 64 mL of alcohol weekly, their average blood pressure fell by 5/3 mmHg.¹ The reasons for this effect are uncertain.

The Atherosclerosis Risk in Communities (ARIC) study involving 8334 subjects who were free from hypertension at baseline and were assessed after 6 years, found that higher levels of consumption of alcoholic beverages (210 g or more of alcohol per week; approximately 3 drinks or more per day) were associated with a higher risk of hypertension. Low to moderate consumption of alcohol (up to 3 drinks/day) was associated with an increase in blood pressure in black, but not in white men.² A study in Japanese men found that the effect of alcohol intake on the risk of developing hypertension was dose-dependent, starting at low-to-moderate levels of alcohol (less than 23 g/day).³

These findings are consistent with those of other studies in hypertensive⁴ and normotensive⁵ subjects. It seems likely that this effect will occur with any antihypertensive. Patients with hypertension who are moderate to heavy drinkers should be encouraged to reduce their intake of alcohol. It may then become possible to reduce the dosage of the antihypertensive. It should be noted that epidemiological studies show that regular light to moderate alcohol consumption is associated with a lower risk of cardiovascular disease.⁶

(b) Hypotensive reaction

A few patients taking some antihypertensives feel dizzy or begin to 'black out' or faint if they stand up quickly or after exercise. This orthostatic and exertional hypotension may be exaggerated in some patients shortly after drinking alcohol, possibly because it can lower the cardiac output (noted in patients with various types of heart disease^{7,8}). For other reports of postural hypotension with alcohol, see 'alpha blockers', (p.42), and 'calcium channel blockers', (p.57). Some manufacturers of antihypertensives e.g. **ACE inhibitors**^{9,10} and **thiazide diuretics**¹¹ warn that acute alcohol intake may enhance the hypotensive effects, particularly at the start of treatment,¹⁰ and this could apply to any antihypertensive. Patients just beginning antihypertensive treatment should be warned.

(c) CNS and other effects

For mention of the possibility of increased sedation with alcohol and clonidine or indoramin, see 'Clonidine and related drugs + CNS depressants', p.883 and 'Alcohol + Alpha blockers', p.42.

For the possible CNS effects of beta blockers and alcohol, see 'Alcohol + Beta blockers', p.55.

For mention of the disulfiram-like reaction when tolazoline is given with alcohol, see 'Alcohol + Tolazoline', p.79.

Alcohol + Antimuscarinics

Propranolol appears not to affect blood-alcohol levels, whereas atropine may cause a modest reduction. Marked impairment of attention can occur if alcohol is taken in the presence of atropine or glycopyrronium (glycopyrrolate), probably making driving more hazardous. No adverse interaction usually appears to occur with transdermal hyoscine and alcohol.

Clinical evidence, mechanism, importance and management

Oral **propranolol** (15 mg four times daily or 30 mg three times daily for 5 days, and 30 mg or 60 mg 2 hours before alcohol) did not affect blood-alcohol levels in 3 subjects.¹ A single 3-mg oral dose of **atropine** 2 hours before alcohol reduced the AUC of alcohol by a modest 20% in 3 subjects.¹ Another study in healthy subjects found that oral **atropine** 500 micrograms or **glycopyrronium** 1 mg given with alcohol 0.5 g/kg either did not affect or improved reaction times and co-ordination, there was a marked impairment of attention, which was large enough to make driving more hazardous.² Patients should be warned.

A double-blind crossover study in 12 healthy subjects found that a transdermal **hyoscine** preparation (*Scopoderm-TTS*) did not alter the effects of alcohol on the performance of several psychometric tests (Critical Flicker Fusion Frequency, Choice Reaction Tasks), nor was the clearance of alcohol or **hyoscine** changed. Blood-alcohol levels of up to 80 mg%, and 130 mg%, were studied.³ Nevertheless, the manufacturer suggests

caution in patients receiving drugs that act on the CNS, and advise that patients should not drink alcohol while using *Scopoderm-TTS*.⁴ This is presumably because drowsiness and other CNS adverse effects have occasionally been reported with the transdermal preparation.^{4,5} The manufacturers of travel tablets and injections containing **hyoscine hydrobromide** recommend avoidance of alcohol.^{6,7} However, unlike **hyoscine** and **hyoscine hydrobromide**, the quaternary derivatives such as **hyoscine butylbromide** or **hyoscine methobromide** do not readily pass the blood-brain barrier,⁸ and would be expected to be less likely to cause additive adverse effects with alcohol.

Alcohol + Antimycobacterials

The hepatotoxicity of some antimycobacterials may possibly be increased by high alcohol consumption. Alcohol may increase the risk of epileptic episodes in patients taking cycloserine. A psychotoxic reaction in a patient taking ethionamide was attributed to concurrent heavy alcohol consumption. Isoniazid slightly increases the hazards of driving after drinking alcohol. Isoniazid-induced hepatitis may also possibly be increased by alcohol, and the effects of isoniazid are possibly reduced in some heavy drinkers. Acute alcohol intake does not appear to affect the pharmacokinetics of a single-dose of isoniazid.

Clinical evidence, mechanism, importance and management

(a) Combined antitubercular regimens

Hepatotoxicity can occur with several antituberculous drugs including **ethionamide**, **isoniazid**, **pyrazinamide** and **rifampicin** and high alcohol consumption/chronic alcoholism has been reported to increase the risk.^{1,2} However, one study in patients with active tuberculosis taking **rifampicin** and **pyrazinamide**, found that of the 14 patients who developed hepatotoxicity, only 5 of these reported alcohol use (not quantified), and alcohol was not found to be associated with an increased risk of hepatotoxicity.³ Similarly, another study found that alcohol consumption was not a risk factor for antimycobacterial-induced hepatotoxicity.⁴

(b) Cycloserine

A brief report describes an enhancement of the effects of alcohol in 2 patients taking cycloserine.⁵ The clinical significance of this case report is unclear. However, the manufacturers of cycloserine state that it is 'incompatible' with alcohol because of an increased risk of epileptic episodes, and contraindicate its use in alcohol abuse.^{6,7}

(c) Ethionamide

A psychotoxic reaction seen in a patient taking ethionamide was attributed to the concurrent heavy consumption of alcohol.⁸ It is unclear whether this represents a clinically meaningful interaction but it appears to be the only case on record. However, the manufacturers advise avoidance of excessive alcohol ingestion.⁹

(d) Isoniazid

The effects of isoniazid 750 mg with alcohol 0.5 g/kg were examined in 100 subjects given various psychomotor tests, and in a further 50 drivers using a driving simulator. No major interaction was seen in the psychomotor tests, but the number of drivers who drove off the road on the simulator was increased.^{10,11} There would therefore appear to be some extra risks for patients taking isoniazid who drink and drive, but the effect does not appear to be large. Patients should nevertheless be warned.

The incidence of severe progressive liver damage due to isoniazid is said to be higher in those who drink alcohol regularly.^{12–14} The clinical effects

of isoniazid are also said to be reduced by heavy drinking in some patients;¹² however, acute alcohol intake in 16 healthy subjects did not have any effect on the pharmacokinetics of a single 200-mg dose of isoniazid.¹⁵ Alcohol is metabolised to acetaldehyde in the liver and isoniazid has been found to interact with acetaldehyde *in vitro*. The clinical significance of this is unknown, but if this binding occurs *in vivo*, it could lead to decreased bioavailability of isoniazid and possibly the acetaldehyde-modified drug formed could mediate some adverse effects.¹⁶ The manufacturer advises care in giving isoniazid to patients with chronic alcoholism.¹⁷

Alcohol + Antipsychotics

The detrimental effects of alcohol on the skills related to driving are made worse by chlorpromazine, and, to a lesser extent, by flupentixol, sulpiride and thioridazine. Small or single-dose studies with haloperidol or tiapride suggest that any interaction would seem to be mild; nevertheless, all antipsychotic drugs which cause drowsiness have the potential to enhance the effects of alcohol. There is evidence that drinking can precipitate the emergence of extrapyramidal adverse effects in patients taking antipsychotics.

Clinical evidence

(a) Effect on driving and other skills

Twenty-one subjects showed a marked deterioration in the performance of a number of skills related to driving when given chlorpromazine 200 mg daily and alcohol (blood levels 42 mg%). Many complained of feeling sleepy, lethargic, dull, groggy, and poorly coordinated; and most considered themselves more unsafe to drive than with alcohol alone.¹ A later study confirmed these findings with chlorpromazine 1 mg/kg and blood-alcohol levels of 80 mg%.² Increased sedation was clearly seen in another study with alcohol and chlorpromazine,³ and clear impairment of psychomotor skills related to driving have also been found.⁴

Single 500-microgram doses of haloperidol or flupentixol strongly impaired attention, but did not significantly interact with alcohol in one study.⁵ However, a double-blind study in subjects given flupentixol 500 micrograms three times a day for 2 weeks found that, when combined with alcohol 0.5 g/kg, their performance of a number of tests (choice reaction, coordination, attention) was impaired to such an extent that driving or handling other potentially dangerous machinery could be hazardous.⁶

Sulpiride 50 mg three times daily for 2 weeks caused a mild decrease in psychomotor skills with alcohol in healthy subjects, but not as much as that seen with chlorpromazine and alcohol.^{4,7} Thioridazine 25 mg caused some additive effects with alcohol, with a moderately deleterious effect on attention.⁵ Another study found that thioridazine and alcohol affected skills related to driving, but not as much as the effects seen with

chlorpromazine.² A further study found no difference between the effects of thioridazine and a placebo with alcohol.^{4,8}

A study in 9 alcoholics given tiapride 400 to 600 mg daily showed that wakefulness was not impaired when alcohol 0.5 g/kg was given, and in fact appeared to be improved, but the effect on driving skills was not studied.⁹

(b) Precipitation of extrapyramidal adverse effects

A report describes 7 patients who developed acute extrapyramidal adverse effects (akathisia, dystonia) while taking trifluoperazine, fluphenazine, perphenazine, or chlorpromazine and drinking alcohol.¹⁰ The author stated that these were examples of numerous such alcohol-induced toxicity reactions observed by him over an 18-year period involving phenothiazines and butyrophenones. Elsewhere he describes the emergence of drug-induced parkinsonism in a woman taking perphenazine and amitrityline when she began to drink alcohol.¹¹ Eighteen cases of haloperidol-induced extrapyramidal reactions among young drug abusers, in most instances associated with the ingestion of alcohol, have also been described.¹² Similarly, a study involving 41 patients with schizophrenia found that those with a substance use disorder (alcohol or cannabis ± cocaine) displayed more extrapyramidal symptoms compared with non-abusing patients.¹³

(c) Toxicity

A study involving 332 fatal poisonings in Finland found that alcohol was present in 65% of cases involving promazine, and when alcohol was present, relatively small overdoses of promazine could result in fatal poisoning.¹⁴ It appears that promazine and possibly levomepromazine may be more toxic when combined with alcohol.¹⁵

(d) Pharmacokinetic studies

A study in 12 patients receiving chlorpromazine 600 mg to 1.2 g daily long-term, found that chlorpromazine had no apparent effect on alcohol metabolism. However, about half of the patients had a statistically significant decrease (up to 33%) in urinary excretion of chlorpromazine and its metabolites during the 24-hour period following the consumption of 50 to 75 mL of alcohol.¹⁶

A study in 7 schizophrenics found that when they were given 40 g of alcohol to drink at about the same time as their regular injection of fluphenazine decanoate (25 to 125 mg every 2 weeks), their serum fluphenazine levels were reduced by 30% at 2 hours and by 16% at 12 hours.¹⁷

Mechanism

Uncertain. Additive CNS depressant effects are one explanation of this interaction. One suggestion to account for the emergence of the drug adverse effects is that alcohol lowers the threshold of resistance to the neurotoxicity of these drugs. Also alcohol may possibly impair the activity of tyrosine hydroxylase so that the dopamine/acetylcholine balance within the corpus striatum is upset.¹¹ In addition, chlorpromazine has been found to inhibit alcohol dehydrogenase, which may facilitate the formation of biogenic amines that have been implicated in extrapyramidal adverse effects.¹⁸

Pharmacokinetic interactions between acute and chronic alcohol ingestion, and single or multiple doses of antipsychotic drug are complex; acute alcohol intake can decrease metabolic clearance, whereas chronic intake can increase clearance.¹⁹ Alcohol may also affect the peripheral circulation and membrane permeability, which might affect absorption from an injection site.¹⁷

Importance and management

The documentation is limited. The manufacturers of flupentixol²⁰ and haloperidol²¹ warn that, in common with other antipsychotic drugs, the effects of alcohol may be enhanced. Warn patients that if they drink alcohol while taking chlorpromazine, and to a lesser extent flupentixol, sulpiride or thioridazine (probably other related drugs as well), they may become very drowsy, and should not drive or handle other potentially dangerous machinery. Some risk is possible with any antipsychotic that causes drowsiness, including those used as antiemetics, such as prochlorperazine.

The authors of the reports describing the emergence of serious adverse effects to antipsychotics in those who drink alcohol, consider that patients should routinely be advised to abstain from alcohol during antipsychotic treatment.

It has been suggested that a less dangerous alternative to promazine, and possibly levomepromazine, should be chosen when indications of alcohol abuse or suicide risk are present.¹⁵

The clinical importance of the pharmacokinetic studies is uncertain.

Alcohol + Antiretrovirals

Heavy alcohol intake may affect the virological response to HAART. Theoretically, alcohol consumption may induce liver enzymes, which interfere with the metabolism of some antiretrovirals such as the protease inhibitors. Alcohol reduces the metabolism of abacavir but this does not appear to be clinically significant.

Clinical evidence, mechanism, importance and management

(a) Alcohol and HAART regimens

A study of 94 HIV-positive patients receiving HAART, which included 2 'nucleoside analogues' plus either **indinavir**, **ritonavir**, **saquinavir**, **nelfinavir**, or **ritonavir/saquinavir**, found that the amount of alcohol consumed did not affect the antiviral response. However, the proportion of complete responders was slightly lower (57%) in heavy drinkers (more than 60 g of alcohol per day) compared with 68% in both non-drinkers and moderate drinkers (less than 60 g of alcohol per day), although this was not a significant finding. There was also a high prevalence of infection with hepatitis C virus, and liver decompensation occurred in 2 patients (both heavy drinkers).¹ Alcohol may affect thymus-induced immune repletion in HIV-positive patients and it has been reported that heavy alcohol users taking antiretrovirals are twice as likely not to achieve a positive virological response, compared with those who do not use alcohol.²

Alcohol consumption can induce the cytochrome P450 isoenzyme CYP3A4 and there is concern that HAART may not be as effective in some individuals who consume alcohol.³ CYP3A4 is involved in the metabolism of the protease inhibitors **amprenavir**, **fosamprenavir**, **indinavir**, **lopinavir**, **nelfinavir**, **ritonavir**, and **saquinavir** and the NNRTIs **delavirdine**, **efavirenz**, and **nevirapine**, and therefore CYP3A4 induction may result in enhanced drug metabolism and reduced therapeutic levels.⁴ Avoidance of alcohol has been suggested for HIV-positive patients receiving protease inhibitor therapy,^{3,4} but at present there does not seem to be

any clinical data to support this. Nevertheless, a reduction in alcohol consumption would seem sensible. More studies are needed. Note that some preparations of **ritonavir** contain alcohol, see 'Alcohol + Disulfiram', p.61.

(b) Effect of alcohol on abacavir

A study in 24 HIV-positive patients found that alcohol 0.7 g/kg increased the AUC of a single 600-mg dose of abacavir by 41%. The half-life of abacavir was increased by 26%, from 1.42 to 1.79 hours. The pharmacokinetics of alcohol were not affected by abacavir.⁵ Alcohol may inhibit the formation of abacavir carboxylate resulting in a trend towards increased abacavir glucuronide formation and reduced abacavir metabolism. The increase in exposure to abacavir was not considered to be clinically significant, since it is within levels seen in other studies using higher doses, which demonstrated no additional safety concerns at doses of up to three times the recommended daily dose of abacavir.⁵ No special precautions therefore appear to be necessary.

Alcohol + Aspirin

A small increase in the gastrointestinal blood loss caused by aspirin occurs in patients if they drink alcohol, but any increased damage to the lining of the stomach is small and appears usually to be of minimal importance in most healthy individuals. However, heavy drinkers who regularly take aspirin should be warned of the increased risk of gastric bleeding. Some limited information suggests that aspirin can raise or lower blood alcohol levels.

Clinical evidence

(a) Effect on blood loss

The mean daily blood loss from the gut of 13 healthy men was 0.4 mL while taking no medication, 3.2 mL while taking 2.1 g of soluble unbuffered aspirin (*Disprin*) and 5.3 mL while taking aspirin with 180 mL of Australian whiskey (alcohol 31.8%). In this study, alcohol alone did not cause gastrointestinal bleeding.¹ Similar results were reported in another study in healthy subjects.²

An epidemiological study of patients admitted to hospital with gastrointestinal haemorrhage showed a statistical association between bleeding and the ingestion of aspirin alone, and the combination with alcohol produced a significant synergistic effect.³ A large case-controlled study found similar results: the overall relative risk of bleeding with regular use of aspirin at doses greater than 325 mg was 7 among drinkers and 5.1 among people who never drank alcohol. For those who drank less than 1 to 20 drinks a week there was no evidence of a trend of increasing or decreasing relative risk as levels of alcohol consumption increased, but among those who consumed 21 or more drinks a week there was a large association with upper gastrointestinal bleeding (crude estimated risk 27). For regular aspirin use at doses of 325 mg or less, the overall relative risk among all current drinkers was 2.8 and among people who never drank alcohol was 2.2.⁴

Endoscopic examination revealed that aspirin and alcohol have additive damaging effects on the gastric mucosa (not on the duodenum), but the extent is small.⁵ However, a further case-control study found that large amounts of red wine (roughly over 500 mL of wine daily) increased the risk of upper gastrointestinal bleeding associated with low-dose aspirin, and small amounts of red wine (roughly less than 200 mL of wine daily) reduced this risk.⁶ Another study using gastric mucosal potential difference as a measure of mucosal damage found that aspirin with alcohol caused additive damage to the mucosa.⁷ In a review of the evidence, it was considered that while more study was needed, data available are highly suggestive that the gastrointestinal toxicity of alcohol and aspirin are com-

bined in individuals who are heavy daily drinkers and heavy aspirin users.⁸ Consider also 'Alcohol + NSAIDs', p.71.

No increased gastrointestinal bleeding occurred in 22 healthy subjects given three double Gins or whiskies (equivalent to 142 mL of alcohol 40%) and 728 mg of buffered sodium acetylsalicylate (*Alka-Seltzer*).⁹

(b) Effect on blood alcohol levels

Five healthy subjects were given a standard breakfast with and without aspirin 1 g followed by alcohol 0.3 g/kg an hour later. The aspirin increased the peak blood alcohol levels by 39% and the AUC by 26%.¹⁰ Similarly, in another study, 28 healthy subjects were given a midday meal (two sandwiches and a cup of tea or coffee), followed 90 minutes later by 600 mg of aspirin or a placebo, and then 30 minutes later by two standard drinks (35.5 mL of vodka 37.5% (21.6 g of alcohol) plus 60 mL of orange juice), which were drunk within a 15-minute period. The blood alcohol levels of the men were raised by 31% after one hour (from 24.29 to 31.85 mg%) and by 18% (from 20.82 to 24.57 mg%) after two hours. The blood alcohol levels of the women were raised by 32% (from 37.39 to 49.23 mg%) after one hour and by 21% (from 37.56 to 45.54 mg%) after two hours.¹¹

However, a later study (effectively a repeat of a study¹⁰ above) in 12 healthy subjects failed to find any effect on blood alcohol levels, but peak aspirin levels were reduced 25%.¹² A crossover study in 10 healthy male subjects found that after taking aspirin 75 mg daily for one week, their mean blood alcohol AUC following a 0.3 g/kg-dose was not significantly altered. However, individual *maximum* blood levels varied; one subject showed a rise, two were unchanged, and five were lowered: overall the reduction was 23%.¹³

Mechanism

(a) Effect on blood loss

Aspirin and alcohol can damage the mucosal lining of the stomach, one measure of the injury being a fall in the gastric potential difference. Once the protective mucosal barrier is breached, desquamation of the cells occurs and damage to the capillaries follows. Aspirin causes a marked prolongation in bleeding times, and this can be increased by alcohol.¹⁴ The total picture is complex.

(b) Effect on blood alcohol levels

The increased blood alcohol levels in the presence of food and aspirin may possibly occur because the aspirin reduces the enzymic oxidation of the alcohol by alcohol dehydrogenase in the gastric mucosa, so that more remains available for absorption.¹⁰ Any decreases with low-dose aspirin may possibly be due to delayed gastric emptying.¹³

Importance and management

The combined effect of aspirin and alcohol on the stomach wall is established. Aspirin 3 g daily for a period of 3 to 5 days induces an average blood loss of about 5 mL or so. Some increased loss undoubtedly occurs with alcohol, but it seems to be quite small and unlikely to be of much importance in most healthy individuals using moderate doses. In one study it was found that alcohol was a mild damaging agent or a mild potentiating agent for other damaging drugs.⁵ On the other hand it should be remembered that chronic and/or gross overuse of salicylates and alcohol may result in gastric ulceration. People who consume at least 3 or more alcoholic drinks daily and who regularly take more than 325 mg of aspirin have been shown to have a high risk of bleeding.¹⁵ The FDA in the US has ruled that non-prescription pain relievers and fever reducers, containing aspirin or salicylates, must carry a warning label advising people who consume 3 or more alcoholic drinks every day to consult their doctor before using these drugs, and that stomach bleeding may occur with these drugs.¹⁶ However, the Australian Medicines Evaluation Committee has decided against such action as, for most people with mild to moderate alcohol intake, there is little risk especially if the aspirin is taken only as needed.¹⁵

Information about the increase in blood alcohol levels caused by aspirin after food is very limited and contradictory, and of uncertain practical importance. However, no practically relevant interaction has been seen with other drugs (such as the 'H₂-receptor antagonists', (p.64)), which have been extensively studied, and which appear to interact by the same mechanism. The pattern for these drugs is that the increases in blood alcohol levels are appreciable with small doses of alcohol, but usually they become proportionately too small to matter with larger doses of alcohol (i.e.

those that give blood and breath levels at or around the legal driving limit in the UK).

Alcohol + Barbiturates

Alcohol and the barbiturates are CNS depressants, which together can have additive and possibly even synergistic effects. Activities requiring alertness and good co-ordination, such as driving a car or handling other potentially dangerous machinery, can be made more difficult and more hazardous. Alcohol may also continue to interact the next day if the barbiturate has hangover effects.

Clinical evidence

A study in healthy subjects of the effects of a single 0.5-g/kg dose of alcohol, taken in the morning after a dose of **amobarbital** 100 mg every night for 2 weeks, found that the performance of co-ordination skills was much more impaired than with either drug alone.¹

This increased CNS depression due to the combined use of alcohol and barbiturates has been described in other clinical studies with **phenobarbital**.^{2,3} However, a study in healthy subjects found that although **phenobarbital** 45 mg daily for one week and alcohol (35 to 45 mg%) affected some perceptual-motor tests when given separately, these effects were not always found when they were given together.⁴ Nevertheless, high doses of **phenobarbital** can affect driving skills⁵ and increased CNS depression has featured very many times in coroners' reports of fatal accidents and suicides involving barbiturates and alcohol.⁶ A study of the fatalities due to this interaction indicated that with some barbiturates the CNS depressant effects are more than additive.⁷ There is also some evidence that blood-alcohol levels may be reduced in the presence of a barbiturate.^{8,9}

For the interaction between thiopental and alcohol, see 'Anaesthetics, general + Alcohol', p.92.

Mechanism

Both alcohol and the barbiturates are CNS depressants, and simple additive CNS depression provides part of the explanation. Acute alcohol ingestion may inhibit the liver enzymes concerned with the metabolism of barbiturates such as phenobarbital and **pentobarbital**, but chronic exposure to alcohol increases hepatic microsomal enzyme activity and may reduce sedation from barbiturates in patients without liver impairment.^{10,11} Similarly, chronic exposure to a barbiturate such as phenobarbital may increase alcohol metabolism due to enzyme induction and consequently reduce blood-alcohol levels.⁷

Importance and management

Few formal studies in normal clinical situations have been made of the interactions between alcohol and the barbiturates, and most of these studies are old and involved barbiturates used as hypnotics. However, the effects (particularly those that result in fatalities) are very well established, serious, and of clinical importance. The most obvious hazards are increased drowsiness, lack of alertness and impaired co-ordination, which make the handling of potentially dangerous machinery (e.g. car driving), and even the performance of everyday tasks (e.g. walking downstairs) more difficult and dangerous. Only amobarbital and phenobarbital appear to have been specifically studied, but this interaction would be expected with all of the barbiturates. Some barbiturate hangover effects may be present the next morning and may therefore continue to interact significantly with alcohol. Patients should be warned.

For comments on the use of alcohol in epileptic patients taking antiepileptics including phenobarbital, see 'Alcohol + Antiepileptics', p.46.

Alcohol + Benzodiazepines and related drugs

Benzodiazepine and related hypno-sedatives increase the CNS depressant effects of alcohol to some extent. The risks of car driving and handling other potentially dangerous machinery are increased. The risk is heightened because the patient may be unaware of being affected. Some benzodiazepines used at night for sedation are still present in appreciable amounts the next day and therefore may continue to interact. Alcohol may also increase the plasma levels of brotizolam, clobazam, diazepam, and possibly triazolam, whereas alprazolam may increase blood-alcohol levels. Alcohol has been reported to increase aggression or amnesia and/or reduce the anxiolytic effects of some benzodiazepines.

Clinical evidence

(a) Additive CNS depressant effects

It is very difficult to assess and compare the results of the very many studies of this interaction because of the differences between the tests, their duration, the dosages of the benzodiazepines and alcohol, whether given chronically or acutely, and a number of other variables. However, the overall picture seems to be that benzodiazepines and related drugs including diazepam,^{1–12} alprazolam,^{13–15} bromazepam,¹⁶ brotizolam,¹⁷ chlordiazepoxide,^{12,18–22} clobazam,²³ dipotassium clorazepate,²⁴ flunitrazepam,^{25,26} flurazepam,^{27–31} lorazepam,^{28,32} lorazepam,^{10,33–36} lormetazepam,³⁷ medazepam,³⁸ midazolam,³⁹ nitrazepam,^{3,40,41} oxazepam,⁶ temazepam,^{41–43} triazolam,^{29,42,44–46} and zopiclone⁴⁶ enhance the effects of alcohol i.e. cause increased drowsiness, impaired performance and driving skills.

Patients taking benzodiazepines including lorazepam³⁴ or triazolam⁴⁴ may be unaware of the extent of the impairment that occurs. Furthermore, changes in CNS functioning may possibly occur in heavy social drinkers;

a placebo-controlled study in 20-year-olds suggested that lorazepam 2 mg had more impairment on delayed auditory verbal memory performance in those who were heavy social drinkers (more than 20 drinks; 200 g of alcohol per week) than light social drinkers (20 g or less of alcohol per week).⁴⁷

Some of the benzodiazepines and related drugs that are used primarily to aid sleep, such as flunitrazepam,^{25,26} flurazepam,^{27,28,30,31,48} nitrazepam,^{3,40} and temazepam,^{48,49} when taken the night before alcohol or in the evening with alcohol, can still interact with alcohol the next morning. However, midazolam,³⁹ lorazepam,²⁸ lormetazepam,³⁷ triazolam,^{31,46} zolpidem,⁵⁰ and zopiclone^{25,30,46} have been reported not to do so. The sedative effects of midazolam alone, and midazolam with fentanyl have been shown to have dissipated within 4 hours, and to not be affected by alcohol after this time.^{51,52} However, some patients may metabolise midazolam more slowly and so an interaction could still be possible,⁵³ especially in older patients or those receiving additional drugs.⁵⁴

Some contrasting effects have also been reported. One study suggested that alcohol might mitigate the effects of lorazepam on psychological performance.³² Similarly, some antagonism has been reported between chlordiazepoxide and alcohol, but this is unlikely to be of practical importance.^{18,19} The development of tolerance between benzodiazepines and alcohol with chronic use has also been suggested.^{55,56}

(b) Increased aggression, anxiety, or amnesia

The anxiolytic effects of lorazepam³⁵ and possibly chlordiazepoxide²⁰ may be opposed by alcohol. Alprazolam and alcohol together may possibly increase behavioural aggression.⁵⁷ Similarly, flunitrazepam abuse can cause violent behaviour, impulsive decision-making and anterograde amnesia: a report looking at violent crimes committed by abusers of flunitrazepam found that alcohol was almost always also present.⁵⁸ Alcoholic drinks also enhance the effects of flunitrazepam when it is used as a 'date rape' drug.⁵⁹

(c) Pharmacokinetic effects

Several studies have reported that alcohol increases plasma levels of diazepam^{13,60} and that alcohol accelerates the absorption of diazepam,⁵ but others have suggested that alcohol has no significant effect on diazepam pharmacokinetics.^{9,11,61} Plasma levels of brotizolam¹⁷ and clobazam²³ may be increased by alcohol. One study reported that the plasma levels of triazolam were increased by alcohol,⁴⁴ but other studies have found only a minimal pharmacokinetic interaction.^{45,46} However, an *in vitro* study demonstrated that alcohol inhibited the metabolism of triazolam by the cytochrome P450 isoenzyme CYP3A.⁶² Another *in vitro* study reported that the formation of flunitrazepam metabolites was weakly inhibited by alcohol,⁶³ but a pharmacokinetic study suggested that there was no interaction.²⁶ Alcohol appears to have minimal effects on the pharmacokinetics of alprazolam,¹³ and zopiclone.^{46,64}

The pharmacokinetics of alcohol do not appear to be affected to a clinically significant extent by diazepam,¹¹ flunitrazepam,²⁶ zolpidem,⁵⁰ or zopiclone⁴⁶ but alprazolam¹³ may increase blood-alcohol levels.

Mechanism

The CNS depressant actions of the benzodiazepines and alcohol are mainly additive and it appears that different aspects of CNS processing may be involved.^{41,65}

A pharmacokinetic interaction can sometimes occur, but the mechanisms seem to be quite complex. Acute alcohol intake increases the absorption and raises the serum levels of some benzodiazepines^{23,60} and there may be direct competitive inhibition of metabolism.⁶⁶ It has been suggested that clearance of benzodiazepines via phase I metabolism, by *N*-demethylation and/or hydroxylation, tends to be more affected by alcohol intake than that of drugs such as lorazepam, oxazepam or lormetazepam that only undergo phase II conjugation. In addition, phase I metabolism is inhibited or decreases with increasing age and liver disease.⁶⁶ However, phase I metabolism is increased by chronic administration of substances that induce the cytochrome P450 isoenzyme system, such as alcohol,⁶⁶ and moderate alcohol consumption may cause intestinal CYP3A induction resulting in reduced bioavailability of some benzodiazepines, such as midazolam.⁶⁷

Importance and management

Extensively studied, well established and clinically important interactions. The overall picture is that these drugs worsen the detrimental effects of alcohol.⁶⁸ Up to a 20 to 30% increase in the impairment of psychomotor function has been suggested.⁴⁴ The deterioration in skills will depend on the particular drug in question, its dosage and the amounts of alcohol taken. With modest amounts of alcohol the effects may be quite small in most patients (although a few may be more markedly affected¹¹), but anyone taking any of these drugs should be warned that their usual response to alcohol may be greater than expected, and their ability to drive a car, or carry out any other tasks requiring alertness, may be impaired. They may be quite unaware of the deterioration or that the effects may still be present the following day. Benzodiazepines and alcohol are frequently found in the blood of car drivers involved in traffic accidents, which suggests that the risks are real.^{56,68-71} Furthermore, alcohol may contribute to fatal poisonings and other deaths involving benzodiazepines, particularly diazepam⁷²⁻⁷⁵ and temazepam.⁷⁶ Alcohol may contribute to drug-related accidents and deaths due to a disregard for safety,^{71,77} and there is also an association between alcohol and benzodiazepines and violence-related accidents.⁷¹

Alcohol + Beta blockers

The haemodynamic and pharmacokinetic effects of atenolol and metoprolol in healthy subjects do not appear to be changed by alcohol. There is some evidence that alcohol modestly reduces the haemodynamic effects of propranolol, and some of the effects of sotalol may also be changed by alcohol. Some evidence suggests that the effects of alcohol and atenolol/chlortalidone or propranolol are additive on the performance of some psychomotor tests, but the importance of this is uncertain.

Clinical evidence, mechanism, importance and management

(a) CNS effects

In 12 healthy subjects the performance of a number of psychomotor tests was found to be impaired by alcohol 0.6 g/kg and by one tablet of *Tenoretic* (atenolol 100 mg with chlortalidone 25 mg). When alcohol and *Tenoretic* were taken together there was some evidence of additive effects but the practical importance of this is not clear.¹

In 12 healthy subjects **propranolol** 40 mg every 6 hours had no effect on the alcohol-induced impairment of performance on a number of psychomotor tests given 50 mL/70 kg of alcohol, except that **propranolol** antagonised the effect of alcohol in one test (pursuit meter).² However, in another study, **propranolol** enhanced the effects of alcohol on some tests (inebriation and divided attention).³

The manufacturer of **oxprenolol** warns that the effects of alcohol and beta blockers on the CNS have been observed to be additive and it is possible that symptoms such as dizziness may be exaggerated if they are taken together.⁴

(b) Haemodynamic and pharmacokinetic effects

In 8 healthy subjects the pharmacokinetics of single 100-mg doses of **atenolol** or **metoprolol** were unaffected 6 hours after they had drunk the equivalent of 200 mL of absolute alcohol. No clinically significant changes in blood pressure or pulse rate were seen.⁵ A study in 6 healthy subjects found that alcohol (sufficient to maintain blood-alcohol levels of 80 mg%) raised the mean AUC of a single 80-mg oral dose of **propranolol** by 17.4% in 5 subjects and decreased it by 37% in the other subject, but this was considered unlikely to be clinically important. No changes in heart rate or blood pressure were seen.⁶ In contrast, a double-blind study in 14 healthy subjects found that alcohol (equivalent to 32 to 72 mL of absolute alcohol) increased the clearance of a single 80-mg dose of **propranolol** and diminished its ability to lower blood pressure. **Propranolol** was not able to abolish the alcohol-induced rise in heart rate.⁷ Similarly, another study found that alcohol decreased the rate of absorption and increased the rate of elimination of **propranolol**, but the clinical significance of this small alteration was not assessed.⁸

A further study in 6 healthy subjects found that although the blood pressure lowering effects of **sotalol** 160 mg were increased by alcohol, **sotalol** did not cancel out the alcohol-induced rise in heart rate.⁷

It would seem prudent to be alert for changes in response to beta blockers that may be due to alcohol. See also, 'Alcohol + Antihypertensives', p.48.

Alcohol + Bicalutamide, Flutamide or Nilutamide

Alcohol intolerance (facial flushing, malaise, hypotension) has been reported in patients receiving nilutamide but not bicalutamide or flutamide.

Clinical evidence, mechanism, importance and management

Several studies have described alcohol intolerance (facial flushes, malaise, hypotension) in patients taking nilutamide.^{1–3} The incidence has been reported to be between 3% and 19%.^{1–4} It is recommended that patients who experience this reaction should avoid drinking alcohol.⁴

Flutamide and bicalutamide have not been reported to produce these effects when patients drink alcohol,³ so they may be considered as an alternative option to nilutamide.

Alcohol + Bromocriptine

There is some very limited evidence to suggest that the adverse effects of bromocriptine may possibly be increased by alcohol.

Clinical evidence, mechanism, importance and management

Intolerance to alcohol, which improved on continued treatment, has been briefly mentioned in a report about patients taking bromocriptine for acromegaly.¹ In another report two patients with high prolactin levels were said to have developed bromocriptine adverse effects, even in low doses, while continuing to drink. When they abstained, the frequency and the severity of the adverse effects fell, even with higher doses of bromocriptine.² This, it is suggested, may be due to some alcohol-induced increase in the sensitivity of dopamine receptors.² There would seem to be little reason, on the basis of this extremely sparse evidence, to tell all patients taking bromocriptine not to drink alcohol, but it would be reasonable to warn them to try avoiding alcohol if adverse effects develop.

Alcohol + Bupropion

The concurrent use of bupropion and alcohol does not appear to affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

Single-dose studies in healthy subjects found that the pharmacokinetics of bupropion 100 mg were not affected by the concurrent use of alcohol, and bupropion did not affect blood-alcohol levels.^{1,2} However, bupropion may

reduce alcohol tolerance and there is an increased risk of seizures if alcohol is withdrawn abruptly, see 'Bupropion + Miscellaneous', p.1206.

Alcohol + Buspirone

Buspirone with alcohol may cause drowsiness and weakness, although it does not appear to impair the performance of a number of psychomotor tests.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects showed that, in contrast to lorazepam, buspirone 10 or 20 mg did not appear to interact with alcohol (i.e. worsen the performance of certain psychomotor tests), but it did make the subjects feel drowsy and weak.^{1,2} Similarly, another study in 13 healthy subjects found that combining buspirone (15 and 30 mg/70 kg) and alcohol caused sedation, but very little impairment of performance. In this study, the sedative effects were broadly similar to those seen with alprazolam plus alcohol, but alprazolam plus alcohol clearly impaired performance.³ Similar findings were reported in another earlier comparison with diazepam.⁴ A further study reported that single 5 to 15-mg doses of buspirone had a minimal effect on performance in both light and moderate female social drinkers.⁵

The UK manufacturer notes that there is no information on higher therapeutic doses of buspirone combined with alcohol, and they suggest that it would be prudent to avoid alcohol while taking buspirone.⁶ They also caution patients of the potential hazards of driving or handling other potentially dangerous machinery until they are certain that buspirone does not adversely affect them.⁶

Alcohol + Butyraldoxime

A disulfiram-like reaction can occur in those exposed to *N*-butyraldoxime if they drink alcohol.

Clinical evidence, mechanism, importance and management

Workers in a printing company complained of flushing of the face, neck and upper trunk, shortness of breath, tachycardia and drowsiness very shortly after drinking alcohol (1.5 oz (about 45 mL) of whiskey), and were found to have increased levels of acetaldehyde in their blood. The reason appeared to be that the printing ink they were using contained *N*-butyraldoxime, an antioxidant which, like disulfiram, can inhibit the metabolism of alcohol causing acetaldehyde to accumulate (see 'Alcohol + Disulfiram', p.61).¹ It is possible that it is a metabolite of *N*-butyraldoxime that causes this effect, rather than *N*-butyraldoxime itself.² This reaction would seem to be more unpleasant and socially disagreeable than serious. No treatment normally seems necessary.

Alcohol + Caffeine

Objective tests show that caffeine may counteract some of the effects of alcohol. However, it does not completely sober up those who have drunk too much, and may even make them more accident-prone.

Clinical evidence

A study in a large number of healthy subjects given a cup of coffee containing caffeine 300 mg/70 kg, either alone or immediately after drinking alcohol 0.75 g/kg, found that caffeine did not antagonise the deleterious effect of alcohol on the performance of psychomotor skill tests. Only reaction times were reversed.¹ Two other studies also found that caffeine did not antagonise the effects of alcohol in a variety of tests.^{2,3} A further study in 8 subjects found that, contrary to expectations, caffeine increased the frequency of errors in the performance of a serial reaction time task,⁴ and similarly, caffeine has been reported to increase the detrimental effects of alcohol.⁵

In contrast, more recent studies usually using caffeine in capsule form, have found that some of the performance-impairing effects of alcohol such as increased simple reaction time,^{6,7} increased errors with four choice reaction time,⁸ sedation,⁹ and slowing of psychomotor speed⁸ can be antagonised by caffeine given with the alcohol. However, caffeine does not appear to restore most subjective effects e.g. feeling of drunkenness.^{6,9,10} One study found that the alcohol-caffeine combination typically altered the effects of caffeine alone rather than altering the effects of alcohol alone. For example the addition of alcohol reduced the jitteriness and alertness produced by caffeine, and although caffeine modestly antagonised alcohol impairment of driving, there was still a 9% increase in brake-response time, when compared with placebo.¹⁰

In a double-blind, placebo-controlled, crossover study in 8 healthy subjects, the AUC of a 400-mg caffeine capsule was 30% greater when it was taken with alcohol 0.8 g/kg than when taken alone. Blood-alcohol levels were not affected by caffeine use.⁶ Similarly, other studies reported that alcohol increases serum-caffeine levels² and that blood-alcohol levels were not modified by caffeine.^{1,2,7}

Mechanism

Not fully understood. Caffeine is a CNS stimulant, which seems to oppose some of the CNS depressant effects of alcohol. It appears that only those objective tests able to detect an enhancement due to a CNS stimulant show the clearest antagonistic effects.⁶

Alcohol appears to inhibit the hepatic metabolism of caffeine.²

Importance and management

It is not known why some studies report that caffeine antagonises some of the detrimental effects of alcohol and others report no interaction. However, the type of psychomotor tests, the amount of alcohol and caffeine consumed, and the timing and administration of the caffeine may affect the results.

Caffeine does appear to improve some of the detrimental effects of alcohol in some psychomotor tests, which is probably why there is a long-standing and time-hallowed belief in the value of strong black coffee to sober up those who have drunk too much. In addition, it is just possible that the time taken to drink the coffee gives the liver just a little more time to metabolise some of the alcohol. However, it seems that it is not effective in all aspects of alcohol impairment, particularly subjective effects. In addition, caffeine does not reduce blood-alcohol levels. Coffee and other sources of caffeine do not make it safe to drive or handle dangerous machinery, and it may even make drivers more accident-prone.

Alcohol + Calcium carbimide

Alcohol causes a disulfiram-like reaction in patients taking calcium carbimide. Calcium carbimide has been used as an alcohol deterrent.

Clinical evidence, mechanism, importance and management

Calcium carbimide interacts with alcohol in a similar way to disulfiram and by a similar mechanism¹ (see ‘Alcohol + Disulfiram’, p.61). Both of these drugs bind to aldehyde dehydrogenase, but calcium carbimide is said to have fewer adverse effects because it does not bind to dopamine beta hydroxylase.² However, marked cardiovascular effects and fatalities have occurred in those who drank alcohol while taking calcium carbimide.^{3,4} Like disulfiram it is used to deter alcoholics from continuing to drink.^{1,2}

Alcohol + Calcium-channel blockers

Blood-alcohol levels can be raised and may remain elevated for a much longer period of time in patients taking verapamil. Alcohol may also increase the bioavailability of felodipine and nifedipine, but amlodipine appears not to interact. An increased incidence of postural hypotension has been reported in patients who took felodipine with alcohol

Clinical evidence

(a) Amlodipine

A study in 30 healthy subjects found that single and multiple doses of amlodipine 10 mg for 15 days (with or without lisinopril and simvastatin) had no effect on the pharmacokinetics of alcohol 0.8 g/kg nor on subjective psychological performance. Alcohol did not alter the pharmacokinetics of amlodipine.¹

(b) Felodipine

A study in 8 healthy subjects given enough alcohol to maintain their blood levels at 80 to 120 mg% found that their felodipine levels (following a single 10-mg oral dose) were approximately doubled (AUC increased by 77%, maximum blood levels increased by 98%). Diuresis was approximately doubled and heart rates were increased.²

A double-blind, crossover study in 10 patients found that alcohol 0.75 g/kg in grapefruit juice enhanced the haemodynamic effects of a single 5-mg dose of felodipine. Four hours after dosing, felodipine with alcohol in grapefruit juice produced lower total peripheral resistance and diastolic blood pressure, and a higher heart rate, compared with felodipine with grapefruit juice alone. Furthermore, the greater blood pressure reduction caused symptoms in 50% of the patients; postural lightheadedness occurred in 5 patients given alcohol and felodipine, compared with 1 patient given felodipine without alcohol. However, felodipine plasma levels were higher than expected, although this may have largely been due to the ‘grapefruit juice’, (p.869), and the incidence of adverse effects for both groups was also higher.³

In a study, 8 non-smoking, healthy subjects were given a single 10-mg dose of an extended-release preparation of felodipine with 250 mL red wine on an empty stomach and 4 hours before a meal. Plasma felodipine levels were lower for the first 4 hours of the study than when taken with 250 mL water, but rose rapidly at 5 hours after dosing, resulting in a peak level that was higher than when taken with water.⁴

(c) Nifedipine

Alcohol (75 mL of alcohol 94% with 75 mL of orange juice) given to 10 healthy subjects increased the AUC of a single 20-mg dose of nifedipine by 54%, but no significant changes in heart rate or blood pressure were seen.⁵ Another study, involving 226 patients receiving sustained-release nifedipine, found that reported alcohol use was associated with reduced nifedipine clearance (8.6 compared with 10.8 mL/minute per kg for alcohol use and no alcohol, respectively).⁶ In another study no evidence was found that nifedipine 10 or 20 mg antagonised the effects of alcohol.⁷

(d) Verapamil

Ten healthy subjects given verapamil 80 mg three times daily for 6 days were given alcohol 0.8 g/kg on day 6. Peak blood-alcohol levels were found to be raised by 16.7% (from 106.45 to 124.24 mg%) and the AUC₀₋₁₂ was raised by almost 30%. The time that blood-alcohol levels exceeded 100 mg% was prolonged from 0.2 to 1.3 hours and the subjects said they felt more intoxicated.⁸ In another study no evidence was found that verapamil 80 or 160 mg antagonised the effects of alcohol.⁷

Mechanism

Not understood. It seems possible that verapamil inhibits the metabolism of alcohol by the liver, thereby reducing its loss from the body. Alcohol also appears to inhibit the metabolism of nifedipine, and to increase the bioavailability of felodipine. Red wine may have caused “dose dumping” of felodipine from the extended-release preparation which altered its pharmacokinetic profile, but the reason why the felodipine levels remained low until after a meal is unclear.⁴ An *in vitro* study demonstrated that alcohol inhibited the oxidative metabolism of nifedipine by the cytochrome P450 isoenzyme CYP3A.⁹

Importance and management

Information seems to be limited to these reports and they need confirmation. An alcohol concentration rise of almost 17% as caused by verapamil is quite small, but it could be enough to raise legal blood levels to illegal levels if driving. Moreover the intoxicant effects of alcohol may persist for a much longer period of time (five times longer in this instance).⁸

The bioavailability of felodipine and nifedipine appear to be increased by alcohol. The manufacturers of some calcium-channel blockers warn that inter-individual variations in the response to these drugs can occur and some patients ability to drive or operate machinery may be impaired, particularly at the start of treatment and in conjunction with alcohol.^{10,11} Patients should therefore be advised about these effects. Note that long-term moderate to heavy drinking can impair the efficacy of antihypertensives. See also ‘Alcohol + Antihypertensives’, p.48.

Alcohol + Cannabis

The detrimental effects of drinking alcohol and smoking cannabis may be additive on some aspects of driving performance. However, there is some evidence that regular cannabis use *per se* does not potentiate the effects of alcohol. Smoking cannabis may alter the bioavailability of alcohol.

Clinical evidence and mechanism

(a) Enhanced CNS-depressant effects

Simultaneous use of alcohol and oral Δ^9 -tetrahydrocannabinol (THC, the major active ingredient of cannabis) reduced the performance of psychomotor tests, suggesting that those who use both drugs together should expect the deleterious effects to be additive.¹ In a further placebo-controlled study, subjects smoked cannabis containing 100 or 200 micrograms/kg of Δ^9 -tetrahydrocannabinol and drank alcohol (to achieve an initial blood level of 70 mg%, with further drinks taken to maintain levels at 40 mg%) 30 minutes before driving. They found that cannabis, even in low to moderate doses, negatively affected driving performance in real traffic situations. Further, the effect of combining moderate doses of both alcohol and cannabis resulted in dramatic performance impairment as great as that observed with blood-alcohol levels of 140 mg% alone.^{2,3}

(b) Opposing or no additive CNS effects

One study in 14 regular cannabis users (long-term daily use) and 14 infrequent cannabis users found that regular use reduced the disruptive effects of alcohol on some psychomotor skills relevant to driving, whereas infrequent use did not have this effect. In this study, neither group had smoked any cannabis in the 12 hours before the alcohol test.⁴ Another study found that moderate doses of alcohol and cannabis, consumed either alone or in combination, did not produce significant behavioural or subjective impairment the following day.⁵

A study in 12 healthy subjects who regularly used both cannabis and alcohol found that alcohol 0.5 g/kg significantly increased brake latency without affecting body sway, whereas cannabis given as a cigarette containing tetrahydrocannabinol 3.33%, increased body sway but did not affect brake latency. There were no significant additive effects on brake latency, body sway, or mood when the two drugs were used together.⁶ A population-based study of 2,777 drivers involved in fatal road crashes, who drank alcohol and/or used cannabis, found that although both cannabis and alcohol increased the risk of being responsible for a fatal crash, no statistically significant interaction was observed between the two drugs.⁷

(c) Pharmacokinetic studies

Fifteen healthy subjects given alcohol 0.7 g/kg developed peak plasma alcohol levels of 78.25 mg% at 50 minutes, but if they smoked a cannabis cigarette 30 minutes after the drink, their peak plasma alcohol levels were only 54.8 mg% and they occurred 55 minutes later. In addition, their subjective experience of the drugs decreased when used together.⁸ However, another study found that smoking cannabis 10 minutes before alcohol consumption did not affect blood-alcohol levels.⁵ A further study found that blood-alcohol levels were not affected by Δ^9 -tetrahydrocannabinol given orally one hour before alcohol.¹

Importance and management

Several studies have found that cannabis and alcohol produce additive detrimental effects on driving performance, but other studies have failed to show any potentiation. This is probably due to the variety of simulated driving tests used and possibly the time lag between the administration of alcohol and cannabis; behavioural impairment after cannabis has been reported to peak within 30 minutes of smoking.⁵ Nevertheless, both drugs have been shown to affect some aspects of driving performance and increase the risk of fatal car accidents. Concurrent use of cannabis and alcohol before driving should therefore be avoided.

Alcohol + Carmofur

A disulfiram-like reaction occurred in a patient taking carmofur when he was given a coeliac plexus blockade with alcohol.

Clinical evidence, mechanism, importance and management

A man with pancreatic carcinoma taking carmofur 500 mg daily for 25 days experienced a disulfiram-like reaction (facial flushing, diaphoresis, hypotension with BP 60/30 mmHg, and tachycardia of 128 bpm) within 30 minutes of being given a coeliac plexus alcohol blockade for pain relief. Blood acetaldehyde levels were found to have risen sharply, supporting the belief that the underlying mechanism is similar to the disulfiram-alcohol interaction (see 'Alcohol + Disulfiram', p.61). It is suggested that alcohol blockade should be avoided for 7 days after treatment with carmofur.¹

Alcohol + Clomethiazole

Clomethiazole has been successfully used to treat alcohol withdrawal, but the long-term use of alcohol with clomethiazole can cause serious, even potentially fatal CNS depression, due to additive CNS depressant effects; fatal respiratory depression can occur even with short-term use in alcoholics with cirrhosis. The concurrent use of clomethiazole and alcohol may also affect driving skills. Clomethiazole bioavailability may be increased by alcohol.

Clinical evidence, mechanism, importance and management

(a) Enhanced adverse effects and bioavailability

The following is taken from an editorial in the British Medical Journal, which was entitled 'Chlormethiazole and alcohol: a lethal cocktail'.¹

Clomethiazole is commonly used to treat withdrawal from alcohol because of its hypnotic, anxiolytic and anticonvulsant effects. It is very effective if a rapidly reducing dosage regimen is followed over six days, but if it is used long-term and drinking continues it carries several serious risks.

Alcoholics readily transfer dependency to clomethiazole and may visit several practitioners and hospitals to get their supplies. Tolerance develops so that very large amounts may need to be taken (up to 25 g daily). Often alcohol abuse continues and the combination of large amounts of alcohol and clomethiazole can result in coma and even fatal respiratory depression, due mainly to simple additive CNS depression.¹

Other factors are that alcohol increases the bioavailability of clomethiazole (probably by impairing first pass metabolism),² and in the case of those with alcoholic cirrhosis, the systemic bioavailability may be increased tenfold because of venous shunting.³ However, one study in 6 healthy subjects reported that intravenous alcohol 0.8 mL/kg given acutely had no effect on the disposition or elimination of clomethiazole. It was proposed that alcohol given orally might affect the absorption or rate of uptake of clomethiazole.⁴

Clomethiazole should not be given long-term for alcohol withdrawal states¹ or to those who continue to drink alcohol.⁵ Use for more than 9 days is not recommended.^{5,6} It has been said that if prescribers choose to manage detoxification at home, it should be done under very close supervision, issuing prescriptions for only one day's supply to ensure daily contact and to minimise the risk of abuse. And if the patient shows evidence of tolerance or clomethiazole dependency or of continuing to drink alcohol, the only safe policy is rapid admission for inpatient care.¹ The manufacturer warns that alcohol combined with clomethiazole particularly in alcoholics with cirrhosis can lead to fatal respiratory depression even with short-term use.⁵

(b) Effects on driving and related skills

There do not appear to be any studies on the combined effects of clomethiazole and alcohol on driving and related skills, but concurrent use would be expected to increase the risks.

There is a report of a man who had a blood-alcohol level of 23 mg% who was driving dangerously and caused a traffic accident. The clinical signs

of impairment were far greater than expected and further analysis of the blood sample identified a high level of clomethiazole (5 mg/L). In 13 other impaired driving cases where clomethiazole was detected in blood samples, the concentrations ranged from 0.3 to 3.3 mg/L.⁷ The manufacturer warns that clomethiazole may potentiate or be potentiated by CNS depressant drugs, including alcohol.⁵

Alcohol + Cloral hydrate

Both alcohol and cloral hydrate are CNS depressants, and their effects may be at least additive, or possibly even synergistic. Some patients may experience a disulfiram-like flushing reaction if they drink alcohol after taking cloral hydrate for several days.

Clinical evidence

Studies in 5 healthy subjects given cloral hydrate 15 mg/kg and alcohol 0.5 g/kg found that both drugs given alone impaired their ability to carry out complex motor tasks. When taken together, the effects were additive, and possibly even more than additive. After taking cloral hydrate for 7 days, one of the subjects experienced a disulfiram-like reaction (bright red-purple flushing of the face, tachycardia, hypotension, anxiety and persistent headache) after drinking alcohol.^{1,2}

The disulfiram-like reaction has been described in other reports.³ Note that the earliest report was published more than a century ago in 1872 and described two patients taking cloral hydrate who experienced this reaction after drinking half a bottle of beer.²

Mechanism

Alcohol, cloral and trichloroethanol (to which cloral hydrate is metabolised) are all CNS depressants. During concurrent use, the metabolic pathways used for their elimination are mutually inhibited: blood-alcohol levels rise because the trichloroethanol competitively depresses the oxidation of alcohol to acetaldehyde, while trichloroethanol levels also rise because its production from cloral hydrate is increased and its further conversion and clearance as the glucuronide is inhibited. As a result the rises in the blood levels of alcohol and trichloroethanol are exaggerated, and their effects are accordingly greater.^{1,2,4,5} In one subject, blood levels of acetaldehyde during the use of cloral hydrate with alcohol were only 50% of those after alcohol alone, so that the flushing reaction, despite its resemblance to the disulfiram reaction, may possibly have a partially different basis.²

Importance and management

A well-documented and established interaction, which has been comprehensively reviewed.^{1,2} Only a few references are given here. Patients given cloral hydrate should be warned about the extensive CNS depression that can occur if they drink, and of the disulfiram-like reaction that may occur after taking cloral hydrate for a period of time. Its incidence is uncertain. The legendary Mickey Finn, which is concocted of cloral hydrate and alcohol, is reputed to be so potent that deep sleep can be induced in an unsuspecting victim within minutes of ingestion, but the evidence seems to be largely anecdotal. Very large doses of both drugs would be likely to cause serious and potentially life-threatening CNS depression.

It seems likely that **cloral betaine**, **triclofos** and other compounds closely related to cloral hydrate will interact with alcohol in a similar manner, but this requires confirmation.

Alcohol + CNS depressants

The concurrent use of small or moderate amounts of alcohol and therapeutic doses of drugs that are CNS depressants can increase drowsiness and reduce alertness. These drugs include antidepressants, antiemetics, antiepileptics, antihistamines, antipsychotics, anxiolytics, barbiturates, hypnotics, opioid analgesics, skeletal muscle relaxants, and others. This increases the risk of accident when driving or handling other potentially dangerous machinery, and may make the performance of everyday tasks more difficult and hazardous.

Clinical evidence, mechanism, importance and management

Alcohol is a CNS depressant (see 'alcohol', (p.40)). With only small or moderate amounts of alcohol and with blood-alcohol levels well within legal driving limits, it may be quite unsafe to drive if another CNS depressant is being taken concurrently. The details of most of the drugs that have been tested are set out in the monographs in this section, but there are others that nobody seems to have tested formally. The summary above contains a list of some of those that commonly cause drowsiness. Quite apart from driving, almost everyone meets potentially dangerous situations every day at home, in the garden, in the street and at work. Crossing a busy street or even walking downstairs can become much more risky under the influence of CNS depressant drugs and alcohol. Elderly patients may be particularly susceptible.¹ A cause for concern is that patients may be partially or totally unaware of the extent of the deterioration in their skills: they should be warned.

1. Gerbino PP. Complications of alcohol use combined with drug therapy in the elderly. *J Am Geriatr Soc* (1982) 30 (11 Suppl), S88–S93.

Alcohol + Cocaine

Alcohol increases cocaine levels and the active metabolite cocaethylene. Subjective effects such as euphoria are enhanced and some of the CNS-depressant effects of alcohol, such as sedation, are attenuated by cocaine. The combination may be potentially more toxic, with increased cardiovascular effects particularly heart rate. The use of alcohol with cocaine may increase violent behaviour.

Clinical evidence

A study in 8 cocaine users found that intranasal cocaine 100 mg and alcohol 0.8 g/kg produced a greater euphoria and feeling of well-being than cocaine alone, and reduced alcohol sedation without altering the feeling of drunkenness. Compared with placebo, the peak heart-rate was increased by 17, 23, and 41 bpm, with alcohol, cocaine, or the combination, respectively. In addition, the combination resulted in higher plasma levels of cocaine and the appearance of cocaethylene, an active and potentially toxic metabolite produced by the interaction of the two drugs.¹ Another similar study with intranasal cocaine 1 mg/kg every 30 minutes for 4 doses and oral alcohol 1 g/kg reported very similar findings.² A further study found that intranasal cocaine 96 mg/70 kg improved behavioural performance, measured by the digit symbol substitution test (DSST), whereas alcohol 1 g/kg decreased DSST performance. The combination of alcohol 1 g/kg with intranasal cocaine 48 or 96 mg/70 kg reduced the DSST below that found with cocaine alone. The combination also additively increased heart rate and diastolic blood pressure. The blood-alcohol levels were not significantly affected by the concurrent use of intranasal cocaine.³

Mechanism

In the presence of alcohol, cocaine is metabolised in the liver to cocaethylene which appears to have the same stimulant effects as cocaine, but a longer half-life (2 hours compared with about 38 minutes for cocaine). *Animal* studies suggest that this metabolite is more toxic than cocaine.⁴ In

addition, chronic alcohol exposure may facilitate the metabolism of cocaine, promoting the formation of intermediate metabolites that may cause liver damage, potentiating the hepatotoxic properties of alcohol.⁵

Importance and management

It has been suggested that the enhanced psychological effects associated with alcohol and cocaine may lead to the use of larger amounts of the combination with an increased risk for toxic effects,² such as cardiotoxicity.¹ It has been reported that users of alcohol and cocaine who also have coronary artery disease have 21.5 times the risk for sudden death than users of cocaine alone.⁴ The longer half-life of the metabolite cocaethylene explains why many people who experience cocaine-related heart attacks and strokes do so when the cocaine levels in their blood are low, as cocaethylene can remain active in the body for 7 hours after cocaine has disappeared.⁴ Patients with coronary artery disease or alcoholics may be particularly vulnerable to the combined toxic effects of alcohol and cocaine.

Alcohol + Codergocrine mesilate (Ergoloid mesylates)

Codergocrine mesilate causes a very small reduction in blood-alcohol levels.

Clinical evidence, mechanism, importance and management

Thirteen subjects were given 0.5 g/kg of alcohol 25% in orange juice after breakfast, before and after taking 4.5 mg of codergocrine mesilate (ergoloid mesylates, *Hydergine*) every 8 hours for nine doses. The codergocrine caused a small reduction in blood-alcohol levels (maximum serum levels reduced from 59 mg% to 55.7 mg%), and the clearance was reduced by a modest 11%.¹ The reason is not understood. This interaction is almost certainly not of clinical importance.

1. Savage IT, James IM. The effect of Hydergine on ethanol pharmacokinetics in man. *J Pharm Pharmacol* (1993) 45 (Suppl 2), 1119.

Alcohol + Cyproterone acetate

Excessive alcohol consumption may reduce the antiandrogenic effect of cyproterone acetate in the treatment of hypersexuality, but the relevance of this in prostatic carcinoma is not known; there seems to be no evidence that normal social amounts of alcohol interact.

Clinical evidence, mechanism, importance and management

The UK manufacturer of cyproterone acetate says that alcohol appears to reduce its effects, and so it is of no value in chronic alcoholics.¹ This appears to be based solely on a simple and unelaborated statement in an abstract of studies² in 84 men whose hyper- or abnormal sexuality was treated with cyproterone acetate, which stated that “antiandrogens do not inhibit male sexual behaviour during alcohol excess.”

The suggested reasons for this reaction are unknown, but it may possibly be due to several factors. These include enzyme induction by the alcohol, which could possibly increase the metabolism and clearance of cyproterone; increased sexual drive caused by alcohol, which might oppose the effects of cyproterone; and reduced compliance by alcoholic patients who forget to take their tablets while drinking to excess.³

It seems therefore that cyproterone may not be effective in alcoholic patients, but there is nothing to suggest that the effects of cyproterone are op-

posed by normal moderate social amounts of alcohol. The relevance of this in prostatic carcinoma is not known, nevertheless, it has been suggested that the use of alcohol during treatment with cyproterone acetate is not advisable.⁴ It would seem prudent to limit alcohol intake in patients taking cyproterone.

Alcohol + Dimethylformamide

A disulfiram-like reaction can occur in workers exposed to dimethylformamide vapour if they drink alcohol; incidences of 20% and 70% have been reported. Alcohol may possibly enhance the toxic effects of dimethylformamide on liver function.

Clinical evidence

A 3-year study in a chemical plant where dimethylformamide (DMF) was used found that about 20% (19 out of 102 men) exposed to DMF vapour experienced flushing of the face, and often of the neck, arms, hands, and chest, after drinking alcohol. Sometimes dizziness, nausea and tightness of the chest also occurred. A single glass of beer was enough to induce a flush lasting 2 hours. The majority of the men experienced the reaction within 24 hours of exposure to DMF, but it could occur even after 4 days.¹ Three further cases of this interaction are described in other reports.^{2,3}

One study in 126 factory workers exposed to DMF and 54 workers who had no contact with DMF indicated that DMF adversely affected liver function, and that concurrent alcohol had a synergistic effect (both drugs are hepatotoxic), although individual differences in tolerance to the interaction were observed. Flush symptoms after alcohol consumption were reported by 86 out of 126 (approximately 70%) of workers exposed to DMF, compared with 2 out of 54 (4%) of controls.⁴

Mechanism

Subjects exposed to DMF vapour develop substantial amounts of DMF and its metabolite (*N*-methylformamide) in their blood and urine.¹ This latter compound in particular has been shown in *rats* given alcohol to raise their blood acetaldehyde levels by a factor of five, so it would seem probable that the *N*-methylformamide is similarly responsible for this disulfiram-like reaction in man (see ‘Alcohol + Disulfiram’, p.61).⁵

Importance and management

An established interaction, with the incidence reported to be between about 20% and 70%.¹ Those who come into contact with DMF, even in very low concentrations, should be warned of this possible interaction with alcohol. It would appear to be more unpleasant than serious in most instances, and normally requires no treatment, however the hepatotoxic effects are clearly more of a concern.

Alcohol + Disopyramide

In healthy subjects, the renal clearance of disopyramide may be slightly increased by alcohol-induced diuresis.

Clinical evidence, mechanism, importance and management

A crossover study in 6 healthy subjects found that the half-life and total body clearance of disopyramide were not affected by alcohol, but the amount of the metabolite mono-*N*-dealkylated disopyramide excreted in

the urine was reduced. Alcohol increased diuresis in 5 of the 6 subjects, and the renal clearance of disopyramide was increased by 19% in these subjects.¹ The overall clinical effect is likely to be minimal.

- Olsen H, Bredeesen JE, Lunde PKM. Effect of ethanol intake on disopyramide elimination by healthy volunteers. *Eur J Clin Pharmacol* (1983) 25, 103–5.

Alcohol + Disulfiram

The ingestion of alcohol while taking disulfiram will result in flushing and fullness of the face and neck, tachycardia, breathlessness, giddiness, hypotension, and nausea and vomiting. This is called the disulfiram or *Antabuse* reaction. It is used to deter alcoholic patients from drinking. A mild flushing reaction of the skin may possibly occur in particularly sensitive individuals if alcohol is applied to the skin or if the vapour is inhaled.

Clinical evidence

(a) Alcoholic drinks

One of the earliest descriptions of this toxic interaction was made in 1937 by Dr EE Williams¹ who noted it amongst workers in the rubber industry who were handling **tetramethylthiuram disulphide**:

“Even beer will cause a flushing of the face and hands, with rapid pulse, and some of the men describe palpitations and a terrible fullness of the face, eyes and head. After a glass of beer the blood pressure falls about 10 points, the pulse is slightly accelerated and the skin becomes flushed in the face and wrists. In 15 minutes the blood pressure falls another 10 points, the heart is more rapid, and the patient complains of fullness in the head.”

The later observation² by Hald and his colleagues of the same reaction with the ethyl congener of **tetramethylthiuram disulphide**, disulfiram, led to its introduction as an alcoholic drink deterrent. Patients experience throbbing in head and neck, giddiness, sweating, nausea, vomiting, thirst, chest pain, difficulty in breathing, and headache. The severity of the reaction can depend upon the amount of alcohol ingested, but some individuals are extremely sensitive. Respiratory depression, cardiovascular collapse, cardiac arrhythmias, unconsciousness, and convulsions may occur. There have been fatalities.³

An unusual and isolated report describes painful, intermittent and transient myoclonic jerking of the arms and legs as the predominant manifestation of the disulfiram reaction in one patient.⁴ Another unusual case has been reported in which a woman with a history of bipolar disorder and alcoholism, who was taking disulfiram, was admitted to hospital with a 3- to 4-day history of changes in her mental state, including difficulties with orientation, concentration and visual hallucinations. The confusional state was attributed to alcohol consumption while taking disulfiram, and the probability of this was supported by an earlier similar, though shorter, episode experienced by the patient.⁵ Some alcoholics find that disulfiram potentiates the euphoric effects of low doses of alcohol, which alone would be relatively ineffective.⁶

(b) Products containing alcohol

A mild disulfiram reaction is said to occur in some patients who apply alcohol to the skin, but it is probably largely due to inhalation of the vapour.⁷ It has been reported after using **after-shave lotion** (50% alcohol),⁷ **tar gel** (33% alcohol)⁸ and a **beer-containing shampoo** (3% alcohol).⁹ A **contact lens wetting solution** (containing **polyvinyl alcohol**) used to irrigate the eye has also been implicated in a reaction,^{10,11} although the probability of an interaction with this secondary alcohol has been disputed.¹² It has also been described in a patient who inhaled vapour from paint in a poorly ventilated area and from the inhalation of ‘**mineral spirits**’.¹³ Furthermore, an unusual case describes a woman taking disulfiram who reported vaginal stinging and soreness during sexual intercourse, and similar discomfort to her husband’s penis, which seemed to be related to the disulfiram dosage and how intoxicated her husband was.¹⁴

The UK manufacturer of the oral solution of **ritonavir** (*Norvir*) says that since it contains alcohol 43% v/v (which they say is about equivalent to 27 mL of wine per dose) the preparation should not be taken with disulfiram or other drugs such as **metronidazole** because a disulfiram-like reaction is possible.¹⁵ However, in practice the risk is probably fairly small because the recommended dose of **ritonavir** in this form is only 7.5 mL. **Ritonavir** (*Norvir*) soft capsules also contain alcohol 12% w/w.¹⁶ The

oral concentrate of sertraline (*Zoloft oral concentrate*) is contraindicated with disulfiram due to the alcohol content (12%).¹⁷

Mechanism

Partially understood. Alcohol is normally rapidly metabolised within the liver, firstly by alcohol dehydrogenase to acetaldehyde, then by acetaldehyde dehydrogenase, and then by a series of biochemical steps to water and carbon dioxide. Disulfiram inhibits the enzyme acetaldehyde dehydrogenase so that the acetaldehyde accumulates.³ The symptoms of the disulfiram-alcohol reaction are due partly to the high levels of acetaldehyde. However, not all of the symptoms can be reproduced by injecting acetaldehyde, so that some other biochemical mechanism(s) must also be involved. The conversion of dopamine to noradrenaline is also inhibited and the depletion of noradrenaline in the heart and blood vessels allows acetaldehyde to act directly on these tissues to cause flushing, tachycardia and hypotension.¹⁸ Prostaglandin release may also be involved.¹⁹ It has been suggested that the mild skin flush that can occur if alcohol is applied to the skin is not a true disulfiram reaction.²⁰

However, some individuals appear to be more sensitive than others, which might be partially due to liver function and variations in the metabolism of disulfiram to its active metabolite by the cytochrome P450 isoenzymes.^{21,22} Disulfiram is eliminated slowly from the body and ingestion of alcohol may produce unpleasant symptoms up to 14 days after taking the last dose of disulfiram.²³

Importance and management

An extremely well-documented and important interaction exploited therapeutically to deter alcoholics from drinking alcohol. Initial treatment should be closely supervised because an extremely intense and potentially serious reaction occurs in a few individuals, even with quite small doses of alcohol. Apart from the usual warnings about drinking alcohol, patients should also be warned about the unwitting ingestion of alcohol in some pharmaceutical preparations.²⁴ The risk of a reaction is real. It has been seen following a single-dose of an alcohol-containing **cough mixture**,²⁵ whereas the ingestion of small amounts of **communion wine** and the absorption of alcohol from a **bronchial nebuliser spray** or **ear drops** did not result in any reaction in 3 individuals.²⁶ The severity of the reaction is reported to be proportional to the dosage of both disulfiram and alcohol.²³ Patients should also be warned about the exposure to alcohol from some foods, cosmetics, solvents etc. The manufacturers advise that certain foods (sauces and vinegars), liquid medicines, remedies (cough mixtures, tonics, back rubs), and toiletries (aftershave, perfumes and aerosol sprays) may contain sufficient alcohol to elicit a reaction.^{18,23} Caution should also be exercised with low-alcohol and “non-alcohol” or “alcohol-free” beers and wines, which may provoke a reaction when consumed in sufficient quantities.¹⁸

Treatment

The disulfiram reaction can be treated, if necessary, with ascorbic acid. A dose of 1 g given orally is reported to be effective in mild cases (heart rate less than 100 bpm and general condition good). It works within 30 to 45 minutes. Moderately severe cases (heart rate 100 to 150 bpm, blood pressure 150/100 mmHg) can be treated with 1 g of intravenous ascorbic acid and this is effective within 2 to 5 minutes. Critically ill patients may need other standard supportive emergency measures.²⁷

Alcohol + Ecstasy

Ecstasy may reduce subjective sedation associated with alcohol, without reversing the effects of alcohol on impulsivity or psychomotor skills. Alcohol may enhance the transient immune dysfunction associated with ecstasy. Alcohol may slightly increase the plasma levels of ecstasy, while alcohol levels may be slightly reduced by ecstasy.

Clinical evidence, mechanism, importance and management

Note that the chemical name of ecstasy is methylenedioxyamphetamine (MDMA).

(a) Effect on behaviour or psychomotor skills

A study in 9 healthy subjects found that the combination of alcohol 0.8 g/kg and ecstasy 100 mg induced a longer lasting euphoria and sense of well-being than either ecstasy or alcohol alone. Ecstasy reversed the subjective feelings of sedation associated with alcohol, but did not reverse feelings of drunkenness, or the effects of alcohol on psychomotor performance.¹ Similarly, in a double-blind, placebo-controlled, crossover study in 18 recreational users of ecstasy, alcohol-induced impairment in response inhibition tasks was not affected by single 75- or 100-mg doses of ecstasy. This indicated that the CNS-stimulating effects of ecstasy do not overcome alcohol-induced impairment of impulse-control or risk-taking behaviour.² This may have implications for road safety, as subjects may consider they are driving better when actual performance is impaired by alcohol.¹ More study is needed. Consider also 'Alcohol + Amfetamines', p.42.

(b) Effect on immune system

A study in 6 healthy subjects found that a single dose of ecstasy produced a time-dependent immune dysfunction. Ecstasy impaired CD4 T-cell function, which is responsible for cellular immunity. Alcohol alone may produce a decrease in T-helper cells and in B lymphocytes, which are responsible for humoral immunity. Concurrent ecstasy and alcohol increased the suppressive effect of ecstasy on CD4 T-cells and increased natural killer cells. It was suggested that the transient defect in immunological homeostasis could have clinical consequences such as increased susceptibility to infectious diseases.³ More study is needed.

(c) Pharmacokinetic studies

A study in 9 healthy subjects found that alcohol 0.8 g/kg increased the maximum plasma levels of a single 100-mg dose of ecstasy by 13%, with no change in AUC. The AUC and maximum plasma levels of alcohol were reduced by 9% and 15%, respectively, after ecstasy use.¹ Another single-dose study in 18 recreational users of ecstasy found a similar decrease in mean blood-alcohol levels and a small increase in ecstasy levels when the two drugs were given together, but the results were not statistically significant.²

Alcohol + Edible fungi

A disulfiram-like reaction can occur if alcohol is taken after eating the smooth ink(y) cap fungus (*Coprinus atramentarius*) or certain other edible fungi.

Clinical evidence

A man who drank 3 pints of beer 2 hours after eating a meal of freshly picked and fried **ink(y) caps (*Coprinus atramentarius*)** developed facial flushing and a blotchy red rash over the upper half of his body. His face and hands swelled and he became breathless, sweated profusely, and vomited during the 3 hours when the reaction was most severe. On admission to hospital he was tachycardic and 12 hours later he was in atrial fibrillation, which lasted for 60 hours. The man's wife, who ate the same meal but without an alcoholic drink, did not show the reaction.¹

This reaction has been described on many occasions in medical and pharmacological reports^{2–7} and in books devoted to descriptions of edible and poisonous fungi. Only a few are listed here. Mild hypotension and "... alarming orthostatic features. ..." are said to be common symptoms⁸ but the arrhythmia seen in the case cited here¹ appears to be rare. Recovery is usually spontaneous and uncomplicated. A similar reaction has been described after eating *Boletus luridus*,^{6,9} and other fungi including *Coprinus micaceus*, *Clitocybe claviceps* and certain **morels**.^{9,10} An African relative of *Coprinus atramentarius*, *Coprinus africanus*, which also causes this reaction, is called the **Ajeimutin** fungus by the Nigerian Yoruba people. The literal translation of this name is the 'eat-without-drinking-alcohol' mushroom.¹¹

Mechanism

An early and attractive idea was that the reaction with *Coprinus atramentarius* was due to the presence of disulfiram (one group of workers actually claimed to have isolated it from the fungus¹²), but this was not confirmed by later work,^{13,14} and it now appears that the active ingredient is coprine (*N*-5-(1-hydroxycyclopropyl)-glutamine).^{15,16} This is metabolised in the body to 1-aminocyclopropanol, which appears, like disulfiram, to inhibit aldehyde dehydrogenase (see 'Alcohol + Disulfiram', p.61). The active ingredients in the other fungi are unknown.

Importance and management

An established and well-documented interaction. It is said to occur up to 24 hours after eating the fungus. The intensity depends upon the quantity of fungus and alcohol consumed, and the time interval between them.^{1,4,17} Despite the widespread consumption of edible fungi and alcohol, reports of this reaction in the medical literature are few and far between, suggesting that even though it can be very unpleasant and frightening, the outcome is usually uncomplicated. Treatment appears normally not to be necessary.

The related fungus *Coprinus comatus* (the 'shaggy ink cap' or 'Lawyers wig') is said not to interact with alcohol,^{8,18} nor is there anything to suggest that it ever occurs with the **common field mushroom (*Agaricus campestris*)** or the cultivated variety (*Agaricus bisporis*).¹⁸

Alcohol + Fluvastatin

Alcohol does not significantly interact with fluvastatin.

Clinical evidence, mechanism, importance and management

Ten healthy subjects took a single 40-mg dose of fluvastatin and 70 g of alcohol diluted in lemonade. This acute ingestion of alcohol had no effect on the peak serum levels of fluvastatin or its AUC, but the half-life was reduced by almost one-third.¹ In a second related study, 20 patients with hypercholesterolaemia were given 40 mg of fluvastatin and 20 g of alcohol daily for 6 weeks. The AUC of fluvastatin was slightly increased and the half-life was increased by almost one-third, but the lipid profile with fluvastatin plus alcohol was little different from fluvastatin alone.^{1,2} The conclusion was reached that although long-term moderate drinking has some small effect on the pharmacokinetics of fluvastatin, its safety and efficacy are unaltered.¹ There would seem to be no reason for patients taking fluvastatin to avoid alcohol.

Alcohol + Food

Food and milk decrease the absorption of alcohol and meals increase the metabolism of alcohol. Foods rich in serotonin (e.g. bananas) taken with alcohol may produce adverse effects such as diarrhoea and headache. Previous alcohol consumption and the glycaemic load of a meal appear to interact to influence both mood and memory.

Clinical evidence, mechanism, importance and management

(a) Alcohol absorption and metabolism

In one study 10 subjects were given 25 mL of alcohol (equivalent to a double whiskey) after drinking a pint and a half of water or milk during the previous 90 minutes. Blood-alcohol levels at 90 minutes were reduced by about 40%, and at 120 minutes by about 25% by the presence of the milk. The intoxicant effects of the alcohol were also clearly reduced.¹ In a randomised, crossover study, 24 healthy subjects were given alcohol 0.3 g/kg either one hour before or after an evening meal. It was found that the maximum alcohol levels were increased by 87% from 21.3 to 39.9 mg%, and the AUC was increased by 63% when alcohol was given in the fasting rather than the fed state. However there was large inter and intra-individual variability in alcohol bioavailability.² Other studies have shown similar effects,^{3–5} and shown that this is not limited to specific components of food,^{4,5} as well as demonstrating that food reduces the feeling of intoxication and reduces the time required to eliminate alcohol from the body.³

After food, the rate of gastric emptying is slower, and hepatic blood flow and the activities of alcohol-metabolising enzymes are increased, which allows greater first-pass metabolism of alcohol. Thus, the effects of alcohol are greatest when taken on an empty stomach.

(b) Dietary serotonin

Serotonin (5-hydroxytryptamine, 5-HT) is excreted in the urine as 5-hydroxyindole-3-acetic acid (5-HIAA) and 5-hydroxytryptophol (5-HTOL) and the ratio of 5-HTOL to 5-HIAA is normally very low (less than 0.01).

A study in 10 healthy subjects found that 4 hours after the ingestion of alcohol 0.5 g/kg the ratio was increased by about 70-fold. When the same amount of alcohol was given with 3 bananas, a food rich in 5-HT, the ratio was increased about 100-fold at 4 hours and was still significantly raised at 24 hours. Within 4 hours, 7 of the 10 subjects experienced adverse effects including diarrhoea, headache and fatigue. The symptoms were attributed to high levels of 5-HTOL, which is usually a minor metabolite of serotonin. Other foods rich in serotonin such as pineapple, kiwi fruit or walnuts may produce similar effects if taken with even moderate amounts of alcohol.⁶

(c) Glycaemic load

Breakfasts that release glucose at different speeds were found to interact with alcohol drunk the previous evening to influence cognition and mood. When less than 4.5 g of alcohol had been drunk, a breakfast high in rapidly available glucose was associated with better memory later in the morning. In contrast, when more than 4.5 g of alcohol had been drunk, a breakfast high in slowly available glucose resulted in better memory. After a high glycaemic-load lunch, the rapidly available glucose breakfast resulted in a more confused feeling than the slowly available glucose breakfast or fasting in those who had drunk more than 4.5 g of alcohol the previous evening.⁷

Alcohol + Furazolidone

A disulfiram-like reaction may occur in patients taking furazolidone if they drink alcohol.

Clinical evidence

A patient taking furazolidone 200 mg four times daily complained of facial flushing, lachrymation, conjunctivitis, weakness, and light-headedness within 10 minutes of drinking beer. It occurred on several occasions and lasted 30 to 45 minutes.¹ A man prescribed furazolidone 100 mg four times daily and who had taken only three doses, developed intense facial flushing, wheezing and dyspnoea (lasting one hour), within one hour of drinking 2 oz (about 60 mL) of brandy. The same thing happened again the next day after drinking a Martini cocktail. No treatment was given.² A report originating from the manufacturers of furazolidone stated that by 1976, 43 cases of a disulfiram-like reaction had been reported, of which 14 were produced experimentally using above-normal doses of furazolidone.³ A later study in 1986 described 9 out of 47 patients (19%) who complained of a disulfiram-like reaction after drinking alcohol while taking furazolidone 100 mg four times daily for 5 days.⁴

Mechanism

Uncertain. It seems possible that furazolidone acts like disulfiram by inhibiting the activity of acetaldehyde dehydrogenase (see 'Alcohol + Disulfiram', p.61).

Importance and management

An established and clinically important interaction of uncertain incidence. One report suggests that possibly about 1 in 5 may be affected.⁴ Reactions of this kind appear to be more unpleasant and possibly frightening than serious, and normally need no treatment, however patients should be warned about what may happen if they drink alcohol.

Alcohol + Glutethimide

The combination of glutethimide and alcohol results in greater impairment in some psychomotor tests, but improvement in others. Alcohol does not interact with glutethimide taken the previous night.

Clinical evidence, mechanism, importance and management

In a series of studies, blood-alcohol levels were raised a mean of 11% by glutethimide, while plasma and urinary glutethimide levels were reduced.¹ Neither glutethimide nor alcohol alone significantly impaired reaction times, but the combination did. However, in two other tests (tracking efficacy and finger tapping) impairment was greatest after glutethimide alone and reduced by the presence of alcohol.¹ In contrast, a later study found that glutethimide did not subjectively or objectively impair the performance of a number of psychomotor skill tests related to driving, and did not interact with alcohol given the morning after the glutethimide dose.² Both drugs are CNS depressants and their effects would be expected to be additive.

The information is limited and somewhat contradictory, nevertheless patients should be warned about the probable results of taking glutethimide and alcohol together. Driving, handling dangerous machinery, or undertaking any task needing alertness and full co-ordination, is likely to be made more difficult and hazardous. There is no evidence of a hangover effect, which could result in an interaction with alcohol the next day.²

Alcohol + Glycerol trinitrate (Nitroglycerin)

Patients who take glycerol trinitrate while drinking may feel faint and dizzy.

Clinical evidence, mechanism, importance and management

The results of studies^{1,2} on the combined haemodynamic effects of alcohol and glycerol trinitrate give support to earlier claims that concurrent use increases the risk of exaggerated hypotension and fainting.^{3,4} Their vasodilatory effects⁵ would appear to be additive. The greatest effect was seen when the glycerol trinitrate was taken one hour or more after starting to drink alcohol.¹ It is suggested that this increased susceptibility to postural hypotension should not be allowed to stop patients from using glycerol trinitrate if they want to drink alcohol, but they should be warned about the possible effects and told what to do if they feel faint and dizzy (i.e. sit or lie down).¹

Alcohol + Griseofulvin

An isolated case report describes a very severe disulfiram-like reaction when a man taking griseofulvin drank a can of beer. Another isolated report notes flushing and tachycardia. A few others have shown increased alcohol effects.

Clinical evidence

A man took griseofulvin 500 mg daily for about 2 weeks without problems. Subsequently he drank a can of beer, took his usual dose of griseofulvin about one hour later, and within 30 to 60 minutes developed a severe disulfiram-like reaction (flushing, severe nausea, vomiting, diarrhoea, hypotension and paraesthesias of all extremities). He was successfully treated with intravenous sodium chloride 0.9%, potassium, dopamine, and intramuscular promethazine.¹

Another isolated case of flushing and tachycardia attributed to the concurrent use of alcohol and griseofulvin has also been described; rechallenge produced the same effects.²

It has been suggested that griseofulvin can increase the effects of alcohol, but the descriptions of this response are very brief. One of them describes³ a man who had a decreased tolerance to alcohol and emotional instability manifested by crying and nervousness, which was said to be so severe that the drug was stopped. Another⁴ states that this effect has been noted in a very small number of patients, but gives no further information.

Mechanism

Not understood. The reaction described above might possibly have the same pharmacological basis as the disulfiram/alcohol reaction (see 'Alcohol + Disulfiram', p.61).

Importance and management

The documentation is extremely sparse, which would seem to suggest that adverse interactions between alcohol and griseofulvin are uncommon. Concurrent use need not be avoided but it may be prudent to warn patients about the possible effects. The disulfiram-like reaction described was unusually severe. The manufacturer cautions that the effects of alcohol may be potentiated by griseofulvin, producing such adverse effects as tachycardia and flush.⁵

Alcohol + H₂-receptor antagonists

Although some studies have found that blood-alcohol levels can be raised to some extent in those taking some H₂-receptor antagonists and possibly remain elevated for longer than usual, others report that no significant interaction occurs. Drinking may worsen the gastrointestinal disease for which these H₂-receptor antagonists are being given. Hypoglycaemia associated with alcohol may be enhanced by H₂-receptor antagonists.

Clinical evidence

(a) Evidence of an interaction

A double-blind study in 6 healthy subjects found that **cimetidine** 300 mg four times daily for 7 days, increased the peak plasma levels of alcohol 0.8 g/kg by about 12% (from 146 to 163 mg%) and increased the AUC by about 7%. The subjects assessed themselves as being more intoxicated while taking **cimetidine** and alcohol than with alcohol alone.¹

An essentially similar study^{2,3} found that the blood-alcohol levels were raised by 17% (from 73 to 86 mg%) by **cimetidine** but not by **ranitidine**. However, another study found that **cimetidine** almost doubled peak blood-alcohol levels, whereas **ranitidine** raised the levels by about 50%.⁴ A study in 6 healthy subjects also found that **cimetidine** 400 mg twice daily for one week approximately doubled the AUC following a single 0.15-g/kg oral dose of alcohol and raised peak alcohol levels by about 33%. No changes were seen when the alcohol was given intravenously.⁵ A further study in healthy subjects given **cimetidine** or **ranitidine** for only 2 days found that peak plasma alcohol levels were raised by 17% and 28%, respectively, and the time that blood levels remained above the 80 mg% mark (the legal driving limit in some countries) was prolonged by about one-third.⁶

A study in subjects given 0.75 g/kg of alcohol found that single doses of **cimetidine** 800 mg, **nizatidine** 300 mg, or **ranitidine** 300 mg raised blood alcohol levels at 45 minutes by 26% (from 75.5 to 95.2 mg%), 17.5% (from 75.5 to 88.7 mg%) and 3.3% (75.5 to 78 mg%), respectively, and the AUCs at 120 minutes were increased by 25%, 20% and 9.8%, respectively. Each of the subjects said they felt more inebriated after taking **cimetidine** or **nizatidine**.⁷ Another report briefly mentions that both **nizatidine** and **ranitidine** have similar effects on alcohol absorption to **cimetidine**.⁸

In subjects with substantial first-pass metabolism of alcohol, **cimetidine** increased the blood levels of repeated small drinks of alcohol to a greater degree than that which occurred after an equivalent single dose. The levels reached were associated with psychomotor impairment.⁹ Similarly, **ranitidine** 150 mg twice daily for 7 days considerably increased blood-alcohol levels and the high levels persisted for longer in social drinkers (with substantial first-pass metabolism) receiving 4 drinks of 0.15 g/kg of alcohol at 45-minute intervals.¹⁰

In contrast, another study found that a combination of chlorphenamine (which blocks H₁-receptors) and **cimetidine** reduced the rate of absorption and peak blood alcohol levels, and suppressed alcohol-induced flushing.¹¹

(b) Evidence of no interaction

The manufacturers of **cimetidine** have on file three unpublished studies that did not find any evidence to suggest that **cimetidine** or **ranitidine** significantly increased the blood levels of alcohol. One study was in 6 healthy subjects given single 400-mg doses of **cimetidine**, another in 6 healthy subjects given **cimetidine** 1 g daily for 14 days, and the last in 10 healthy subjects given either **cimetidine** 400 mg twice daily or **ranitidine** 150 mg twice daily.¹² A number of other studies have also found that no significant interaction occurs between **cimetidine**, **famotidine**, **nizatidine**, or **ranitidine**, and a number of different alcoholic drinks (low to high dose), either on an empty stomach or after eating.¹³⁻²⁶ Two other studies showing an interaction between other H₂-receptor antagonists and alcohol found that **famotidine** had no significant effect on blood-alcohol levels.^{4,7}

(c) Hypoglycaemia

A study in 10 healthy subjects given alcohol 0.5 g/kg before and after **cimetidine** 400 mg twice daily, **ranitidine** 150 mg twice daily, or **famotidine** 40 mg once daily, all taken for 7 days, found that hypoglycaemia following alcohol ingestion was enhanced by all three H₂-receptor antagonists. The effect was especially marked with **famotidine**.²⁷

Mechanism

It would appear that the interacting H₂-receptor antagonists inhibit the activity of alcohol dehydrogenase (ADH) in the gastric mucosa so that more alcohol passes unmetabolised into the circulation, thereby raising the levels.²⁸⁻³² Most of the studies assessing the interaction of H₂-receptor antagonists with larger quantities of alcohol have not found an interaction. The decrease in first pass metabolism with increasing amounts of alcohol could explain this, as it implies that a significant interaction with H₂-receptor antagonists would be more likely with smaller quantities of alcohol.^{9,33} Other factors that affect the first pass metabolism of alcohol, such as fasting, chronic alcoholism and female gender may also affect the outcome. The increase in blood-alcohol levels with cimetidine or ranitidine and a low alcohol dose may also be explained by the effect of H₂-receptor antagonists or alcohol on gastric emptying times.^{24,33} In one study the decrease in first-pass metabolism correlated with a ranitidine-induced increase in the rate of gastric emptying and an increase in blood-alcohol levels.³⁴ However, with small quantities of alcohol the magnitude of the effect on peak levels may be too small to increase effects on psychomotor performance,^{33,35} although two studies suggested that an effect might occur.⁹

The hypoglycaemic effect is not considered to be due to effects on alcohol absorption but may be an effect of H₂-receptor antagonists on glucose metabolism.²⁷

Importance and management

The contrasting and apparently contradictory results cited here clearly show that this interaction is by no means established. Extensive reviews of the data concluded that the interaction is, in general, clinically insignificant.^{32,33,36-38} Under conditions mimicking social drinking there is some evidence that H₂-receptor antagonists may^{10,27} or may not²⁶ increase blood-alcohol levels to those associated with impairment of psychomotor skills. However, as yet, there are insufficient grounds to justify any gener-

al warning regarding alcohol and H₂-receptor antagonists. However, note that many of the conditions for which H₂-receptor antagonists are used may be made worse by alcohol, so restriction of alcohol intake may be prudent.

Alcohol + Herbal medicines; Ginseng

Ginseng increases the clearance of alcohol and lowers blood-alcohol levels.

Clinical evidence, mechanism, importance and management

Fourteen healthy subjects, each acting as their own control, were given alcohol (72 g/65 kg as a 25% solution) with and without a ginseng extract (3 g/65 kg) mixed in with it. They drank the alcohol or the alcohol/ginseng mixture over a 45-minute period in 7 portions, the first four at 5-minute intervals and the next three at 10-minute intervals. Measurements taken 40 minutes later showed that the presence of the ginseng lowered blood-alcohol levels by an average of 38.9%. The alcohol levels of 10 subjects were lowered by 32 to 51% by the ginseng, 3 showed reductions of 14 to 18% and one showed no changes at all.¹

The reasons for this interaction are uncertain, but it is suggested that ginseng possibly increases the activity of the enzymes (alcohol and aldehyde dehydrogenase)² that are concerned with the metabolism of the alcohol, thereby increasing the clearance of the alcohol. What this means in practical terms is not clear but the authors of the report suggest the possibility of using ginseng to treat alcoholic patients and those with acute alcohol intoxication.¹ *Panax ginseng* has been shown to reduce voluntary alcohol intake in animals.³

Alcohol + Herbal medicines; Kava

There is some evidence that kava may worsen the CNS depressant effects of alcohol.

Clinical evidence, mechanism, importance and management

Forty healthy subjects underwent a number of cognitive tests and visuo-motor tests after taking alcohol alone, kava (Kava-Kava; the pepper plant *Piper methysticum*) alone, or both together. The subjects took 0.75 g/kg of alcohol (enough to give blood alcohol levels above 50 mg%) and the kava dose was 1 g/kg. The kava drink was made by mixing middle grade Fijian kava with water and straining it to produce about 350 mL of kava liquid. It was found that kava alone had no effect on the tests, but when given with alcohol it potentiated both the perceived and measured impairment that occurred with alcohol alone.¹ However, another study found that a kava extract (WS 1490) did not enhance the negative effects of alcohol on performance tests.²

No very strong conclusions can be drawn from the results of the studies, but it is possible that car driving and handling other machinery may be more hazardous if kava and alcohol are taken together. However, note that the use of kava-kava is restricted in the UK because of reports of idiosyncratic hepatotoxicity.³

Alcohol + Herbal medicines; Liv.52

***Liv.52*, an Ayurvedic herbal remedy, appears to reduce the hangover symptoms after drinking, reducing both urine and blood-alcohol and acetaldehyde levels at 12 hours. However it also raises the blood alcohol levels of moderate drinkers for the first few hours after drinking.**

Clinical evidence

Nine healthy subjects who normally drank socially (alcohol 40 to 100 g weekly) took six tablets of *Liv.52* two hours before drinking alcohol (four

60 mL doses of whiskey, equivalent to 90 g of alcohol). Their blood-alcohol levels at one hour were increased by 15% (from 75 to 86.2 mg%). After taking three tablets of *Liv.52* daily for two weeks, their 1-hour blood-alcohol levels were raised by 27% (from 75 to 95.3 mg%).¹ Acetaldehyde levels in the blood and urine were markedly lowered at 12 hours, and hangover symptoms seemed to be reduced.¹ In a similar study, the blood-alcohol levels of 9 moderate drinkers were raised over the first 2 hours by about 28 to 44% after taking three tablets of *Liv.52* twice daily for two weeks, and by 17 to 19% over the following 2 hours.² Only a minor increase in the blood-alcohol levels of 8 occasional drinkers occurred.²

Mechanism

Not understood. *Liv.52* contains the active principles from *Capparis spinosa*, *Cichorium intybus*, *Solanum nigrum*, *Cassia occidentalis*, *Terminalia arjuna*, *Achillea millefolium*, *Tamarix gallica* and *Phyllanthus amarus*.¹ These appear to increase the absorption of alcohol, or reduce its metabolism by the liver, thereby raising the blood-alcohol levels. It is suggested that the reduced hangover effects may possibly occur because it prevents the binding of acetaldehyde to cell proteins allowing a more rapid elimination.¹

Importance and management

Direct pharmacokinetic evidence seems to be limited to these two studies.^{1,2} *Liv.52* appears to reduce the hangover effects after drinking, but at the same time it can significantly increase the blood alcohol levels of moderate drinkers, for the first few hours after drinking. Increases of up to 30% may be enough to raise the blood alcohol from legal to illegal levels when driving. Moderate drinkers should be warned. Occasional drinkers appear to develop higher blood-alcohol levels than moderate drinkers but *Liv.52* does not seem to increase them significantly.²

Alcohol + Hormonal contraceptives

The detrimental effects of alcohol may be reduced to some extent in women taking oral contraceptives, but alcohol clearance may also possibly be reduced. Alcohol does not affect the pharmacokinetics of ethinylestradiol.

Clinical evidence, mechanism, importance and management

(a) *Effect of oral contraceptives on alcohol*

A controlled study in 54 women found that those taking a combined oral contraceptive (30, 35, or 50 micrograms of **oestrogen**) unexpectedly tolerated the effects of alcohol better than those not taking oral contraceptives (as measured by a reaction-time test and a bead-threading test), but their blood-alcohol levels and its rate of alcohol clearance were unchanged.¹ For mention of a trend towards improved cognitive performance with small amounts of alcohol and oestrogen replacement therapy, see 'Alcohol + HRT', p.67.

The authors say that they do not recommend women taking oral contraceptives should attempt to drink more than usual, since even if alcohol is tolerated better, blood-alcohol levels are not reduced.¹ However, two other studies suggest that peak blood-alcohol levels may be reduced in those taking oral contraceptives, but alcohol clearance is also reduced and so alcohol may be present longer in women who are taking oral contraceptives.^{2,3}

(b) *Effect of alcohol on oral contraceptives*

Alcohol ingestion did not have any significant effect on **ethinylestradiol** pharmacokinetics in 9 healthy women taking a combined oral contraceptive (ethinylestradiol/gestodene 30/75 micrograms). In this study, alcohol was given as a single dose of 0.4 g/kg (2 to 3 standard drinks) on day 14 then 0.4 g/kg twice daily for 7 days. The findings of this study contrast

with those of the effect of alcohol on estradiol in postmenopausal women (see 'Alcohol + HRT', below). This may be because the ethinyl group in **ethinylestradiol** confers protection from the effects of alcohol.⁴

Alcohol + HRT

Acute ingestion of alcohol markedly increases the levels of circulating estradiol in women using oral HRT; a smaller increase is seen with transdermal HRT. In addition, alcohol intake appears to increase the risk of breast cancer in women receiving HRT. Small amounts of alcohol may possibly improve some aspects of cognitive function in patients using HRT. Estradiol does not affect blood-alcohol levels.

Clinical evidence, mechanism, importance and management

(a) Hormone and blood-alcohol levels

Twelve healthy postmenopausal women receiving HRT (estradiol 1 mg daily and medroxyprogesterone acetate 10 mg daily for 10 out of each 25 days) were given an alcoholic drink (0.7 g/kg, a dose shown to achieve mean peak alcohol serum levels of about 97 mg% after about 1 hour) during the oestrogen-only phase of the HRT cycle. It was found that their peak estradiol levels rose threefold and were significantly above the baseline for 5 hours. No significant increases in the levels of circulating oestrogen (an oestrogen secreted by the ovaries) were seen, and blood-alcohol levels were not changed.¹ A similar, smaller 1.2-fold increase in peak estradiol levels was seen in another study when women using transdermal estradiol were given alcohol.²

The reasons for these changes are not understood. Alcohol can increase endogenous estradiol levels in postmenopausal women, although the findings are variable. Another possible explanation is altered clearance of estradiol in women who drink alcohol.³ Note that alcohol does not affect ethinylestradiol levels, see 'Alcohol + Hormonal contraceptives', p.66.

(b) Risk of breast cancer

Since both alcohol and HRT are linked with a small increase in breast cancer risk, it has been postulated that the combination of HRT and alcohol could be additive.⁴ A prospective study of 51 847 postmenopausal women confirmed an association with alcohol intake and breast cancer risk (for oestrogen receptor-positive (ER+) tumours, but not ER– tumours). Furthermore, among women who consumed alcohol, postmenopausal hormone use was associated with an increased risk for the development of ER+ tumours. For women with the highest alcohol intake (10 g (approximately 1 drink) or more daily) the relative risk of developing oestrogen receptor-positive/progesterone receptor-positive (ER+PR+) breast cancer was 1.2 and 1.8 for non-users and users of HRT, respectively, compared with non-drinkers who had never used postmenopausal hormones; the relative risk of developing ER+PR– tumours was even greater, being approximately 2.5 and 3.5, respectively.⁵ Another study also reported a similar increased risk of developing ER+PR+ tumours with alcohol and oestrogen replacement therapy, but only a slight risk for ER+PR– tumours; the risk for ER–PR– breast cancer was, however, greatest.⁶

Regular consumption of alcohol as low as 1 to 2 drinks per day may possibly contribute to a modest increased risk,³ and it has been suggested that women taking HRT should limit their alcohol intake;⁴ about one drink or less per day has been proposed.³ More study is needed to confirm the amount and frequency of alcohol consumption needed to have a deleterious effect both in women who use HRT and in non-users.

(c) Visuospatial performance

A study of 214 postmenopausal women suggested that small amounts of alcohol may enhance visuospatial processes (improved cognitive function measured by block design performance). HRT also appeared to be linked

with better visuospatial performance, but only when the task was difficult. There was a trend (not statistically significant) towards improved performance with alcohol consumption (up to approximately half a standard drink per day) and oestrogen replacement therapy.⁷ For mention of improved tolerance to alcohol in premenopausal women taking oestrogen, see 'Alcohol + Hormonal contraceptives', p.66.

Alcohol + Interferons

A study found a reduced response to interferon in patients who drank alcohol.

Clinical evidence, mechanism, importance and management

In a study involving 245 patients, alcohol intake, and its effect on treatment were retrospectively evaluated between 1 and 3 years after diagnosis of hepatitis C virus-related chronic liver disease. Less than 50% of the patients who drank alcohol stopped after being diagnosed with liver disease, despite being advised to abstain from alcohol. Alcohol intake affected fibrosis, especially in women, and response to interferon therapy. Seventeen out of 65 patients (26.1%) who were treated with **interferon alfa** had a sustained response to therapy. However, the number of responders decreased as alcohol intake increased; there were more drinkers (63.1%) than abstainers (10.7%) among the 73.8% of patients who did not respond.¹ One manufacturer notes that hepatotoxicity has been reported with **interferon beta-1a** and the potential additive toxicity with hepatotoxic drugs such as alcohol has not been determined, and caution is warranted.²

There appears to be insufficient information to suggest that patients receiving interferons should avoid alcohol completely, however, alcohol intake, particularly heavy drinking, may increase the risk of hepatotoxicity with interferon.

Alcohol + Ivermectin

Alcohol may increase the bioavailability of ivermectin.

Clinical evidence, mechanism, importance and management

Anecdotal reports from Nigeria suggest that ivermectin is more potent when taken with palm wine, a local alcoholic drink, and a few cases of ataxia and postural hypotension occurring with ivermectin were considered to be due to an interaction with alcohol.¹ Ivermectin formulated as an alcoholic solution has been found to have about twice the systemic availability of tablets and capsules.² In another study, 20 healthy subjects were given ivermectin 150 micrograms/kg with either 750 mL of beer (alcohol 4.5%) or 750 mL of water. Plasma levels of ivermectin at 1 to 4 hours were increased by about 51% to 66%, respectively, when it was given with beer, when compared with water. No adverse effects were reported in either group.¹ The evidence suggest that concurrent use may be of benefit,

if adverse effects such as postural hypotension are not troublesome; this may be more of a problem in those with pre-existing heart disease.

Alcohol + Ketoconazole

A few cases of disulfiram-like reactions have been reported in patients who drank alcohol while taking ketoconazole.

Clinical evidence, mechanism, importance and management

One patient (an alcoholic), out of group of 12 patients with *Candida* infections taking ketoconazole 200 mg daily, experienced a disulfiram-like reaction (nausea, vomiting, facial flushing) after drinking alcohol.¹ No further details are given, and the report does not say whether any of the others drank alcohol. A woman taking ketoconazole 200 mg daily developed a disulfiram-like reaction when she drank alcohol.² Another report describes a transient 'sunburn-like' rash or flush on the face, upper chest and back of a patient taking ketoconazole 200 mg daily when she drank modest quantities of wine or beer.³ The reasons for the reactions are not known but it seems possible that ketoconazole may act like disulfiram and inhibit the activity of acetaldehyde dehydrogenase (see 'Alcohol + Disulfiram', p.61). The incidence of this reaction appears to be very low (these appear to be the only reports) and its importance is probably small. Reactions of this kind are usually more unpleasant than serious, with symptoms resolving within a few hours.⁴ Nevertheless, the manufacturer advises avoidance of alcohol while taking ketoconazole.⁵

Alcohol + Lithium

Some limited evidence suggests that lithium carbonate combined with alcohol may make driving more hazardous.

Clinical evidence, mechanism, importance and management

In 9 out of 10 healthy subjects alcohol 0.5 g/kg raised the serum levels of a single 600-mg dose of lithium carbonate by 16%. Four subjects had at least a 25% increase in lithium levels. However these rises were not considered to be clinically important.¹ In contrast a study in 20 healthy subjects given lithium carbonate (to achieve lithium serum levels of 0.75 mmol/L) and alcohol 0.5 g/kg, and who were subjected to various psychomotor tests (choice reaction, coordination, attention) to assess any impairment of skills related to driving, indicated that lithium carbonate both alone and with alcohol may increase the risk of an accident. In this study, lithium did not affect blood-alcohol levels.² Information is very limited but patients should be warned about the possible increased risk of driving or other potentially hazardous activities when taking both drugs.

Alcohol + Mefloquine

Mefloquine does not normally appear to interact with alcohol, although excessive alcohol may possibly contribute to its adverse effects on the liver. An isolated report describes two incidents of severe psychosis and depression in a man taking mefloquine who drank large quantities of alcohol.

Clinical evidence, mechanism, importance and management

Mefloquine 250 mg or placebo was given to two groups of 20 healthy subjects on three occasions, each time the day before they took enough alcohol to achieve blood levels of about 35 mg%. Mefloquine did not affect blood-alcohol levels, nor did it increase the effects of alcohol on two real-highway driving tests or on psychomotor tests done in the laboratory. In fact, the mefloquine group actually drove better than the placebo group.¹

A 40-year old man with no previous psychiatric history taking mefloquine 250 mg weekly for malaria prophylaxis had no problems with the first 2 doses. However, on two separate occasions when taking the third and fourth doses he also drank about half a litre of whisky, whereupon he developed severe paranoid delusions, hallucinations and became suicidal. When he stopped drinking he had no further problems while taking subsequent doses of mefloquine. He was used to drinking large amounts of alcohol and had experienced no problems while previously taking proguanil and chloroquine.²

The broad picture is that mefloquine appears not to worsen the psychomotor effects of moderate amounts of alcohol. Just why an unusual toxic reaction developed in one individual is not known, although mefloquine alone can increase the risk of psychiatric events.^{3,4} It has been postulated that many of the adverse effects of mefloquine are associated with liver damage, and concurrent insults to the liver, such as from alcohol and dehydration, may be related to the development of severe or prolonged adverse reactions to mefloquine. In a review of 516 published case reports of mefloquine adverse effects, 11 cited alcohol as a possible contributing factor.⁴ It was suggested that travellers taking mefloquine should avoid alcohol particularly within 24 hours of their weekly mefloquine dose.⁴ However, the manufacturers have not issued such a warning.^{5,6} More study is needed.

Alcohol + Meprobamate

The intoxicant effects of alcohol can be considerably increased by the presence of normal daily doses of meprobamate. Driving or handling other potentially dangerous machinery is made much more hazardous.

Clinical evidence

A study in 22 subjects, given meprobamate 400 mg four times daily for one week, showed that with blood-alcohol levels of 50 mg% their performance of a number of coordination and judgement tests was much more impaired than with either drug alone.¹ Four of the subjects were quite obviously drunk while taking both meprobamate and alcohol showed marked incoordination and social disinhibition. Two could not walk without assistance. The authors say this effect was much greater than anything seen with alcohol alone.

Other studies confirm this interaction, although the effects appeared to be less pronounced.^{2–6}

Mechanism

Both meprobamate and alcohol are CNS depressants, which appear to have additive effects. There is also some evidence that alcohol may inhibit or increase meprobamate metabolism, depending on whether it is taken acutely or chronically, but the contribution of this to the enhanced CNS depression is uncertain.^{7,8} Meprobamate does not appear to increase blood alcohol levels.⁵

Importance and management

A well-documented and potentially serious interaction. Normal daily dosages of meprobamate in association with relatively moderate blood-alcohol levels, well within the UK legal limit for driving, can result in obviously hazardous intoxication. Patients should be warned; the patient information leaflet for meprobamate says that alcohol should be avoided.⁹

Alcohol + Mercaptopurine

Alcohol has been tolerated in patients receiving mercaptopurine.

Clinical evidence, mechanism, importance and management

A study in 207 patients with inflammatory bowel disease assessed (using a phone survey) the presence of adverse reactions to alcohol in patients taking chronic mercaptopurine and/or metronidazole or neither drug. All of the patients consumed less than 4 alcoholic beverages per day. The proportion of patients experiencing any clinically significant adverse effects was: metronidazole group 16.3%, mercaptopurine group 14.5%, control group (not taking either drug) 8.97%. Although there was a trend towards more adverse effects in the drug study groups, this was not statistically significant. The authors suggest a cautious trial of alcohol is advisable in patients that are starting and will be taking either of the medications on a chronic basis.¹

1. Ginzburg L, Present DH. Alcohol is well tolerated in IBD patients taking either metronidazole or 6-mercaptopurine. *Am J Gastroenterol* (2003) 98 (Suppl), S241.

Alcohol + Methaqualone

The CNS depressant effects of alcohol and its detrimental effects on the skills relating to driving or handling other potentially dangerous machinery are increased by the concurrent use of methaqualone with or without diphenhydramine.

Clinical evidence

(a) Methaqualone

A retrospective study of drivers arrested for driving under the influence of drugs and/or alcohol found that, generally speaking, those with blood methaqualone levels of 1 mg/L or less had no symptoms of sedation, whereas those with levels above 2 mg/L demonstrated staggering gait, drowsiness, incoherence and slurred speech. These effects were increased if the drivers had also been drinking alcohol. The authors state that the levels of methaqualone needed for driving skills to become impaired are considerably lowered by alcohol, but no precise measure of this is presented in the paper.¹

(b) Methaqualone with diphenhydramine

A double-blind study in 12 healthy subjects given two *Mandrax* tablets (methaqualone 250 mg with diphenhydramine 25 mg) showed that the resulting sedation and reduction in cognitive skills were enhanced by alcohol 0.5 g/kg. Residual amounts of a single-dose of *Mandrax* continued to interact for as long as 72 hours. Methaqualone blood levels are also raised by regular moderate amounts of alcohol.² Enhanced effects were also seen in another study.³

Mechanism

Alcohol, methaqualone and 'diphenhydramine', (p.47), are all CNS depressants, the effects of which are additive. A hangover can occur because the elimination half-life of methaqualone is long (10 to 40 hours).

Importance and management

An established interaction of importance. Those taking either methaqualone or methaqualone with diphenhydramine should be warned that handling machinery, driving a car, or any other task requiring alertness and full coordination, will be made more difficult and hazardous if they drink alcohol. Levels of alcohol below the legal driving limit with normal amounts of methaqualone may cause considerable sedation. Patients should also be told that a significant interaction may possibly occur the following day, because it has a long half-life.

Note that methaqualone has been withdrawn from the market in many countries because of problems of abuse.

Alcohol + Methotrexate

There is some inconclusive evidence that the consumption of alcohol may increase the risk of methotrexate-induced hepatic cirrhosis and fibrosis.

Clinical evidence, mechanism, importance and management

It has been claimed that alcohol can increase the hepatotoxic effects of methotrexate.¹ Two reports of patients treated for psoriasis indicate that this may be so; in one, 3 out of 5 patients with methotrexate-induced cirrhosis were reported to have taken alcohol concurrently (2 patients greater than 85 g, one patient 25 to 85 g of alcohol per week),² and in the other, the subject was known to drink excessively.³ The evidence is by no means conclusive and no direct causal relationship has been established. However, the manufacturers of methotrexate advise the avoidance of drugs, including alcohol, which have hepatotoxic potential,⁴ and contraindicate its use in patients with alcoholism or alcoholic liver disease.^{4,5}

Alcohol + Methylphenidate

Alcohol may increase methylphenidate levels and exacerbate some of its CNS effects.

Clinical evidence, mechanism, importance and management

In 17 subjects who had taken methylphenidate orally or intranasally with alcohol on at least 10 separate occasions, the primary reason for concurrent use was given as an alteration in psychotropic effects with increased euphoria and energy and a diminished sense of drunkenness. In addition, a minority of subjects also reported occasionally experiencing unpleasant adverse effects such as increased nausea (3 subjects), insomnia (2), and 'jaw clenching' (1).¹ In a study in 20 subjects alcohol 0.6 g/kg was given either 30 minutes before or 30 minutes after a single 0.3-mg/kg dose of methylphenidate. Alcohol significantly increased the AUC and maximum serum levels of methylphenidate, regardless of the timing of administration, by about 25% and 40%, respectively.²

Methylphenidate has a short half-life mainly due to conversion to the inactive metabolite ritalinic acid, but co-administration of alcohol and methylphenidate has been reported to result in production of a minor me-

tabolite, ethylphenidate, which has CNS activity.^{3,4} However, a more recent study found that the ethylphenidate formed is predominantly of the inactive enantiomer, so is unlikely to contribute to the additive CNS effects of alcohol and methylphenidate.²

The manufacturer of methylphenidate advises that alcohol may exacerbate the CNS effects of methylphenidate and therefore recommends that alcohol should be avoided during treatment.⁵ In addition, methylphenidate should be given cautiously to patients with a history of drug dependence or alcoholism because of its potential for abuse.^{1,5,6}

6. Ritalin (Methylphenidate hydrochloride). Novartis Pharmaceuticals Corporation. US Prescribing information, April 2007.

Alcohol + Metoclopramide

There is some evidence that metoclopramide can increase the rate of absorption of alcohol, raise maximum blood-alcohol levels, and possibly increase alcohol-related sedation.

Clinical evidence, mechanism, importance and management

A study in 7 subjects found that 20 mg of intravenous metoclopramide increased the rate of alcohol absorption, and the peak blood levels were raised from 55 to 86 mg%. Similar results were seen in 2 healthy subjects given metoclopramide orally.¹ Another study in 7 healthy subjects found that 10 mg of intravenous metoclopramide accelerated the rate of absorption of alcohol 70 mg/kg given orally, and increased its peak levels, but not to a statistically significant extent. Blood alcohol levels remained below 12 mg%. More importantly the sedative effects of the alcohol were increased.² The reasons for this effect are not fully understood, but it appears to be related to an increase in gastric emptying. These two studies were done to find out more about intestinal absorption mechanisms rather than to identify daily practicalities, so the importance of the findings is uncertain. However, it seems possible that the effects of alcohol will be increased. Metoclopramide alone can sometimes cause drowsiness, and if affected, patients should not drive or operate machinery.

2. Bateman DN, Kahn C, Mashiter K, Davies DS. Pharmacokinetic and concentration-effect studies with intravenous metoclopramide. *Br J Clin Pharmacol* (1978) 6, 401–7.

Alcohol + Mirtazapine

The sedative effects of mirtazapine may be increased by alcohol.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects alcohol (equivalent to 60 g) had a minimal effect on plasma levels of mirtazapine 15 mg.¹ However the sedation and CNS impairment seen with mirtazapine is additive with that produced by alcohol, and the manufacturers recommend avoiding concurrent use.^{1,2} Mirtazapine does not affect the absorption of alcohol.³

Alcohol + Muscle relaxants

Three reported cases of overdose with methocarbamol and alcohol resulted in death due to combined CNS depression. Concurrent use of small or moderate amounts of alcohol with muscle relaxants may increase drowsiness and reduce alertness.

Clinical evidence, mechanism, importance and management

(a) Baclofen

The manufacturer of baclofen warns that baclofen may enhance the sedative effect of alcohol.¹ However, tolerance to baclofen's sedative effect has been reported in alcohol-addicted patients after a period of abstinence, as well as after a relapse.²

(b) Dantrolene

The manufacturer of dantrolene advises caution if it is given with alcohol³ and the patient information leaflet suggests that alcohol should be avoided because it may increase drowsiness.⁴

(c) Methocarbamol

Fatal cerebral anoxia produced by CNS respiratory depression occurred in a 31-year-old man after ingestion of significant amounts of methocarbamol and alcohol. Two other lethal overdoses have been reported with these 2 drugs. In all 3 cases the methocarbamol doses exceeded the recommended daily dosages, but were estimated to be less than the reported maximum tolerated single dose of 12 g. Acute alcohol intoxication combined with methocarbamol usage can lead to combined CNS depression, which may be sufficient to cause death.⁵ The manufacturers of methocarbamol warn that it may potentiate the effects of alcohol^{6,7} and the patient information leaflet suggests that patients taking methocarbamol should avoid alcohol.⁸

(d) Other muscle relaxants

For enhanced CNS effects with alcohol with other muscle relaxants, see 'benzodiazepines', (p.53), 'meprobamate', (p.68), and 'tizanidine', (p.1287).

Alcohol + Nefazodone

In one study nefazodone 400 mg was found not to increase the sedative-hypnotic effects of alcohol.¹

1. Frewer LJ, Lader M. The effects of nefazodone, imipramine and placebo, alone and combined with alcohol, in normal subjects. *Int Clin Psychopharmacol* (1993) 8, 13–20.

Alcohol + Niclosamide

Alcohol may possibly increase the adverse effects of niclosamide.

Clinical evidence, mechanism, importance and management

The manufacturer of niclosamide advises avoiding alcohol while taking niclosamide. The reasoning behind this is that while niclosamide is virtually insoluble in water, it is slightly soluble in alcohol, which might possibly increase its absorption by the gut, resulting in an increase in its adverse effects. There are no formal reports of this but the manufacturer says that they have some anecdotal information that is consistent with this suggestion.¹

1. Bayer. Personal communication, July 1992.

Alcohol + Nicotine

Nicotine (as a patch) may possibly enhance the effect of alcohol on heart rate and reduce the time to peak alcohol levels. The concur-

rent use of alcohol and a nicotine nasal spray did not affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 12 otherwise healthy tobacco smokers found that alcohol-induced increases in heart rate were enhanced by pre-treatment with a 21-mg nicotine transdermal patch. The time to peak alcohol levels with a 0.4 g/kg dose of ethanol was faster with nicotine pretreatment (43 minutes compared with 52 minutes, respectively); however, this effect was not seen with a 0.7 g/kg dose of ethanol.¹ Another study in 12 otherwise healthy tobacco smokers found that although alcohol 0.4 or 0.8 g/kg (equivalent to approximately 2 or 4 drinks, respectively) influenced selected subjective responses and heart rate, pre-treatment with alcohol did not affect the subjects responses to low-dose nicotine 3 to 20 micrograms/kg given as a nasal spray (20 microgram/kg dose is equivalent to about one-half of a cigarette). Neither nicotine or alcohol influenced the blood levels of the other.²

Alcohol + Nicotinic acid (Niacin)

An isolated report describes delirium and metabolic acidosis when a patient taking nicotinic acid for hypercholesterolaemia drank about one litre of wine. The manufacturers warn that the concurrent use of nicotinic acid and alcohol may result in an increase in adverse effects such as flushing and pruritus, and possibly liver toxicity.

Clinical evidence, mechanism, importance and management

An isolated report describes delirium and metabolic acidosis after a patient taking nicotinic acid 3 g daily for hypercholesterolaemia drank about one litre of wine. Delirium had occurred on a previous similar occasion after he drank a large quantity of beer while taking nicotinic acid. It is suggested that the nicotinic acid may have caused liver impairment, which was exacerbated by the large amount of alcohol. The patient did have some elevations in liver enzymes.¹ Acidosis has been associated with alcohol intoxication² and there has been a report of lactic acidosis associated with high-dose (3 g daily) nicotinic acid treatment,³ and therefore a combined effect would seem possible. However, no general conclusions can be drawn from this single case.

Hepatic toxicity can occur with nicotinic acid and the manufacturers advise caution in patients who consume substantial quantities of alcohol. They also suggest the avoidance of alcohol around the same time as ingestion of nicotinic acid as the adverse effects of flushing and pruritus may be increased.^{4,5}

5. Niaspan (Nicotinic acid). Kos Pharmaceuticals, Inc. US Prescribing information, April 2007.

Alcohol + Nitrous oxide

In a double-blind study in 11 healthy subjects there were several instances when alcohol 0.25 to 5 g/kg (equivalent to 1 to 3 drinks) enhanced the effects of nitrous oxide 30% in oxygen, inhaled for 35 minutes. Some effects were seen with the drug combination, which were not seen with either drug alone; these included subjective effects and delayed free recall.¹ For mention of the effect of alcohol following anaesthesia, see 'Anaesthetics, general + Alcohol', p.92.

1. Zacny JP, Camarillo VM, Sadeghi P, Black M. Effects of ethanol and nitrous oxide, alone and in combination, on mood, psychomotor performance and pain reports in healthy volunteers. *Drug Alcohol Depend* (1998) 52, 115–23.

Alcohol + NSAIDs

Alcohol may increase the risk of gastrointestinal haemorrhage associated with NSAIDs. The skills related to driving are impaired by indometacin and phenylbutazone and this is made worse if patients drink alcohol while taking phenylbutazone, but this does not appear to occur with indometacin. A few isolated reports attribute acute renal failure to the concurrent use of NSAIDs and acute excessive alcohol consumption.

Clinical evidence, mechanism, importance and management

(a) Gastrointestinal complications

In healthy subjects the concurrent use of alcohol with **ibuprofen** 2.4 g over 24 hours increased the damaging effect of **ibuprofen** on the stomach wall, although this did not reach statistical significance.¹ A case-control study involving 1224 patients admitted to hospital with upper gastrointestinal bleeding and 2945 controls found that alcohol consumption was associated with a threefold increase in the incidence of acute upper gastrointestinal haemorrhage from light drinking (less than one alcoholic drink per week) to heavy drinking (21 alcoholic drinks or more per week). There was some evidence to suggest that the risk of upper gastrointestinal bleeding was increased by the concurrent use of **ibuprofen**.² Another case-control study found that the use of prescription NSAIDs or non-prescription **naproxen** or **ibuprofen** in those with a history of alcohol abuse produced a risk ratio of adverse gastrointestinal effects that was greater than the expected additive risk. Both NSAID use and excessive alcohol consumption carry the risk of gastrointestinal adverse effects. This information suggests that NSAIDs should be used with caution in heavy drinkers.³ The FDA in the US has ruled that non-prescription pain relievers and fever reducers containing **ibuprofen**, **ketoprofen**, or **naproxen** must carry a warning label advising people who consume 3 or more alcoholic drinks every day to consult their doctor before using these drugs, and that stomach bleeding may occur with these drugs.⁴ Consider also 'Alcohol + Aspirin', p.51.

(b) Psychomotor skills and alcohol levels

A study in a large number of healthy subjects showed that the performance of various psychomotor skills related to driving (choice reaction, coordination, divided attention tests) were impaired by single doses of **indometacin** 50 mg or **phenylbutazone** 200 mg. Alcohol 0.5 g/kg made things worse in those taking **phenylbutazone**, but the performance of those taking **indometacin** was improved to some extent.⁵ The reasons are not understood. The study showed that the subjects were subjectively unaware of the adverse effects of **phenylbutazone**. Information is very limited, but patients should be warned if they intend to drive. In two studies, **ibuprofen** 800 mg had no significant effect on blood-alcohol levels of healthy subjects.^{6,7}

The pharmacokinetics of alcohol 1 g/kg and the results of performance tests were found to be similar in subjects given **dipyron** 1 g or a placebo.⁸ No special precautions seem to be necessary.

(c) Renal complications

After taking **ibuprofen** 400 mg the evening before, 400 mg the following morning, and then 375 mL of **rum** later in the day, followed by two further 400-mg tablets of **ibuprofen**, a normal healthy young woman with no history of renal disease developed acute renal failure.⁹ Another similar case was reported in a 22-year-old woman who had taken **ibuprofen** 1.2 g the morning after binge drinking.¹⁰ Both recovered.^{9,10} A further case describes renal impairment in a young woman, which was associated with the use of **ketoprofen** 600 mg and binge drinking.¹¹ It is suggested that volume depletion caused by the alcohol (and compounded by vomiting) predisposed these patients to NSAID-induced renal toxicity.^{10,11} The general importance of these isolated cases remains to be determined.

Alcohol + Olanzapine

Postural hypotension and possibly drowsiness may be increased when alcohol is given with olanzapine.

Clinical evidence, mechanism, importance and management

The manufacturer says that patients taking olanzapine have shown an increased heart rate and accentuated postural hypotension when given a single-dose of alcohol.¹ In a study, 9 of 11 subjects experienced orthostatic hypotension when they drank alcohol one hour after taking olanzapine 10 mg.² No pharmacokinetic interaction has been seen.^{1–3} In practical terms this means that patients should be warned of the risk of faintness and dizziness if they stand up quickly. The manufacturers also say that drowsiness is a common adverse effect of olanzapine, and they warn about taking other products that can cause CNS depression, including alcohol.^{3,4} The US manufacturer³ says that patients should not drink alcohol with olanzapine because of the potential drowsiness that would result.

Alcohol + Opioids

In general the opioid analgesics can enhance the CNS depressant effects of alcohol, which has been fatal in some cases: this appears to be a particular problem with dextropropoxyphene. Alcohol has been associated with rapid release of hydromorphone and morphine from extended-release preparations, which could result in potentially fatal doses. Acute administration of alcohol and methadone appears to increase the blood levels of methadone. The bioavailability of dextropropoxyphene is increased by alcohol.

Clinical evidence

(a) Buprenorphine

See under *methadone*, below.

(b) Codeine

Double-blind studies in a large number of professional army drivers found that 50 mg of codeine and alcohol 0.5 g/kg, both alone and together, impaired their ability to drive safely on a static driving simulator. The number of 'collisions', neglected instructions and the times they 'drove off the road' were increased.^{1,2} Alcohol does not appear to affect the pharmacokinetics of codeine.³ See also, *controlled-release opioids*, below.

(c) Dextropropoxyphene

In a study in 8 healthy subjects, alcohol alone (blood levels of 50 mg%) impaired the performance of various psychomotor tests (motor co-ordination, mental performance and stability of stance) more than dextropropoxyphene 65 mg alone. When given together there was some evidence that the effects were greater than with either drug alone, but in some instances the impairment was no greater than with just alcohol. The effect of alcohol clearly predominated.⁴ In contrast, other studies have found that dextropropoxyphene does not enhance the psychomotor impairment seen with

alcohol,^{5,6} but the bioavailability of the dextropropoxyphene has been reported to be raised by 25 to 31% by alcohol.^{6,7} A retrospective study involving 332 fatal poisonings in Finland found that alcohol was present in 73% of cases involving dextropropoxyphene and, when alcohol was present, relatively small overdoses of dextropropoxyphene could result in fatal poisoning.⁸ Further reports describe alcohol reducing the lethal dose of dextropropoxyphene.^{9–11}

(d) Hydromorphone

A young man died from the combined cardiovascular and respiratory depressant effects of hydromorphone and alcohol.¹² He fell asleep, the serious nature of which was not recognised by those around him. Post-mortem analysis revealed alcohol and hydromorphone concentrations of 90 mg% and 100 nanograms/mL, respectively, neither of which is particularly excessive. A study in 9 healthy subjects found that pre-treatment with hydromorphone 1 or 2 mg did not significantly affect the subject-rated effects of alcohol 0.5 or 1 g/kg. However, hydromorphone enhanced the sedative scores of alcohol on the adjective rating scale.¹³ See also, *controlled-release opioids*, below.

(e) Methadone

A study in 21 opioid-dependent subjects who had been receiving maintenance methadone or buprenorphine for 3 months, and 21 matched non-drug-using controls, found that although alcohol (target blood-alcohol level around 50 mg%) resulted in decreased driving performance, there appeared to be no difference in simulated driving tests in the opioid-treated patients, when compared with controls. It was suggested that restrictions on opioids and driving are not necessary in stabilised patients receiving maintenance buprenorphine or methadone treatment, but little is known about the effects in the initial treatment period.¹⁴ This study also found that blood-alcohol levels were lower in the opioid-treated patients when compared with the controls despite receiving the same amount of alcohol.

However, clinical anecdotal reports have indicated that co-ingestion of alcohol and methadone produces an additive and/or synergistic response,¹⁵ which may result in serious respiratory depression and hypotension.¹⁶

(f) Controlled-release opioids

Pharmacokinetic data in healthy subjects has shown that consuming alcohol with a particular 24-hour extended-release formulation of **hydromorphone** (*Palladone XL Capsules*; *Purdue Pharma, USA*) could lead to rapid release (dose dumping) and absorption of a potentially fatal dose of hydromorphone.^{17,18} Although no reports of serious problems had been received, the FDA in the US asked for the product to be withdrawn from the market.¹⁹ Health Canada warned that this interaction might occur with other slow-release opioid painkillers.²⁰ However, the Canadian distributor of hydromorphone has commented that the controlled-release technology employed in *Palladone XL* is not the same as that of many other controlled-release opioid formulations. Dose-dumping with alcohol is said not to occur with:

- **morphine** sustained-release tablets: *MS Contin*,^{21,22} *MST continus* suspension and tablets, *MXL* capsules,²²
- **codeine** controlled-release tablets: *Codeine Contin*,^{21,22}
- **dihydrocodeine** controlled-release tablets: *DHC Continus* tablets,²²
- **hydromorphone** controlled-release capsules: *Hydromorph Contin*,²¹ *Palladone SR*,²²
- **oxycodone** controlled-release tablets: *OxyContin*,^{21,22}
- or **tramadol** (once daily and twice daily formulations).²²

In contrast, in laboratory studies, an extended-release capsule preparation of **morphine** (*Avinza*; *Ligand Pharmaceuticals, USA*) was found to release morphine earlier than expected when exposed to alcohol, and this effect increased dramatically with increasing alcohol concentration.^{23,24} The product literature for *Avinza* now carries a warning to avoid alcohol, including medications containing alcohol, while taking this preparation.²⁴

Although most opioid preparations do not appear to interact with alcohol in this way, co-ingestion of alcohol and opioid analgesics is never advisable because of the potential for an interaction between CNS depressant drugs, see above.

Mechanism

Both opioids and alcohol are CNS depressants, and there may be enhanced suppression of the medullary respiratory control centre.^{9–11} Acute administration of alcohol appears to increase methadone effects due to inhibition

of hepatic microsomal enzymes, but chronic alcoholism reduces the AUC and half-life of methadone because of induction of cytochrome P450 isoenzymes.¹⁵

Importance and management

The fatality and increased sedation emphasise the importance of warning patients about the potentially hazardous consequences of drinking while taking potent CNS depressants like the opioids. This seems to be a particular risk with dextropropoxyphene overdosage, and it has been suggested that a less dangerous alternative could be chosen when indications of alcohol abuse or suicide risk are present.²⁵ The US manufacturers recommend caution when prescribing dextropropoxyphene in patients who use alcohol in excess.²⁶ There is less information about therapeutic doses of dextropropoxyphene with moderate social drinking. In general it is suggested that alcohol intake should be avoided where possible, or limited in those taking opioids, but some manufacturers actually contraindicate alcohol. The objective evidence is that the interaction with moderate doses of alcohol and opioids is quite small (with the exception of the dose dumping effect). It would seem prudent to warn patients that opioids can cause drowsiness and this may be exaggerated to some extent by alcohol. They should be warned that driving or handling potentially hazardous machinery may be more risky, but total abstinence from alcohol does not seem to be necessary. Smaller doses, such as those available without a prescription, would be expected to have a smaller effect, but this does not appear to have been studied.

Alcohol + Orlistat

A study in healthy subjects found that orlistat 120 mg three times daily for 6 days had no significant effect on the pharmacokinetics of alcohol.¹ There is nothing to suggest that alcohol should be avoided while taking orlistat.

Alcohol + Paracetamol (Acetaminophen)

Many case reports describe severe liver damage, sometimes fatal, in some alcoholics and persistent heavy drinkers who take only moderate doses of paracetamol. However, other controlled studies have found no association between alcoholism and paracetamol-induced hepatotoxicity. There is controversy about the use of paracetamol in alcoholics. Some consider standard therapeutic doses can be used, whereas others recommend the dose of paracetamol should be reduced, or paracetamol avoided. Occasional and light to moderate drinkers do not seem to be at any extra risk. One study found that chronic alcohol intake, but not acute alcohol intake, enhanced paracetamol hepatotoxicity following overdose.

Clinical evidence

(a) Increased hepatotoxicity

Three chronic alcoholic patients developed severe liver damage after taking paracetamol. They had AST levels of about 7 000 to 10 000 units. Two of them had taken 10 g of paracetamol over 24 or 48 hours before admission (normal dosage is up to 4 g daily), and the third patient had taken about 50 g of paracetamol over 72 hours. One of them developed hepatic encephalopathy and died, and subsequent post-mortem revealed typical paracetamol toxicity. Two of them also developed renal failure.¹ A case of severe liver impairment has also been reported in a moderate social drinker who regularly drank 3 glasses of wine with dinner, but had stopped drinking alcohol whilst taking paracetamol for a viral infection.²

There are numerous other case reports of liver toxicity in alcoholics or chronic heavy alcohol users attributed to the concurrent use of alcohol and paracetamol. In the reports cited here, which include a total of about 30 patients, about one-third had been taking daily paracetamol doses of up to 4 g daily, and one-third had taken doses within the range 4 to 8 g daily.^{3–19} Fasting possibly makes things worse.²⁰ A later survey reviewed a total of 94 cases from the literature, and described a further 67 patients who were regular users of alcohol, 64% of whom were alcoholics, who developed liver toxicity after taking paracetamol. In 60% of cases the paracetamol dose did not exceed 6 g daily and in 40% of cases the dose did not exceed 4 g daily. More than 90% of the patients developed AST levels ranging from 3 000 to 48 000 units.²¹ A study of 209 consecutive cases of paracetamol overdose admitted to a liver unit in Denmark (57 identified as chronic alcohol intake and 45 as acute alcohol intake), found that chronic alcohol intake enhanced paracetamol hepatotoxicity. The relative risks for hepatic encephalopathy and death were 5.3 and 1.4, respectively, in the chronic alcohol intake group, compared with the non-chronic alcohol intake group, when adjusted for factors such as the total quantity of paracetamol ingested and the time to treatment with N-acetylcysteine. Acute alcohol intake did not affect the clinical course of paracetamol overdose.²²

(b) No effect on hepatotoxicity

In a retrospective review of 553 cases of paracetamol-induced severe hepatotoxicity treated at a liver failure unit over a 7-year period, there was no association between the level of alcohol consumption and the severity of the hepatotoxicity (mean INR and serum creatinine levels in the first 7 days after overdose). Alcohol consumption was categorised into 4 groups ranging from non-drinkers to heavy drinkers (greater than 60 g of alcohol daily in men and 40 g daily in women).²³

In a randomised, placebo-controlled study, there was no difference in measures of hepatotoxicity (mean AST levels, mean INR) between 102 alcoholic patients who received paracetamol 1 g four times daily for 2 days, and 99 alcoholic patients who received placebo. In this study, patients had entered an alcohol detoxification centre, and were given paracetamol im-

mediately after stopping alcohol use²⁴ (the assumed time of greatest susceptibility, see Mechanism, below). A systematic review by the same research group concluded that the use of therapeutic doses of paracetamol in alcoholic patients is not associated with hepatic injury.²⁵

(c) Effect on alcohol levels

Paracetamol 1 g was found to have no effect on the single-dose pharmacokinetics of alcohol in 12 healthy subjects.²⁶ Another study found that blood-alcohol levels were raised by 1 g of paracetamol but this was not statistically significant.²⁷

Mechanism

Uncertain. The paracetamol-alcohol interaction is complex, because acute and chronic alcohol consumption can have opposite effects.^{28,29} Paracetamol is usually predominantly metabolised by the liver to non-toxic sulfate and glucuronide conjugates. Persistent heavy drinking appears to stimulate a normally minor biochemical pathway involving the cytochrome P450 isoenzyme CYP2E1, and possibly CYP3A, which allows the production of unusually large amounts of highly hepatotoxic metabolites via oxidation.^{20,29,30} Unless sufficient glutathione is present to detoxify these metabolites (alcoholics often have an inadequate intake of protein), they become covalently bound to liver macromolecules and damage results. Fasting may also make things worse by reducing the availability of glucose, and thus shifting paracetamol metabolism from glucuronidation towards microsomal oxidation.²⁰ However, most studies have failed to demonstrate an increase in hepatotoxic metabolites in alcoholics.^{28,31} In fact alcoholics may possibly be most susceptible to toxicity during alcohol withdrawal because, while drinking, alcohol may possibly compete with the paracetamol for metabolism, and even inhibit it. Acute ingestion of alcohol by non-alcoholics may possibly protect them against damage because the damaging biochemical pathway is inhibited rather than stimulated. The relative timing of alcohol and paracetamol intake is therefore critical.²⁸

Importance and management

The incidence of unexpected paracetamol toxicity in chronic alcoholics is uncertain, but possibly fairly small, bearing in mind the very wide-spread use of paracetamol and alcohol. Note that most of the evidence for an interaction comes from anecdotal case reports and case series, albeit in large numbers. However, the damage, when it occurs, can be serious and therefore some have advised that alcoholics and those who persistently drink heavily should avoid paracetamol or limit their intake considerably.²¹ The normal daily recommended 'safe' maximum of 4 g is said to be too high in some alcoholics.²¹ Because of this, the FDA in the US have required that all paracetamol-containing non-prescription products bear the warning that those consuming 3 or more alcoholic drinks every day should ask their doctor whether they should take paracetamol.³² However, others consider that the evidence does not prove that there is an increase in paracetamol hepatotoxicity in alcoholics,^{25,28} and is insufficient to support any change in paracetamol use or dose in alcoholics.^{25,33} They note that the alternatives, aspirin and NSAIDs, are associated with a greater risk of gastrointestinal adverse effects in alcoholics,²⁵ see 'Alcohol + Aspirin', p.51 and 'Alcohol + NSAIDs', p.71. Further study is needed. The risk for non-alcoholics, moderate drinkers and those who very occasionally drink a lot appears to be low, although some chronic moderate social drinkers may be at risk, especially if alcohol intake is abruptly stopped.³⁴

It is still prudent to consider patients who are alcoholics as being at high risk of hepatotoxicity after a paracetamol overdose, and to treat them with acetylcysteine.^{28,30} Some workers have questioned the use of a lower plasma-paracetamol concentration threshold for the treatment of paracetamol poisoning in alcoholics,³¹ but most advocate treatment at the lower threshold.^{28,30} Possible malnutrition and fasting in these patients would further support the need for such treatment.³⁰

Alcohol + Paraldehyde

Both alcohol and paraldehyde have CNS depressant effects, which can be additive. The use of paraldehyde in the treatment of acute alcohol intoxication has caused fatalities.

Clinical evidence, mechanism, importance and management

A report describes 9 patients who died suddenly and unexpectedly after treatment for acute alcohol intoxication with 30 to 90 mL of paraldehyde (the authors quote a normal dose range of 8 to 30 mL; fatal dose 120 mL or more, usually preceded by coma). None of the patients had hepatic impairment, although one did have some fatty changes.¹ Both drugs are CNS depressants and may therefore be expected to have additive effects at any dosage, although an *animal* study suggested that it might be less than additive,² and cross-tolerance may occur as paraldehyde is pharmacologically similar to alcohol.³

Alcohol + Phosphodiesterase type-5 inhibitors

Sildenafil, tadalafil and vardenafil do not usually alter the effects of alcohol on blood pressure, although postural hypotension has been seen in some subjects given tadalafil and alcohol, and headache and flushing has been reported in one patient taking sildenafil.

fil and alcohol. Alcohol does not affect the pharmacokinetics of tadalafil or vardenafil.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

Sildenafil 50 mg did not potentiate the hypotensive effect of alcohol (mean maximum blood-alcohol levels of 80 mg%) in healthy subjects.^{1,2} A study in 8 healthy subjects also found that sildenafil 100 mg did not affect the haemodynamic effects of red wine (e.g. heart rate, mean arterial pressure).³ However, a case report describes potentiation of the adverse effects of sildenafil when alcohol was consumed within one hour of taking the drug. A 36-year-old hypertensive patient receiving regular treatment with a calcium-channel blocker (amlodipine) was additionally prescribed sildenafil 25 mg, which he used 3 times a week without any adverse effects. However, after having 2 drinks of whiskey (55.2 g of alcohol) he experienced severe headache and flushing about 15 minutes after taking sildenafil. The next day he took sildenafil 25 mg without any alcohol and no symptoms developed, but one week later, a challenge dose of sildenafil was given after a single 30-mL drink of whiskey and similar symptoms of severe headache and flushing occurred.⁴ The UK patient information leaflet says that drinking alcohol can temporarily impair the ability to get an erection and advises patients not to drink large amounts of alcohol before taking sildenafil.⁵

(b) Tadalafil

Studies in subjects given alcohol 0.6 or 0.7 g/kg found that the effect of alcohol on blood pressure was unchanged by tadalafil 20 mg, although some subjects experienced dizziness and postural hypotension. In addition, the effects of alcohol on cognitive function were unchanged by tadalafil 10 mg.⁶ The pharmacokinetics of tadalafil 10 or 20 mg and alcohol were also unaffected by concurrent use.^{6,7} However, the manufacturers say that because both alcohol and tadalafil can cause peripheral vasodilation, additive blood pressure lowering effects are possible,^{7,8} especially with substantial amounts of alcohol (5 units) and the US manufacturer states that this may result in postural hypotension, increased heart rate, dizziness and headache.⁷ Alcohol may also affect the ability to have an erection.⁸

(c) Vardenafil

Alcohol (mean blood level of 73 mg%) did not affect the pharmacokinetics of vardenafil 20 mg.⁹ The effects of alcohol on heart rate and blood pressure were also not affected by vardenafil.^{9,10} There would therefore seem to be no need to avoid the combination. However, alcoholic drink can worsen erection difficulties.¹¹

Alcohol + Procaïnamide

Alcohol may modestly increase the clearance of procaïnamide.

Clinical evidence, mechanism, importance and management

In 11 healthy subjects alcohol 0.73 g/kg, followed by alcohol 0.11 g/kg every hour increased the clearance and decreased the elimination half-life of a single 10-mg/kg oral dose of procaïnamide by 34% and 25%, respec-

tively. This was due to increased acetylation of procaïnamide to its active metabolite *N*-acetylprocaïnamide.¹ The clinical relevance of these modest changes is probably small.

1. Olsen H, Mørland J. Ethanol-induced increase in procaïnamide acetylation in man. *Br J Clin Pharmacol* (1982) 13, 203–8.

Alcohol + Procarbazine

A flushing reaction has been seen in patients taking procarbazine who drank alcohol.

Clinical evidence

One report describes 5 patients taking procarbazine whose faces became very red and hot for a short time after drinking wine.¹ Another says that flushing occurred in 3 patients taking procarbazine after they drank beer.² Two out of 40 patients taking procarbazine in a third study complained of facial flushing after taking a small alcoholic drink, and one patient thought that the effects of alcohol were markedly increased.³ Yet another study describes a 'flush syndrome' in 3 out of 50 patients who drank alcohol while taking procarbazine.⁴

Mechanism

Unknown, but it seems possible that in man, as in *rats*,⁵ the procarbazine inhibits acetaldehyde dehydrogenase in the liver causing a disulfiram-like reaction (see 'Alcohol + Disulfiram', p.61).

Importance and management

An established interaction but of uncertain incidence. It seems to be more embarrassing, possibly frightening, than serious and if it occurs it is unlikely to require treatment, however patients should be warned. The manufacturers say it is best to avoid alcohol.⁶ Procarbazine is also a weak MAOI and therefore interactions with certain foodstuffs, including alcoholic drinks, especially heavy red wines, although very rare, must be borne in mind (see 'Procarbazine + Sympathomimetics', p.657).

Alcohol + Proton pump inhibitors

Lansoprazole, omeprazole and pantoprazole do not interact with alcohol: other proton pump inhibitors therefore seem unlikely to interact.

Clinical evidence

(a) Lansoprazole

A study in 30 healthy subjects given 0.6 g/kg of alcohol before and after taking lansoprazole 30 mg daily for 3 days found that the pharmacokinetics of alcohol were not significantly changed, and blood-alcohol levels were not raised, by lansoprazole.¹

(b) Omeprazole

A number of studies have shown that omeprazole does not affect blood alcohol levels.^{2–6}

(c) Pantoprazole

Pantoprazole 40 mg daily or placebo were given to 16 healthy subjects for 7 days. On day 7 they were also given alcohol 0.5 g/kg in 200 mL of or-

ange juice 2 hours after a standard breakfast. The maximum serum levels and the AUC of alcohol were not significantly changed by pantoprazole.⁷

Mechanism

The proton pump inhibitors do not affect alcohol dehydrogenase activity^{3,8} (compare with the 'H₂-receptor antagonists', (p.64)), and would not be expected to alter the first-pass metabolism of alcohol.

Importance and management

The proton pump inhibitors do not appear to interact with alcohol, and no special precautions are necessary with concurrent use. But note that some of the conditions for which these drugs are used may be made worse by alcohol, so restriction of drinking of alcohol may be prudent.

Alcohol + Quetiapine

Postural hypotension and possibly drowsiness may be increased when alcohol is given with quetiapine. Quetiapine does not appear to affect the pharmacokinetics of alcohol.

Clinical evidence, mechanism, importance and management

A randomised, crossover study in 8 men with psychotic disorders found that quetiapine 250 mg three times daily did not affect the mean breath-alcohol concentration after they took 0.8 g/kg of alcohol in orange juice. Some statistically significant changes in the performance of psychomotor tests were seen, but these were considered to have little clinical relevance. However, the US manufacturers of quetiapine say that, in clinical studies, the motor and cognitive effects of alcohol were potentiated by quetiapine. Therefore the US manufacturers of quetiapine¹ advise avoiding alcohol, and the UK manufacturers² advise caution with the concurrent use of alcohol.³ Note that drowsiness is the most common adverse effect of quetiapine, occurring in over 10% of patients.^{1,2} Quetiapine may occasionally induce postural hypotension,^{1,2} which could be exacerbated by alcohol administration.

2. Seroquel (Quetiapine fumarate). AstraZeneca UK Ltd. UK Summary of product characteristics, November 2006.
3. Zeneca Pharma. Personal communication, October 1997.

Alcohol + Reboxetine

A study in 10 healthy subjects found that reboxetine does not affect cognitive or psychomotor function, and there is no interaction with alcohol.¹

1. Kerr JS, Powell J, Hindmarch I. The effects of reboxetine and amitriptyline, with and without alcohol on cognitive function and psychomotor performance. *Br J Clin Pharmacol* (1996) 42, 239–41.

Alcohol + Retinoids

There is evidence that the consumption of alcohol may increase the serum levels of etretinate in patients taking acitretin. A single case report describes a marked reduction in the effects of isotretinoin following the acute intake of alcohol.

Clinical evidence, mechanism, importance and management

(a) Acitretin

A study in 10 patients with psoriasis taking acitretin found that the concurrent use of alcohol seemed to be associated with an increase in the formation of its metabolite etretinate, which has a much longer half-life than acitretin. The implications of this study are not known, but it is suggested that it may have some bearing on the length of the period after acitretin therapy during which women are advised not to conceive.¹

(b) Isotretinoin

A former alcoholic, who no longer drank alcohol, was treated for acne conglobata, with some success, with isotretinoin 60 mg daily for 3 months. When for 2 weeks he briefly started to drink alcohol again as part of his job (he was a sherry taster) his skin lesions reappeared and the isotretinoin adverse effects (mucocutaneous dryness) vanished. When he stopped drinking alcohol his skin lesions became controlled again and the drug adverse effects re-emerged. The following year, while receiving another course of isotretinoin, the same thing happened when he started and stopped drinking alcohol. The reasons are not known, but one suggestion is that the alcohol briefly induced the liver microsomal enzymes responsible for the metabolism of isotretinoin, thereby reducing both its therapeutic and adverse effects.² The general importance of this apparent interaction is not known.

Alcohol + Salbutamol (Albuterol)

A patient with high blood-alcohol levels developed lactic acidosis after being exposed to smoke and receiving salbutamol.

Clinical evidence, mechanism, importance and management

An isolated report describes a 49-year-old male alcoholic who developed severe lactic acidosis after exposure to fire smoke and treatment of bronchospasm with salbutamol. The correction of lactic acidosis followed salbutamol withdrawal and a transitory increase in lactate after salbutamol re-introduction suggested hypersensitivity to salbutamol. However, the patient also had a very high plasma-alcohol level (240 mg%), and the metabolism of the alcohol was thought to have competed with the conversion of lactate to pyruvate resulting in reduced lactate clearance, thus potentiating the acidosis caused by the salbutamol.¹ The clinical significance of this report is unclear as beta agonist-induced exacerbation of lactic acidosis has been reported in asthmatics, both adults and children. The authors of the above report suggest close monitoring of lactate levels in alcoholic patients receiving beta-agonists.¹

1. Taboulet P, Clemessy J-L, Fréminet A, Baud FJ. A case of life-threatening lactic acidosis after smoke inhalation – interference between β-adrenergic agents and ethanol? *Intensive Care Med* (1995) 21, 1039–42.

Alcohol + Sibutramine

There does not seem to be a clinically relevant interaction between sibutramine and alcohol.

Clinical evidence, mechanism, importance and management

In a randomised study, 20 healthy subjects were given sibutramine 20 mg with 0.5 g/kg of alcohol diluted in ginger beer, or placebo. Sibutramine did not potentiate the cognitive or psychomotor effects of alcohol, and in one test, sibutramine slightly reduced the impairment caused by alcohol.¹

However, the manufacturer notes that the consumption of alcohol is generally not compatible with recommended adjuvant dietary modification.²

Alcohol + SNRIs

No important psychomotor interaction normally appears to occur between duloxetine or venlafaxine and alcohol. However, the manufacturer warns that use of duloxetine with heavy alcohol intake may be associated with severe liver injury.

Clinical evidence, mechanism, importance and management

(a) Duloxetine

In a single-dose study in healthy subjects, duloxetine 60 mg, and alcohol given in a dose sufficient to produce blood levels of about 100 mg%, did not worsen the psychomotor impairment observed with alcohol alone.¹ Nevertheless, the UK manufacturer advises caution,² and the US manufacturer warns that duloxetine should ordinarily not be prescribed for patients with substantial alcohol use as severe liver injury may result.³

(b) Venlafaxine

Venlafaxine 50 mg every 8 hours was found to have some effect on psychomotor tests (digit symbol substitution, divided attention reaction times, profile of mood scales) in 15 healthy subjects, but these changes were small and not considered to be clinically significant. No pharmacodynamic or pharmacokinetic interactions occurred when alcohol 0.5 g/kg was also given.⁴

In therapeutic doses venlafaxine does not appear to interact significantly with alcohol, however, the manufacturers state that, as with all centrally-active drugs, patients should be advised to avoid alcohol whilst taking venlafaxine.^{5,6} This is presumably because both drugs act on the CNS and also because alcohol is more likely to be abused by depressed patients.

Alcohol + Sodium cromoglicate (Cromolyn sodium)

No adverse interaction occurs between sodium cromoglicate and alcohol.

Clinical evidence, mechanism, importance and management

A double-blind, crossover study in 17 healthy subjects found that the inhalation of 40 mg of sodium cromoglicate had little or no effect on the performance of a number of tests on human perceptual, cognitive, and motor skills, whether taken alone or with alcohol 0.75 g/kg. Nor did it affect blood-alcohol levels.¹ This is in line with the common experience of patients, and no special precautions seem to be necessary.

1. Crawford WA, Franks HM, Hensley VR, Hensley WJ, Starmer GA, Teo RKC. The effect of disodium cromoglycate on human performance, alone and in combination with ethanol. *Med J Aust* (1976) 1, 997–9.

Alcohol + SSRIs

Citalopram, escitalopram, fluoxetine, paroxetine and sertraline have no significant pharmacokinetic interaction with alcohol, but

some modest increase in sedation may possibly occur with fluvoxamine and paroxetine.

Clinical evidence and mechanism

(a) Citalopram

The manufacturers of citalopram say that no pharmacodynamic interactions have been noted in clinical studies in which citalopram was given with alcohol.^{1,2}

(b) Escitalopram

The manufacturers of escitalopram say that no pharmacokinetic or pharmacodynamic interactions are expected to occur with concurrent use of alcohol and escitalopram.³

(c) Fluoxetine

The concurrent use of fluoxetine 30 to 60 mg and alcohol (4 oz of whiskey) did not affect the pharmacokinetics of either drugs in healthy subjects, and fluoxetine did not alter the effect of alcohol on psychomotor activity (stability of stance, motor performance, manual co-ordination).⁴ Similarly, blood-alcohol levels of 80 mg% impaired the performance of a number of psychomotor tests in 12 healthy subjects, but the addition of fluoxetine 40 mg daily taken for 6 days before the alcohol had little further effect.⁵ Another study also found no change in the performance of a number of psychophysiological tests when fluoxetine was combined with alcohol.⁶ No problems were found in a study of 20 alcohol-dependent patients taking fluoxetine 60 mg daily when they drank alcohol, or in approximately 31 patients taking fluoxetine 20 mg daily who drank unspecified small quantities of alcohol.⁷

(d) Fluvoxamine

One study found that fluvoxamine 150 mg daily with alcohol impaired alertness and attention more than alcohol alone,⁸ whereas another study in subjects given 40 g of alcohol (blood-alcohol levels up to 70 mg%) found no evidence to suggest that the addition of fluvoxamine 50 mg twice daily worsened the performance of the psychomotor tests, and it even appeared to reverse some of the effects.⁹ The pharmacokinetics of alcohol were hardly affected by fluvoxamine, but the steady state maximum plasma levels of the fluvoxamine were increased by 20%, although the fluvoxamine AUC was unchanged.⁹ It was suggested that administration of alcohol may have promoted dissolution of fluvoxamine and increased the absorption rate without affecting bioavailability.⁹ Another study also found that fluvoxamine does not appear to enhance the detrimental effects of alcohol on the performance of psychomotor tests.¹⁰

(e) Paroxetine

Studies have found that paroxetine alone caused little impairment of a series of psychomotor tests related to car driving, and with alcohol the effects were unchanged, except for a significant decrease in attentiveness and an increase in reaction time.^{11,12} Another study suggested that the alcohol-induced sedation was antagonised by paroxetine.¹³

(f) Sertraline

Sertraline (in doses of up to 200 mg for 9 days) was found not to impair cognitive or psychomotor performance, and it also appeared not to increase the effects of alcohol.¹⁴

Importance and management

The results of the few studies reported above suggest that no pharmacokinetic or pharmacodynamic interactions occur with most SSRIs and alcohol, although modest effects were seen with fluvoxamine and possibly paroxetine. However, most manufacturers of SSRIs suggest that concurrent use with alcohol is not advisable. This is presumably because both drugs act on the CNS and also because of the risk of alcohol abuse in depressed patients.¹⁵

Alcohol + Sulfiram

Disulfiram-like reactions have been seen in at least three patients who drank alcohol after using a solution of sulfiram on the skin for the treatment of scabies.

Clinical evidence

A man who used undiluted *Tetmosol* (a solution of sulfiram) for 3 days on the skin all over his body developed a disulfiram-like reaction (flushing, sweating, skin swelling, severe tachycardia and nausea) on the third day, after drinking 3 double whiskies. The same thing happened on two subsequent evenings again after drinking 3 double whiskies.¹ Similar reactions have been described in 2 other patients who drank alcohol while using *Tetmosol* or *Ascabiol* (also containing sulfiram).^{2,3}

Mechanism

Sulfiram (tetraethylthiuram *monosulphide*) is closely related to disulfiram (tetraethylthiuram *disulphide*) and can apparently undergo photochemical conversion to disulfiram when exposed to light. The longer it is stored, the higher the concentration.^{4,5} The reaction with alcohol appears therefore to be largely due to the presence of disulfiram,⁶ see 'Alcohol + Disulfiram', p.61.

Importance and management

An established interaction. The manufacturers of sulfiram preparations and others advise abstinence from alcohol before, and for at least 48 hours after application, but this may not always be necessary. The writer of a letter,⁷ commenting on one of the cases cited,¹ wrote that he had never encountered this reaction when using a diluted solution of *Tetmosol* on patients at the Dreadnought Seamen's Hospital in London who he described as "not necessarily abstemious". This would suggest that the reaction is normally uncommon and unlikely to occur if the solution is correctly diluted (usually with 2 to 3 parts of water), thereby reducing the amount absorbed through the skin. However, one unusually sensitive patient is said to have had a reaction (flushing, sweating, tachycardia) after using diluted *Tetmosol*, but without drinking alcohol. It was suggested that she reacted to the alcohol base of the formulation passing through her skin.⁸

Alcohol + Sumatriptan

Alcohol does not alter the pharmacokinetics of sumatriptan.

Clinical evidence, mechanism, importance and management

A single 0.8-g/kg dose of alcohol was given to 16 healthy subjects, followed 30 minutes later by 200 mg of sumatriptan. No statistically significant changes were seen in the pharmacokinetics of sumatriptan.¹ There is nothing to suggest that alcohol should be avoided while taking sumatriptan.

- Kempsford RD, Lacey LF, Thomas M, Fowler PA. The effect of alcohol on the pharmacokinetic profile of oral sumatriptan. *Fundam Clin Pharmacol* (1991) 5, 470.

Alcohol + Tacrolimus or Pimecrolimus

Alcohol may cause facial flushing or skin erythema in patients being treated with tacrolimus ointment; this reaction appears to be fairly common. Alcohol intolerance has been reported rarely with pimecrolimus cream.

Clinical evidence

Six patients reported facial flushing with small quantities of beer or wine during facial treatment with tacrolimus ointment. Re-exposure to tacrolimus 0.1% ointment, applied to the face twice daily for 4 days, followed by 100 mL of white wine on the fifth day, resulted in a facial flush reaction in all the patients, which occurred within 5 to 15 minutes of alcohol ingestion. The intensity of the erythema varied among the patients and was not confined to the treated areas, but started to fade after 30 minutes; a slight headache occurred in one patient. Forearm skin was also exposed to an epicutaneous patch containing 70 mg of tacrolimus 0.1% ointment, but these sites remained unchanged following alcohol exposure. After a tacrolimus washout period of at least 4 weeks, controlled exposure to alcohol in 2 patients was tolerated normally.¹ Another report describes one patient using tacrolimus ointment for mild eyelid eczema who experienced eyelid erythema, limited to the area the tacrolimus ointment was applied, after wine ingestion. Two other patients experienced an erythematous rash after alcohol when using topical tacrolimus; areas affected included the elbows, ears, eyes and face. The response to alcohol disappeared within 2 weeks of discontinuing tacrolimus ointment.²

Three patients experienced application site erythema following the consumption of alcohol after using topical tacrolimus or pimecrolimus for the treatment of facial dermatoses. Two of the patients then participated in a double-blind, controlled evaluation of the reaction. Both patients consumed alcohol (240 mL of red or white wine) without experiencing flushing, but following tacrolimus or pimecrolimus application, they experienced moderate or severe facial flushing (limited to the area of application) 5 to 10 minutes after alcohol consumption. The intensity of the erythema was sharply reduced after taking aspirin 325 mg twice daily for 3 days before alcohol consumption, but cetirizine 10 mg daily with cimetidine 400 mg twice daily for 3 days appeared to have little effect.³

There are other reports of this interaction between tacrolimus and alcohol.³⁻⁷ The reaction is usually confined to the face and the intensity may be related to the amount of alcohol ingested.⁴ In an open study of 316 patients, alcohol intolerance (facial flushing) was observed in 19% of the patients using tacrolimus 0.1% ointment⁶ and in a controlled study, 6.9% of patients experienced the reaction with tacrolimus 0.1% ointment, and 3.4% of patients experienced the reaction with tacrolimus 0.03% ointment.⁵

Mechanism

The mechanism of this interaction is not understood. It has been proposed that tacrolimus may act on the same biochemical pathway as alcohol potentiating a capsaicin-mediated release of neuropeptides, which increase vasodilatory effects. Alternatively, cutaneous aldehyde dehydrogenase inhibition in areas where tacrolimus has been applied may increase cutaneous aldehyde levels that, through prostaglandins as mediators, could lead to vasodilation following alcohol consumption.^{1,4}

Importance and management

The interaction between topical tacrolimus and alcohol is established and appears to occur in about 6 to 7% of patients treated with tacrolimus 0.1% ointment. Patients should be warned of the possibility of a flushing reaction with alcohol and that consumption of alcohol may need to be avoided if this occurs. Clinicians should be aware of the interaction and obtain a careful history, including alcohol use, in patients who present with new acute symptoms while using tacrolimus. It has been suggested that aspirin may possibly reduce the symptoms of this reaction,³ but this needs further study. Alcohol intolerance with pimecrolimus has been reported,^{3,8} but appears to be rare.⁹

Alcohol + Tetracyclic antidepressants

Mianserin and maprotiline can cause drowsiness and impair the ability to drive or handle other dangerous machinery, particularly during the first few days of treatment. This impairment may be increased by alcohol. Pirlindole does not appear to interact with alcohol.

Clinical evidence

(a) Maprotiline

A double-blind, crossover study in 12 healthy subjects found that a single 75-mg oral dose of maprotiline subjectively caused drowsiness, which was increased by 1 g/kg of alcohol. The performance of a number of psychomotor tests was also worsened after the addition of alcohol.¹ However, in a later study the same group found that maprotiline 50 mg twice daily, for 15 days, did not increase the detrimental effects of alcohol.²

(b) Mianserin

A double-blind, crossover study in 13 healthy subjects given 10 to 30 mg of mianserin twice daily for 8 days, with and without alcohol 1 g/kg, found that their performance in a number of psychomotor tests (choice reaction, coordination, critical flicker frequency) were impaired both by mianserin alone and by concurrent use with alcohol. The subjects were aware of feeling drowsy, muzzy, and less able to carry out the tests.³ These results confirm the findings of other studies.^{4,5}

(c) Pirlindole

A study in healthy subjects given pirlindole 75 to 150 mg daily for 4 days indicated that it did not affect the performance of a number of psychomotor tests, both with and without 0.4 g/kg of alcohol.⁶

Mechanism

The CNS depressant effects of mianserin, and possibly maprotiline, appear to be additive with those of alcohol.

Importance and management

Drowsiness is a frequently reported adverse effect of mianserin, particularly during the first few days of treatment. Patients should be warned that driving or handling dangerous machinery will be made more hazardous if they drink. It would also be prudent to warn patients taking maprotiline of the possible increased risk if they drink.² Pirlindole appears not to interact.

Alcohol + Tianeptine

Alcohol reduced the absorption of tianeptine and lowered plasma levels by about 30%.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects the absorption and peak plasma levels of a single 12.5-mg dose of tianeptine were reduced by about 30% by alcohol. The subjects were given vodka diluted in orange juice to give blood alcohol levels between 64 and 77 mg%. The plasma levels of the major metabolite of tianeptine were unchanged.¹ No behavioural studies were done so that the clinical significance of these studies is as yet uncertain.

- Salvadori C, Ward C, DeFrance R, Hopkins R. The pharmacokinetics of the antidepressant tianeptine and its main metabolite in healthy humans — influence of alcohol co-administration. *Fundam Clin Pharmacol* (1990) 4, 115–25.

Alcohol + Tolazoline

A disulfiram-like reaction may occur in patients taking tolazoline if they drink alcohol.

Clinical evidence, mechanism, importance and management

Seven healthy subjects were given tolazoline 25 mg daily for 4 days. Within 15 to 90 minutes of drinking 90 mL of port wine (alcohol 18.2%), 2 hours after the last dose of tolazoline, 6 experienced tingling over the head, and 4 developed warmth and fullness of the head.¹ The reasons are not understood, but this reaction is not unlike a mild disulfiram reaction, and may possibly have a similar mechanism (see 'Alcohol + Disulfiram', p.61). Patients given tolazoline should be warned about this reaction if they drink alcohol, and advised to limit their consumption. Reactions of this kind with drugs other than disulfiram are usually more unpleasant or frightening than serious, and treatment is rarely needed. In infants given tolazoline, it would seem sensible to avoid preparations containing alcohol, where possible.

- Boyd EM. A search for drugs with disulfiram-like activity. *Q J Stud Alcohol* (1960) 21, 23–5.

Alcohol + Trazodone

Trazodone can make driving or handling other dangerous machinery more hazardous, particularly during the first few days of treatment, and further impairment may occur with alcohol.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects comparing the effects of single-doses of amitriptyline 50 mg and trazodone 100 mg found that both drugs impaired the performance of a number of psychomotor tests, causing drowsiness and reducing 'clearheadedness' to approximately the same extent. Only manual dexterity was further impaired when the subjects taking trazodone were given sufficient alcohol to give blood levels of about 40 mg%.¹

Another study similarly found that the impairment of psychomotor performance by trazodone was increased by alcohol.² This appears to be due to a simple additive depression of the CNS. This is an established interaction, and of practical importance. Patients should be warned that their ability to drive, handle dangerous machinery or to do other tasks needing

complex psychomotor skills might be impaired by trazodone, and further worsened by alcohol.

Alcohol + Trichloroethylene

A flushing skin reaction similar to a mild disulfiram reaction can occur in those who drink alcohol following exposure to trichloroethylene. Alcohol may also increase the risk of liver toxicity due to solvent exposure.

Clinical evidence

An engineer from a factory where trichloroethylene was being used as a degreasing agent, developed facial flushing, a sensation of increased pressure in the head, lachrymation, tachypnoea and blurred vision within 12 minutes of drinking 85 mL of bourbon whiskey. The reaction did not develop when he was no longer exposed to the trichloroethylene. Other workers in the same plant reported the same experience.¹ Vivid red blotches in a symmetrical pattern on the face, neck, shoulders and back were seen in other workers when they drank about 2 pints of beer² after having been exposed for a few hours each day for 3 weeks to increasing concentrations of trichloroethylene vapour (up to 200 ppm). Note that this was twice the maximum permissible level for trichloroethylene in air at that time.³ This reaction has been described as the “degreasers’ flush”.²

A later study involving 188 workers occupationally exposed to trichloroethylene found a statistically significant synergistic toxic interaction between trichloroethylene and alcohol. There were 30 cases (15.9%) of degreasers’ flush and 10 cases (5.3%) of clinical liver impairment.⁴

There is also some evidence that short-term exposure to the combination may possibly reduce mental capacity, although in this study the concentration of trichloroethylene was quite high (200 ppm).⁵

Another study investigated the metabolism of trichloroethylene in 5 healthy subjects who inhaled trichloroethylene 50 ppm for 6 hours per day for 5 days and then again 2 weeks later in the presence of alcohol. Inhalation of trichloroethylene with blood-alcohol concentrations of 0.6% resulted in increased blood and expired air concentrations of trichloroethylene 2 to 3 times greater than without alcohol.⁶ A simulation study suggested that ingestion of moderate amounts of alcohol (0.23 to 0.92 g/kg) before the start of work or at lunchtime, but not at the end of work, could cause pronounced increases in blood-trichloroethylene concentrations and decreases in the urinary excretion rates of trichloroethylene metabolites. However, the effect of enzyme induction on trichloroethylene metabolism by consumption of alcohol the previous evening was negligible when exposure to trichloroethylene was below 100 ppm.⁷

Mechanism

Uncertain. One suggested mechanism is a disulfiram-like inhibition of acetaldehyde metabolism by trichloroethylene (see ‘Alcohol + Disulfiram’, p.61). Another suggested mechanism is inhibition of trichloroethylene metabolism in the presence of alcohol, resulting in increased plasma levels and possibly an accumulation of trichloroethylene in the CNS.⁶

Importance and management

The flushing reaction is an established interaction that has been reported to occur in about 16% of workers exposed to trichloroethylene when they drink alcohol. It would seem to be more unpleasant and socially disagreeable than serious, and normally requires no treatment. However, the hepatotoxicity of trichloroethylene and other organic solvents may be increased by alcohol. Several factors have been shown to affect the handling of solvents by the liver and the final toxicity. Increased body fat has been reported to increase the risk of solvent toxicity and heavy alcohol consumption may further increase the risk of liver toxicity.⁸

Alcohol + Tricyclic antidepressants

The ability to drive, to handle dangerous machinery or to do other tasks requiring complex psychomotor skills may be impaired by amitriptyline, and to a lesser extent by doxepin or imipramine, particularly during the first few days of treatment. This impairment can be increased by alcohol. Amoxapine, clomipramine, desipramine, and nortriptyline appear to interact with alcohol only minimally. Information about other tricyclics appears to be lacking, although most manufacturers of tricyclics warn that the effects of alcohol may be enhanced. There is also evidence that alcoholics (without liver disease) may need larger doses of desipramine and imipramine to control depression. However, the toxicity of some tricyclics may be increased by alcohol, and in alcoholics with liver disease.

Clinical evidence

(a) Amitriptyline

A single-dose, crossover study in 5 healthy subjects found that the plasma levels of amitriptyline 25 mg over an 8-hour period were markedly increased by alcohol (blood-alcohol concentration maintained at approximately 80 mg%). Compared with amitriptyline alone, the AUC₀₋₈ increased by a mean of 44% following alcohol consumption, and was associated with decreased standing steadiness, recent memory and alertness.¹ Amitriptyline 800 micrograms/kg impaired the performance of three motor skills tests related to driving in 21 healthy subjects. When alcohol to produce blood levels of about 80 mg% was also given the performance was even further impaired.² Similar results have been very clearly demonstrated in considerable numbers of subjects using a variety of psychomotor skill tests,¹⁻⁶ the interaction being most marked during the first few days of treatment, but tending to wane as treatment continues.⁵ Unexplained blackouts lasting a few hours have been described in 3 women after they drank only modest amounts of alcohol;⁷ they had been taking amitriptyline or imipramine for a month. There is some limited evidence from *animal* studies that amitriptyline may possibly enhance the fatty changes induced in the liver by alcohol,⁸ but this still needs confirmation from human studies.

A study involving 332 fatal poisonings in Finland found that alcohol was present in 67% of cases involving amitriptyline, and when alcohol was present, relatively small overdoses of amitriptyline could result in fatal poisoning.⁹ It appears that amitriptyline may be more toxic when given with alcohol and it has been suggested that a less dangerous alternative could be chosen when indications of alcohol abuse or suicide risk are present.¹⁰

(b) Amoxapine

The interaction between amoxapine and alcohol is said to be slight,¹¹ but two patients have been described who experienced reversible extrapyramidal symptoms (parkinsonism, akathisia) while taking amoxapine, apparently caused by drinking alcohol.¹²

(c) Clomipramine

Studies in subjects with blood-alcohol levels of 40 to 60 mg% found that clomipramine had only slight or no effects on various choice reaction, coordination, memory and learning tests.^{4,13,14} A case describes a fatal poisoning in a chronic alcoholic patient taking clomipramine for depression. The ultimate toxic effect was thought to be due to alcohol-induced decreased biotransformation of clomipramine, as post-mortem examination revealed toxic liver damage, and low levels of the metabolite were found in blood and hair samples.¹⁵

(d) *Desipramine*

Plasma desipramine levels were transiently, but non-significantly increased after healthy subjects drank alcohol, and breath-alcohol concentrations were not affected by the antidepressant. Further, skilled performance tests in subjects given desipramine 100 mg indicated that no significant interaction occurred with alcohol.¹⁶ The half-life of oral desipramine was about 30% lower in recently detoxified alcoholics (without liver disease), when compared with healthy subjects, and the intrinsic clearance was 60% greater.¹⁷

(e) *Doxepin*

A double-blind, crossover study in 20 healthy subjects given various combinations of alcohol and either doxepin or a placebo found that with blood-alcohol levels of 40 to 50 mg% their choice reaction test times were prolonged and the number of mistakes increased. Coordination was obviously impaired after 7 days of treatment with doxepin, but not after 14 days.⁴ In an earlier study doxepin appeared to cancel out the deleterious effects of alcohol on the performance of a simulated driving test.¹⁸ It appears that doxepin may be more toxic when given with alcohol and it has been suggested that a less dangerous alternative could be chosen when indications of alcohol abuse or suicide risk are present.¹⁰

(f) *Imipramine*

Imipramine 150 mg daily has also been reported to enhance some of the hypno-sedative effects of alcohol,¹⁹ and unexplained blackouts lasting a few hours have been described in 3 women after they drank only modest amounts of alcohol;⁷ they had been taking amitriptyline or imipramine for only a month. The half-life of oral imipramine was about 45% lower in recently detoxified alcoholics (without liver disease) compared with healthy subjects, and the intrinsic clearance was 200% greater.¹⁷

(g) *Nortriptyline*

Studies in subjects with blood-alcohol levels of 40 to 60 mg% found that nortriptyline had only slight or no effects on various choice reaction, coordination, memory and learning tests,^{4,13,20} although the acute use of alcohol with nortriptyline impaired learning in one study.¹³

Mechanism

Part of the explanation for the increased CNS depression is that both alcohol and some of the tricyclics, particularly amitriptyline, cause drowsiness and other CNS depressant effects, which can be additive with the effects of alcohol.⁶ The sedative effects have been reported to be greatest with amitriptyline, then doxepin and imipramine, followed by nortriptyline, and least with amoxapine, clomipramine, desipramine, and **protriptyline**.²¹⁻²⁴ In addition acute alcohol intake causes marked increases (100 to 200%) in the plasma levels of amitriptyline, probably by inhibiting its first pass metabolism.^{1,25} Alcohol-induced liver damage could also result in impaired amitriptyline metabolism.²³ The lower serum levels of imipramine and desipramine seen in abstinent alcoholics are attributable to induction of the cytochrome P450 isoenzymes by alcohol.¹⁷

Importance and management

The increased CNS depression resulting from the interaction between amitriptyline and alcohol is well documented and clinically important. The interaction between alcohol and doxepin or imipramine is less well documented and the information is conflicting. Amoxapine, clomipramine, desipramine, and nortriptyline appear to interact only minimally with alcohol. Direct information about other tricyclics seems to be lacking, but there appear to be no particular reasons for avoiding concurrent use, although tricyclics with greater sedation such as **trimipramine** are more likely to interact. During the first 1 to 2 weeks of treatment many tricyclics (without alcohol) may temporarily impair the skills related to driving.¹¹ Therefore it would seem prudent to warn any patient given a tricyclic that driving or handling dangerous machinery may be made more hazardous if they drink alcohol, particularly during the first few days of treatment, but the effects of the interaction diminish during continued treatment. Most manufacturers of tricyclic antidepressants warn that the effects of alcohol may be enhanced by tricyclics and several suggest avoidance of alcohol whilst taking tricyclic antidepressants.

Also be aware that alcoholic patients (without liver disease) may need higher doses of imipramine (possibly doubled) and desipramine to control depression, and if long-term abstinence is achieved the dosages may then eventually need to be reduced.

Alcohol + Trinitrotoluene

Men exposed to trinitrotoluene (TNT) in a munitions factory were found to have a greater risk of TNT-induced liver damage if they had a long history of heavy alcohol drinking than if they were non-drinkers.¹

- Li J, Jiang Q-G, Zhong W-D. Persistent ethanol drinking increases liver injury induced by trinitrotoluene exposure: an in-plant case-control study. *Hum Exp Toxicol* (1991) 10, 405-9.

Alcohol + Vitamin A (Retinol)

Heavy consumption of alcohol may also increase betacarotene levels and affect vitamin A metabolism; there have been reports of possible increased toxicity.

Clinical evidence, mechanism, importance and management

A study involving 30 abstinent male alcoholics found that 5 of 15 given high-dose vitamin A (10 000 units daily by mouth) for 4 months devel-

oped liver abnormalities during treatment, compared with 1 of 15 patients given placebo. Two of the 6 patients admitted intermittent alcohol consumption. Five of these patients continued with vitamin A and the abnormal liver function tests resolved in 4 of these patients.¹

The interaction between alcohol and vitamin A is complex. They have overlapping metabolic pathways; a similar 2-step process is involved in the metabolism of both alcohol and vitamin A, with alcohol dehydrogenases and acetaldehyde dehydrogenases being implicated in the conversion of vitamin A to retinoic acid.^{2,3} Alcohol appears to act as a competitive inhibitor of vitamin A oxidation.^{2,4} In addition, chronic alcohol intake can induce cytochrome P450 isoenzymes that appear to increase the breakdown of vitamin A (retinol and retinoic acid) into more polar metabolites in the liver, which can cause hepatocyte death. So chronic alcohol consumption may enhance the intrinsic hepatotoxicity of high-dose vitamin A. Alcohol has also been shown to alter retinoid homeostasis by increasing vitamin A mobilisation from the liver to extrahepatic tissues, which could result in depletion of hepatic stores of vitamin A.^{2,3}

It appears that consumption of substantial amounts of alcohol is associated with vitamin A deficiency partially due to poor nutrition and also the direct effects of alcohol on the metabolism of vitamin A. Vitamin A supplementation may therefore be indicated in heavy drinkers, but is complicated by the hepatotoxicity of large amounts of vitamin A, which may be potentiated by alcohol.³ It would therefore seem reasonable to try to control drinking of alcohol when vitamin A supplementation is required. Patients who consume alcohol, particularly heavy drinkers or alcoholics, should be questioned about their use of vitamin supplements as some non-prescription vitamin A and D supplements contain substantial amounts of vitamin A.

Alcohol + Xylene

Some individuals exposed to xylene vapour, who subsequently drink alcohol, may experience dizziness and nausea. A flushing skin reaction has also been seen.

Clinical evidence, mechanism, importance and management

Studies in subjects exposed to *m*-xylene vapour at concentrations of approximately 145 or 280 ppm for 4 hours who were then given 0.4 or 0.8 g/kg of alcohol found that about 10 to 20% experienced dizziness and nausea.^{1,2} One subject exposed to 300 ppm of *m*-xylene vapour developed a conspicuous dermal flush on his face, neck, chest and back. He also showed some erythema with alcohol alone.³ A study using a population-based pharmacokinetic and pharmacodynamic model predicted that the probability of experiencing CNS effects following exposure to xylene at the current UK occupational exposure standard (100 ppm time-weighted average over 8 hours) increased markedly and non-linearly with alcohol dose.⁴

The reasons for these reactions are not fully understood, but it is possible that xylene plasma levels are increased because alcohol impairs its metabolic clearance by the cytochrome P450 isoenzyme CYP2E1.⁴ After alcohol intake, blood xylene levels have been reported to rise about 1.5- to 2-fold;² acetaldehyde levels may also be transiently increased.²

Alcoholic beverages are quite often consumed during lunchtime or after work, and since the excretion of xylene is delayed by its high solubility and storage in lipid-rich tissues, the simultaneous presence of xylene and alcohol in the body is probably not uncommon and could result in enhancement of the toxicity of xylene.⁵

Alpha blockers

The selective and non-selective alpha blockers are categorised and listed in 'Table 4.1', (see below). The principal interactions of the alpha blockers are those relating to enhanced hypotensive effects. Early after the introduction of the selective alpha blockers it was discovered that, in some individuals, they can cause a rapid reduction in blood pressure on starting treatment (also called the 'first-dose effect' or 'first-dose hypotension'). The risk of this may be higher in patients already taking other antihypertensive drugs. The first-dose effect has been minimised by starting with a very low dose of the alpha blocker, and then escalating the dose slowly over a couple of weeks. A similar hypotensive effect can occur when the dose of the alpha blocker is increased, or if treatment is interrupted for a few days and then re-introduced. Some manufacturers recommend giving the first dose on retiring to bed, or if not, avoiding tasks that are potentially hazardous if syncope occurs (such as driving) for the first 12 hours. If symptoms such as dizziness, fatigue or sweating develop, patients should be warned to lie down, and to remain lying flat until they abate completely.

It is unclear whether there are any real differences between the alpha blockers in their propensity to cause this first-dose effect. With the exception of indoramin, postural hypotension, syncope, and dizziness are listed as adverse effects of the alpha blockers available in the UK and for most it is recommended that they should be started with a low dose and titrated as required. Tamsulosin is reported to have some selectivity for the alpha receptor 1A subtype, which are found mostly in the prostate, and therefore have less effect on blood pressure: an initial titration of the dose is therefore not considered to be necessary. Nevertheless, it would be prudent to exercise caution with all the drugs in this class.

Alpha blockers are also used to increase urinary flow-rate and improve obstructive symptoms in benign prostatic hyperplasia. In this setting, their effects on blood pressure are more of an adverse effect, and their additive hypotensive effect with other antihypertensives may not be beneficial.

Table 4.1 Alpha blockers

<i>Drug</i>	<i>Principal indications</i>
Selective alpha₁ blockers (Alpha blockers)	
Alfuzosin	BPH
Bunazosin	Hypertension
Doxazosin	BPH; Hypertension
Indoramin	BPH; Hypertension; Migraine
Prazosin	BPH; Heart failure; Hypertension; Raynaud's syndrome
Tamsulosin	BPH
Terazosin	BPH; Hypertension
Other drugs with alpha-blocking actions	
Moxisylate	Peripheral vascular disease; Erectile dysfunction
Phenoxybenzamine	Hypertensive episodes in phaeochromocytoma; Neurogenic bladder; Shock
Phentolamine	Erectile dysfunction; Hypertensive episodes in phaeochromocytoma
Urapidil	Hypertension

Alpha blockers + ACE inhibitors

Severe first-dose hypotension, and synergistic hypotensive effects that occurred when a patient taking enalapril was given bunazosin have been replicated in healthy subjects. The first-dose effect seen with other alpha blockers (particularly alfuzosin, prazosin and terazosin) is also likely to be potentiated by ACE inhibitors. In one small study tamsulosin did not have any clinically relevant effects on blood pressure that was already well controlled by enalapril.

Clinical evidence

After a patient taking **enalapril** developed severe first-dose hypotension after being given **bunazosin**, this interaction was further studied in 6 healthy subjects. When given **enalapril** 10 mg or **bunazosin** 2 mg, their mean blood pressure over 6 hours was reduced by 9.5/6.7 mmHg. When **bunazosin** was given one hour after **enalapril** the blood pressure fell by 27/28 mmHg, and still fell by 19/22 mmHg, even when the dose of **enalapril** was reduced to 2.5 mg.¹

The manufacturers of **alfuzosin**² and **prazosin**³ warn that patients receiving antihypertensive drugs (the manufacturers of **prazosin** specifically name the ACE inhibitors) are at particular risk of developing postural hypotension after the first dose of alpha blocker.

Retrospective analysis of a large multinational study in patients given **terazosin** 5 or 10 mg daily found that **terazosin** only affected the blood pressure of patients taking ACE inhibitors (**enalapril**, **lisinopril** or **perindopril**) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by ACE inhibitors). The most common adverse effect in the 10-week **terazosin** phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than those not (21 to 25%).⁴ However, the manufacturer of **terazosin** notes that the incidence of dizziness in patients with BPH taking **terazosin** was higher when they were also receiving an ACE inhibitor.⁵

In a placebo-controlled study in 6 hypertensive men with blood pressure well controlled by **enalapril**, the addition of **tamsulosin** 400 micrograms daily for 7 days then 800 micrograms daily for a further 7 days had no clinically relevant effects on blood pressure (assessed after 6 and 14 days of **tamsulosin**). In addition, no first-dose hypotensive effect was seen on the day **tamsulosin** was started, or on the day the **tamsulosin** dose was increased.⁶

Mechanism

The first-dose effect of alpha blockers (see 'Alpha blockers', (p.83)) may be potentiated by ACE inhibitors. Tamsulosin possibly has less effect on blood pressure since it has some selectivity for alpha receptors in the prostate.

Importance and management

Direct information is limited. Acute hypotension (dizziness, fainting) sometimes occurs unpredictably with the first dose of some alpha blockers (particularly, alfuzosin, prazosin and terazosin; but see 'Alpha blockers', (p.83)), and this can be exaggerated if the patient takes or is already taking a beta blocker or a calcium-channel blocker (see 'Alpha blockers + Beta blockers', below, and 'Alpha blockers + Calcium-channel blockers', p.85). It would therefore seem prudent to apply the same precautions to ACE inhibitors, namely reducing the dose of the ACE inhibitor to a maintenance level if possible, then starting the alpha blocker at the lowest dose, with the first dose given at bedtime. Note that the acute hypotensive reaction appears to be short-lived. There is limited evidence that terazosin and tamsulosin may not cause an additional hypotensive effect in the longer term in patients with BPH who have hypertension already well-controlled with ACE inhibitors. Nevertheless, caution should be exercised in this situation, and a dose reduction of the ACE inhibitor may be required.

Alpha blockers + Beta blockers

The risk of first-dose hypotension with prazosin is higher if the patient is already taking a beta blocker. This is also likely to be true of other alpha blockers, particularly alfuzosin, bunazosin and terazosin. In a small study tamsulosin did not have any clinically relevant effects on blood pressure that was already well controlled by atenolol. Alpha blockers and beta blockers may be combined for additional lowering of blood pressure in patients with hypertension.

Clinical evidence

(a) Alfuzosin

No pharmacokinetic interaction occurred between alfuzosin 2.5 mg and atenolol 100 mg in a single-dose study in 8 healthy subjects.¹ The manufacturer notes that postural hypotension may occur in patients receiving antihypertensives when they start alfuzosin,^{2,3} and note a study in which the combination of single doses of alfuzosin 2.5 mg and atenolol 100 mg caused significant reductions in mean heart rate and blood pressure. The AUCs of both drugs were raised up to about 20%.³

(b) Doxazosin

The manufacturer of doxazosin states that no adverse drug interaction has been observed between doxazosin and beta blockers,^{4,5} although they do note that the most common adverse reactions associated with doxazosin are of a postural hypotension type.⁴ They specifically note that doxazosin has been given with atenolol and propranolol without evidence of an adverse interaction.⁵

(c) Indoramin

The manufacturer of indoramin states that concurrent use with beta blockers may enhance their hypotensive action, and that titration of the dose of the beta blocker may be needed when initiating therapy.⁶

(d) Prazosin

A marked hypotensive reaction (dizziness, pallor, sweating) occurred in 3 out of 6 hypertensive patients taking alprenolol 400 mg twice daily when they were given the first 500-microgram dose of prazosin. All 6 patients had a greater reduction in blood pressure after the first prazosin dose than after 2 weeks of treatment with prazosin 500 microgram three times daily with no beta blocker (mean reduction 22/11 mmHg compared with 4/4 mmHg). A further 3 patients already taking prazosin 500 microgram three times daily had no unusual fall in blood pressure when they were given the first dose of alprenolol 200 mg.⁷ Two studies have shown that the pharmacokinetics of prazosin are not affected by either alprenolol⁷ or propranolol.⁸

The severity and the duration of the first-dose effect of prazosin was also found to be increased in healthy subjects given a single dose of propranolol.⁹

(e) Tamsulosin

In a placebo-controlled study in 8 hypertensive men with blood pressure well controlled by atenolol, the addition of tamsulosin 400 micrograms daily for 7 days, then 800 micrograms daily for a further 7 days, had no clinically relevant effect on blood pressure (assessed after 6 and 14 days of tamsulosin). No hypotension was seen with the first dose of tamsulosin or when the dose of tamsulosin was increased.¹⁰

(f) Terazosin

Retrospective analysis of a large multinational study in patients given terazosin 5 or 10 mg daily found that terazosin only affected the blood pressure of patients taking beta blockers (atenolol, labetalol, metoprolol, sotalol, and timolol) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by beta blockers). The most common adverse effect in the 10-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than those not (21 to 25%).¹¹

In addition to these drugs the manufacturers of terazosin note that it has been taken by at least 50 patients with propranolol without evidence of an adverse interaction.¹²

Mechanism

The normal cardiovascular response (a compensatory increased heart output and rate) that should follow the first-dose hypotensive reaction to alpha blockers is apparently compromised by the presence of a beta blocker. The problem is usually only short-lasting because some physiological compensation occurs within hours or days, and this allows the blood pressure to be lowered without falling precipitously. Tamsulosin possibly has less effect on blood pressure since it has some selectivity for alpha receptors in the prostate (see 'Alpha blockers', (p.83)).

Importance and management

An established interaction. Some patients experience acute postural hypotension, tachycardia and palpitations when they begin to take prazosin or other alpha blockers (particularly alfuzosin, bunazosin and terazosin; but see also 'Alpha blockers', (p.83)). A few patients even collapse in a sudden faint within 30 to 90 minutes, and this can be exacerbated if they are already taking a beta blocker. It is recommended that those already taking a beta blocker should have their dose of beta blocker reduced to a maintenance dose and begin with a low-dose of these alpha blockers, with the first dose taken just before going to bed. They should also be warned about the possibility of postural hypotension and how to manage it (i.e. lay down, raise the legs and get up slowly). Similarly, when adding a beta blocker to an alpha blocker, it may be prudent to decrease the dose of the alpha blocker and re-titrate as necessary. There is limited evidence that terazosin and tamsulosin may not cause an additional hypotensive effect in the longer term in patients with BPH who have hypertension already well-controlled with beta blockers. Nevertheless, caution should be exercised in this situation, and a dose reduction of the beta blocker may be required.

Alpha blockers + Calcium-channel blockers

Blood pressure may fall sharply when calcium-channel blockers are first given to patients already taking alpha blockers (particularly prazosin and terazosin), and vice versa. In a small study, tamsulosin did not have any clinically relevant effects on blood pressure well controlled by nifedipine. Verapamil may increase the AUC of prazosin and terazosin. Alpha blockers and calcium-channel blockers may be combined for additional blood pressure lowering in patients with hypertension.

Clinical evidence

(a) Dihydropyridine calcium-channel blockers

1. *Doxazosin*. Although there was a tendency for first-dose hypotension no serious adverse events or postural symptoms were seen in 6 normotensive subjects given **nifedipine** 20 mg twice daily for 20 days, with doxazosin

2 mg once daily for the last 10 days. The same results were noted in 6 other normotensive subjects given the drugs in the opposite order. No pharmacokinetic interactions were found.¹ However, the US manufacturers note a study in which slight (less than 20%) alterations were found in the pharmacokinetics of **nifedipine** and doxazosin when they were given concurrently. As would be expected, blood pressures were lower when both drugs were given.²

2. *Prazosin*. In a placebo-controlled, crossover study 12 hypertensive subjects were given **nifedipine** 20 mg and prazosin 2 mg, separated by one hour. Concurrent use reduced blood pressure more than either drug alone, but when prazosin was given after **nifedipine** its effects were delayed.³ Two patients with severe hypertension given prazosin 4 or 5 mg experienced a sharp fall in blood pressure shortly after being given **nifedipine** *sublingually*. One of them complained of dizziness and had a reduction in standing blood pressure from 232/124 to 88/48 mmHg about 20 minutes after taking **nifedipine** 10 mg. However, in a further 8 patients with hypertension taking prazosin, the reduction in blood pressure 20 minutes after the addition of *sublingual* nifedipine was smaller (mean reduction of 25/12 mmHg when lying and 24/17 mmHg when standing).⁴ It is not clear what contribution prazosin had to the effect seen with *sublingual* **nifedipine**, since the experiment was not repeated using a prazosin placebo, but blood pressure in these patients had earlier remained unchanged 1 hour after taking prazosin alone. Note that *sublingual* **nifedipine** alone may cause a dangerous drop in blood pressure.

3. *Tamsulosin*. In a placebo-controlled study in 8 hypertensive men with blood pressure well controlled by **nifedipine**, the addition of tamsulosin 400 micrograms daily for 7 days then 800 micrograms daily for a further 7 days had no clinically relevant effect on blood pressure (assessed after 6 and 14 days of tamsulosin). In addition, no first-dose hypotension was seen on the first day of tamsulosin, or when the tamsulosin dose was increased.⁵

4. *Terazosin*. Retrospective analysis of a large multinational study in patients given terazosin 5 or 10 mg daily found that terazosin only affected the blood pressure of patients taking calcium-channel blockers (**amlodipine**, **felodipine**, **flunarizine**, **isradipine** and **nifedipine**) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by calcium-channel blockers). The most common adverse effect in the 10-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than those not taking antihypertensives (21 to 25%).⁶

(b) Diltiazem

The US manufacturers note that when diltiazem 240 mg daily was given with **alfuzosin** 2.5 mg three times daily the maximum serum levels and AUC of **alfuzosin** were raised by 50% and 30%, respectively, and the maximum serum levels and AUC of diltiazem were raised by 40%. However, no changes in blood pressure were seen.⁷

(c) Verapamil

1. *Prazosin*. A study in 8 normotensive subjects given a single 1-mg dose of prazosin found that the peak serum prazosin levels were raised by 85% (from 5.2 to 9.6 nanograms/mL) and the prazosin AUC was increased by 62% when it was given with a single 160-mg dose of verapamil. The standing blood pressure, which was unchanged after verapamil alone, fell from 114/82 to 99/81 mmHg with prazosin alone, and was further reduced to 89/68 mmHg when both drugs were given together.⁸ A similar pharmacokinetic interaction was noted in another study in hypertensive patients.⁹ In this study, the first 1-mg dose of prazosin alone caused a 23 mmHg fall in standing systolic blood pressure, and half the patients (3 of 6) experienced symptomatic postural hypotension. A similar fall in blood pressure occurred when the first 1-mg dose of prazosin was given to 6 patients who had been taking verapamil for 5 days, and 2 patients experienced symptomatic postural hypotension.⁹

2. *Tamsulosin*. A study into the safety of tamsulosin, with particular regard to the use of other medications, found that the concurrent use of verapamil increased the risk of adverse events related to tamsulosin treatment by threefold. The use of other calcium-channel blockers (not specified) did not appear to increase adverse effects, although there was a trend towards an increase.¹⁰

3. *Terazosin*. When verapamil 120 mg twice daily was added to terazosin 5 mg daily in 12 hypertensive patients, the peak plasma levels and the AUC of the terazosin were increased by about 25%. In contrast, in another 12 patients taking verapamil 120 mg twice daily, the addition of terazosin

(1 mg increased to 5 mg daily) had no effect on verapamil pharmacokinetics.¹¹ Both groups of patients had significant falls in standing blood pressure when they first started taking both drugs. Symptomatic orthostatic hypotension (which lessened within about 3 weeks) occurred in 4 patients when verapamil was first added to terazosin, and in 2 patients when terazosin was first added to verapamil.¹¹

Mechanism

Not fully understood. It would seem that the vasodilatory effects of the alpha blockers and the calcium-channel blockers can be additive or synergistic, particularly after the first dose.^{1,12} The fall in blood pressure seen with prazosin and verapamil may, in part, result from a pharmacokinetic interaction,¹² as does the interaction between alfuzosin and diltiazem. Tamsulosin possibly has less effect on blood pressure since it has some selectivity for alpha receptors in the prostate (see 'Alpha blockers', (p.83)).

Importance and management

The interaction between calcium-channel blockers and alpha blockers would appear to be established and of clinical importance, although the documentation is limited. Marked additive hypotensive effects can occur when concurrent use is first started, particularly with alfuzosin, bunazosin, prazosin and terazosin; but see also 'Alpha blockers', (p.83). It is recommended that patients already taking calcium-channel blockers should have their dose of calcium-channel blocker reduced and begin with a low-dose of alpha blocker, with the first dose taken just before going to bed. Caution should also be exercised when calcium-channel blockers are added to established treatment with an alpha blocker. Patients should be warned about the possibilities of exaggerated hypotension, and told what to do if they feel faint and dizzy. There is limited evidence that terazosin and tamsulosin may not cause an additional hypotensive effect in the longer term in patients with BPH who have hypertension already well-controlled with calcium-channel blockers. Nevertheless, caution should be exercised in this situation, and a dose reduction of the calcium-channel blocker may be required. It seems likely that any pharmacokinetic interaction will be accounted for by this dose titration.

Alpha blockers + Cimetidine

No important interaction occurs between cimetidine and either alfuzosin or doxazosin. Tamsulosin does not appear to have a clinically significant interaction with cimetidine, but caution is recommended with high tamsulosin doses.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects cimetidine 1 g daily in divided doses for 20 days was found to have minimal effects on the pharmacokinetics of a single 5-mg dose of **alfuzosin**. The maximum serum levels and AUC of **alfuzosin** were increased by up to 24%, (not statistically significant) and the half-life was shortened by 14%. Cimetidine did not appear to increase the incidence of postural hypotension seen with **alfuzosin**.¹ These changes are

not clinically relevant, and there would seem to be no reason for avoiding concurrent use.

The manufacturers of **doxazosin** note that in a placebo-controlled study in healthy subjects cimetidine 400 mg twice daily increased the AUC of a single 1-mg dose of **doxazosin** given on day 4 by 10%.^{2,3} This seems unlikely to be of clinical significance, especially as this is within the expected intersubject variation of the **doxazosin** AUC.³

A study in 10 healthy subjects found that giving cimetidine 400 mg four times daily with a single 400-microgram dose of **tamsulosin** resulted in a 44% increase in the AUC of **tamsulosin** and a 26% reduction in **tamsulosin** clearance. Adverse events were not increased by concurrent use.⁴ The UK manufacturer of **tamsulosin** considers that no dosage adjustment is necessary.⁵ However, the US manufacturers advise caution, particularly with doses greater than 400 micrograms.⁶ In practice this probably means being aware that any increase in the adverse effects of **tamsulosin** occur as a result of this interaction. If adverse effects do occur, consider changing to a non-interacting, alternative alpha blocker, such as alfuzosin. Other H₂-receptor antagonists would not be expected to interact, but there does not seem to be any evidence to support this suggestion.

Alpha blockers + CYP3A4 inhibitors

Potent CYP3A4 inhibitors may increase the levels of alfuzosin.

Clinical evidence, mechanism, importance and management

The US manufacturers of alfuzosin XL briefly cite a study in which **ketokonazole** 400 mg increased the AUC and maximum levels of a 10-mg dose of alfuzosin by 3.2-fold and 2.3-fold, respectively. They therefore contraindicate the concurrent use of potent CYP3A4 inhibitors (they name **itraconazole**, **ketokonazole** and **ritonavir**).¹

Based on the information available the contraindication with alfuzosin seems somewhat cautious, although the **protease inhibitors** may be expected to have a greater effect than **ketokonazole**. If any of the potent CYP3A4 inhibitors named is given with alfuzosin it would seem prudent to use the minimum dose of the alpha blocker and titrate the dose as necessary, monitoring for adverse effects, particularly first-dose hypotension when the dose is increased. Be aware that risks are likely to be greater in patients also taking other antihypertensives. There is no evidence to suggest that other alpha blockers interact similarly, and they may therefore be suitable alternatives in some patients.

1. Uroxatral (Alfuzosin hydrochloride extended-release tablets). Sanofi-Aventis US LLC. US Prescribing information, March 2007.

Alpha blockers + Diuretics

As would be expected, the use of an alpha blocker with a diuretic may result in an additive hypotensive effect, but aside from first-dose hypotension, this usually seems to be a beneficial interaction in patients with hypertension. The effects in patients with congestive heart failure may be more severe.

Clinical evidence, mechanism, importance and management

(a) Alfuzosin

No pharmacokinetic interaction occurred between alfuzosin 5 mg and **hydrochlorothiazide** 25 mg in a single-dose study in 8 healthy subjects.¹ The manufacturer notes that postural hypotension may occur in patients receiving antihypertensives when they start alfuzosin.²

(b) *Doxazosin*

The manufacturer of doxazosin notes that no adverse drug interaction has been seen between doxazosin and **thiazides**^{3,4} or **furosemide**.³ However, they point out that doxazosin doses of greater than 4 mg daily increase the likelihood of adverse effects such as postural hypotension and syncope.⁴

(c) *Indoramin*

The manufacturer of indoramin states that concurrent use with diuretics may enhance their hypotensive action, and that titration of the dose of the diuretic may be needed.⁵

(d) *Prazosin*

The acute first-dose hypotension that can occur with alpha blockers such as prazosin can be exacerbated by 'beta blockers', (p.84) and 'calcium-channel blockers', (p.85), but there seems to be no direct evidence that diuretics normally do the same. However, the manufacturer of prazosin suggests that it is particularly important that patients with congestive heart failure who have undergone vigorous diuretic treatment should be given the initial dose of prazosin at bedtime and started on the lowest dose (500 micrograms two to four times daily). The reason is that left ventricular filling pressure may decrease in these patients with a resultant fall in cardiac output and systemic blood pressure.⁶ There seems to be no reason for avoiding concurrent use if these precautions are taken.

(e) *Tamsulosin*

The US manufacturer of tamsulosin⁷ notes that when 10 healthy subjects taking tamsulosin 800 micrograms daily were given a single 20-mg intravenous dose of **furosemide** the AUC of tamsulosin was reduced by 12%. Both the UK and US manufacturers note that as levels remained within the normal range no change in dosage is necessary.^{7,8}

(f) *Terazosin*

Retrospective analysis of a large multinational study in patients given terazosin 5 or 10 mg daily found that terazosin only affected the blood pressure of patients taking diuretics (**amiloride**, **bendroflumethiazide**, **chlortalidone**, **hydrochlorothiazide** and **spironolactone**) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by diuretics). The most common adverse effect in the 10-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than those not taking antihypertensives (21 to 25%).⁹ However, the UK manufacturer of terazosin notes that the incidence of dizziness in patients with BPH taking terazosin was higher when they were also taking a diuretic.¹⁰ Similarly, in clinical studies in patients with hypertension, a higher proportion experienced dizziness when they took terazosin with a diuretic, than when they took a placebo with a diuretic (20% versus 13%).¹¹ The manufacturer states that when terazosin is added to a diuretic, dose reduction and re-titration may be necessary.^{10,12} In addition to these drugs the manufacturers of terazosin note that it has been given to at least 50 patients taking **methylothiazide** without evidence of an adverse interaction.¹²

Alpha blockers + Dutasteride or Finasteride

No clinically important interaction has been found to occur between finasteride and doxazosin. In one study terazosin did not interact with finasteride, but in another there was a suggestion of modestly increased finasteride levels. No clinically significant interaction appears to occur between dutasteride and tamsulosin or terazosin.

Clinical evidence, mechanism, importance and management

(a) *Dutasteride*

A study in 24 subjects given dutasteride 500 micrograms daily for 14 days found that when **tamsulosin** 400 micrograms or **terazosin** (titrated to 10 mg) were also given once daily for 14 days, the pharmacokinetics of the alpha blockers remained unchanged.¹ Furthermore, a clinical study in 327 men demonstrated that the combination of **tamsulosin** and dutasteride was well-tolerated over a period of 6 months.²

(b) *Finasteride*

In a parallel study, 48 healthy subjects were divided into three groups. One group took **terazosin** 10 mg daily for 18 days, another took finasteride 5 mg daily for 18 days, and the third group took both drugs. The pharmacokinetics and pharmacodynamics of both drugs remained unchanged, and the serum levels of testosterone and dihydrotestosterone were also unaltered by concurrent use.³ However, another study, comparing groups of healthy subjects taking finasteride and alpha blockers found that after 5 days of combined use the group taking finasteride and **terazosin** had an 11% lower maximum plasma level of finasteride and a 12% higher AUC, compared with the group taking finasteride alone (both differences were not statistically significant). Conversely, after 10 days of combined use, the maximum finasteride level was 16% higher and the AUC 31% higher, which was statistically significant. The levels of the group taking finasteride and **doxazosin** were not significantly different. The clinical significance of the possible modest increased finasteride levels with **terazosin** is not clear,⁴ but is likely to be small.

Alpha blockers + Miscellaneous

The manufacturers of several of the alpha blockers provide lists of drugs that are not expected to interact. These are shown in 'Table 4.2', (p.88). In some cases these predictions are based on *in vitro* studies or from observation of clinical usage. Although this type of data can provide a guide, remember that it gives only the broadest indication of whether or not a drug interacts.

Alpha blockers + NSAIDs

Indometacin reduces the blood pressure-lowering effects of prazosin in some individuals. Other alpha blockers do not appear to interact with NSAIDs.

Clinical evidence

A study in 9 healthy subjects found that **indometacin** 50 mg twice daily for 3 days had no statistically significant effect on the hypotensive effect of a single 5-mg dose of **prazosin**. However, in 4 of the subjects it was noted that the maximum fall in the mean standing blood pressure due to the **prazosin** was 20 mmHg less when they were taking **indometacin**. Three of these 4 felt faint when given **prazosin** alone, but not while taking the **indometacin** as well.¹

Table 4.2 Drugs that are not expected to interact with alpha blockers as listed by the manufacturers

	<i>Doxazosin</i> ¹	<i>Prazosin</i> ²	<i>Tamsulosin</i> ^{3,4}	<i>Terazosin</i> ⁵
Amitriptyline			No expected interaction (<i>in vitro</i> study)	
Amoxicillin	No expected interaction			
Antacids	No expected interaction			No expected interaction
Antidiabetic drugs	No expected interaction	No expected interaction with chlorpropamide, insulin, phenformin, tolazamide, or tolbutamide	No expected interaction with glibenclamide (<i>in vitro</i> study)	No expected interaction
Antigout drugs		No expected interaction with allopurinol, colchicine, or probenecid		No expected interaction with allopurinol
Anxiolytics and Hypnotics	No expected interaction with diazepam	No expected interaction with chlordiazepoxide or diazepam	No expected interaction with diazepam (<i>in vitro</i> study)	No expected interaction with diazepam
Chlorphenamine	No expected interaction			No expected interaction

5. Hytrin (Terazosin hydrochloride). Abbott Laboratories. US Prescribing information, February 2001.

Mechanism

Not established. It seems probable that indometacin inhibits the production of hypotensive prostaglandins by the kidney.

Importance and management

Direct information seems to be limited to this study but what occurred is consistent with the way indometacin reduces the effects of many other different antihypertensives (e.g. see 'ACE inhibitors + NSAIDs', p.28, and 'Beta blockers + Aspirin or NSAIDs', p.835). It apparently does not affect every patient. If indometacin is added to established treatment with prazosin, be alert for a reduced antihypertensive response. It is not known exactly what happens in patients taking both drugs long-term, but note that with other interactions between antihypertensives and NSAIDs the effects seem to be modest. The manufacturers say that prazosin has been given with indometacin (and also **aspirin** and **phenylbutazone**) without any adverse interaction in clinical experience to date.² Other manufacturers also

note that no adverse interaction has been seen between **doxazosin** and NSAIDs, or **terazosin** and **aspirin**, **ibuprofen**, or indometacin.^{3,4}

Bunazosin + Rifampicin (Rifampin)

Rifampicin markedly reduces bunazosin serum levels.

Clinical evidence, mechanism, importance and management

In 15 healthy subjects a 7-day course of rifampicin 600 mg daily reduced the mean maximum serum levels of bunazosin 6 mg daily by 82% (from 11.6 to 2.1 nanograms/mL). The bunazosin AUC was reduced by more

than sevenfold. The duration of the blood pressure-lowering effect of bunazosin was shortened, the heart rate increase was less pronounced, and some adverse effects of bunazosin treatment (fatigue, headache) disappeared.^{1,2} The probable reason is that the rifampicin (a recognised, potent enzyme inducer) increases the metabolism of bunazosin by the liver so that its levels are reduced, and its effects therefore diminished.

The evidence seems to be limited to this study, but anticipate the need to raise the bunazosin dosage if rifampicin is added. Information about other alpha blockers does not seem to be available.

Indoramin + MAOIs

Based on early theoretical considerations, the manufacturers of indoramin contraindicate its use with MAOIs.

Clinical evidence, mechanism, importance and management

The concurrent use of MAOIs is contraindicated by the manufacturers of indoramin.¹ This was included in the datasheet at the time indoramin was first licensed, and was based on a theoretical suggestion that the effects of noradrenaline (norepinephrine) may be potentiated by indoramin,² leading to vasoconstriction with a possible increase in blood pressure. However, the pharmacology of these drugs suggests just the opposite, namely that hypotension is the more likely outcome. (Note that the hypertensive effects of noradrenaline (norepinephrine) may be treated with a non-selective alpha blocker such as phentolamine.) The manufacturers are not aware of any reported interactions between indoramin and MAOIs.² Note that the MAOIs are not contraindicated with any of the other alpha blockers.

Anaesthetics and Neuromuscular blockers

This section is concerned with the interactions where the effects of anaesthetics (both general and local) and neuromuscular blocking drugs are affected by the presence of other drugs. Where the anaesthetics or neuromuscular blocking drugs are responsible for an interaction they are dealt with under the heading of the drug affected.

Many patients undergoing anaesthesia may be taking long-term medication, which may affect their haemodynamic status during anaesthesia. This section is limited to drug interactions and therefore does not cover the many precautions relating to patients taking long-term medication and undergoing anaesthesia in general (for example, drugs affecting coagulation).

(a) General anaesthetics and neuromuscular blockers

In general anaesthesia a balanced approach is often used to meet the main goals of the anaesthetic procedure. These goals are unconsciousness/amnesia, analgesia, muscle relaxation, and maintenance of homeostasis. Therefore general anaesthesia often involves the use of several drugs, including benzodiazepines, opioids, and anticholinesterases, as well as general anaesthetics (sometimes more than one) and neuromuscular blockers. The use of several different types of drugs in anaesthesia means that there is considerable potential for drug interactions to occur in the peri-operative period, but this section is limited to the effects of drugs on general anaesthetics and neuromuscular blockers. The interactions of drugs affecting these other drugs used in anaesthesia are covered in other sections ('anticholinesterases', (p.352), 'benzodiazepines', (p.706), and 'opioids', (p.133)).

There may be difficulty in establishing which of the drugs being used in a complex regimen are involved in a suspected interaction. It should also be borne in mind that disease processes and the procedure for which anaesthesia is used may also be factors to be taken into account when evaluating a possible interaction.

Some established interactions are advantageous and are employed clinically. For example, the hypnotic and anaesthetic effects of 'propofol and midazolam', (p.96), are found to be greater than the expected additive effects and this synergy allows for lower dosage regimens in practice. Similarly nitrous oxide reduces the required dose of inhalational general anaesthetics (see 'Anaesthetics, general + Anaesthetics, general', p.92). Anticholinesterases oppose the actions of competitive neuromuscular blockers, and are used to restore muscular activity after surgery (see 'Neuromuscular blockers + Anticholinesterases', p.114).

The general anaesthetics mentioned in this section are listed in 'Table 5.1', (p.91). Barbiturates used as anaesthetics (e.g. thiopental) are largely covered here, whereas those used predominantly for their antiepileptic or sedative properties (e.g. phenobarbital or secobarbital) are dealt with in the appropriate sections.

The competitive (non-depolarising) neuromuscular blockers and depolarising neuromuscular blockers mentioned in this section are listed in 'Table 5.2', (p.91). The modes of action of the two types of neuromuscular blocker are discussed in the monograph 'Neuromuscular blockers + Neuromuscular blockers', p.128. It should be noted that mivacurium (a competitive blocker) and suxamethonium (a depolarising blocker) are hydrolysed by cholinesterase, so share some interactions in common that are not relevant to other competitive neuromuscular blockers.

(b) Local anaesthetics

The local anaesthetics mentioned in this section are listed in 'Table 5.1', (p.91). The interactions discussed in this section mainly involve the interaction of drugs with local anaesthetics used for epidural or spinal anaesthesia. The interactions of lidocaine used as an antiarrhythmic is dealt with in 'Antiarrhythmics', (p.243).

Table 5.1 Anaesthetics

<i>General anaesthetics</i>			
Halogenated inhalational anaesthetics	Miscellaneous inhalational anaesthetics	Barbiturate parenteral anaesthetics	Miscellaneous parenteral anaesthetics
Chloroform	Anaesthetic ether	Methohexital	Alfadolone
Desflurane	Cyclopropane	Thiamylal	Alfaxolone

	Tubocurarine (d-Tubocurarine)	

Anaesthetics, general + Alcohol

Those who regularly drink alcohol may need more thiopental or propofol than those who do not. In theory, alcohol may increase the risk of renal damage with sevoflurane. It is also probably unsafe to drink for several hours following anaesthesia because of the combined central nervous depressant effects.

Clinical evidence, mechanism, importance and management

A study in 532 healthy patients, aged from 20 to over 80 years, found that those who normally drank alcohol (more than 40 g weekly, roughly 400 mL of wine) needed more **thiopental** to achieve anaesthesia than non-drinkers. After adjusting for differences in age and weight distribution, men and women who were heavy drinkers (more than 40 g alcohol daily) needed 33% and 44% more **thiopental**, respectively, for induction than non-drinkers.¹ Chronic alcohol intake is known to increase barbiturate metabolism by cytochrome P450 enzymes.²

Another study found that 26 chronic alcoholics (drinkers of about 40 g of alcohol daily, with no evidence of liver impairment) needed about one-third more **propofol** to induce anaesthesia than another 20 patients who only drank socially. However, there was great interindividual variation in the alcoholic group.³

When 12 healthy subjects were given 0.7 g/kg of alcohol 4 hours after receiving 5 mg/kg of **thiopental** 2.5%, body sway and lightheadedness were accentuated.⁴ This suggests that an interaction may occur if an ambulatory patient drinks alcohol within 4 hours of receiving an induction dose of **thiopental**. Patients should be cautioned not to drink alcohol following anaesthesia and surgery.

The manufacturer of **sevoflurane** notes that its metabolism may be increased by known inducers of the cytochrome P450 isoenzyme CYP2E1 including alcohol.^{5,6} This may increase the risk of kidney damage because of an increase in plasma fluoride, although no cases appear to have been reported.

Anaesthetics, general + Anaesthetics, general

In general, the effects of the combined use of general anaesthetics are at least additive. The required dose of propofol will be lower if it is given with nitrous oxide, halothane or isoflurane. The anaesthetic effects of propofol and sevoflurane appear to be additive in ECT, and synergy has been reported between propofol and etomidate.

The dose requirement of inhalational anaesthetics and barbiturate anaesthetics is reduced by nitrous oxide, and the effect of ketamine may be prolonged by barbiturate anaesthetics.

An isolated report described myoclonic seizures in a man anaesthetised with *Alfathesin* (alfaxalone/alfadolone) when he was also given enflurane.

Clinical evidence, mechanism, importance and management

In general, the effects of the combined use of general anaesthetics are at least additive.

(a) Propofol

In a study in 20 healthy patients the concurrent use of either **halothane** or **isoflurane** increased the serum concentrations of propofol by about 20% during the maintenance of general anaesthesia.¹ The US manufacturer of propofol notes that **inhalational anaesthetics** (such as **halothane** or **isoflurane**) would be expected to increase the effects of propofol. The man-

ufacturer also states that the dosage of propofol required may be reduced if it is given with supplemental **nitrous oxide**.²

Synergy has been reported between propofol and **etomidate** – patients given induction doses of either **etomidate** or propofol alone required about a 15% higher dose than those given half etomidate and half propofol in sequence.³

For reports of enhanced sedation when propofol is given with midazolam, **thiopental** or other anaesthetics, see ‘Anaesthetics, general + Benzodiazepines’, p.96.

In a study of the induction of anaesthesia in patients undergoing ECT, subjects were given one of three treatments: propofol 1.5 mg/kg intravenously, **sevoflurane** 5% in oxygen, or propofol followed by **sevoflurane** in oxygen. **Sevoflurane** alone was associated with greater increases in heart rate and blood pressure than the other regimens and seizure duration was greatest in patients receiving propofol alone. Recovery time was longest with the propofol/**sevoflurane** combination, possibly because the combination produced deeper anaesthesia than the individual drugs alone.⁴ The manufacturer of **sevoflurane** notes that lower concentrations may be required following the use of an intravenous anaesthetic such as propofol.⁵ Note that the UK manufacturers of propofol do not recommend its use in ECT.⁶

(b) Miscellaneous anaesthetics

Nitrous oxide usually reduces the MAC of **inhalational anaesthetics** in a simple additive manner; an inspired concentration of 60 to 70% nitrous oxide is commonly used with volatile anaesthetics.⁷ Similarly, the concurrent use of **nitrous oxide** reduces the dose of intravenous **barbiturate anaesthetics**⁸ and **sevoflurane**⁹ required for anaesthesia.

The manufacturers of **ketamine** note that **barbiturates** may prolong the effects of **ketamine** and delay recovery.^{10,11}

Myoclonic activity occurred in a healthy 23-year-old man after anaesthesia was induced with 2.5 mL of *Alfathesin* (**alfaxalone/alfadolone**) given intravenously over 2 minutes, and then maintained with 2% **enflurane** in oxygen. The myoclonic activity subsided after stopping the **enflurane**, and anaesthesia was maintained with **nitrous oxide/oxygen**. The myoclonus recurred when the **enflurane** was restarted, but it resolved when the **enflurane** was replaced with **halothane**.¹² Since both *Alfathesin* and **enflurane** can cause CNS excitation, it seems possible that these effects might have been additive, and it was suggested that concurrent use should be avoided, particularly in patients with known convulsive disorders.¹² However, note that *Alfathesin* has been withdrawn from general use.

Anaesthetics, general + Anaesthetics, local

An isolated report describes convulsions associated with the use of propofol with topical cocaine. Cocaine abuse may increase the risk of cardiovascular complications during inhalational anaesthesia. Abstinence from cocaine or the avoidance of anaesthetics with sympathomimetic properties has been suggested.

The dosage of propofol may need to be reduced after the use of bupivacaine or lidocaine (e.g. during regional anaesthetic techniques). Similarly, epidural lidocaine reduces sevoflurane requirements, and is likely to have the same effect on other inhalational anaesthetics.

Clinical evidence, mechanism, importance and management

(a) Cocaine

A patient with no history of epilepsy, undergoing septorhinoplasty for cosmetic reasons, was premedicated with papaveretum and hyoscine, and intubated after **propofol** and succinylcholine (succinylcholine) were given. Anaesthesia was maintained with **nitrous oxide/oxygen** and 2% **isoflurane**. During anaesthesia a paste containing 10% **cocaine** was applied to the nasal mucosa. During recovery the patient experienced a dystonic reaction, which developed into a generalised convulsion. The authors of the report suggest that a possible interaction between the **propofol** and **cocaine** might have been responsible, although they also suggest that the convulsions may have been an adverse effect of the propofol.¹

Reviews of the anaesthetic implications of illicit drug use have stated that anaesthetists should be aware of the medical complications of cocaine abuse, such as myocardial ischaemia, hypertension and tachycardia due to sympathetic nervous system stimulation.^{2,3} It was suggested that the concurrent use of **cocaine** and **inhalational anaesthetics**, such as **halothane**, that are known to significantly sensitise the myocardium to circulating catecholamines, should be avoided, and that other halogenated anaesthetics should be used with caution.^{2,3} Theoretically, **isoflurane** would be a better choice of inhalational anaesthetic since it has less cardiovascular effects.² **Ketamine** should also be avoided because of its sympathomimetic effects. **Nitrous oxide**, **thiopental** and fentanyl were considered to be useful for general anaesthesia in patients who regularly abuse **cocaine**.^{2,3} Although it has been suggested that anaesthesia is safe for patients with chronic cocaine abuse after abstinence for 24 hours, the occurrence of ventricular fibrillation in one such patient during anaesthesia with **thiopental** and **isoflurane**, led the authors of the case report to conclude that there should be a cocaine-free interval of at least one week before elective surgical procedures. They also suggest that if an emergency operation is required during acute **cocaine** intoxication, all sympathomimetic anaesthetic drugs should be avoided.⁴

(b) Lidocaine or Bupivacaine

A double-blind, randomised study of 17 patients requiring ventilatory support demonstrated that hourly laryngotracheal instillation of 5 mL of 1% lidocaine significantly reduced the dose of **propofol** required to maintain adequate sedation (overall reduction of 50%) when compared with pre-study values.⁵

In a placebo-controlled, double-blind study of 90 patients undergoing minor gynaecological surgery, intramuscular administration of 4% lidocaine (1 to 3 mg/kg) 10 minutes before induction of anaesthesia or 0.5% bupivacaine (500 to 1000 micrograms/kg) 30 minutes before induction of anaesthesia, significantly enhanced the hypnotic effect of intravenous **propofol** in a dose-dependent manner. Only the lowest doses of lidocaine and bupivacaine tested (500 and 250 micrograms/kg, respectively) lacked a significant effect on the hypnotic dose of **propofol**. The highest doses of lidocaine and bupivacaine (3 and 1 mg/kg, respectively) reduced the hypnotic requirements for **propofol** by about 34% and 40%, respectively. The dose of **propofol** should therefore be modified after the intramuscular use of lidocaine or bupivacaine.⁶ The UK manufacturer of **propofol** also notes that required doses may be lower when general anaesthesia is used in association with regional anaesthetic techniques.⁷ An *in vitro* study using liver microsomes found that **propofol** inhibited the metabolism of lidocaine by cytochrome P450 isoenzymes.⁸ However, a further study by the same authors in 31 patients undergoing anaesthesia with either **propofol** or **sevoflurane**, and receiving epidural lidocaine, found that, compared with **sevoflurane** (which does not inhibit lidocaine metabolism), **propofol** similarly did not affect the metabolism of epidural lidocaine. The lack of interaction in the latter study could be due to the lower doses of **propofol** involved and because other isoenzymes or extrahepatic metabolism of lidocaine might possibly be involved.⁹

A randomised, double-blind, placebo-controlled study involving 44 patients found that lidocaine epidural anaesthesia (15 mL of 2% plain lidocaine) reduced the MAC of **sevoflurane** required for general anaesthesia by approximately 50% (from 1.18 to 0.52%). This implies that a lower dose of **inhalational anaesthetic** provides adequate anaesthesia during combined epidural-general anaesthesia than for general anaesthesia alone.¹⁰

(c) Adrenaline in local anaesthetics

Note that drugs such as adrenaline (epinephrine), which are used with local anaesthetics, may interact with inhalational anaesthetics such as ha-

lothane to increase the risk of arrhythmias, see 'Anaesthetics, general + Inotropes and Vasopressors', p.99.

Anaesthetics, general + Anthracyclines

Pretreatment with anthracyclines may result in prolongation of the QT interval during isoflurane anaesthesia.

Clinical evidence, mechanism, importance and management

A study in women with breast cancer found that the QTc interval was prolonged (to more than 440 milliseconds) during anaesthesia with **isoflurane** (end-tidal concentration 0.5 vol%) in more than 50% of the 20 patients who had received treatment (about 1 month before surgery) with fluorouracil and cyclophosphamide and either **doxorubicin** or **epirubicin**, compared with only 1 of 20 patients who had not previously received chemotherapy. However, QTc intervals of 600 milliseconds and above, which may be associated with serious arrhythmias, were not observed. Anthracyclines (such as **doxorubicin** and **epirubicin**) and **isoflurane** can prolong the QT interval. The patients had also received midazolam, which is reported to reduce QTc prolongation induced by other anaesthetics. It was noted that the use of higher **isoflurane** concentrations in patients given anthracyclines could result in greater QTc interval prolongation.¹ In patients treated with anthracyclines or other drugs that prolong the QT interval, it should also be borne in mind that several drugs used in anaesthesia may affect the QT interval. For example **thiopental** and **sufentanil** are also reported to prolong the QT interval, while **propofol** and **halothane** are said to shorten it.¹

- Owczuk R, Wujtewicz MA, Sawicka W, Wujtewicz M, Swierblewski M. Is prolongation of the QTc interval during isoflurane anaesthesia more prominent in women pretreated with anthracyclines for breast cancer? *Br J Anaesth* (2004) 92, 658–61.

Anaesthetics, general + Anticholinesterases

Inhalation anaesthetics may impair the efficacy of anticholinesterases in reversing neuromuscular blockade. Propofol does not affect the reversal of rocuronium block by neostigmine. Physostigmine pre-treatment increased propofol requirements by 20% in one study.

Clinical evidence, mechanism, importance and management

(a) Inhalational anaesthetics

Inhalational anaesthetics can impair **neostigmine** reversal of neuromuscular blockade. In one study, **neostigmine** took longer to reverse **pancuronium** blockade after anaesthesia with **enflurane** compared with fentanyl or **halothane**.¹ Another study demonstrated that the reversal of **vecuronium** block with **neostigmine** 40 micrograms/kg was more dependent on the concentration of **sevoflurane** than the degree of block present. At the lowest concentration of **sevoflurane** (0.2 MAC), adequate reversal was obtained in all patients within 15 minutes, but with increasing concentrations (up to 1.2 MAC) satisfactory restoration of neuromuscular function was not achieved within 15 minutes, probably because of a greater contribution of **sevoflurane** to the degree of block.² In another study, 120 patients were normally allocated maintenance of anaesthesia with one of

three drugs: **sevoflurane** or **isoflurane** (adjusted to 1.5 MAC), or intravenous **propofol** 6 to 12 mg/kg per hour. Neuromuscular block was induced with **rocuronium** and monitored using train-of-four stimulation (TOF) of the ulnar nerve. **Neostigmine** was given when the first response in TOF had recovered to 20 to 25%. At this point **isoflurane** or **sevoflurane** was stopped, or the **propofol** dose reduced, in half of the patients in each of the three groups. The times to recovery of the TOF ratio to 0.8 were 12 and 6.8 minutes in the **sevoflurane** continued and stopped groups respectively, 9 and 5.5 minutes in the **isoflurane** continued and stopped groups respectively, and 5.2 and 4.7 minutes in the **propofol** continued and reduced groups respectively. Only 9/20 and 15/20 patients in the **sevoflurane** and **isoflurane** continued groups, respectively, achieved a TOF ratio of 0.8 within 15 minutes. This showed that the reversal of **rocuronium** block by **neostigmine** is slowed by **sevoflurane** and to a lesser extent by **isoflurane**, but not significantly affected by **propofol**.³

Note that inhalation anaesthetics potentiate neuromuscular blockers, see 'Anaesthetics, general + Neuromuscular blockers', p.101.

(b) Intravenous anaesthetics

A study of 40 patients found that **physostigmine** pre-treatment (2 mg intravenously 5 minutes before induction) increased **propofol** requirements by 20%.⁴ **Propofol** does not appear to delay the reversal of **rocuronium** block by **neostigmine**. See (a) above.

Anaesthetics, general + Antiemetics

Metoclopramide pre-treatment reduces the dosage requirements of propofol and thiopental. Droperidol, but not ondansetron, reduces the dose requirements of thiopental.

Clinical evidence

(a) Metoclopramide or Droperidol

In a randomised, placebo-controlled, double-blind study of 60 surgical patients, half of whom were given metoclopramide 150 micrograms/kg 5 minutes before induction, it was found that the induction dose of **propofol** was reduced by 24% in the group given metoclopramide.¹ Similar results were seen in another study of 21 patients, in which metoclopramide 10 or 15 mg reduced the dose requirements of **propofol** by 24.5% and 41.2%, respectively.² In a randomised, double-blind, placebo-controlled study in 96 women patients, both metoclopramide and droperidol reduced the amount of **thiopental** needed to induce anaesthesia by about 45%.³

(b) Ondansetron

In a double-blind, placebo-controlled, randomised study of 168 female patients ondansetron 100 or 200 micrograms/kg given intravenously 5 minutes before **thiopental** induction did not influence the hypnotic requirements of the **thiopental**.⁴

Mechanism

The exact mechanism by which metoclopramide reduces propofol or thiopental dose requirements is unclear, but it appears to involve the blockade of dopamine (D₂) receptors.

Importance and management

Although the evidence is limited these interactions between metoclopramide and thiopental or propofol, and between droperidol and thiopental would appear to be established. Droperidol has not been studied with propofol, but, on the basis of other interactions it would be expected to behave like metoclopramide. When patients are pretreated with either metoclopramide or droperidol, be alert for the need to use less propofol and thiopental to induce anaesthesia. Ondansetron appears not to interact.

Anaesthetics, general + Antihypertensives

The concurrent use of general anaesthetics and antihypertensives generally need not be avoided but it should be recognised that the normal homeostatic responses of the cardiovascular system will be impaired. For example, marked hypotension has been seen in patients taking ACE inhibitors or angiotensin-II receptor antagonists during anaesthetic induction. Profound hypotension may occur in patients taking alfuzosin during general anaesthesia.

Clinical evidence, mechanism, importance and management

The antihypertensive drugs differ in the way they act, but they all interfere with the normal homeostatic mechanisms that control blood pressure and, as a result, the reaction of the cardiovascular system during anaesthesia to fluid and blood losses, body positioning, etc. is impaired to some extent. For example, enhanced hypotension was seen in a study of the calcium-channel blocker **nimodipine** during general anaesthesia (see 'Anaesthetics, general + Calcium-channel blockers', p.98), and marked hypotension has also been seen with ACE inhibitors in this setting (see below). This instability of the cardiovascular system needs to be recognised and allowed for, but it is widely accepted that antihypertensive treatment should normally be continued.^{1–3} In some cases there is a real risk in stopping, for example a hypertensive rebound can occur if **clonidine** or the beta blockers are suddenly withdrawn. See also 'Anaesthetics, general + Beta blockers', p.97.

(a) ACE inhibitors

Marked hypotension (systolic BP 75 mmHg), which did not respond to surgical stimulation, occurred in a 42-year-old man taking **enalapril** when he was anaesthetised with **propofol**. He responded slowly to the infusion of one litre of Hartmann's solution.⁶ Severe and unexpected hypotension has been seen during anaesthetic induction in patients taking **captopril**.⁷ In a randomised clinical study, the incidence of hypotension during anaesthetic induction was higher in patients who had taken **captopril** or **enalapril** on the day of surgery than in those who had stopped these drugs 12 or 24 hours prior to surgery.⁸ In 18 patients induction of anaesthesia for coronary artery bypass surgery resulted in a significant reduction in blood pressure and heart rate, irrespective of whether or not they were taking ACE inhibitors. The patients taking ACE inhibitors showed a marked decrease in cardiac index but no changes in systemic vascular resistance compared with the patients not taking ACE inhibitors.⁹ In another study in patients undergoing coronary artery bypass surgery, short-lasting hypotensive episodes (less than 60 seconds) occurred in 9 of 16 patients receiving **captopril**, **enalapril**, **perindopril** or **lisinopril**, compared with 2 of 16 who were not taking ACE inhibitors. The patients experiencing hypotension required additional intravenous fluids and vasoconstrictors to maintain haemodynamic stability.¹⁰ Similar findings are reported in another study which included patients taking **captopril**, **enalapril**, **ramipril**, or **lisinopril**.¹¹ Another experimental study found that a single dose of **captopril** at induction of anaesthesia caused a small reduction in cerebral blood flow, when compared with control patients or patients given metoprolol.¹²

Particular care would seem to be needed with patients taking ACE inhibitors, but there is insufficient evidence to generally recommend discontinuing ACE inhibitors before surgery. It is noted that whether ACE inhibitors are discontinued or continued, haemodynamic instability may occur after induction of anaesthesia.⁴ One report in patients undergoing cardiac surgery found that intravenous **enalaprilat** effectively reduced blood pressure and also exerted a beneficial effect on the endocrine regulators of macro- and microcirculation by blunting the increase in vasoconstrictors.¹³

One recommendation is that intravenous fluids should be given to all patients taking ACE inhibitors who are anaesthetised.⁶ If hypotension occurs, blood pressure can be restored in most patients by giving sympathomimetics such as phenylephrine.⁴ However, sympathomimetics may not be fully effective in treating hypotension due to ACE inhibitors

and anaesthesia because ACE inhibitor administration may result in a decrease in the adrenergic vasoconstrictive response.^{5,10} Terlipressin (a vasopressin analogue that has some effects as a vasopressin agonist) is reported to be an effective treatment for refractory hypotension during anaesthesia in patients taking ACE inhibitors.^{4,14,15} One study found that severe hypotension during anaesthetic induction in patients chronically taking ACE inhibitors could be controlled with an intravenous injection of angiotensin II (*Hypertensine*).¹⁶

(b) Alpha blockers

The UK manufacturers of **alfuzosin** note that the use of general anaesthetics in patients taking **alfuzosin** could cause profound hypotension, and they recommend that **alfuzosin** should be withdrawn 24 hours before surgery.¹⁷

(c) Angiotensin II receptor antagonists

A study in 12 hypertensive patients taking angiotensin-II receptor antagonists found that hypotension occurred in all patients after induction of anaesthesia. This was more frequent than that found in matched groups of hypertensive patients receiving either beta blockers and/or calcium-channel blockers (27 out of 45) or ACE inhibitors (18 of 27). The magnitude of hypotension was also significantly greater in those treated with angiotensin II receptor antagonists and it was less responsive to ephedrine and phenylephrine.¹⁴ Terlipressin has been found to be effective in patients with refractory hypotension taking angiotensin II receptor antagonists.^{14,15}

Anaesthetics, general + Antipsychotics

An isolated report describes a grand mal seizure in a man taking chlorpromazine and flupentixol when he was anaesthetised with enflurane. The sedative properties of antipsychotics may be enhanced by thiopental. Lower etomidate doses are recommended in patients taking antipsychotics.

Clinical evidence, mechanism, importance and management

An isolated report¹ describes an unexpected grand mal seizure in a schizophrenic patient without a history of epilepsy when he was given **enflurane** anaesthesia. He was taking **chlorpromazine** 50 mg three times daily (irregularly) and **flupentixol** 40 mg intramuscularly every 2 weeks. The suggested reason is that the **enflurane** had a synergistic effect with the two

antipsychotics, all of which are known to lower the seizure threshold. The general importance of this interaction is not known.

The manufacturer of thiopental notes that, as would be expected, the sedative properties of antipsychotics may be potentiated by **thiopental**.² The manufacturer of etomidate recommends that the dose of **etomidate** should be reduced in patients taking antipsychotics.³ **Droperidol** reduces the dose requirements of **thiopental**, see 'Anaesthetics, general + Antiemetics', p.94.

Anaesthetics, general + Aspirin or Probenecid

The anaesthetic dosage of thiopental is reduced, and its effects prolonged by pretreatment with aspirin or probenecid.

Clinical evidence

A study in patients about to undergo surgery found that pretreatment with aspirin 1 g (given as intravenous **lysine acetylsalicylate**) one minute before induction reduced the dosage of thiopental by 34%, from 5.3 to 3.5 mg/kg. Initially thiopental 2 mg/kg was given followed by increments of 25 mg until the eyelash reflex was abolished.¹ The same study¹ also found that oral probenecid 1 g given one hour before anaesthesia reduced the thiopental dosage by 23%, from 5.3 to 4.1 mg/kg.

A further double-blind study² in 86 women found that probenecid given 3 hours before surgery prolonged the duration of anaesthesia with thiopental:

- In patients premedicated with atropine 7.5 micrograms/kg, pethidine (meperidine) 1 mg/kg, and 500 mg of probenecid, the duration of anaesthesia with thiopental 7 mg/kg was prolonged by 65%.
- In patients premedicated with atropine 7.5 micrograms/kg, pethidine 1 mg/kg, and 1 g of probenecid, the duration of anaesthesia with thiopental 7 mg/kg was prolonged by 46%.
- In patients premedicated with atropine 7.5 micrograms/kg (*no pethidine*) and 500 mg of probenecid, the duration of anaesthesia with thiopental 7 mg/kg was prolonged by 26%.
- In patients premedicated with atropine 7.5 micrograms/kg (*no pethidine*) and 500 mg of probenecid, and *no surgical stimulus* the duration of anaesthesia with thiopental 4 mg/kg was prolonged by 109%.

Mechanism

Not understood. It has been suggested that aspirin and probenecid increase the amount of free (and active) thiopental in the plasma since they compete for the binding sites on the plasma albumins.¹

Importance and management

Information is limited but what is known shows that the effects of thiopental are increased by aspirin and probenecid. Be alert for the need to reduce the dosage. However, note also that regular aspirin use may increase the risk of bleeding during surgery, and it is often recommended that aspirin should not be taken in the week before surgery.³

Anaesthetics, general + Baclofen

Severe seizures occurred during induction of anaesthesia with propofol in a patient taking baclofen.

Clinical evidence, mechanism, importance and management

A 48-year-old man with syringomyelia taking baclofen for flexor spasms underwent surgery for the relief of obstructive hydrocephalus. His last

dose of baclofen was 6 hours before induction of anaesthesia with pethidine (meperidine) 40 mg followed by **propofol**. After he had received about 60 mg of **propofol** he developed severe myoclonic seizures, which lasted about 3 minutes. The patient was given additional **propofol** 40 mg because he appeared to be awakening, and severe generalised seizures lasting 2 minutes occurred. He was then given vecuronium and anaesthesia was maintained with isoflurane and nitrous oxide/oxygen without further problem.¹

Seizures have been reported in patients with and without epilepsy receiving **propofol**. They mainly occur at induction or emergence or are delayed after anaesthesia, suggesting changes in cerebral levels of **propofol** may be causal.² Baclofen can cause acute desensitisation of GABA_B receptors producing persistent epileptiform discharges.¹ It was suggested that in this patient the seizures were mediated by both baclofen and **propofol**.¹ Opioid analgesics may induce seizures and opisthotonos has been reported in patients given opioids and **propofol** (see 'Anaesthetics, general + Opioids', p.103). However, generalised seizures attributed to pethidine are probably due to a metabolite. The time course therefore makes pethidine an unlikely cause of the seizure in this patient.¹

Anaesthetics, general + Benzodiazepines

Midazolam markedly potentiates the anaesthetic action of halothane. Similarly, the effects of propofol or thiopental are greater than would be expected by simple addition when midazolam is given concurrently, although the extent varies between the end-points measured (analgesic, motor, hypnotic). Quazepam reduces induction time for propofol anaesthesia and premedication with diazepam reduces the dose of ketamine required.

Clinical evidence

(a) Halothane

In a study in 50 women undergoing surgery **midazolam** markedly potentiated the anaesthetic action of halothane: a mean **midazolam** dose of 278 micrograms/kg reduced the halothane MAC by 51.3%.¹

(b) Ketamine

A study in patients undergoing major abdominal surgery found that in 10 patients premedicated with rectal **diazepam** one hour before induction, the haemodynamic effects of ketamine (increases in heart rate and blood pressure) were significantly reduced, when compared with 31 controls. Also, a lower rate of ketamine infusion was required during the initial 30 minutes of anaesthesia, the half-life of ketamine was significantly increased and the plasma levels of the hydroxylated metabolites were reduced. These findings suggest that both pharmacodynamic and pharmacokinetic interactions exist between **diazepam** and ketamine. In the same study, 3 patients were given 20 mg of intravenous **clorazepate** about one hour before induction of anaesthesia, but this did not affect either the dose of ketamine required or its pharmacokinetics.²

(c) Propofol

Two studies found that if propofol and **midazolam** were given together, the hypnotic and anaesthetic effects were greater than would be expected by the simple additive effects of both drugs.^{3,4} In one of these studies, the ED₅₀ (the dose required for 50% of the patients to respond) for hypnosis was 44% less than that expected of the individual drugs and the addition of **midazolam** 130 micrograms/kg caused a 52% reduction in the ED₅₀ of propofol required for anaesthesia.³ A pharmacokinetic study found a very modest 20% increase in the levels of free **midazolam** in the plasma when it was given with propofol, but this was considered too small to explain the considerable synergism.⁵ In a further double-blind, placebo-controlled study in 24 patients, premedication with intravenous **midazolam**, 50 micrograms/kg given 20 minutes before induction of anaesthesia, reduced the propofol dose requirements for multiple anaesthetic end-points, including hypnotic, motor, EEG and analgesia. However, the potentiating effect and the mechanism of the interaction appeared to vary with the anaesthetic end-point and the dose of propofol. Notably, the interaction was most marked for analgesia.⁶ Another double-blind, placebo-controlled

study in 60 children aged 1 to 3 years found that oral **midazolam** 500 micrograms/kg approximately 30 minutes before the induction of anaesthesia delayed early recovery from anaesthesia, which was induced with propofol and maintained with **sevoflurane** and **nitrous oxide/oxygen**. However, the time to hospital discharge was not prolonged.⁷

A further double-blind, placebo-controlled study in 24 patients found that propofol decreased the clearance of **midazolam** by 37% and increased its elimination half-life by 61%.⁸

A study in 33 patients found that **quazepam** 15 or 30 mg given the night before induction of anaesthesia with propofol and fentanyl reduced the induction time when compared with a third group of patients not given a hypnotic. **Quazepam** did not affect blood pressure or heart rate, but the 30 mg dose of **quazepam** did increase anterograde amnesia.⁹

(d) Thiopental

Thiopental has been shown to act synergistically with **midazolam** at induction of anaesthesia in two studies.^{10,11} In one of these studies, **midazolam** reduced the dose of thiopental required to produce anaesthesia by 50%.¹¹ In a further double-blind, placebo-controlled study in 23 patients, premedication with intravenous **midazolam** 50 micrograms/kg, given 20 minutes before the induction of anaesthesia, reduced the thiopental dose requirements for multiple anaesthetic end-points, including hypnotic, motor, EEG and analgesia. Potentiation was greatest for the motor end-point (about 40%) and smallest for analgesia (18%).¹²

Mechanism

Propofol, barbiturates and halothane appear to interact with benzodiazepines through their effects on the gamma-aminobutyric acid (GABA) receptor.

Diazepam appears to undergo similar oxidative processes as ketamine and therefore competitively inhibits ketamine metabolism.² Clorazepate is only slowly decarboxylated and is therefore not affected.²

An *in vitro* study suggests that propofol may reduce the clearance of **midazolam** by inhibition of the cytochrome P450 isoenzyme CYP3A4.⁸

Importance and management

The interactions between propofol or thiopental and **midazolam** are well established. This synergy has been utilised for the induction of anaesthesia.¹³ **Midazolam** also reduces the dose requirements of halothane. Other benzodiazepines may also potentiate the effects of general anaesthetics.

Anaesthetics, general + Beta-agonist bronchodilators

Two patients developed arrhythmias when terbutaline was given to patients anaesthetised with halothane.

Clinical evidence, mechanism, importance and management

Two patients developed ventricular arrhythmias while anaesthetised with **halothane** and nitrous oxide/oxygen when given **terbutaline** 250 to 350 micrograms subcutaneously for wheezing. Both developed unifocal premature ventricular contractions followed by bigeminy, which responded to lidocaine.¹ **Halothane** was replaced by **enflurane** in one case, which allowed the surgery to be completed without further incident.¹

Halothane is known to cause arrhythmias and it has been suggested that it may increase susceptibility to the adverse cardiac effect of beta-agonist bronchodilators,² which can cause arrhythmias. Note that beta agonists such as **terbutaline** are sympathomimetics (see 'Table 24.1', (p.879)), like adrenaline (epinephrine), which has also been shown to cause arrhythmias in the presence of **halothane** (see 'Anaesthetics, general + Inotropes and Vasopressors', p.99).

Anaesthetics, general + Beta blockers

Anaesthesia in the presence of beta blockers normally appears to be safer than withdrawal of the beta blocker before anaesthesia, provided certain inhalational anaesthetics are avoided (methoxyflurane, cyclopropane, ether, trichloroethylene) and atropine is used to prevent bradycardia. Bradycardia and marked hypotension occurred in a man using timolol eye drops when he was anaesthetised.

Acute peri-operative administration of beta blockers may reduce the dose of anaesthetic required for induction and may result in deeper anaesthesia.

Clinical evidence and mechanism

A. Cardiac depressant effects

It used to be thought that beta blockers should be withdrawn from patients before surgery because of the risk that their cardiac depressant effects would be additive with those of inhalational anaesthetics, resulting in a reduction in cardiac output and blood pressure, but it seems that any effect depends on the anaesthetic used.¹ It has been suggested that the ranking order of compatibility (from the least to the most compatible with beta blockers) is as follows: **methoxyflurane, ether, cyclopropane, trichloroethylene, enflurane, halothane, isoflurane.**¹

(a) Cyclopropane, Ether, Methoxyflurane, and Trichloroethylene

A risk of cardiac depression certainly seems to exist with cyclopropane and ether because their depressant effects on the heart are normally counteracted by the release of catecholamines, which would be blocked by the presence of a beta blocker. There is also some evidence (clinical and/or animal) that unacceptable cardiac depression may occur with methoxyflurane and trichloroethylene when a beta blocker is present. This has been the subject of two reviews.^{2,3} For these four inhalational anaesthetics it has been stated that an absolute indication for their use should exist before giving them in combination with a beta blocker.¹

(b) Enflurane, Halothane, and Isoflurane

Although a marked reduction in cardiac performance has been described in a study in dogs given **propranolol** and enflurane (discussed in two reviews^{2,3}) these drugs have been widely used without apparent difficulties.¹ Normally beta blockers and halothane or isoflurane appear to be safe. On the positive side there appear to be considerable benefits to be gained from the continued use of beta blockers during anaesthesia. Their sudden withdrawal from patients treated for angina or hypertension can result in the development of acute and life-threatening cardiovascular complications whether the patient is undergoing surgery or not.

In the peri-operative period patients benefit from beta blockade because it can minimise the effects of sympathetic overactivity of the cardiovascular system during anaesthesia and surgery (for example during endotracheal intubation, laryngoscopy, bronchoscopy and various surgical manoeuvres), which can cause cardiac arrhythmias and hypertension.

(c) Unnamed general anaesthetic

A 75-year-old man being treated with **timolol** eye drops for glaucoma developed bradycardia and severe hypotension when anaesthetised [drug not

named], and responded poorly to intravenous atropine, dextrose-saline infusion and elevation of his feet.⁴ It would seem that there was sufficient systemic absorption of the **timolol** for its effects to be additive with the anaesthetic and cause marked cardiodepression.

B. Reduction of anaesthetic requirements

Intra-operative intravenous **atenolol** given in 5-mg stepwise doses (median dose 20 mg; range 10 to 80 mg) was found to reduce the **isoflurane** requirement by about 40% without affecting the bispectral index (BIS; a predictor of the depth of anaesthesia). Patients also received on average 21% less fentanyl compared with control patients who were not given **atenolol.**⁵

Several studies have similarly found that the use of **esmolol** reduced the required dose of **isoflurane** or **propofol**, or resulted in a deeper anaesthesia (as measured by BIS), but only in the presence of an opioid.^{6–10} As there appears to be no pharmacokinetic interaction between **esmolol** and **propofol**^{6,8} it has been suggested that **esmolol** could be interacting with the opioid.^{6,10}

However, in one study 60 patients were given one of three treatments before induction of anaesthesia with **propofol**: **esmolol** 1 mg/kg followed by an infusion of 250 micrograms/kg per minute; midazolam; or placebo (sodium chloride 0.9%). No opioids were given. **Esmolol** and midazolam reduced the required induction doses of **propofol** by 25% and 45%, respectively. **Esmolol** reduced the mean heart rate by 7.6 bpm compared with placebo in the pre-induction period, and the only adverse effect noted was a transient episode of bradycardia (44 bpm) in one patient receiving **esmolol.** **Esmolol** reduces cardiac output by reduction of heart rate and stroke volume and this possibly reduces the required induction dose of **propofol** by changing its distribution.¹¹

Another study found that a single 80-mg dose of **esmolol** after induction of anaesthesia with **propofol** and either fentanyl or placebo did not affect the depth of anaesthesia (measured by BIS) in either group of patients, even though cardiovascular effects were seen (reduction in systolic arterial pressure and heart rate).¹²

Importance and management

A. The consensus of opinion is that beta blockers should not be withdrawn before anaesthesia and surgery^{13,14} because of the advantages of maintaining beta-blockade, and because the risks accompanying withdrawal are considerable. But, if inhalational anaesthetics are used, it is important to select the safest anaesthetics (isoflurane, halothane), and avoid those that appear to be most risky (methoxyflurane, ether, cyclopropane, trichloroethylene: most of which are no longer regularly used), as well as ensuring that the patient is protected against bradycardia by atropine.

The authors of the report⁴ concerning topically applied beta blockers suggest that if such patients are to be anaesthetised, low concentrations of timolol should be used (possibly withhold the drops pre-operatively), and that "induction agents should be used judiciously and beta-blocking antagonists kept readily available." It is easy to overlook the fact that systemic absorption from eye drops can be high enough to cause adverse interactions.

B. Several studies suggest that beta blockers, such as atenolol and esmolol, given before induction reduce the anaesthetic dose requirement and may potentiate hypnosis. However, there are concerns that reducing the dose of anaesthetic may increase the risk of intra-operative awareness and it has been suggested that the use of BIS to predict the depth of anaesthesia in the presence of beta blockers may not be valid.¹⁵ There is a possibility that acute as well as chronic administration of beta blockers may prevent peri-operative cardiac complications,^{12,14} but more study is needed on this.^{14,15}

Anaesthetics, general + Calcium-channel blockers

Impaired myocardial conduction has been seen in two patients taking diltiazem after they were anaesthetised with enflurane, and prolonged anaesthesia has been seen with verapamil and etomidate, but it has been suggested that chronic administration of oral calcium-channel blockers up to the day of surgery is usually beneficial. Intravenous dihydropyridines have been used to control peri-operative hypertension, but the use of intravenous verapamil is not recommended in patients anaesthetised with either halothane or enflurane.

Clinical evidence, mechanism, importance and management

(a) Dihydropyridines

Enhanced hypotension was seen in a study in which patients were given intravenous **nimodipine** during general anaesthesia, which included either **halothane** or **isoflurane**.¹

The presence of low concentrations of **isoflurane** (0.6%) or **sevoflurane** (0.9%) are reported not to have a marked effect on the pharmacological action of **nicardipine**.² In one study intravenous **nicardipine** 17 micrograms/kg was given to 30 neurosurgical patients anaesthetised with either **enflurane**, **isoflurane** or **sevoflurane**. Peak reductions in blood pressure occurred 3 minutes after **nicardipine** was given and were greatest in the group receiving **sevoflurane**. However, peak reductions in blood pressure persisted for longer (30 minutes), as did increases in heart rate, with **isoflurane**. However, clearance of **nicardipine** was most rapid in patients given **isoflurane** anaesthesia.³

Some caution is clearly appropriate, especially with intravenous calcium-channel blockers given during surgery, but general experience suggests that long-term treatment with oral dihydropyridine calcium-channel blockers need not be avoided in most patients undergoing anaesthesia, and may be continued until the day of surgery. Further, intravenous dihydropyridines have been reported to be safe and effective for the control of peri-operative hypertension.⁴

(b) Diltiazem or Verapamil

The author of a review about calcium-channel blockers and anaesthetics concludes that their concurrent use in patients with reasonable ventricular function is normally beneficial, except where there are other complicating factors. Thus he warns about possible decreases in ventricular function in patients undergoing open chest surgery given intravenous verapamil or diltiazem.⁵ A report describes a patient taking diltiazem and atenolol who had impaired AV and sinus node function before anaesthesia, which worsened following the use of **enflurane**.⁶ Another patient also taking diltiazem (and atenolol) had to be paced due to bradycardia of 35 bpm at induction, but despite this he developed severe sinus bradycardia, which progressed to asystole when **enflurane** was given.⁶ The authors of this latter report suggest that **enflurane** and diltiazem can have additive depressant effects on myocardial conduction. Two cases of prolonged anaesthesia and Cheyne-Stokes respiration have been reported in patients who were undergoing cardioversion. Both received verapamil and were induced with **etomidate**.⁷ The presence of low concentrations of **isoflurane** (0.6%) or **sevoflurane** (0.9%) are reported not to have a marked effect on the pharmacological action of diltiazem.²

The authors of a review concluded that intravenous verapamil or diltiazem are not recommended in patients anaesthetised with either **halothane** or **enflurane**, especially if the patients have cardiac failure or conduction disturbances.⁸

Anaesthetics, general + Dexmedetomidine

Dexmedetomidine can reduce the dose requirements of thiopental, isoflurane, and other similar anaesthetics.

Clinical evidence, mechanism, importance and management

Dexmedetomidine reduced the **thiopental** dose requirement for EEG burst suppression by 30% in 7 patients, when compared with 7 control patients given placebo. In this study, dexmedetomidine was given for 35 minutes before anaesthesia and during anaesthesia at a dose of 100 nanograms/kg per minute for the first 10 minutes, 30 nanograms/kg per minute for the following 15 minutes, and 6 nanograms/kg per minute thereafter. There was no pharmacodynamic synergism, and pharmacokinetic analysis showed that dexmedetomidine significantly reduced the **thiopental** distribution, probably due to reduced cardiac output and decreased regional blood flow.¹

A placebo-controlled study in women undergoing abdominal hysterectomy found that a dexmedetomidine infusion started 15 minutes before induction of anaesthesia caused a dose-dependent reduction in **isoflurane** MAC (by 35% and 47% with dexmedetomidine plasma levels maintained at 0.37 and 0.69 nanograms/mL, respectively).² In another study, dexmedetomidine reduced the ED₅₀ dose requirement of **isoflurane** for anaesthesia (motor response) in 9 healthy subjects. Dexmedetomidine plasma levels of 0.35 and 0.75 nanograms/mL reduced the requirements for **isoflurane** by about 30% and 50%, respectively. Subjects who had received dexmedetomidine took longer to wake up.³ Dexmedetomidine has sedative, analgesic and anxiolytic effects⁴ and therefore, like other sedatives, may reduce the dose requirements of anaesthetics. However, it may also affect the distribution of **thiopental** and possibly other intravenous anaesthetics.

Anaesthetics, general + Herbal medicines

Animal data suggest that valerian may prolong the effect of thiopental. It has been predicted that kava kava and St John's wort may also prolong the effects of anaesthetics. There is an isolated report of profound hypotension during anaesthesia following the long-term use of St John's wort, and a tentative report of increased bleeding attributed to the concurrent use of sevoflurane and aloe vera. The American Society of Anesthesiologists recommends that all herbal medicines should be stopped two weeks prior to elective surgery.

Clinical evidence and mechanism

(a) Aloe vera

A case report describes a 35-year-old woman undergoing surgery for a hemangioma of the left thigh, who had twice the expected intra-operative blood loss. The patient had been taking 4 tablets of aloe vera for 2 weeks

prior to surgery, and so the blood loss was attributed to an interaction between the herbal medicine and the **sevoflurane**, which was used to maintain anaesthesia.¹ **Sevoflurane** can inhibit platelet aggregation by inhibiting thromboxane A₂, and aloe vera affects prostaglandin synthesis, which may also impair platelet aggregation. However, it should be noted that the patient's aPTT and INR were not assessed pre-operatively and the authors do state that the vascularity and size of the haemangioma were the most important factors in the blood loss,¹ so an interaction is by no means proven.

(b) *Kava kava*

There is one case report of kava kava potentiating the effect of benzodiazepines (see 'Benzodiazepines + Kava', p.730), and it has been suggested that it could potentiate other CNS depressants including **barbiturates**^{2,3} (e.g. **thiopental**), and may prolong or potentiate the effects of anaesthetics.⁴⁻⁶ Kava may act via GABA receptors, and kavalactones (one group of active constituents) also have skeletal muscle relaxant and local anaesthetic properties.^{2,3} Toxic doses can produce muscle weakness and paralysis.^{2,3}

(c) *St John's wort (Hypericum perforatum)*

It has been suggested that St John's wort (*Hypericum perforatum*) may prolong anaesthesia,^{4,7} but there are no reports of this. This appears to have been based on the possibility that St John's wort acts as an MAOI,^{5,7,8} (although this has been disputed⁹) and the limited evidence that MAOIs may cause hepatic enzyme inhibition and potentiate the effects of barbiturates (see 'MAOIs + Barbiturates', p.1132). However, there is now increasing evidence that St John's wort induces hepatic enzymes, and might therefore increase the metabolism of barbiturates (see 'Antiepileptics + St John's wort (*Hypericum perforatum*)', p.523), which suggests that it could increase requirements for **thiopental** anaesthesia. The possible MAOI activity of St John's wort has led to the recommendation that the same considerations apply as for other MAOIs and general anaesthetics,^{7,8} see 'Anaesthetics, general + MAOIs', p.100. A case report describes a healthy 23-year-old woman who had been taking St John's wort on a daily basis for 6 months, who developed severe hypotension (BP 60/20 mmHg) during general anaesthesia, which responded poorly to ephedrine and phenylephrine (BP increased to 70/40 mmHg). It was suggested that the St John's wort might have caused adrenergic desensitisation with decreased responsiveness to the vasopressors.¹⁰

(d) *Valerian*

An ethanol extract of valerian (*Valeriana officinalis*) was shown to modestly prolong **thiopental** anaesthesia in mice, possibly via its effects on the GABA-benzodiazepine receptor.¹¹

Importance and management

Not established. The evidence presented suggests that some caution may be warranted in patients using valerian, kava kava, or St John's wort if they are given general anaesthetics. The situation with aloe vera is less clear. Many other herbs have the potential to cause problems in the care of patients undergoing surgery (other than via drug interactions with anaesthetics) and these have been reviewed.⁵⁻⁷ Because of the limited information, the American Society of Anesthesiologists have recommended discontinuation of all herbal medicines 2 weeks before an elective anaesthetic^{4,6} and if there is any doubt about the safety of a product, this may be a prudent precaution.⁵

Anaesthetics, general + Inotropes and Vasopressors

Patients anaesthetised with inhalational anaesthetics (particularly cyclopropane and halothane, and to a lesser extent desflurane, enflurane, ether, isoflurane, methoxyflurane, and sevoflurane) can develop cardiac arrhythmias if they are given adrenaline (epinephrine) or noradrenaline (norepinephrine), unless the dosages are very low. Children appear to be less susceptible to this interaction. The addition of adrenaline to intrathecal tetracaine enhances the sedative effects of propofol.

Clinical evidence, mechanism, importance and management

As early as 1895, it was noted that an adrenal extract could cause ventricular fibrillation in a *dog* anaesthetised with **chloroform**,¹ and it is now very well recognised that similar cardiac arrhythmias can be caused by **adrenaline** and **noradrenaline** in humans anaesthetised with **inhalational anaesthetics**. The mechanism appears to be a sensitisation of the myocardium to β -adrenergic stimulation, caused by the **inhalational anaesthetic**. The likelihood of arrhythmias is increased by hypoxia and marked hypercapnia. It has been reported that the highest incidence of complications has been in patients anaesthetised with **cyclopropane**, but that the incidence is also high with **trichloroethylene** and **halothane**.² A suggested listing of inhalational anaesthetics in order of decreasing sensitising effect on the myocardium is as follows:³ **cyclopropane**, **halothane**, **enflurane/methoxyflurane**, **isoflurane**, **ether**. **Sevoflurane**⁴ and **desflurane**⁵ appear to behave like **isoflurane**.

It has been recommended that if **adrenaline** is used to reduce surgical bleeding in patients anaesthetised with **halothane/nitrous oxide/oxygen** the dosage should not exceed 10 mL of 1:100 000 in any given 10 minute period, nor 30 mL per hour (i.e. about a 100 microgram bolus or 1.5 micrograms/kg per 10 minutes for a 70 kg person), and adequate alveolar ventilation must be assured.⁶ This dosage guide should also be safe for use with other inhalational anaesthetics since **halothane** is more arrhythmogenic than the others,³ with the exception of **cyclopropane**, which is no longer widely used. However, some have suggested that concurrent **halothane** and **adrenaline** may have been a contributing factor in 3 deaths in patients undergoing tooth implant surgery.⁷ Others consider that if **adrenaline** is used for haemostasis during surgery, **isoflurane** or **sevoflurane** carry less risk of cardiac arrhythmias than **halothane**.⁸ Solutions containing 0.5% **lidocaine** with **adrenaline** 1:200 000 also appear to be safe because lidocaine may help to control the potential dysrhythmic effects. For example, a study in 19 adult patients anaesthetised with **halothane** found that the dose of **adrenaline** needed to cause three premature ventricular contractions in half the group was 2.11 micrograms/kg when it was given in saline, but 3.69 micrograms/kg when it was given in 0.5% **lidocaine**. Note that both these values were less than that in 16 patients anaesthetised with **isoflurane** (6.72 micrograms/kg), demonstrating that **isoflurane** was still safer.⁹ It should be borne in mind that the arrhythmogenic effects of **adrenaline** are increased if sympathetic activity is increased, and in hyperthyroidism and hypercapnia.³

Children appear to be much less susceptible to these effects than adults. A retrospective study of 28 children found no evidence of arrhythmia during **halothane** anaesthesia with **adrenaline** doses of up to 8.8 micrograms/kg, and a subsequent study in 83 children (aged 3 months to 17 years) found that 10 micrograms/kg doses of **adrenaline** were safe.¹⁰

A study in 20 patients undergoing spinal anaesthesia with tetracaine found that **propofol** sedation (as measured by bispectral index monitoring (BIS)) was enhanced when **adrenaline** was added to the intrathecal tetracaine.¹¹ A study in *sheep* found that **adrenaline**, **noradrenaline** and **dopamine** decreased **propofol** concentrations during a continuous propofol infusion, with the result that **propofol** anaesthesia was reversed. This was thought to be due to increased first pass clearance of **propofol** secondary to increased cardiac output. It was concluded that this could be of clinical importance if **propofol** is used in hyperdynamic circulatory conditions induced by either catecholamine infusions or disease states such as sepsis.¹²

Anaesthetics, general + Isoniazid

Isoniazid may increase the metabolism of enflurane, isoflurane or sevoflurane and thereby increase plasma-fluoride concentrations. However, this does not seem to have resulted in clinically important renal impairment.

Clinical evidence, mechanism, importance and management

A 46-year-old woman underwent anaesthesia for renal transplantation 6 days after starting isoniazid 300 mg daily. Anaesthesia was induced with intravenous thiopental and maintained for 4 hours with 60% nitrous oxide, fentanyl and **isoflurane**. Serum fluoride ions increased from 4.3 micromol preoperatively to approximately 30 micromol between 2 and 8 hours after starting **isoflurane**. However, no impairment of renal function occurred. A second patient who was given 5 times the first patient's exposure to **isoflurane** and who had received isoniazid for 13 years showed no increase in serum fluoride concentrations over preoperative values, but did show an increase in trifluoroacetic acid levels.¹

When **enflurane** was given to 20 patients who had been taking isoniazid 300 mg daily for between one week and one year, 9 had an increase in peak fluoride ion levels. These 9 patients had a fourfold higher fluoride level than 36 control subjects not taking isoniazid and the 11 other subjects taking isoniazid. By 48 hours after anaesthesia, there was no difference in fluoride levels. Despite the increase in fluoride levels, there was no change in renal function.²

Isoniazid may increase the metabolism of **enflurane**, **isoflurane** or **sevoflurane**^{3,4} in some patients (probably related to isoniazid acetylase phenotype²) and so increase the release of fluoride ions that may cause nephrotoxicity. However, there do not appear to be any reports of a significant clinical effect on renal function.

Anaesthetics, general + Levothyroxine

Marked hypertension and tachycardia occurred in two patients taking levothyroxine when they were given ketamine.

Clinical evidence, mechanism, importance and management

Two patients taking levothyroxine developed severe hypertension (240/140 and 210/130 mmHg, respectively) and tachycardia (190 and 150 bpm) when they were given **ketamine**. Both were effectively treated with 1 mg of intravenous propranolol.¹ It was not clear whether this was an interaction or simply a particularly exaggerated response to **ketamine**, but care is clearly needed if **ketamine** is given to patients taking thyroid replacement.

Anaesthetics, general + MAOIs

It is generally recommended that MAOIs should be withdrawn at least 2 weeks before anaesthesia. Individual cases of both hypotension and hypertension have been seen and MAOIs can interact dangerously with other drugs sometimes used during surgery (particularly pethidine (meperidine) and ephedrine).

Clinical evidence

The absence of problems during emergency general anaesthesia in 2 patients taking MAOIs prompted further study in 6 others receiving long-term treatment with unnamed MAOIs. All 6 were premedicated with 10 to 15 mg of diazepam 2 hours before surgery, induced with **thiopental**, given suxamethonium (succinylcholine) before intubation, and maintained with **nitrous oxide/oxygen** with either **halothane** or **isoflurane**. Pancuronium was used for muscle relaxation, and morphine was given postoperatively. One patient experienced hypotension that responded to repeated 100-microgram intravenous doses of phenylephrine without hypertensive reactions. No other untoward events occurred either during or after the anaesthesia.¹

No adverse reactions occurred in 27 other patients taking MAOIs (**tranylcypromine**, **phenelzine**, **isocarboxazid**, **pargyline**) when they were anaesthetised.² A retrospective review of 32 patients taking **isocarboxazid** 10 mg daily who underwent elective surgery (involving **thiopental** or **ketamine** for induction of anaesthesia and maintenance with an inhalation anaesthetic with or without a muscle relaxant or analgesic) found that 5 patients experienced intra-operative hypotension, another patient had hypertension, and bradycardia occurred in 4 patients. No postoperative complications were attributed to interaction between the MAOI and the drugs given peri-operatively.³

No problems were seen in *dogs* given **tranylcypromine**, anaesthetised with **enflurane** and fentanyl, and then given the vasopressors noradrenaline (norepinephrine) and ephedrine.⁴ Two case reports describe the safe and uneventful use of **propofol** in a patient taking **phenelzine**⁵ and another taking **tranylcypromine**.⁶ The latter was also given alfentanil. No problems were seen in one patient taking **tranylcypromine** when **ketamine** was given,⁷ and in another taking **selegiline** when fentanyl, **isoflurane** and midazolam were given.⁸ No problems were seen in another patient taking **phenelzine** when anaesthetised firstly with **sevoflurane** in oxygen, followed by **isoflurane**, oxygen, air and an infusion of remifentanyl.⁹

Unexplained hypertension has been described in a patient taking **tranylcypromine** when **etomidate** and atracurium were given.¹⁰ Severe and prolonged cardiovascular collapse occurred in one patient in whom long-term **tranylcypromine** 10 mg four times daily therapy was discontinued 20 days before surgery. During surgery **etomidate** and suxamethonium were given for induction, and **isoflurane** and **nitrous oxide/oxygen** for maintenance, as well as epidural anaesthesia with bupivacaine, but without an opioid.¹¹ **Moclobemide** was stopped on the morning of surgery in a patient who was anaesthetised with **propofol** and later **isoflurane** in **nitrous oxide** and oxygen. Atracurium, morphine and droperidol were also used. No adverse reactions occurred.¹² **Ketorolac**, **propofol** and midazolam were used uneventfully in one patient taking **phenelzine**.¹³

There are a few anecdotal reports of MAOIs potentiating the effects of amobarbital, butobarbital and secobarbital—see 'MAOIs + Barbiturates', p.1132.

Mechanism, importance and management

There seems to be little documentary evidence that the withdrawal of MAOIs before giving an anaesthetic is normally necessary. Scrutiny of reports¹⁴ alleging an adverse reaction usually shows that what happened could be attributed to an interaction between other drugs used during the surgery (e.g. either 'directly-acting sympathomimetics', (p.1146), 'indirectly-acting sympathomimetics', (p.1147), 'pethidine', (p.1140), or 'fentanyl', (p.1138)) rather than with the anaesthetics.

The authors of two of the reports cited here offer the opinion that 'general and regional anaesthesia may be provided safely without discontinuation of MAOI therapy, provided proper monitoring, adequate preparation, and prompt treatment of anticipated reactions are utilised'.^{1,2} This implies that the possible interactions between the MAOI and other drugs are fully recognised, but be alert for the rare unpredictable response. The conclusion of another report was that patients on low-dose MAOIs could be safely anaesthetised.³

The BNF¹⁵ states that 'in view of their hazardous interactions MAOIs should normally be stopped 2 weeks before surgery.' It has also been suggested that a longer period of time (more than 20 days) between discontinuing MAOIs and surgery may be required, not so much to recover MAO enzyme activity but to recover depressed adrenergic receptor function.¹¹ These warnings are probably more to avoid interactions with the anaesthetic adjuncts mentioned above, rather than the MAOIs themselves. Therefore in an emergency situation it would seem possible to anaesthetise a patient, but it must be remembered that the choice of anaesthetic adjuncts is likely to be restricted.

Anaesthetics, general + Methylphenidate

A single report described difficulty in sedating a child taking methylphenidate, and a possible delayed interaction between ketamine and methylphenidate, which resulted in nausea, vomiting and dehydration. The use of methylphenidate after ketamine anaesthesia increased the incidence of vomiting, excessive talking, and limb movements in one study. Methylphenidate should probably be withheld before surgery using inhalational anaesthetics, because of the potential risk of hypertension and/or arrhythmias.

Clinical evidence, mechanism, importance and management

A 6-year-old boy weighing 22 kg, who was taking methylphenidate 5 mg twice daily for attention deficit disorder, was found to be difficult to sedate for an echocardiogram. Sedation was attempted with oral cloral hydrate 75 mg/kg without success. One week later he received midazolam 20 mg orally, but was only mildly sedated 20 minutes later and would not lie still. Despite an additional oral dose of midazolam 10 mg mixed with oral **ketamine** 60 mg the child was still alert and uncooperative 20 minutes later. He was finally given intravenous glycopyrronium (glycopyrrolate) 100 micrograms followed by intravenous midazolam 5 mg given over 5 minutes and was successfully sedated. He recovered from sedation uneventfully, but developed nausea, vomiting and lethargy after discharge from hospital, which responded to rehydration treatment.¹ In a double-blind study, methylphenidate was given as a single 20-mg intravenous dose to try to speed recovery at the end of **ketamine** anaesthesia for short urological procedures. However, methylphenidate did not improve recovery, and increased the incidence of vomiting, excessive talking, and limb movements.²

In the first case, the stimulant effect of the methylphenidate was thought to have antagonised the sedative effect of the midazolam and **ketamine**. The methylphenidate may also have delayed the absorption of the oral drugs. In addition, methylphenidate may inhibit liver microsomal enzymes and could therefore possibly delay elimination of both **ketamine** and midazolam so that hazardous plasma concentrations could develop.¹ However, the study did not find evidence of these effects.

These appear to be the only reports, so any effect is not established. Be aware that methylphenidate may possibly antagonise the effect of sedative

drugs, and may also be associated with an increased incidence of vomiting. Note that methylphenidate is an indirectly-acting sympathomimetic, and as such might be expected to increase the risk of hypertension and arrhythmias if used with **inhalational anaesthetics** (consider 'Anaesthetics, general + Inotropes and Vasopressors', p.99). Because of this, the manufacturer of one brand of methylphenidate recommends that, if surgery with halogenated anaesthetics is planned, methylphenidate treatment should not be given on the day of surgery.³ Taken together, these reports suggest this advice may be a prudent precaution for any form of sedation and/or general anaesthesia.

Anaesthetics, general + Neuromuscular blockers

The inhalational anaesthetics increase the effects of the neuromuscular blockers to differing extents, but nitrous oxide appears not to interact significantly. Ketamine has been reported to potentiate the effects of atracurium. Propofol does not appear to interact with mivacurium or vecuronium. Xenon is reported not to interact with mivacurium or rocuronium, and has less effect than sevoflurane on vecuronium neuromuscular blockade. Bradycardia has been seen in patients given vecuronium with etomidate or thiopental. Propofol can cause serious bradycardia if it is given with suxamethonium (succinylcholine) without adequate antimuscarinic premedication, and asystole has been seen when fentanyl, propofol and suxamethonium were given sequentially.

Clinical evidence, mechanism, importance and management

A. Effects of anaesthetics on neuromuscular blockade

(a) Inhalational anaesthetics

The effects of neuromuscular blockers are increased by inhalational anaesthetics, the greater the dosage of the anaesthetic the greater the increase in blockade. In broad terms **desflurane**, **ether**, **enflurane**, **isoflurane**, **methoxyflurane** and **sevoflurane** have a greater effect than **halothane**, which is more potent than **cyclopropane**, whereas **nitrous oxide** appears not to interact significantly with competitive blockers.^{1–7}

The mechanism is not fully understood but seems to be multifactorial. It has been suggested that the anaesthetic may:

- have an effect via the CNS (including depression of spinal motor neurones);
- have an effect on the neuromuscular junction (including a decrease in the release of acetylcholine and in the sensitivity of the motor end-plate to acetylcholine);
- affect the muscle tissue itself.^{6,8}

It has also been suggested that for **mivacurium**, higher plasma levels, especially of the potent *trans-trans* isomer, occur in the presence of **isoflurane**, and these could contribute to the enhanced neuromuscular blockade observed.⁹

One study in children found that the potentiation of **vecuronium** was greater with **isoflurane** than with **enflurane**, and **halothane** had a lesser effect.¹⁰

The dosage of the neuromuscular blocker may need to be adjusted according to the anaesthetic in use. For example, the dosage of **atracurium** can be reduced by 25 to 30% if, instead of balanced anaesthesia (with **thiopental**, fentanyl and **nitrous oxide/oxygen**),¹¹ **enflurane** is used, and by up to 50% if **isoflurane** or **desflurane** are used.^{4,12,13} Another study recommended reduced doses of neuromuscular blockers such as **atracurium** and **tubocurarine** in children undergoing anaesthesia with **enflurane** or **isoflurane**.¹⁴ In one study, **enflurane** and **isoflurane** reduced the **vecuronium** infusion rate requirements by as much as 70%, when compared with fentanyl anaesthesia.¹⁵ Another study demonstrated that although **halothane** and **isoflurane** could both increase the neuromuscular potency of **vecuronium**, only **isoflurane** prolonged the recovery from neuromuscular blockade.¹⁶

The duration of exposure to the anaesthetic and the duration of effect of the various neuromuscular blockers also appear to affect the degree of potentiation that occurs.^{8,17} In a study in which the muscle relaxant was given about 5 minutes after the start of inhalational anaesthesia, **enflurane** prolonged the action of **atracurium**, **pipecuronium** and **pancuronium**, but did not significantly affect **vecuronium**. However, **halothane** did not significantly prolong the clinical duration of any of the neuromuscular blockers.¹⁷ It was suggested that more prolonged exposure to the anaesthetic, allowing equilibration of the anaesthetic to the tissues, might result in more significant potentiation of the neuromuscular blockers. In addition, the duration of effect of the **vecuronium** may have been too short for interaction with a volatile anaesthetic that had not had time to equilibrate with the tissues.¹⁷ The duration of exposure to **sevoflurane** also influences the dose-response of **vecuronium**, but it has been suggested that sevoflurane-induced potentiation of neuromuscular blockers might be more rapid than with other inhalational anaesthetics.⁸ In one study when the volatile anaesthetics were given about 10 minutes before the neuromuscular blocker, **sevoflurane** was reported to increase and prolong the blockade of **rocuronium** more than **isoflurane** or **propofol**.¹⁸ However, another study found that after a 40-minute equilibration period of the inhalation anaesthetic (steady-state conditions), there was no significant difference between **desflurane**, **isoflurane** and **sevoflurane** in relation to potency, infusion requirements or recovery characteristics of **rocuronium**; the potency of **rocuronium** was increased by 25 to 40% under inhalational anaesthesia compared with **propofol**.¹⁹ Another study demonstrated considerable prolongation of neuromuscular blockade with **rapacuronium** in the presence of **sevoflurane**; the recovery times were approximately doubled compared with those given in the published literature using thiopental/opioid-nitrous oxide anaesthesia. This led to the study being prematurely terminated as spontaneous recovery of neuromuscular function was required after short surgical procedures.²⁰ Marked potentiation of neuromuscular block following the combination of **sevoflurane** and a small dose of **cisatracurium** 25 micrograms/kg has been reported in a myasthenic patient.²¹

Although it is generally assumed that **nitrous oxide** does not affect the potency of neuromuscular blockers, one study found that the administration of **nitrous oxide** increased **suxamethonium** (**succinylcholine**) neuromuscular blockade.²²

Xenon is reported not to prolong the neuromuscular blocking effects of **rocuronium**.²³ It is also reported to have less effect on recovery from **vecuronium**-induced neuromuscular block than **sevoflurane**.²⁴ **Xenon** is also reported not to affect the onset time, duration and recovery from **mivacurium**.²⁵

In two early studies, **halothane** was found to shorten the recovery from **pancuronium**²⁶ and **gallamine**.²⁷

(b) Intravenous anaesthetics

Ketamine prolonged the duration of neuromuscular blockade induced by **atracurium**,²⁸ but did not influence **suxamethonium** (**succinylcholine**)-induced neuromuscular blockade.²⁹ However, the UK manufacturers of **suxamethonium** still warn of a possible interaction because they say that **ketamine** may reduce normal plasma cholinesterase activity.³⁰

In *animals*, **ketamine** and **thiopental** potentiated the neuromuscular blocking effects of **rocuronium**, whereas **propofol** had no effect.³¹

The original formulation of **propofol** in *Cremophor* was found to increase the blockade due to **vecuronium**,³² but the more recent formulation in soybean oil and egg phosphatide has been found in an extensive study not to interact with **vecuronium**.³³ **Propofol** also appears not to interact with **mivacurium**.⁹

B. Cardiac effects

Serious sinus bradycardia (heart rates of 30 to 40 bpm) developed rapidly in two young women when they were anaesthetised with a slow intravenous injection of **propofol** 2.5 mg/kg, followed by **suxamethonium** (**succinylcholine**) 1.5 mg/kg. This was controlled with 600 micrograms of intravenous atropine. Four other patients premedicated with 600 micrograms of intramuscular atropine given 45 minutes before induction of anaesthesia did not develop bradycardia.³⁴ It would appear that **propofol** lacks central vagolytic activity and can exaggerate the muscarinic effects of **suxamethonium**.³⁴ Another report describes a woman who became asystolic when given an anaesthetic induction sequence of fentanyl, **propofol** and **suxamethonium**.³⁵ Bradycardia and asystole has also been seen following the sequential administration of **propofol** and fentanyl in 2 patients.^{36,37} All of these three drugs (fentanyl, **propofol**, **suxam-**

ethonium) alone have been associated with bradycardia and their effects can apparently be additive.

Bradycardia and asystole occurred in another patient given **propofol**, fentanyl and **atracurium**.³⁸ The authors of one report suggest that atropine or glycopyrrolate pretreatment should attenuate or prevent such reactions.³⁵

Bradycardia occurring during anaesthetic induction with **vecuronium** and **etomidate**, or to a lesser extent **thiopental**, has also been reported, particularly in patients also receiving fentanyl,³⁹ see also 'Neuromuscular blockers + Opioids', p.130.

C. Muscle effects

In children receiving **suxamethonium**, those who had anaesthesia induced and maintained with **halothane** had much higher levels of serum myoglobin than those undergoing intravenous induction with **thiopental** followed by **halothane**. This suggests that prior use of **halothane** may have potentiated **suxamethonium**-induced muscle damage.⁴⁰

Anaesthetics, general + Opioids

The respiratory depressant effects of ketamine and morphine may be additive. The dose requirements of desflurane, etomidate, propofol and thiopental may be lower after opioid use. Opisthotonos or grand mal seizures have rarely been associated with the use of propofol with alfentanil and/or fentanyl. The effects of inhalational anaesthetics may be enhanced by opioid analgesics.

Clinical evidence, mechanism, importance and management

(a) Inhalational anaesthetics

Opioid analgesics have been reported to reduce the MAC values of inhalational anaesthetics. For example, **fentanyl** has been shown to lower the MAC value of **desflurane**, probably in a dose-dependent manner, and this has been the subject of a review.¹ The manufacturer notes that lower doses of **desflurane** are required in patients receiving opioids.² **Remifentanyl** at a target-controlled plasma level of 1 nanogram/mL was found to decrease the MAC of **sevoflurane** with nitrous oxide by 60%, and **remifentanyl** 3 nanograms/mL produced a further 30% decrease in the MAC of **sevoflurane**.³ Another study found that **remifentanyl** (dose-dependently) decreased the level of **sevoflurane** required to maintain anaesthesia.⁴ However, 100 microgram/kg doses of **morphine** given during anaesthesia did not alter the awakening concentration of **sevoflurane**.⁵

(b) Etomidate

The manufacturer of etomidate recommends that the dose of etomidate should be reduced in patients who have already received opioids.⁶

(c) Ketamine

Ketamine is a respiratory depressant like **morphine**, but less potent, and its effects can be additive with morphine.⁷ The manufacturer notes that prolonged recovery time may occur if opioids are used with ketamine.⁸

A study in 11 healthy subjects found that the combination of ketamine and **morphine** almost abolished wind-up-like pain (progressive increase in pain intensity on repeated stimulation) in a skin burn injury. This effect was not found with either drug alone. Further, ketamine alone, but not **morphine** reduced the area of secondary hyperalgesia of the local burn and increased the pain threshold, but the combination did not appear to enhance this effect. The reduction of wind-up pain may be due to ketamine-induced prevention of acute tolerance to **morphine**.⁹

Another study in healthy subjects using various experimental pain models found that ketamine *antagonised* the respiratory depressant effect of **remifentanyl**. **Remifentanyl** alone produced analgesic effects with all pain tests, but ketamine only enhanced the effect of **remifentanyl** on intramuscular electrical stimulation. Acute **remifentanyl**-induced hyperalgesia and tolerance were detected only by the pressure pain test and were not suppressed by ketamine. The combined effects of **remifentanyl** and ketamine probably depend on the type of pain.¹⁰

(d) Propofol

A 71-year-old man undergoing a minor orthopaedic operation was given a 500-microgram intravenous injection of **alfentanil** followed by a slow injection of propofol 2.5 mg/kg. Approximately 15 seconds after the propofol, the patient developed strong bilateral fits and grimaces, which lasted for 10 seconds. Anaesthesia was maintained with nitrous oxide/oxygen and halothane and there were no other intra- or postoperative complications. The patient had no history of convulsions.¹¹ Propofol has also been associated with opisthotonos (a spasm where the head and heels bend backwards and the body arches forwards) in two patients given **fentanyl**

with or without **alfentanil**.¹² There is a further report of opisthotonos during recovery from anaesthesia with **alfentanil**, propofol and nitrous oxide.¹³ Seizures have been reported in patients with and without epilepsy receiving propofol. They mainly occur during induction and emergence or are delayed after anaesthesia, suggesting that they may be caused by changes in cerebral levels of propofol,¹⁴ and postanaesthetic opisthotonos may be due to a propofol-induced tolerance to inhibitory transmitters (glycine and gamma-aminobutyric acid).¹³ Any association with the opioid remains unknown, although it has been suggested that opioids may aggravate propofol-induced opisthotonos by antagonising the actions of glycine.¹³

Alfentanil has been found to reduce the amount of propofol needed for loss of eyelash reflex and loss of consciousness, as well as increasing the blood pressure fall produced by propofol.¹⁵ Propofol inhibits both **alfentanil** and **sufentanil** metabolism causing an increase in plasma concentrations of these opioids, while **alfentanil** also increases propofol concentrations (reviewed by Vuyk¹⁶ and also described in more recent reports^{17–20}). Pretreatment with **fentanyl** may also decrease the propofol requirements for induction of anaesthesia,¹⁶ and increase blood concentrations of propofol.²¹ However, another study was unable to confirm an effect on blood propofol concentrations.²² **Remifentanyl** has been reported to reduce the dose of propofol needed for anaesthesia and also to reduce the recovery time.^{23,24} Further, propofol and **remifentanyl** caused dose-dependent respiratory-depression, which, during combined use, was synergistic.²⁵ One study using EEG-controlled dosing of propofol and **remifentanyl** for anaesthesia found their pharmacodynamic effects were no more than additive.²⁶ Although **remifentanyl** alone appears to be ineffective at countering the response to stimuli, a study in healthy subjects has found that **remifentanyl** can significantly reduce the levels of propofol required to ablate response to shouting, shaking or laryngoscopy (synergistic effect), but the effects on EEG measures were additive.²⁷ In another study in healthy subjects, the synergy that occurred for both analgesic and hypnotic endpoints was found to be greatest at lower levels of the drugs which for each drug alone would not be producing maximal effects.²⁸ Another study found changes in BIS (Bispectral Index) that suggested that **remifentanyl** may have some hypnotic properties or that it can potentiate the hypnotic effect of propofol.²⁹ It has been suggested that the increased hypnotic effects may be due to a dose-dependent decrease in cardiac output by **remifentanyl**, resulting in an increase in arterial and brain propofol with increased anaesthetic effect.³⁰ One pharmacokinetic study found that the levels of **remifentanyl** may be increased during concurrent propofol infusion,³¹ while another study found that concurrent propofol reduced volume of distribution and distribution clearance of **remifentanyl** by 41%. It was concluded that although propofol affects **remifentanyl** bolus dose pharmacokinetics, maintenance infusion rates and recovery times would not be significantly affected.³²

The manufacturer notes that the required induction dose of propofol may be reduced in patients who have received opioids, and that these drugs may increase the anaesthetic and sedative effects of propofol, and also cause greater reductions in blood pressure and cardiac output. They also state that the rate of propofol administration for maintenance of anaesthesia may be reduced in the presence of supplemental analgesics such as opioids.³³

Two reviews have discussed the use of opioids and propofol in anaesthesia, their pharmacokinetic and pharmacodynamic interactions, and administration and monitoring techniques.^{34,35}

(e) Thiopental

Opioid analgesics would be expected to potentiate the respiratory depressant effects of barbiturate anaesthetics. A study has found that the dose of thiopental required to induce anaesthesia was reduced by pretreatment with **fentanyl**.³⁶ The manufacturer recommends reduced doses of thiopental in patients premedicated with opioids.³⁷

Anaesthetics, general + Parecoxib

Limited evidence suggests parecoxib does not affect the pharmacokinetics or clinical effects of propofol. Parecoxib does not appear to interact with nitrous oxide and isoflurane.

Clinical evidence, mechanism, importance and management

A randomised, placebo-controlled, double-blind, crossover study in 12 healthy subjects found that pretreatment with 40 mg of intravenous parecoxib given one hour before a 2 mg/kg intravenous bolus of propofol did not significantly affect the pharmacokinetics of the propofol. Moreover, parecoxib did not alter the clinical effects of propofol (e.g. the time to loss of consciousness or the speed of awakening).¹ These limited data suggest that no special precautions should be required during concomitant use.

The UK manufacturer of parecoxib says that no formal interaction studies have been done with inhalational anaesthetics, but in surgical studies, where parecoxib was given preoperatively, there was no evidence of phar-

macodynamic interactions in patients who had been given nitrous oxide and isoflurane.²

Anaesthetics, general + Phenylephrine, topical

Phenylephrine eye drops given to patients undergoing general anaesthesia caused marked cyanosis and bradycardia in a baby, and hypertension in a woman.

Clinical evidence, mechanism, importance and management

A 3-week-old baby anaesthetised with halothane and nitrous oxide/oxygen became cyanosed shortly after 2 drops of 10% phenylephrine solution were put into one eye. The heart rate decreased from 160 to 60 bpm, S-T segment and T wave changes were seen, and blood pressure measurements were unobtainable. The baby recovered uneventfully when anaesthesia was stopped and oxygen given. It was suggested that the phenylephrine caused severe peripheral vasoconstriction, cardiac failure and reflex bradycardia.¹ A 54-year-old woman anaesthetised with isoflurane developed hypertension (a rise from 125/70 to 200/90 mmHg) shortly after having two drops of 10% phenylephrine put into one eye. The hypertension responded to nasal glyceryl trinitrate (nitroglycerin) and increasing concentrations of isoflurane.¹ The authors of this report consider that general anaesthesia may have contributed to the systemic absorption of the phenylephrine. They suggest that phenylephrine should be given 30 to 60 minutes prior to anaesthesia, and not during anaesthesia. However, if it is necessary, use the lowest concentrations of phenylephrine (2.5%). They also point out that the following are effective mydriatics: single drop combinations of 0.5% cyclopentolate and 2.5% phenylephrine or 0.5% tropicamide and 2.5% phenylephrine.

Phenylephrine is a sympathomimetic, and as such may carry some risk of potentiating arrhythmias if it is used with inhalational anaesthetics such as halothane –see ‘Anaesthetics, general + Inotropes and Vasopressors’, p.99. However, it is considered that it is much less likely than adrenaline (epinephrine) to have this effect, since it has primarily alpha-agonist activity.²

Anaesthetics, general + Phenytoin, Phenobarbital or Rifampicin (Rifampin)

Phenytoin toxicity occurred in a child following halothane anaesthesia. A near fatal hepatic reaction occurred in a woman given rifampicin (rifampin) after halothane anaesthesia, and hepatitis occurred in a patient taking phenobarbital who was given halothane anaesthesia. See also ‘Anaesthetics, general + Isoniazid’, p.100 and ‘Anaesthetics, general; Methoxyflurane + Antibacterials or Barbiturates’, p.107.

Clinical evidence

A 10-year-old girl receiving long-term treatment with phenytoin 300 mg daily was found to have phenytoin plasma levels of 25 micrograms/mL before surgery. Three days after anaesthesia with halothane her plasma phenytoin levels had risen to 41 micrograms/mL and she had marked signs of phenytoin toxicity.¹

A woman taking promethazine and phenobarbital 60 mg three times daily died from halothane associated hepatitis within 6 days of being given halothane for the first time.² A nearly fatal shock-producing hepatic reaction occurred in a woman 4 days after having halothane anaesthesia immediately followed by a course of rifampicin 600 mg daily and isoniazid 300 mg daily.³

Mechanism

It seems possible that the general adverse hepatotoxic effects of halothane can slow the normal rate of phenytoin metabolism. One suggested explanation for the increased adverse effects on the liver is that, just as in *animals*, pre-treatment with phenobarbital and phenytoin increases the rate of drug metabolism and therefore the hepatotoxicity of halogenated hydrocarbons, including carbon tetrachloride and halothane.^{4,5} As well as increased metabolism, the halothane-rifampicin interaction might also involve additive hepatotoxicity.

Importance and management

No firm conclusions can be drawn from these isolated cases, but they serve to emphasise the potential hepatotoxicity when halogenated anaesthetics are given to patients taking these drugs. It has been suggested that patients taking enzyme-inducing drugs such as phenobarbital and phenytoin may constitute a high-risk group for liver damage after halogenated anaesthetics.⁶ Consider also 'Anaesthetics, general + Isoniazid', p.100 and 'Anaesthetics, general; Methoxyflurane + Antibacterials or Barbiturates', p.107.

Anaesthetics, general + Sparteine sulfate

Patients given thiamylal sodium had a marked increase in cardiac arrhythmias when they were given intravenous sparteine sulfate, but those given thiopental or etomidate did not.

Clinical evidence, mechanism, importance and management

A group of 109 women undergoing dilatation and curettage were premedicated with atropine and fentanyl, and given either 2% **thiamylal sodium** (5 mg/kg), 0.2% **etomidate** (0.3 mg/kg) or 2.5% **thiopental** (4 mg/kg) to induce anaesthesia, which was maintained with **nitrous oxide/oxygen**. During the surgical procedure they were given a slow intravenous injection of sparteine sulfate 100 mg. Fourteen out of 45 patients given **thiamylal sodium** developed cardiac arrhythmias; 10 had bigeminy and 4 had frequent ventricular premature contractions. Only two patients given **etomidate** or **thiopental** developed any cardiac arrhythmias. It is not understood why sparteine should interact with **thiamylal sodium** in this way. Although the arrhythmias were effectively treated with lidocaine, the authors of this report suggest that the concurrent use of sparteine and thiamylal sodium should be avoided.¹

Anaesthetics, general + SSRIs

One patient had a seizure when she was given methohexital while taking paroxetine. Spontaneous movements have been seen in two patients taking fluoxetine when they were anaesthetised with propofol.

Clinical evidence, mechanism, importance and management

(a) Methohexital

A generalised tonic-clonic seizure occurred in a 42-year-old woman immediately after she was anaesthetised with 120 mg of intravenous methohexital for the last in a series of six electroconvulsive therapies. She had been receiving **paroxetine** 40 mg daily throughout the series.¹ The au-

thors suggest that paroxetine should be given with caution to patients receiving ECT or methohexital anaesthesia.¹ Note that this appears to be an isolated report.

(b) Propofol

Two women in their mid-twenties, who had been taking **fluoxetine** 20 mg daily for 4 to 6 months, had pronounced involuntary upper limb movements lasting 20 to 30 seconds immediately after anaesthetic induction with 180 mg of propofol (2 to 2.5 mg/kg). The movements ceased spontaneously and the rest of the anaesthesia and surgery were uneventful. Neither had any history of epilepsy or movement disorders. It is not clear whether this was an interaction between propofol and **fluoxetine** or just a rare (but previously reported) reaction to propofol.²

Anaesthetics, general + Sulfonamides

The anaesthetic effects of thiopental are increased but shortened by sulfafurazole. Phenobarbital appears not to affect the pharmacokinetics of sulfafurazole or sulfisomidine.

Clinical evidence

A study in 48 patients found that intravenous **sulfafurazole** 40 mg/kg reduced the required anaesthetic dosage of **thiopental** by 36%, but the duration of action was shortened.¹ This interaction has also been observed in *animal* experiments.² A study in children showed that **phenobarbital** did not affect the pharmacokinetics of **sulfafurazole** or **sulfisomidine**.³

Mechanism

It has been suggested that sulfafurazole successfully competes with thiopental for plasma protein binding sites,⁴ the result being that more free and active barbiturate molecules remain in circulation to exert their anaesthetic effects and therefore smaller doses are required.

Importance and management

The evidence for an interaction between sulfafurazole and thiopental is limited, but it appears to be strong. Less thiopental than usual may be required to achieve adequate anaesthesia, but since the awakening time is shortened repeated doses may be needed. Phenobarbital does not appear to affect the pharmacokinetics of the sulfonamides.

Anaesthetics, general and/or Neuromuscular blockers + Theophylline

Cardiac arrhythmias can develop during the concurrent use of halothane and aminophylline but this seems less likely with isoflurane. One report attributes seizures to an interaction between ketamine and aminophylline. Supraventricular tachycardia occurred in a patient taking aminophylline when pancuronium was given. Isolated cases suggest that the effects of pancuronium, but not vecuronium, can be opposed by aminophylline.

Clinical evidence, mechanism, importance and management

(a) Development of arrhythmias

A number of reports describe arrhythmias apparently due to an interaction between **halothane** and theophylline or aminophylline. One describes intraoperative arrhythmias in three out of 45 adult asthmatics who had received preoperative theophylline or aminophylline then **halothane**

anaesthesia.¹ Nine other patients developed heart rates exceeding 140 bpm when given aminophylline and **halothane**, whereas tachycardia did not occur in 22 other patients given only **halothane**.¹ There are other reports of individual adult and child patients who developed ventricular tachycardias attributed to this interaction.²⁻⁵ One child had a cardiac arrest.⁵ The same interaction has been reported in *animals*.^{6,7} One suggested reason for the interaction with **halothane** is that theophylline causes the release of endogenous catecholamines (adrenaline (epinephrine), noradrenaline (norepinephrine)), which are known to sensitise the myocardium (see also 'Anaesthetics, general + Inotropes and Vasopressors', p.99). Another report describes supraventricular tachycardia in a patient taking aminophylline who was anaesthetised with **thiopental** and fentanyl, and then given **pancuronium**. Three minutes later his heart rate rose to 180 bpm and an ECG revealed supraventricular tachycardia.⁸ The authors of this report attributed this reaction to an interaction between the **pancuronium** and the aminophylline, because previous surgery with these drugs in the absence of aminophylline had been without incident.⁸

The authors of one of the reports advise the avoidance of concurrent use i.e. to wait approximately 13 hours after the last dose of aminophylline before using **halothane**² but another⁹ says that: "... my own experience with the liberal use of these drugs has convinced me of the efficacy and wide margin of safety associated with their use in combination." A possibly safer anaesthetic may be **isoflurane**, which in studies with *dogs* has been shown not to cause cardiac arrhythmias in the presence of aminophylline,¹⁰ and is considered to be less arrhythmogenic than halothane.

(b) Development of seizures

Over a period of 9 years, tachycardia and extensor-type seizures were observed in 4 patients taking theophylline or aminophylline, who were initially anaesthetised with **ketamine**, and later with **halothane** or **enflurane**.¹¹ Based on subsequent study in *mice*, the authors attributed the seizures to an interaction between **ketamine** and theophylline or aminophylline, and they suggest that the combination should perhaps be avoided in some, or antiseizure premedication be given to patients at risk. However, these cases come from one isolated report. Note that, in *mice*, **ketamine** had no effect on aminophylline-induced seizures.¹²

(c) Altered neuromuscular blockade

Marked resistance to the effects of **pancuronium** (but not **vecuronium**) was seen in one patient receiving an aminophylline infusion.¹³ Two other patients are reported to have shown a similar resistance but they had also been given hydrocortisone, which could have had a similar effect^{14,15} (see also 'Neuromuscular blockers + Corticosteroids', p.121). These appear to be the only reports of such an interaction.

A study in *rabbits* showed that, at therapeutic concentrations of theophylline, the effects of **tubocurarine** were increased,¹⁶ but there do not appear to have been any studies done in humans.

Anaesthetics, general + Topiramate

A placebo-controlled study in healthy subjects found that pre-treatment with topiramate 50 mg did not affect the reaction time after sub-anaesthetic doses of ketamine (slow intravenous injection of 120 micrograms/kg followed by 500 micrograms/kg over one hour).¹

Anaesthetics, general + Trichloroethane

Two patients with chronic cardiac toxicity after repeated exposure to trichloroethane had a deterioration in cardiac function following halothane anaesthesia.

Clinical evidence, mechanism, importance and management

Two patients who had been repeatedly exposed to trichloroethane (one during solvent abuse including *Tipp-Ex* typewriter correcting fluid thinner and the other due to industrial exposure including *Genklene* for degreasing steel) showed evidence of chronic cardiac toxicity. In both cases there was circumstantial evidence of cardiac deterioration after routine anaesthesia with **halothane**. Some solvents have a close chemical similarity to **inhalational anaesthetic** drugs, particularly the halogenated hydrocarbons, and these related compounds might have a toxic interaction.¹

Anaesthetics, general and/or Neuromuscular blockers + Tricyclic and related antidepressants

Tricyclic antidepressants may increase the risk of arrhythmias and hypotension during anaesthesia. Tachyarrhythmias have been seen in patients taking imipramine who were given halothane and pancuronium. Some very limited evidence suggests that amitriptyline may increase the likelihood of enflurane-induced seizure activity. A man taking maprotiline and lithium developed a tonic-clonic seizure when given propofol. Tricyclics may cause an increase in the duration of barbiturate anaesthesia and lower doses of barbiturates may be required.

Clinical evidence, mechanism, importance and management

(a) Development of arrhythmias

Two patients who were taking **nortriptyline** (one also taking fluphenazine) developed prolonged cardiac arrhythmias during general anaesthesia with **halothane**.¹ Two further patients taking **imipramine** developed marked tachyarrhythmias when anaesthetised with **halothane** and given **pancuronium**.² This adverse interaction was subsequently clearly demonstrated in *dogs*.² The authors concluded on the basis of their studies that:

- **pancuronium** should be given with caution to patients taking any **tricyclic antidepressant** if **halothane** is used;
- **gallamine** probably should be avoided but **tubocurarine** may be an acceptable alternative to **pancuronium**;
- **pancuronium** is probably safe in the presence of a tricyclic if **enflurane** is used.

However, this last conclusion does not agree with that reached by the authors of another report³, who found that this combination increased the risk of seizures.

Some manufacturers⁴ have recommended stopping tricyclics several days before elective surgery where possible. However, the BNF advises that tricyclic antidepressants need not be stopped, but there may be an increased risk of arrhythmias and hypotension (and dangerous interaction with va-

sopressor drugs—see ‘Tricyclic antidepressants + Inotropes and Vasopressors’, p.1237). Therefore, the anaesthetist should be informed if they are not stopped.⁵

(b) Development of seizures

1. *Enflurane + Tricyclics*. Two patients taking **amitriptyline** developed clonic movements of the leg, arm and hand during surgery while anaesthetised with enflurane and **nitrous oxide**. The movements stopped when the enflurane was replaced by **halothane**.³ A possible reason is that **amitriptyline** can lower the seizure threshold at which enflurane-induced seizure activity occurs. It is suggested that it may be advisable to avoid enflurane in patients needing tricyclic antidepressants, particularly in those who have a history of seizures, or when hyperventilation or high concentrations of enflurane are likely to be used.³

2. *Propofol + Maprotiline*. A man with a bipolar disorder taking maprotiline 200 mg four times daily and lithium carbonate 300 mg daily, underwent anaesthesia during which he received fentanyl, **tubocurarine** and propofol 200 mg. Shortly after the injection of the propofol the patient complained of a burning sensation in his face. He then became rigid, his back and neck extended and his eyes turned upwards. After 15 seconds, rhythmic twitching developed in his eyes, arms and hands. This apparent seizure lasted about 1 minute until suxamethonium (succinylcholine) was given. The patient regained consciousness after several minutes and the surgery was cancelled.⁶ It is not known whether the reaction was due to an interaction between propofol and the antidepressants, or due to just one of the drugs, because both propofol^{7,8} and maprotiline⁹ have been associated with seizures. However, the authors of this report suggest that it would now be prudent to avoid using propofol in patients taking drugs that significantly lower the convulsive threshold. More study of this possible interaction is needed.

(c) Increased duration of anaesthesia

A study in *dogs* found that **imipramine** caused about a 50% increase in the duration of **thiopental**-induced sleep.¹⁰ In an early review of electroconvulsive therapy and anaesthetic considerations, it was noted that tricyclics interact with **barbiturates** resulting in an increased sleep time and duration of anaesthesia, and therefore it was suggested that lower doses of barbiturate anaesthetics such as **thiopental** should be employed during concurrent use.¹¹ However, in a later review, it was noted that no complications have been attributed to the use of ECT (which is often undertaken using methohexital or possibly propofol) in patients taking tricyclic antidepressants.¹² Apart from the study in *animals*,¹⁰ there seems little published information to suggest that tricyclics interact significantly with barbiturate anaesthetics, but even if there is an interaction, as the dose of barbiturate should be carefully adjusted according to the patient's response any interaction will probably be accounted for by standard anaesthetic procedures. See also ‘Tricyclic antidepressants + Barbiturates’, p.1231.

Anaesthetics, general; Methoxyflurane + Antibacterials or Barbiturates

The nephrotoxic effects of methoxyflurane appear to be increased by the use of tetracyclines, and possibly some aminoglycoside antibiotics and barbiturates.

Clinical evidence, mechanism, importance and management

Methoxyflurane has been withdrawn in many countries because it is nephrotoxic. This damage can be exacerbated by the concurrent use of other nephrotoxic drugs or possibly by the chronic use of hepatic enzyme-inducing drugs. Five out of 7 patients anaesthetised with methoxyflurane who had been given **tetracycline** before or after surgery showed rises in blood urea nitrogen, and three died. Post-mortem examination showed pathological changes (oxalosis) in the kidneys.¹ Another study identified renal tubular necrosis associated with calcium oxalate crystals in 6 patients who had been anaesthetised with methoxyflurane and given **tetracycline** (4 patients) and **penicillin** with **streptomycin** (2 patients).² Other reports support the finding of increased nephrotoxicity with **tetracycline** and methoxyflurane.^{3–5} Another study suggested that **penicillin**, **streptomycin** and **chloramphenicol** appear not to increase the renal toxicity of methoxyflurane,¹ but **gentamicin** and **kanamycin** possibly do so.⁶ There is also some evidence that **barbiturates** can exacerbate the renal toxicity because they enhance the metabolism of the methoxyflurane and increase the production of nephrotoxic metabolites.^{7,8}

The risk of nephrotoxicity with methoxyflurane would therefore appear to be increased by some of these drugs and the concurrent use of **tetracycline** or **nephrotoxic antibiotics** should be avoided. Similarly, methoxyflurane should only be used with great caution, if at all, following the chronic use of hepatic enzyme-inducing drugs.

Anaesthetics, local + Acetazolamide

The mean procaine half-life in 6 healthy subjects was increased by 66% (from 1.46 to 2.43 minutes) 2 hours after they were given acetazolamide 250 mg orally. This appears to be because the hydrolysis of the procaine is inhibited by the acetazolamide.¹ As the evidence of this interaction is limited to one report, its general significance is unclear.

1. Calvo R, Carlos R, Erill S. Effects of disease and acetazolamide on procaine hydrolysis by red blood cell enzymes. *Clin Pharmacol Ther* (1980) 27, 179–83.

Anaesthetics, local + Alcohol and/or Antirheumatics

Limited evidence suggests that the failure rate of spinal anaesthesia with bupivacaine may be markedly increased in patients who are receiving antirheumatic drugs and/or who drink alcohol.

Clinical evidence, mechanism, importance and management

The observation that regional anaesthetic failures seemed to be particularly high among patients undergoing orthopaedic surgery who were suffering from rheumatic joint diseases, prompted further study of a possible interaction. It was found that the failure rate of low-dose spinal anaesthesia with 0.5% **bupivacaine** (average volume of 2 mL) increased from 5% in the control group (no alcohol or long-term treatment) to 32% to 42% in those who had been taking antirheumatic drugs (**indometacin** or unspecified) for at least 6 months or who drank at least 80 g of ethanol daily, or both. The percentage of those patients who had a reduced response (i.e. an

extended latency period and/or a reduced duration of action) also increased from 3% up to 39 to 42%.¹ The reasons are not understood. This appears to be the only report of such an effect.

1. Sprotte G, Weis KH. Drug interaction with local anaesthetics. *Br J Anaesth* (1982) 54, 242P–243P.

Anaesthetics, local + Anaesthetics, local

Mixtures of local anaesthetics are sometimes used to exploit the most useful characteristics of each drug. This normally seems to be safe although it is sometimes claimed that it increases the risk of toxicity. There is a case report of a man who developed toxicity when bupivacaine and mepivacaine were mixed together. Spinal bupivacaine followed by epidural ropivacaine may also interact to produce profound motor blockade. However, the effectiveness of bupivacaine in epidural anaesthesia may be reduced if it is preceded by chloroprocaine.

Clinical evidence and mechanism

(a) Evidence of no interaction

A study designed to assess the possibility of adverse interactions retrospectively studied the records of 10 538 patients over the period 1952 to 1970 who had been given tetracaine combined with chloroprocaine, lidocaine, mepivacaine, prilocaine or propoxycaine for caudal, epidural, or peripheral nerve block. The incidence of systemic toxic reactions was found to be no greater than when used singly and the conclusion was reached that combined use was advantageous and safe.¹ An animal study using combinations of bupivacaine, lidocaine and chloroprocaine also found no evidence that the toxicity was greater than if the anaesthetics were used singly.²

A study on the use of chloroprocaine 3%, bupivacaine 0.5% or a mixture of chloroprocaine 1.5% with bupivacaine 0.375% in obstetric epidural anaesthesia found that time to onset of analgesia, time to maximum analgesia, and effectiveness of analgesia were similar irrespective of the treatment regimen. Bupivacaine 0.5% alone had a longer duration of action than chloroprocaine or the mixture of anaesthetics.³ Another study found that lidocaine did not affect the pharmacokinetics of bupivacaine.⁴

(b) Evidence of reduced analgesia

A study set up to examine the clinical impression that bupivacaine given epidurally did not relieve labour pain effectively if preceded by chloroprocaine confirmed that this was so. Using an initial 10-mL dose of 2% chloroprocaine followed by an 8-mL dose of 0.5% bupivacaine, given when pain recurred, the pain relief was less and the block took longer to occur, had a shorter duration of action and had to be augmented more frequently than if only bupivacaine was used.⁵ This interaction could not be corrected by adjusting the pH of the local anaesthetics.⁶

(c) Evidence of enhanced effect/toxic interaction

There is a single case report of a patient given 0.75% bupivacaine and 2% mepivacaine who demonstrated lethargy, dysarthria and mild muscle tremor, which the authors of the report correlated with a marked increase in the percentage of unbound (active) mepivacaine. They attributed this to its displacement by the bupivacaine from protein binding sites.⁷ Bupivacaine has also been shown *in vitro* to displace lidocaine from α_1 -acid glycoprotein.⁸ Two cases of prolonged, profound motor blockade, with patient-controlled epidural analgesia using 0.1% ropivacaine following spinal bupivacaine for caesarean section, have been reported. Including these two patients, a total of 11 out of 23 patients given regional anaesthesia with bupivacaine had clinical evidence of motor weakness 8 hours after starting ropivacaine.⁹

Importance and management

Well studied interactions. The overall picture is that combined use does not normally result in increased toxicity, although there may be some exceptions. For example, until more is known, caution should be exercised when giving epidural ropivacaine postoperatively to patients who have

had bupivacaine spinal anaesthesia, as unexpected motor block may occur.⁹ Reduced effectiveness might be seen if bupivacaine is preceded by chloroprocaine.

Anaesthetics, local + Antihypertensives

Severe hypotension and bradycardia have been seen in patients taking captopril or verapamil when they were given epidural anaesthesia with bupivacaine. Acute hypotension also occurred in a man taking prazosin when he was given epidural anaesthesia with bupivacaine. Clonidine may increase the duration of caudal block with bupivacaine, although there are reports of reduced plasma levels of lidocaine with concurrent clonidine. Verapamil does not appear to interact with epidural lidocaine.

Clinical evidence

(a) ACE inhibitors

An 86-year-old man who had been receiving captopril 25 mg twice daily and bendroflumethiazide 25 mg daily [sic] for hypertension, underwent a transurethral resection of his prostate under spinal anaesthesia using 3 to 3.5 mL of 'heavy' bupivacaine 0.5%. At the end of surgery, he was returned to the supine position and suddenly developed a severe sinus bradycardia (35 bpm), his arterial blood pressure fell to 65/35 mmHg and he became unrousable. Treatment with head-down tilt, oxygen and 1.2 mg of atropine produced rapid improvement in cardiovascular and cerebral function. A further hypotensive episode (without bradycardia) occurred approximately one hour later, which responded rapidly to 4 mg of methoxamine.¹

(b) Alpha blockers

A man taking prazosin (5 mg three times daily for hypertension) developed marked hypotension (BP 60/40 mmHg) within 3 to 5 minutes of receiving 100 mg of bupivacaine through an L3–4 lumbar epidural catheter.² He was unresponsive to intravenous phenylephrine (five 100-microgram boluses) but his blood pressure rose within 3 to 5 minutes of starting an infusion of adrenaline (epinephrine) 0.05 micrograms/kg per minute.

(c) Beta blockers

See 'Anaesthetics, local + Beta blockers', p.110.

(d) Calcium-channel blockers

Four patients taking long-term verapamil developed severe hypotension (systolic pressure as low as 60 mmHg) and bradycardia (48 bpm) 30 to 60 minutes after an epidural block with bupivacaine 0.5% and adrenaline (epinephrine). This was totally resistant to atropine and ephedrine, and responded only to calcium gluconate or chloride. No such interaction was seen in a similar group of patients when epidural lidocaine was used.³

Animal experiments have shown that the presence of verapamil increases the toxicity of lidocaine, and greatly increases the toxicity of bupivacaine, and that pretreatment with calcium chloride blocked this effect.⁴ Another animal study found that bupivacaine had a more marked cardio-depressant effect than lidocaine when given with either verapamil or diltiazem.⁵ One animal study found that bupivacaine accentuates the cardiovascular depressant effects of verapamil.⁶ Other studies in animals have found that diltiazem,^{7–9} felodipine,¹⁰ nifedipine,^{10,11} nitren-

dipine,¹⁰ and **verapamil**^{7,8,10} increase the toxicity of **bupivacaine**. However, another *animal* study indicated that pretreatment with **nimodipine** or **verapamil** reduced **bupivacaine** cardiotoxicity.¹²

(e) Clonidine

A study in 35 children undergoing ureteroneocystostomy found that the addition of clonidine 1 microgram/kg increased the duration of caudal block with **bupivacaine** 0.125% (with adrenaline (epinephrine) 1:400 000) and reduced the postoperative morphine requirements.¹³ A study in *animals* found that clonidine increased the levels of **bupivacaine** and decreased its clearance.¹⁴ However, another study in children found that oral clonidine premedication reduced the plasma levels of **lidocaine** by 25 to 50%.¹⁵ Similar findings are reported in another study in which clonidine was given with epidural **lidocaine**.¹⁶

Mechanism

Spinal anaesthesia can produce bradycardia and a fall in cardiac output resulting in arterial hypotension, which may be magnified by the action of the antihypertensive drug, and by hypovolaemia. Other factors probably contributed to the development of this interaction in these particular patients.

The reported differences in effects of clonidine on levels of local anaesthetics are not fully understood. An *in vitro* study using liver microsomes found that clonidine at clinical levels is unlikely to affect the metabolism of **lidocaine**.¹⁷ However, the haemodynamic effects of clonidine may lead to decreased hepatic blood flow and reduced metabolism.¹⁷

Importance and management

Direct information seems to be limited to the reports cited. Their general relevance is uncertain, but they serve to emphasise the importance of recognising that all antihypertensive drugs interfere in some way with the normal homeostatic mechanisms that control blood pressure, so that the normal physiological response to hypotension during epidural anaesthesia may be impaired. In this context **lidocaine** would appear to be preferable to **bupivacaine**. Intravenous calcium effectively controls the hypotension and bradycardia produced by verapamil toxicity by reversing its calcium-channel blocking effects.^{3,18}

Accidental intravenous administration of local anaesthetics during spinal anaesthesia may cause cardiovascular collapse and, on theoretical grounds, the serious cardiac depressant effects could be enhanced in patients taking antihypertensives, especially elderly patients with impaired cardiovascular function.¹¹ Particular care would seem to be important with any patient given epidural anaesthesia while taking antihypertensives.

Anaesthetics, local + Azoles or Macrolides

Itraconazole may reduce the clearance of **bupivacaine**, and **itraconazole**, **ketoconazole** or **clarithromycin** may slightly decrease **ropivacaine** clearance, but the clinical importance of these interactions appears to be limited.

Clinical evidence, mechanism, importance and management

(a) Bupivacaine

In a double-blind, placebo-controlled, crossover study in 7 healthy subjects pretreatment with **itraconazole** 200 mg once daily for 4 days reduced the clearance of **bupivacaine** (0.3 mg/kg given intravenously over 60 minutes) by 20 to 25%. The increase in plasma concentrations of **bupivacaine** should be taken into account when **itraconazole** is used concurrently, although the interaction is probably of limited clinical significance.¹

(b) Ropivacaine

Pretreatment with **itraconazole** 200 mg daily or **clarithromycin** 250 mg twice daily for 4 days did not significantly affect the pharmacokinetics of **ropivacaine** 600 microgram/kg given intravenously to 8 healthy subjects. However, there was considerable interindividual variation. A small but insignificant 20% increase in the AUC of **ropivacaine** occurred, and the peak plasma concentrations of the metabolite 2',6'-pipercoloxylidide were significantly decreased by **clarithromycin** and **itraconazole**, by 44% and 74%, respectively. Both **itraconazole** and **clarithromycin** inhibit the formation of this metabolite by the cytochrome P450 isoenzyme CYP3A4.² Similar results were found with **ketoconazole** and **ropivacaine**.³ Potent inhibitors of CYP3A4 appear to cause only a minor decrease in clearance of **ropivacaine**, which is unlikely to be of clinical relevance.³ For a report of **erythromycin**, an inhibitor of CYP3A4 enhancing the effect of **fluvoxamine**, an inhibitor of CYP1A2, on the clearance of **ropivacaine**, see 'Anaesthetics, local + Fluvoxamine', p.110.

Anaesthetics, local + Benzodiazepines

Diazepam may increase the maximum plasma concentrations of **bupivacaine**, but its rate of elimination may also be increased. **Midazolam** has been reported to cause a modest decrease in **lidocaine** but not **mepivacaine** levels. Spinal anaesthesia with **bupivacaine**, **lidocaine**, or **tetracaine** may increase the sedative effects of **midazolam**. A case of possible **lidocaine** toxicity has been described when a woman taking **sertraline** was given **flurazepam** before intraoperative **lidocaine**.

Clinical evidence, mechanism, importance and management

(a) Effect of benzodiazepines on local anaesthetics

Twenty-one children aged 2 to 10 years were given single 1-mL/kg caudal injections of a mixture of 0.5% **lidocaine** and 0.125% **bupivacaine** for regional anaesthesia. Pretreatment with **diazepam** 10 mg rectally half-an-hour before the surgery had no significant effect on the plasma levels of **lidocaine**, but the AUC and maximum plasma **bupivacaine** levels were increased by 70 to 75%.¹ In another study, prior use of intravenous **diazepam** in adult patients slightly, but not significantly, increased the mean maximum plasma levels of epidural **bupivacaine** or **etidocaine**. However, the elimination half-lives of both anaesthetics were significantly decreased by about a half.²

A study in 20 children aged 2 to 7 years receiving caudal block with 1 mL/kg of a solution containing 0.5% **lidocaine** and 0.125% **bupi-**

vacaine, found that **midazolam** 400 micrograms/kg given rectally half-an-hour before surgery caused a slight but not significant reduction in the AUC and serum levels of **bupivacaine**, whereas the AUC of **lidocaine** was reduced by 24%.³ In contrast, **midazolam** 400 micrograms/kg given rectally as a premedication was found to have no significant effect on plasma **mepivacaine** levels.⁴

There has been a single report of possible **lidocaine** toxicity following tumescent liposuction in a patient given perioperative sedation with **flurazepam** 30 mg orally. Ten hours after the completion of the procedure, in which a total of 58 mg/kg of lidocaine was used, the patient had nausea and vomiting, unsteady gait, mild confusion, and speech impairment. Her lidocaine level was 6.3 mg/L (levels greater than 6 mg/L were considered to be associated with an increased risk of toxicity). The patient was also on long-term treatment with sertraline. The authors suggested that sertraline and **flurazepam** may have had an additive effect on reducing the rate of **lidocaine** metabolism via inhibition of cytochrome P450 isoenzyme CYP3A4.⁵

The clinical importance of these interactions is uncertain, but anaesthetists should be aware that increased **bupivacaine** plasma levels have been seen with **diazepam**, and reduced **lidocaine** levels have been seen with **midazolam**. More study is needed.

(b) Effect of local anaesthetics on benzodiazepines

Twenty patients undergoing surgery were given repeated 1-mg intravenous doses of **midazolam** as induction anaesthesia every 30 seconds until they failed to respond to three repeated commands to squeeze the anaesthetist's hand. This was considered as the induction end-point 'titrated' dose. It was found that the 10 who had been given prior spinal anaesthesia with **tetracaine** 12 mg needed only half the dose of **midazolam** (7.6 mg) than the 10 other patients who had not received tetracaine (14.7 mg). The reasons are not known. The authors of this report simply advise care in this situation.⁶ In another study in which patients were given intravenous **midazolam** following an intramuscular injection of either **bupivacaine**, **lidocaine** or saline, it was found that both anaesthetics enhanced the effect of **midazolam**. This effect was dose-dependent and it was concluded that the use of **lidocaine** or **bupivacaine** for regional blocks or local infiltration could alter the effect of **midazolam** from sedative to hypnotic.⁷

Anaesthetics, local + Beta blockers

Propranolol reduces the clearance of bupivacaine and so theoretically the toxicity of bupivacaine may be increased. There has been a single report of enhanced bupivacaine cardiotoxicity in a patient also receiving metoprolol and digoxin. The coronary vasoconstriction caused by cocaine is increased by propranolol. Beta blockers may interact with adrenaline (epinephrine)-containing local anaesthetics.

Clinical evidence, mechanism, importance and management

(a) Bupivacaine

1. *Metoprolol*. There is a case report of possible enhanced bupivacaine cardiotoxicity in a patient who was taking enalapril 5 mg daily, metoprolol 25 mg twice daily and digoxin 250 micrograms four times a day (serum digoxin level 1.1 nanograms/mL). Cardiac arrest occurred 15 minutes after the injection of 0.5% bupivacaine with adrenaline (epinephrine) for intercostal nerve block (total dose 100 mg). The cardiodepressant effects of metoprolol, digoxin and bupivacaine may have combined to produce toxicity at a dose of bupivacaine not usually considered toxic. The authors

caution that patients taking digoxin with a calcium channel blocker and/or beta blocker should be considered at higher risk for bupivacaine cardiotoxicity.¹

2. *Propranolol*. The clearance of bupivacaine was reduced by about 35% in 6 healthy subjects given bupivacaine 30 to 50 mg intravenously over 10 to 15 minutes after taking propranolol 40 mg every 6 hours for a day. The reason is thought to be that the propranolol inhibits the activity of the liver microsomal enzymes, thereby reducing the metabolism of the bupivacaine. Changes in blood flow to the liver are unlikely to affect bupivacaine metabolism substantially because it is relatively poorly extracted from the blood. The clinical importance of this interaction is uncertain, but it is suggested that an increase in local anaesthetic toxicity might occur and caution should be exercised if multiple doses of bupivacaine are given.²

(b) Cocaine

A study in 30 patients being evaluated for chest pain found that 2 mg/kg of a 10% intranasal solution of cocaine reduced coronary sinus flow by about 14% and coronary artery diameter by 6 to 9%. The coronary vascular resistance increased by 22%. The addition of propranolol 400 micrograms/minute by intracoronary infusion, (to a total of 2 mg) reduced coronary sinus flow by a further 15% and increased the coronary vascular resistance by 17%. The probable reason is that the cocaine stimulates the alpha-receptors of the coronary blood vessels causing vasoconstriction. When the beta-receptors are blocked by propranolol, the resultant unopposed alpha-adrenergic stimulation may lead to enhanced coronary vasoconstriction (see also 'Beta blockers + Inotropes and Vasopressors', p.848). The clinical importance of these findings is uncertain but the authors of the report suggest that beta blockers should be avoided in patients with myocardial ischaemia or infarction associated with the use of cocaine.³

(c) Local anaesthetics with vasoconstrictors

In a double-blind, randomised, placebo-controlled, crossover study in 10 healthy subjects, the upper lateral incisor teeth were anaesthetised using lidocaine with or without adrenaline (epinephrine). The mean duration of anaesthesia using 1 mL of 2% lidocaine containing 1:100 000 adrenaline was increased by 58% (17 minutes) for pulpal anaesthesia and 19% (16.5 minutes) for soft-tissue anaesthesia in subjects pretreated with **nadolol** 80 mg orally. Pretreatment with the beta blocker did not affect the duration of anaesthesia when lidocaine without adrenaline was used.⁴ It is likely that the combined effects of adrenaline and **nadolol** caused increased local vasoconstriction, which resulted in the lidocaine persisting for longer. Therefore when a small amount of local anaesthetic with adrenaline is injected for dental procedures an increased duration of analgesia may result. Also note that a case report describes a transient hypertensive reaction in a patient taking **propranolol** when injections of 2% mepivacaine with 1:20 000 corbadrine were given for dental anaesthesia.⁵ Larger doses of adrenaline have resulted in serious hypertension and bradycardia because of the interaction between non-selective beta blockers and adrenaline (see 'Beta blockers + Inotropes and Vasopressors', p.848). It has been suggested that, for dental procedures, the minimum amount of local anaesthetic containing the lowest concentration of adrenaline should be used. Alternatively, if excessive bleeding is unlikely, a local anaesthetic without adrenaline is preferred.⁴

Propranolol and some other beta blockers are known to reduce the metabolism of lidocaine—see 'Lidocaine + Beta blockers', p.263.

Anaesthetics, local + Fluvoxamine

Fluvoxamine inhibits the clearance of ropivacaine; therefore, prolonged administration of ropivacaine should be avoided in patients taking fluvoxamine.

Clinical evidence, mechanism, importance and management

Fluvoxamine decreased the mean total plasma clearance of **ropivacaine** by 68% from 354 to 112 mL/minute, and almost doubled the half-life of **ropivacaine** in a randomised, crossover study in 12 healthy subjects. Fluvoxamine was given at a dose of 25 mg twice daily for 2 days, and a single 40 mg intravenous dose of **ropivacaine** was given over 20 minutes one hour after the morning dose of fluvoxamine on the second day.¹

Fluvoxamine is a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2 and so reduces the metabolism of **ropivacaine** to its major metabolite 3-hydroxyropivacaine. In one study in healthy subjects the combination of fluvoxamine with **erythromycin**, an inhibitor of CYP3A4, which on its own has little effect on the pharmacokinetics of **ropivacaine**, was found to decrease the clearance of **ropivacaine** more than fluvoxamine alone.²

The UK manufacturer recommends that prolonged administration of **ropivacaine** should be avoided in patients concurrently treated with potent CYP1A2 inhibitors such as fluvoxamine.³ Be aware that CYP3A4 inhibitors such as erythromycin in combination with CYP1A2 inhibitors may further reduce **ropivacaine** clearance.²

Anaesthetics, local + H₂-receptor antagonists

Some studies suggest that both cimetidine and ranitidine can raise plasma bupivacaine levels, whereas other evidence suggests that no significant interaction occurs. Ranitidine does not appear to significantly affect lidocaine. Some studies found that cimetidine does not affect lidocaine when used as an anaesthetic. Other studies found that cimetidine increased plasma lidocaine levels and that famotidine had less effect. See also 'Lidocaine + H₂-receptor antagonists', p.264 for interactions of lidocaine used as an antiarrhythmic.

Clinical evidence

(a) Cimetidine + Bupivacaine

Pretreatment with cimetidine 300 mg intramuscularly 1 to 4 hours before epidural anaesthesia with 0.5% bupivacaine (for caesarean section) had no effect on the pharmacokinetics of bupivacaine in 16 women or their foetuses when compared with 20 control women, although the maternal unbound bupivacaine plasma levels rose by 22%.¹ These findings were confirmed in two similar studies^{2,3} in which women were pretreated with cimetidine before caesarean section, and a further study⁴ in 7 healthy subjects (6 women and one man) given two oral doses of cimetidine 400 mg before intramuscular bupivacaine. However, the AUC of bupivacaine in 4 healthy male subjects was increased by 40% (when compared to placebo) by cimetidine 400 mg at 10 pm the previous evening and 8 am on the study day, followed by a 50-mg infusion of bupivacaine at 11 am.⁵

(b) Cimetidine + Lidocaine

In 5 women given epidural anaesthesia for caesarean section, the pharmacokinetics of 400 mg of lidocaine 2% (administered with adrenaline (epinephrine) 1:200 000) were unchanged by a single 400-mg oral dose of cimetidine given about 2 hours preoperatively.⁶ Another very similar study in 9 women found no statistically significant rises in whole blood lidocaine levels (although they tended to be higher), in the presence of cimetidine 300 mg, given intramuscularly, at least an hour preoperatively.⁷ However, in patients pretreated with cimetidine (200 mg orally on the night before surgery and 400 mg one hour before induction) peak plasma levels of epidural lidocaine 2% (with adrenaline 1:200 000) were 3.2 micrograms/mL. Lidocaine levels in patients who did not receive pretreatment with H₂-receptor antagonists were 2.3 micrograms/mL.⁸

(c) Famotidine + Lidocaine

In patients pretreated with famotidine (20 mg orally on the night before surgery plus 20 mg intramuscularly one hour before induction) peak plas-

ma levels of epidural lidocaine 2% (with adrenaline 1:200 000) were 2.4 micrograms/mL. Lidocaine levels in patients who did not receive pretreatment with H₂-receptor antagonists were 2.3 micrograms/mL.⁸ In another study the effects of famotidine on lidocaine were found to be less than those of cimetidine but greater than in patients not given an H₂-receptor antagonist.⁹

(d) Ranitidine + Bupivacaine

Pretreatment with oral ranitidine 150 mg 1.5 to 2 hours before bupivacaine for extradural anaesthesia for caesarean section, increased the maximum plasma levels of bupivacaine in 10 patients by about 36%, when compared with 10 patients given no pretreatment.³ Another study found that two oral doses of ranitidine 150 mg caused a 25% increase in the mean AUC of bupivacaine, but this was not statistically significant.⁵ No increased bupivacaine toxicity was described in any of these reports. However, two other studies in 36 and 28 women undergoing caesarean section found no measurable effect on the bupivacaine disposition when given ranitidine 150 mg the night before and on the morning of anaesthesia,² or ranitidine 50 mg intramuscularly 2 hours before anaesthesia, respectively.¹⁰

(e) Ranitidine + Lidocaine

In 7 women given epidural anaesthesia for caesarean section the pharmacokinetics of 400 mg of lidocaine 2%, (given with adrenaline (epinephrine) 1:200 000) were unchanged after a single 150-mg oral dose of ranitidine given about 2 hours preoperatively.⁶ A similar study in 8 women also found no statistically significant rises in whole blood lidocaine levels in the presence of ranitidine 150 mg given orally at least 2 hours preoperatively.⁷

Mechanism

Not understood. It has been suggested that cimetidine reduces the hepatic metabolism of bupivacaine. Protein binding displacement has also been suggested.

Importance and management

A confusing situation. No clinically important interaction has been established, but be alert for any evidence of increased bupivacaine toxicity resulting from raised total plasma levels and rises in unbound bupivacaine levels during the concurrent use of cimetidine and possibly ranitidine. Cimetidine (but not ranitidine) has been shown to raise plasma lidocaine levels when lidocaine is used as an antiarrhythmic (see 'Lidocaine + H₂-receptor antagonists', p.264), but some of the studies cited above found cimetidine did not affect lidocaine levels when lidocaine is used as an anaesthetic. However, in the studies comparing the effects of cimetidine and famotidine, cimetidine was found to increase lidocaine levels and it was suggested that famotidine may be preferable to cimetidine as pretreatment before epidural lidocaine.^{8,9}

Anaesthetics, local + Ondansetron

In a placebo-controlled study oral ondansetron 4 mg was given to patients the evening before surgery, followed by intravenous ondansetron 4 mg given over 15 minutes before subarachnoid anaesthesia with lidocaine 5% in dextrose 8%. Ondansetron

significantly reduced the sensory block measured at 30 minutes. In this study 54 patients were enrolled, but not all patients were assessed for both motor and sensory block.¹

Anaesthetics, local + Quinolones

Ciprofloxacin may decrease the clearance of ropivacaine and this could be significant in some patients. It is also likely that enoxacin will inhibit the metabolism of ropivacaine. Therefore prolonged administration of ropivacaine should be avoided in patients taking enoxacin.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects found that ciprofloxacin 500 mg twice daily decreased the mean clearance of a single 0.6-mg/kg intravenous dose of ropivacaine, by 31%, but there was considerable inter-individual variation. Ciprofloxacin modestly decreases the clearance of ropivacaine by inhibiting the cytochrome P450 isoenzyme CYP1A2-mediated metabolism of ropivacaine to its major metabolite 3-hydroxyropivacaine. For some patients concurrent use may cause toxicity.¹ On the basis of data with 'fluvoxamine', (p.110), the UK manufacturer of ropivacaine has recommended that prolonged administration of ropivacaine should be avoided in patients taking strong CYP1A2 inhibitors such as enoxacin.²

Anaesthetics, local + Rifampicin (Rifampin) and/or Tobacco

Rifampicin increases the metabolism of ropivacaine, but this probably has little clinical relevance to its use as a local anaesthetic. Smoking appears to have only a minor effect on ropivacaine pharmacokinetics. Tobacco smoking may enhance cocaine-associated myocardial ischaemia.

Clinical evidence, mechanism, importance and management

(a) Cocaine

In a study involving 42 smokers (36 with proven coronary artery disease) the mean product of the heart rate and systolic arterial pressure increased by 11% after intranasal cocaine 2 mg/kg, by 12% after one cigarette and by 45% after both cocaine use and one cigarette. Compared with baseline measurements, the diameters of non-diseased coronary arterial segments decreased on average by 7% after cocaine use, 7% after smoking and 6% after cocaine and smoking. However, the diameters of diseased segments decreased by 9%, 5% and 19%, respectively.¹ Cigarette smoking increases myocardial oxygen demand and induces coronary-artery vasoconstriction through an alpha-adrenergic mechanism similar to cocaine and therefore tobacco smoking may enhance cocaine-associated myocardial ischaemia.^{1,2}

(b) Ropivacaine

A study in 10 healthy non-smokers and 8 healthy smokers given ropivacaine 600 micrograms/kg by intravenous infusion over 30 minutes found that smoking increased the urinary excretion of the metabolite 3-hydroxyropivacaine and decreased the urinary excretion of 2',6'-pipecoloxylidide by 62%, but did not significantly affect the ropivacaine AUC. However, pretreatment with rifampicin 600 mg daily for 5 days increased the clearance (by 93% and 46%) and decreased the AUC by 52% and 38% and half-life of ropivacaine in both non-smokers and smokers, respectively.³ Ropivacaine undergoes oxidative hepatic metabolism mainly by the cytochrome P450 isoenzymes CYP1A2 and CYP3A4. Cigarette smoking may increase CYP1A2-mediated metabolism of ropivacaine, and the elimination of ropivacaine may be considerably accelerated by rifampicin, which is a potent cytochrome P450 enzyme inducer. However, in clinical use the local anaesthetic is given near the nerves to be desensitised and in-

duction of isoenzymes is not likely to affect the local anaesthetic before it enters the systemic blood circulation.³ This interaction is therefore of little clinical relevance.

Rifampicin may also increase the metabolism of lidocaine to a minor extent, see 'Lidocaine + Rifampicin (Rifampin)', p.267, and smoking may reduce the oral bioavailability of 'lidocaine', (p.267).

Anaesthetics, local; Cocaine + Adrenaline (Epinephrine)

Arrhythmias occurred in 3 patients given a concentrated nasal paste containing cocaine and adrenaline (epinephrine).

Clinical evidence, mechanism, importance and management

Two children and one adult patient undergoing general anaesthesia¹ developed arrhythmias shortly after nasal application of a paste containing cocaine 25% and adrenaline (epinephrine) 0.18%. All 3 patients received doses of cocaine that exceeded the maximum dose (1.5 mg/kg) currently recommended in the BNF² for healthy adults.

Cocaine has sympathomimetic actions (tachycardia, peripheral vasoconstriction, and hypertension). Combined use with sympathomimetics such as adrenaline increases these effects, and the risk of life-threatening arrhythmias. This risk may be further increased if halothane anaesthesia is used (two of the above patients received halothane¹). See also 'Anaesthetics, general + Anaesthetics, local', p.92 and 'Anaesthetics, general + Inotropes and Vasopressors', p.99.

The use of adrenaline with topical cocaine is controversial. Some consider that the addition of adrenaline is of doubtful value and that the combination should not be used, especially in the form of a concentrated paste.¹ However, others consider the combination to be safe and useful.³ Whether or not adrenaline is combined with cocaine, the BNF considers that topical cocaine should be used only by those skilled in the precautions needed to minimise absorption and the consequent risk of arrhythmias.²

Note also that the use of local anaesthetics containing adrenaline should be avoided in patients who abuse cocaine, unless it is certain that they have not used cocaine for at least 24 hours.⁴

Botulinum toxin + Miscellaneous

Theoretically, the neuromuscular blocking effects of botulinum toxin can be increased by other drugs with neuromuscular blocking effects, such as the aminoglycosides and muscle relaxants, but no such interactions have been reported.

Clinical evidence, mechanism, importance and management

A case report describes a 5-month-old baby boy who was admitted to hospital because of lethargy, poor feeding, constipation and muscle weakness (later identified as being due to a *Clostridium botulinum* infection). An hour after starting intravenous treatment with ampicillin and gentamicin 7.5 mg/kg daily in divided doses every 8 hours for presumed sepsis, he stopped breathing and died. The reason appeared to be the additive neuromuscular blocking effects of the systemic botulinum toxin produced by the *Clostridium botulinum* infection and the gentamicin.¹ Animal studies confirm that gentamicin and tobramycin potentiate the neuromuscular blocking effects of systemic botulinum toxin (used to mimic botulism),¹ and there is every reason to believe that any of the other drugs known to cause neuromuscular blockade (aminoglycosides, conventional neuromuscular blockers, etc.) will behave similarly. However, note that

clinically, botulinum A toxin is injected for local effect in specific muscles, and is not used systemically; and so the situation is not analogous to that described in the case of the child with systemic botulism.

Up until 2002, the UK manufacturers of botulinum A toxin stated in their prescribing information that the **aminoglycosides** and **spectinomycin** were contraindicated. They also advised caution with **polymyxins**, **tetracyclines** and **lincomycin**, and a reduced starting dose with **muscle relaxants** with a long-lasting effect, or the use of an intermediate action drug such as vecuronium or atracurium.² Later prescribing information notes that these interactions are theoretical.³ Similarly the UK manufacturer of botulinum B cautions use with aminoglycosides or other drugs that affect neuromuscular transmission.⁴

Neuromuscular blockers + Aminoglycosides

The aminoglycoside antibacterials possess neuromuscular blocking activity. Appropriate measures should be taken to accommodate the increased neuromuscular blockade and the prolonged and potentially fatal respiratory depression that can occur if these antibacterials are used with conventional neuromuscular blocking drugs.

Clinical evidence

Two examples from many:

A 38-year-old patient anaesthetised with cyclopropane experienced severe respiratory depression after being given intraperitoneal **neomycin** 500 mg. She had also received **suxamethonium (succinylcholine)** and **tubocurarine**. This antibacterial-induced neuromuscular blockade was resistant to treatment with edrophonium.¹

A 71-year-old woman received a standard bowel preparation consisting of oral erythromycin and **neomycin** (a total of 3 g). Surgery was postponed for one day and she received a second similar bowel preparation pre-operatively. Anaesthesia was induced with sufentanil and etomidate and maintained with isoflurane and sufentanil. **Rocuronium** (total dose of 60 mg over 2 hours) was used to facilitate tracheal intubation and maintain muscle relaxation. Despite clinical appearance of a reversal of the neuromuscular blockade by neostigmine 3.5 mg and glycopyrrolate 400 micrograms, the patient complained of dyspnoea and required reintubation twice. The effects of additional doses of neostigmine were inconsistent and the use edrophonium 50 mg or calcium chloride 500 mg intravenously did not result in an improvement.²

Many other reports confirm that some degree of respiratory depression or paralysis can occur if aminoglycosides are given to anaesthetised patients. When a conventional neuromuscular blocker is also used, the blockade is deepened and recovery prolonged. If the antibacterial is given towards the end of surgery the result can be that a patient who is recovering normally from neuromuscular blockade suddenly develops serious apnoea which can lead on to prolonged and in some cases fatal respiratory depression. A review of the literature³ lists more than 100 cases over the period 1956 to 1970 involving:

- **tubocurarine** with **neomycin** or **streptomycin**,
- **gallamine** with **neomycin**, **kanamycin** or **streptomycin**,
- **suxamethonium** with **neomycin**, **kanamycin** or **streptomycin**.

The routes of antibacterial administration were oral, intraperitoneal, oesophageal, intraluminal, retroperitoneal, intramuscular, intrapleural, cystic, beneath skin flaps, extradural and intravenous. Later reports involve:

- **pancuronium**; with **amikacin**,⁴ **gentamicin**,⁵ **neomycin**,⁶ or **streptomycin**,^{7,8}
- **pipecuronium** with **netilmicin**,⁹
- **suxamethonium** with **dibekacin**.¹⁰

- **tubocurarine**; with **amikacin**,¹¹ **dibekacin**,^{10,12} **framycetin** (eye irrigation),¹³ **ribostamycin**,^{10,12} or **tobramycin**.¹⁴
- **vecuronium**; with **amikacin/polymyxin**,¹⁵ **gentamicin**,^{16–18} **gentamicin/clindamycin**,¹⁹ or **tobramycin**.^{17,20}

Aminoglycosides and neuromuscular blockers that have been reported not to interact are:

- **tobramycin** with **alcuronium**,²¹ **atracurium**¹⁷ or **suxamethonium**,¹⁰
- **gentamicin** with **atracurium**,¹⁷
- **ribostamycin** with **suxamethonium**.¹⁰

Mechanism

The aminoglycosides appear to reduce or prevent the release of acetylcholine at neuromuscular junctions (related to an impairment of calcium influx) and they may also lower the sensitivity of the post-synaptic membrane, thereby reducing transmission. These effects would be additive with those of conventional neuromuscular blockers, which act at the post-synaptic membrane.

Importance and management

Extremely well documented, very long established, clinically important and potentially serious interactions. Ten out of the 111 cases in one review³ were fatal, related directly or indirectly to aminoglycoside-induced respiratory depression. Concurrent use need not be avoided, but be alert for increased and prolonged neuromuscular blockade with every aminoglycoside and neuromuscular blocker although the potencies of the aminoglycosides differ to some extent. In *animal* studies at concentrations representing the maximum therapeutic levels, the neuromuscular blocking potency of various aminoglycosides was rated (from highest to lowest) neomycin, streptomycin, gentamicin, kanamycin.²² The postoperative recovery period should also be closely monitored because of the risk of recurarisation if the aminoglycoside is given during surgery. High-risk patients appear to be those with renal disease and hypocalcaemia, who may have elevated serum antibacterial levels, and those with pre-existing muscular weakness. Treatment of the increased blockade with anticholinesterases and calcium has met with variable success because the response seems to be inconsistent.

Neuromuscular blockers + Anaesthetics, local

The neuromuscular blockade due to suxamethonium (succinylcholine) can be increased and prolonged by lidocaine, procaine and possibly procainamide. These local anaesthetics all have some neuromuscular blocking activity and may theoretically also enhance the block produced by competitive neuromuscular blockers. Increased toxicity occurred when mivacurium and prilocaine were given together for regional anaesthesia.

Clinical evidence

A patient anaesthetised with fluroxene and nitrous oxide demonstrated 100% blockade with **suxamethonium (succinylcholine)** and **tubocurarine**. About 50 minutes later when twitch height had fully returned and tidal volume was 400 mL, she was given **lidocaine** 50 mg intravenously for premature ventricular contractions. She immediately stopped breathing and the twitch disappeared. About 45 minutes later the tidal volume was 450 mL. Later it was found that the patient had a dibucaine number (a measure of cholinesterase activity) of 23%.¹

A study in 10 patients has confirmed that **lidocaine** and **procaine** prolong the apnoea following the use of **suxamethonium** 700 micrograms/kg. A dose-relationship was established. The duration of apnoea was approximately doubled by 5 mg/kg of lidocaine or 2.2 mg/kg of procaine intravenously, and tripled by 16.6 mg/kg and 11.2 mg/kg, respectively, although the effects of procaine at higher doses were more marked.²

Procainamide has been reported to increase the effects of **suxamethonium** in *animals*,³ increase muscle weakness in a myasthenic patient,⁴ and reduce plasma cholinesterase activity in healthy subjects.⁵ An *animal* study demonstrated potentiation of the neuromuscular blocking effect of **tubocurarine** by **lidocaine** alone and combined with antibiotics having neuromuscular blocking activity (**neomycin** or **polymyxin B**).⁶

In a study of 10 healthy subjects, prolonged muscle weakness and symptoms of local anaesthetic toxicity were experienced after deflation of the tourniquet when 40 mL of **prilocaine** 0.5% and **mivacurium** 600 micrograms were used together for intravenous regional anaesthesia of the forearm. Giving **prilocaine** or **mivacurium** alone did not produce these effects. The slow recovery suggested that **mivacurium** was not broken down in the ischaemic limb,⁷ but inhibition of plasma cholinesterase by **prilocaine** would not fully explain the prolonged weakness once the cuff was deflated.⁸

Mechanism

Uncertain. Some local anaesthetics (ester-type⁹) such as procaine appear to inhibit plasma cholinesterase,¹⁰ which might prolong the activity of suxamethonium. There may additionally be competition between suxamethonium and procaine for hydrolysis by plasma cholinesterase, which metabolises them both.^{2,5} These effects are particularly important in patients with abnormal plasma cholinesterase.¹¹ Therapeutic procainamide plasma concentrations of 5 to 10 micrograms/mL have been found to inhibit cholinesterase activity by 19 to 32%.⁵

All local anaesthetics have some neuromuscular blocking activity and may enhance the block produced by competitive neuromuscular blockers if given in sufficient doses.^{11,12} Procainamide also has acetylcholine receptor channel blocking activity.¹²

Importance and management

Information is limited but the interactions of suxamethonium with lidocaine, and suxamethonium with procaine appear to be established and of clinical importance. Be alert for signs of increased blockade and/or recurarisation with apnoea during the recovery period from suxamethonium.

Despite the potential for an interaction between suxamethonium and procainamide, no marked interaction has yet been reported. Nevertheless be aware that some increase in the neuromuscular blocking effects is possible.

Lidocaine, procaine and procainamide all have some neuromuscular blocking activity and may also enhance the block produced by competitive neuromuscular blockers if given in sufficient doses. However, again, there seems to be an absence of reports of this, probably because the amount of local anaesthetic absorbed into the circulation following a local block is usually modest.¹²

Animal studies indicate that low and otherwise safe doses of lidocaine given with other drugs having neuromuscular blocking activity (e.g. polymyxin B, aminoglycosides) may possibly be additive with conventional neuromuscular blockers and so some caution may be warranted.⁶

Neuromuscular blockers + Anticholinesterases

Anticholinesterases oppose the actions of competitive neuromuscular blockers (e.g. tubocurarine) and can therefore be used as an antidote to restore muscular activity following their use. Conversely, anticholinesterases increase and prolong the actions of the depolarising neuromuscular blockers (e.g. suxamethonium (succinylcholine)). Anticholinesterases used to treat Alzheimer's disease may also interact with neuromuscular blockers.

Clinical evidence, mechanism, importance and management

There are two main types of neuromuscular blockers: competitive (non-depolarising) and depolarising, see 'Table 5.2', (p.91).

(a) Competitive (non-depolarising) neuromuscular blockers

Competitive (non-depolarising) neuromuscular blockers (e.g. **tubocurarine**) compete with acetylcholine for receptors on the motor endplate. Anticholinesterases (e.g. **ambenonium**, **edrophonium**, **neostigmine**, **physostigmine**, **pyridostigmine**, etc.) can be used as an antidote to this kind of neuromuscular blockade, because they inhibit the enzymes that destroy acetylcholine so that the concentration of acetylcholine at the neuromuscular junction builds up. In this way the competition between the molecules of the blocker and the acetylcholine for occupancy of the receptors swings in favour of the acetylcholine so that transmission is restored. These drugs are used routinely following surgery to reactivate paralysed muscles. However, note that the **aminoglycosides** can act as neuromuscular blockers (see 'Neuromuscular blockers + Aminoglycosides', p.113) and therefore their use may unintentionally antagonise the effects of the anticholinesterases.

Some inhalational anaesthetics can impair the effect of anticholinesterases on neuromuscular blockers (see 'Anaesthetics, general + Anticholinesterases', p.93).

(b) Depolarising neuromuscular blockers

The depolarising blockers (such as **suxamethonium (succinylcholine)**) act like acetylcholine to depolarise the motor endplate, but unlike acetylcholine, they are not immediately removed by cholinesterase. The anticholinesterase drugs increase the concentration of acetylcholine at the neuromuscular junction, which enhances and prolongs this type of blockade, and therefore anticholinesterases cannot be used as an antidote for this kind of blocker. Care should be taken if an anticholinesterase has been given to antagonise a competitive neuromuscular block prior to the use of **suxamethonium**, as the duration of the **suxamethonium** block may be prolonged.¹

(c) Tacrine and other centrally-acting anticholinesterases

Tacrine, like other anticholinesterases, has been used *intravenously* in anaesthetic practice to reverse the effects of competitive (non-depolarising) blockers such as **tubocurarine**² and to prolong the effects of depolarising

blockers such as **suxamethonium**.²⁻⁶ For example, one study found that only one-third of the normal dosage of **suxamethonium** was needed in the presence of 15 mg of intravenous tacrine.⁷

However, tacrine is now more commonly used *orally* for its central effects in the treatment of Alzheimer's disease. Therefore be alert for changes in the effects of both types of neuromuscular blocking drugs in patients in whom tacrine is being used. Other cholinesterase inhibitors (including **galantamine**, **rivastigmine** and possibly **donepezil**) will behave like tacrine. There is a report of such an interaction in a 72-year-old woman taking **donepezil** who had prolonged paralysis after induction of anaesthesia with propofol and **suxamethonium**. It is possible that levels of **donepezil** in this patient were high due to concurrent omeprazole and fluoxetine and this may have contributed to the prolonged action of **suxamethonium**.⁸ Another report describes an 85-year-old woman taking **donepezil**, who developed prolonged neuromuscular blockade after the administration of **neostigmine** to reverse the effects of pancuronium (she had also received suxamethonium). This patient probably had atypical pseudocholinesterase activity, and the authors suggest the interaction may not be clinically relevant in patients with normal enzyme activity.⁹

(d) Organophosphorus compounds

Organophosphorus compounds are potent anticholinesterases, see 'Neuromuscular blockers + Organophosphorus compounds', p.130.

Neuromuscular blockers + Antiepileptics

The effects of many competitive neuromuscular blockers are reduced and shortened if carbamazepine or phenytoin are given for longer than one week, but they appear to be increased if phenytoin, and possibly carbamazepine, are given acutely (e.g. during surgery). Carbamazepine and phenytoin appear not to interact with mivacurium.

Clinical evidence

(a) Carbamazepine given long term: neuromuscular blocking effects reduced

The recovery from neuromuscular blockade with **pancuronium** in 18 patients undergoing craniotomy for tumours, seizure foci or cerebrovascular surgery was on average 65% shorter in those taking carbamazepine.¹ Another 9 patients taking carbamazepine for at least a week and undergoing surgery were given **doxacurium** took 66 minutes to reach 50% recovery compared with 161 minutes in the control group.² Similar findings were obtained in another study.³ Further studies found that carbamazepine significantly shortened the recovery time from **vecuronium** blockade in adults⁴ and in children.⁵ Several reports and studies have demonstrated a shorter duration of action of **rocuronium** following long-term carbamazepine use,⁶⁻⁹ although preliminary investigations found no effect.^{10,11} A reduced duration of action has been reported with **rapacuronium** in a patient taking carbamazepine.¹² The effects of **pipecuronium** are also reduced by carbamazepine.^{13,14} In one study it was found that the *onset* time for **pipecuronium** blockade was lengthened (although this was not statistically significant) in patients with therapeutic plasma concentrations of carbamazepine or phenytoin, but not in those with subtherapeutic levels. However, a shorter duration of action was seen regardless of anticonvulsant levels.¹⁴ One study found that the recovery time from intravenous **atracurium** 500 micrograms/kg was significantly shorter in 14 patients taking long-term carbamazepine (5.93 minutes) when compared with 21 nonepileptic patients (8.02 minutes). This was assessed using the recovery index (time between 25% and 75% recovery of baseline electromyogram values).¹⁵ However, other studies have reported

no effect, see (e) below. Another study found that the recovery time from intravenous **cisatracurium** was shorter in patients taking carbamazepine or **phenytoin** than in patients not receiving these antiepileptics; the recovery index (times between 25% and 75% recovery) was 16.2 and 21.2 minutes, respectively. Clearance of **cisatracurium** was increased by about 25% in patients taking the antiepileptics. The steady-state plasma level of **cisatracurium** required to maintain 95% block was increased by 20% in the patients taking antiepileptics, indicating increased resistance to the action of **cisatracurium**.¹⁶

(b) Carbamazepine given short term: neuromuscular blocking effects increased

An *in vitro* study found that the acute neuromuscular effects of **carbamazepine** reduced the concentrations required for 50% paralysis with both a depolarising neuromuscular blocker (**suxamethonium (succinylcholine)**) and a competitive neuromuscular blocker (**atracurium**) by about 30%.¹⁷

(c) Phenytoin given long term: neuromuscular blocking effects reduced

In the preliminary report of a study, the reduction in the time to recover from 25 to 75% of the response to ulnar nerve stimulation, in patients who had received phenytoin for longer than one week was: **metocurine** 58%, **pancuronium** 40%, **tubocurarine** 24%, **atracurium** 8% (the last two were not statistically significant).¹⁸ The **metocurine** results are published in full elsewhere.¹⁹ In another study about 80% more **pancuronium** was needed by 9 patients taking long-term phenytoin (58 micrograms/kg per hour) than in 18 others not receiving phenytoin (32 micrograms/kg per hour).²⁰ Resistance to **pancuronium** and a shortening of the recovery period due to long-term phenytoin^{3,21} or unspecified antiepileptics²² has also been described in other reports. The recovery period from **doxacurium**,^{2,3} **pipecuronium**,^{13,14} **rapacuronium** (case report),¹² **rocuronium**^{23,24} and **vecuronium**^{5,25-28} is also reduced by phenytoin. In one study it was found that the *onset* time for **pipecuronium** blockade was lengthened (although this was not statistically significant) for patients with therapeutic plasma concentrations of phenytoin or carbamazepine, but not in those with subtherapeutic levels. However, a shorter duration of action occurred regardless of the anticonvulsant level.¹⁴

A reduced recovery time from **atracurium**-induced neuromuscular blockade was found in one study in patients taking long-term antiepileptics including phenytoin¹⁵ but other studies have reported a minimal effect, see (e) below. For a report of reduced recovery time, increased clearance of **cisatracurium** and increased resistance to its actions in the presence of phenytoin, see (a) above.

(d) Phenytoin given short term: neuromuscular blocking effects increased

A retrospective review of 8 patients taking long-term phenytoin (greater than 2 weeks) and 3 others given phenytoin within 8 hours of surgery found that the average doses of **vecuronium** used from induction to extubation were 155 micrograms/kg per hour (long term) and 61.5 micrograms/kg per hour (acute).²⁹ Others have reported similar results.²⁶ Short-term phenytoin use may have been a contributing factor in the prolonged clearance of **vecuronium** in another patient.^{30,31} Another study found that the sensitivity of patients to **vecuronium** was increased by phenytoin given intravenously during surgery,³² and this has also been seen in *animal* studies using **tubocurarine** and phenytoin.³³ Similarly, a study of 20 patients undergoing craniotomy found that phenytoin (10 mg/kg over about 30 minutes) given during the operation augmented the neuromuscular block produced by **rocuronium**.³⁴

(e) Antiepileptics given long term: neuromuscular blocking effects not significantly affected

Long-term (greater than 4 weeks) **carbamazepine** appears not to affect **mivacurium**-induced neuromuscular blockade.³⁵ Similarly, a study in 32 patients who had been taking **carbamazepine** alone or with **phenytoin** or **valproic acid** for greater than 2 weeks found no resistance to **mivacurium**,³⁶ although an earlier preliminary study by the same research group found a trend towards a shorter recovery from **mivacurium** in 13 patients taking unspecified antiepileptics (not statistically significant).³⁷ **Carbamazepine** has also been reported to have no effect on **atracurium**^{4,38} and two studies suggest that **atracurium** is normally minimally affected by **phenytoin**.^{25,39} However, one study¹⁵ found that the recovery time from **atracurium** blockade was significantly reduced in patients on long-term anticonvulsant therapy, see (a) and (c) above.

Eight patients who had been taking **phenytoin** and/or **carbamazepine** for at least one month took longer to recover from **suxamethonium (succinylcholine)** blockade compared with 9 control patients; the time for re-

turn to baseline twitch height was 14.3 and 10 minutes, respectively. The slight prolongation of **suxamethonium** action was considered to have few clinical implications.⁴⁰

Mechanism

Not fully understood, but it appears to be multifactorial. Acute administration of phenytoin or carbamazepine may result in neuromuscular block and potentiation of the action of competitive (non-depolarising) blockers.¹⁷

Long-term therapy with antiepileptics may produce subclinical neuromuscular blockade thought to be due to modest blockade of acetylcholine effects and a decrease in acetylcholine release; this antagonism may induce changes at the neuromuscular junction including increased number of acetylcholine receptors on the muscle membrane (up-regulation), with decreased sensitivity.^{5,40,41} Other suggestions to account for the reduced response with chronic antiepileptics include: induction of liver enzyme activity (phenytoin and carbamazepine are both potent inducers of cytochrome P450 isoenzymes), which would increase the metabolism and clearance of the neuromuscular blocker; and changes in plasma protein binding.^{5,40,41} It has been shown that carbamazepine doubles the clearance of vecuronium^{5,42} and phenytoin possibly increases the plasma clearance of pancuronium²¹ and rocuronium.²³

Importance and management

Established and clinically important interactions. More is known about phenytoin and carbamazepine than other antiepileptics.

Anticipate the need to use more (possibly up to twice as much) doxacurium, metocurine, pancuronium, pipecuronium, rocuronium and vecuronium in patients who have taken these antiepileptics for more than a week,²⁶ and expect an accelerated recovery. The effects on tubocurarine and atracurium appear only to be small or moderate, whereas mivacurium appears not to interact.

Anticipate the need to use a smaller neuromuscular blocker dosage, or prepare for a longer recovery time if phenytoin and possibly carbamazepine are given acutely.

Neuromuscular blockers + Antineoplastics

The effects of suxamethonium (succinylcholine) can be increased and prolonged in patients receiving cyclophosphamide because their plasma cholinesterase levels are depressed. Respiratory insufficiency and prolonged apnoea have been reported. Irinotecan may prolong the neuromuscular blocking effects of suxamethonium and antagonise that of non-depolarising drugs. Animal data suggests that thiotepa may also enhance the effects of suxamethonium. An isolated report describes a marked increase in the neuromuscular blocking effects of pancuronium in a myasthenic patient who was given thiotepa, but normally it appears not to interact with competitive neuromuscular blockers.

Clinical evidence

(a) Cyclophosphamide

Respiratory insufficiency and prolonged apnoea occurred in a patient on two occasions while receiving cyclophosphamide and undergoing anaesthesia during which **suxamethonium (succinylcholine)** and **tubocurarine** were used. Plasma cholinesterase levels were found to be low. Anaesthesia without the **suxamethonium** was uneventful. Seven out of 8 patients subsequently examined also showed depressed plasma cholinesterase levels while taking cyclophosphamide.¹

Respiratory depression and low plasma cholinesterase levels have been described in other reports in patients receiving cyclophosphamide.^{2–4} Similarly, in the discussion of an *in vitro* study, the authors report preliminary

results from a study in patients, showing a 35 to 70% reduction in cholinesterase activity for several days after cyclophosphamide use.² See also (d) below.

(b) *Irinotecan*

The manufacturer warns that irinotecan could possibly prolong the neuromuscular blocking effects of suxamethonium (succinylcholine) and antagonise the neuromuscular blockade of competitive (non-depolarising) drugs.⁵ This is based on the fact that irinotecan has anticholinesterase activity^{5,6} (see also 'Neuromuscular blockers + Anticholinesterases', p.114, for an explanation of this mechanism).

(c) *Thiotepa*

A myasthenic patient developed very prolonged respiratory depression very shortly after being given thiotepa intraperitoneally, following the use of **pancuronium**.⁷ Thiotepa has also been shown to increase the duration of **suxamethonium (succinylcholine)** neuromuscular blockade in *dogs*.⁸ However, an *in vitro* study showed that thiotepa was a poor inhibitor of plasma cholinesterase.² See also (d) below.

(d) *Other antineoplastics*

A patient with myasthenia gravis and thymoma experienced severe myasthenic crises during 2 cycles of treatment with **doxorubicin**, **cisplatin** and **etoposide**. He also received dexamethasone with the first but not the second cycle of treatment. It was suggested that at least one of the antineoplastics had a direct inhibitory effect on neuromuscular transmission leading to exacerbation of pre-existing myasthenia gravis.⁹

An *in vitro* study found that human motor endplate or red blood cell acetylcholinesterase was inhibited by alkylating antineoplastics, with **chlormethine** exerting the greatest effect, followed by **dacarbazine**, **nimustine**, **cyclophosphamide** and **ifosfamide**. **Chlormethine** and **cyclophosphamide** inhibited plasma pseudocholinesterase most strongly, followed by **thiotepa**, **nimustine**, **dacarbazine**, **ifosfamide**, and **carmustine**.¹⁰

Mechanism

Cyclophosphamide inhibits the activity of plasma cholinesterase,⁴ and as a result the metabolism of the suxamethonium is reduced and its actions are enhanced and prolonged. Other alkylating agents are also reported to reduce plasma cholinesterase activity.¹⁰

Importance and management

The interaction between suxamethonium and cyclophosphamide is well documented and established. It is of clinical importance, but whether all patients are affected to the same extent is uncertain. The depression of the plasma cholinesterase levels may last several days, possibly weeks, so that ideally plasma cholinesterase levels should be checked before using suxamethonium. In patients taking cyclophosphamide it should certainly be used with caution, and the dosage should be reduced.² Some have suggested that concurrent use should be avoided.¹ Irinotecan may possibly enhance the effects of suxamethonium and antagonise the effects of non-depolarising drugs. *Animal* data suggest thiotepa may enhance the effects of suxamethonium and *in vitro* data suggest some other antineoplastics may also have an effect. The general silence in the literature would seem to indicate that no special precautions are normally necessary. However, patients with malignant tumours often have a reduced plasma cholinesterase activity, so care is warranted in these patients.¹¹

Neuromuscular blockers + Antipsychotics

An isolated report describes prolonged apnoea in a patient given promazine while recovering from neuromuscular blockade with suxamethonium (succinylcholine). Recovery from the neuromuscular blocking effects of suxamethonium is prolonged by fentanyl/droperidol.

Clinical evidence

(a) *Suxamethonium (succinylcholine) + Fentanyl/droperidol*

The observation that patients who had received *Innovar* (fentanyl/droperidol) before anaesthesia appeared to have prolonged suxamethonium effects, seen as apnoea, prompted further study of this possible interaction.¹ An average delay in recovery from neuromuscular blockade of 36% to 80% was seen in two studies.^{1,2} Another study³ showed that the droperidol component of *Innovar* was probably responsible for this interaction.

(b) *Suxamethonium (succinylcholine) + Promazine*

A woman recovering from surgery during which she had received suxamethonium, was given promazine 25 mg intravenously for sedation. Within 3 minutes she had become cyanotic and apnoeic, and required assisted respiration for 4 hours.⁴

Mechanism

Not understood. It has been suggested that promazine⁴ and droperidol³ depress plasma cholinesterase levels, which would reduce the metabolism of the suxamethonium and thereby prolong recovery. It has also been suggested that droperidol might act as a membrane stabiliser at neuromuscular junctions.³

Importance and management

Some caution would seem appropriate if promazine is given to any patient who has been given suxamethonium. There seems to be no information about other phenothiazines and other neuromuscular blockers.

Delayed recovery should be anticipated in patients given suxamethonium if droperidol is used. This is an established interaction.

Neuromuscular blockers + Aprotinin

Apnoea developed in a number of patients after they were given aprotinin while recovering from neuromuscular blockade with suxamethonium (succinylcholine) alone or with tubocurarine.

Clinical evidence

Three patients undergoing surgery who had received **suxamethonium (succinylcholine)**, alone or with **tubocurarine**, were given aprotinin intravenously in doses of 2500 to 12 000 KIU (kallikrein inactivator units) at the end of, or shortly after the operation, when spontaneous breathing had resumed. In each case respiration rapidly became inadequate and apnoea lasting periods of 7, 30 and 90 minutes occurred.¹ Seven other cases have been reported elsewhere.²

Mechanism

Not fully understood. Aprotinin is only a very weak inhibitor of serum cholinesterase (100 000 KIU caused a maximal 16% inhibition in man)³ and on its own would have little effect on the metabolism of suxamethonium. However, it might tip the balance in those whose cholinesterase was already very depressed.

Importance and management

The incidence of this interaction is uncertain but probably low. Only a few cases have been reported. It seems probable that it only affects those whose plasma cholinesterase levels are already very low for other reasons. No difficulties should arise in those whose plasma cholinesterase levels are normal.

Neuromuscular blockers + Benzodiazepines

A few studies report that diazepam and other benzodiazepines increase the effects of neuromuscular blockers, but many others have not found an interaction. If an interaction does occur, the response is likely to be little different from the individual variations in response of patients to neuromuscular blockers.

Clinical evidence

(a) Increased blockade

A comparative study of 10 patients given **gallamine** and 4 others given **gallamine** with intravenous **diazepam** 150 to 200 micrograms/kg found that the **diazepam** prolonged the duration of activity of the blocker by a factor of three, and doubled the depression of the twitch response.¹ Persistent muscle weakness and respiratory depression was seen in 2 other patients given **tubocurarine** after premedication with **diazepam**.² A small reduction (approximately 10%) in neuromuscular blocker requirement has been described with **diazepam** and **tubocurarine**³ or **suxamethonium** (**succinylcholine**), but see also (b) below.⁴

Another study found that recovery to 25% and 75% of the twitch height after **vecuronium** was prolonged by about 25% by 15 mg of intravenous **midazolam**, when compared with control patients.⁵ The same study found that **midazolam** prolonged the recovery from the effects of **atracurium** by about 20%. However, the increased recovery time due to **midazolam** was not statistically significant when compared with control patients, but was significantly longer when compared with patients receiving 20 mg of intravenous **diazepam**.⁵ See also (b) below.

(b) Reduced blockade or no effect

The duration of paralysis due to **suxamethonium** was reduced in one study by 20% when **diazepam** (150 micrograms/kg) was also given and the recovery time was shortened.¹ **Diazepam** also slightly reduced the time to 25% and 75% recovery of twitch height in patients given **vecuronium** by about 15% (not statistically significant).⁵ In *animals*, **diazepam** increased the mean dose of **rocuronium** required by 13%, but this was not statistically significant.⁶

In other studies **diazepam** was found to have no significant effect on the neuromuscular blockade due to **alcuronium**,⁷ **atracurium**,⁵ **gallamine**,⁸ **pancuronium**,^{7,9} **suxamethonium**^{7,10} or **tubocurarine**.^{7,8,10,11} **Lorazepam** and **lormetazepam** have been reported to have little or no effects on **atracurium** or **vecuronium**,⁵ and **midazolam** has been reported to have no effect on **suxamethonium** or **pancuronium**.¹²

Mechanism

Not understood. One suggestion is that where some alteration in response is seen it may be a reflection of a central depressant action rather than a direct effect on the myoneural junction.⁸ Another study instead suggests that a direct action on the muscle may be responsible.¹³

Importance and management

There is no obvious explanation for these discordant observations. What is known shows that the benzodiazepines may sometimes unpredictably alter the depth and prolong the recovery period from neuromuscular blockade, but the extent may not be very great and may possibly be little different from the individual variations in the response of patients to neuromuscular blockers.

Given that benzodiazepines are commonly given as pre-medication it seems likely that any significant interaction would have come to light by now.

Neuromuscular blockers + Beta-agonist bronchodilators

Bambuterol can prolong the recovery time from neuromuscular blockade with suxamethonium (succinylcholine) or mivacurium. A case report describes modestly enhanced neuromuscular blockade when pancuronium or vecuronium were given after intravenous salbutamol.

Clinical evidence

(a) Bambuterol

A double-blind study in 25 patients found that the recovery time from neuromuscular blockade with **suxamethonium** (**succinylcholine**) was prolonged by about 30% in those who had received 10 mg of bambuterol 10 to 16 hours before surgery, and by about 50% in those who had received 20 mg of bambuterol.¹

This confirms two previous studies,^{2,3} one of which found that 30 mg of bambuterol given about 10 hours before surgery approximately doubled the duration of **suxamethonium** blockade.² Furthermore, in 7 patients who were heterozygous for abnormal plasma cholinesterase, 20 mg of bambuterol taken 2 hours before surgery prolonged **suxamethonium** blockade two- to threefold, and in 4 patients a phase II block occurred.⁴

Similar results have been found in a study involving 27 patients given **mivacurium**. A marked decrease in plasma cholinesterase activity, leading to reduced clearance and prolonged elimination half-life of **mivacurium**, occurred when oral bambuterol 20 mg was given 2 hours before induction of anaesthesia. The duration of action of **mivacurium** was prolonged three- to fourfold compared with placebo.⁵

(b) Salbutamol

A case report describes a 28-year-old man undergoing elective surgery who was given three intravenous doses of salbutamol 125 micrograms over 3.5 hours for treatment and prophylaxis of bronchospasm. Muscle relaxation was maintained with **pancuronium** and then **vecuronium**. The neuromuscular blockade (measured by the force of contraction of the adductor pollicis in response to ulnar nerve stimulation) increased following salbutamol injection, from 45 to 66% during **pancuronium** blockade and from 66 to 86% following **vecuronium**. In addition, recovery of neuromuscular function with neostigmine appeared to be slower than expected.⁶

Mechanism

Bambuterol is an inactive prodrug which is slowly converted enzymatically in the body to its active form, terbutaline. The carbamate groups that are split off can selectively inhibit the plasma cholinesterase that is necessary for the metabolism of suxamethonium and mivacurium. As a result, the metabolism of these neuromuscular blockers is reduced and their effects are thereby prolonged. The effect appears to be related to the dose of the

bambuterol and the time lag after administration; maximal depression of plasma cholinesterase activity appears to occur about 2 to 6 hours following oral administration, but is still markedly depressed after 10 hours.²

The effect of intravenous salbutamol was probably a direct effect at the neuromuscular junction.⁶

Importance and management

The interaction with bambuterol is an established interaction, which anaesthetists should be aware of. It may be more important where other factors reduce plasma cholinesterase activity or affect the extent of blockade in other ways (e.g. subjects heterozygous for abnormal plasma cholinesterase). This interaction only applies to beta agonists that are metabolised to carbamic acid (bambuterol appears to be the only one available).

The interaction between intravenous salbutamol and pancuronium or vecuronium appears to be limited to this single report and is probably of only minor clinical importance.

Neuromuscular blockers + Beta blockers

Increases or decreases (often only modest) in the extent of neuromuscular blockade have been seen in patients taking beta blockers. The bradycardia and hypotension sometimes caused by anaesthetics and beta blockers is not counteracted by atracurium.

Clinical evidence

(a) Reduced neuromuscular blockade

The effects of **suxamethonium (succinylcholine)** were slightly, but not significantly, reduced in 8 patients given a dose of **propranolol** of 1 mg/15 kg body weight intravenously 15 minutes pre-operatively. In another 8 patients, **propranolol**, given intravenously 20 to 40 minutes after the onset of action of **tubocurarine**, was also observed to shorten the recovery from **tubocurarine**.¹ Another study described a shortened recovery period from **tubocurarine** due to **oxprenolol** or **propranolol**, but **pindolol** only slightly affected a few subjects.²

(b) Increased neuromuscular blockade

Two patients with thyrotoxicosis showed prolonged neuromuscular blockade with **tubocurarine** after they had received **propranolol** 120 mg daily for 14 days prior to surgery.³ In 8 patients, intravenous **esmolol** 300 to 500 micrograms/kg per minute reduced the increase in heart rate during intubation, and slightly but significantly prolonged the recovery from blockade with **suxamethonium** by approximately 3 minutes when compared with 8 patients given placebo.⁴ See also (d) below.

(c) Bradycardia and hypotension

Eight out of 42 patients taking unnamed beta blockers given **atracurium** developed bradycardia (less than 50 bpm) and hypotension (systolic pressure less than 80 mmHg). Most of them had been premedicated with diazepam, induced with methohexital, and maintained with droperidol, fentanyl and nitrous oxide/oxygen. A further 24 showed bradycardia, associated with hypotension on 9 occasions. All responded promptly to 300 to 600 micrograms of intravenous atropine.⁵

Another patient using **timolol** 0.5% eye drops for glaucoma similarly developed bradycardia and hypotension when **atracurium** was given.⁶ Bradycardia and hypotension have been seen in 2 other patients, one given

alcuronium while using **timolol** eye drops for glaucoma, and the other given **atracurium** while taking **atenolol** for hypertension.⁷

For reports of bradycardia associated with **vecuronium** and opioids in patients also receiving beta blockers, see 'Neuromuscular blockers + Opioids', p.130.

(d) No interaction

A study of 16 patients who had been taking various beta blockers (**propranolol** 5, **atenolol** 5, **metoprolol** 2, **bisoprolol** 2, **oxprenolol** 1, **celiprolol** 1) for longer than one month found no difference in the onset and duration of action of **rocuronium**, when compared with a control group.⁸ Similarly, intra-operative **esmolol** did not affect the onset and recovery time from **suxamethonium (succinylcholine)** blockade in patients with normal plasma cholinesterase (pseudocholinesterase) activity,⁹ but see also (b) above.

Mechanism

The changes in the degree of blockade are not understood but the interaction appears to occur at the neuromuscular junction. It has been seen in *animal* studies.^{10,11} The bradycardia and hypotension (c) were probably due to the combined depressant effects on the heart of the anaesthetics and the beta blocker not being offset by atracurium, which has little or no effect on the vagus nerve at doses within the recommended range. Note that neuromuscular blockers with vagolytic activity can cause tachycardia and hypotension.

Importance and management

Information is fairly sparse, but these interactions appear normally to be of relatively minor importance. Be aware that changes in neuromuscular blockade (increases or decreases) can occur if beta blockers are used, but they seem to be unpredictable, and then often only modest in extent. The possible combined cardiac depressant effects of beta blockade and anaesthesia are well known (see 'Anaesthetics, general + Beta blockers', p.97). These effects may not be prevented when a neuromuscular blocker is used that has little or no effect on the vagus (such as atracurium or vecuronium).

Neuromuscular blockers + Bretylium

In theory there is the possibility of increased and prolonged neuromuscular blockade if bretylium is given with neuromuscular blockers.

Clinical evidence, mechanism, importance and management

Although case reports seem to be lacking, there is some evidence from *animal* studies that the effects of **tubocurarine** can be increased and prolonged by bretylium.¹ There is a theoretical possibility that if the bretylium were to be given during surgery to control arrhythmias, its effects (which are delayed) might be additive with the residual effects of the neuromuscular blocker during the recovery period, resulting in apnoea.

1. Welch GW, Waud BE. Effect of bretylium on neuromuscular transmission. *Anesth Analg* (1982) 61, 442–4.

Neuromuscular blockers + Calcium-channel blockers

Limited evidence indicates that intra-operative intravenous diltiazem, nifedipine, nifedipine and verapamil can increase the neuromuscular blocking effects of vecuronium and other competitive neuromuscular blockers. Intravenous nimodipine did not alter vecuronium effects in one study.

An isolated case report describes potentiation of tubocurarine and pancuronium by oral verapamil. However, long-term oral nifedipine did not alter vecuronium or atracurium effects, and long-term therapy with various calcium-channel blockers did not interact with rocuronium. Calcium-channel blockers do not increase the plasma potassium rise due to suxamethonium (succinylcholine).

Clinical evidence

(a) Competitive (non-depolarising) neuromuscular blockers + Intravenous calcium-channel blockers

A study in 24 surgical patients¹ anaesthetised with nitrous oxide and isoflurane found that diltiazem 5 or 10 microgram/kg per minute decreased the vecuronium requirements by up to 50%. Another study in 24 surgical patients found that diltiazem (5 mg bolus followed by a 4-microgram/kg per minute infusion) decreased vecuronium requirements by 45% when compared with a control group (no diltiazem), or those receiving diltiazem at half the infusion dose.² Reductions in the requirements for vecuronium were also noted in other surgical patients receiving intravenous diltiazem or nicardipine.³ A study in patients given vecuronium 100 micrograms/kg for tracheal intubation found that nicardipine 10 micrograms/kg shortened the onset of blockade, making it the same as in other patients given a higher dose of vecuronium 150 micrograms/kg alone. Recovery times were unaffected by the nicardipine.⁴ Yet another study showed that nicardipine reduced the requirements for vecuronium in a dose-dependent manner: nicardipine 1, 2 and 3 micrograms/kg per minute reduced the vecuronium dose requirement to 79%, 60% and 53% of control, respectively.⁵ A study involving 44 patients anaesthetised with isoflurane in nitrous oxide/oxygen found that 1 mg of intravenous nifedipine prolonged the neuromuscular blockade due to atracurium from 29 to 40 minutes, and increased the neuromuscular blockade of atracurium or vecuronium from 75 to 90%.⁶ In contrast, a study involving 20 patients found that an intravenous infusion of nimodipine had no significant effect on the time course of action of vecuronium.⁷

A 66-year-old woman with renal impairment, receiving 5 mg of intravenous verapamil three times a day for supraventricular tachycardia, underwent abdominal surgery during which she was initially anaesthetised with thiopental and then maintained on nitrous oxide/oxygen with fentanyl. Vecuronium was used as the muscle relaxant. The effects of the vecuronium were increased and prolonged, and at the end of surgery reversal of the blockade using neostigmine was difficult and extended.⁸ Intravenous verapamil alone has caused respiratory failure in a patient with poor neuromuscular transmission (Duchenne's dystrophy).⁹ Note that *in vitro* and *animal* studies have confirmed that the neuromuscular blocking effects of tubocurarine, pancuronium, vecuronium, atracurium and suxamethonium (succinylcholine) are increased by diltiazem, verapamil and nifedipine.⁹⁻¹¹

(b) Competitive (non-depolarising) neuromuscular blockers + Oral calcium-channel blockers

A report describes increased neuromuscular blockade in a patient taking long-term verapamil 40 mg three times daily who was given pancuronium 2 mg and tubocurarine 5 mg. The neuromuscular blockade was difficult to reverse with neostigmine, but which responded well to edrophonium.¹² However, the authors of this report say that many patients taking long-term verapamil do not show a clinically significant increase in sensitivity to muscle relaxants.¹² This case also contrasts with another study in which 30 predominantly elderly patients taking chronic nifedipine (mean daily dose 33 mg) showed no changes in the time of onset to maximum block nor the duration of clinical relaxation in response to atracurium or vecuronium, when compared with 30 control patients.¹³ Similarly, a study of 17 patients taking calcium-channel blockers (nifedipine 12, diltiazem 2, nicardipine 2, amlodipine 1) found no changes in the neuromuscular blocking effects of rocuronium.¹⁴

(c) Suxamethonium + Oral calcium-channel blockers

A comparative study in 21 patients taking calcium-channel blockers long term (diltiazem, nifedipine, verapamil) and 15 other patients not taking calcium-channel blockers found that, although suxamethonium (succinylcholine) caused a modest average peak rise of 0.5 mmol/L in plasma potassium levels, there were no differences between the two groups.¹⁵ See also (a) above.

Mechanism

Not fully understood. Although one suggested explanation has been given: nerve impulses arriving at nerve endings release calcium ions, which in turn causes the release of acetylcholine. Calcium-channel blockers can reduce the concentration of calcium ions within the nerve so that less acetylcholine is released. This would be additive with the effects of a neuromuscular blocker.^{11,12}

Importance and management

Direct information so far seems to be limited. Be alert for increased neuromuscular blockade in any patient given an intravenous calcium-channel blocker during surgery. However, this may not apply to nimodipine. From the limited evidence available it appears that increased blockade is not likely in patients taking long-term oral calcium-channel blockers, although one case has been reported with verapamil.

It would seem from the study quoted above¹⁵ that patients taking chronic calcium-channel blocker treatment are at no greater risk of hyperkalaemia with suxamethonium than other patients.

Neuromuscular blockers + Chloroquine or Quinine

A report describes respiratory insufficiency during the recovery period following surgery, which was attributed to the use of chloroquine diorotate. An isolated report describes recurarisation and dyspnoea in a patient given intravenous quinine after recovering from neuromuscular blockade with suxamethonium (succinylcholine) and pancuronium.

Clinical evidence, mechanism, importance and management

(a) Chloroquine

Studies were carried out on the possible neuromuscular blocking actions of chloroquine diorotate in *animals*, because it was noticed that when it was used in the peritoneal cavity to prevent adhesions following abdominal surgery in man, it caused respiratory insufficiency during the recovery period. These studies found that it had a non-depolarising blocking action at the neuromuscular junction, which was opposed by neostigmine.¹ It

would seem therefore that during the recovery period the effects of the chloroquine can be additive with the residual effects of the conventional neuromuscular blocker used during the surgery.

Although this appears to be the only report of this interaction, it is consistent with the way chloroquine can unmask or aggravate myasthenia gravis, or oppose the effects of drugs used in its treatment. Be alert for this reaction if chloroquine is used.

(b) Quinine

A 47-year-old man with acute pancreatitis, taking quinine 600 mg three times daily, was given penicillin and gentamicin intravenously before undergoing surgery, during which **pancuronium** and **suxamethonium (succinylcholine)** were used uneventfully. After surgery the neuromuscular blockade was reversed with neostigmine and atropine, and the patient awoke and was breathing well. A 6-hour intravenous infusion of quinine 500 mg was started 90 minutes postoperatively. Within 10 minutes (after receiving about 15 mg of quinine) he became dyspnoeic, his breathing became totally ineffective and he needed re-intubation. Muscle flaccidity persisted for 3 hours.² The reason for this reaction is not fully understood. A possible explanation is that it may have been the additive neuromuscular blocking effects of the gentamicin (well recognised as having neuromuscular blocking activity; see 'Neuromuscular blockers + Aminoglycosides', p.113) and the quinine (an optical isomer of quinidine; see 'Neuromuscular blockers + Quinidine', p.131) and the residual effects of the **pancuronium** and **suxamethonium**.

There seem to be no other reports of problems in patients receiving neuromuscular blockers with quinine, but this isolated case serves to emphasise the importance of being alert for any signs of re-occurance in patients concurrently treated with one or more drugs possessing some neuromuscular blocking activity.

2. Sher MH, Mathews PA. Recurarization with quinine administration after reversal from anaesthesia. *Anaesth Intensive Care* (1983) 11, 241–3.

Neuromuscular blockers + Clonidine

There is limited evidence to suggest that clonidine modestly increases the duration of action of vecuronium.

Clinical evidence, mechanism, importance and management

In a study of 16 surgical patients, 8 took oral clonidine 4 to 5.5 micrograms/kg 90 minutes before their operation. Anaesthesia was induced by thiopental, and maintained with nitrous oxide/isoflurane/oxygen supplemented by fentanyl. Clonidine increased the duration of neuromuscular blockade following the use of vecuronium by 26.4%, when compared with the patients not taking clonidine.¹

The reasons are not understood. The clinical importance of this interaction would appear to be small.

1. Nakahara T, Akazawa T, Kinoshita Y, Nozaki J. The effect of clonidine on the duration of vecuronium-induced neuromuscular blockade in humans. *Jpn J Anesthesiol* (1995) 44, 1458–63.

Neuromuscular blockers + Corticosteroids

Two reports describe antagonism of the neuromuscular blocking effects of pancuronium by high-dose prednisone, or prednisolone and hydrocortisone. A third report in a patient with adrenocortical insufficiency describes reversal of the pancuronium block by hydrocortisone. Some evidence suggests the dosage of vecuronium may need to be almost doubled in those receiving intramuscular betamethasone. However, prolonged coadministration of high-dose corticosteroids and neuromuscular blockers may increase the risk of myopathy, resulting in prolonged paralysis following the discontinuation of the neuromuscular blocker.

Clinical evidence

(a) Neuromuscular blocking effects

A man undergoing surgery who was taking **prednisone** 250 mg daily by mouth, had good muscular relaxation in response to intravenous **pancuronium** 8 mg (100 micrograms/kg) early in the operation, but an hour later

he began to show signs of inadequate relaxation, and continued to do so for the next 75 minutes despite being given four additional 2-mg doses of **pancuronium**.¹ Another patient taking large doses of **hydrocortisone**, **prednisolone** and aminophylline proved to be resistant to the effects of **pancuronium**.² A hypophysectomised man taking **cortisone** developed profound paralysis when given **pancuronium**, which was rapidly reversed with 100 mg of **hydrocortisone sodium succinate**.³

Inadequate neuromuscular blockade with **vecuronium** (presenting as unexpected movements) occurred in 2 patients during neurosurgery. They had both been given a preoperative course of **betamethasone** 4 mg four times daily to reduce raised intracranial pressure.⁴ This prompted a retrospective search of the records of 50 other patients, which revealed that those given intramuscular **betamethasone** preoperatively had needed almost double the dose of **vecuronium** (134 compared with 76 micrograms/kg per hour).⁴

These reports contrast with another,⁵ in which 25 patients who had no adrenocortical dysfunction or histories of corticosteroid therapy were given **pancuronium**, **metocurine**, **tubocurarine** or **vecuronium**. They showed no changes in their neuromuscular blockade when given a single intravenous dose of **dexamethasone** 400 micrograms/kg or **hydrocortisone** 10 mg/kg.

(b) Increased risk of myopathy

A report describes 3 patients in status asthmaticus who developed acute reversible myopathy after treatment with high-dose intravenous **methylprednisolone** 320 to 750 mg daily and steroidal neuromuscular blockers (**vecuronium** or **pancuronium**), used concurrently for at least 8 days.⁶ A review of the literature from 1977 to 1995 found over 75 cases of prolonged weakness associated with combined use of neuromuscular blockers and **corticosteroids**.⁷ This condition has been referred to as 'blocking agent–corticosteroid myopathy' (BACM). Prior to 1994, virtually all cases involved either **pancuronium** or **vecuronium**, leading some authors to suggest that **atracurium** might be safer as it does not have the steroidal structure of these neuromuscular blockers.⁶ However, there have since been reports of prolonged paralysis associated with extended treatment with high-dose **corticosteroids** and **atracurium**^{8,9} or **cisatracurium**.¹⁰

Mechanism

Not understood. For the partial reversal of neuromuscular blockade, one idea, based on *animal* studies, is that adrenocortical insufficiency causes a defect in neuromuscular transmission, which is reversed by the corticosteroids.³ Another idea is that the effects seen are connected in some way with the steroid nucleus of the pancuronium and vecuronium, and are mediated presynaptically.^{4,11}

The increased myopathy may be due to an additive effect as both neuromuscular blockers and corticosteroids can cause myopathy. Results of an *in vitro* study suggested that the combination of vecuronium and methylprednisolone might augment pharmacologic denervation, which may lead to myopathy and contribute to the prolonged weakness observed in some critically ill patients.¹²

Importance and management

The evidence for antagonism of neuromuscular blocking effects seems to be limited to the reports cited, and involve only pancuronium and vecuronium. Careful monitoring is clearly needed if either is used in patients who have been treated with corticosteroids, being alert for the need to increase the dosage of the neuromuscular blocker. Note that *animal* studies suggest that atracurium may also possibly be affected by betamethasone to the same extent as vecuronium.¹¹ However, also be aware that prolonged coadministration of competitive neuromuscular blockers and corticosteroids, particularly in patients in intensive care, may result in a marked prolongation of muscle weakness (several months' rehabilitation have been needed in some cases⁶). The complex state of the critically ill patient means that the effects of neuromuscular blockers may be unpredictable.

Neuromuscular blockers + Danazol or Tamoxifen

Two isolated case reports describe prolonged atracurium effects, which were attributed to tamoxifen and danazol.

Clinical evidence, mechanism, importance and management

A case report describes a 67-year-old mastectomy patient taking methyldopa, hydrochlorothiazide, triamterene and long-term tamoxifen 10 mg twice daily who showed prolonged neuromuscular blockade after a single 500-microgram/kg dose of **atracurium**, which the authors suggest might be due to an interaction between **atracurium** and tamoxifen.¹ The authors also point out an earlier report² of prolonged **atracurium** blockade where the patient was taking danazol. These interactions are probably not of general importance.

Neuromuscular blockers + Dantrolene

One patient developed increased vecuronium effects when given dantrolene, whereas two others were unaffected.

Clinical evidence, mechanism, importance and management

A 60-year-old woman, given a total of 350 mg of dantrolene orally during the 28 hours before surgery to prevent malignant hyperthermia, developed increased neuromuscular blockade and a slow recovery rate when **vecuronium** was subsequently given.¹ This report contrasts with another describing two patients taking long-term dantrolene 20 to 50 mg daily who had no changes in **vecuronium**-induced neuromuscular blockade during or after surgery.² Dantrolene is a muscle relaxant that acts directly on the muscle by lowering intracellular calcium concentrations in skeletal muscle; it reduces the release of calcium from the sarcoplasmic reticulum. It may also possibly inhibit calcium-dependent pre-synaptic neurotransmitter release.³ Be alert for any increased effects if both drugs are used. These case reports indicate that the effects could be dose-related, and so patients receiving higher doses of dantrolene may be at greater risk, although more study is needed to confirm this.

Neuromuscular blockers + Dexmedetomidine

Dexmedetomidine caused a minor increase in plasma rocuronium levels.

Clinical evidence, mechanism, importance and management

A study in 10 healthy subjects under general anaesthesia with alfentanil, propofol and nitrous oxide/oxygen, found that an intravenous infusion of dexmedetomidine (950 to 990 nanograms/kg) increased plasma **rocuronium** levels by 7.6%, which was not clinically significant, and decreased the twitch tension from 51% to 44% after 45 minutes. Dexmedetomidine also decreased finger blood flow and increased systemic blood pressure. It was suggested these pharmacokinetic changes occurred due to peripheral vasoconstriction.¹ These effects are unlikely to be of clinical significance.

Neuromuscular blockers + Dexpanthenol

An isolated report of an increase in the neuromuscular blocking effects of **suxamethonium (succinylcholine)** was attributed to the concurrent use of **dexpanthenol** in one patient, but a further study using **pantothenic acid** failed to confirm this interaction.

Clinical evidence, mechanism, importance and management

A study in 6 patients under general anaesthesia found that their response to **suxamethonium (succinylcholine)** was unaffected by the infusion of 500 mg of **pantothenic acid**.¹ This study was conducted in response to an earlier case report, which reported respiratory depression requiring re-intubation following the use of intramuscular **dexpanthenol** (which is converted to pantothenic acid in the body) shortly after stopping a **suxamethonium** infusion.¹

Apart from the single unconfirmed report there seems to be little other reason for avoiding concurrent use or for taking particular precautions. However, the US manufacturer of **dexpanthenol** recommends that it should not be given within one hour of **suxamethonium**.²

- Dexpanthenol Injection. American Reagent, Inc. US Prescribing information, January 2003.

Neuromuscular blockers + Disopyramide

An isolated case report suggests that **disopyramide** may oppose the effects of **neostigmine** used to reverse neuromuscular blockade with **vecuronium**.

Clinical evidence, mechanism, importance and management

A case report¹ suggests that the normal antagonism by **neostigmine** of **vecuronium** neuromuscular blockade may be opposed by therapeutic serum levels of **disopyramide** (5 micrograms/mL). **Disopyramide** has also been shown to decrease the antagonism by **neostigmine** of the neuromuscular blockade of **tubocurarine** on the *rat* phrenic nerve-diaphragm preparation.² The general clinical importance of these observations is not known.

Neuromuscular blockers + Ecothiopate iodide

The neuromuscular blocking effects of **suxamethonium (succinylcholine)** are markedly increased and prolonged in patients receiving **ecothiopate iodide**. The dosage of **suxamethonium** should be reduced appropriately.

Clinical evidence

In 1965 a study¹ showed that **ecothiopate iodide** eye drops could markedly lower pseudocholinesterase levels. It was noted that "... within a few days of commencing therapy, levels are reached at which protracted apnoea could occur, should these patients require general anaesthesia in which muscle relaxation is obtained with **succinylcholine**". Cases of apnoea due to this interaction were reported the following year,^{2,3} and other cases have been subsequently reported.^{4,5} In one case a woman given **suxamethonium (succinylcholine)** 200 mg showed apnoea for 5½ hours.² Other stud-

ies have confirmed that ecothiopate given orally⁶ or as eye drops⁷ markedly reduced the levels of plasma cholinesterase, and can prolong recovery after **suxamethonium**.⁶ On discontinuing ecothiopate, it takes several weeks to 2 months for enzyme activity to return to normal.⁷

Mechanism

Suxamethonium is metabolised in the body by plasma cholinesterase. Ecothiopate iodide depresses the levels of this enzyme so that the metabolism of the suxamethonium is reduced and its effects are thereby enhanced and prolonged.^{3,6} One study in 71 patients found that two drops of ecothiopate iodide 0.06% three times a week in each eye caused a twofold reduction in plasma cholinesterase (pseudocholinesterase) activity in about one-third of the patients, and a fourfold reduction in 1 in 7 patients.⁸

Importance and management

An established, adequately documented and clinically important interaction. The dosage of suxamethonium should be reduced appropriately because of the reduced plasma cholinesterase levels caused by ecothiopate. The study cited above⁸ suggests that prolonged apnoea is likely in about 1 in 7 patients. One report describes the successful use of approximately one-fifth of the normal dosage of suxamethonium in a patient receiving 0.125% ecothiopate iodide solution, one drop twice a day in both eyes, and with a plasma cholinesterase activity 62% below normal. Recovery from the neuromuscular blockade was rapid and uneventful.⁹ Another report describes the successful and uneventful use of atracurium in a patient receiving ecothiopate.⁵ **Mivacurium** is also metabolised by plasma cholinesterase, and would be expected to interact with ecothiopate in the same way as suxamethonium.¹⁰ Consider also 'Neuromuscular blockers + Anticholinesterases', p.114.

Neuromuscular blockers + Ephedrine

A study in 80 patients found that premedication with ephedrine 10 mg reduced the onset time of rocuronium by roughly 30% but did not significantly affect that of atracurium.¹ The clinical significance of these effects is unclear.

1. Santiveri X, Mansilla R, Pardina B, Navarro J, Álvarez JC, Castillo J. La efedrina acorta el inicio de acción del rocuronio pero no del atracurio. *Rev Esp Anestesiol Reanim* (2003) 50, 176–81.

Neuromuscular blockers + Furosemide

The effects of the neuromuscular blockers have been both increased and decreased by furosemide.

Clinical evidence

(a) Increased neuromuscular blockade

Three patients receiving kidney transplants¹ developed increased neuromuscular blockade with **tubocurarine** (seen as a pronounced decrease in twitch tension) when given furosemide 40 or 80 mg and mannitol 12.5 g

intravenously. One of them had the same reaction when later given only 40 mg of furosemide but no mannitol. The residual blockade was easily antagonised with pyridostigmine 14 mg or neostigmine 3 mg with atropine 1.2 mg.

(b) Decreased neuromuscular blockade

Ten neurosurgical patients given furosemide 1 mg/kg 10 minutes before induction of anaesthesia, took 14.7 minutes to recover from 95 to 50% blockade with **pancuronium** (as measured by a twitch response) compared with 21.8 minutes in 10 similar patients who had not received furosemide.²

Mechanism

Uncertain. *Animal* studies indicate that what happens probably depends on the dosage of furosemide: 0.1 to 10 micrograms/kg increased the blocking effects of tubocurarine and suxamethonium (succinylcholine) whereas 1 to 4 mg/kg opposed the blockade.³ One suggestion is that low doses of furosemide may inhibit protein kinase causing a reduction in neuromuscular transmission, whereas higher doses cause inhibition of phosphodiesterase resulting in increased cyclic AMP activity and causing antagonism of neuromuscular blockade. It has also been suggested that large doses of loop diuretics may affect the renal excretion of neuromuscular blockers that are cleared by this route, resulting in more rapid recovery from the blockade.³

Importance and management

The documentation is very limited. Be on the alert for changes in the response to any blocker if furosemide is used.

Neuromuscular blockers + H₂-receptor antagonists

One report suggests that recovery from the neuromuscular blocking effects of suxamethonium (succinylcholine) is prolonged by cimetidine, but this may possibly have been due to the presence of metoclopramide. Four other reports say that no interaction occurs between suxamethonium and either cimetidine, famotidine or ranitidine. Cimetidine, but not ranitidine, has been reported to increase the effects of vecuronium. Cimetidine does not alter the effects of atracurium or rocuronium and ranitidine does not alter the effects of atracurium.

Clinical evidence

(a) Evidence of increased neuromuscular blockade

A study in 10 patients given **cimetidine** 300 mg orally at bedtime and another 300 mg 2 hours before anaesthesia, found that while the onset of action of **suxamethonium (succinylcholine)** 1.5 mg/kg intravenously was unchanged, when compared with 10 control patients, the time to recover 50% of the twitch height was prolonged 2 to 2.5-fold (from 8.6 to 20.3 minutes). One patient took 57 minutes to recover. His plasma cholinesterase levels were found to be normal.¹ It was later reported that some patients were also taking **metoclopramide**, which is known to interact in this way.² See also 'Neuromuscular blockers + Metoclopramide', p.127.

Another study³ in 24 patients found that **cimetidine** 400 mg significantly prolonged the recovery (T1–25 period) from **vecuronium**, but few patients had any response to **cimetidine** 200 mg or **ranitidine** 100 mg. This slight prolongation of action of **vecuronium** due to **cimetidine** 400 mg was confirmed in another placebo-controlled study (mean time to return of T1 was 30 versus 22.5 minutes).⁴ A study using a *rat* phrenic nerve dia-

phragm preparation found that **cimetidine** increased the neuromuscular blocking effects of **tubocurarine** and **pancuronium**, but there seem to be no reports confirming this in man.⁵

(b) Evidence of unchanged neuromuscular blockade

A study in 10 patients given 400 mg of **cimetidine** orally at bedtime and again 90 minutes before anaesthesia found no evidence of an effect on the neuromuscular blockade caused by **suxamethonium**, nor on its duration or recovery period, when compared with 10 control patients.⁶ Another controlled study in patients given **cimetidine** 300 mg or **ranitidine** 150 mg, both the night before and 1 to 2 hours before surgery, found no evidence that the duration of action of **suxamethonium** or the activity of plasma cholinesterase were altered.² A study in 15 patients undergoing caesarean section also found no evidence that either **cimetidine** or **ranitidine** affected the neuromuscular blocking effects of **suxamethonium**.⁷ A study in 70 patients⁸ found no changes in the neuromuscular blocking effects of **suxamethonium** in those given **cimetidine** 400 mg, **ranitidine** 80 mg or **famotidine** 20 mg.

Cimetidine and **ranitidine** appear not to affect **atracurium**, **cimetidine** appears not to affect **rocuronium**,⁹ and **ranitidine** appears not to affect **vecuronium**.⁴ Another study found that premedication with **ranitidine** did not affect **vecuronium** blockade in postpartum patients, but that the neuromuscular blockade was prolonged in these patients compared with non-pregnant controls.¹⁰

Mechanism

Not understood. Studies with human plasma failed to find any evidence that **cimetidine** in therapeutic concentrations inhibits the metabolism of **suxamethonium**.^{2,11} However, metoclopramide may do and therefore is possibly the drug responsible for any interaction seen. *In vitro* studies with very high **cimetidine** concentrations found inhibition of plasma cholinesterase (pseudocholinesterase) activity.¹² The **cimetidine/vecuronium** interaction is not understood, but it has been suggested that **cimetidine** may reduce the hepatic metabolism of **vecuronium**.⁴

Importance and management

Information seems to be limited to the reports cited. The most likely explanation for the discord between the **cimetidine/suxamethonium** results is that in the one study reporting increased **suxamethonium** effects¹ some of the patients were also given metoclopramide, which can inhibit plasma cholinesterase and prolong the effects of **suxamethonium**.^{2,8} (see also 'Neuromuscular blockers + Metoclopramide', p.127). In four other studies, **cimetidine** and other H₂-receptor antagonists did not alter **suxamethonium** effects. Therefore, it seems unlikely that an interaction exists. There is some evidence that **cimetidine** may slightly prolong the effects of **vecuronium**, but **ranitidine** appears not to interact. **Atracurium** and **rocuronium** appear not to be affected. Overall these possible interactions seem to be of little clinical significance.

Neuromuscular blockers + Immunosuppressants

There is limited evidence to suggest that the neuromuscular blocking effects of atracurium, pancuronium and vecuronium may be increased in some patients taking ciclosporin. There is also some evidence of reduced neuromuscular blockade with azathioprine and antilymphocyte immunoglobulins, but other evidence suggests that there is no clinically relevant interaction with azathioprine.

Clinical evidence

(a) Azathioprine or Antilymphocyte immunoglobulins

A retrospective study found that patients taking azathioprine or antilymphocyte immunoglobulins following organ transplantation needed an increased dosage of unspecified **muscle relaxants** to achieve satisfactory muscle relaxation.¹ A control group of 74 patients not receiving immunosuppression needed 0 to 10 mg of a **competitive (non-depolarising) muscle relaxant**; 13 patients taking azathioprine needed 12.5 to 25 mg; 11 patients receiving antilymphocyte immunoglobulins (antilymphocyte globulin) needed 10 to 20 mg and two patients taking azathioprine and guanethidine needed 55 and 90 mg.¹ However, a controlled study of 28 patients undergoing renal transplantation, who were receiving **atracurium**, **pancuronium** or **vecuronium** at a constant infusion rate, found that an injection of azathioprine 3 mg/kg given over 3 minutes caused a rapid, but only small and transient decrease of neuromuscular blockade. Ten minutes after the end of the azathioprine injection, a residual interaction was only detectable in those patients who had received **pancuronium**.²

(b) Ciclosporin

A retrospective study found that 4 of 36 patients receiving **atracurium** and 4 of 29 patients receiving **vecuronium** experienced prolonged neuromuscular blockade after anaesthesia for kidney transplantation. Respiratory failure occurred more often in patients who received intravenous ciclosporin during surgery.³ Extended recovery times after **atracurium** and **vecuronium** are described in another report in renal transplant patients who had been taking oral ciclosporin.⁴ Similarly, a prolonged duration of action of **vecuronium** was noted in 7 kidney transplant recipients, when compared with patients with normal renal function, and ciclosporin was considered to be a factor in this.⁵ Two case reports describe prolonged neuromuscular blockade attributed to intravenous ciclosporin.

In the first report,⁶ a woman with a 2-year renal transplant underwent surgery during which **pancuronium** 5.5 mg was used as the neuromuscular blocker. She was also given intravenous ciclosporin before and after surgery. The surgery lasted for 4 hours and no additional doses of **pancuronium** were given. Residual paralysis was inadequately reversed with neostigmine and atropine, and so edrophonium was given prior to extubation. However, she had to be re-intubated 20 minutes later because of increased respiratory distress.

In the second report,⁷ a 15-year-old girl receiving intravenous ciclosporin with serum levels of 138 micrograms/L was anaesthetised using fentanyl, thiopental and **vecuronium** 100 micrograms/kg. Anaesthesia was maintained with nitrous oxide, oxygen and isoflurane. Attempts were later made to reverse the blockade with edrophonium, atropine and neostigmine but full neuromuscular function was not restored until 3 hours and 20 minutes after the **vecuronium** was given. Another report describes a prolongation of the effects of **vecuronium** in a renal-transplant recipient taking oral ciclosporin, azathioprine, and prednisolone.⁸

Mechanism

The reasons for the reduction in neuromuscular blockade with azathioprine and antilymphocyte immunoglobulins are not understood. It has been suggested that azathioprine may inhibit phosphodiesterase at the motor nerve terminal resulting in increased release of acetylcholine.⁹

The ciclosporin interaction may be partly due to the vehicle used in intravenous preparations. One idea is that *Cremophor*, a surfactant which has been used as a solvent for the ciclosporin, may increase the effective concentration of **pancuronium** at the neuromuscular junction.⁶ Both compounds have been observed in *animal* studies to increase **vecuronium** blockade,¹⁰ and *Cremophor* has also been seen to decrease the onset time

of pancuronium blockade in patients given *Cremophor*-containing anaesthetics.¹¹ However, this is not the entire answer because the interaction has also been seen with oral ciclosporin, which does not contain *Cremophor*.⁸

Importance and management

Direct information seems to be limited to the reports cited, and the interactions are not established. Although retrospective data suggest that azathioprine and antilymphocyte immunoglobulins can cause a reduction in the effects of neuromuscular blockers, and in some cases the dosage may need to be increased two- to fourfold,¹ the only prospective study found that the interaction with azathioprine was not clinically significant.² The general importance of the ciclosporin interaction is also uncertain, but be alert for an increase in the effects of atracurium, pancuronium or vecuronium in any patient receiving ciclosporin. Not all patients appear to develop this interaction.³ More study is needed.

Neuromuscular blockers + Lansoprazole

There is some evidence that lansoprazole increases the duration of action of vecuronium.

Clinical evidence, mechanism, importance and management

In a study of 50 adult surgical patients, half of whom received lansoprazole 30 mg on the night before their operation, it was found that there was no significant difference between the time of onset of neuromuscular blockade by **vecuronium** in the two groups, but lansoprazole increased the duration of effect by about 34%.¹ This needs confirmation but be alert for this interaction in any patient treated with lansoprazole.

Neuromuscular blockers + Lithium

The concurrent use of neuromuscular blockers and lithium is normally safe and uneventful, but four patients taking lithium experienced prolonged blockade and respiratory difficulties after receiving standard doses of pancuronium and/or suxamethonium (succinylcholine).

Clinical evidence

A manic depressive woman taking lithium carbonate with a lithium level of 1.2 mmol/L, underwent surgery and was given thiopental, 310 mg of **suxamethonium (succinylcholine)** over a period of 2 hours, and 500 micrograms of **pancuronium**. Prolonged neuromuscular blockade with apnoea occurred.¹

Three other patients taking lithium experienced enhanced neuromuscular blockade when given **pancuronium** alone,² with **suxamethonium**,³ or both.⁴ The authors of one of these reports⁴ say that "... We have seen potentiation of the neuromuscular blockade produced by **succinylcholine** in several patients taking lithium carbonate. ..." but give no further details. In contrast, a retrospective analysis of data from 17 patients taking lithium carbonate, who received **suxamethonium** during a total of 78 ECT treatments, failed to reveal any instances of unusually prolonged recovery.⁵ In-

teractions between lithium and pancuronium¹ or suxamethonium^{6,7} have been demonstrated in *dogs*, and an interaction between lithium and **tubocurarine** has been demonstrated in *cats*,⁸ but no clear interaction has been demonstrated with any other neuromuscular blocker.^{7,9} A case of lithium toxicity has been described in a woman taking lithium who was given **suxamethonium**, but it is doubtful if it arose because of an interaction.¹⁰

Mechanism

Uncertain. One suggestion is that, when the interaction occurs, it may be due to changes in the electrolyte balance caused by the lithium, which results in changes in the release of acetylcholine at the neuromuscular junction.^{8,11}

Importance and management

Information is limited. There are only four definite reports of this interaction in man, and good evidence that no adverse interaction normally occurs. Concurrent use need not be avoided but it would be prudent to be on the alert for this interaction in any patient taking lithium who is given any neuromuscular blocker.

Neuromuscular blockers + Magnesium compounds

The effects of cisatracurium, mivacurium, pancuronium, rocuronium, tubocurarine, vecuronium, and probably other competitive neuromuscular blockers can be increased and prolonged by magnesium sulfate given parenterally. There is some evidence that magnesium may interact similarly with suxamethonium (succinylcholine), but also evidence from well-controlled trials that it does not.

Clinical evidence

(a) *Competitive (non-depolarising) neuromuscular blockers*

A pregnant 40-year-old with severe pre-eclampsia and receiving magnesium sulfate by infusion, underwent emergency caesarean section during which she was initially anaesthetised with thiopental, maintained with nitrous oxide/oxygen and enflurane, and given firstly suxamethonium and later **vecuronium** as muscle relaxants. At the end of surgery she rapidly recovered from the anaesthesia but the neuromuscular blockade was very prolonged (an eightfold increase in duration).¹ In a series of randomised studies involving 125 patients, pretreatment with intravenous magnesium sulfate 40 mg/kg reduced the dose requirement of **vecuronium** by 25%, approximately halved the time to the onset of action, and prolonged the duration of action from 25.2 to 43.3 minutes.² Another study found that pretreatment with 40 mg/kg of magnesium sulfate decreased the onset and prolonged the recovery time from **vecuronium** blockade, but magnesium sulfate 20 mg/kg had no effect.³ Evidence of enhanced **vecuronium** neuromuscular blockade by magnesium sulfate is described in one other study,⁴ and case report.⁵ Another study in 20 patients found that recurarisation (sufficient to compromise respiration) occurred when magnesium sulfate 60 mg/kg was given in the postoperative period, shortly after recovery from neuromuscular block with **vecuronium**.⁶ Neostigmine-induced recovery from **vecuronium** block was attenuated by about 30% in

patients pretreated with magnesium sulfate in a randomised study. The authors demonstrated this was due to slower spontaneous recovery and not decreased response to neostigmine.⁷

In two patients who underwent cardiac surgery, neuromuscular block with either **pancuronium**, or **pancuronium** and **rocuronium** was prolonged by more than 10 hours. This was attributed to the effects of high doses of neuromuscular blockers potentiated by magnesium sulfate 2.5 g: moderate renal impairment may also have been a factor.⁸ A fourfold increase in the duration of neuromuscular blockade of **rocuronium** 0.9 mg/kg was reported in a pregnant woman receiving magnesium sulfate.⁹ A further randomised placebo-controlled study confirmed that pretreatment with magnesium sulfate 60 mg/kg increased the duration of neuromuscular block produced by **rocuronium** (time to initial recovery increased from 25.1 to 42.1 minutes), but the onset time was not affected.¹⁰

A patient given **cisatracurium** 14 mg during induction of anaesthesia, which was reversed postoperatively with 2 doses of neostigmine and glycopyrrolate, was then given intravenous magnesium sulfate 2 g over 5 minutes for atrial fibrillation, which had developed about 15 minutes after the end of surgery. Within a few minutes of receiving magnesium, re-ventilation occurred and the patient required re-intubation and artificial ventilation for about 20 minutes.¹¹ A study in 20 patients undergoing elective cardiac surgery found that magnesium sulfate 70 mg/kg prior to induction followed by 30 mg/kg per hour prolonged the neuromuscular blockade induced with the first maintenance dose of **cisatracurium** by just over 30 minutes.¹²

The infusion rate of **mivacurium** required to obtain relaxation in women undergoing a caesarean section was about threefold lower in 12 women who had received magnesium sulfate for pre-eclampsia than in 12 women who had not.¹³

Prolonged neuromuscular block with **rapacurium** has also been reported in a patient undergoing emergency caesarean section who received magnesium sulfate and clindamycin, although the clindamycin was thought to be mainly responsible (see also 'Neuromuscular blockers + Miscellaneous anti-infectives', p.127).¹⁴

Prolonged neuromuscular blockade has been described in three women with pre-eclampsia who were given magnesium sulfate and either **tubocurarine** alone or with **suxamethonium**.^{15,16} Increased blockade by magnesium has been demonstrated with **tubocurarine** in *animals*.^{15,17}

(b) Depolarising neuromuscular blockers

An early study in 59 women undergoing caesarean section found that those given magnesium sulfate for eclampsia and pre-eclampsia needed less **suxamethonium (succinylcholine)** than control patients (4.73 compared with 7.39 mg/kg per hour).¹⁸ A 71-year-old woman given magnesium sulfate and lidocaine for ventricular tachycardia underwent emergency cardioversion and had a delayed onset and prolonged neuromuscular blockade when she was given **suxamethonium**.¹⁹ Increased blockade by magnesium has been seen with **suxamethonium** in *animals*.^{15,17}

However, a randomised study involving 20 patients found that pretreatment with a single 60-mg/kg bolus dose of magnesium sulfate did not significantly affect the onset or prolong the block produced by **suxamethonium**.²⁰ Similar results were found in a non-randomised study⁴ and in a double-blind randomised study.²¹ In randomised studies, the use of magnesium sulfate has also been reported to reduce **suxamethonium**-associated fasciculations²¹ and reduce the increase in serum potassium levels produced by **suxamethonium**.²⁰

Mechanism

Not fully understood. Magnesium sulfate has direct neuromuscular blocking activity by inhibiting the normal release of acetylcholine from nerve endings, reducing the sensitivity of the postsynaptic membrane and depressing the excitability of the muscle membranes. These effects are seen when serum magnesium levels rise above the normal range (hypermagnesaemia) and are possibly simply additive (or perhaps more than additive) with the effects of competitive neuromuscular blockers.

Importance and management

The interaction between competitive (non-depolarising) neuromuscular blockers and parenteral magnesium is established. Magnesium may decrease the time to onset (vecuronium but not rocuronium), prolong the duration of action and reduce the dose requirement of competitive neuromuscular blockers. Be alert for an increase in the effects of any competi-

itive neuromuscular blocker if intravenous magnesium sulfate has been used, and anticipate the need to reduce the dose. Some have suggested that the decreased time to onset with vecuronium may be of use clinically to improve the intubating conditions for rapid sequence induction if suxamethonium is not suitable.² Intravenous calcium gluconate was used to assist recovery in one case of prolonged block.¹⁵ Also be aware that re-ventilation may occur when intravenous magnesium compounds are used in the postoperative period.^{6,11} The authors of one report suggest that magnesium sulfate should be avoided for at least 30 minutes after reversal of residual neuromuscular block, to minimise the risk of re-ventilation.¹¹ Hypermagnesaemia can occur in patients receiving magnesium in antacids, enemas or parenteral nutrition, especially if there is impaired renal function, but an interaction would not normally be expected, as oral magnesium compounds generally result in lower systemic levels than intravenous magnesium due to poor absorption.²²

The interaction between magnesium and suxamethonium is not established. Although some *animal* and clinical evidence suggests potentiation of suxamethonium can occur, well-controlled studies have not confirmed this. Therefore some authors consider that magnesium sulfate does not significantly affect the clinical response to suxamethonium.^{4,23}

Neuromuscular blockers + MAOIs

The effects of suxamethonium (succinylcholine) were enhanced in 3 patients taking phenelzine.

Clinical evidence, mechanism, importance and management

Two patients, one taking **phenelzine** and the other who had ceased to do so 6 days previously, developed apnoea following ECT during which **suxamethonium (succinylcholine)** was used. Both responded to injections of nikethamide and positive pressure ventilation with oxygen.¹ A later study observed the same response in another patient taking **phenelzine**.² This would appear to be explained by the finding that **phenelzine** caused a reduction in the levels of plasma cholinesterase (pseudocholinesterase) in 4

out of 10 patients studied. Since the metabolism of **suxamethonium** depends on this enzyme, reduced levels of the enzyme would result in a reduced rate of **suxamethonium** metabolism and in a prolongation of its effect. None of 12 other patients taking **tranlycypromine**, **isocarboxazid** or **mebanazine** had reduced plasma cholinesterase levels.²

It would clearly be prudent to be on the alert for this interaction in patients taking **phenelzine**. **Phenelzine** may be anticipated to react similarly with **mivacurium** as it is also metabolised by plasma cholinesterase.³ On the basis of limited evidence this interaction seems less likely to occur with the other MAOIs cited.

Neuromuscular blockers + Metoclopramide

The neuromuscular blocking effects of suxamethonium (succinylcholine) and mivacurium can be increased and prolonged in patients taking metoclopramide.

Clinical evidence

Metoclopramide 10 mg given intravenously 1 to 2 hours before induction of anaesthesia prolonged the time to 25% recovery after **suxamethonium (succinylcholine)** by 1.83 minutes (23%) in 19 patients, when compared with 21 control patients.^{1,2} A larger 20-mg dose of metoclopramide prolonged the time to recovery by 56% in a further 10 patients.¹ In another study by the same research group, the recovery from neuromuscular blockade (time from 95% to 25% suppression of the activity of the adductor pollicis muscle) due to **suxamethonium** was prolonged by 67% in 11 patients who were given metoclopramide 10 mg intravenously during surgery, one minute before the **suxamethonium**.³

A randomised, placebo-controlled, double-blind study in 30 patients found that 150 micrograms/kg of intravenous metoclopramide given prior to anaesthetic induction about 10 minutes before **mivacurium** 150 micrograms/kg prolonged the duration of action of **mivacurium** by about 30%.⁴ Another report found that infusion rates of **mivacurium** were reduced by up to about 80% in patients given metoclopramide 10 or 20 mg intravenously, 5 minutes before induction, and metoclopramide delayed complete recovery from neuromuscular block after **mivacurium** by 36% (10 mg dose) and 50% (20 mg dose).⁵ Delays in recovery from **mivacurium** block of 78% after metoclopramide 20 mg were found in another study.⁶

Mechanism

Metoclopramide is postulated to reduce the activity of plasma cholinesterase, which is responsible for the metabolism of **suxamethonium** and **mivacurium**. One *in vitro* study found that a metoclopramide level of 800 nanograms/mL inhibited plasma cholinesterase activity by 50%. However, a 10-mg dose of metoclopramide in adult patients weighing 50 to 70 kg produces peak plasma levels five times less than this (140 nanograms/mL).⁷ Further, in an *in vivo* study, metoclopramide had only minimal inhibitory effects on plasma cholinesterase, and there was no difference in plasma cholinesterase levels in patients who had received metoclopramide and those who had not.⁴

Importance and management

The interaction between metoclopramide and **suxamethonium** is an established but not extensively documented interaction of only moderate or minor clinical importance. However anaesthetists should be aware that some enhancement of blockade can occur. The interaction between metoclopramide and **mivacurium** has only more recently been demonstrated. Metoclopramide appears to allow a reduction in the infusion rate of **mivacurium** and it causes a significant delay in recovery from neuromuscular block. Care is recommended during combined use.⁵ The authors of the **suxamethonium** reports also point out that plasma cholinesterase activity is reduced in pregnancy and so **suxamethonium** sensitivity is more likely in obstetric patients. Ester-type local anaesthetics also depend on plasma

cholinesterase activity for metabolism^{1,7} and their effects would therefore be expected to be additive with the effects of metoclopramide, see 'Neuromuscular blockers + Anaesthetics, local', p.114.

Neuromuscular blockers + Miscellaneous anti-infectives

Colistin, colistimethate sodium, polymyxin B, clindamycin, lincomycin, some penicillins (apalcillin, azlocillin, mezlocillin, piperacillin) and vancomycin possess some neuromuscular blocking activity. Increased and prolonged neuromuscular blockade is possible if these antibacterials are used with neuromuscular blocking drugs. In theory amphotericin B might also interact, but the tetracyclines probably do not. No clinically significant interaction has been seen with cefoxitin, cefuroxime, chloramphenicol or metronidazole. See also 'Neuromuscular blockers + Aminoglycosides', p.113.

Clinical evidence

(a) Amphotericin B

Amphotericin B can induce hypokalaemia resulting in muscle weakness,¹ which might be expected to enhance the effects of neuromuscular blockers, but there appear to be no reports in the literature confirming that a clinically significant interaction actually occurs.

(b) Cephalosporins

No change in neuromuscular blockade was seen in patients given intravenous **cefuroxime** shortly before **pipecuronium**² or **rocuronium**³ in a controlled study. Similarly, intravenous **cefoxitin** given before, during and after surgery was not associated with a clinically important prolongation of **vecuronium** blockade.⁴

(c) Chloramphenicol

No interaction was seen in myasthenic patients given chloramphenicol.⁵

(d) Clindamycin, Lincomycin

Enhanced blockade has been seen in patients given **pancuronium** and lincomycin, which was reversed by neostigmine.⁶ Respiratory paralysis was seen 10 minutes after lincomycin 600 mg was given intramuscularly to a man recovering from neuromuscular blockade with **tubocurarine**⁷ and this interaction was confirmed in another report.⁸ Other case reports^{9–11} and clinical studies¹² describe minor to marked increases in neuromuscular blockade in patients receiving **pancuronium**,¹⁰ **pipecuronium**,¹² **rapacuronium**¹¹ or **suxamethonium (succinylcholine)**⁹ when they were given **clindamycin**. One patient developed very prolonged blockade after being unintentionally given clindamycin 2.4 g instead of 600 mg shortly after recovery from **suxamethonium** and **tubocurarine**.¹³ Prolongation of the neuromuscular blocking effects of **vecuronium** has also been reported in a patient who received both clindamycin and gentamicin.¹⁴

(e) Metronidazole

An increase in the neuromuscular blocking effects of **vecuronium** with metronidazole has been reported in *cats*,¹⁵ but a later study in patients failed to find any evidence of an interaction,¹⁶ and another study with **rocuronium** also found no evidence of an interaction with metronidazole.³ Similarly, no interaction was seen with **rocuronium** and metronidazole/**cefuroxime**.³ Another study found no significant interaction between **pipecuronium** and metronidazole.²

(f) Penicillins

A study in patients found that the neuromuscular blocking effects of **vecuronium** were prolonged by a number of penicillins: apalcillin 26%, **azlocillin** 55%, **mezlocillin** 38%, and **piperacillin** 46%.¹⁷ Reinstitution of neuromuscular blockade and respiratory failure occurred in a patient given **piperacillin** 3 g by intravenous infusion postoperatively, following the reversal of **vecuronium** blockade.¹⁸ However, a randomised, double-blind study involving 30 patients found that **piperacillin** or **cefoxitin**, given by intravenous infusion, pre- and intraoperatively, were not associated with clinically important prolongation of the neuromuscular block induced by **vecuronium**. Of 27 patients who could be evaluated, 22 showed a modest overall decrease in recovery time and 5 patients (2 patients after receiving **piperacillin** and 3 patients after **cefoxitin**) exhibited a slight prolongation in recovery time, but these patients all responded readily to neostigmine or other anticholinesterases and subsequent recurarisation did not occur.⁴ No interaction was seen in a myasthenic patient given **ampicillin**.¹⁹

(g) Polymyxins

A literature review of interactions between antibiotics and neuromuscular blockers identified 17 cases over the period 1956 to 1970 period in which **colistin (polymyxin E)** or **colistimethate sodium**, with or without conventional neuromuscular blockers, were responsible for the development of increased blockade and respiratory muscle paralysis. Some of the patients had renal disease.²⁰ A later report describes prolonged respiratory depression in a patient receiving **pancuronium** and **colistin**.²¹ Calcium gluconate was found to reverse the blockade.²¹ A placebo-controlled study found that one million units of **colistin** also considerably prolonged the recovery time from **pipecuronium** blockade.¹² Six cases of enhanced neuromuscular blockade involving **polymyxin B** have also been reported.²⁰ An increase in the blockade due to **pancuronium** by **polymyxin B** and bacitracin wound irrigation is described in another report; pyridostigmine, neostigmine and edrophonium were ineffective antagonists of this block and only partial improvement occurred after calcium chloride was given.²² Prolonged and fatal apnoea occurred in another patient given **suxamethonium** when his peritoneal cavity was instilled with a solution containing 100 mg of **polymyxin B** and 100 000 units of bacitracin.²³

(h) Tetracyclines

Four cases of enhanced neuromuscular blockade with **rolitetracycline** or **oxytetracycline** in myasthenic patients have been reported²⁰ (2 cases originally reported elsewhere¹⁹) but there seem to be no reports of interactions in patients without myasthenia given neuromuscular blocking drugs.

(i) Vancomycin

A man recovering from neuromuscular blockade with **suxamethonium** (with some evidence of residual Phase II block) developed almost total muscle paralysis and apnoea when given an intravenous infusion of vancomycin. He recovered spontaneously when the vancomycin was stopped, but it took several hours.²⁴ The neuromuscular blockade due to **vecuronium** was increased in a patient when given an infusion of vancomycin (1 g in 250 mL of saline over 35 minutes).²⁵ Transient apnoea and apparent cardiac arrest have also been described in a patient following a 1-g intravenous injection of vancomycin given over 2 minutes.²⁶ However, in both of these cases^{25,26} the vancomycin was given more rapidly than the current recommendations. It is now known that rapid infusion of vancomycin can provoke histamine release, which can result in apnoea, hypotension, anaphylaxis and muscular spasm, effects similar to those seen in these two patients.

Mechanism

Not fully understood but several sites of action at the neuromuscular junction (pre and/or post, effects on ion-channels or receptors) have been suggested.

The neuromuscular blocking properties of the polymyxins (polymyxin B, colistin, colistimethate sodium) involve a number of mechanisms, which may explain the difficulty in reversing the blockade.²⁷

Importance and management

The interactions involving polymyxin B, colistin, colistimethate sodium, lincomycin, and clindamycin are established and clinically important. The incidence is uncertain. Concurrent use need not be avoided, but be alert for increased and prolonged neuromuscular blockade. The recovery period should be well monitored because of the risk of recurarisation. Check the outcome of using amphotericin. No interaction would be expected with

the tetracyclines, cefuroxime, cefoxitin, metronidazole or metronidazole/cefuroxime, and probably with ampicillin and chloramphenicol, but some caution would seem appropriate with azlocillin, mezlocillin and piperacillin. The situation with vancomycin is less clear. The evidence does suggest a link between vancomycin and increased neuromuscular blockade following the use of suxamethonium, and possibly vecuronium. However, vancomycin is given routinely as antibiotic prophylaxis before surgical procedures. The sparsity of reports therefore suggests that in practice vancomycin rarely causes a clinically significant interaction with neuromuscular blockers.

Neuromuscular blockers + Neuromuscular blockers

Combinations of competitive neuromuscular blockers may have additive or synergistic effects. However, the sequence of administration may also affect the interaction. Prior administration of a small dose of a competitive neuromuscular blocker (e.g. vecuronium) generally reduces the effects of a depolarising blocker (e.g. suxamethonium), but if the depolarising blocker is given during recovery from a competitive neuromuscular blocker, antagonism, enhancement or a combination of the two may occur. The effects of a competitive blocker may be increased if it is given after a depolarising blocker.

Clinical evidence, mechanism, importance and management

Neuromuscular blockers are of two types: **competitive (non-depolarising)** and **depolarising**:

The **competitive or non-depolarising** blockers (**atracurium** and others listed in 'Table 5.2', (p.91)) compete with acetylcholine for the receptors

on the endplate of the neuromuscular junction. Thus the receptors fail to be stimulated and muscular paralysis results. Competitive neuromuscular blockers may be divided by chemical structure into the **aminosteroid** group (e.g. **pancuronium**) and the **benzylisoquinolinium** group (e.g. **atracurium**), see also 'Table 5.2', (p.91).

The **depolarising blockers (suxamethonium (succinylcholine) and decamethonium)** also occupy the receptors on the endplate but they act like acetylcholine to cause depolarisation. However, unlike acetylcholine, they are not immediately removed by cholinesterase so that the depolarisation persists and the muscle remains paralysed.

(a) *Competitive neuromuscular blockers + Competitive neuromuscular blockers*

Combinations of competitive (non-depolarising) neuromuscular blockers may have additive or synergistic effects. Structural differences between the interacting neuromuscular blockers may have an effect; it has been suggested that structurally similar neuromuscular blockers tend to produce an additive response, whereas structurally different blockers may be synergistic.^{1,2} For example, additive effects have been found between the structurally similar combinations of:

- **atracurium** and **cisatracurium**³ or **mivacurium**,⁴
- **pancuronium** and **vecuronium**,⁵
- **pipecuronium** and **vecuronium**,⁶
- **tubocurarine** and **metocurine**.¹

Potential of neuromuscular blockade or synergy has been reported between the structurally different combinations of:

- **cisatracurium** and **rocuronium**^{3,7,8} or **vecuronium**,³
- **metocurine** and **pancuronium**,¹
- **mivacurium** and **pancuronium**^{2,9} or **rocuronium**,¹⁰
- **tubocurarine** and **pancuronium**¹ or **vecuronium**.¹¹

However, contrary to the prediction, synergism has been reported with the structurally similar combinations of:

- **cisatracurium** and **mivacurium**,³
- **tubocurarine** and **atracurium**.¹¹

In addition to affecting response, the initial blocker may modify the duration of action of the supplemental blocker.^{12,13} The blocking action of **pancuronium** was shortened when it was given during **vecuronium**-induced partial neuromuscular blockade.¹³ Conversely, the duration of action of **mivacurium**^{2,14} or **vecuronium**¹³ was lengthened when they were given after **pancuronium**-induced neuromuscular block. Therefore, care should be taken if a small dose of a short-acting blocker is given near the end of an operation in which a longer-acting blocker has already been given.

(b) *Competitive then depolarising neuromuscular blockers*

The combination of a competitive and a depolarising neuromuscular blocker has an intrinsic antagonistic effect. This interaction has been used clinically to reduce muscle fasciculations caused by **suxamethonium**. A small dose of competitive neuromuscular blocker given shortly before the **suxamethonium** generally reduces effects and the duration of action of the **suxamethonium**.¹⁵ However, following **pancuronium** pretreatment, the duration of **suxamethonium** blockade appears to be prolonged,¹⁵ and this is probably due to the inhibition of cholinesterase by **pancuronium**.¹⁶ Antagonism of **decamethonium** has also been seen when it was given after a small dose of **vecuronium**.¹⁷

If **suxamethonium** is given during the recovery from a paralysing dose of a competitive neuromuscular blocker, the resultant neuromuscular block is influenced by the depth of residual block and the dose of **suxamethonium** used.^{18,19} In a study involving 38 patients recovering from **atracurium** 400 micrograms/kg, lower intravenous doses of **suxamethonium** 0.25 to 1 mg/kg mainly antagonised the partial block, whereas higher doses 1.5 to 3 mg/kg usually enhanced the blockade.¹⁸ However, the degree of recovery from the underlying block also influences the effects of **suxamethonium**: early on when the residual block is still considerable, **suxamethonium** may appear to have no effect or produce a partial antagonism of the block, but later, a biphasic response may be seen (antagonism of the competitive block initially before superimposing a depolarising block); a combination of antagonism and enhancement may also occur in different muscle groups.¹⁹ Partial antagonism of **vecuronium** block has been seen in 5 patients given **decamethonium** during the recovery from **vecuronium** block.²⁰ The neuromuscular blockade will also be affected by the compet-

itive neuromuscular blocker used and whether or not an anticholinesterase has been given.^{18,19} See also, 'Neuromuscular blockers + Anticholinesterases', p.114.

Suxamethonium and **decamethonium** would be expected to antagonise competitive neuromuscular blockers due to their opposite mechanisms of action (**suxamethonium** and **decamethonium** exert a receptor agonist-type activity whereas competitive blockers exhibit receptor antagonism). However, the depolarising blockers may also reverse a competitive block by enhancing the effect of acetylcholine postsynaptically.^{20,21}

(c) *Depolarising then competitive neuromuscular blockers*

In general, when a competitive blocker is given following **suxamethonium**, the onset time may be reduced and the potency or duration of the block may be increased, although not always significantly. In a study involving 350 patients, prior administration of **suxamethonium** 1 mg/kg significantly accelerated the onset of neuromuscular blockade with **atracurium**, **pancuronium**, **pipecuronium** and **vecuronium**, when these were given after full recovery from the **suxamethonium** block. However, the duration of blockade was only significantly prolonged with **vecuronium**.²² One study found potentiation of **vecuronium** when it was given up to 30 minutes after full recovery from a single intravenous dose of **suxamethonium** 1 mg/kg.²³ Another study found the effects of **vecuronium** or **pancuronium** were potentiated for at least 2 hours after full recovery from an intubating dose of **suxamethonium**.²⁴ Another study showed that the effect of prior administration of **suxamethonium** on **atracurium** neuromuscular block appears to depend on the level of recovery from **suxamethonium**. As with previous studies, the onset of **atracurium** blockade was shortened when given after full recovery from the **suxamethonium**. However, this effect was less apparent when the **atracurium** was given before full **suxamethonium** recovery.²⁵ Pretreatment with **suxamethonium** reduced the time to onset of **cisatracurium** block, but did not potentiate it or prolong recovery.²⁶ Pretreatment with **suxamethonium** decreased the onset time and increased the duration of action or **rocuronium**²⁷ although a study in *animals* suggested **rocuronium** is not affected by **suxamethonium**.²⁸

Prior administration of **decamethonium** 100 micrograms/kg caused a sevenfold increase in sensitivity to **vecuronium** (reducing the ED₅₀ from 24 to 3.5 micrograms/kg).²⁰

It has been suggested that depolarising neuromuscular blockers such as **decamethonium** and **suxamethonium** may have a presynaptic action resulting in reduced acetylcholine output.²⁰ Although not always clinically significant, be aware that a reduction in the dose of competitive blocker may be necessary following the use of a depolarising neuromuscular blocker.

Neuromuscular blockers + Ondansetron

Ondansetron does not affect atracurium-induced neuromuscular blockade.

Clinical evidence, mechanism, importance and management

A double-blind placebo-controlled study of 30 patients undergoing elective surgery found that intravenous ondansetron 8 or 16 mg given over 5 minutes had no effect on subsequent neuromuscular blockade with **atracurium**.¹ No special precautions would therefore seem necessary. The authors suggest that no interaction is likely with other non-depolarising neuromuscular blockers, but this needs confirmation.

Neuromuscular blockers + Opioids

A woman experienced hypertension and tachycardia when she was given pancuronium after induction of anaesthesia with morphine and nitrous oxide/oxygen. Bradycardia has been reported with vecuronium and alfentanil, fentanyl, or sufentanil, sometimes in patients receiving beta blockers and/or calcium channel blockers.

Clinical evidence, mechanism, importance and management

(a) Pancuronium

A woman about to receive a coronary by-pass graft was premedicated with **morphine** 10 mg and hyoscine 400 micrograms, intramuscularly, one hour before the induction of anaesthesia. **Morphine** 1 mg/kg was then slowly infused while the patient was ventilated with 50% nitrous oxide/oxygen. With the onset of neuromuscular relaxation with pancuronium 150 micrograms/kg, her blood pressure rose sharply from 120/60 to 200/110 mmHg and her pulse rate increased from 54 to 96 bpm, persisting for several minutes but stabilising when 1% halothane was added.¹ The suggested reason is that pancuronium can antagonise the vagal tone (heart slowing) induced by the **morphine**, thus allowing the blood pressure and heart rate to rise. The authors of the report point out the undesirability of this in those with coronary heart disease.

(b) Vecuronium

Two patients, one aged 72 and the other aged 84, undergoing elective carotid endarterectomy developed extreme bradycardia following induction with **alfentanil** and vecuronium; both were premedicated with **morphine**. The first was taking **propranolol** 20 mg 8-hourly and as the drugs were injected his heart rate fell from 50 to 35 bpm, and his blood pressure fell from 160/70 to 75/35 mmHg. He responded to atropine, ephedrine and phenylephrine. The other patient was taking nifedipine and quinidine. His heart rate fell from 89 to 43 bpm, and his blood pressure dropped from 210/80 to 120/45 mmHg. Both heart rate and blood pressures recovered following skin incision.²

Bradycardia in the presence of vecuronium has been seen during anaesthetic induction with other drugs including **fentanyl**,^{3,4} and **sufentanil** (in 3 patients taking beta blockers with or without diltiazem).⁵ The lack of vagolytic effects associated with vecuronium may mean that opioid-induced bradycardia is unopposed.^{4,5} The beta blockers and diltiazem may also have played a part in the bradycardia seen in some of these patients⁵ (see also 'Neuromuscular blockers + Beta blockers', p.119). Be alert for this effect if vecuronium is given with any of these drugs. Atropine 500 micrograms given intravenously at the time of induction may prevent the bradycardia.⁴

For reports of bradycardia occurring with **atracurium** or **suxamethonium** used with propofol and **fentanyl**, see 'Anaesthetics, general + Neuromuscular blockers', p.101.

Neuromuscular blockers + Organophosphorus compounds

Exposure to organophosphorus insecticides such as malathion and dimpylate (diazinon) can markedly prolong the neuromuscular blocking effects of suxamethonium (succinylcholine).

Clinical evidence

A man admitted to hospital for an appendectomy became apnoeic during the early part of the operation when given **suxamethonium (succinylcholine)** 100 mg to facilitate tracheal intubation, and remained so throughout the 40 minutes of surgery. Restoration of neuromuscular activity occurred about 180 minutes after he had received the **suxamethonium**. Later studies showed that he had an extremely low plasma cholinesterase activity (3 to 10%), even though he had a normal phenotype. It subsequently turned out that he had been working with **malathion** for 11 weeks without any protection.¹

Another report describes a man whose recovery from neuromuscular blockade with **suxamethonium** was very prolonged. He had attempted suicide approximately 2 weeks earlier with **dimpylate (diazinon)**, a household insecticide. His pseudocholinesterase was found to be 2.5 units/L (normal values 7 to 19) and his dibucaine number (a measurement of cholinesterase activity) was too low to be measured.²

Other cases of prolonged **suxamethonium**-induced paralysis associated with organophosphate poisoning have been reported.^{3–7} These cases have involved accidental ingestion of **chlorpyrifos**³ or **dichlorvos**⁷ in children, and one case resulted from subclinical exposure to **chlorpyrifos** and **propramphos** following the treatment of carpets for pests.⁴ Also, prolonged **suxamethonium**-induced paralysis has occurred following suicide attempts in adults with **chlorpyrifos**⁶ or **Diazinon [dimpylate]**.⁵ In one report ECT was performed 2 weeks after attempted suicide with **chlorpyrifos** and, despite low plasma cholinesterase levels, paralysis with **suxamethonium** was carried out successfully using one fifth of the normal dose.⁶

Mechanism

Malathion, dimpylate, and other organophosphorus insecticides inhibit the activity of plasma cholinesterase, thereby reducing the metabolism of the suxamethonium and prolonging its effects.

Importance and management

An established and well understood interaction. The organophosphorus pesticides are potent anticholinesterases used in agriculture and horticulture to control insects on crops, and in veterinary practice to control various ectoparasites. They are applied as sprays and dips. Anyone who is exposed to these toxic pesticides may therefore show changes in their responses to neuromuscular blockers. Widely used organophosphorus pesticides include **azamethiphos**, **bromophos**, **chlorpyrifos**, **clofenvinfos**,

coumafos, cythioate, dichlorvos, dimethoate, dimpylate, dioxation, ethion, famphur, fenitrothion, fenthion, heptenophos, iodofenphos, malathion, naled, parathion, phosmet, phoxim, pirimiphos-methyl, propetamphos, pyraclofos, temefos.⁸ A number of the **nerve gases** (such as **sarin, soman, tabun** and **VX**) are also potent anticholinesterases. Consider also 'Neuromuscular blockers + Anticholinesterases', p.114

Neuromuscular blockers + Quinidine

The effects of both depolarising neuromuscular blockers (e.g. **suxamethonium (succinylcholine)**) and competitive neuromuscular blockers (e.g. **tubocurarine**) can be increased by **quinidine**. **Recurarisation and apnoea** have been seen in patients when **quinidine** was given during the recovery period from neuromuscular blockade.

Clinical evidence

A patient given **metocurine** during surgery regained her motor functions and was able to talk coherently during the recovery period. However, within 15 minutes of additionally being given quinidine sulfate 200 mg by injection she developed muscular weakness and respiratory depression. She needed intubation and assisted respiration for a period of two and a half hours. Edrophonium and neostigmine were used to aid recovery.¹

This interaction has also been described in case reports involving **tubocurarine**² and **suxamethonium (succinylcholine)**,^{3,4} and has been confirmed in *animal* studies.^{5–7}

Mechanism

Not fully understood, but it has been shown that quinidine can inhibit the enzyme (choline acetyltransferase) which is concerned with the synthesis of acetylcholine at nerve endings.⁸ Neuromuscular transmission would be expected to be reduced if the synthesis of acetylcholine is reduced. Quinidine also inhibits the activity of plasma cholinesterase, which is concerned with the metabolism of suxamethonium.⁴

Importance and management

The interaction between quinidine and neuromuscular blockers is an established interaction of clinical importance, but the documentation is limited. The incidence is uncertain, but it was seen in one report cited to a greater or lesser extent in 5 of the 6 patients studied.³ It has only been reported clinically with metocurine, tubocurarine and suxamethonium, but it occurs in *animals* with **gallamine**, and it seems possible that it could occur clinically with any depolarising or non-depolarising neuromuscular blocker. Be alert for increased neuromuscular blocking effects during and after surgery.

Neuromuscular blockers + Testosterone

An isolated report describes marked resistance to the effects of suxamethonium (succinylcholine) and vecuronium, apparently due to the long-term use of testosterone. Another case reports resistance to vecuronium in a patient with elevated plasma testosterone levels.

Clinical evidence, mechanism, importance and management

A woman transsexual who had been receiving testosterone enantate 200 mg intramuscularly twice monthly for 10 years was resistant to 100 mg of intravenous **suxamethonium (succinylcholine)**, and needed 100 micrograms/kg of intravenous **vecuronium** for effective tracheal intubation before surgery. During the surgery it was found necessary to use a total of 22 mg of **vecuronium** over a 50-minute period to achieve acceptable relaxation of the abdominal muscles for a hysterectomy and salpingo-oophorectomy to be carried out.¹ Considerably higher than usual doses of **vecuronium** were required in a patient with testicular feminisation and elevated plasma testosterone levels.²

The reasons are not understood. However, it has been suggested that the close structural similarity between testosterone and **vecuronium**, with respect to their common steroidal core, might mean that they share similar metabolic pathways. Chronic elevation of circulating testosterone may up-regulate the hepatic metabolism of steroidal molecules in general, and so enhance the hepatic elimination of **vecuronium**.²

Neuromuscular blockers + Tobacco

There is some evidence that smokers may need more vecuronium and possibly more rocuronium, but less atracurium to achieve the same effects as non-smokers. However, results are variable and another study found that rocuronium appeared to be unaffected by smoking.

Clinical evidence, mechanism, importance and management

Variable results have been reported on the effect of smoking on neuromuscular blockers. The amount of **atracurium** required was about 25% lower in smokers, when compared with non-smokers.¹ However, in another study, smokers required more **vecuronium** than non-smokers did (96.8 compared with 72.11 micrograms/kg per hour, respectively; a 34% increase).² Similarly another study involving patients undergoing minor surgery found that the 20 smokers required about 20% more **rocuronium** than the 20 non-smokers.³ However, this study has been criticised for having too few patients, which meant that it was unable to properly detect a statistically significant difference between the smokers and non-smokers.⁴ In yet another study, the onset and recovery times from the neuromuscular blocking effects of **rocuronium** 600 micrograms/kg were reported to be not significantly affected by smoking more than 10 cigarettes daily.⁵

Tobacco smoke contains many different compounds and has enzyme-inducing properties, which may affect the dose requirements of neuromuscular blockers. In addition, the time interval in refraining from smoking will affect plasma nicotine concentrations; small doses of nicotine may stimulate the neuromuscular junction, but larger doses may block transmission.² More studies are needed.

Neuromuscular blockers + Trimetaphan

Trimetaphan can increase the effects of suxamethonium (succinylcholine), which may result in prolonged apnoea. This may possibly occur with other neuromuscular blocking drugs, such as alcuronium.

Clinical evidence

A man undergoing neurosurgery was given **tubocurarine** and **suxamethonium (succinylcholine)**. Neuromuscular blockade was prolonged postoperatively, lasting about 2.5 hours, and was attributed to the concurrent use of trimetaphan 4.5 g, given over a 90-minute period. Later when he underwent further surgery using essentially the same anaesthetic techniques and drugs, but with a very much smaller dose of trimetaphan (35 mg over a 10-minute period), the recovery was normal.¹

Nine out of 10 patients receiving ECT treatment and given **suxamethonium** showed an almost 90% prolongation in apnoea (from 142 to 265 seconds) when trimetaphan 10 to 20 mg was used instead of 1.2 mg of atropine.² Prolonged apnoea has been seen in another patient given **suxamethonium** and trimetaphan.³ On the basis of an *in vitro* study it was calculated that a typical dose of trimetaphan would double the duration of paralysis due to **suxamethonium**.⁴ Prolonged neuromuscular blockade was also seen in a man given **alcuronium** and trimetaphan.⁵

Mechanism

Not fully understood. Trimetaphan can inhibit plasma cholinesterase to some extent,^{2,5} which would reduce the metabolism of the suxamethonium and thereby prolong its activity. Studies in *rats*^{6,7} and case reports⁸ also indicate that trimetaphan has direct neuromuscular blocking activity. Its effects are at least additive with the neuromuscular blocking effects of the **aminoglycosides**.⁷

Importance and management

Information is limited but the interaction appears to be established. If trimetaphan and suxamethonium are used concurrently, be alert for enhanced and prolonged neuromuscular blockade. This has also been seen with alcuronium, and trimetaphan may interact with other competitive

neuromuscular blockers.⁵ Respiratory arrest has been seen when large doses of trimetaphan were given in the absence of a neuromuscular blocker, so that caution is certainly needed.⁸ *Animal* studies suggested that the blockade might not be reversed by neostigmine or calcium chloride,⁷ but neostigmine and calcium gluconate were successfully used to reverse the effects of alcuronium and trimetaphan in one case.⁵

Neuromuscular blockers + Ulinastatin

Ulinastatin delays the onset and hastens the recovery from vecuronium neuromuscular block.

Clinical evidence, mechanism, importance and management

A randomised, placebo-controlled study involving 60 patients found that a 5000 unit/kg intravenous bolus dose of ulinastatin given before induction of anaesthesia, and again 2 minutes before intravenous **vecuronium** 100 micrograms/kg, delayed the onset of neuromuscular blockade compared with placebo (250 compared with 214 seconds). The recovery from neuromuscular block (measured as return of post-tetanic count) was significantly shorter after ulinastatin than placebo (11 compared with 17.7 minutes). The effects of ulinastatin were thought to be due to an increase in the release of acetylcholine at the neuromuscular junction and enhanced **vecuronium** elimination due to increases in liver blood flow and urine volume.¹

Analgesics and NSAIDs

The drugs dealt with in this section include aspirin and other salicylates, NSAIDs, opioid analgesics, and the miscellaneous analgesics, such as nefopam and paracetamol. 'Table 6.1', (p.134) contains a listing, with a further classification of the NSAIDs.

Interactions

(a) Aspirin and NSAIDs

Aspirin and the NSAIDs generally undergo few clinically significant pharmacokinetic interactions. The majority are highly protein bound, and have the potential to interact with other drugs via this mechanism. However, with a few exceptions, most of these interactions are not clinically important (see 'Protein-binding interactions', (p.3)).

Of the newer NSAIDs, celecoxib is metabolised by the cytochrome P450 isoenzyme CYP2C9, and inhibits CYP2D6. Rofecoxib, now withdrawn, inhibits CYP1A2, see 'Tizanidine + CYP1A2 inhibitors', p.1286. Nevertheless, most of the important interactions with NSAIDs and aspirin are pharmacodynamic. Aspirin and all non-selective NSAIDs inhibit platelet aggregation, and so can increase the risk of bleeding and interact with other drugs that have this effect. NSAIDs that are highly selective for cyclooxygenase-2 (COX-2) do not inhibit platelet aggregation.

Aspirin and all NSAIDs (including COX-2 selective NSAIDs) affect the synthesis of renal prostaglandins, and so can cause salt and water retention. This can increase blood pressure and affect antihypertensive therapy.

Aspirin and non-selective NSAIDs inhibit the mechanisms that protect the gastrointestinal mucosa and so cause gastrointestinal toxicity. COX-2 selective NSAIDs (coxibs) are less likely to have this effect.

(b) Opioids

Morphine is metabolised by glucuronidation by UDP-glucuronyltransferases, mainly to one active and one inactive metabolite. The glucuronidation of morphine can be induced or inhibited by various drugs. Morphine is not significantly affected by the cytochrome P450 isoenzymes. The semi-synthetic morphine analogues, hydromorphone and oxycodone, are metabolised similarly.

Codeine, dihydrocodeine, and hydrocodone are thought to be pro-drugs,

and require metabolic activation, possibly by CYP2D6 or UGT enzymes. Inhibitors of these enzymes may therefore reduce their efficacy. Oxycodone is also metabolised by CYP2D6 and CYP3A4.

Pethidine is metabolised via several cytochrome P450 isoenzymes. If the metabolism of pethidine is increased it can lead to increased production of the toxic metabolite, norpethidine, and increased CNS adverse effects.

Methadone is principally metabolised by CYP3A4 and CYP2D6, although CYP2C8 may also play a role. Buprenorphine is metabolised by CYP3A4.

Alfentanil is extensively metabolised by CYP3A4, and has been used as a probe drug for assessing CYP3A4 activity. Fentanyl and sufentanil are also metabolised, but because they are high hepatic-extraction drugs (see 'Changes in first-pass metabolism', (p.4)) they are less affected by inhibitors or inducers of CYP3A4, although in some instances this may still lead to clinically significant effects.

(c) Paracetamol

Paracetamol is not absorbed from the stomach, and the rate of absorption is well correlated with the gastric emptying rate. Paracetamol has therefore been used as a marker drug in studies of gastric emptying. Paracetamol is primarily metabolised by the liver to a variety of metabolites, principally the glucuronide and sulfate conjugates. Hepatotoxicity of paracetamol is thought to be due to a minor metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI), which is inactivated with glutathione and excreted as mercapturate and cysteine conjugates. When the liver stores of glutathione are depleted, and the rate of production of NAPQI exceeds the rate of production of glutathione, excess NAPQI attaches to liver proteins and causes liver damage. CYP2E1 may be involved in the formation of this hepatotoxic metabolite.

Table 6.1 Analgesics and NSAIDs

<i>Group</i>	<i>Drugs</i>
Aspirin and oral salicylates	Aloxiprin, Aspirin, Benorilate, Choline salicylate, Diflunisal, Ethenzamide, Lysine aspirin, Magnesium salicylate, Salsalate, Sodium salicylate
NSAIDs	
Fenamates	Floctafenine, Flufenamic acid, Meclofenamic acid, Mefenamic acid, Tolfenamic acid
Indole- and indene-acetic acids	Acemetacin, Indometacin, Sulindac
Oxicams	Lornoxicam, Meloxicam, Piroxicam, Tenoxicam
Phenylacetic acid derivatives	Alclofenac, Diclofenac
Propionic acid derivatives	Dexketoprofen, Fenoprofen, Flurbiprofen, Ibuprofen, Ketoprofen, Naproxen, Oxaprozin, Tiaprofenic acid
Pyrazolone derivatives	Azapropazone, Feprazone, Kebuzone, Metamizole sodium (Dipyrone), Oxyphenbutazone, Phenylbutazone
Selective inhibitors of cyclo-oxygenase-2 (Coxibs)	Celecoxib, Etodolac, Etoricoxib, Meloxicam (see under <i>Oxicams</i>), Nimesulide, Parecoxib, Rofecoxib, Valdecoxib
Other	Benzydamine hydrochloride, Felbinac, Ketorolac, Nabumetone, Phenazone (Antipyrine), Tolmetin
Opioid and related analgesics	
Anaesthetic adjuncts	Alfentanil, Fentanyl, Remifentanil, Sufentanil
Mild to moderate pain	Codeine, Dextropropoxyphene (Propoxyphene), Dihydrocodeine
Moderate to severe pain:	
Partial agonists and agonists/antagonists	Buprenorphine (also used for opioid dependence), Butorphanol, Meptazinol, Nalbuphine, Pentazocine
Pure agonists	Dextromoramide, Diamorphine (Heroin), Dipipanone, Hydrocodone, Hydromorphone, Methadone (also used for opioid dependence), Morphine, Oxycodone, Oxymorphone, Papaveretum, Pethidine (Meperidine), Tramadol
Miscellaneous	Nefopam, Paracetamol (Acetaminophen)

Aspirin or other Salicylates + Antacids

The serum salicylate levels of patients taking large, anti-inflammatory doses of aspirin or other salicylates can be reduced to subtherapeutic levels by some antacids. The maximum plasma levels of aspirin may be increased by antacids, although the extent of absorption is unaltered.

Clinical evidence

A child with rheumatic fever taking aspirin 600 mg five times daily had a serum salicylate level of between 82 and 118 mg/L while taking 30 mL of *Maalox* (aluminium/magnesium hydroxide suspension). When the *Maalox* was withdrawn, the urinary pH fell from a range of 7 to 8 down to a range of 5 to 6.4, whereupon the serum salicylate level rose three- to fourfold to about 380 mg/L, which required a dosage reduction.¹ An associated study in 13 healthy subjects taking aspirin 4 g daily for a week found that sodium bicarbonate 4 g daily reduced serum salicylate levels by 44%, from 270 to 150 mg/L. This reflected a rise in the urinary pH from a range of 5.6 to 6.1 up to around 6.2 to 6.9.^{1,2} Similar changes have been reported in other studies with: aspirin or choline salicylate and aluminium/magnesium hydroxide; aspirin and magnesium trisilicate/aluminium hydroxide; and aspirin or sodium salicylate and sodium bicarbonate.³⁻⁷ There is some evidence to suggest that this effect does not occur at low serum salicylate levels,^{4,5} or if the pH of the urine is unchanged by the antacid.⁵

A study in 10 healthy subjects found that the mean maximum plasma level of a single 650-mg dose of aspirin was about 70% higher when it was given 10 minutes after an antacid (aluminium/magnesium hydroxide), when compared with aspirin alone. However, there was no change in the time to reach the peak level or the AUC. There were also no significant changes in the pharmacokinetics of the metabolites, salicylic acid and salicylic acid.⁸

Mechanism

Aspirin and other salicylates are acidic compounds that are excreted by the kidney tubules and are ionised in solution. In alkaline solution, much of the drug exists in the ionised form, which is not readily reabsorbed, and therefore is lost in the urine. If the urine is made more acidic (e.g. with ammonium chloride), much more of the drug exists in the un-ionised form, which is readily reabsorbed, so that less is lost in the urine and the drug is retained in the body.^{6,7}

In vitro data show that magnesium oxide and aluminium hydroxide strongly adsorb aspirin and sodium salicylate.⁹ However, in three of the studies above aluminium hydroxide-containing antacids had no effect on the extent of absorption of salicylate,^{3,5,8} although the rate of absorption may be increased as a result of an increase in the solubility of salicylate in a less acidic gastric environment.⁸

Importance and management

A well established and clinically important interaction for those receiving long-term treatment with large doses of salicylates because the serum salicylate level may become subtherapeutic. This interaction can occur with both 'systemic' antacids (e.g. sodium bicarbonate) as well as some 'non-systemic' antacids (e.g. aluminium/magnesium hydroxide), but only appears to occur if there is an increase in the urinary pH. Care should be taken to monitor serum salicylate levels if any antacid is started or stopped in patients where the control of salicylate levels is critical.

No important adverse interaction would be expected in those taking occasional doses of aspirin for analgesia. Some aspirin formulations actually include antacids as buffering agents to increase absorption rates and raise peak serum levels,¹⁰ which gives more rapid analgesia, and/or in an attempt to decrease gastric irritation. Note that antacids may also increase the rate of absorption of aspirin given as enteric-coated tablets.¹¹

Aspirin + Bile-acid binding resins

Colestyramine and colestipol do not appear to have any clinically important effects on the absorption of aspirin.

Clinical evidence, mechanism, importance and management

(a) Colestipol

In 12 healthy subjects the extent of absorption of a single 650-mg dose of aspirin was unaffected by colestipol 10 g. However, the rate of aspirin absorption was increased by colestipol: at 60 minutes after the dose the plasma level was increased by about 40%.¹ No particular precautions seem to be necessary during concurrent use.

(b) Colestyramine

A study in 3 healthy subjects and 3 patients, and a later study in 7 healthy subjects, found that colestyramine 4 g delayed the absorption of a single 500-mg dose of aspirin (time to peak levels extended from 30 to 60 minutes) but the total amount absorbed was only reduced by 5 to 6%. Some of the subjects had slightly higher serum aspirin levels while taking colestyramine.² Similar results were reported in another study (a 31% lower plasma aspirin level at 60 minutes, but no difference in total absorption).¹ There would seem to be little reason for avoiding concurrent use unless rapid analgesia is needed.

Aspirin or other Salicylates + Carbonic anhydrase inhibitors

A severe and even life-threatening toxic reaction can occur in patients taking high-dose salicylates if they are given carbonic anhydrase inhibitors (acetazolamide, diclofenamide).

Clinical evidence

An 8-year-old boy with chronic juvenile arthritis, taking prednisolone, indometacin and **aloxiprin**, was admitted to hospital with drowsiness, vomiting and hyperventilation (diagnosed as metabolic acidosis) within a month of the **aloxiprin** dosage being increased from 3 to 3.6 g daily and starting to take **diclofenamide** 25 mg three times daily for glaucoma.¹

Other cases of toxicity (metabolic acidosis) have included a 22-year-old woman taking **salsalate** with **acetazolamide** 250 mg four times daily,¹ and 2 elderly women taking large doses of aspirin with **acetazolamide** or **diclofenamide**.² A 50-year-old woman taking **acetazolamide** for glaucoma was admitted to hospital with confusion and cerebellar ataxia, associated with hyperchloraemic acidosis, 14 days after starting to take aspirin for acute pericarditis.³ A man taking **diclofenamide** developed salicylate poisoning within 10 days of starting to take aspirin 3.9 g daily.⁴ Coma developed in an 85-year-old woman taking aspirin 3.9 g daily when her dosage of **acetazolamide** was increased from 500 mg to 1 g daily,^{5,6} and toxicity was seen in a very elderly man given both drugs: levels of unbound **acetazolamide** were found to be unusually high.⁶ An elderly man became confused, lethargic, incontinent and anorexic while taking **acetazolamide** and **salsalate**. He needed intravenous hydration.⁷

Mechanism

Not fully established. One idea is that these carbonic anhydrase inhibitors (acetazolamide, diclofenamide) affect the plasma pH, so that more of the salicylate exists in the un-ionised (lipid-soluble) form, which can enter the CNS and other tissues more easily, leading to salicylate toxicity.² However, carbonic anhydrase inhibitors also make the urine more alkaline, which increases the loss of salicylate⁸ (see also 'Aspirin or other Salicylates + Antacids', p.135). *Animal* studies confirm that carbonic anhydrase inhibitors increase the lethal toxicity of aspirin.⁴ An alternative suggestion is that because salicylate inhibits the plasma protein binding of acetazolamide and its excretion by the kidney, acetazolamide toxicity, which mimics salicylate toxicity, may occur.⁶

Importance and management

Although there are few clinical reports on record, the interaction between carbonic anhydrase inhibitors and salicylates is established, well confirmed by *animal* studies, and potentially serious. One study recommended that carbonic anhydrase inhibitors should probably be avoided in those receiving high-dose salicylate treatment.⁶ If they are used, the patient should be well monitored for any evidence of toxicity (confusion, lethargy, hyperventilation, tinnitus) because the interaction may develop slowly and insidiously.² In this context NSAIDs may be a safer alternative. Naproxen proved to be a satisfactory substitute in one case.¹ The authors of one study suggest that **methazolamide** may possibly be a safer alternative to acetazolamide because it is minimally bound to plasma proteins. They also suggest paracetamol (acetaminophen) as an alternative to salicylate in patients taking acetazolamide.⁶ The reports cited here concern carbonic anhydrase inhibitors given orally, not as eye drops. It is not known whether the latter interact similarly, but there appear to be no reports.

Aspirin or other Salicylates + Corticosteroids or Corticotropin

Serum salicylate levels are reduced by corticosteroids and therefore salicylate levels may rise, possibly to toxic concentrations, if the corticosteroid is withdrawn without first reducing the salicylate dosage. Concurrent use increases the risk of gastrointestinal bleeding and ulceration.

Clinical evidence

A 5-year-old boy taking long-term **prednisone** in doses of at least 20 mg daily, was given **choline salicylate** 3.6 g daily, and the **prednisone** was gradually tapered off to 3 mg daily over a 3-month period. Severe salicylate toxicity developed, and in a retrospective investigation of the cause, using frozen serum samples drawn for other purposes, it was found that the serum salicylate levels had risen from less than 100 mg/L up to 880 mg/L during the withdrawal of the **prednisone**.¹ Later studies in 3 other patients taking **choline salicylate** or aspirin and either **prednisone** or another unnamed corticosteroid, found about a threefold rise in salicylate levels during corticosteroid withdrawal.¹ **Hydrocortisone** was also found to increase the clearance of **sodium salicylate** in 4 other patients.¹

A serum salicylate rise has been described in a patient taking **aloxiprin**

when **prednisolone** was withdrawn.² Other studies in both adults and children show that **prednisone**, **methylprednisolone**, **betamethasone** and **corticotropin** reduce serum salicylate levels.^{3–5} Two studies also found that intra-articular **dexamethasone**, **methylprednisolone**, and **triamcinolone** transiently reduced serum salicylate levels in patients given enteric-coated aspirin.^{6,7} However one study in patients found that **prednisone** 12 to 60 mg daily had no effect on the clearance of single doses of **sodium salicylate**.⁸

Mechanism

Uncertain. One idea is that the presence of the corticosteroid increases the glomerular filtration rate, which increases salicylate clearance. When the corticosteroid is withdrawn, the clearance returns to normal and the salicylate accumulates. Another suggestion is that the corticosteroids increase the metabolism of the salicylate.³

Importance and management

Well established interactions. Patients should be monitored to ensure that salicylate levels remain adequate when corticosteroids are added⁴ and do not become excessive if they are withdrawn. It should also be remembered that concurrent use may increase the incidence of gastrointestinal bleeding and ulceration. See also 'Corticosteroids + NSAIDs', p.1058.

Aspirin + Dapsone

Dapsone does not significantly affect the pharmacokinetics of aspirin.

Clinical evidence, mechanism, importance and management

A comparison of the pharmacokinetics of aspirin in 8 healthy subjects and 8 patients with uncomplicated lepromatous leprosy found that the pharmacokinetics of a single 600-mg dose of aspirin was not affected by either leprosy, or by treatment with dapsone 100 mg daily for 8 days.¹ No special precautions would seem likely to be needed on concurrent use.

Aspirin + Food

Food delays the absorption of aspirin.

Clinical evidence, mechanism, importance and management

A study in 25 subjects given aspirin 650 mg in five different preparations showed that food roughly halved their serum salicylate levels (measured 10 and 20 minutes later), compared with those seen when the same dose of aspirin was taken while fasting.¹ Similar results were found in subjects given calcium aspirin 1.5 g.² In another study in 8 healthy subjects who were given effervescent aspirin 900 mg, serum salicylate levels at 15 minutes were roughly halved by food, but were more or less unchanged after one hour.³

A further study in 16 healthy subjects showed that the extent of absorption of a single 900-mg dose of soluble aspirin was not significantly affected by a high-fat meal. The rate of absorption was reduced by food and the maximum plasma level was reduced by 18%, which was not considered to be clinically significant. Furthermore, there was no statistically significant

change in the time to maximum plasma levels (20 minutes fasted; 30 minutes fed).⁴

A possible reason for the reduced rate of absorption is that food delays gastric emptying. Thus if rapid analgesia is needed, aspirin should be taken without food, but if aspirin is needed long-term, giving it with food is thought to help to protect the gastric mucosa.

Aspirin + Griseofulvin

An isolated report describes a marked fall in serum salicylate levels in a child given aspirin and griseofulvin.

Clinical evidence, mechanism, importance and management

An 8-year-old boy with rheumatic fever taking aspirin 110 mg/kg daily and furosemide, digoxin, captopril, potassium, aluminium/magnesium hydroxide and iron, had a very marked fall in his serum salicylate levels (from a range of 18.3 to 30.6 mg/dL to less than 0.2 mg/dL) within 2 days of starting griseofulvin 10 mg/kg daily. Two days after the griseofulvin was stopped, the salicylate levels were back to their former levels. The reasons for this effect are not known, but it was suggested that the salicylate absorption was impaired in some way.¹ This appears to be the first and only report of this interaction so that its general importance is uncertain.

1. Phillips KR, Wideman SD, Cochran EB, Becker JA. Griseofulvin significantly decreases serum salicylate concentrations. *Pediatr Infect Dis J* (1993) 12, 350–2.

Aspirin + Kaolin-pectin

Kaolin-pectin causes a small reduction in the absorption of aspirin, which is not clinically relevant.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects the absorption of aspirin 975 mg was reduced by 5 to 10% by 30 or 60 mL of kaolin-pectin.¹ A likely explanation is that the aspirin becomes adsorbed by the kaolin so that the amount available for absorption through the gut wall is reduced. However, this small reduction in absorption is unlikely to be of clinical importance.

1. Juhl RP. Comparison of kaolin-pectin and activated charcoal for inhibition of aspirin absorption. *Am J Hosp Pharm* (1979) 36, 1097–8.

Aspirin + Laxatives

Sodium sulfate and castor oil used as laxatives can cause a modest, but probably clinically unimportant, reduction in aspirin absorption.

Clinical evidence, mechanism, importance and management

In an experimental study of the possible effects of laxatives on drug absorption, healthy subjects were given 10 to 20 g of oral **sodium sulfate** and 20 g of **castor oil** (doses sufficient to provoke diarrhoea). Absorption, measured by the amount of drug excreted in the urine, was decreased at 4 hours. The reduction was 21% for **castor oil** and aspirin, and 27% for **sodium sulfate** and aspirin. However, serum levels of aspirin were relatively unchanged. The overall picture was that while these laxatives can alter the pattern of absorption, they do not seriously impair the total amount of drug absorbed.¹

1. Mattila MJ, Takki S, Jussila J. Effect of sodium sulphate and castor oil on drug absorption from the human intestine. *Ann Clin Res* (1974) 6, 19–24.

Aspirin + Levamisole

The salicylate levels of a patient taking aspirin rose when levamisole was given, but this effect was not confirmed in a subsequent controlled study.

Clinical evidence, mechanism, importance and management

A preliminary report of a patient who had an increase in salicylate levels when levamisole was given with aspirin¹ prompted a study in 9 healthy subjects of this possible interaction. Sustained-release aspirin 3.9 g daily in two divided doses was given over a period of 3 weeks, with levamisole 50 mg three times a day for a week, each subject acting as his own control. No significant changes in plasma salicylate levels were found.²

2. Rumble RH, Brooks PM, Roberts MS. Interaction between levamisole and aspirin in man. *Br J Clin Pharmacol* (1979) 7, 631–3.

Aspirin + Pentazocine

A man regularly taking large doses of aspirin developed renal papillary necrosis when he was given pentazocine.

Clinical evidence, mechanism, importance and management

An isolated report describes a man, regularly taking aspirin 1.8 to 2.4 g daily, who developed renal papillary necrosis within 6 months of also starting to take pentazocine 800 to 850 mg daily. He developed abdominal pain, nausea and vomiting, and passed tissue via his urethra. Before starting the pentazocine and after it was stopped, no necrosis was apparent. The postulated reason for this reaction is that a pentazocine-induced reduction in blood flow through the kidney potentiated the adverse effects of chronic aspirin use.¹ The general importance of this case is uncertain, but it emphasises the risks of long-term use (possibly abuse) of aspirin with pentazocine.

1. Muhalwas KK, Shah GM, Winer RL. Renal papillary necrosis caused by long-term ingestion of pentazocine and aspirin. *JAMA* (1981) 246, 867–8.

Aspirin + Phenylbutazone

Phenylbutazone reduces the uricosuric effects of high-dose aspirin. Concurrent use is likely to be associated with an increased risk of gastrointestinal damage.

Clinical evidence

The observation that several patients given aspirin and phenylbutazone developed elevated serum urate levels, prompted a study in 4 patients without gout. This found that aspirin 2 g daily had little effect on the excretion of uric acid in the urine, but marked uricosuria occurred with aspirin 5 g daily. When phenylbutazone 200, 400 and then 600 mg daily (over 3 days) was also given the uricosuria was abolished. Serum uric acid levels rose from an average of about 40 mg/L to 60 mg/L. The interaction was confirmed in a patient with tophaceous gout. The retention of uric acid also occurs if the phenylbutazone is given first.¹

Mechanism

Not understood. Phenylbutazone is structurally related to sulfinpyrazone, which interacts similarly, see 'Aspirin or other Salicylates + Sulfinpyrazone', p.138.

Importance and management

An established but sparsely documented interaction. The potential problems arising from this interaction should be recognised in any patient given aspirin and phenylbutazone. The concurrent use of aspirin and NSAIDs increases the risk of gastrointestinal damage and is not recommended. Al-

though there does not appear to be any specific evidence for phenylbutazone, it would be expected to interact in the same way as other NSAIDs, see 'NSAIDs + Aspirin; Anti-inflammatory dose', p.142.

- Oyer JH, Wagner SL, Schmid FR. Suppression of salicylate-induced uricosuria by phenylbutazone. *Am J Med Sci* (1966) 225, 39–45.

Aspirin or other Salicylates + Probenecid

The uricosuric effects of high doses of aspirin or other salicylates and probenecid are not additive as might be expected but are mutually antagonistic. Low dose, enteric-coated aspirin appears not to interact with probenecid.

Clinical evidence

A study found that the average urinary uric acid excretion in 24 hours was 673 mg with a single 3-g daily dose of probenecid, 909 mg with a 6-g daily dose of **sodium salicylate**, but only 114 mg when both drugs were given.¹ Similar antagonism has been seen in other studies in patients given aspirin 2.6 to 5.2 g daily.^{2–4} No antagonism is seen until serum salicylate levels of 50 to 100 mg/L are reached.⁴ Therefore no interaction would be expected with low, antiplatelet dose aspirin. This was confirmed by a crossover study in 11 patients with gouty arthritis, regularly taking probenecid, which found that enteric-coated aspirin 325 mg daily, taken either with probenecid or 6 hours after probenecid, had no effect on serum urate levels or on the 24-hour urate excretion.⁵

Mechanism

Not understood. The interaction probably occurs at the site of renal tubular secretion, but it also seems that both drugs can occupy the same site on plasma albumins.

Importance and management

A well established and clinically important interaction. Regular dosing with substantial amounts of salicylates should be avoided if this antagonism is to be avoided, but small very occasional analgesic doses probably do not matter. Serum salicylate levels of 50 to 100 mg/L are necessary before this interaction occurs. Low-dose aspirin (325 mg or less daily) does not seem to interact.

Aspirin or other Salicylates + Sulfapyridazine

The uricosuric effects of the salicylates and sulfapyridazine are not additive, as might be expected, but are mutually antagonistic.

Clinical evidence

When **sodium salicylate** 6 g was given with sulfapyridazine 600 mg daily to one patient the average urinary uric acid excretion in 24 hours was 30 mg, whereas when each drug was used alone in the same doses the average 24-hour urinary excretion was 281 mg for **sodium salicylate** and 527 mg for sulfapyridazine.¹ A later study in 5 men with gout given a sulfapyridazine infusion for about an hour (300 mg bolus followed by 10 mg/minute) found that the additional infusion of **sodium salicylate** (3 g bolus followed by 10 to 20 mg/minute) virtually abolished the uricosuria. When the drugs were given in the reverse order to 3 other patients the same result was seen.²

In another study, the uricosuria caused by sulfapyridazine 400 mg daily was found to be completely abolished by aspirin 3.5 g.³ The clearance of

a single 400-mg dose of sulfapyridazine was modestly increased by 12 to 27% in 5 healthy subjects given four doses of aspirin 325 mg over 24 hours.⁴

Mechanism

Not fully understood. Sulfapyridazine competes successfully with salicylate for secretion by the kidney tubules so that salicylate excretion is reduced, but the salicylate blocks the inhibitory effect of sulfapyridazine on the tubular reabsorption of uric acid causing the uric acid to accumulate within the body.²

Importance and management

An established and clinically important interaction. Concurrent use for uricosuria should be avoided. Doses of aspirin as low as 700 mg can cause an appreciable fall in uric acid excretion,³ but the effects of an occasional small dose are probably of little practical importance.

Nefopam + Miscellaneous

The manufacturer states that nefopam should not be given to patients taking non-selective MAOIs and caution should be used in those taking tricyclic antidepressants, antimuscarinics and sympathomimetics. The intensity and incidence of adverse effects are somewhat increased when nefopam is given with codeine, pentazocine or dextropropoxyphene (propoxyphene), and the CNS depressant effect of dihydrocodeine may have contributed to a fatal overdose with nefopam. However, a morphine-sparing effect has been reported. Nefopam may also have a synergistic analgesic effect with ketoprofen.

Clinical evidence, mechanism, importance and management

Detailed information about adverse interactions between nefopam and other drugs does not seem to be available.¹ The manufacturer advises caution if nefopam is given with a **tricyclic antidepressant** because they lower the convulsive threshold; convulsions have been seen in some patients taking nefopam. In addition, the antimuscarinic adverse effects of nefopam may be additive with those of **tricyclics** and other drugs with antimuscarinic effects.¹ For example, the CSM in the UK has a number of reports of urinary retention caused by nefopam², which would be expected to be worsened by drugs with antimuscarinic activity. Nefopam appears to have sympathomimetic activity and the manufacturer therefore says it should not be given with the **MAOIs**¹ (see 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1147).

A controlled study was conducted in 45 healthy subjects divided into nine groups of five, each given oral nefopam 60 mg three times daily for 3 days with either **aspirin** 650 mg, **diazepam** 5 mg, **phenobarbital** 60 mg, **dextropropoxyphene (propoxyphene)** 65 mg, **codeine** 60 mg, **pentazocine** 50 mg, **indometacin** 25 mg or **hydroxyzine** 50 mg (all three times daily). The only changes were a possible additive increase in the intensity and incidence of adverse effects with nefopam and **codeine**, **pentazocine** or **dextropropoxyphene**. There was no evidence that the bioavailability of nefopam was change by the other drugs.³

The incidence of sedation with nefopam is 20 to 30% which, depending on the circumstances, may present a problem if it is given with other **sedative drugs**.⁴ A report describes a fatal overdose with nefopam, which was complicated by the CNS depressant effect of **dihydrocodeine**.⁵

In a study in *animals*, nefopam enhanced the analgesic potency of **morphine**,⁶ but in a study in patients the effects were found to be less than additive.⁷ However, another study in patients undergoing orthopaedic surgery found that the concurrent use of intravenous nefopam 20 mg every 4 hours with **morphine** given as patient-controlled analgesia (PCA) had a significant morphine-sparing effect, without major adverse effects. The amount of **morphine** used over 24 hours was 22% less for those receiving nefopam compared with placebo; the analgesic effect was particularly

notable for patients with intense preoperative pain who required 35% less morphine with nefopam.⁸ A study in 72 surgical patients found that the use of nefopam with **ketoprofen** had a synergistic analgesic effect.⁹

NSAIDs + Allopurinol

Allopurinol does not affect indometacin clearance or phenylbutazone levels.

Clinical evidence, mechanism, importance and management

Allopurinol 300 mg each morning was given to 8 patients for 5 days with **indometacin** 50 mg every 8 hours. The allopurinol had no significant effect on the AUC of **indometacin** and the amounts of **indometacin** excreted in the urine were not significantly altered.¹

Allopurinol 100 mg three times daily for a month had no effect on the elimination of a 200-mg daily dose of **phenylbutazone** in 6 healthy subjects, and no effect on the steady-state plasma levels of **phenylbutazone** 200 or 300 mg daily in 3 patients.² In another study in 8 patients with acute gouty arthritis it was found that allopurinol 100 mg every 8 hours produced small but clinically unimportant effects on the half-life of **phenylbutazone** 6 mg/kg.³

There seems to be no reason for avoiding the concurrent use of these NSAIDs and allopurinol.

1. Pullar T, Myall O, Haigh JRM, Lowe JR, Dixon JS, Bird HA. The effect of allopurinol on the steady-state pharmacokinetics of indomethacin. *Br J Clin Pharmacol* (1988) 25, 755–7.

NSAIDs + Amoxicillin

A study in healthy subjects found that diclofenac increased the clearance of amoxicillin. An isolated report describes acute interstitial nephritis with nephrotic syndrome associated with the use of naproxen and amoxicillin.

Clinical evidence, mechanism, importance and management

(a) Diclofenac

In a study in 20 healthy subjects diclofenac 100 mg caused a slight reduction in the AUC and a slight increase in the mean renal clearance of a single 2-g dose of amoxicillin.¹ It should be noted that there was considerable individual variation and overlapping between the two groups, and the clinical significance of this finding is unclear.

An *animal* study found that diclofenac caused an 8.5-fold reduction in amoxicillin serum levels, when compared with amoxicillin alone. However, amoxicillin retained its efficacy despite lowered serum levels and it was suggested that diclofenac was unlikely to cause an increase in renal clearance of amoxicillin, nor an effect on its liver metabolism.² These studies therefore suggest that a clinically significant interaction would not be expected.

(b) Naproxen

A man without any previous renal problems developed acute interstitial nephritis with nephrotic syndrome after taking naproxen for 4 days (total

4 g) and amoxicillin for 10 days (total 24 g). He appeared to recover when the drugs were stopped, but 3 months later he developed renal failure and needed haemodialysis.³ Acute interstitial nephritis is not only a rare syndrome (reported to be only 55 cases in the world literature in 1988)³ but this is the first case involving both of these drugs. No special precautions would normally seem to be necessary.

NSAIDs + Anabolic steroids

Serum oxyphenbutazone levels are raised about 40% by the use of methandienone (methandrostenolone). Phenylbutazone appears to be unaffected.

Clinical evidence

The serum levels of oxyphenbutazone 300 to 400 mg daily for 2 to 5 weeks were raised by 43% (range 5 to 100%) in 6 subjects given **methandienone**. Neither prednisone 5 mg nor dexamethasone 1.5 mg daily were found to affect oxyphenbutazone levels.¹

Two other studies confirm this interaction with oxyphenbutazone.^{2,3} One of them found no interaction with phenylbutazone.²

Mechanism

Uncertain. One idea is that the anabolic steroids alter the distribution of oxyphenbutazone between the tissues and plasma so that more remains in circulation. There may also possibly be some changes in metabolism.

Importance and management

The interaction is established but its importance is uncertain. There seem to be no reports of toxicity arising from concurrent use but the possibility should be borne in mind.

NSAIDs; Azapropazone + Antacids or Laxatives

A study in 15 patients taking azapropazone 300 mg three times daily found that antacids (dihydroxyaluminium sodium carbonate, aluminium magnesium silicate), bisacodyl or anthraquinone laxatives only caused a minor (5 to 7%) reduction in azapropazone plasma levels.¹ No special precautions would seem to be needed if any of these drugs are given together with azapropazone. Consider also 'NSAIDs; Miscellaneous + Antacids', p.142.

NSAIDs; Coxibs + Antacids

The manufacturers say that antacids (unspecified) do not affect the pharmacokinetics of etoricoxib to a clinically relevant extent.¹ Aluminium/magnesium hydroxides had no clinically significant effect on the bioavailability of celecoxib,^{2,3} or lumiracoxib.⁴

NSAIDs; Diclofenac + Antacids

The absorption of diclofenac is not affected by aluminium hydroxide, magnesium hydroxide, or the combination.

Clinical evidence, mechanism, importance and management

About 10 mL of a 5.8% suspension of **aluminium hydroxide** had no effect on the bioavailability of a single 50-mg dose of diclofenac in 7 healthy subjects.¹ In another study, 10 mL of **magnesium hydroxide** suspension (850 mg) was found to have no significant effect on the rate or extent of absorption of a single 50-mg dose of diclofenac in 6 healthy, fasted subjects.² However, there was a tendency to an increased rate of absorption. *Aluco Gel* (**aluminium/magnesium hydroxide**) had no effect on the extent of absorption of enteric-coated diclofenac, but may have reduced the rate of absorption.³ No particular precautions would seem to be needed if these antacids are given with diclofenac.

- Schumacher A, Faust-Tinnefeldt G, Geissler HE, Gilfrich HJ, Mutschler E. Untersuchungen potentieller Interaktionen von Diclofenac-Natrium (Voltaren) mit einem Antazidum und mit Digitoxin. *Therapiewoche* (1983) 33, 2619–25.

In: *Voltarol — New Findings*, ed Kass E. Proc Int Symp Voltarol, Paris June 22nd, 1981. 15th Int Congress of Rheumatology. p 19–30.

NSAIDs; Diflunisal + Antacids

Antacids containing aluminium with or without magnesium can reduce the absorption of diflunisal by up to 40%, but no important interaction occurs if food is taken at the same time. Magnesium hydroxide can increase the rate of diflunisal absorption.

Clinical evidence

A study in 4 healthy, fasted subjects found that when a single 500-mg oral dose of diflunisal was given 2 hours before, together with, and 2 hours after three 15-mL doses of *Aludrox* (**aluminium hydroxide**), the diflunisal AUC was reduced by about 40%.¹ Another study found that the AUC of a single 500-mg dose of diflunisal was reduced by 13% when given with a single 30-mL dose of *Maalox* (**aluminium/magnesium hydroxide**), by 21% when given 1 hour after the antacid, and by 32% when the antacid was given four times daily.² However, in another study, **aluminium/magnesium hydroxide** had no effect on the AUC diflunisal when the diflunisal was given 30 minutes after food.³ This study also found that the AUC of diflunisal was reduced by 26% by 15 mL of **aluminium hydroxide** gel in fasted subjects, but not when the diflunisal was given after food.³ **Magnesium hydroxide** suspension markedly increased the rate of diflunisal absorption in fasted subjects. The plasma diflunisal level was increased by 130% at 30 minutes, and by 64% at one hour but the AUC was only increased by a modest 10%.³

Mechanism

Just how aluminium antacids reduce the absorption of diflunisal is not clear, but adsorption or formation of insoluble salts has been suggested. Food appears to diminish the effect of antacids on diflunisal absorption.³ By raising the pH, magnesium hydroxide may promote the dissolution of diflunisal, so increasing its absorption.³ Consider also ‘NSAIDs; Fenamates + Antacids’, below.

Importance and management

Aluminium-containing antacids appear to reduce the absorption of diflunisal in the fasted state, but not if taken with food. Since NSAIDs should be taken with or after food, it appears that this interaction has little clinical relevance. See also ‘NSAIDs; Miscellaneous + Antacids’, p.142. Magnesium hydroxide increases the absorption of diflunisal in the fasted state,

which may improve the onset of analgesia. However, note that magnesium hydroxide increased the endoscopically-detected gastric toxicity of ibuprofen in one study, see ‘NSAIDs; Ibuprofen and related drugs + Antacids’, below.

NSAIDs; Fenamates + Antacids

The absorption of mefenamic acid and tolfenamic acid is markedly accelerated by magnesium hydroxide in fasted subjects. The rate of tolfenamic acid absorption is reduced by aluminium hydroxide alone or combined with magnesium hydroxide/magnesium carbonate, but is not affected by sodium bicarbonate.

Clinical evidence

Studies in 6 healthy, fasted subjects given a single dose of **mefenamic acid** 500 mg or **tolfenamic acid** 400 mg found that **magnesium hydroxide** accelerated the absorption of both drugs (the **mefenamic acid** AUC after 1 hour was increased threefold and the **tolfenamic acid** AUC was increased sevenfold) but the total bioavailability was only slightly increased. In contrast, **aluminium hydroxide**, alone and in combination with **magnesium hydroxide/magnesium carbonate** (*Medisan Forte*), markedly reduced the rate of absorption of **tolfenamic acid** without causing a marked change in the total amount absorbed. **Sodium bicarbonate** 1 g did not significantly alter the absorption of **tolfenamic acid**.¹

Mechanism

Uncertain. It is suggested that magnesium hydroxide increases the solubility of acidic drugs such as the fenamates, possibly by forming a soluble salt and therefore enhancing their dissolution. In contrast, aluminium antacids may form insoluble salts of the drug. Note that food may reduce these effects, see ‘NSAIDs; Diflunisal + Antacids’, above.

Importance and management

Information is very limited but it would appear that if rapid analgesia is needed with either mefenamic acid or tolfenamic acid, magnesium hydroxide can be given concurrently but aluminium hydroxide should be avoided. However, note that this applies to the fasted state, whereas NSAIDs are usually taken with or after food. Also note that magnesium hydroxide increased the endoscopically-detected gastric toxicity of ibuprofen in one study, see ‘NSAIDs; Ibuprofen and related drugs + Antacids’, below. Aluminium hydroxide markedly reduces the speed of absorption. Sodium bicarbonate does not interact. Consider also ‘NSAIDs; Miscellaneous + Antacids’, p.142.

NSAIDs; Ibuprofen and related drugs + Antacids

Magnesium hydroxide increased the initial absorption of ibuprofen and flurbiprofen, but had no effect on ketoprofen. Unexpectedly, a pharmacodynamic study showed increased gastric erosions when ibuprofen was formulated with magnesium hydroxide.

A small reduction in ketoprofen absorption occurred with aluminium-magnesium hydroxide, but dexketoprofen, ibuprofen and flurbiprofen were not affected, and naproxen showed a slight increase in rate and extent of absorption. Aluminium phosphate had no effect on ketoprofen absorption.

Sodium bicarbonate increased the rate of naproxen absorption, and aluminium hydroxide and magnesium oxide decreased it.

Dimeticone did not affect ketoprofen bioavailability.

Clinical evidence

(a) Dexketoprofen

In 24 healthy subjects an **aluminium/magnesium hydroxide** antacid (*Maalox*) had no effect on the rate or extent of absorption of a single 25-mg dose of dexketoprofen, although the maximum level was slightly (13%) lower.¹

(b) Flurbiprofen

Maalox (**aluminium/magnesium hydroxide**) 30 mL, taken 30 minutes before a single 100-mg dose of flurbiprofen, was found to affect neither the rate nor extent of flurbiprofen absorption in a group of young and old fasting healthy subjects. Similarly, the antacid had no effect on steady-state flurbiprofen pharmacokinetics when both drugs were given 90 minutes before food.² Another study found that **magnesium hydroxide** increased the AUC₀₋₂ by 61%, but the AUC₀₋₈ was not changed in fasted subjects, which demonstrated an increased rate of flurbiprofen absorption.³

(c) Ibuprofen

In 8 healthy, fasted subjects an antacid containing **aluminium/magnesium hydroxide**, given before, with, and after a single 400-mg dose of ibuprofen, did not alter the pharmacokinetics of ibuprofen.⁴ In another study, the absorption of ibuprofen formulated with **aluminium** was delayed and reduced, when compared to that of ibuprofen without **aluminium**.⁵ Another study in 6 healthy fasted subjects found that **magnesium hydroxide** 850 mg increased the AUC₀₋₁ and the peak levels of a single 400-mg dose of ibuprofen by 65% and 31%, respectively. The time to the peak was shortened by about 30 minutes but the total bioavailability was unchanged.⁶ In a pharmacodynamic study in healthy subjects, a 400-mg ibuprofen tablet buffered with 200 mg of **magnesium hydroxide**, given at a dose of two tablets three times daily for 5 days resulted in about a threefold increase in number of endoscopically-detected gastric erosions, when compared with the same dose of conventional ibuprofen tablets.⁷

A **sodium/potassium salt** (kanwa), often taken as an antacid in some West African countries, appeared to reduce the absorption of ibuprofen. The bioavailability of ibuprofen 400 mg given to 6 healthy subjects with a millet meal containing the salt extract (pH of 8.9) was reduced, compared with the millet meal alone (pH 5.3) or following overnight fasting (approximate AUCs 20, 120, 110 micrograms/mL per hour, respectively).⁸

(d) Ketoprofen

Five healthy, fasted subjects had a 22% reduction in the absorption of a 50-mg dose of ketoprofen (as measured by the amount excreted in the urine) when they were given a 1-g dose of **aluminium hydroxide**.⁹ Conversely, **aluminium phosphate** 11 g (as a single then a daily dose) had no effect on the pharmacokinetics of ketoprofen 100 mg in 10 patients.¹⁰ Another study in 12 healthy, fasted subjects showed that **dimeticone** did not significantly affect the bioavailability of a single 100-mg dose of ketoprofen.¹¹ In another study 10 mL of **magnesium hydroxide** suspension (equivalent to 850 mg) was found to have no significant effect on the rate or extent of absorption of ketoprofen 50 mg in fasted subjects, although the rate of ketoprofen absorption was already noted to be fast.⁶

(e) Naproxen

Sodium bicarbonate 700 mg or 1.4 g increased the rate of absorption of a single 300-mg dose of naproxen in 14 healthy fasted subjects, whereas **magnesium oxide** or **aluminium hydroxide** 700 mg had the opposite effect, and reduced the rate of absorption. **Magnesium carbonate** had little effect.¹² On the other hand when 15 or 60 mL of **aluminium/magnesium hydroxide** (*Maalox*) was given, the rate and extent of absorption of naproxen were slightly increased.¹²

Mechanism

Magnesium hydroxide appears to improve the rate of absorption of some acidic NSAIDs (which become more soluble as the pH rises) such as ibuprofen and flurbiprofen. Why this increased the gastric toxicity of ibuprofen in the one pharmacodynamic study is unclear.⁷ Sodium bicarbonate appears to have a similar effect on rate of absorption. Aluminium antacids do not produce soluble salts with these NSAIDs, and may therefore reduce the rate/extent of absorption.

Importance and management

It would appear that the initial absorption of both ibuprofen and flurbiprofen is increased by magnesium hydroxide, but not if aluminium hydroxide is present as well. Thus if rapid analgesia is needed, an antacid containing magnesium hydroxide but without aluminium hydroxide could be used with these NSAIDs. However, the unexpected finding that magnesium hydroxide increased the endoscopically-detected gastric toxicity of ibuprofen⁷ suggests that caution may be warranted, particularly on long-term use. Further study is needed.

Sodium bicarbonate and aluminium hydroxide appear to have a similar effect on naproxen, namely an increased and decreased effect, respectively, on the rate of absorption. However, note that these effects were seen in the fasted state, and may not apply when the NSAIDs are taken with or after food (as is recommended), as is the case with 'diflunisal', (p.140).

No particular precautions would seem to be needed if dimeticone, aluminium phosphate or magnesium hydroxide are given with ketoprofen, and it seems doubtful if the effects of ketoprofen will be reduced to any great extent by aluminium hydroxide.

NSAIDs; Indometacin or Sulindac + Antacids

Although a variety of different antacids have slightly altered the absorption of indometacin the changes are probably not clinically important. Aluminium/magnesium hydroxide had no effect on sulindac absorption.

Clinical evidence

In 12 healthy, fasted subjects the AUC of a single 50-mg dose of indometacin was reduced by 35% when formulated with 80% *Mergel* (an antacid formulation of **aluminium/magnesium hydroxide**, and **magnesium carbonate**) and by 18% when taken with 90% *Mergel*.¹

In another single-dose study in 6 healthy, fasted subjects, **aluminium hydroxide** suspension 700 mg reduced the rate of indometacin absorption, and reduced the peak indometacin plasma levels. Conversely, **sodium bicarbonate** 1.4 g appeared to increase the rate of absorption, but this did not reach significance because of wide inter-individual variation.² In a further study 30 mL of **aluminium/magnesium hydroxide** caused only slight changes in the absorption of a 50-mg dose of indometacin in fasted subjects.³

The manufacturer of sulindac notes that an antacid (**aluminium/magnesium hydroxide** suspension) had no effect on the absorption of sulindac.⁴

Mechanism

Not known. Aluminium compounds might form insoluble salts with indometacin.² Food might reduce this effect, see 'NSAIDs; Diflunisal + Antacids', p.140.

Importance and management

Adequately but not extensively documented. Some small reduction in plasma indometacin levels is possible with some aluminium containing antacids. Despite this the manufacturers of indometacin recommend that it be taken with food, milk or an antacid to minimise gastrointestinal disturbances.⁵ Sulindac absorption is not affected.

NSAIDs; Miscellaneous + Antacids

The rate and extent of absorption of ketorolac, metamizole and tolmetin was not significantly affected by aluminium/magnesium hydroxide. Nabumetone absorption was not affected by aluminium hydroxide, and an unspecified antacid did not affect etodolac absorption.

Clinical evidence

(a) Etodolac

A study in 18 healthy, fasted subjects found that when given a single 400-mg dose of etodolac with 30 mL of an unnamed antacid neither the rate nor the extent of etodolac absorption were altered.¹

(b) Ketorolac

The AUC of oral ketorolac 10 mg was found to be reduced by 11% (not statistically significant) when taken with an unstated amount of **aluminium/magnesium hydroxide** suspension (*Maalox*) in 12 healthy fasted subjects. The rate of absorption was not affected.²

(c) Metamizole sodium (Dipyrone)

The concurrent use of 20 mL of *Maaloxan* (**aluminium/magnesium hydroxide** gel) was reported to have had no effect on the pharmacokinetics of the metabolites of metamizole sodium.³

(d) Nabumetone

The absorption of a single 1-g dose of nabumetone (as assessed by AUC and maximum plasma level) was not significantly altered by 160 mL of **aluminium hydroxide** suspension (*Aludrox*) in 15 healthy fasted subjects.⁴

(e) Tolmetin

A pharmacokinetic study in 24 healthy, fasted subjects showed that **aluminium/magnesium hydroxide** suspension (*Maalox*), given as a single 20-mL dose four times daily for 3 days, had no significant effect on the absorption of a single 400-mg dose of **tolmetin**.⁵

Mechanism

None.

Importance and management

Although information is limited, no particular precautions would seem to be needed if aluminium or aluminium/magnesium antacids are given with any of these NSAIDs. Note that antacids have been frequently given with NSAIDs to reduce their gastric irritant effects. Consider also 'coxibs', (p.139), 'diclofenac', (p.140), 'diflunisal', (p.140), 'ibuprofen and related drugs', (p.140), 'indometacin', (p.141), 'fenamates', (p.140), and 'oxi-cams', (below) for information about the interaction of other NSAIDs with antacids.

5. Ayres JW, Weidler DJ, MacKichan J, Sakmar E, Hallmark MR, Lemanowicz EF, Wagner JG. Pharmacokinetics of tolmetin with and without concomitant administration of antacid in man. *Eur J Clin Pharmacol* (1977) 12, 421–8.

NSAIDs; Oxamic derivatives + Antacids

The pharmacokinetics of lornoxicam, meloxicam, piroxicam and tenoxicam were not affected by aluminium/magnesium hydroxide antacids. Lornoxicam pharmacokinetics were also not altered by tripotassium dicitratobismuthate or aluminium hydroxide with calcium carbonate.

Clinical evidence, mechanism, importance and management

(a) Lornoxicam

Neither 10 mL of *Maalox* (**aluminium/magnesium hydroxide**) nor 10 g of *Solugastril* (**aluminium hydroxide with calcium carbonate**) had any effect on the pharmacokinetics of a 4-mg lornoxicam film-coated tablet in 18 healthy fasted subjects.¹ A later study similarly found no changes in the absorption or pharmacokinetics of a lornoxicam film-coated tablet given with **bismuth chelate (tripotassium dicitratobismuthate)** 120 mg twice daily.² There would seem to be no reason for avoiding concurrent use.

(b) Meloxicam

In an open, randomised, crossover study 9 healthy, fasted subjects were given meloxicam 30 mg alone or with *Maalox* suspension (**aluminium/magnesium hydroxide** 900/600 mg) four times daily for 4 days. *Maalox* had no significant effect on the pharmacokinetics of the meloxicam.³ Therefore no adjustments of the dosage of meloxicam are needed if given with this type of antacid.

(c) Piroxicam

A multiple-dose study in 20 healthy subjects found that *Mylanta* (**aluminium/magnesium hydroxide**) and *Amphojel* (**aluminium hydroxide**) did not significantly affect the bioavailability of piroxicam 20 mg daily taken after food.⁴ Concurrent use need not be avoided.

(d) Tenoxicam

The bioavailability of tenoxicam 20 mg was found to be unaffected in 12 healthy subjects by **aluminium hydroxide** (*Amphojel*) or **aluminium/magnesium hydroxide** (*Mylanta*) whether taken before, with, or after the tenoxicam, and in the fasted state or with food.⁵ No special precautions seem necessary.

NSAIDs + Aspirin; Anti-inflammatory dose

The combined use of aspirin and NSAIDs increases the risk of gastrointestinal damage. There is no clinical rationale for the combined use of anti-inflammatory/analgesic doses of aspirin and NSAIDs, and such use should be avoided. There are numerous early pharmacokinetic studies of aspirin and NSAIDs, many of which showed that aspirin reduced the levels of NSAIDs.

Clinical evidence

A. Gastrointestinal damage

In a case-control study of data from 1993 to 1998 in the UK General Practice Research Database the risk of upper gastrointestinal bleeding or perforation was increased by slightly more than an additive effect in patients taking both aspirin and NSAIDs (8.2-fold), when compared with aspirin alone (2.4-fold), or NSAIDs alone (3.6-fold). The specific NSAIDs were not mentioned.¹ Another study provided similar findings,² as have studies

specifically looking at low-dose aspirin (325 mg or less daily), see 'NSAIDs + Aspirin; Antiplatelet dose', p.144. Analysis of Yellow Card reports to the CSM in the UK gastrointestinal perforation/obstruction, ulceration or bleeding with **diclofenac**, **naproxen**, and **ibuprofen** revealed that 28% of the patients were receiving concurrent aspirin (dose not stated).³

The one pharmacodynamic study below, that also measured gastrointestinal blood loss, found increased bleeding when anti-inflammatory doses of aspirin were given with **sodium meclofenamate**.⁴

A case report described acute ulcerative colitis in a woman taking **rofecoxib** 25 mg daily who also took aspirin.⁵ See also *gastrointestinal effects*, in 'NSAIDs + Aspirin; Antiplatelet dose', p.144.

B. Pharmacokinetic and pharmacodynamic studies

Early studies evaluating non-aspirin NSAIDs in rheumatoid arthritis commonly permitted the concurrent use of aspirin, which was then in wide use for this condition. The unexpected finding that **indometacin** was no more effective than placebo in patients taking aspirin in one study led to a number of pharmacokinetic studies with this combination (see *Indometacin*, below), and subsequently other NSAID/aspirin combinations. These studies generally have little clinical relevance to current clinical practice where anti-inflammatory doses of aspirin should not be used in combination with NSAIDs because of the increased risk of gastrointestinal bleeding (see above) and lack of proven additional benefit. However, the pharmacokinetic studies are briefly summarised below.

(a) Diclofenac

Aspirin 900 mg reduced the AUC of diclofenac 50 mg by about one-third in a single-dose study.⁶ In a clinical study, there was no significant difference in efficacy between diclofenac 50 mg three times daily alone or with aspirin 900 mg three times daily.⁷

(b) Fenamates

A study in 20 healthy subjects given aspirin 600 mg and **sodium meclofenamate** 100 mg both three times daily for 14 days found no significant reductions in plasma salicylate levels, but plasma **meclofenamate** levels were reduced to some extent. However, gastrointestinal blood loss was approximately doubled compared with either drug alone.⁴

(c) Ibuprofen and related drugs

Aspirin 1.3 to 3.6 g daily more than halved the serum levels of ibuprofen 800 mg to 2.4 g daily,^{8,9} without affecting salicylate levels.⁹ There was little additional clinical benefit from the combination.⁹ Similarly, aspirin reduced the AUC of **flurbiprofen** by about two-thirds,¹⁰ but without any clear changes in clinical effectiveness.¹¹ The pharmacokinetics of the aspirin were unchanged by **flurbiprofen**.¹⁰ Aspirin 3.9 g daily also virtually halved the AUC of **fenoprofen** 2.4 g daily,¹² and reduced the AUC of **ketoprofen** 200 mg daily¹³ by about one-third. The AUC of **naproxen** was only minimally reduced (by 10 to 15%).^{14,15} **Choline magnesium trisalicylate** increased the clearance of **naproxen** by 56% and decreased its serum levels by 26% in one study.¹⁶

(d) Indometacin

The overall picture with aspirin and indometacin is confusing and contradictory. One early study found that indometacin had no additional benefit in patients already taking aspirin.¹⁷ Consequently, a number of studies were conducted to see if there was a drug interaction. Some studies reported that aspirin reduced serum indometacin levels^{12,18-20} or its efficacy,²¹ or that the combination was no more effective than either drug alone.²² Others report that no change in indometacin levels occurred.²³⁻²⁵ Further studies using buffered aspirin claimed that it increased the rate of absorption of indometacin and was associated with an increase in adverse effects (tiredness, lack of coordination).^{26,27} One study found that indometacin 50 mg given as suppositories at night was found to have a significant additive effect when given with slow-release aspirin 2 or 4.5 g daily, estimated by articular index and subjective ratings of pain and morning stiffness. However, the dose of aspirin (most often the 4.5 g dose) had to be reduced in 7 of the 24 treatment periods due to adverse effects.²⁸

(e) Oxicams

Aspirin 3 g daily increased the maximum plasma levels of **meloxicam** 30 mg daily by 25% and its AUC by 10%.²⁹ Plasma levels of **piroxicam** 40 mg then 20 mg daily were not significantly affected by aspirin 3.9 g

daily, and salicylate levels were unaffected by **piroxicam**.³⁰ Aspirin 2.6 to 3.9 g daily more than halved the serum levels of **tenoxicam** 20 mg daily.³¹

(f) Miscellaneous NSAIDs

Aspirin 600 mg four times daily caused a 15% reduction in the plasma levels of **diflunisal** 250 mg twice daily for 3 days.³² Single-dose studies have shown that the absorption of **nabumetone** 1 g is not significantly altered by aspirin 1.5 g.³³ The plasma levels of **tolmetin** 1.2 g daily were slightly reduced by aspirin 3.9 g daily.³⁴

Mechanism

The damaging effects of aspirin and NSAIDs on the gut appear to be additive. The mechanisms behind the pharmacokinetic changes have not been resolved. Changes in the rates of absorption and renal clearance and competition for plasma protein binding have been proposed.

Importance and management

The additive risk of gastrointestinal damage from combining aspirin and NSAIDs is established. Because of this, and the lack of clear benefit from the combination, the use of anti-inflammatory/analgesic doses of aspirin with NSAIDs should be avoided. For information on low-dose aspirin and NSAIDs see 'NSAIDs + Aspirin; Antiplatelet dose', p.144. Consider also 'NSAIDs + NSAIDs', p.151.

Clinical evidence

(a) Cardioprotective effects

A number of pharmacodynamic studies have investigated whether or not NSAIDs affect the antiplatelet effects of aspirin. **Celecoxib** 200 mg twice daily,¹ **diclofenac** 75 mg twice daily,² **etoricoxib** 120 mg daily,³ **lumiracoxib** 400 mg daily,⁴ **meloxicam** 15 mg daily,⁵ **naproxen** 500 mg twice daily,⁶ **parecoxib** 40 mg twice daily,⁷ and **rofecoxib** 25 mg daily² have all been shown not to alter the antiplatelet effects of aspirin in doses of 75 to 325 mg daily. The effects of **ibuprofen** are less clear, and may be related to the order of drug administration.

As a consequence of these pharmacodynamic studies, various cohort/case-control studies or sub-group analyses have been conducted to see if **ibuprofen** and/or other NSAIDs reduce the cardioprotective effect of low-dose aspirin in patients, see 'Table 6.2', (below). Because these studies are neither prospective nor randomised, their findings are suggestive only, nevertheless they provide some useful insight.

(b) Gastrointestinal effects

Low-dose aspirin alone (300 mg or less daily) was associated with an increased risk of hospitalisation for bleeding peptic ulcer in a case-control study. The odds ratios were 2.3 for aspirin 75 mg daily, 3.2 for aspirin

NSAIDs + Aspirin; Antiplatelet dose

There is some evidence that non-selective NSAIDs such as ibuprofen antagonise the antiplatelet effects of low-dose aspirin, but that COX-2-selective NSAIDs (coxibs) do not. Some, but not other, epidemiological studies have shown that non-selective NSAIDs reduce the cardioprotective effects of low-dose aspirin. Furthermore, some NSAIDs (particularly coxibs) are associated with increased thrombotic risk. Combined use of NSAIDs and low-dose aspirin increases the risk of gastrointestinal bleeds. This seems to apply equally to coxibs.

Table 6.2 Summary of studies on the effect of NSAIDs on the cardioprotective effect of antiplatelet dose aspirin

Study type	Criteria	Outcome	Drugs (Number of patients)	Comments	Refs
Studies showing a decrease in the cardioprotection of aspirin with NSAIDs					
Retrospective cohort	Discharge after CVD	Mortality	Aspirin alone (6285) Aspirin with Ibuprofen (187) Aspirin with Diclofenac (206) Aspirin with other NSAID (429)	Increased all-cause mortality and cardiovascular mortality in those taking aspirin with ibuprofen compared with the other groups.	1
Subgroup analysis of an RCT	Male physicians randomised to aspirin 325 mg on alternate days or placebo	First MI	Aspirin alone (5273) Aspirin with intermittent NSAID (5147) Aspirin with regular NSAID (598)	Use of NSAIDs for 60 days or more per year was associated with an increased risk of MI in those taking aspirin.	2
Case-control		First non-fatal MI	Aspirin alone (694) Aspirin with NSAIDs (170) NSAIDs alone (128)	Both aspirin alone, and NSAIDs alone were associated with a reduced risk of MI, but combined use was not.	3
Studies showing no effect of NSAIDs on the cardioprotection of aspirin					
Retrospective cohort	Discharge after MI	Death in first year	Aspirin alone (36211) NSAID alone (736) Aspirin with NSAID (2096) Neither (9541)	Risk of death reduced to a similar extent by aspirin, NSAIDs, and the combination.	4
Retrospective cohort	Discharge after MI and on aspirin	Death in first year	Aspirin alone (66739) Aspirin with Ibuprofen (844) Aspirin with other NSAID (2733)	Risk of death comparable between the 3 groups.	5
Retrospective cohort	General Practice Research Database	Acute MI or death from coronary heart disease	NSAID alone (417) NSAID with aspirin (163) Aspirin alone (1119) Non-NSAID users (1878)	Incidence of acute MI unaffected by NSAID alone. NSAID with aspirin similar to aspirin alone.	6
Studies showing an increase in the cardioprotection of aspirin with NSAIDs					
Retrospective cohort	Two consecutive prescriptions for aspirin or ibuprofen	Biochemical evidence of MI	Aspirin alone (10239) Aspirin with Ibuprofen (3859)	The aspirin alone group experienced 0.0044 MIs per patient month, compared with 0.0026 in the aspirin with ibuprofen group.	7

150 mg daily, and 3.9 for aspirin 300 mg daily. Use of NSAIDs combined with low-dose aspirin was associated with a greater risk of bleeding (odds ratio 7.7) than use of either NSAIDs alone (5.4) or low-dose aspirin alone (3.3).⁸ Similar findings were reported in a cohort study (rate ratio for gastrointestinal bleed for low-dose aspirin 2.6, and for combined use with NSAIDs, 5.6).⁹

Patients taking low-dose aspirin (325 mg or less daily) with **celecoxib** had a higher frequency of gastrointestinal complications than those taking **celecoxib** alone. Moreover, there was no difference in frequency of gastrointestinal complications between those taking low-dose aspirin with **celecoxib** and those taking low-dose aspirin with **ibuprofen** or **diclofenac**. This was despite **celecoxib** alone being associated with a lower frequency of gastrointestinal adverse effects than **ibuprofen** or **diclofenac** alone.¹⁰ Similar results were found with **rofecoxib** 25 mg daily, which increased the incidence of ulcers in patients taking enteric-coated aspirin 81 mg per day.¹¹

Mechanism

Aspirin irreversibly blocks the production of thromboxane A₂ by binding to cyclo-oxygenase (COX-1) in platelets, and so inhibits platelet aggregation. The beneficial cardiovascular effects are attributed to this effect. Other NSAIDs that are COX-1 inhibitors also have this effect, but it is more short-lived since they bind reversibly. These NSAIDs can therefore competitively inhibit the binding of aspirin to platelets (a fact that was shown *in vitro* as early as the 1980s¹²). When these NSAIDs are present in sufficient quantities when a daily low-dose of aspirin is given, they therefore reduce its antiplatelet effect. *In vitro* study confirms that COX-2 selective NSAIDs have less effect.¹³

It is well known that aspirin and NSAIDs have additive gastrointestinal adverse effects (see 'NSAIDs + Aspirin; Anti-inflammatory dose', p.142). This occurs even at the low doses of aspirin used for antiplatelet effects (doses as low as 75 mg daily).⁸

Importance and management

The evidence currently available on the antagonism of antiplatelet effects is insufficient to recommend that ibuprofen is not used with low-dose aspirin. Nevertheless, some have concluded that when patients taking low-dose aspirin for cardioprotection require long-term NSAIDs for inflammatory conditions, the use of diclofenac or naproxen would seem preferable to ibuprofen.¹⁴ A coxib was also suggested as an alternative,¹⁴ but the subsequent suggestion of an increased risk of serious cardiovascular effects with the coxibs (as a class¹⁵) probably precludes this. Recently the Commission on Human Medicines (CHM) in the UK has advised that there may be a small increased risk of thrombotic events with the non-selective NSAIDs, particularly when used at high doses and for long-term treatment.¹⁶

It is important to also consider the possible increased risk of gastrointestinal adverse effects from any combination. From a gastrointestinal perspective, the lowest dose of aspirin should be used (75 mg).⁸ However, when combined with low-dose aspirin, the available evidence indicates that there is no gastrointestinal benefit to be obtained from using a coxib as opposed to diclofenac or ibuprofen.¹⁰ Note that the CSM in the UK has advised that the combination of a non-aspirin NSAID and low-dose aspirin should be used only if absolutely necessary.^{17,18} They state that patients taking long-term aspirin should be reminded to avoid NSAIDs, including those bought without prescription.¹⁸ If concurrent use is necessary, where appropriate, the use of a proton pump inhibitor may be considered for prophylaxis of NSAID-induced gastrointestinal damage.

NSAIDs + Azoles

Fluconazole markedly raises celecoxib levels, whereas ketoconazole has no effect on celecoxib levels. Fluconazole and ketoconazole moderately increase the levels of valdecoxib (the main metabolite of parecoxib). Ketoconazole moderately raises etoricoxib plasma levels, but this is unlikely to be of clinical relevance. Fluconazole has no clinically relevant effect on lumiracoxib pharmacokinetics.

Clinical evidence

(a) Celecoxib

The manufacturer notes that **fluconazole** 200 mg daily increased the AUC of a single 200-mg dose of celecoxib by 130% and increased the maximum level by 60%. Conversely, **ketoconazole** had no effect on the pharmacokinetics of celecoxib.¹

(b) Etoricoxib

A single 60-mg dose of etoricoxib was given to healthy subjects on day 7 of an 11-day course of **ketoconazole** 400 mg daily. The AUC of etoricoxib was increased by 43% and the maximum plasma levels was increased by 29%.²

(c) Lumiracoxib

A placebo-controlled, crossover study in 13 healthy subjects³ found that **fluconazole** 400 mg on day 1 and 200 mg on days 2 to 4 had no clinically relevant effect on the pharmacokinetics of a single 400-mg dose of lumiracoxib given on day 4.

(d) Parecoxib

The manufacturer of parecoxib reports a study in which **fluconazole** increased the plasma levels of valdecoxib (the main metabolite of parecoxib) by 19% and raised its AUC by 62%.⁴ **Ketoconazole** had a similar, but more moderate effect on the levels of valdecoxib (maximum plasma levels increased by 24%, AUC increased by 38%).⁴

Mechanism

Fluconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP2C9 and ketoconazole inhibits CYP3A4. Celecoxib is extensively metabolised by CYP2C9, and therefore shows marked rises in plasma levels when given with fluconazole but not ketoconazole. Etoricoxib is partially metabolised by CYP3A4, therefore shows moderate rises in plasma levels with ketoconazole. Valdecoxib is metabolised by both CYP2C9 and CYP3A4, therefore was modestly affected by both fluconazole and ketoconazole. Parecoxib is a valdecoxib prodrug, and interacts similarly. From the study with lumiracoxib it appears that its pharmacokinetics are unlikely to be affected by inhibitors of CYP2C9, because, even though lumiracoxib is largely metabolised by CYP2C9, other pathways are also important (e.g. glucuronidation).³

Importance and management

These pharmacokinetic interactions are established, although their effect in clinical practice has not been assessed. The marked rise in celecoxib levels with fluconazole could be important, and the UK manufacturer recommends that the dose of celecoxib should be halved in patients receiving fluconazole,¹ whereas the US manufacturer suggests starting with the lowest recommended dose.⁵ The rise in valdecoxib levels with fluconazole is less marked, nevertheless the manufacturer recommends that for parecoxib the dosage should be reduced (but they do not suggest by how much).⁴ No dosage adjustments are thought to be necessary if etoricoxib or parecoxib are given with ketoconazole, and if lumiracoxib is given with fluconazole.

NSAIDs + Bile-acid binding resins

Simultaneous colestyramine markedly reduced the absorption of diclofenac and sulindac, modestly reduced the absorption of ibuprofen, but only delayed and did not reduce the extent of absorption of naproxen. Administration of colestyramine three or more hours after oral sulindac, piroxicam, or tenoxicam still markedly reduced their plasma levels. Markedly reduced NSAID levels have also been found when colestyramine is given after intravenous meloxicam or tenoxicam.

Simultaneous colestipol modestly reduced the oral absorption of diclofenac, but had no effect on ibuprofen absorption.

Clinical evidence

(a) Diclofenac

A single-dose, crossover study in 6 healthy, fasting subjects found that the simultaneous use of **colestyramine** 8 g markedly reduced the AUC of a single 100-mg oral dose of enteric-coated diclofenac by 62% and reduced its maximum plasma levels by 75%. **Colestipol** 10 g reduced the diclofenac AUC by 33% and its maximum plasma levels by 58%.¹

(b) Ibuprofen and related drugs

A single-dose, crossover study in 6 healthy fasting subjects found that the simultaneous use of **colestyramine** 8 g modestly reduced the AUC of a single 400-mg oral dose of ibuprofen by 26% and reduced its maximum serum levels by 34%. The rate of absorption was also reduced. Conversely, **colestipol** 10 g had no significant effect on the pharmacokinetics of ibuprofen.²

The absorption of a single 250-mg dose of **naproxen** was delayed but not reduced in 8 healthy fasting subjects by the simultaneous use of **colestyramine** 4 g in 100 mL of orange juice. The amount absorbed after 2 hours was reduced from 96% to 51%, but was complete after 5 hours.³

(c) Oxicams

A study in 12 healthy subjects found that **colestyramine** 4 g taken 2 hours before a 30 mg intravenous dose of **meloxicam** increased its clearance by 49% and reduced its mean residence time in the body by 39%.⁴

Another study in 8 healthy subjects found that **colestyramine** increased the clearance of a single 20-mg oral dose of **piroxicam** and a single 20-mg intravenous dose of **tenoxicam** by 52% and 105%, respectively, and reduced their half-lives by 40% and 52%, respectively. In this study, **colestyramine** 4 g three times daily was started 2 hours before the intravenous **tenoxicam** and 3.5 hours after the oral **piroxicam**.⁵ In another multiple-dose study **colestyramine**, given 4 hours after oral **piroxicam** or oral **tenoxicam**, gave similar results,⁶ as did a study starting **colestyramine** 24 hours after the last dose of a 14-day course of **piroxicam** 20 mg daily [which has a long half-life].⁷ The elimination half-life of both analgesics was roughly doubled by **colestyramine** 24 g daily.⁶

(d) Sulindac

In 6 healthy subjects **colestyramine** 4 g twice daily with meals was found to reduce the AUC of a simultaneous single 400-mg dose of sulindac by 78%: the AUC of its sulfide metabolite was reduced by 84%. Even when the sulindac was given 3 hours before the **colestyramine**, its AUC of colestyramine and its sulphide metabolite were reduced by 44% and 55%, respectively.⁸

Mechanism

The studies of simultaneous oral use suggest that the anion exchange resin colestyramine, and to a lesser extent colestipol, bind anionic NSAIDs (e.g. diclofenac) in the gut, so reducing their absorption. The studies showing reduced plasma levels when colestyramine was given after intravenous oxicams or separated by at least 3 hours from some oral NSAIDs, suggest that colestyramine can reduce the enterohepatic recirculation of these drugs.

Importance and management

Established interactions. Colestyramine markedly reduces the initial absorption of some NSAIDs (shown for diclofenac), and if these NSAIDs also undergo enterohepatic recirculation, their clearance will also be increased (shown for meloxicam, piroxicam, sulindac, and tenoxicam). This latter interaction cannot be avoided by separating the doses, and it may be best not to use colestyramine with these NSAIDs. Colestyramine can be used to speed the removal of piroxicam and tenoxicam following overdose.³ Diclofenac has been formulated with colestyramine in an attempt to reduce gastric mucosal damage by reducing direct mucosal contact: 140 mg of diclofenac-colestyramine is considered equivalent to 70 mg of diclofenac.⁹

The reduction in absorption of ibuprofen with colestyramine is probably not clinically important, and naproxen is not affected. Nevertheless, colestyramine delayed the absorption of both ibuprofen and naproxen, which may be relevant if they are being taken for the management of acute pain. Information on many other NSAIDs appears to be lacking. Animal studies suggest that **mefenamic acid**, **flufenamic acid** and **phenylbutazone** will also be affected by colestyramine.^{10,11} Note that it is usually recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine.

The reduction in diclofenac absorption with colestipol may be clinically relevant; if the combination is required monitor well. Note that it is usually recommended that other drugs are given 1 hour before or 4 hours after colestipol.

NSAIDs or Aspirin + Caffeine

Caffeine modestly increases the bioavailability, rate of absorption and plasma levels of aspirin. Adding caffeine to diclofenac may improve its efficacy in the treatment of migraine.

Clinical evidence, mechanism, importance and management

Caffeine citrate 120 mg given to healthy subjects with a single 650-mg dose of aspirin increased the aspirin AUC by 36%, increased the maximum plasma levels by 15%, and increased the rate of absorption by 30%.¹ This confirms the results of previous studies.^{2,3} These studies suggest that caffeine may modestly potentiate the efficacy of aspirin via a pharmacokinetic mechanism.

A meta analysis of randomised, controlled studies concluded that there was no therapeutic advantage of adding caffeine to analgesic doses of aspirin in patients experiencing postoperative pain.⁴ In a placebo-controlled study in patients with migraine, there was a non significant trend towards improved analgesic effect in patients receiving diclofenac softgel 100 mg and caffeine 100 mg compared with diclofenac alone, although the sample size was too small to provide meaningful results.⁵

NSAIDs + Food

In general, food has no clinically significant effect on the absorption of the NSAIDs; however, the delay in absorption that occurs may be important if NSAIDs are given in acute pain management.

Clinical evidence

(a) Coxibs

A study in 50 children showed that a single 250-mg/m² dose of **celecoxib**, given with high-fat food, increased the maximum plasma concentration by 82% and the AUC by 60%. When steady-state levels were achieved with **celecoxib** 250 mg/m² twice daily, food increased the maximum plasma concentration by 99% and the AUC by 75%.¹ The manufacturers of **celecoxib** note that a **high-fat meal** delayed absorption by about one to 2 hours^{2,3} and the total absorption was increased by 10% to 20%.³

A **high-fat meal** reduced the maximum level of **etoricoxib** by 36% and delayed it by 2 hours, without affecting the extent of absorption.⁴

(b) Diclofenac

Thirteen healthy subjects were given a single 105-mg dose of diclofenac potassium suspension (*Flogan*) while fasting and after food. The pharmacokinetics of diclofenac were not changed to a clinically relevant extent by food, except that absorption was delayed (time to maximum level increased by about 30 minutes).⁵ Similar findings (an increase in time to maximum level of 1.5 to 3 hours) were reported for single doses of enteric-coated diclofenac tablets.⁶ However, there was no difference in steady state levels of diclofenac 50 mg twice daily when given before or after food.⁶

(c) Etodolac

When 18 healthy subjects were given etodolac 400 mg after a **high-fat meal**, peak serum levels were roughly halved, and delayed, from 1.4 to 3.8 hours, but the total amount absorbed was not markedly changed, when compared to the fasting state.⁷

(d) Ibuprofen and related drugs

1. *Aceclofenac*. The manufacturer states that the rate, but not the extent, of aceclofenac absorption was affected by food.⁸

2. *Dexketoprofen*. The absorption of a single 25-mg dose of dexketoprofen was delayed by food (maximum level reduced by 45% and time to maximum level delayed by about 1 hour), but the AUC was not affected.⁹

3. *Flurbiprofen*. Food slightly increased the maximum plasma level and AUC of sustained-release flurbiprofen (*Froben SR*) by 15% and 25%, respectively, but delayed the time to achieve the maximum level by about 5 hours.¹⁰ In a study in 14 healthy subjects the pharmacokinetics of flurbiprofen were not affected by **cranberry juice**, **grape juice** or **tea**.¹¹

4. *Ibuprofen*. Food had no effect on the pharmacokinetics of the *S*- and *R*-enantiomers of ibuprofen in one study.¹² However, in another study, food significantly delayed the absorption of both enantiomers of ibuprofen, and slightly increased the ratio of the *S*- to *R*-enantiomer.¹³ A study considering the effect of food on ibuprofen pharmacokinetics also showed that the maximum level of a single 400-mg dose of a standard release ibuprofen tablet and two readily soluble preparations (ibuprofen lysinate and ibuprofen extrudate), was consistently lower and appeared later when the dose was given after a standardised breakfast; the extent of ibuprofen absorption was also reduced by food for all three formulations.¹⁴ However, in a further study, food increased the maximum plasma level of sustained-release ibuprofen (*Brufen Retard*) by 42% without affecting the time to achieve the maximum level or the bioavailability.¹⁰

5. *Ketoprofen*. Food significantly decreased the rate and extent of absorption of ketoprofen in both single and multiple dose studies in healthy subjects. The AUC was decreased by about 40% and the time to maximum levels decreased by about 5 hours.¹⁵ A further study found that the rate of absorption and the peak plasma levels of ketoprofen were reduced by food, although the AUC was unaltered.¹⁶ In another study, the absorption of ketoprofen (200 mg daily, as a gastric-juice resistant, sustained-release formulation, given 4 hours before the first meal of the day) was about 15 to 24% greater when 16 healthy subjects were given a **low-calorie/low-fat diet** rather than a **high-calorie/high-fat diet**.¹⁷ In a further study in 4 healthy subjects, which measured the urinary excretion of ketoprofen after a single 50-mg dose given with water, whole skimmed milk, or a traditional Egyptian breakfast, it was concluded that the rate and extent of absorption of ketoprofen had been reduced by the presence of food, and the extent of absorption was also reduced by **milk**.¹⁸

6. *Naproxen*. Food did not have any clinically relevant effect on the pharmacokinetics of sustained-release **naproxen** in two studies.^{19,20} Taking a single 550-mg dose of **naproxen sodium** with a **meal** had no effect on its analgesic efficacy in postoperative pain, when compared with the fasted state.²¹ However, the rate of absorption of a single 550-mg dose of *S*-naproxen betainate sodium salt monohydrate was found to be reduced by a high-fat meal, when compared with the fasting state.²²

(e) Indometacin

Studies in patients and healthy subjects, given single or multiple oral doses of indometacin, found that food delayed and reduced peak serum indometacin levels, but fluctuations in levels were somewhat reduced.²³

(f) Nabumetone

The absorption of a single 1-g dose of nabumetone was increased by food and **milk**, as shown by an increase of about 50% in the maximum levels and a 40% increase in the AUC₀₋₂₄. However, the AUC₀₋₇₂ was not significantly increased.²⁴

(g) Oxicams

Food caused some delay in the time to reach maximum levels of **piroxicam** in a single-dose study, but had no effect on total absorption.²⁵ In another study, the steady-state plasma levels of **piroxicam** 20 mg daily were unaffected by food.²⁶ The bioavailability of **tenoxicam** 20 mg was unaffected by food in 12 healthy subjects, although the time taken to reach peak serum levels was delayed by about 4 hours.²⁷ The rate (time to peak serum levels) and extent of absorption (AUC) of **meloxicam** 30 mg was not altered by food intake.²⁸

(h) Sulindac

The manufacturer of sulindac notes that food delayed the time to achieve peak plasma levels of the active metabolite by 1 to 2 hours.²⁹

Mechanism

Food delays gastric emptying, therefore frequently affects the rate, but not the extent, of absorption of the NSAIDs.

Importance and management

Food reduces the rate of absorption, but has little or no effect on the extent of absorption, of most of the NSAIDs studied. This was seen to vary with different formulations of NSAIDs; however, these changes in absorption will have no clinical relevance when these drugs are being used regularly to treat chronic pain and inflammation. If these drugs are being used for the treatment of acute pain, administration on an empty stomach would be preferable in terms of onset of effect, and is suggested by the manufacturers of dexketoprofen³⁰ and etoricoxib.⁴ However, administration with or

after food is a usual recommendation for NSAIDs in an attempt to minimise their gastrointestinal adverse effects.

Although food delayed the absorption of celecoxib, the UK manufacturer says that it can be taken with or without food.² However, high-fat food may increase the total absorption of celecoxib and the US manufacturer suggests that higher doses (400 mg twice daily) should be administered with food to improve absorption.³

NSAIDs + *Ginkgo biloba*

An isolated case describes fatal intracerebral bleeding in a patient taking *Ginkgo biloba* with ibuprofen, and another case describes prolonged bleeding and subdural haematomas in another patients taking *Ginkgo biloba* with rofecoxib. Studies involving diclofenac and flurbiprofen showed that *Ginkgo biloba* had no effect on the pharmacokinetics of these drugs.

Clinical evidence

A case of fatal intracerebral bleeding has been reported in a 71-year-old patient taking a *Ginkgo biloba* supplement (*Gingium*) 4 weeks after he started to take **ibuprofen** 600 mg daily.¹ A 69-year-old man taking a *Ginkgo biloba* supplement and **rofecoxib** had a subdural haematoma after a head injury, then recurrent small spontaneous haematomas. He was subsequently found to have a prolonged bleeding time, which returned to normal one week after stopping the *Ginkgo biloba* supplement and **rofecoxib**, and remained normal after restarting low-dose **rofecoxib**.²

A placebo-controlled study in 11 healthy subjects who were given *Ginkgo biloba* leaf (*Ginkgold*) 120 mg twice daily for three doses, followed by a single 100-mg dose of **flurbiprofen**, found that the pharmacokinetics of flurbiprofen were unchanged.³

A study in 12 healthy subjects who were given **diclofenac** 50 mg twice daily for 14 days, with *Ginkgo biloba* extract (*Ginkgold*) 120 mg twice daily on days 8 to 15, found no alteration in the AUC or oral clearance of diclofenac.⁴

Mechanism

The reason for the bleeding is not known, but *Ginkgo biloba* extract contains ginkgolide B, which is a potent inhibitor of platelet-activating factor that is needed for arachidonate-independent platelet aggregation. On their own, *Ginkgo biloba* supplements have been associated with prolonged bleeding times,^{5,6} left and bilateral subdural haematomas,^{5,7} a right parietal haematoma,⁸ post-laparoscopic cholecystectomy bleeding,⁹ and subarachnoid haemorrhage.⁶ Ibuprofen is an inhibitor of platelet aggregation, but selective inhibitors of COX-2 such as rofecoxib have no effect on platelets and would not be expected to potentiate any bleeding effect of *Ginkgo biloba*.

The pharmacokinetic study involving diclofenac was designed to identify whether *Ginkgo biloba* exerted an inhibitory effect on cytochrome P450 isoenzyme CYP2C9, which is involved in the metabolism of diclofenac. Although an indication that such an effect may occur was noted in studies *in vitro* using *S*-warfarin, the *in vivo* study did not confirm that this interaction would be seen clinically.⁴

Importance and management

The evidence from these reports is too slim to forbid patients to take NSAIDs and *Ginkgo biloba* concurrently, but some do recommend caution.¹⁰ Medical professionals should be aware of the possibility of increased bleeding tendency with *Ginkgo biloba*, and report any suspected cases.⁸ Consider also 'Antiplatelet drugs + Herbal medicines', p.699.

NSAIDs or Aspirin + Gold

Gold appears to increase the risk of aspirin-induced liver damage. The use of gold with fenoprofen seems to be safer with regard to liver toxicity. An isolated report suggested that naproxen may have contributed to gold-induced pneumonitis.

Clinical evidence, mechanism, importance and management

A study in rheumatoid patients given aspirin 3.9 g or **fenoprofen** 2.4 g daily suggested that gold induction therapy (**sodium aurothiomalate**, by intramuscular injection, to a total dose of 985 mg over 6 months) increased aspirin-induced hepatotoxicity. Levels of AST, lactate dehydrogenase, and alkaline phosphatase were higher during aspirin than during

fenoprofen treatment. These indicators of liver impairment suggest that **fenoprofen** is safer than aspirin in this context. Combined treatment with gold and NSAIDs was more effective than the NSAIDs alone.¹

A patient with rheumatoid arthritis taking gold (**sodium aurothiomalate**) developed pneumonitis soon after **naproxen** 500 mg twice daily was added. An *in vitro* study suggested the pneumonitis was due to hypersensitivity to gold. However, the patient's condition continued to deteriorate despite stopping the gold, then showed marked improvement when the **naproxen** was also stopped. The authors suggest that the **naproxen** may have altered the patient's immune system in some way to make them more sensitive to the gold.² This appears to be the only report of such an effect, and is therefore unlikely to be of general relevance.

NSAIDs or Aspirin + H₂-receptor antagonists

The H₂-receptor antagonists have no effect or cause only modest and normally clinically unimportant changes in the serum levels of aspirin and the NSAIDs. More importantly H₂-receptor antagonists may protect the gastric mucosa from the irritant effects of the NSAIDs.

Clinical evidence

(a) Aspirin

Cimetidine 300 mg, given 1 hour before a single 1.2-g dose of aspirin caused only a modest increase in the serum salicylate levels of 3 out of 6 healthy subjects.¹ When 13 patients with rheumatoid arthritis taking enteric-coated aspirin were given **cimetidine** 300 mg four times daily for 7 days the total amount of aspirin absorbed was unaltered, but aspirin levels were slightly raised, from 161 to 180 micrograms/mL.² The pharmacokinetics of a single 1-g dose of aspirin were largely unchanged in 6 healthy subjects given **ranitidine** 150 mg twice daily for a week.³ **Famotidine** has been found to cause some small changes in the pharmacokinetics of aspirin, but this is of doubtful clinical importance.⁴

(b) Azapropazone

A randomised pharmacokinetic study in 12 healthy subjects found that after taking **cimetidine** 300 mg every 6 hours for 6 days the AUC of a single 600-mg dose of azapropazone was increased by 25%, and the AUC of **cimetidine** was altered by less than 20%. No significant changes in laboratory values (blood counts, enzyme levels) were seen, and adverse effects were minor (headaches in 3 subjects).⁵

(c) Diclofenac

In 14 healthy subjects **famotidine** 40 mg raised the peak plasma levels of enteric-coated diclofenac 100 mg from 5.84 to 7.04 mg/L. Peak plasma diclofenac levels also occurred more rapidly (2 versus 2.75 hours). The extent of the absorption was unchanged.⁶ Diclofenac did not affect the pharmacokinetics of **ranitidine** nor its ability to suppress gastric pH.⁷ Another study also found that the pharmacokinetics of diclofenac were unaffected by **ranitidine**.⁸

(d) Dipyrrone

In a study in 12 patients with confirmed duodenal ulcer, but no gastrointestinal bleeding, **cimetidine** 200 mg was given three times daily with another 400 mg at night for 20 days. A single 1.5-g or 750-mg dose of dipyrrone was given on days 8 and 13 of cimetidine treatment. In the presence of **cimetidine**, the AUC of the active metabolite of dipyrrone, 4-methyl-amino-antipyrine (4-MAA), was significantly increased, by 74%, with dipyrrone doses of 1.5 g, but the renal clearance of 4-MAA remained unchanged.⁹

(e) Flurbiprofen

In 30 patients with rheumatoid arthritis **cimetidine** 300 mg three times daily for 2 weeks increased the maximum serum level of flurbiprofen 150 to 300 mg daily, but **ranitidine** 150 mg twice daily had no effect. The efficacy of the flurbiprofen (assessed by Ritchie score, 50 foot walking time, grip strength) was not altered.¹⁰ Another study in healthy subjects found that **cimetidine** 300 mg four times daily slightly increased the serum levels of a single 200-mg dose of flurbiprofen, and raised the flurbiprofen AUC by 13%.¹¹ No statistically significant interaction occurred with **ran-**

itidine 150 mg twice daily.¹¹ Although the activity of flurbiprofen is thought to be related to the *S*-enantiomer, neither **cimetidine** nor **ranitidine** were shown to interact preferentially with one enantiomer over the other.¹²

(f) Ibuprofen

Cimetidine 400 mg three times daily raised the peak serum levels and AUC of a 600-mg dose of ibuprofen by 14% and 6%, respectively. No changes were seen with **ranitidine** 300 mg daily.¹³ Another study found that the (AUC of *R*-ibuprofen and *S*-ibuprofen increased by 37% and 19%, respectively, but these were not statistically significant.¹⁴ However, five other studies with ibuprofen found no interaction with **cimetidine** or **ranitidine**,^{15–19} or **nizatidine**.¹⁶ However, analysis of the results of one study showed that peak serum ibuprofen levels in black subjects (USA) were 54% higher and occurred sooner, whereas in white subjects (USA) they were 27% lower and delayed.^{17,20}

(g) Indometacin

Cimetidine 1 g daily for 2 weeks was given to 10 patients with rheumatoid arthritis taking indometacin 100 to 200 mg daily for over a year. The plasma indometacin levels fell by an average of 18%, but there was no significant change in the clinical effectiveness of the anti-inflammatory treatment (as measured by articular index, pain, grip strength and erythrocyte sedimentation rate).²¹ Another study found no changes in the pharmacokinetics of indometacin in healthy subjects given **ranitidine**.²² No marked changes in the bioavailability of either **cimetidine** or **ranitidine** were seen when they were given with indometacin in a single-dose study in healthy subjects.²³

(h) Ketoprofen

Cimetidine 600 mg twice daily was found not to affect the pharmacokinetics of enteric-coated ketoprofen 100 mg twice daily in 12 healthy subjects.²⁴

(i) Lornoxicam

In 12 healthy subjects **cimetidine** 400 mg twice daily increased the maximum serum levels and AUC of lornoxicam 8 mg twice daily by 28% and 9%, respectively. **Ranitidine** 150 mg twice daily had no significant effect on lornoxicam pharmacokinetics in these same subjects, except that one subject had a very marked increase in serum lornoxicam levels while taking both drugs. He dropped out of the study after 6 days because of severe gastric irritation. It is not clear what part, if any, the **ranitidine** had to play in this effect.²⁵

(j) Meloxicam

In an open, randomised, crossover study, a group of 9 healthy subjects was given meloxicam 30 mg either alone, or with **cimetidine** 200 mg four times daily for 5 days. **Cimetidine** had no significant effect on the pharmacokinetics of the meloxicam.²⁶

(k) Naproxen

One study found no adverse interaction between naproxen and **cimetidine** and no alteration in the beneficial effects of **cimetidine** on gastric acid secretion,²⁷ but another study found that cimetidine caused a moderate 39 to 60% decrease in the naproxen half-life,^{28,29} and a 20% reduction in the AUC of naproxen.²⁹ In one of these studies the half-life of naproxen was reduced by about 40% by **ranitidine** and 50% by **famotidine**.²⁹ A further study found that **nizatidine** does not affect the pharmacokinetics of naproxen.³⁰

(l) Piroxicam

In 10 healthy subjects **cimetidine** 300 mg four times daily for 7 days slightly increased the half-life and the AUC of a single 20-mg dose of piroxicam by 8% and 16%, respectively.³¹ Another study found that **cimetidine** caused a 15% rise in the AUC of piroxicam.³² In 12 healthy subjects the half-life and AUC of a single-dose of piroxicam were increased by 41% and 31%, respectively, by **cimetidine** 200 mg three times daily, and the plasma levels were raised accordingly:³³ for example, at 4 hours they were raised by almost 25%.³³ **Ranitidine** was not found to affect the pharmacokinetics of piroxicam.³⁴ No clinically significant changes occurred in the steady-state serum levels of piroxicam in a further study when either **cimetidine** or **nizatidine** were given.³⁵

(m) Tenoxicam

The pharmacokinetics of a single 20-mg oral dose of tenoxicam was unaltered in 6 healthy subjects after they took **cimetidine** 1 g daily for 7 days.³⁶

Mechanism

Uncertain. Azapropazone, 4-MAA (the active metabolite of dipyrone), lornoxicam, and piroxicam serum levels are possibly increased because their metabolism via the cytochrome P450 system is reduced by the cimetidine.^{5,9,25,33} There may also be some effects on renal excretion.⁵

Importance and management

Most of these interactions between the NSAIDs and cimetidine, famotidine, nizatidine or ranitidine appear to be of no particular clinical importance. The general relevance of the isolated case of increased lornoxicam levels and severe gastric irritation with ranitidine is uncertain, but probably small. The H₂-receptor antagonists as a group may protect the gastric mucosa from the irritant effects of the NSAIDs and concurrent use may therefore be advantageous.

NSAIDs or Aspirin + Hormonal contraceptives or HRT

Oral contraceptives increase diflunisal clearance in women, but only to the level normally seen in men. One study showed modestly reduced levels of ibuprofen with oral contraceptives, but another study did not. Oral contraceptives reduced the levels of aspirin, but not phenylbutazone. There are no clinically relevant changes in the pharmacokinetics of oxaprozin with conjugated oestrogens.

Clinical evidence, mechanism, importance and management

(a) Aspirin

The AUCs of single 300- and 600-mg doses of aspirin were lower in 10 women after they started to take a combined oral contraceptive (**ethinylestradiol/norethisterone** 30 micrograms/1 mg). After the oral contraceptive had been discontinued, the pharmacokinetics of aspirin returned to baseline values.¹

(b) Coxibs

For a report of pulmonary embolism in a patient taking valdecoxib with a combined oral contraceptive, and for the effects of coxibs on contraceptive metabolism, see 'Hormonal contraceptives or HRT + Coxibs', p.994.

(c) Diflunisal

The clearance of a single 250-mg dose of diflunisal was 53% higher in 6 women taking oral contraceptives than in 6 control women, but was similar to the clearance in 6 men.² This difference is unlikely to be of clinical importance.

(d) Ibuprofen

In one study, the pharmacokinetics of R-ibuprofen did not differ between women taking combined oral contraceptives, control women, and control men.³ However, in another study, the median AUC₀₋₁₂ of S-ibuprofen lysinate was 29% lower in users of oral contraceptives, and pain-intensity was higher (possibly due to reduced pain tolerance).⁴

(e) Oxaprozin

There was no difference in the pharmacokinetics of a single 1.2-g dose of oxaprozin in 11 women taking **conjugated oestrogens (Premarin)** than in 11 control women, except that the time to peak concentration was shorter (4 versus 8.9 hours).⁵ This difference is unlikely to be of clinical importance.

(f) Phenylbutazone

The pharmacokinetics of a single 400-mg dose of phenylbutazone did not change in 10 women after they started to take a combined oral contraceptive containing **ethinylestradiol/norethisterone** 30 micrograms/1 mg.¹

NSAIDs or Salicylates + Mazindol

Mazindol does not appear to interact adversely with indometacin or salicylates.

Clinical evidence, mechanism, importance and management

In an 8-week, placebo-controlled, double-blind study, mazindol was given to 26 patients with obesity and arthritis, 15 of whom were taking **sali-**

cylates, 11 were taking **indometacin** and one was taking dextropropoxyphene (propoxyphene) with paracetamol (acetaminophen). Additional analgesic and anti-inflammatory drugs used were ibuprofen (4 patients), phenylbutazone (1), dextropropoxyphene (7) and paracetamol (3). No symptoms attributable to salicylism or **indometacin** toxicity (gastric intolerance, headache) were observed.¹

NSAIDs or Aspirin + Metoclopramide

Metoclopramide increases the rate of absorption of aspirin and tolfenamic acid. Conversely, metoclopramide reduces the bioavailability of ketoprofen.

Clinical evidence

(a) Aspirin

In one study, intramuscular metoclopramide given before oral effervescent aspirin increased the rate of aspirin absorption during a migraine attack to that seen when aspirin was given alone to subjects who were headache free.¹ Similarly, in another study, intramuscular or oral metoclopramide 10 mg increased the rate of absorption of aspirin in patients with migraine.² However, in healthy subjects metoclopramide did not alter the pharmacokinetics of aspirin.³ In addition, in one clinical study there was no difference in analgesic efficacy between aspirin with metoclopramide (*Migravess*) and aspirin alone (*Alka-Seltzer*) for migraine attacks.⁴

(b) Ketoprofen

In a single-dose study in 4 healthy subjects, metoclopramide 10 mg reduced the AUC of a 50-mg capsule of ketoprofen by 28%. The maximum plasma levels of ketoprofen were almost halved and the time to reach this maximum was prolonged by 30%.⁵

(c) Tolfenamic acid

Rectal metoclopramide 20 mg, given to 8 healthy subjects 30 minutes before oral tolfenamic acid 300 mg, caused a threefold increase in the serum tolfenamic acid levels at 45 minutes. There was no change in the maximum level or the AUC.⁶ In another study, rectal metoclopramide similarly enhanced the rate of oral absorption of tolfenamic acid when given during a migraine attack.⁷

Mechanism

Metoclopramide speeds up gastric emptying. The relatively poorly soluble ketoprofen spends less time in the stomach where it dissolves, and as a result less is available for absorption in the small intestine. Conversely, the absorption rate of tolfenamic acid is increased, without a change in the extent of absorption.

Importance and management

The clinical importance of the reduction in ketoprofen levels is unknown, but the authors of the study recommend that ketoprofen (and possibly other NSAIDs that are poorly soluble) should be taken 1 to 2 hours before metoclopramide. Conversely, for aspirin, tolfenamic acid, and other NSAIDs, metoclopramide can be used to increase the rate of absorption, and therefore possibly speed up the onset of analgesic effect in conditions such as migraine.

NSAIDs + NSAIDs

The concurrent use of two or more NSAIDs increases the risk of gastrointestinal damage. Diflunisal raises serum indometacin levels about twofold but does not affect naproxen levels. The concurrent use of indometacin and flurbiprofen does not appear to affect the pharmacokinetics of either drug. Floctafenine does not alter diclofenac levels. Indometacin caused renal impairment in a patient recovering from phenylbutazone-induced acute renal failure.

Clinical evidence

(a) Gastrointestinal effects

The risk of serious upper gastrointestinal bleeding was increased by the use of more than one NSAID in a meta-analysis of data from three case-controlled studies (odds ratio 4.9 with one NSAID and 10.7 with two).¹ Another study provided similar findings: the odds ratio was 7.1 with one NSAID and 12.3 with two or more NSAIDs.² Similar findings have been reported with aspirin and NSAIDs, see 'NSAIDs + Aspirin; Anti-inflammatory dose', p.142. Analysis of yellow card reports to the CSM in the UK, of gastrointestinal perforation, obstruction, ulceration or bleeding with **diclofenac**, **naproxen**, and **ibuprofen**, revealed that 6% of the patients were receiving another non-aspirin NSAID.³

One pharmacodynamic study in healthy subjects found that gastric instillation of a solution of **diflunisal** before an **indometacin** solution prevented the fall in transmucosal potential difference seen with **indometacin** alone. This was interpreted as evidence that **diflunisal** protects the human gastric mucosa against the damaging effects of **indometacin**.⁴ However, the relevance of this test to the adverse effects of NSAIDs used clinically is unknown. Note that fatal gastrointestinal haemorrhage has been reported in a patient taking **diflunisal** and **indometacin**.⁵

(b) Pharmacokinetic studies

No clinically significant changes in the pharmacokinetics of either **indometacin** 75 mg daily or **flurbiprofen** 150 mg daily occurred when both drugs were given together.⁶

Diflunisal 250 mg twice daily had no effect on plasma levels or urinary excretion of **naproxen** 250 mg twice daily.⁷

A study in 16 healthy subjects showed that **diflunisal** 500 mg twice daily raised the steady-state plasma levels and the AUC of **indometacin** 50 mg twice daily about twofold. Combined use was associated with more gastrointestinal and CNS adverse effects, but there was no clear effect on blood loss in the faeces.⁸ Another study produced similar findings.⁹

No change in free **diclofenac** levels was seen when 6 healthy subjects were given **floctafenine** 400 mg with **diclofenac** 75 mg daily for a week.¹⁰

(c) Renal effects

An isolated report describes deterioration in renal function in a patient during recovery from **phenylbutazone**-induced renal failure when **indometacin** 25 mg three times a day was given. The **indometacin** was discontinued with improvement of renal function.¹¹

Mechanism

The damaging effects of the NSAIDs on the gut appear to be additive. Diflunisal may inhibit the glucuronidation of indometacin, or could compete for renal clearance of unmetabolised indometacin.⁹ All NSAIDs have the propensity to cause renal impairment.

Importance and management

The gastrointestinal toxicity of the NSAIDs is well documented, and it appears that combined use increases this risk. The CSM in the UK state that not more than one NSAID should be used concurrently.^{3,12} The marked rise in plasma levels of indometacin with diflunisal gives an additional reason why this combination in particular should not be used. Some NSAIDs cause more gastrointestinal toxicity than others, a suggested broad 'rank order' of seven NSAIDs is as follows. Highest risk (**azapropazone**); intermediate risk (**diclofenac**, **indometacin**, **ketoprofen** and **naproxen**, with **piroxicam** more risky); lowest risk (**ibuprofen**),¹² which has been borne out in another analysis.³ The ranking was based on epidemiological studies and the yellow card database. **Ketorolac** may also be

particularly associated with gastrointestinal bleeding, and concurrent use with other NSAIDs has been identified as a risk factor,¹³ therefore the manufacturer consequently specifically contraindicates its use with other NSAIDs.¹⁴

NSAIDs or Aspirin + Paracetamol (Acetaminophen)

Paracetamol levels are increased by diflunisal. Aspirin, diclofenac, nabumetone and sulindac pharmacokinetics do not appear to be affected by paracetamol. There is no pharmacokinetic interaction between ibuprofen and paracetamol. Propacetamol, and possibly paracetamol, increase the antiplatelet effects of diclofenac, although the evidence is limited and the clinical relevance of this is uncertain.

One epidemiological study found that paracetamol alone, and particularly when combined with NSAIDs, was associated with an increased risk of gastrointestinal bleeding, but other studies have not found such an effect. Two isolated case reports describe renal toxicity in three patients taking ibuprofen or flurbiprofen in which paracetamol use was a theoretical contributing factor.

Clinical evidence, mechanism, importance and management

(a) Antiplatelet effects

In healthy subjects combining single doses of intravenous **propacetamol** 30 mg/kg and **diclofenac** 1.1 mg/kg augmented the platelet inhibitory effect of **diclofenac** by about one-third at 90 minutes post dose. At 5 minutes, the inhibitory effect of both **diclofenac** alone and the combination was 100%, and by 22 to 24 hours, neither **diclofenac** alone nor the combination had any inhibitory effect.¹ In a previous study, the authors had shown that **propacetamol** (which is hydrolysed to paracetamol) also inhibited platelet function, and they suggested that the effects of **diclofenac** and **propacetamol** were additive.¹ The clinical relevance of these findings is unclear, but the authors say it should be considered when assessing the risk of surgical bleeding.¹ Further study is needed.

An *in vitro* study suggested that high doses of paracetamol, and a combination of paracetamol and **diclofenac**, may cause platelet inhibition and may increase the risk of bleeding, particularly post-surgery.²

Intravenous **parecoxib** 40 mg was found not to alter the platelet function in 18 healthy subjects when given with intravenous paracetamol 1 g, when compared with paracetamol alone.³

(b) Gastrointestinal damage

In a case-control study of the UK General Practice Research Database from 1993 to 1998 the risk of upper gastrointestinal bleeding or perfora-

tion was slightly increased in those taking both aspirin and paracetamol (relative risk 3.3), when compared with aspirin alone (2.4), or paracetamol alone (2.4). Moreover, the risk was markedly increased in those taking NSAIDs and paracetamol (16.6), when compared with NSAIDs alone (3.6). The paracetamol doses used were at least 2 g daily. Paracetamol in doses of less than 2 g daily was not associated with an increased risk. Other drug doses and specific NSAIDs were not mentioned.⁴ However, other epidemiological studies have not found any increased risk of upper gastrointestinal bleeding with paracetamol at any dose.⁵ Paracetamol is usually considered not to increase the risk of upper gastrointestinal adverse effects, and the results of this case-control study are probably insufficient to change prescribing practice. Further studies are needed, controlled for the dose of the NSAID and indication for treatment.

(c) Pharmacokinetic studies

1. **Aspirin.** In a study in 6 healthy subjects, two doses of dextropropoxyphene with paracetamol 65 mg/650 mg, given one hour before and 3 hours after a single 1.2-g dose of soluble aspirin did not affect the plasma salicylate levels. A reduction in plasma salicylate levels was seen in one subject after a single 1.2-g dose of enteric-coated aspirin was taken with dextropropoxyphene and paracetamol, although the authors suggested that this was related to erratic absorption rather than a pharmacokinetic interaction.⁶

2. **Diclofenac.** Diclofenac 25 mg given with paracetamol 500 mg, both three times daily for 14 days, had no effect on the pharmacokinetics of diclofenac in 6 healthy subjects.⁷

3. **Diflunisal.** Diflunisal significantly raised serum paracetamol levels by 50% but the total bioavailability was unchanged in healthy subjects. Diflunisal levels were not affected.^{8,9} This interaction has not been shown to be clinically important. Nevertheless, the manufacturer of diflunisal recommends that the combination should be used with caution, because of the association of high levels of paracetamol with hepatotoxicity.⁹

4. **Ibuprofen.** Ibuprofen 400 mg given with paracetamol 650 mg, both every 6 hours for 2 days, had no effect on the pharmacokinetics of either drug in a crossover study in 20 healthy subjects.¹⁰

5. **Nabumetone.** In a single-dose study, the absorption of nabumetone 1 g was not significantly altered by paracetamol 1.5 g.¹¹

6. **Sulindac.** The manufacturer of sulindac notes that paracetamol had no effect on the plasma levels of sulindac or its sulfide metabolite.¹²

(d) Renal effects

Two children (aged 12 and 14 years) developed acute flank pain and reversible renal function impairment during the short-term use of **flurbiprofen** or **ibuprofen**. They had also taken paracetamol.¹³ Similarly, a 14-month-old infant with febrile status epilepticus was treated with an alternating regimen of paracetamol and **ibuprofen**, and subsequently developed acute renal failure.¹⁴ NSAIDs can cause renal toxicity, whereas paracetamol is less likely to cause renal toxicity, except perhaps in overdose.¹⁵ The authors of the first case report proposed that tubular toxicity of NSAIDs and paracetamol are theoretically synergistic.¹³ This is because NSAIDs inhibit the production of glutathione (needed to prevent the accumulation of toxic metabolites of paracetamol) and renal ischaemia (possibly induced by NSAIDs, or by dehydration) might lead to the accumulation of paracetamol in the renal medulla.¹³

A review concluded that the available evidence does not support an increased risk of renal toxicity with the use of combination products of aspirin and paracetamol when compared with either drug alone.¹⁶ Paracetamol is often combined with NSAIDs in the management of chronic pain. In addition, paracetamol and **ibuprofen** are often used concurrently (as alternating doses) in the management of fever, particularly in children. This latter practice has become controversial. Opponents cite the lack of efficacy data to support combined use (rather than appropriate doses of single agents), and the theoretical increased risk of overdose and renal toxicity.^{17,18} Others consider that, in the absence of true safety issues, professional judgement should be used for recommending combined treatment.¹⁹ Further study is clearly needed.

NSAIDs + Pentoxifylline

A review of bleeding events associated with the use of postoperative ketorolac revealed that a small number of patients were also taking pentoxifylline.¹ The UK manufacturers therefore recommend that this drug combination should be avoided,² whereas the US manufacturers³ make no mention of this tentative interaction. There seems to be no evidence regarding this interaction with other NSAIDs.

NSAIDs + Pesticides

Chronic exposure to lindane and other chlorinated pesticides can slightly increase the rate of metabolism of phenazone (antipyrene) and phenylbutazone.

Clinical evidence, mechanism, importance and management

(a) Phenazone (Antipyrene)

A study in 26 men occupationally exposed to a mixture of insecticides, predominantly **DDT**, **chlordane** and **lindane**, found that the half-life of phenazone 10 or 15 mg/kg was reduced from 13.1 hours, in a group of 33 unexposed subjects, to 7.7 hours in the exposed group.¹ The significance of this is unclear as changes in working practices have reduced occupational exposure to such chemicals.

(b) Phenylbutazone

The plasma half-life of phenylbutazone in a group of men who regularly used **chlorinated insecticide** sprays (mainly **lindane**) as part of their work, was found to be 20% shorter (51 hours) than in a control group (64 hours), due, it is believed, to the enzyme-inducing effects of the **pes-**

ticides.² This modest increase in rate of metabolism is of doubtful direct clinical importance, but it illustrates the changed metabolism that can occur in those exposed to environmental chemical agents.

- Kolmodin B, Azarnoff DL, Sjöqvist F. Effect of environmental factors on drug metabolism: decreased plasma half-life of antipyrine in workers exposed to chlorinated hydrocarbon insecticides. *Clin Pharmacol Ther* (1969) 10, 638–42.
- Kolmodin-Hedman B. Decreased plasma half-life of phenylbutazone in workers exposed to chlorinated pesticides. *Eur J Clin Pharmacol* (1973) 5, 195–8.

NSAIDs + Phenobarbital

Phenobarbital modestly decreases the AUC of fenoprofen and increases the clearance of phenylbutazone.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects pretreatment with phenobarbital 15 or 60 mg every 6 hours for 10 days reduced the AUC of a single 200-mg dose of **fenoprofen** by 23% and 37%, respectively.¹

In 5 healthy subjects the half-life of a single 6-mg/kg dose of **phenylbutazone** was reduced by 38% after pretreatment with phenobarbital 2 to 3 mg/kg daily for 3 weeks.² Other studies confirm that phenobarbital increases the clearance of **phenylbutazone**.^{3,4}

The probable reason is that the phenobarbital increases the metabolism of these NSAIDs by the liver, thereby hastening their clearance. **Phenazone** is metabolised by mixed function oxidase enzymes in the liver, for which reason it is extensively used as a model drug for studying whether other drugs induce or inhibit liver enzymes. In one study phenobarbital caused about a 40% reduction thereby demonstrating that the liver enzymes were being stimulated to metabolise the phenazone more rapidly.⁵

The clinical importance of these interactions is uncertain (probably small) but be alert for any evidence of reduced NSAID effects if phenobarbital is added.

NSAIDs + Probenecid

Probenecid reduces the clearance of dexketoprofen, diflunisal, indometacin (toxicity seen), ketoprofen, ketorolac, naproxen, sodium meclofenamate, tenoxicam and tiaprofenic acid and raises their levels. Ketorolac and probenecid are specifically contraindicated. The uricosuric effects of probenecid are not affected by indometacin but may be slightly reduced by sulindac.

Clinical evidence

(a) Diflunisal

In 8 healthy subjects probenecid 500 mg twice daily increased the steady-state plasma levels of diflunisal 250 mg twice daily by 65%, and reduced the clearances of the glucuronide metabolites.¹

(b) Indometacin

A study in 28 patients with osteoarthritis, taking indometacin 50 to 150 mg daily orally or rectally, showed that probenecid 500 mg to 1 g daily roughly doubled their indometacin plasma levels and this paralleled the increased effectiveness (relief of morning stiffness, joint tenderness and raised grip strength indices). However, 4 patients developed indometacin toxicity.²

Other studies have also demonstrated the marked rise in plasma indometacin levels caused by probenecid.^{3–5} Clear signs of indometacin toxicity (nausea, headache, tinnitus, confusion and a rise in blood urea) occurred when a woman with stable mild renal impairment was given probenecid.⁶ The uricosuric effects of probenecid were not altered.³

(c) *Ketoprofen and Dexketoprofen*

In 6 healthy subjects probenecid 500 mg every 6 hours reduced the clearance of ketoprofen 50 mg every 6 hours by 67%.⁷ The manufacturer of dexketoprofen notes that plasma levels may be increased by probenecid, and adjustment of the dose of dexketoprofen is required.⁸

(d) *Ketorolac*

Probenecid 500 mg four times daily for 4 days increased the total AUC of a single 10-mg dose of ketorolac in 8 subjects by more than threefold, increased its half-life from 6.6 to 15.1 hours, raised its maximum plasma levels by 24% and reduced its clearance by 67%.⁹

(e) *Meclofenamate*

Single-dose studies in 6 healthy subjects on the pharmacokinetics of sodium meclofenamate 100 mg found that pretreatment with probenecid (dosage unstated) increased its AUC and reduced its apparent plasma clearance by 60%, primarily due to a decrease in non-renal clearance.¹⁰

(f) *Naproxen*

Probenecid 500 mg twice daily increased the plasma levels of naproxen 250 mg twice daily by 50% in 12 healthy subjects.¹¹

(g) *Sulindac*

The manufacturers of sulindac note that probenecid increased plasma levels of sulindac and its sulfone metabolite, but had little effect on the active sulfide metabolite. Sulindac produced a modest reduction in the uricosuric action of probenecid,^{12,13} which is said not to be clinically significant in most circumstances.¹³

(h) *Tenoxicam*

Probenecid 1 g twice daily for 4 days increased the maximum serum levels of a single 20-mg oral dose of tenoxicam by 25%. None of the other pharmacokinetic parameters was significantly altered.¹⁴

(i) *Tiaprofenic acid*

Probenecid appeared to reduce the urinary excretion of tiaprofenic acid in one healthy subject. The maximum urinary excretion rate was reduced by 66% and delayed by 2 hours.¹⁵

Mechanism

Probenecid is a known substrate for renal glucuronidation, and possibly competitively inhibits the renal glucuronidation of these NSAIDs.^{8,16}

Importance and management

The interaction between indometacin and probenecid is established and adequately documented. Concurrent use should be well monitored because, while clinical improvement can undoubtedly occur, some patients may develop indometacin toxicity (headache, dizziness, light-headedness, nausea, etc.). This is particularly likely in those with some renal impairment. Reduce the indometacin dosage as necessary. Information about other NSAIDs is limited, but these interactions also appear to be established. The clinical importance of most of them is uncertain, but probably small. Reports of adverse effects seem to be lacking, but it would still be prudent to be alert for any evidence of increased adverse effects. Reduce the NSAID dosage if necessary. The exception is ketorolac, which its manufacturers^{17,18} contraindicate with probenecid because of the marked increases seen in its plasma levels.

NSAIDs or Aspirin + Prostaglandins

Misoprostol increases the incidence of abdominal pain and diarrhoea when used with diclofenac or indometacin. Isolated cases of neurological adverse effects have been seen with naproxen or phenylbutazone given with misoprostol. However, no important pharmacokinetic interactions seem to occur between aspirin, diclofenac, ibuprofen or indometacin and misoprostol. NSAIDs are reported not to affect the abortive effects of intravaginal misoprostol.

Clinical evidence, mechanism, importance and management

(A) Oral misoprostol

(a) *Gastrointestinal adverse effects*

A higher incidence of abdominal pain, diarrhoea, nausea and dyspepsia occurred when **diclofenac** was combined with misoprostol.^{1,2} Concurrent use of **indometacin** and misoprostol also resulted in an increase in frequency and severity of abdominal symptoms, frequency of bowel movements and a decrease in faecal consistency.³ The most frequent adverse effect of misoprostol alone is diarrhoea, and this may limit the dose tolerated. When using misoprostol with NSAIDs, warn patients about the possibility of increased stomach pain and diarrhoea. Preparations combining **diclofenac** or **naproxen** with misoprostol are available.

(b) *Neurological adverse effects*

A man with rheumatoid arthritis taking long-term **naproxen** developed ataxic symptoms a few hours after starting to take misoprostol. He said he felt like a drunk person, staggering about and vomiting. He rapidly improved when he stopped the misoprostol but the adverse symptoms recurred on two further occasions when he restarted misoprostol.⁴

Adverse effects developed in 3 patients taking **phenylbutazone** 200 to 400 mg daily when they took misoprostol 400 to 800 micrograms daily.⁵ One had headaches, dizziness and ambulatory instability that disappeared and then reappeared when the misoprostol was stopped and then restarted. No problems occurred when the **phenylbutazone** was replaced by **etodolac** 400 mg daily. The other 2 patients developed symptoms including headache, tingles, dizziness, hot flushes and transient diplopia.^{5,6} No problems developed when one of them was given **naproxen** and misoprostol.⁶ The reasons for this reaction are not understood but theoretically it could possibly be due to a potentiation of the adverse effects of **phenylbutazone**. The general relevance of these few reports is unclear, but bear them in mind should unexpected neurological effects occur.

(c) *Pharmacokinetic studies*

No clinically important pharmacokinetic interactions have been found to occur between **aspirin** 975 mg and misoprostol 200 micrograms,⁷ or between **ibuprofen** and misoprostol.⁸ One study found that misoprostol 800 micrograms daily decreased the AUC of a single 100-mg dose of **diclofenac** by a modest 20%.² However, other studies have found that misoprostol had no effect on steady-state **diclofenac** pharmacokinetics.⁹ One study found that misoprostol 200 micrograms raised the steady-state levels of **indometacin** 50 mg three times daily by about 30%,¹⁰ whereas another found that **misoprostol** 400 micrograms twice daily reduced the AUC of **indometacin** 50 mg twice daily by 13% after one dose and reduced the maximum steady-state plasma concentration by 24%.³ These modest changes in serum **indometacin** levels are unlikely to be clinically important.

(B) Vaginal prostaglandins

NSAIDs and aspirin are frequently avoided before the use of **prostaglandins** for induction of uterine contractions, because of the theoretical concern that they may inhibit efficacy.¹¹ For example, the UK manufacturer of **dinoprostone** says that NSAIDs including aspirin should be stopped before giving intravaginal **dinoprostone** for induction of labour.¹² However, a study involving 416 women given intravaginal misoprostol to induce early abortion found that the concurrent use of oral NSAIDs did not interfere with the efficacy of misoprostol,¹¹ and the US manufacturer of **dinoprostone** does not list NSAIDs or aspirin as possible interacting drugs.¹³ Further study is needed. Consider also 'Mifepristone + Aspirin or NSAIDs', p.1265.

- Proress (Dinoprostone). Ferring Pharmaceuticals Ltd. UK Summary of product characteristics, December 2005.
- Prostin E2 (Dinoprostone). Pfizer Inc. US Prescribing information, April 2006.

(c) Ketoprofen

There were no significant changes in the pharmacokinetics of enteric-coated ketoprofen, given with or without **omeprazole**, although a trend towards higher plasma concentrations with omeprazole was noted, indicating the possibility of increased drug release in the stomach in the presence of an elevated pH.⁷

(d) Naproxen

Naproxen 250 mg twice daily given to healthy subjects with **omeprazole** 20 mg daily,⁵ **pantoprazole** 40 mg daily,⁸ or **esomeprazole** 40 mg daily⁹ for one week had no effect on the pharmacokinetics of either naproxen or the proton pump inhibitor.

(e) Phenazone (Antipyrene)

The pharmacokinetics of **pantoprazole** 40 mg orally daily for 8 days was not altered to a clinically relevant extent by a single 5-mg/kg oral dose of phenazone given on day 8 of the study. **Pantoprazole** did not affect the pharmacokinetics of phenazone.¹⁰

(f) Piroxicam

Omeprazole 20 mg daily given to 24 healthy subjects with piroxicam 10 mg daily for one week had no effect on the pharmacokinetics of either drug.⁵

(g) Rofecoxib

Esomeprazole 40 mg daily given to 30 healthy subjects with rofecoxib 12.5 mg daily for one week had no effect on the pharmacokinetics of either drug apart from a slight increase in the maximum level and AUC of rofecoxib, which was not thought to be clinically relevant.⁹

Mechanism

Data from *animal* studies suggest that the absorption and thus the effects of aspirin and NSAIDs can be reduced by omeprazole and H₂-receptor antagonists via a pH dependent mechanism.^{11,12} However, note that clinical studies have not found H₂-receptor antagonists to have any important effect on the pharmacokinetics of aspirin or NSAIDs, see 'NSAIDs or Aspirin + H₂-receptor antagonists', p.149. It has been suggested that reducing gastric acidity with omeprazole results in the earlier disruption of enteric-coated tablets, and an increased absorption rate.³

Importance and management

The interaction between aspirin and omeprazole is not established. The balance of evidence suggests that omeprazole is unlikely to have an important effect on the pharmacokinetics and efficacy of aspirin. However, because of the uncertainty generated by the *animal* and preliminary clinical data,^{1,11,12} it would be of benefit to confirm this in further studies.^{2,13}

No clinically significant pharmacokinetic interactions have been identified between any of the other NSAIDs and PPIs cited here, and no special precautions are needed during concurrent use. For mention that valdecoxib raises plasma levels of omeprazole see 'NSAIDs; Parecoxib + Miscellaneous', p.160. Note that omeprazole and other proton pump inhibitors are widely used in the management of the gastrointestinal complications of aspirin and NSAIDs.

NSAIDs or Aspirin + Proton pump inhibitors

The antiplatelet activity and the pharmacokinetics of aspirin do not appear to be affected by omeprazole. There was no clinically relevant pharmacokinetic interaction between omeprazole and diclofenac, enteric-coated ketoprofen, naproxen or piroxicam, or between pantoprazole and diclofenac or naproxen, or between esomeprazole and naproxen or rofecoxib.

Clinical evidence

(a) Aspirin

In a preliminary study in 11 healthy subjects, **omeprazole** 20 mg daily for 2 days reduced the serum levels of the salicylic acid metabolite of aspirin at 30 and 90 minutes after a single 650-mg dose of aspirin by 40% and 52%, respectively.¹ However, another study in 14 healthy subjects given **omeprazole** 20 mg daily for 4 days with a final dose one hour before a single 125-mg dose of aspirin found that **omeprazole** did not significantly affect the plasma levels of either aspirin or salicylic acid. **Omeprazole** also did not affect the antiplatelet effects of aspirin.² Similarly, **omeprazole** had no effect on the bioavailability of aspirin (uncoated or enteric-coated tablets) in another study, although it increased the rate of absorption of aspirin from enteric-coated tablets.³

(b) Diclofenac

A single 105-mg dose of diclofenac potassium suspension (*Flogan*) was given to 13 healthy subjects while fasting and after gastric acid secretion blockade with **omeprazole**. The pharmacokinetics of the diclofenac were not changed to a clinically relevant extent by **omeprazole**.⁴ Similarly, **omeprazole** 20 mg daily given with diclofenac 50 mg twice daily for one week had no effect on the pharmacokinetics of either drug in 24 healthy subjects.⁵

In another study a single 40-mg oral dose of **pantoprazole** and diclofenac 100 mg (as enteric-coated *Voltarol*) were given to 24 healthy subjects together and separately. Neither drug affected the pharmacokinetics of the other.⁶

NSAIDs + Rifampicin (Rifampin)

The plasma levels of celecoxib, diclofenac, and etoricoxib are reduced by rifampicin. Metamizole (dipyrone) increased the maximum level of rifampicin. Piroxicam appears unaffected by rifampicin.

Clinical evidence

(a) Celecoxib

In 12 healthy subjects pretreatment with rifampicin 600 mg daily for 5 days reduced the AUC of a single 200-mg dose of celecoxib by 64% and increased the clearance by 185%.¹ A preliminary report of another study found broadly similar results.²

(b) Diclofenac

A study in 6 healthy subjects found that after taking rifampicin 450 mg daily for 6 days, the maximum serum level of diclofenac, measured 8 hours after a single 100-mg dose of an enteric-coated tablet, was reduced by 43% and the AUC was reduced by 67%.³

(c) Etoricoxib

The AUC of a single 60-mg dose of etoricoxib has been found to be reduced by 65% when given on day 8 of a 12-day course of rifampicin 600 mg daily. The maximum plasma concentration of etoricoxib was reduced by 40%.⁴

(d) Metamizole sodium (Dipyrone)

A study in untreated patients with leprosy showed that the pharmacokinetics of a single 600-mg dose of rifampicin were not markedly changed by 1 g of metamizole sodium (dipyrone), but peak serum rifampicin levels occurred sooner (at 3 instead of 4 hours) and were about 50% higher.⁵

(e) Phenazone (Antipyrine)

Plasma concentrations following treatment with single 1.2-g oral doses of phenazone were lower after a 13-day course of rifampicin 600 mg daily. The mean AUC of phenazone was reduced by 59% and had not returned to the pre-rifampicin level 13 days after the final rifampicin dose.⁶

(f) Piroxicam

A study in 6 healthy subjects given a single 40-mg dose of piroxicam before and after a 7-day course of rifampicin 600 mg daily found that rifampicin did not significantly alter the pharmacokinetics of piroxicam.⁷

Mechanism

Rifampicin is a potent inducer of hepatic enzymes, and it is likely that it increased the metabolism of these NSAIDs.

Importance and management

Although information is limited, these pharmacokinetic interactions appear to be established. Their clinical relevance remains to be determined, but it seems likely that the efficacy of these NSAIDs will be reduced by rifampicin. Combined use should be well monitored, and the NSAID dosage increased if necessary. See also 'NSAIDs; Parecoxib + Miscellaneous', p.160. The clinical relevance of the increase in rifampicin maximum levels with metamizole is uncertain.

NSAIDs or Aspirin + SSRIs

SSRIs may increase the risk of bleeding, including upper gastrointestinal bleeding, and the risk appears to be further increased by concurrent use of NSAIDs and/or aspirin (including low-dose aspirin).

Clinical evidence

A retrospective study of the UK general practice research database identified 1651 cases of upper gastrointestinal bleeding diagnosed between 1993 and 1997. Concurrent use of an SSRI significantly increased the risk of bleeding threefold when compared with 10,000 controls. In addition, the concurrent use of an SSRI with an NSAID greatly increased the risk of upper gastrointestinal bleeding (relative risk of bleeding compared with non-use of either drug: 15.6 for SSRIs with NSAIDs, 3.7 for NSAIDs alone, and 2.6 for SSRIs alone); the use of SSRIs with low-dose aspirin was associated with a relative risk of 7.2. Another study found a significant association between the degree of serotonin reuptake inhibition by antidepressants and risk of hospital admission for abnormal bleeding.¹ A retrospective cohort study in elderly patients taking antidepressants found a trend towards an increased risk of upper gastrointestinal bleeding for patients taking antidepressants with greater inhibition of serotonin reuptake. This association was statistically significant when controlled for previous upper gastrointestinal bleeding or age, and octogenarians, in particular, were at high risk.² Other studies or case reports have also found that SSRIs increase the risk of upper gastrointestinal bleeding,^{3–6} and this effect is potentiated by the concurrent use of NSAIDs^{3,4} or low-dose aspirin.³

In contrast, some workers have disagreed with these results and found no evidence to suggest that SSRIs are more likely to cause gastrointestinal bleeding than other drugs.⁷ Another study reported both SSRIs and NSAIDs were associated with a twofold increase in risk of gastrointestinal bleeding, but that the risk of bleeding was not substantially increased when both drugs were taken together (odds ratio for NSAIDs was 2.19, SSRIs was 2.63 and combined use was 2.93).⁸

Mechanism

Serotonin is not synthesised by platelets but is taken up into platelets from the bloodstream. Serotonin released from platelets has an important role in regulating the haemostatic response to injury as it potentiates platelet aggregation. At therapeutic doses SSRIs can block this reuptake of serotonin by platelets leading to serotonin depletion, impairment of haemostatic function and so increase the risk of bleeding.^{2,9–11}

Importance and management

Serotonin released by platelets plays an important role in haemostasis and there appears to be an association between the use of antidepressant drugs that interfere with serotonin reuptake and the occurrence of bleeding, including gastrointestinal bleeding. In addition, the concurrent use of an NSAID or aspirin (including low-dose aspirin) may potentiate the risk of bleeding. Therefore, the manufacturers of SSRIs advise caution in patients taking SSRIs with NSAIDs, aspirin or other drugs that affect coagulation or platelet function. Alternatives such as paracetamol (acetaminophen) or less gastrotoxic NSAIDs such as ibuprofen may be considered, but if the combination of an SSRI and NSAID cannot be avoided, prescribing of gastroprotective drugs such as proton pump inhibitors, H₂-receptor antagonists, or prostaglandin analogues should be considered, especially in elderly patients or those with a history of gastrointestinal bleeding. Patients,

particularly those taking multiple drugs that may cause bleeding, should be advised to seek informed medical opinion before using non-prescription drugs such as ibuprofen on a regular basis.

NSAIDs or Aspirin + Sucralfate

Sucralfate appears not to have a clinically important effect on the pharmacokinetics of aspirin, choline-magnesium trisalicylate, diclofenac, ibuprofen, indometacin, ketoprofen, naproxen or piroxicam.

Clinical evidence, mechanism, importance and management

Sucralfate 2 g was given to 18 healthy subjects 30 minutes before single-doses of **ketoprofen** 50 mg, **indometacin** 50 mg, or **naproxen** 500 mg. Some statistically significant changes were seen (modestly reduced maximum serum levels of **ketoprofen**, **indometacin**, and **naproxen**, reduced the rate of absorption of **naproxen** and **indometacin**, and increased the time to achieve maximal serum levels with **indometacin**) but no alterations in bioavailability occurred.¹ A delay, but no reduction in the total absorption of **naproxen** is described in two studies:^{2,3} it is unlikely that its clinical efficacy will be reduced.² Sucralfate 1 g four times daily for 2 days was found not to decrease the rate of absorption of a single 400-mg dose of **ibuprofen**⁴ or of a single 650-mg dose of **aspirin**.⁵ Sucralfate 5 g in divided doses did not significantly alter the absorption of a single 600-mg dose of **ibuprofen**.⁶ Similarly, another study also found that sucralfate had no important effect on the pharmacokinetics of **ibuprofen** enantiomers.⁷ In one study, sucralfate 2 g was found not to affect significantly the pharmacokinetics of either **piroxicam** 20 mg or **diclofenac** 50 mg.⁸ However, in another study, sucralfate 2 g twice daily modestly reduced the AUC_{0–8} and maximum serum levels of a single 105-mg dose of **diclofenac potassium** by 20% and 38%, respectively.⁹ Sucralfate 1 g every 6 hours was found not to affect the pharmacokinetics of **choline-magnesium trisalicylate** 1.5 g every 12 hours.¹⁰

Single dose studies do not necessarily reliably predict what will happen when patients take drugs regularly, but most of the evidence available suggests that sucralfate is unlikely to have an adverse effect on treatment with these NSAIDs.

NSAIDs or Aspirin + *Tamarindus indica*

***Tamarindus indica* fruit extract markedly increases the absorption and plasma levels of aspirin and ibuprofen.**

Clinical evidence, mechanism, importance and management

(a) Aspirin

A study in 6 healthy subjects found that the bioavailability of a single 600-mg dose of aspirin was increased when it was taken with a millet meal containing *Tamarindus indica* fruit extract, compared with the millet meal alone or following overnight fasting. The aspirin AUC rose sixfold, the maximum plasma levels rose almost threefold (from about 10 micrograms/mL with the meal or fasting to about 29 micrograms/mL with the *Tamarindus indica* extract) and the half-life increased moderately (from about 1.04 to 1.5 hours).¹ The reasons are not known, nor has the clinical importance of these large increases been evaluated, but this interaction should be borne in mind if high (analgesic or anti-inflammatory) doses of aspirin are taken with this fruit extract. There would seem to be the possible risk of aspirin toxicity.

(b) Ibuprofen

A study in 6 healthy subjects found that the bioavailability of a single 400-mg dose of ibuprofen was increased when it was taken with a millet meal containing *Tamarindus indica* fruit extract compared with the millet meal alone, or following overnight fasting. The ibuprofen AUC rose approximately twofold and the maximum plasma levels rose from about 38 micrograms/mL to 45 micrograms/mL. There was also an increase in the plasma levels of the metabolites of ibuprofen. Ingestion of the meal containing *Tamarindus indica* was thought to favour the absorption of ibuprofen. This might result in an increased risk of toxicity.²

NSAIDs + Tobacco

The clearance of diflunisal, phenazone (antipyrene) and phenylbutazone is greater in smokers than in non-smokers.

Clinical evidence, mechanism, importance and management

(a) Diflunisal

The clearance of a single 250-mg dose of diflunisal was 35% higher in 6 women who smoked 10 to 20 cigarettes a day than in 6 non-smoking women.¹ This change does not appear to be large enough to be of clinical importance.

(b) Phenazone (Antipyrene)

The clearance of phenazone was increased by 63% and the half-life reduced from 13.2 to 8 hours when a single 1-g dose of phenazone was given intravenously to 10 healthy women who smoked cigarettes, when compared with a control group of 26 non-smoking women.² Similar results were reported in another study.³ This is likely to be as a result of cigarette smoking causing induction of CYP1A2, the enzyme involved in the metabolism of phenazone.²

(c) Phenylbutazone

The half-life of a single 6-mg/kg dose of phenylbutazone was 37 hours in a group of smokers (10 or more cigarettes daily for 2 years) compared with 64 hours in a group of non-smokers. The metabolic clearance was roughly

doubled.⁴ The conclusion to be drawn is that those who smoke may possibly need larger or more frequent doses of phenylbutazone to achieve the same therapeutic response, but this needs confirmation.

NSAIDs + Tricyclic antidepressants

The tricyclic antidepressants can delay the absorption of phenylbutazone and oxyphenbutazone from the gut, but their antirheumatic effects are probably not affected.

Clinical evidence, mechanism, importance and management

The absorption of a single 400-mg dose of phenylbutazone in 4 depressed women was considerably delayed (time to maximum level, 4 to 10 hours compared with 2 hours), but the total amount absorbed (measured by the urinary excretion of oxyphenbutazone) remained unchanged when they were pretreated with **desipramine** 75 mg daily for 7 days.¹ In another 5 depressed women the half-life of oxyphenbutazone was found to be unaltered by 75 mg of **desipramine** or **nortriptyline** daily.² *Animal* studies have confirmed that the absorption of phenylbutazone and oxyphenbutazone are delayed by the tricyclic antidepressants, probably because their antimuscarinic effects reduce the motility of the gut,^{3,4} but there seems to be no direct clinical evidence that the antirheumatic effects of either drug are reduced by this interaction. No particular precautions appear to be needed.

NSAIDs; Acemetacin + Miscellaneous

Acemetacin is a glycolic acid ester of indometacin, and its major metabolite is indometacin. Therefore the interactions of indometacin would be expected.

NSAIDs; Azapropazone + Chloroquine

The plasma levels of azapropazone are not significantly altered by chloroquine.

Clinical evidence, mechanism, importance and management

A study in 12 subjects given azapropazone 300 mg three times daily found that the plasma levels of azapropazone, measured at 4 hours, were not affected by chloroquine 250 mg daily for 7 days.¹ No special precautions would seem to be needed if these drugs are given together.

1. Faust-Tinnefeldt G, Geissler HE. Azapropazon und rheumatologische Basistherapie mit Chloroquin unter dem Aspekt der Arzneimittelinteraktion. *Arzneimittelforschung* (1977) 27, 2170–4.

NSAIDs; Celecoxib + Selenium

Selenium enriched baker's yeast does not appear to affect the pharmacokinetics of celecoxib.

Clinical evidence, mechanism, importance and management

In a study in 73 healthy subjects, celecoxib 400 mg was given daily for 2 weeks, then selenium enriched baker's yeast (*Saccharomyces cerevisiae*) 200 micrograms daily or matched placebo were added for 30 days. Following blood chemistry analysis (urea and electrolytes, full blood count etc), there were no clinically significant changes from baseline, nor were there any changes in celecoxib steady-state plasma levels.¹

1. Frank DH, Roe DJ, Chow H-HS, Guillen JM, Choquette K, Gracie D, Francis J, Fish A, Alberts DS. Effects of a high-selenium yeast supplement on celecoxib plasma levels: a randomized phase II trial. *Cancer Epidemiol Biomarkers Prev* (2004) 13, 299–303.

NSAIDs; Diclofenac + Cephalosporins

Cefadroxil does not alter the pharmacokinetics of diclofenac. The biliary excretion of ceftriaxone is increased by diclofenac.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of diclofenac 100 mg daily were unaffected by either **cefadroxil** 2 g daily (8 patients) or doxycycline 100 mg daily (7) for one week.¹ No special precautions are needed while taking either of these drugs and diclofenac.

A pharmacokinetic study in 8 patients who had undergone cholecystectomy and who had a T-drain in the common bile duct, found that diclofenac 50 mg every 12 hours increased the excretion of intravenous **ceftriaxone** 2 g in the bile by about fourfold and roughly halved the urinary excretion.² The clinical importance of this is uncertain, but probably small.

Animal studies have shown that diclofenac may alter the pharmacokinetics of some cephalosporins (the AUCs of **cefotiam** and **ceftriaxone** were increased by diclofenac, although the pharmacokinetics of **cefmenoxime** were not affected). The significance of these findings in humans is unknown and further studies are required before any valid conclusions can be drawn from this data.³

2. Merle-Melet M, Bresler L, Lokiec F, Dopff C, Boissel P, Dureux JB. Effects of diclofenac on ceftriaxone pharmacokinetics in humans. *Antimicrob Agents Chemother* (1992) 36, 2331–3.
3. Joly V, Pagon B, Brion N, Vallois J-M, Carbon C. Enhancement of the therapeutic effect of cephalosporins in experimental endocarditis by altering their pharmacokinetics with diclofenac. *J Pharmacol Exp Ther* (1988) 246, 695–700.

NSAIDs; Diclofenac topical + Miscellaneous

Topical diclofenac intended for use on the skin is very unlikely to interact adversely with any of the drugs known to interact with diclofenac given orally.

Clinical evidence, mechanism, importance and management

The manufacturer of *Pennsaid* (a topical solution containing diclofenac 16 mg/mL in dimethyl sulfoxide) says that when the maximum dosage of 1 mL is used on the skin, the maximum plasma levels of diclofenac achieved are less than 10 nanograms/mL.¹ This is 50 times lower than the maximum plasma levels achieved with oral diclofenac 25 mg. Despite these very low concentrations, the manufacturer lists all the interactions that have been observed after systemic administration of diclofenac sodium (**aspirin**, **digoxin**, **lithium**, **oral hypoglycaemic agents**, **diuretics**, **NSAIDs** including other **diclofenac** preparations, **methotrexate**, **ciclosporin**, **quinolones** and **antihypertensives**).¹ They note that the risk of these interactions in association with topical use is not known, but is probably low.¹ None of the drugs listed have yet been reported to interact with topical diclofenac.

The manufacturers of other topical preparations (*Solaraze* 3% w/w gel and *Voltarol* 1% w/w gel patch) state that interactions are not anticipated due to the low level of systemic absorption,^{2,3} although one manufacturer still warns not to administer concurrently, by either the topical or systemic route, any medicinal product containing diclofenac or other NSAIDs.³

NSAIDs; Etoricoxib + Miscellaneous

The manufacturer of etoricoxib recommends care when using etoricoxib with drugs that are metabolised by human sulfotransferases (they name oral salbutamol and minoxidil). This is because etoricoxib is an inhibitor of human sulfotransferase activity, and may increase the levels of these drugs. The increase in ethinylestradiol levels with etoricoxib is thought to be via this mechanism,¹ see 'Hormonal contraceptives or HRT + Coxibs', p.994.

- Arcoxia (Etoricoxib). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, January 2007.

NSAIDs; Ibuprofen + Moclobemide

Moclobemide did not alter the pharmacokinetics of ibuprofen, or ibuprofen-induced faecal blood loss in one study. Ibuprofen does not affect the pharmacokinetics of moclobemide.

Clinical evidence, mechanism, importance and management

A study in 24 healthy subjects found that moclobemide 150 mg three times daily for 7 days had no effect on the steady-state pharmacokinetics of ibuprofen 600 mg three times daily, and the amount of ibuprofen-induced faecal blood loss was unaffected.¹ Ibuprofen did not affect the pharmacokinetics of moclobemide. No special precautions appear to be required during concurrent use.

- Güntert TW, Schmitt M, Dingemans J, Jonkman JHG. Influence of moclobemide on ibuprofen-induced faecal blood loss. *Psychopharmacology (Berl)* (1992) 106, S40-S42.

NSAIDs; Indometacin + Cocaine

An isolated report describes marked oedema, anuria and haematemesis in a premature child attributed to an interaction between cocaine and indometacin, which were taken by the mother before the birth.

Clinical evidence, mechanism, importance and management

A woman who was a cocaine abuser and who was in premature labour was unsuccessfully treated with terbutaline and magnesium sulfate. Indometacin proved to be more effective, but after being given 400 mg over 2 days she gave birth to a boy estimated at 34 to 35 weeks. Before birth the child was noted to be anuric and at birth showed marked oedema, and later haematemesis. The suggested reasons for this effect are that the anuria and oedema were due to renal vascular constriction of the foetus caused by the cocaine combined with an adverse effect of indometacin on ADH-mediated water reabsorption. Both drugs can cause gastrointestinal bleeding, which would account for the haematemesis. The authors of this report point out that one of the adverse effects of cocaine is premature labour, and that the likelihood is high that indometacin may be used to control it. They advise screening likely addicts in premature labour for evidence of cocaine usage before indometacin is given.¹

- Carlan SJ, Stromquist C, Angel JL, Harris M, O'Brien WF. Cocaine and indomethacin: fetal anuria, neonatal edema and gastrointestinal bleeding. *Obstet Gynecol* (1991) 78, 501-3.

NSAIDs; Indometacin + Vaccines

Some very limited evidence suggests that the response to immunisation with live vaccines may be more severe than usual in the presence of indometacin.

Clinical evidence, mechanism, importance and management

A man with ankylosing spondylitis taking indometacin 25 mg three times daily had a strong primary-type reaction 12 days after smallpox vaccination. He experienced 3 days of severe malaise, headache and nausea, as well as enlarged lymph nodes. The scab that formed was unusually large (3 cm in diameter) but he suffered no long term ill-effects.¹ The suggestion was that indometacin alters the response of the body to viral infections, whether originating from vaccines or not.¹ This suggestion is supported by the case of a child taking indometacin who developed haemorrhagic chickenpox during a ward outbreak of the disease.² These appear to be isolated reports, and of little general importance. Note that NSAIDs such as indometacin may mask some of the signs and symptoms of infection.

- Maddocks AC. Indomethacin and vaccination. *Lancet* (1973) ii, 210-11.
- Rodriguez RS, Barbabosa E. Hemorrhagic chickenpox after indomethacin. *N Engl J Med* (1971) 285, 690.

NSAIDs; Ketorolac + Vancomycin

An isolated report describes temporary acute renal failure and gastrointestinal bleeding following the use of ketorolac and vancomycin.

Clinical evidence, mechanism, importance and management

A previously healthy middle-aged man developed complete kidney shut down and subsequent gastrointestinal bleeding following uncomplicated surgery and treatment with ketorolac trometamol and vancomycin. The reason for the temporary kidney failure is not known, but the authors of the report suggest that the ketorolac inhibited the normal production of the vasodilatory renal prostaglandins so that renal blood flow was reduced. This would seem to have been additive with nephrotoxic effects of the vancomycin. Note that a vancomycin level taken on postoperative day 3 was found to be above the normal therapeutic range (although the timing of the sample was not stated).¹ Ketorolac alone can cause dose-related and transient renal impairment.¹ It has also been suggested that the trometamol component may be associated with hyperkalaemia.² The gastrointestinal bleeding appeared to be due to the direct irritant effects of the ketorolac, possibly made worse by the previous use of piroxicam¹ (see also 'NSAIDs + NSAIDs', p.151). The general importance of this interaction is uncertain, but it may be prudent to monitor renal function during concurrent use.

- Waters JH. Ketorolac-induced hyperkalaemia. *Am J Kidney Dis* (1995) 26, 266.

NSAIDs; Naproxen + Diphenhydramine

There appears to be no significant pharmacokinetic interaction between diphenhydramine and naproxen.

Clinical evidence, mechanism, importance and management

Diphenhydramine hydrochloride 50 mg had no clinically significant effects on the pharmacokinetics of a single 220-mg dose of naproxen sodium in 27 healthy subjects. The pharmacokinetics of diphenhydramine were similarly unaffected by naproxen.¹ No special precautions appear to be necessary.

- Toothaker RD, Barker SH, Gillen MV, Helsing SA, Kindberg CG, Hunt TL, Powell JH. Absence of pharmacokinetic interaction between orally co-administered naproxen sodium and diphenhydramine hydrochloride. *Biopharm Drug Dispos* (2000) 21, 229-33.

NSAIDs; Naproxen + Sulglicotide

Sulglicotide does not affect the absorption of naproxen.

Clinical evidence, mechanism, importance and management

Sulglicotide 200 mg had no significant effects on the pharmacokinetics of a single 500-mg dose of naproxen in 12 healthy subjects.¹ Sulglicotide

may therefore be used to protect the gastric mucosa from possible injury by naproxen without altering its absorption.

1. Berté F, Feletti F, De Bernardi di Valserra M, Nazzari M, Cenedese A, Cornelli U. Lack of influence of sulglycotide on naproxen bioavailability in healthy volunteers. *Int J Clin Pharmacol Ther Toxicol* (1988) 26, 125–8.

NSAIDs; Naproxen + Zileuton

There appears to be no clinically significant pharmacokinetic or pharmacodynamic interaction between naproxen and zileuton.

Clinical evidence, mechanism, importance and management

In a randomised, placebo-controlled study in 24 healthy subjects zileuton 800 mg every 12 hours was given with naproxen 500 mg every 12 hours for 5 days. No clinically significant change was found in the pharmacokinetics of either drug. Naproxen did not affect the inhibitory effect of zileuton on leukotriene B₄ levels and similarly zileuton did not affect the inhibitory effect of naproxen on thromboxane B₂. The inhibition of the 5-lipoxygenase pathway by zileuton did not appear to worsen the gastrointestinal effects associated with naproxen. No special precautions would seem necessary.¹

NSAIDs; Parecoxib + Miscellaneous

As parecoxib is rapidly metabolised to valdecoxib, the interactions are usually considered to be due to the effects of valdecoxib. The manufacturer of parecoxib cautions the concurrent use with carbamazepine, dexamethasone and rifampicin as their effects on parecoxib have not been studied. Valdecoxib increases the levels of dextromethorphan and omeprazole. Because of these interactions, caution is advised with drugs that are metabolised by the same isoenzymes, namely flecainide, metoprolol, propafenone, omeprazole, diazepam, imipramine and phenytoin. No interaction appears to occur between parecoxib and midazolam.

Clinical evidence, mechanism, importance and management

Parecoxib is a parenteral drug that is rapidly metabolised in the liver to the active COX-2 inhibitor valdecoxib. Valdecoxib is predominantly metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP2C9. The interactions therefore are usually considered to be due to the effects of valdecoxib.

The manufacturers have done several interaction studies to find out whether parecoxib or valdecoxib can inhibit or induce the cytochrome P450 isoenzymes CYP2C9, CYP2D6, CYP2C19, and CYP3A4 and thereby determine their potential to interact with drugs metabolised by these isoenzymes.

1. *CYP2C19*. The manufacturers say that the AUC of **omeprazole** 40 mg was increased by 46% by valdecoxib 40 mg twice daily for a week. This indicates that valdecoxib is an inhibitor of CYP2C19 and although the manufacturers consider it to be a weak inhibitor¹ they suggest that caution should be observed with drugs that have a narrow therapeutic margin and are known to be metabolised by CYP2C19. They list **diazepam**, **imipramine** and **phenytoin**.² The implication is that the serum levels of these drugs and their effects may possibly be increased by the use of parecoxib.

2. *CYP2D6*. The manufacturers say that treatment with 40 mg of valdecoxib twice daily for a week caused a threefold increase in the serum levels of **dextromethorphan**. This indicates that valdecoxib is an inhibitor of CYP2D6, and therefore the manufacturers¹ suggest that caution should be observed with drugs that have a narrow therapeutic margin and are known to be predominantly metabolised by CYP2D6. They list **flecainide**, **metoprolol** and **propafenone**.² The implication is that the serum levels of these

drugs and their effects may possibly be increased by the use of parecoxib, but so far there appears to be no direct clinical reports of any problems with concurrent use.

3. *CYP3A4*. A study in 12 healthy adults found no significant changes in the pharmacokinetics of **midazolam** 70 micrograms/kg given an hour after a 40-mg dose of intravenous parecoxib.³ This suggests that parecoxib and valdecoxib are unlikely to inhibit or induce the activity of CYP3A4. This means that parecoxib would not be expected to affect other drugs that are metabolised by CYP3A4.

4. *Enzyme inducers*. The effects of the enzyme inducers **carbamazepine**, **dexamethasone**, **phenytoin** and **rifampicin** have not been studied with parecoxib. Nevertheless, the manufacturer of parecoxib warns that they may increase the metabolism of valdecoxib.²

NSAIDs; Phenylbutazone + Methylphenidate

Methylphenidate significantly increased the serum levels of phenylbutazone 200 to 400 mg daily in 5 out of 6 patients, due, it is suggested, to inhibition of liver metabolising enzymes.¹ The clinical importance of this is uncertain, especially as the report does not indicate the magnitude of the interaction.

1. Sellers EM ed. *Clinical Pharmacology of Psychoactive Drugs*. Ontario: Addiction Research Foundation, 1973. p183–202.

NSAIDs; Sulindac + Dimethyl sulfoxide (DMSO)

Isolated case reports describe serious peripheral neuropathy, which occurred when DMSO was applied to the skin of two patients taking sulindac.

Clinical evidence, mechanism, importance and management

A man with a long history of degenerative arthritis took sulindac 400 mg daily uneventfully for 6 months until, without his doctor's knowledge, he began regularly to apply a topical preparation containing DMSO 90% to his upper and lower extremities. Soon afterwards he began to experience pain, weakness in all his extremities, and difficulty in standing or walking. He was found to have both segmental demyelination and axonal neuropathy. He made a partial recovery but was unable to walk without an artificial aid.¹

A second case describes a 68-year-old man with a history of mild osteoarthritis of the knees who was taking sulindac 150 mg twice daily. He later started to apply aqueous solutions of DMSO to his lower extremities, whilst continuing to take sulindac. Within 3 months he reported difficulty in climbing stairs, and myalgia of the thighs and legs. Over the next 5 months he experienced a progressive loss of gait, wasting of thigh and leg muscles, and more intense myalgia, cramps and fasciculations. Nerve conduction studies revealed damage to the nerves. During the year after discontinuing the DMSO, and supplementing his diet with vitamins B₆ and B₁₂, the patient showed improvement in the myalgia and physical disabilities, and a return to normal muscle strength. He continued to take the sulindac at a dose of 200 mg twice daily.²

The reason for this reaction is not known, but studies in *rats* have shown that DMSO can inhibit a reductase enzyme by which sulindac is metabolised,³ and it may be that the high concentrations of unmetabolised sulindac increased the neurotoxic activity of the DMSO. Although there are only these two cases on record, its seriousness suggests that patients should not use sulindac and DMSO-containing preparations concurrently.

Opioids + Amfetamines and related drugs

Dexamfetamine and methylphenidate increase the analgesic effects of morphine and other opioids and reduce their sedative and respiratory depressant effects.

Clinical evidence, mechanism, importance and management

Dexamfetamine increased the analgesic effect of **morphine** and reduced its respiratory depressant effects to some extent in studies during postoperative analgesia¹ and in healthy subjects.² **Methylphenidate** 15 mg daily similarly increased the analgesic effects of various opioids (**morphine**, **hydromorphone**, **levorphanol**, **oxycodone**) and reduced the sedative effects in patients with chronic pain due to advanced cancer.³ Therefore, the analgesic dose of an opioid may be lower than expected in patients on these drugs.

Opioids + Antiemetics

Metoclopramide increases the rate of absorption of oral morphine and increases its rate of onset and sedative effects. However, opioids may antagonise the effects of metoclopramide on gastric emptying. The use of droperidol with opioids can be beneficial, but an increase in sedation appears to occur.

Clinical evidence

(a) Alizapride

Intravenous alizapride 100 mg given to 60 women undergoing caesarean section under spinal anaesthesia, reduced **morphine**-induced pruritus, and the amount of sedation (8.3% both peri- and postoperatively) was less than with droperidol,¹ see below.

(b) Droperidol

1. **Fentanyl.** Epidural droperidol given with epidural fentanyl improved postsurgical analgesia following anaerect surgery and there was less nausea compared with fentanyl alone.²

2. **Hydromorphone.** Early respiratory depression has been reported when droperidol was given 10 minutes before epidural hydromorphone 1.25 mg; the patient became apnoeic 15 minutes after the epidural was given. Naloxone did not reverse the respiratory depression, but spontaneous ventilation resumed within 3 minutes of a 1-mg intravenous dose of physostigmine.³

3. **Morphine.** In a double-blind study in 179 patients following abdominal hysterectomy, droperidol 50 micrograms given with morphine 1 mg on demand via patient-controlled analgesia (PCA) provided a morphine-sparing effect and reduced the frequency of postoperative nausea and vomiting, when compared with morphine PCA alone.⁴ However, in a study of 107 patients undergoing caesarean section, intravenous droperidol 2.5 mg given just after delivery, reduced the incidence and severity of epidural morphine-induced pruritus, but the incidence of nausea and vomiting was not affected. Furthermore, somnolence was greater in the droperidol-treated patients (17% versus 2% in the control group) but it was never incapacitating.⁵ Similar sedative effects were seen with spinal morphine and intravenous droperidol in another study.¹

(c) Metoclopramide

1. **Butorphanol.** The pharmacokinetics of a single 1-mg intranasal dose of butorphanol were unaffected by a single 10-mg oral dose of metoclopramide in 24 healthy women. The pharmacokinetics of metoclopramide were also not affected, except for a delay in the time to reach maximum plasma levels (increased from 1 to 2 hours), which was probably due to reduction of gastrointestinal motility by butorphanol.⁶ Metoclopramide reduced the nausea associated with butorphanol, probably by antagonism of central and peripheral dopamine receptors.⁷

2. **Morphine.** A single 10-mg dose of oral metoclopramide, given to 10 patients before surgery, markedly increased the extent and speed of sedation due to a 20-mg oral dose of modified-release morphine (*MST Continus Tablets*) in the first 1.5 hours after the dose. The time to peak plasma levels of morphine was almost halved, but peak plasma morphine levels and the total absorption remained unaltered.⁷ A study involving 40 patients found that intravenous metoclopramide 10 mg antagonised the reduction in gastric emptying caused by premedication with intramuscular morphine 10 mg given 20 minutes earlier. However, intramuscular metoclopramide given at the same time as the morphine had no effect on the reduced gastric emptying.⁸

Mechanism

Metoclopramide increases the rate of gastric emptying so that the rate of morphine absorption from the small intestine is increased. An alternative idea is that both drugs act additively on opiate receptors to increase sedation.⁷ Droperidol may also enhance adverse effects such as sedation, and in some cases respiratory depression, possibly through opioid and other receptor sites in the CNS.² In one case the respiratory depression was not reversed by naloxone, suggesting that the droperidol was at least partially if not completely responsible.³

Importance and management

The effect of metoclopramide on oral morphine absorption is an established interaction that can be usefully exploited in anaesthetic practice, but the increased sedation may also represent a problem if the morphine is being given long-term. The morphine-sparing effect of droperidol is also a useful interaction, but the increased sedation and possible respiratory depression and hypotension should be borne in mind. One manufacturer of fentanyl specifically warns that concurrent use with droperidol can result in a higher incidence of hypotension.⁹

Morphine appears to antagonise the effects of metoclopramide on gastric emptying. As a reduction in gastric motility occurs with all opioids they would all be expected to interact with metoclopramide, and other motility stimulants such as **domperidone**. However, these drugs are commonly used together and the clinical significance of such effects is not clear.

Opioids + Antiemetics; Ondansetron

Ondansetron reduces the analgesic efficacy of tramadol and at least double the dose was required in one clinical study. This resulted in more vomiting despite the ondansetron. In contrast, in studies in healthy subjects, ondansetron had no effect on the analgesic effects of morphine and alfentanil.

Clinical evidence

(a) Alfentanil

In a study in healthy subjects single doses of intravenous ondansetron 8 or 16 mg were found to have no effect on the sedation or ventilatory depression due to alfentanil (a continuous infusion of 0.25 to 0.75 micrograms/kg following a 5 microgram/kg bolus dose) and had no effect on the rate of recovery.¹ Similarly, in another study, intravenous ondansetron 8 mg had no effect on the reaction of 8 healthy subjects to pres-

sure, cold, or electrical stimulation, nor did it oppose the analgesic effect of intramuscular alfentanil 30 micrograms/kg.²

(b) Morphine

A double-blind, placebo-controlled study in 12 healthy subjects found that a single 16-mg intravenous dose of ondansetron given 30 minutes after a single 10-mg intravenous dose of morphine did not alter the pharmacokinetics of morphine or its metabolites, morphine-3- and morphine-6-glucuronides. The analgesic effect of morphine (as measured by a contact thermode system) was also unaffected by ondansetron.³

(c) Tramadol

Patients who were given a single 4-mg dose of ondansetron one minute before induction of anaesthesia required 26 to 35% more tramadol by patient controlled analgesia (PCA) from 1 to 4 hours postoperatively than those who received placebo.⁴ Similarly, a 1-mg/hour ondansetron infusion increased the dose of postoperative tramadol used during PCA by two- to threefold in 30 patients, when compared with 29 patients who received placebo. Moreover, in this study the group receiving ondansetron actually experienced more vomiting, probably because they used more tramadol, which caused an emetic effect not well controlled by the ondansetron.⁵

Mechanism

On theoretical grounds ondansetron (a 5-HT₃-receptor antagonist) might be expected to decrease the effects of drugs that reduce pain transmission because serotonin (5-HT) is thought to affect pain responses via presynaptic 5-HT₃ receptors in the spinal dorsal horn. This has been demonstrated for tramadol, which is not a pure opioid and also acts by enhancing the effects of serotonin and noradrenaline (norepinephrine). However, ondansetron had no effect on alfentanil or morphine analgesia in healthy subjects.

Importance and management

The interaction between ondansetron and tramadol appears to be established and of clinical importance. Ondansetron may double the dose requirement of tramadol, and so result in increased emetic effects, consequently ondansetron does not appear to be the best antiemetic to use with tramadol.³ Although not tested, other 5-HT₃-receptor antagonists would be expected to interact similarly. Ondansetron appears to have no effect on alfentanil or morphine.

Opioids + Antiepileptics; Enzyme-inducing

Patients taking enzyme-inducing antiepileptics appear to need more fentanyl than those not taking antiepileptics. Similarly, the efficacy of buprenorphine may be reduced by carbamazepine, phenobarbital and phenytoin. Carbamazepine appears to increase the production of a more potent metabolite of codeine, normorphine. The plasma levels of tramadol are reduced by carbamazepine, and the analgesic efficacy would be expected to be reduced. There is also an increased risk of seizures with tramadol. An isolated report describes pethidine toxicity in a man taking phenytoin. A pharmacokinetic study confirms that phenytoin increases the production of the toxic metabolite of pethidine.

Clinical evidence, mechanism, importance and management

(a) Buprenorphine

Although interaction studies have not been performed, the metabolism of buprenorphine is mediated by the cytochrome P450 isoenzyme CYP3A4 and therefore drugs that induce this enzyme such as **carbamazepine, phe-**

nobarbital and phenytoin may induce the metabolism and increase clearance of buprenorphine.^{1,2} The manufacturers of buprenorphine comment that inducers of CYP3A4 may reduce the efficacy of buprenorphine¹⁻³ and, if necessary, dose adjustments should be considered,² or the combination avoided.¹

(b) Codeine

An experimental study in 7 epileptic patients to find out if **carbamazepine** induces the enzymes concerned with the metabolism of codeine found that it increased *N*-demethylation (to norcodeine and normorphine) by two- to threefold, but did not affect *O*-demethylation (to morphine). The patients were given a single 25-mg dose of codeine before and 3 weeks after starting to take **carbamazepine** 400 to 600 mg daily.⁴ Similarly, an *in vitro* study found that **carbamazepine** and **phenytoin** did not alter the *O*-demethylation of codeine (methylmorphine) into morphine.⁵

Normorphine is an active metabolite, so that the authors of the first study suggest those taking both codeine and **carbamazepine** may possibly experience a stronger analgesic effect.⁴ However, this needs further study. There would seem to be no reason for avoiding concurrent use.

(c) Dextropropoxyphene (Propoxyphene)

Dextropropoxyphene may increase the plasma levels of antiepileptics, particularly carbamazepine, see 'Carbamazepine or Oxcarbazepine + Dextropropoxyphene (Propoxyphene)', p.527.

(d) Fentanyl

Twenty-eight patients, undergoing craniotomy for seizure focus excision and receiving long-term treatment with antiepileptics in various combinations, needed 48 to 144% more fentanyl during anaesthesia than a control group of 22 patients who were not taking antiepileptics.⁶ The fentanyl maintenance requirements in micrograms/kg per hour were:

- 2.7 in the control group,
- 4.0 in patients taking **carbamazepine**,
- 4.7 in patients taking **carbamazepine** and **phenytoin** or **valproate**,
- 6.3 in patients taking **carbamazepine**, **valproate** and either **phenytoin** or **primidone**.

Similar results were reported by the same authors in a study involving 61 patients.⁷ The increased opioid requirement probably occurs because these antiepileptics are potent enzyme inducers (with the exception of **valproate**), which increase the metabolism of fentanyl by the liver, so that its levels are reduced.⁶ Changes in the state of opiate receptors induced by chronic antiepileptic exposure may also be involved.⁷ A marked increase in the fentanyl requirements should therefore be anticipated in any patient receiving long-term treatment with these interacting antiepileptics, but not **valproate**.

(e) Methadone

Methadone levels can be reduced by carbamazepine, phenobarbital or phenytoin. See 'Opioids; Methadone + Antiepileptics', p.163.

(f) Pethidine (Meperidine)

A 61-year-old man who was addicted to pethidine, taking 5 to 10 g weekly, developed repeated seizures and myoclonus when he also took **phenytoin**. The problem resolved when both drugs were stopped.⁸

It is known that **phenytoin** increases the metabolism of pethidine with increased production of norpethidine,^{9,10} the metabolic product of pethidine that is believed to be responsible for its neurotoxicity (seizures, myoclonus, tremors etc). A study¹¹ in healthy subjects found that **phenytoin** 300 mg daily for 9 days decreased the elimination half-life of pethidine (100 mg orally and 50 mg intravenously) from 6.4 to 4.3 hours, and the systemic clearance increased by 27%. This seems to be the only report⁸ of an adverse interaction between **phenytoin** and pethidine so its general importance is uncertain. Since the study cited¹¹ found that pethidine given orally produced more of the toxic metabolite (norpethidine) than when given intravenously, it may be preferable to give pethidine intravenously in patients taking **phenytoin**, or use an alternative opioid.

Consider also 'Opioids + Barbiturates', p.165.

(g) Tramadol

An unpublished study by the manufacturers found that the maximum plasma levels and the elimination half-life of a single 50-mg dose of tramadol were reduced by 50% by **carbamazepine** 400 mg twice daily for 9 days.¹² It is likely that **carbamazepine** increases the metabolism of tramadol. On the basis of this study the manufacturers say that the analgesic effectiveness of tramadol^{13,14} and its duration of action would be expected to be reduced.^{12,14} The US manufacturer recommends avoidance of concurrent

use because of the increased metabolism and also the seizure risk associated with tramadol.¹³ The UK manufacturer says that patients with a history of epilepsy or those susceptible to seizures should only be given tramadol if there are compelling reasons.¹⁴ Monitor carefully if tramadol and antiepileptics, particularly **carbamazepine**, are required.

Opioids + Antiepileptics; Gabapentin

Gabapentin has been reported to enhance the analgesic effects of morphine and other opioids. Morphine can increase the bioavailability of gabapentin.

Clinical evidence, mechanism, importance and management

A single-dose, placebo-controlled study in 12 healthy subjects given controlled-release **morphine** 60 mg found that gabapentin 600 mg given after an interval of 2 hours had no effect on the pharmacokinetics of morphine, morphine-3- and morphine-6-glucuronides. In the presence of **morphine** the gabapentin AUC increased by 44% and its oral clearance and apparent renal clearance decreased by 23% and 16%, respectively. Analgesic effect was evaluated by changes in the area under the curve of pain tolerance. Gabapentin plus placebo had no significant analgesic effect, but a significant increase in the pain threshold and pain tolerance was found when gabapentin was given with morphine, when compared with placebo. The opioid adverse effects were similar in the gabapentin/morphine and gabapentin/placebo groups.¹ Other clinical studies have reported that gabapentin used in conjunction with opioids has an analgesic and opioid-sparing effect in acute postoperative pain management^{2,3} and neuropathic pain.⁴ The manufacturer of gabapentin warns that patients should be carefully observed for signs of CNS depression, such as somnolence, and the dose of gabapentin or **morphine** should be reduced appropriately.⁵

A study in *animals* reported a synergistic antinociceptive interaction between **tramadol** and gabapentin.⁶

Opioids; Methadone + Antiepileptics

Methadone levels can be reduced by carbamazepine, phenobarbital or phenytoin. Valproate appears not to interact. An isolated report describes lamotrigine-associated rash and blood dyscrasias, which may have been associated with methadone use.

Clinical evidence

(a) Enzyme-inducing antiepileptics

A study in 37 patients taking methadone maintenance found that those receiving enzyme-inducing drugs (10 patients: taking **carbamazepine**, **phenobarbital** or **phenytoin**) had low trough methadone levels of less than 100 nanograms/mL. One patient taking carbamazepine complained of daily withdrawal symptoms and had signs of opioid withdrawal.¹ Withdrawal symptoms have been seen in other patients taking **carbamazepine**,² **phenobarbital**,³ and **phenytoin**.^{1,2,4,5} Similarly methadone withdrawal symptoms developed in 5 patients within 3 to 4 days of starting to take **phenytoin** 300 to 500 mg daily. Methadone plasma levels were reduced about 60%. The symptoms disappeared within 2 to 3 days of stopping the **phenytoin** and the plasma methadone levels rapidly climbed to their former values.⁶

A further patient experienced methadone-induced respiratory depression after discontinuing **carbamazepine**.⁷

(b) Lamotrigine

Lamotrigine-associated rash and blood dyscrasias occurred in a 40-year-old opioid-dependent woman with hepatitis C. Lamotrigine was considered to be the causal factor as haematological values returned to normal 53 days after discontinuation. However, the woman was also receiving methadone maintenance treatment and it was thought that the methadone together with liver impairment might possibly have caused elevated levels of lamotrigine [not measured].⁸

(c) Valproate

Two patients who had methadone withdrawal symptoms while taking phenytoin 300 to 400 mg daily, and one of them later when taking carbamazepine 600 mg daily, became free from withdrawal symptoms when they were given valproate instead. It was also found possible to virtually halve their daily methadone dosage.²

Mechanism

Not fully established, but all of these antiepileptics (except lamotrigine and valproate) are recognised enzyme-inducers that can increase the metabolism of other drugs by the liver, thereby hastening their loss from the body. In one study it was found that phenytoin increased the urinary excretion of the main metabolite of methadone.⁶

Importance and management

Information is limited but the interaction between methadone and these enzyme-inducing antiepileptics appears to be established and of clinical importance. Anticipate the need to increase the methadone dosage in patients taking carbamazepine, phenytoin or phenobarbital. It may be necessary to give the methadone twice daily to prevent withdrawal symptoms appearing towards the end of the day. It seems probable that **primidone** will interact similarly because it is metabolised to phenobarbital. Also be aware of the need to reduce the methadone dose if any enzyme-inducing antiepileptic is stopped. Valproate appears not to interact.

It is unclear whether the methadone or the liver impairment contributed to the lamotrigine-associated rash and blood dyscrasias and therefore this isolated cases is of unknown significance.

Opioids + Antihistamines

Increased respiratory depression has been seen with hydroxyzine and opioids in one study,¹ but not in two others.^{2,3} The US manufacturers warn that hydroxyzine may enhance the effects of opio-

ids and particularly pethidine (meperidine).⁴ A reduction in dosage may be necessary. All sedating antihistamines (see 'Table 15.1', (p.582)) would be expected to have additive CNS depressant effects with opioids. This may lead to increased sedation and respiratory depression, and therefore some caution is warranted when both drugs are given.

Opioids + Azoles

Several of the opioids (buprenorphine, hydromorphone, methadone) are metabolised by CYP3A, at least in part, and their metabolism is expected to be reduced by the azoles, which, to varying extents, inhibit CYP3A4. This has been seen when fluconazole and voriconazole are given with methadone, and when ketoconazole is given with buprenorphine. It has been suggested that ketoconazole inhibits the metabolism of morphine and oxycodone, but evidence for this is sparse.

Clinical evidence

(a) Buprenorphine

Ketoconazole increases the AUC of buprenorphine by 50% and increases its maximum level by 70% or more; levels of the metabolite norbuprenorphine are less affected.¹

(b) Hydromorphone

An *in vitro* study found that **ketoconazole** reduced norhydromorphone formation by about 50%.²

(c) Methadone

1. **Fluconazole.** A randomised, double-blind, placebo-controlled study in 25 patients taking methadone found that fluconazole 200 mg daily for 2 weeks increased the steady-state serum methadone levels and AUC by about 30%, but no signs of methadone overdose were seen and no changes in the methadone dosage were needed.³ However, a case report describes a man with advanced cancer who had received regular methadone 20 mg every 8 hours and one to three 5-mg rescue doses daily for 10 days, and who rapidly developed respiratory depression of 4 breaths per minute and became unresponsive 4 days after starting fluconazole 100 mg daily, initially orally, then intravenously. Within a few minutes of receiving naloxone he regained consciousness and his respiratory rate increased.⁴

2. **Ketoconazole.** An *in vitro* study suggests that clinically relevant concentrations of ketoconazole decreased the hepatic metabolism of methadone by about 50 to 70%.⁵

3. **Voriconazole.** In a double-blind, placebo-controlled study in 23 patients taking methadone, voriconazole 400 mg twice daily for one day then 200 mg twice daily for 4 days increased the AUC of *R*-methadone (active) by 47% and *S*-methadone (inactive) by 103%. Methadone appeared to have no effect on voriconazole pharmacokinetics when compared with a reference study in healthy subjects. There were no signs or symptoms of significant opioid withdrawal or overdose and the combination was generally well tolerated.⁶

(d) Morphine

In an *in-vitro* study **ketoconazole** inhibited morphine glucuronidation to morphine-3-glucuronide and morphine-6-glucuronide.⁷ The clinical relevance of this is unknown.

(e) Oxycodone

The UK manufacturer of oxycodone suggests that inhibitors of CYP3A enzymes such as **ketoconazole** may inhibit the metabolism of oxycodone,⁸ although oxycodone is also metabolised via CYP2D6.⁸

Mechanism

Since the metabolism of methadone is mainly mediated by the cytochrome P450 isoenzyme CYP3A4, methadone clearance can be decreased by drugs that inhibit CYP3A4 activity such as azole antifungals.⁹ Buprenorphine is also metabolised by CYP3A4¹⁰ and may therefore be similarly affected. Most azoles inhibit CYP3A4 to a greater or lesser extent.

Importance and management

It has been suggested that although a statistically significant pharmacokinetic interaction occurs between methadone and fluconazole, it is unlikely to be clinically important in patients taking methadone.³ However, the case report introduces a note of caution. The authors of the second study suggest caution should be exercised if voriconazole is given with methadone and a dose reduction of methadone may be required.⁶ Caution may also be warranted with ketoconazole. Further study is needed.

One manufacturer recommends that the dose of buprenorphine should be halved when starting treatment with ketoconazole, and then further titrated as clinically indicated.¹ Other manufacturers recommend close monitoring and possibly a dose reduction if buprenorphine is given with inhibitors of CYP3A4 including azole antifungals such as ketoconazole.¹¹ The clinical significance of the potential effects of azoles on other opioids, such as hydromorphone, morphine and oxycodone is unclear.

Opioids; Fentanyl and related drugs + Azoles

Some patients may experience prolonged and increased alfentanil effects if they are given fluconazole or voriconazole. *In vitro* data suggest itraconazole and ketoconazole may interact similarly. Intravenous fentanyl does not appear to interact with itraconazole in healthy subjects, but one case of possible opioid toxicity from transdermal fentanyl has been reported.

Clinical evidence

(a) Alfentanil

A double-blind, randomised, crossover study in 9 healthy subjects given intravenous alfentanil 20 micrograms/kg after receiving **fluconazole** 400 mg, orally or by infusion, found that fluconazole reduced alfentanil clearance by about 60%. Both the alfentanil-induced ventilatory depression and its subjective effects were increased.¹

A randomised, crossover study in 12 healthy subjects found that oral **voriconazole** (400 mg twice daily on the first day and 200 mg twice daily on the second day) caused an approximately fivefold increase in the mean AUC of alfentanil 20 micrograms/kg, given intravenously one hour after the last dose of the antifungal. The mean plasma clearance of alfentanil was decreased by 85% and its elimination half-life was prolonged from 1.5 to 6.6 hours. Nausea occurred in 5 subjects and vomiting in 4 subjects.²

(b) Fentanyl

In a crossover study in 10 healthy subjects the pharmacokinetics and pharmacodynamics of a single 3-micrograms/kg intravenous dose of fentanyl were not altered by **itraconazole** 200 mg once daily for 4 days.³ However, the manufacturer says that increased fentanyl plasma concentrations have been observed in individual subjects taking itraconazole,⁴ and a case report describes a man with cancer and severe oropharyngeal candidiasis receiving transdermal fentanyl 50 micrograms/hour who developed signs of opioid toxicity (agitated delirium, bilateral myoclonus of muscles in the hand) the day after starting oral **itraconazole** 200 mg twice daily.⁵

Mechanism

Fluconazole, itraconazole, and voriconazole inhibit the cytochrome P450 isoenzyme CYP3A4 in the liver, which is concerned with the metabolism of alfentanil and fentanyl. However, fentanyl has a high hepatic extraction, and so is more affected by changes in hepatic blood flow than changes in the isoenzymes responsible for its metabolism; it is therefore less affected by CYP3A inhibitors than alfentanil. **Sufentanil** also has a high hepatic extraction, see 'Opioids; Fentanyl and related drugs + Macrolides', p.174.

Importance and management

The interaction of alfentanil with fluconazole and voriconazole appears to be established and clinically important. *In vitro* data indicate that **ketoconazole** and itraconazole may interact in a similar way.⁶⁻⁸ Alfentanil should be given with care to those who have recently received these drugs, and it may be necessary to use a lower alfentanil dose.⁷ Be alert for evidence of prolonged alfentanil effects and respiratory depression.

Intravenous fentanyl was not affected by itraconazole in healthy subjects, but the single case report involving transdermal fentanyl introduces a note of caution, particularly in those with unstable advanced disease. Further study is needed. The manufacturers comment that concurrent use of potent CYP3A4 inhibitors including azole antifungals (e.g. fluconazole, itraconazole, ketoconazole) with oral⁹ or transdermal^{4,10} fentanyl may result in increased plasma concentrations of fentanyl. This may increase or prolong both the therapeutic effects and the adverse reactions, which may cause severe respiratory depression. Careful monitoring is required, with dosage adjustment if necessary.

Opioids + Baclofen

The effects of fentanyl and morphine, but probably not pentazocine, may be increased by baclofen.

Clinical evidence, mechanism, importance and management

A study in three groups of 10 patients found that pretreatment with baclofen 0.6 mg/kg, either in four intramuscular doses for 5 days, or intravenously in 100 mL of glucose 5%, 45 minutes before surgery, prolonged the duration of **fentanyl** anaesthesia from 18 to 30 minutes. The baclofen reduced the amounts of **fentanyl** needed by 30 to 40%.¹

In a placebo-controlled study in 69 patients undergoing surgery for the removal of third molar teeth, oral baclofen (5 mg three times daily for 3 days and then a 10-mg dose 6 hours before surgery and again immedi-

ately before surgery) enhanced postoperative analgesia due to intravenous **morphine** 6 mg. However, analgesia due to intravenous **pentazocine** 30 mg was not enhanced.²

These limited reports suggest that baclofen may potentiate the effects of **fentanyl** and **morphine**. The reasons for this effect are not understood, but it may be connected in some way with the action of baclofen on GABA receptors, since the spinal cord circuits that are important in opioid analgesia contain GABAergic receptors.^{1,2} It appears that baclofen enhances the analgesic effect of **fentanyl** and **morphine**, which are pure opioid agonists that act primarily through μ -opioid receptors, whereas it does not affect pentazocine, a predominantly κ -opioid analgesic.²

The manufacturer of baclofen warns that increased sedation may occur if baclofen is taken with synthetic opioids and that the risk of respiratory depression is also increased. Careful monitoring of respiratory and cardiovascular functions is essential.³

Opioids + Barbiturates

A single case report describes greatly increased sedation with severe CNS toxicity in a woman given pethidine after she took phenobarbital for two weeks. The analgesic effects of pethidine can be reduced by barbiturates. Secobarbital increases the respiratory depressant effects of morphine. Other barbiturates would also be expected to increase the CNS depressant effects of opioids.

Clinical evidence*(a) Codeine*

A study found that codeine 60 mg increased the hypnotic actions of **secobarbital** 100 mg resulting in synergism in the sedative effects in pain-free patients.¹

(b) Morphine

In 30 healthy subjects it was found that both intravenous **secobarbital** and intravenous **morphine** depressed respiration when given alone, and a much greater and more prolonged respiratory depression occurred when they were given together.² The combination should be used with caution.

A study in *animals* demonstrated that **pentobarbital** caused a synergistic enhancement of **morphine** analgesia and morphine significantly enhanced pentobarbital-induced anaesthesia.³

(c) Pethidine (Meperidine)

1. *Increased pethidine toxicity.* A woman whose pain had been satisfactorily controlled with pethidine without particular CNS depression, had prolonged sedation with severe CNS toxicity when she was given pethidine after taking **phenobarbital** 30 mg four times daily for 2 weeks.⁴

2. *Pethidine effects reduced.* Studies in women undergoing dilatation and curettage found that **thiopental** and **pentobarbital** increased their sensitivity to pain, and opposed the analgesic effects of pethidine.⁵ This confirmed the findings of previous studies.⁶ A marked anti-analgesic effect has been seen for up to 5 hours after high doses (6 to 10 mg/kg) of **thiopental**.⁵ This anti-analgesic effect also occurred with **phenobarbital**.⁵

(d) Miscellaneous

Increased CNS depression may occur with opioids and other CNS depressants such as hypnotics and manufacturers of several opiates specifically mention that barbiturates can potentiate sedation, respiratory depression, and hypotension. A reduction in dosage may be required. One manufacturer of **methadone** contraindicates the use of the injection, but not the oral solution, with other CNS depressants including barbiturates;^{7,8} however, other manufacturers warn of the potential for increased CNS depression, but do not contraindicate barbiturates.^{9,10}

For comment on the effect of enzyme inducers such as phenobarbital on opioid metabolism, see 'Opioids + Antiepileptics; Enzyme-inducing', p.162 and 'Opioids; Methadone + Antiepileptics', p.163.

Mechanism

Studies suggest that phenobarbital stimulates the liver enzymes concerned with the metabolism (*N*-demethylation) of pethidine so that the production of its more toxic metabolite (norpethidine) is increased. The toxicity seen appears to be the combined effects of this compound and the directly sedative effects of the barbiturate.^{4,11}

Importance and management

There is only one report of toxicity when phenobarbital was given with pethidine, but metabolic changes have been seen in other patients and subjects. The general clinical importance is uncertain but concurrent use should be undertaken with care. It has also been suggested that if the pethidine is continued but the barbiturate suddenly withdrawn, the toxic levels of norpethidine might lead to convulsions in the absence of an antiepileptic.⁴ Be aware that the barbiturates may reduce analgesia. The metabolic product of pethidine is a less effective analgesic than the parent compound. Both the barbiturates and the opioids have CNS depressant effects, which would be expected to be additive. Therefore care is warranted on concurrent use.

Opioids + Benzodiazepines

In general the concurrent use of opioids and benzodiazepines results in both beneficial analgesic effects, and enhanced sedation and respiratory depression; however, in some cases benzodiazepines have antagonised the respiratory depressant effects of opioids, and, rarely, have antagonised their analgesic effects.

Clinical evidence, mechanism, importance and management

(a) Analgesia

In one study, low-dose **midazolam** (given to achieve levels of 50 nanograms/mL) reduced the dose of **morphine** required for postoperative analgesia in the first 12 hours.¹ However, in another study postoperative pain scores were higher in patients premedicated with oral **diazepam** 10 mg than with placebo, although **morphine** consumption did not differ.² Similarly, in another study, the benzodiazepine antagonist flumazenil enhanced **morphine** analgesia in patients who had been premedicated with **diazepam**.³ It is suggested that benzodiazepines antagonise the analgesic effect of opioids via their effect on supraspinal GABA receptors. Why this has been shown in some studies, but not others, is unclear. Benzodiazepines and opioids are commonly used in surgical anaesthesia, and the relevance of these findings to clinical practice is uncertain.

(b) Overdose

Sudden deaths in patients who abuse opioids are frequently associated with ingestion of other CNS depressants, particularly **benzodiazepines**. Cases have been reported with **buprenorphine**,^{4,5} **oxycodone**,⁶ and **tramadol**⁷ taken with various **benzodiazepines**. It has not been established exactly why this occurs, but both pharmacodynamic and pharmacokinetic mechanisms are possible. The deleterious interaction of benzodiazepines and opioids on respiration is possibly due to central effects and/or additive actions on the different neuromuscular components of respiration.⁸ For **buprenorphine**, it is considered most likely that ex-

cessive CNS depression is solely due to combined pharmacological effects, and not to any pharmacokinetic interaction.^{9–11} See also *Pharmacokinetics*, below.

(c) Pharmacokinetics

Intramuscular **pethidine** 100 mg and intramuscular **morphine** 10 mg delayed the absorption of oral **diazepam** 10 mg. **Diazepam** levels were found to be lower and peak levels were not reached in the 90-minute study period, when compared with the peak level at 60 minutes in the control group.¹² The underlying mechanism is that the opioid analgesics delay gastric emptying so that the rate of absorption of the **diazepam** is reduced. The maximal effect of **diazepam** would be expected to be delayed in patients receiving these opioids.

Another study in healthy subjects found that **dextropropoxyphene** 65 mg every 6 hours prolonged the **alprazolam** half-life from 11.6 to 18.3 hours, and decreased the clearance from 1.3 to 0.8 mL/minute per kg. The pharmacokinetics of single doses of **diazepam** and **lorazepam** were not significantly affected.¹³ It would seem that **dextropropoxyphene** inhibits the metabolism (hydroxylation) of the **alprazolam** by the liver, thereby reducing its loss from the body, but has little or no effect on the *N*-demethylation or glucuronidation of the other two benzodiazepines. The clinical importance of this is uncertain, but the inference to be drawn is that the CNS depressant effects of **alprazolam** will be increased, over and above the simple additive CNS depressant effects likely when other benzodiazepines and **dextropropoxyphene** are taken together. More study is needed.

Extended-release **oxymorphone** did not affect the metabolism of **midazolam** in healthy subjects.¹⁴ An *in vitro* study found that **buprenorphine** metabolism to norbuprenorphine was only weakly or negligibly inhibited by benzodiazepines, but **midazolam** had some modest effects and it was suggested that it may possibly cause some clinically relevant inhibition of buprenorphine metabolism.¹⁵

(d) Respiratory depression

A 14-year-old boy with staphylococcal pneumonia secondary to influenza developed adult respiratory distress syndrome. It was decided to suppress his voluntary breathing with opioids and use assisted ventilation and he was therefore given **phenoperidine** and **diazepam** for 11 days, and later **diamorphine** with **lorazepam**. Despite receiving **diamorphine** 19.2 mg in 24 hours his respiratory drive was not suppressed. On day 17, despite serum morphine and **lorazepam** levels of 320 and 5.3 micrograms/mL, respectively, he remained conscious and his pupils were not constricted.¹⁶ Later *animal* studies confirmed that **lorazepam** opposed the respiratory depressant effects of morphine.¹⁶

In contrast, intravenous **diazepam** 150 micrograms/kg did not alter the respiratory depressant effect of intravenous **pethidine** 1.5 mg/kg in a study in healthy subjects¹⁷ or in patients with chronic obstructive pulmonary disease.¹⁸ Moreover, in the setting of overdose (see (b) above), benzodiazepines might increase the respiratory depressant effects of opioids.

(e) Sedation

The sedative effects of **midazolam** and **morphine** were additive in a study in patients given these drugs intravenously prior to surgery.¹⁹ A prospective study of 80 patients undergoing elective endoscopy found that deep sedation occurred frequently (68% of patients) with **pethidine** and **midazolam** used with the intent of moderate sedation.²⁰ Another study found that single oral doses of **diazepam** 10 or 20 mg given to 8 **buprenorphine**-maintained patients increased subjective effects such as sedation and strength of drug effects, and also caused a deterioration in performance measures such as cancellation time, compared with placebo.²¹

Opioids; Fentanyl and related drugs + Benzodiazepines

In general the combined use of benzodiazepines with alfentanil or fentanyl is synergistic but may also result in additive effects on respiratory depression and/or hypotension. A pharmacokinetic study found that fentanyl reduced the metabolism of midazolam. Retrospective evidence suggests that midazolam can increase the dose requirement of sufentanil, but midazolam did not alter the analgesic efficacy of fentanyl in healthy subjects.

Clinical evidence

(a) Anaesthetic induction

Combining midazolam and alfentanil or fentanyl for the induction of anaesthesia reduces the dose required of both the benzodiazepine and the opioid, when compared with either drug alone.^{1–3} The interaction is synergistic.²

(b) Analgesic effects

An analysis of 43 patients who were mechanically ventilated following major trauma, and who were given infusions of sufentanil alone or sufentanil plus midazolam, found that midazolam appeared to reduce the efficacy of the sufentanil. The rate of sufentanil infusion in the group given both drugs (21 patients) was increased by more than 50%, when compared with the group given sufentanil alone (22 patients). It was found possible to reduce the sufentanil infusion in 8 of the patients given sufentanil alone, whereas this was possible in only one patient given both drugs.⁴

Conversely, in a study in healthy subjects, intravenous midazolam 500 micrograms to 2 mg per 70 kg did not affect the analgesia produced by intravenous fentanyl 100 micrograms per 70 kg in a cold pressor test.⁵

(c) Hypotension and respiratory depression

1. **Neonates.** Hypotension occurred in 6 neonates with respiratory distress who were given midazolam (a bolus of 200 micrograms/kg and/or an infusion of 60 micrograms/kg per hour) for sedation during the first 12 to 36 hours of life. Five of them were also given fentanyl either as an infusion (1 to 2 micrograms/kg per hour) or a bolus (1.5 to 2.5 micrograms/kg), or both. Blood pressures fell from an average of 55/40 mmHg to 36/24 mmHg in 5 of them, and from 42/28 to less than 20 mmHg in one.⁶ Another report describes respiratory arrest in a child of 14 months who was given both drugs.⁷

2. **Adults.** Midazolam 50 micrograms/kg alone caused no episodes of apnoea or hypoxaemia in 12 healthy subjects, whereas fentanyl 2 micrograms/kg alone caused hypoxaemia in 6 subjects but no apnoea. When both drugs were given together 6 subjects had apnoea and 11 subjects had hypoxaemia.⁸ Similarly, fentanyl with diazepam caused more respiratory depression in 12 healthy subjects than either drug alone.⁹ Hypotension has also been seen in adult patients given fentanyl with midazolam¹⁰ or diazepam.¹¹

Acute hypotension occurred in a man receiving clonidine, captopril and furosemide who was premedicated with intramuscular midazolam 5 mg and anaesthetised with sufentanil 150 micrograms.¹² This is consistent with another report of sudden hypotension during anaesthetic induction in 4 patients given high-dose sufentanil who had been given lorazepam before induction.¹³

(d) Pharmacokinetics

A double-blind, placebo-controlled study in 30 patients undergoing orthopaedic surgery found that a single 200-microgram dose of fentanyl given one minute before intravenous midazolam 200 micrograms/kg decreased the systemic clearance of midazolam by 30%. The elimination half-life of midazolam was prolonged by approximately 50%.¹⁴

(e) Sedation

A study in patients undergoing an abdominal hysterectomy under alfentanil and midazolam anaesthesia found that although the pharmacokinetics of midazolam were unchanged, postoperative sedation was more pronounced, when compared with a group of patients that did not receive alfentanil.¹⁵

Mechanism

Uncertain. The additional use of other CNS depressants may produce additive respiratory depressant and sedative effects. Reduced metabolism of midazolam might also enhance its effects. Why midazolam appeared to increase the analgesic dose requirement for sufentanil is unknown. An *in vitro* study found that fentanyl competitively inhibited the metabolism of midazolam by the cytochrome P450 isoenzyme CYP3A4.¹⁶

Importance and management

Increased sedative and respiratory depressant effects are to be expected when benzodiazepines are used with opioids. The manufacturers of sufentanil¹⁷ and alfentanil¹⁸ suggest that clinically important hypotension may occur and this may be exacerbated by the use of benzodiazepines: it would seem prudent to be alert for this. The manufacturers of transdermal fentanyl also warn of the possibility of respiratory depression, hypotension, profound sedation and potentially coma with concurrent CNS depressants¹⁹ including benzodiazepines.²⁰ When such combined therapy is contemplated, the dose of one or both drugs should be significantly reduced.²⁰

What effect the use of midazolam has on the dose requirement of sufentanil and other opioids in the intensive care setting is unclear, although it would seem that hypotension is a risk.

Opioids; Methadone + Benzodiazepines

Patients taking methadone who are given diazepam may experience increased drowsiness and possibly enhanced opioid effects. Temazepam may have contributed to the sudden death of a patient taking methadone.

Clinical evidence, mechanism, importance and management

A study in patients taking methadone noted that **diazepam** abuse was prevalent, and that many patients reported that **diazepam** boosted the effects of methadone.¹ The possible reasons for this have been studied. Four addicts, taking methadone for at least 6 months, were given **diazepam** 300 micrograms/kg for 9 days. The pharmacokinetics of methadone were unaltered and the opioid effects of the methadone remained unchanged, but all 4 subjects were sedated.² However, another study suggested that the opioid effects of methadone (subjective effects and pupil constriction) may be enhanced by **diazepam**. This was significant at higher doses (methadone at 150% of the maintenance dose with **diazepam** 40 mg).³ Later analysis of blood samples from this study confirmed that there is no pharmacokinetic interaction between methadone and **diazepam**.⁴ It has been suggested that the absence of increased opioid effects in the earlier study² may possibly be explained by the relatively low regular daily doses of diazepam they used, in contrast to the higher more intermittent doses used in the later study,³ which is the pattern of dosage reportedly used by patients. A further study in patients taking methadone found that single oral doses of **diazepam** 10 or 20 mg, which are within the usual therapeutic range, increased subjective effects such as sedation, strength of drug effects and euphoria, and also caused a significant deterioration in performance measures such as reaction time, when compared with placebo.⁵

A 39-year-old man taking methadone 60 mg daily and **temazepam** 20 mg twice daily was found dead. Blood levels of methadone and **temazepam** were not particularly high, and revealed that amitriptyline had also been taken. The cause of death was considered to be accidental owing to methadone toxicity enhanced by **temazepam** and amitriptyline.⁶ Another case is reported of ventricular arrhythmias associated with high-dose methadone given with CYP3A4 substrates including **midazolam**.⁷

Concurrent use involving low-to-moderate diazepam dosage need not be avoided, but patients given both drugs are likely to experience increased drowsiness and reduced psychomotor performance and should be warned against driving or operating machinery under these circumstances. With a high diazepam dose the possibility of opioid enhancement should be borne in mind. Bear in mind that concurrent use of benzodiazepines appears to be a risk factor in sudden death in patients taking methadone.

Opioids + Calcium-channel blockers

Bradycardia and hypotension may be enhanced in patients taking opioids with calcium-channel blockers. The analgesic effects of morphine appear to be enhanced by some calcium-channel blockers. Diltiazem prolonged the effects of alfentanil in one study.

Clinical evidence, mechanism, importance and management

(a) Cardiovascular effects

The manufacturers of **remifentanil** and **sufentanil** caution that cardiovascular effects (bradycardia and hypotension) may be greater in patients also taking calcium-channel blockers.^{1,2}

(b) Delayed recovery from anaesthesia

A 24% increase in the AUC of **alfentanil** and a 50% increase in its half-life were seen in 15 patients anaesthetised with midazolam and alfentanil (induced with 50 micrograms/kg, then maintained with 1 microgram/kg per minute) when they were given **diltiazem** 60 mg orally 2 hours before induction, then an infusion for 23 hours starting at induction. Tracheal extubation was performed on average 2.5 hours later in the patients receiving **diltiazem** than in a placebo group.³ **Diltiazem** is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, which is responsible for the metabolism of **alfentanil**.³ Caution is required as there could be an increased risk of prolonged or delayed respiratory depression. The manufacturer says that the concurrent use of **diltiazem** and **alfentanil** requires special patient care and observation; it may be necessary to lower the dose of alfentanil.⁴

(c) Enhanced analgesia

A double-blind, placebo-controlled study in 26 patients undergoing surgery found that 2 doses of slow-release **nifedipine** 20 mg given on the day preceding surgery and a further dose given 60 to 90 minutes before surgery increased the analgesic effect of **morphine**.⁵ A study in *animals* found that **verapamil** potentiated **morphine** analgesia.⁶ A further study in *animals* found that **diltiazem**, **nimodipine** and **verapamil**, given before **morphine**, potentiated the analgesic effect of morphine and markedly increased morphine serum levels.⁷

Opioids + Cannabis

Low doses of cannabis enhanced the effect of morphine in three patients. Animal studies have shown that cannabinoids may enhance the potency of opioids.

Clinical evidence, mechanism, importance and management

A report of 3 patients with chronic pain (due to multiple sclerosis, HIV-related peripheral neuropathy, and lumbar spinal damage) found that small doses of smoked cannabis potentiated the antinociceptive effects of **morphine**. The patients were able to decrease the dose of opioid by 60 to 100%.¹ Studies in *animals* have shown that Δ^9 -tetrahydrocannabinol, the major psychoactive constituent of cannabis, enhances the potency of opioids such as **morphine**, **codeine**, **hydromorphone**, **methadone**, **oxycodone** and **pethidine (meperidine)**.^{2–4} It has been suggested that low doses of Δ^9 -tetrahydrocannabinol given with low doses of **morphine** may increase opioid potency without increasing adverse effects.⁵ Cannabis use in **methadone**-maintained patients did not appear to affect treatment progress, although some psychological difficulties were slightly more prevalent.⁶ However, other workers have suggested that heavy cannabis use is associated with poorer progress when methadone is given in the treatment of opioid addiction.⁷

Opioids + Carisoprodol

Carisoprodol may enhance the CNS depressant effects of opioids.

Clinical evidence, mechanism, importance and management

A 49-year-old woman who had been taking **oxycodone** (*OxyContin*) 40 mg twice daily for more than a year was given carisoprodol 350 mg (one tablet) four times daily because of muscle spasm and uncontrolled pain. After taking this regimen for a week without relief, she increased the dosage to 8 to 10 tablets daily. She was found unconscious, was responsive only to painful stimuli, and her respiration was also depressed. She rapidly returned to full alertness when she was given naloxone 2 mg intravenously, although she had not taken any extra **oxycodone** tablets. The adverse effects were thought to be due to additive CNS depressant effects of both **oxycodone** and carisoprodol.¹ In a retrospective review of deaths recorded in Jefferson County over a 12-year period, carisoprodol was present in the blood of 24 cases, but was never the sole drug detected; **dextropropoxyphene** (**propoxyphene**) was also present in 8 of the 24 cases. Respiratory depression was a major cause of death and as carisoprodol causes respiratory depression, it was considered to be probably responsible, in part, for those deaths.²

The manufacturer of carisoprodol reports that effects of overdose can be additive with other CNS depressants and that concurrent use of other CNS depressants should be avoided. Dependence has occurred with carisoprodol.³

Opioids + Chlorobutanol

Chlorobutanol used as a preservative may possibly contribute to the QT prolongation seen with methadone. Higher maximum total bilirubin levels were observed among newborns exposed to morphine that contained chlorobutanol than those exposed to morphine without chlorobutanol. Somnolence in a patient on high-dose morphine may have been due to the effects of morphine and also to a high intake of chlorobutanol preservative.

Clinical evidence, mechanism, importance and management

(a) Methadone

A study in patients receiving intravenous methadone found an approximately linear relationship between the log-dose of methadone and QTc measurements. In addition, methadone and chlorobutanol (a preservative used in intravenous methadone preparations) were both found to block cardiac potassium ion channels *in vitro*, and chlorobutanol potentiated this effect with methadone.¹ High doses of methadone have been reported to cause torsades de pointes, but chlorobutanol used as a preservative in methadone injection may possibly contribute to the QT prolongation.¹

(b) Morphine

A report describes a 19-year-old woman who required increasing doses of morphine to control pain, reaching a peak of 275 mg/hour, which was maintained for 4 days. After palliative radiotherapy the rate was reduced to 100 to 150 mg/hour, but only partial pain relief was achieved; however the patient was somnolent, which was attributed to an effect of the chlorobutanol. At doses of morphine 275 mg/hour, chlorobutanol intake was 90 mg/hour, which is in excess of the dose used to aid sleep (150 mg);

chlorobutanol accumulation may also have occurred as it has a long half-life.² This appears to be an isolated report, the general importance of which is unknown.

- Kornick CA, Kilborn MJ, Santiago-Palma J, Schulman G, Thaler HT, Keefe DL, Katchman AN, Pezzullo JC, Ebert SN, Woosley RL, Payne R, Manfredi PL. QTc interval prolongation associated with intravenous methadone. *Pain* (2003) 105, 499–506.
- DeChristoforo R, Corden BJ, Hood JC, Narang PK, Magrath IT. High-dose morphine infusion complicated by chlorobutanol-induced somnolence. *Ann Intern Med* (1983) 98, 335–6.

Opioids + Cocaine

Cocaine-related torsade de pointes occurred in a patient taking methadone. Ventricular arrhythmias and increased cardiovascular effects have been reported when other patients taking methadone were given cocaine. The cardiovascular effects of cocaine and morphine appear to be similar to those seen with cocaine alone.

Clinical evidence, mechanism, importance and management

A 46-year-old woman who had been taking **methadone** 80 mg daily for over one year, started abusing cocaine by inhalation and injection and subsequently developed frequent self-limiting episodes of syncope. These syncopal events consistently occurred within an hour of cocaine use. She was admitted to hospital after collapsing and becoming comatose and was found to have torsade de pointes arrhythmia. She developed irreversible anoxic brain injury secondary to cardiac arrest. Although **methadone** can cause QT prolongation, the serum methadone level was well within the therapeutic range and it was felt that several factors might have contributed to the arrhythmias including cocaine abuse.¹ Another patient taking **methadone** was withdrawn from a study due to the occurrence of premature ventricular contractions for several minutes after a single 32-mg/70 kg intravenous dose of cocaine.² Furthermore increased cardiovascular effects (e.g. increased diastolic pressure and heart rate) have been reported when cocaine is given to patients taking **methadone**.² Both cocaine and **methadone** are considered to have effects on the QTc interval and both are potassium-channel blockers. The combination of these two drugs creates a potentially dangerous risk for torsade de pointes.³

In contrast, a study in 9 healthy subjects found that although the combination of **morphine** and cocaine produced significant cardiovascular and subjective effects, for the most part, the cardiovascular effects were similar to those produced by cocaine alone. Neither cocaine nor **morphine** altered the plasma levels of the other drug.⁴

- Foltin RW, Fischman MW. The cardiovascular and subjective effects of intravenous cocaine and morphine combinations in humans. *J Pharmacol Exp Ther* (1992) 261, 623–32.

Opioids + Food

Food can delay the absorption of dextropropoxyphene (propoxyphene), but the total amount absorbed may be slightly increased. Food increases the bioavailability of oral morphine solution and produces a sustained serum level, however, the absorption of some controlled-release preparations of morphine may be delayed by food. Food may also increase the bioavailability of oxycodone solution, but sustained-release preparations of oxycodone and tramadol and immediate-release hydromorphone appear not to be affected by food.

Clinical evidence, mechanism, importance and management

Studies in *animals* suggest that ingestion of **sucrose** for short duration may activate the endogenous opioid system and may modify **morphine** withdrawal.^{1,2} Sucrose ingestion has also been shown to alleviate pain and distress in infants and adults.¹

(a) *Dextropropoxyphene (Propoxyphene)*

A study in healthy subjects given a single 130-mg dose of dextropropoxyphene (as capsules) found that while fasting, peak plasma dextropropoxyphene levels were reached after about 2 hours. **High-fat and high-carbohydrate meals** delayed peak serum levels by about 1 hour, and **high protein** delayed the peak serum levels by about 2 hours. Both the **protein** and **carbohydrate meals** caused a small 25 to 30% increase in the total amount of dextropropoxyphene absorbed.³ The delay in absorption probably occurs because food delays gastric emptying. Avoid food if rapid analgesic effects are needed.

(b) *Hydromorphone*

A crossover study in 24 healthy subjects found that food had no clinically relevant effect on the pharmacokinetics of a single 8-mg dose of immediate-release hydromorphone.⁴

(c) *Morphine*

Twelve patients with chronic pain were given oral morphine hydrochloride 50 mg in 200 mL of water either while fasting or after a **high-fat breakfast** (fried eggs and bacon, toast with butter, and milk). The maximum blood morphine levels and the time to achieve these levels were not significantly altered by the presence of the food, but the AUC was increased by 34% and blood morphine levels were maintained at higher levels over the period from 4 to 10 hours after the morphine had been given.⁵ The reasons are not understood. The inference to be drawn is that pain relief is likely to be increased if the morphine solution is given with food. This appears to be an advantageous interaction. More confirmatory study is needed.

Some differences in pharmacokinetic parameters have also been reported between the fed and fasted states for controlled-release formulations, but these are not necessarily translated into measurable differences in the pharmacodynamic effects of pain relief and adverse effects.⁶ One single-dose study found that the AUC, maximum plasma level, and time to maximum plasma level were increased by food, when compared with the fasting state for two modified-release morphine tablets available in the United Kingdom (*MST Continus*; *Oramorph SR*).⁷ Whereas in another single-dose study, no difference in these pharmacokinetic parameters was found for *MS Contin* (*Purdue Frederick Company, USA*) between the fed and fasted states.⁸ Yet another single-dose study reported that the rate of absorption of morphine from sustained-release morphine sulfate capsules (*Kapanol*; *Purdue Frederick Company USA*) was slower with food; there was a 28% increase in the absorption half-life and a 19% increase in the time to maximum plasma level, but the AUC and maximum plasma level were not significantly affected.⁹ However, another study reported that sustained-release capsules (*Kapanol*) were bioequivalent under fed and fasting conditions, but the rate and extent of morphine absorption from modified-release capsules (*MXL*) was significantly reduced by food.¹⁰

Most of these studies used single doses in healthy subjects and food was given in the form of a **high-fat breakfast** and although it appears that there might be some delay in the absorption of some sustained-release preparations of morphine with food, the overall effect is unlikely to be clinically significant.

(d) *Oxycodone*

A study in 22 healthy subjects found that the bioavailability of oxycodone as an immediate-release solution was significantly altered by consumption of a **high-fat meal**; the AUC was increased by 20% and the maximum plasma level was decreased by 18%, when compared with the fasted state. However, there was no significant effect of food on the bioavailability of oxycodone given as a controlled-release tablet.¹¹

(e) *Tramadol*

In an open, crossover study in 24 healthy subjects, tramadol sustained-release capsules were found to be bioequivalent with and without concurrent food intake (**high-fat breakfast**).¹²

Opioids + Glutethimide

A study in animals suggested that glutethimide might potentiate and prolong the analgesic effect of codeine by increasing plasma levels of morphine.¹ Glutethimide combined with codeine can produce a euphoric state and may be addictive; seizures and psychosis have been reported.²

Opioids + Grapefruit juice

Grapefruit juice has been associated with a modest increase in oral methadone bioavailability. Grapefruit juice does not appear to affect the bioavailability of intravenous alfentanil or transmucosal fentanyl to a clinically significant extent; the clearance of oral alfentanil may be reduced.

Clinical evidence, mechanism, importance and management

(a) *Alfentanil*

A study in 10 healthy subjects found that grapefruit juice had no effect on the bioavailability of intravenous alfentanil. However, the clearance of oral alfentanil was reduced by about 40% and the maximum plasma level and oral bioavailability were increased by approximately 40% and 60%, respectively. This was thought to be due to selective inhibition of intestinal CYP3A by grapefruit juice.¹ Therefore should alfentanil be given orally its effects would be expected to be increased and prolonged.

(b) *Fentanyl*

In a study in 12 healthy subjects, grapefruit juice had minimal effect on peak plasma levels or clinical effects of oral transmucosal fentanyl, despite a considerable proportion of the dose being swallowed and absorbed enterally.²

(c) *Methadone*

A study in 8 patients taking methadone found that 200 mL of grapefruit juice given 30 minutes before and also with their daily dose of methadone was associated with a modest increase in methadone bioavailability. The mean AUC and the maximum plasma levels increased by about 17%.³ A study in healthy subjects found that grapefruit juice caused a similar modest increase in methadone bioavailability following oral methadone, but had no effect on intravenous methadone bioavailability.⁴ The increase in methadone levels were not considered to be clinically significant in the patients studied.³ On the basis of this evidence dosage adjustments of methadone seem unlikely to be necessary in the presence of grapefruit juice.

Opioids + H₂-receptor antagonists

No clinically significant interaction appears to occur between cimetidine and butorphanol (intranasal), hydromorphone, morphine, pethidine and tramadol; between famotidine and hydromorphone; or between ranitidine and hydromorphone, morphine, or pethidine. However, isolated reports describe adverse reactions in patients taking methadone, morphine or mixed opium alkaloids with cimetidine, or morphine with ranitidine.

Clinical evidence

(a) Butorphanol

The pharmacokinetics of intranasal butorphanol 1 mg every 6 hours and oral cimetidine 300 mg every 6 hours for 4 days were not significantly altered by concurrent use in 16 healthy subjects, except for a moderate increase in the elimination half-life of cimetidine.¹

(b) Hydromorphone

The US manufacturer of hydromorphone says that the concurrent use of H₂-receptor antagonists (cimetidine, famotidine, ranitidine) had no significant effect on hydromorphone steady-state pharmacokinetics.²

(c) Methadone

An *in vitro* study briefly mentions an elderly patient receiving methadone 25 mg daily who developed apnoea 2 days after starting cimetidine 1.2 g daily.³ Another elderly patient taking methadone 5 mg every 8 hours by mouth and subcutaneous morphine 8 mg every 3 hours also developed apnoea (respiratory rate 2 breaths per minute) after receiving intravenous cimetidine 300 mg every 6 hours for 6 days. This was controlled with naloxone. The patient had previously shown no ill effects from the administration of morphine while taking cimetidine and methadone.⁴

(d) Morphine

1. *Cimetidine*. In a study in 7 healthy subjects cimetidine 300 mg four times daily for 4 days had no effect on the pharmacokinetics of a single 10-mg dose of intravenous morphine. The extent and duration of the morphine-induced pupillary miosis was also unchanged.⁵ In other healthy subjects, cimetidine 600 mg, given one hour before a 10-mg dose of intramuscular morphine prolonged the respiratory depression due to morphine, but the extent was small and not considered to be clinically significant.⁶ Another study in 118 patients undergoing major abdominal surgery found that there were no significant differences between the effects of preoperative or postoperative intravenous cimetidine 4 mg/kg or placebo on postoperative pain intensity, sedation score, cumulative morphine consumption, or the incidence of adverse effects.⁷

In contrast, an acutely ill patient with grand mal epilepsy, gastrointestinal bleeding and an intertrochanteric fracture who was undergoing haemodialysis three times a week, was taking cimetidine 300 mg three times daily. After being given the sixth dose of intramuscular morphine (15 mg every 4 hours) he became apnoeic (three breaths per minute), which was managed with naloxone. He remained confused and agitated for the next 80 hours with muscular twitching and further periods of apnoea controlled with naloxone. He had received nine 10-mg intramuscular doses of morphine on a previous occasion in the absence of cimetidine without problems. About a month later he experienced the same adverse reactions when given opium alkaloids while still taking cimetidine (see below).⁸ Apnoea has also been reported in a patient receiving morphine, methadone and cimetidine, see (c) above.

2. *Ranitidine*. A man with terminal cancer receiving intravenous ranitidine 150 mg every 8 hours became confused, disorientated and agitated when given the ranitidine after an intravenous infusion of morphine 50 mg daily was started. When the ranitidine was stopped his mental state improved but worsened when he was given ranitidine again 8 hours and 16 hours later. He again improved when the ranitidine was stopped.⁹ Similarly, another report describes hallucinations in a patient receiving ranitidine and sustained-release morphine followed by rectal methadone, but the author discounted the possibility of an interaction.¹⁰

(e) Opium alkaloids, mixed

A patient taking cimetidine 150 mg twice daily developed apnoea, confusion, and muscle twitching after receiving 7 doses of intramuscular *Pantopon* (hydrochlorides of mixed opium alkaloids) postoperatively. He required 4 doses of naloxone over the next 24 hours.⁸

(f) Pethidine (Meperidine)

Cimetidine 600 mg twice daily for one week reduced the total body clearance of a single 70-mg intravenous dose of pethidine in 8 healthy subjects by a modest 22%.¹¹ In a similar study by the same research group, ranitidine 150 mg twice daily had no effect on pethidine pharmacokinetics.¹²

(g) Tramadol

In an unpublished study on file with the manufacturers, cimetidine increased the AUC of tramadol by 15% to 27% and decreased the total body clearance by 14% to 22% in healthy subjects.¹³ The manufacturers say that these changes are not clinically significant.^{14,15}

Mechanism

Cimetidine inhibits the activity of the liver enzymes concerned with the *N*-demethylation of methadone³ and pethidine,^{11,12} reducing their metabolism, so they accumulate in the body, thereby exaggerating their respiratory depressant effects. A reduction in liver function might possibly have contributed towards, or even been largely responsible for the cases with methadone, because both patients were elderly.

The isolated cases of possible interactions between morphine and H₂-receptor antagonists remain unexplained.^{8,9} *In vitro* studies have shown that the conjugation of morphine is not affected by cimetidine or ranitidine,¹⁶ although one study in 8 healthy subjects suggested that ranitidine might slightly increase the bioavailability of morphine.¹⁷

Importance and management

The virtual absence of a generally important interaction between morphine and cimetidine is adequately documented. Concurrent use normally causes only a slight and normally unimportant prolongation of the respiratory depression due to morphine, but it might possibly have some importance in patients with pre-existing respiratory disorders. One manufacturer warns that cimetidine may inhibit the metabolism of morphine¹⁸ and another warns that, because of the isolated report (see (d) above), patients should be monitored for increased respiratory and CNS depression.¹⁹ *In vitro* evidence suggests that ranitidine is unlikely to interact with morphine,⁸ although one pharmacokinetic study indicated that ranitidine might cause a slight increase in morphine levels.¹⁷

Information about the interaction between pethidine and cimetidine is very limited, and its clinical importance is uncertain, but probably small given the minor changes in pharmacokinetics. However, some manufacturers warn that cimetidine may inhibit the metabolism of pethidine^{20,21} and thus caution should be used with concurrent use.²¹ Ranitidine has been shown not to affect the pharmacokinetics of pethidine.

It also seems doubtful if the interaction between methadone and cimetidine is of any general importance when the two isolated reports cited here are viewed against the background of the widespread use of both of these two drugs for a good number of years and the lack of other published adverse reports. However, some manufacturers warn that methadone clearance may be decreased when it is given with drugs that inhibit CYP3A4 activity including cimetidine.^{22,23} There is no clinically important pharmacokinetic interaction between intranasal butorphanol and oral cimetidine, between hydromorphone and H₂-receptor antagonists, or between tramadol and cimetidine. Consider also 'Opioids; Fentanyl and related drugs + H₂-receptor antagonists', p.172.

Opioids; Fentanyl and related drugs + H₂-receptor antagonists

Cimetidine, but not ranitidine, increases the plasma levels of alfentanil. Some preliminary observations suggest that the effects of fentanyl may be increased by cimetidine.

Clinical evidence, mechanism, importance and management

(a) Alfentanil

In a pharmacokinetic study in 19 intensive care patients, intravenous **cimetidine** 1.2 g daily for 2 days was given with a single 125-microgram/kg intravenous dose of alfentanil. When compared with an oral aluminium/magnesium hydroxide antacid or intravenous **ranitidine** 300 mg daily the cimetidine increased the alfentanil half-life by 75 and 61%, respectively, and reduced the clearance by 64 and 54%, respectively. The alfentanil plasma levels were significantly raised by the **cimetidine**, probably because **cimetidine** inhibits the metabolism of the alfentanil.¹ Whether the alfentanil effects are increased to a clinically important extent awaits assessment. However, be alert for increased alfentanil effects because pharmacokinetic changes of this size are known to be clinically important in some patients (see ‘macrolides’, (p.174) and ‘azoles’, (p.164)). The manufacturer of alfentanil warns that alfentanil is metabolised mainly by CYP3A4, and therefore inhibitors of this enzyme, including **cimetidine**, could increase the risk of prolonged or delayed respiratory depression. The concurrent use of such drugs requires special patient care and observation; it may be necessary to lower the dose of alfentanil.^{2,3}

Ranitidine does not appear to interact.¹

(b) Fentanyl

The terminal half-life of fentanyl 100 micrograms/kg was reported to be more than doubled, from 155 to 340 minutes, by pretreatment with **cimetidine** (10 mg/kg the night before and 5 mg/kg 90 minutes before the fentanyl dose). This increase in half-life probably occurs because **cimetidine** inhibits the metabolism of fentanyl by the liver, thereby delaying its clearance from the body.⁴ The clinical importance of this interaction has not been assessed, but if both drugs are used concurrently, be alert for increased and prolonged fentanyl effects.

Opioids + Haloperidol

A patient treated with long-term haloperidol and morphine experienced extrapyramidal symptoms when naloxone was given.

Clinical evidence, mechanism, importance and management

An 18-year-old woman with nasopharyngeal carcinoma who had been treated with long-term haloperidol and **morphine** developed profound extrapyramidal adverse effects during an attempt to reverse an intrathecal morphine overdose with naloxone. It was suggested that long-term morphine treatment might suppress haloperidol-induced extrapyramidal symptoms through its antimuscarinic and dopaminergic effects. Abrupt opioid withdrawal could be potentially hazardous in patients who are also taking haloperidol.¹

- Guo S-L, Lin C-J, Huang H-H, Chen L-K, Sun W-Z. Reversal of morphine with naloxone precipitates haloperidol-induced extrapyramidal side effects. *J Pain Symptom Manage* (2006) 31, 391–2.

Opioids + Herbal medicines

St John’s wort reduces the plasma concentrations of methadone and withdrawal symptoms may occur. Some herbal teas may contain opioids.

Clinical evidence, mechanism, importance and management

Some herbal preparations may actually contain opioids; the **morphine** content of two herbal teas containing *Papaveris fructus* was found to be 10.4 micrograms/mL and 31.5 micrograms/mL, respectively. Furthermore, **morphine** was detected in the urine of 5 healthy subjects one hour after drinking 2 cups of either of the herbal teas and was maximal at 4 to 6 hours: positive urine samples were detected up to 6 to 9 hours after drinking the teas.¹ Therefore it may be expected that additive CNS depressant effects will occur if teas such as this are taken with other opioid preparations.

In contrast, a study in 4 patients taking **methadone** found that **St John’s wort** (*Jarsin*) 900 mg daily for 14 to 47 days decreased methadone plasma concentration-to-dose ratios (indicating decreased methadone levels) by 19 to 60%. Two patients reported symptoms that suggested a withdrawal syndrome.² **St John’s wort** (*Hypericum perforatum*) is metabolised in the liver and induces the cytochrome P450 enzyme CYP3A4 and P-glycoprotein, and so could affect plasma levels of drugs metabolised in this way including methadone² and other natural or some synthetic opioids.³

Opioids + Hormonal contraceptives

The clearance of morphine is roughly doubled by combined oral contraceptives. Combined oral contraceptives do not appear to alter the pharmacokinetics of pethidine. The manufacturer of buprenorphine predicts that gestodene may increase plasma levels of buprenorphine.

Clinical evidence, mechanism, importance and management

(a) Buprenorphine

Although no data from clinical studies are available, the manufacturer predicts that inhibitors of the cytochrome P450 isoenzyme CYP3A4 such as **gestodene** may increase exposure levels to buprenorphine and a dose reduction should be considered when initiating treatment.¹ Halving the starting dose of buprenorphine has been suggested for patients taking CYP3A4 inhibitors and receiving buprenorphine as a substitute for opioid depend-

ence.¹ However, the same manufacturer suggests that, since the magnitude of an inhibitory effect is unknown, such drug combinations should be avoided when buprenorphine is used parenterally or sublingually as a strong analgesic.^{2,3} Note that, there appear to be no cases or studies reporting interactions where **gestodene** is acting as a CYP3A4 inhibitor.

(b) Morphine

The clearance of intravenous morphine 1 mg and oral morphine 10 mg was increased by 75% and 120%, respectively, in 6 young women taking a combined oral contraceptive.⁴ It is suggested that the oestrogen component of the contraceptive increases the activity of the liver enzyme (glucuronyl transferase) concerned with the metabolism of morphine, which results in an increased clearance. This implies that the dosage of morphine would need to be increased to achieve the same degree of analgesia. Whether this is so in practice requires confirmation.

(c) Pethidine (Meperidine)

One early study suggested that 4 of 5 women taking a combined oral contraceptive (**mestranol** with **noretynodrel** or **norethisterone**) excreted more unchanged pethidine in the urine than a control group of 4 women not taking contraceptives, who were found to excrete more of the demethylated metabolite.⁵ However a later, well-controlled, comparative study in 24 healthy subjects (8 women taking a combined oral contraceptive containing **ethinylestradiol/norgestrel** 50/500 micrograms, and 8 women and 8 men not taking contraceptives) found no differences between the plasma levels or excretion patterns of pethidine between the three groups.⁶ No special precautions appear to be needed if pethidine is given to women taking combined oral contraceptives.

Opioids + Interferons

Peginterferon alfa does not affect the pharmacokinetics of methadone, but an isolated report describes a patient who relapsed to heroin use following treatment with peginterferon. Methadone maintenance does not appear to affect the pharmacokinetics of peginterferon alfa or the virological response to interferons. Similarly, buprenorphine does not appear to influence the effect of interferon.

Clinical evidence, mechanism, importance and management

A study involving 22 patients with chronic hepatitis C who had been receiving **methadone** maintenance for a least 3 months found that subcutaneous **peginterferon alfa-2a** 180 micrograms once weekly for 4 weeks did not influence the pharmacokinetics of methadone to a clinically significant extent. The pharmacokinetics of **peginterferon alfa-2a** did not appear to be altered by **methadone** when compared with values from other patients.¹ However, a case report describes a patient who stopped taking **methadone** and then relapsed to heroin use approximately 5 months after completing treatment of chronic hepatitis C with **peginterferon** and **ribavirin**.² Although interferon does not appear to affect **methadone** levels pharmacokinetically, patients taking methadone may experience increased cravings while receiving antiviral therapy because the adverse effects may mimic opioid withdrawal symptoms. Craving may also be secondary to mood changes caused by antiviral therapy or be related to the use of needles used to deliver interferon.² It may, therefore, be necessary to increase the dose of **methadone** during interferon treatment.^{2,3}

Although opioids may possibly facilitate the outbreak of infections through immunomodulating effects on the immune response against a virus, several studies suggest that the use of opioids (**buprenorphine**,³

methadone,^{3,4}) has no effect on the outcome of treatment with interferons^{4–6} (**peginterferon alfa-2b**^{4,5}) in heroin addicts with chronic hepatitis C.^{3–5}

Opioids + Local anaesthetics

Chlorprocaine can reduce the efficacy of epidural morphine and fentanyl analgesia. Bupivacaine may enhance the local anaesthetic effect of fentanyl, but does not appear to affect respiration. Similarly, lidocaine does not appear to increase respiratory depressant effects of morphine. However, two cases of respiratory depression have been reported with lidocaine and opioids. Morphine given as an intravenous bolus does not alter lidocaine serum levels given as a continuous intravenous infusion.

Clinical evidence, mechanism, importance and management

(a) Bupivacaine

A study involving 40 elderly patients undergoing spinal anaesthesia found that bupivacaine 9 mg, with **fentanyl** 20 micrograms reduced the incidence of hypotension compared with bupivacaine 11 mg alone. Respiratory rates were not depressed in either group. The rate of failed spinal block and discomfort was similar in both groups. The addition of the fentanyl allowed a reduction in the minimum dose of bupivacaine to produce an adequate block, and consequently less hypotension.¹

(b) Chlorprocaine

Two studies^{2,3} have found that chlorprocaine decreases the duration of epidural **morphine** analgesia (16 hours for chlorprocaine compared with 24 hours for lidocaine²). Another study found that **morphine** requirements after caesarean section were much higher in women who had received chlorprocaine for epidural anaesthesia than in those receiving lidocaine.⁴ The authors of one of the studies suggest that chlorprocaine should be avoided if epidural **morphine** is used.² Epidural **fentanyl** also appears to be antagonised by chlorprocaine.⁵

(c) Lidocaine

A double-blind study in 10 patients who were receiving continuous lidocaine infusions during suspected myocardial infarction found that a 10-mg intravenous **morphine sulfate** bolus did not significantly alter the steady-state serum levels of lidocaine.⁶ In another study, giving lidocaine with extradural **morphine** did not increase the risk of respiratory depression associated with the morphine.⁷ However, in one case, respiratory depression occurred within 5 minutes of giving intravenous lidocaine for an episode of ventricular tachycardia in a patient who had previously been given spinal **fentanyl** and **morphine**. Naloxone successfully reversed this.⁸ Similarly, respiratory depression occurred in a 3-year-old boy given lidocaine with adrenaline (epinephrine) about 5 minutes after a submucosal injection of the narcotic **alphaprodine**. Again naloxone reversed the respiratory depression.⁹

Opioids + Macrolides

An isolated report describes a marked increase in the effects of dextromoramide, resulting in coma, in a man treated with troleandomycin. Macrolides including troleandomycin and erythromycin are predicted to increase buprenorphine bioavailability. Similarly, the metabolism of hydromorphone is reduced by troleandomycin *in vitro*. Some manufacturers have suggested that the metabolism of methadone and oxycodone may be decreased by these macrolides, but there do not appear to be any clinical reports confirming this.

Clinical evidence, mechanism, importance and management

(a) Buprenorphine

Although no data from clinical studies are available, the manufacturers predict that inhibitors of the cytochrome P450 isoenzyme CYP3A4 such as macrolide antibacterials including **erythromycin**¹ and **troleandomycin**^{2–4} may increase the levels of buprenorphine. Some manufacturers recommend close monitoring and possibly a dose reduction;¹ however, it has also been said that, since the magnitude of an inhibitory effect is unknown, such drug combinations should be avoided when buprenorphine is used parenterally or sublingually as an analgesic.^{3,4} The manufacturers of buprenorphine for the treatment of opioid addiction suggest using half the dose if potent CYP3A4 inhibitors, such as some macrolides, are given.²

(b) Dextromoramide

A man taking dextromoramide developed signs of overdosage (a morphine-like coma, mydriasis and depressed respiration) 3 days after he started to take **troleandomycin** for a dental infection. He recovered when given naloxone. A possible explanation is that the **troleandomycin** reduced the metabolism of the dextromoramide, thereby increasing its serum levels and effects.⁵ The general importance of this interaction is uncertain but concurrent use should be well monitored.

(c) Hydromorphone

An *in vitro* study found that the cytochrome P450 isoenzyme subfamily CYP3A, and to a lesser extent the isoenzyme CYP2C9, catalyse hydromorphone *N*-demethylation to norhydromorphone. **Troleandomycin** (an inhibitor of CYP3A) reduced norhydromorphone formation by about 45%.⁶ The clinical relevance of this is unknown.

(d) Methadone

A randomised, crossover study in 12 healthy subjects found that **troleandomycin** did not significantly affect oral or intravenous methadone bioavailability. **Troleandomycin** caused only a small reduction in methadone *N*-demethylation after oral methadone, suggesting only a small role for CYP3A4 in human methadone metabolism.⁷ However, one manufacturer of methadone warns that its clearance may be decreased if it is given with drugs that inhibit CYP3A4 activity, such as some macrolide antibacterials.⁸

(e) Oxycodone

The UK manufacturer of oxycodone suggests that inhibitors of CYP3A enzymes such as **erythromycin** may inhibit the metabolism of oxycodone,⁹ although oxycodone is also metabolised via CYP2D6,⁹ which would make a clinically significant interaction seem unlikely.

Opioids; Fentanyl and related drugs + Macrolides

Some patients may experience prolonged and increased alfentanil effects if they are given erythromycin or particularly troleandomycin. Troleandomycin also interacts with fentanyl but to a lesser extent. Erythromycin appears not to interact with sufentanil.

Clinical evidence

(a) Erythromycin

Erythromycin 500 mg twice daily for 7 days increased the mean half-life of **alfentanil** in 6 subjects from 84 to 131 minutes and decreased the clearance by 26%. The two most sensitive subjects had considerable changes with only one day of erythromycin treatment, and overall showed a marked change. The other 4 subjects had only small or moderate changes.¹

A 32-year old man undergoing exploratory laparotomy was given erythromycin 1 g and neomycin 1 g, both three times daily, on the day before surgery. During the induction and maintenance of anaesthesia he received a total of 20.9 mg of **alfentanil**. An hour after recovery he was found to be unrousable and with a respiratory rate of only 5 breaths per minute. He was successfully treated with naloxone.² Another patient given **alfentanil** and erythromycin is said to have developed respiratory arrest during recovery.³

In contrast, in 6 healthy subjects erythromycin 500 mg twice daily for 7 days did not affect the pharmacokinetics of intravenous **sufentanil** 3 micrograms/kg in the 9 hours following administration.⁴ Two of the subjects were the same as those who had shown an alfentanil/erythromycin interaction cited above.

(b) Troleandomycin

A study in 9 healthy subjects given troleandomycin 500 mg orally found that the clearance of intravenous **alfentanil** 20 micrograms/kg was reduced by almost 70%, when compared with subjects given placebo.⁵ Similar results were found in another study.⁶ A further study found that oral troleandomycin (500 mg starting 105 minutes before alfentanil infusion then 250 mg every 6 hours for 3 doses) reduced the clearance of **alfentanil** by 88%.⁷ This study found that troleandomycin only reduced intravenous **fentanyl** clearance by 39%. In another study in 12 healthy subjects, peak **fentanyl** concentrations and maximum miosis following oral transmucosal fentanyl 10 micrograms/kg were minimally affected by oral troleandomycin (500 mg given about 3 hours before and 9 hours after the opioid), but fentanyl metabolism, elimination and duration of effects were significantly affected (fentanyl AUC increased by 77%; norfentanyl AUC decreased by 36%; AUC_{0–10} of miosis increased 53%).⁸

Mechanism

Troleandomycin, and to a lesser extent erythromycin, inhibit the cytochrome P450 isoenzyme CYP3A4 in the liver, which is involved in the metabolism of alfentanil, fentanyl and sufentanil. In addition, troleandomycin has been reported to inhibit CYP3A5 as well as CYP3A4 and alfentanil appears to be metabolised by multiple CYP3A enzymes including CYP3A5.⁹ Alfentanil is a low-extraction drug cleared mainly by hepatic metabolism,⁶ whereas fentanyl and sufentanil are high extraction drugs (see 'Changes in first-pass metabolism', (p.4)) and are therefore less likely to be affected by changes in liver metabolism.^{7,10} Alterations in intestinal or hepatic CYP3A activity also appear to have little influence on oral transmucosal fentanyl absorption and onset of effect, however, a significant proportion (approximately 75%) is swallowed and its systemic clearance may be decreased by CYP3A inhibitors.^{8,11}

Importance and management

The interactions of alfentanil with erythromycin and troleandomycin appear to be established and clinically important. Alfentanil should be given in reduced amounts or avoided in those who have recently taken either of these drugs.¹ Be alert for evidence of prolonged alfentanil effects and respiratory depression. The interaction appears not to affect all patients given erythromycin. Alternatively, sufentanil in doses of 3 micrograms/kg or less may be used instead, but much larger doses of sufentanil should be given with caution.⁴ Fentanyl is another alternative for use with erythromycin, but should probably be used with caution with troleandomycin. Caution is also advised if transmucosal fentanyl is given with CYP3A4 inhibitors including macrolide antibacterials (e.g. **clarithromycin**, erythromycin, troleandomycin) as there may be increased bioavailability of swallowed fentanyl resulting in increased or prolonged opioid effects.^{11,12} The patient should be carefully monitored and dosage adjustments made if necessary.^{12,13} Consider also 'Opioids + Macrolides', p.174.

Opioids + Magnesium compounds

Magnesium compounds can potentiate opioid analgesia, although some studies have failed to find an effect. Magnesium sulfate may also reduce opioid requirements during anaesthesia.

Clinical evidence, mechanism, importance and management

Several clinical studies have found that magnesium enhances the analgesic effect of opioids, including intrathecal magnesium with intrathecal **fentanyl**,¹ and intravenous magnesium with intravenous **remifentanyl**,² or intravenous **tramadol**.³ However, one placebo-controlled study found that perioperative administration of intravenous magnesium sulfate did not decrease postoperative pain and patient-controlled **pethidine (meperidine)** consumption following caesarean delivery. Furthermore, intraoperative blood loss appeared to increase.⁴ Another study found a similar lack of effect of intravenous magnesium on the amount of **morphine** used postoperatively.⁵

Magnesium sulfate infusion also decreased **sufentanil** requirements for sedation⁶ and reduced the drug requirements of propofol, rocuronium and **fentanyl** during anaesthesia.⁷ Intrathecal magnesium sulfate prolonged the period of spinal anaesthesia induced by bupivacaine and **fentanyl** without additional adverse effects, but the onset of anaesthesia was also significantly delayed.⁸ Magnesium sulfate may also prolong the effects of the 'competitive neuromuscular blockers', (p.125).

Divalent cations appear to be involved in the pain pathway and magnesium sulfate can potentiate the opioid analgesic effect,⁶ possibly by antagonism of *N*-methyl-D-aspartate receptor ion channels.^{3,6} It has been suggested that as magnesium ions do not easily cross the blood brain bar-

rier, the intrathecal use of magnesium may modulate pain relief via central effects, whereas the intravenous route mainly only affects peripheral mechanisms.²

Opioids + NRTIs

Zidovudine had no effect on methadone levels in one study, but there is one report of a patient requiring a modest increase in methadone dose after starting zidovudine. Similarly case reports describe patients requiring a modest increase in methadone dose after starting abacavir. Methadone can increase zidovudine serum levels, and reduce levels of abacavir, stavudine, and didanosine from the tablet formulation, but not the enteric-coated capsule preparation. Tenofovir, and a single dose of zidovudine/lamivudine had no effect on methadone pharmacokinetics.

Clinical evidence

(a) Abacavir

Eleven patients given methadone with abacavir had a 23% increase in the rate of methadone clearance but no change in the half-life or renal clearance. In addition, there was a delay, and a 34% decrease in the peak concentration of abacavir, but no change in abacavir clearance or half-life.¹ Of 3 patients taking methadone who started taking abacavir, lamivudine and zidovudine, 2 required methadone dosage increases (31% and 46%, respectively). The abacavir was thought to be responsible for this effect.² A patient receiving methadone experienced torsades de pointes when receiving abacavir, lamivudine and zidovudine.³

(b) Didanosine

A study in 17 subjects taking methadone found that the AUC and maximum levels of didanosine tablets were 57% and 66% lower, respectively, when compared with 10 control subjects. Trough levels of methadone did not differ from historical controls, suggesting that didanosine had no effect on methadone pharmacokinetics.⁴ A later study found that there was no reduction in the AUC of didanosine given as enteric-coated capsules.⁵

(c) Stavudine

A study in 17 subjects taking methadone found that the AUC and maximum levels of stavudine were 23% and 44% lower, respectively, when compared with 10 control subjects. Trough levels of methadone did not differ from historical controls suggesting that stavudine had no effect on methadone pharmacokinetics.⁴

(d) Tenofovir

In a study in 13 healthy subjects receiving methadone, tenofovir 300 mg daily for 2 weeks did not alter the pharmacokinetics of methadone, and no symptoms of opioid toxicity or opioid withdrawal were detected.⁶

(e) Zidovudine

1. *Buprenorphine*. In one study, there was no difference in the pharmacokinetics of oral zidovudine between patients receiving buprenorphine and control subjects.⁷ Buprenorphine is not expected to cause zidovudine toxicity.

2. *Methadone effects reduced or unaffected*. A drug abuser with AIDS needed an increase in his levomethadone (*R*-methadone) dosage from 40 to 60 mg daily, within a month of starting to take zidovudine 1 g daily.⁸

In contrast, a study found no evidence of any change in the pharmacokinetics of methadone in HIV-positive patients taking methadone 14 days after they started zidovudine 200 mg every 4 hours. No methadone withdrawal symptoms occurred.⁹ Another study in 16 patients taking methadone found that a single-dose of a fixed combination of zidovudine 300 mg with lamivudine 150 mg (*Combivir*) had no effect on the pharmacokinetics of methadone, and there was no evidence of withdrawal or toxicity.¹⁰

3. *Zidovudine effects increased.* In one study the mean AUC of zidovudine was increased by 43% by methadone, and in 4 of 9 patients it was doubled.⁹ In another study, 8 HIV-positive patients starting methadone found a 29% increase in the AUC of oral zidovudine and a 41% increase in the AUC of intravenous zidovudine. Three of the 8 patients stopped zidovudine because of adverse effects or haematologic toxicity.¹¹ Decreased zidovudine clearance in patients taking methadone is described in another report.¹²

Mechanism

Uncertain. It appears that methadone reduces the bioavailability of didanosine, and to a lesser extent, stavudine, possibly because it delays gastric emptying. Thus, the enteric-coated didanosine preparation appears not to be affected.^{4,5} Conversely, methadone apparently reduces the glucuronidation of the zidovudine by the liver, resulting in an increase in its serum levels.¹³ Methadone may also reduce renal clearance of zidovudine.¹¹

Importance and management

The increase in zidovudine levels with methadone is established, although the clinical relevance is uncertain. Be alert for any increase in zidovudine adverse effects. The balance of evidence suggests that zidovudine is unlikely to reduce methadone levels, and the one case reported remains unexplained, although note that some of the adverse effects of zidovudine may be mistaken for opioid withdrawal effects.

The reduction in didanosine levels with methadone may be clinically relevant, and the authors suggest increasing the dose of the tablet formulation. Monitor virological response. The enteric-coated didanosine preparation is not affected and it may therefore be worth considering using this preparation instead.

The reduction in stavudine levels and the changes in abacavir peak levels with methadone are probably not clinically relevant, but again, further data are required. The reports with abacavir suggest that it would be prudent to monitor methadone dose requirements when this drug is started. Tenofovir does not appear to affect methadone levels.

Opioids; Methadone + NNRTIs

Methadone plasma levels can be markedly reduced by efavirenz or nevirapine and withdrawal symptoms have been seen. In contrast, delavirdine slightly increased methadone levels in one study.

Clinical evidence

(a) Delavirdine

The pharmacokinetics of delavirdine 600 mg twice daily did not differ between 16 HIV-negative subjects taking methadone and 15 healthy control subjects.¹ In another study methadone did not affect delavirdine pharmacokinetics. However, delavirdine decreased methadone clearance and increased its AUC by 19%.²

(b) Efavirenz

An HIV-positive woman who had been taking methadone for over a year began to complain of discomfort within 4 weeks of having nelfinavir replaced by efavirenz 600 mg daily, and by 8 weeks typical methadone withdrawal symptoms were occurring late in the afternoon. It was found that the levels of R-methadone (the active enantiomer) had fallen from 168 to 90 nanograms/mL, and those of the S-methadone from 100 to 28 nanograms/mL. The methadone dosage had to be increased from 100 mg to 180 mg daily before the symptoms disappeared.³ A further case is reported in which a man taking methadone stopped taking efavirenz 600 mg daily because of the occurrence of withdrawal symptoms in spite of increased methadone dosage.⁴ Another report describes a man who required a 133% increase in his methadone dose over 4 weeks after starting efavirenz, and mentions two other patients who complained of opioid withdrawal shortly after starting efavirenz. They also required methadone dose increases.⁵

In a pharmacokinetic study, 11 patients taking methadone 35 to 100 mg daily were given efavirenz with two nucleoside analogues. Nine of the patients developed methadone withdrawal symptoms and needed dose increases of 15 to 30 mg (mean 22%). A pharmacokinetic study of these patients found that 3 weeks after starting efavirenz their mean methadone AUCs were reduced by 57% and their maximum plasma levels by 48%.⁶ Similar results were found in another study in 5 HIV-positive patients taking methadone: 4 patients experienced opioid withdrawal symptoms and a mean methadone dose increase of 52% was required.⁷ In another retrospective study, 6 out of 7 patients needed methadone dosage increases of 8% to 200% within 2 weeks to 8 months of starting an efavirenz-based regimen.⁸

(c) Nevirapine

A retrospective review revealed 7 cases of patients taking methadone who developed withdrawal symptoms after starting regimens including nevirapine. The symptoms developed within 4 to 8 days, and methadone dose increases of 21% to 186% were required. Despite this, 3 patients did not respond. They elected to discontinue nevirapine, and in 2 of them somnolence developed within 2 weeks, so the methadone dosage was reduced. Methadone plasma levels were available in 2 patients, and these suggested that nevirapine decreased methadone levels by about 90%.⁹ In a pilot study of a once daily nevirapine-containing regimen, 30% of patients required an increase in methadone dosage.¹⁰ In another study 4 of 5 patients taking methadone developed withdrawal symptoms on starting nevirapine-containing regimens and 2 refused further nevirapine, despite increasing their methadone dose. Another 2 patients were successfully treated with increases in their methadone doses of 33% and 100%.¹¹ Three other similar cases have been reported.^{4,12,13}

In a pharmacokinetic study, 8 patients taking methadone 30 to 120 mg daily had methadone levels measured before and 14 days after starting an antiretroviral regimen including nevirapine 200 mg daily. The methadone AUC decreased by 52%, and the maximum level by 36%. Six patients complained of symptoms of methadone withdrawal, and required a mean increase in methadone dose of 16%.¹⁴

Mechanism

Efavirenz and nevirapine induce the metabolism of methadone (possibly by the cytochrome P450 isoenzyme CYP3A4, or CYP2B6¹⁵), which results in reduced levels and effects. In contrast, delavirdine is an inhibitor

of various cytochrome P450 isoenzymes, and might therefore be expected to inhibit the metabolism of methadone, although the effects appear small.

Importance and management

The interaction between methadone and efavirenz or nevirapine is established and of clinical importance. Some authors have found that the dosage increase required is much less than that predicted based on the reduction in methadone levels,^{6,14} whereas others have questioned this.^{5,16} It may be important not to confuse the adverse effects of the NNRTIs with withdrawal symptoms.⁶ It has been suggested that patients taking methadone who are given these drugs should be screened for opioid withdrawal beginning on the fourth day of the new medication. If symptoms develop, the methadone dose should be increased by 10 mg every 2 to 3 days until symptoms abate.¹⁷ However, others have suggested dose increments should be made at one-week intervals to avoid overdose, as methadone has a long half-life (reported to range from 13 to 47 hours).¹⁸ Note that some patients may require an increase in methadone dose frequency to twice daily.¹¹ If efavirenz or nevirapine is stopped, the methadone dose should be gradually reduced to pretreatment levels over the course of 1 to 2 weeks.¹⁷

The US manufacturers of delavirdine¹⁹ suggest that the methadone dose may need to be reduced; however, the effects in the study reported are small, and would not be expected to be of clinical significance.

mately 50% and 71%, respectively. **Delavirdine** 600 mg twice daily for 7 days caused a greater than fourfold increase in the buprenorphine AUC, but norbuprenorphine AUC was decreased by about 60%.¹ In this study buprenorphine did not alter the pharmacokinetics of **delavirdine** or **efavirenz**.¹

In a study in 50 opioid-dependent patients treated with sublingual buprenorphine/naloxone alone for at least 2 weeks and then additionally given an antiretroviral agent (**delavirdine**, **efavirenz**, **nefinavir**, **lopinavir/ritonavir**, or **ritonavir**) for 5 to 15 days investigated the effect of these drugs on QT interval. Buprenorphine/naloxone alone did not significantly alter the QT interval; however, when delavirdine and efavirenz were given there was a statistically, but probably not clinically, significant increase in the QT interval. The greatest increase in QTc intervals were seen in patients taking **delavirdine** 600 mg twice daily.²

Mechanism

Buprenorphine is a substrate for the cytochrome P450 isoenzyme CYP3A4 and inducers of CYP3A enzymes such as **efavirenz** would be expected to increase buprenorphine clearance, whereas **delavirdine**, which is an inhibitor of CYP3A, would be expected to reduce the CYP3A-mediated metabolism of buprenorphine to norbuprenorphine.

Importance and management

Despite the magnitude of the changes in buprenorphine levels seen with efavirenz and delavirdine, clinically significant consequences of these interactions (opioid withdrawal symptoms, cognitive effects and adverse effects) were not observed and it was suggested that dosage adjustments were not likely to be necessary.¹ However, the study was in HIV-negative subjects and it has been suggested that the interaction may be of significance in HIV-positive individuals.³ More clinical studies in HIV-positive patients are needed. Furthermore, the study showing QT-prolongation with these NNRTIs and buprenorphine suggest that some caution would be prudent.

The manufacturers predict that inhibitors of the cytochrome P450 isoenzyme CYP3A4 [such as delavirdine] may increase the exposure to buprenorphine.^{4–7} One manufacturer recommends close monitoring and possibly a dose reduction;⁷ halving the starting dose of buprenorphine has been suggested by another manufacturer for patients taking CYP3A4 inhibitors and receiving buprenorphine as a substitute for opioid dependence.⁴ However, the same manufacturer suggests that, since the magnitude of an inhibitory effect is unknown, such drug combinations should be avoided when buprenorphine is used parenterally or sublingually as a strong analgesic.^{5,6}

Opioids; Buprenorphine + NNRTIs

Preliminary evidence suggests that buprenorphine does not affect the antiretroviral efficacy or pharmacokinetics of delavirdine and efavirenz. Delavirdine may increase buprenorphine plasma levels and efavirenz may decrease buprenorphine levels, but the clinical significance has not been fully investigated. Delavirdine given with buprenorphine/naloxone has been shown to slightly prolong the QT interval.

Clinical evidence

A study in 20 opioid-dependent subjects taking **buprenorphine** with naloxone found that **efavirenz** 600 mg daily for 15 days decreased the AUC of buprenorphine and its metabolite, norbuprenorphine, by approxi-

Opioids + NSAIDs

Ketoprofen reduced morphine-associated respiratory depression, and did not alter morphine pharmacokinetics. Similarly, diclofenac did not alter morphine pharmacokinetics in one study. Improved pain relief and reduced adverse effects have been found when morphine was given with lornoxicam, ketoprofen, or ketorolac. However, in another, diclofenac slightly increased respiratory depression despite reducing morphine use, possibly because of persistent levels of an active metabolite of morphine. Diclofenac did not affect the pharmacokinetics or analgesic effects of codeine in healthy subjects. Intramuscular diclofenac did not affect the pharmacokinetics of methadone solution in cancer patients. Ibuprofen did not appear to interact

pharmacokinetically with oxycodone. No pharmacokinetic interaction occurred between meclonfenamate and dextropropoxyphene, and dextropropoxyphene did not alter sulindac plasma levels. A single case report describes marked respiratory depression in a man given buprenorphine when ketorolac was added. An isolated report describes grand mal seizures in a patient given diclofenac and pentazocine. For mention of other NSAIDs see 'coxibs', (p.179).

Clinical evidence, mechanism, importance and management

NSAIDs are often administered with opioids because they usually reduce the opioid requirements and some of the opioid-induced adverse effects.¹

Enhanced pain relief has been reported with various combinations including **dextromethorphan** with **ketorolac**² or **tenoxicam**,³ **oxycodone** with **ibuprofen**,⁴ and **tramadol** with **ketorolac**⁵ without increased adverse effects. See also 'coxibs', (p.179). However, cases of respiratory depression have been reported, see *Morphine* below. Myoclonus has been reported with high doses of morphine administered with NSAIDs, see 'Opioids; Morphine + Miscellaneous', p.190.

(a) Buprenorphine

A man underwent thoracotomy for carcinoma of the middle third of his oesophagus. An hour after transfer to the recovery ward he complained of severe pain at the operative site and was given epidural buprenorphine 150 micrograms (3 micrograms/kg), and 2 hours later intramuscular **ketorolac** 30 mg because of continued pain. During the next hour he became more drowsy, stopped obeying commands and his respiratory rate dropped to 6 breaths per minute. He recovered after 6 hours of mechanical ventilation. The authors of this report suggest that it may be necessary to use less buprenorphine in the presence of ketorolac to avoid the development of these respiratory depressant effects.⁶ This appears to be the only report of this possible interaction.

As with other opioids, NSAIDs such as **etodolac** have been used with buprenorphine to reduce the postoperative pain score without increasing side effects.⁷

(b) Codeine

A single 50-mg dose of **diclofenac sodium** did not have an important effect on the pharmacokinetics of a single 100-mg dose of codeine phosphate in a placebo-controlled crossover study in 12 healthy subjects. There was no effect on the metabolic clearance of morphine, and only a slight (about 5% to 10%) increase in the levels of glucuronide metabolites. In addition, **diclofenac** did not alter the analgesic effects of codeine as assessed in a cold pressor test (a test in which opioids, but not NSAIDs, are effective).⁸

These findings are in contrast to an earlier *in vitro* study by the same research group, which found that **diclofenac** markedly inhibited the glucuronidation of codeine in human liver tissue.⁹

Although this interaction perhaps requires confirmation in a multiple-dose study in a clinical setting, the findings in healthy subjects suggest that no special precautions are required during the concurrent use of **diclofenac** and codeine.

Single oral-dose studies in 24 healthy subjects showed that the bioavailability of both codeine phosphate 25 mg and **ibuprofen** 200 mg were unaffected by concurrent use.¹⁰

(c) Dextropropoxyphene (Propoxyphene)

In healthy subjects dextropropoxyphene 260 mg daily and **sodium meclonfenamate** 400 mg daily for a week was found to have no effect on the plasma levels of either drug.¹¹

The manufacturer of **sulindac** notes that dextropropoxyphene had no effect on the plasma levels of **sulindac** or its sulfide metabolite.¹²

(d) Methadone

Intramuscular **diclofenac** 75 mg twice daily given for 5 days with oral methadone solution every 8 hours had no effect on the AUC or maximum plasma levels of methadone in 16 patients with cancer pain.¹³ No special precautions would appear to be necessary during concurrent use.

(e) Morphine

An infusion of **ketoprofen** 1.5 mg/kg with morphine 100 micrograms/kg reduced the respiratory depression associated with morphine alone in 11

healthy subjects. There was no change in plasma morphine levels.¹⁴ Another study in 6 patients found that intramuscular **diclofenac** 75 mg twice daily for 5 days did not affect the half-life and AUC of oral morphine solution.¹⁵ Other studies have reported superior pain relief with morphine and NSAIDs e.g. **lornoxiam**,² **ketoprofen**,¹⁶ and **ketorolac**,¹⁷ with fewer adverse effects. See also 'coxibs', (p.179).

However, in contrast to these reports, a study in 7 patients on the first postoperative day after spinal surgery found that, although **diclofenac** 100 mg rectally reduced patient-controlled morphine consumption by 20%, respiratory rates were significantly lower after the **diclofenac**, and minimal at about 200 minutes. Levels of an active metabolite, morphine-6-glucuronide did not significantly decrease until 420 minutes.¹⁸

NSAIDs are frequently used with opioids because of their lack of respiratory depression and opioid-sparing effects. However, this study demonstrates that there may be a risk of respiratory depression and other adverse effects due to persistently high levels of morphine-6-glucuronide for a number of hours after receiving an NSAID. During this time period, patients should be more closely monitored.¹⁸

For mention of the suggestion that NSAIDs may increase the incidence of myoclonus with high-dose morphine, see 'Opioids; Morphine + Miscellaneous', p.190.

(f) Oxycodone

A study involving 23 healthy subjects found that the single-dose pharmacokinetics of **ibuprofen** 400 mg and oxycodone 5 mg were similar when given as monotherapy or in combination.¹⁹

(g) Pentazocine

A man with Buerger's disease had a grand mal seizure while watching television 2 hours after being given a single 50-mg suppository of **diclofenac**. He was also taking pentazocine 50 mg three times daily. He may possibly have had a previous seizure some months before after taking a single 100-mg slow-release **diclofenac** tablet.⁸ The reasons for this reaction are not known, but on rare occasions **diclofenac** alone has been associated with seizures (incidence said to be 1 in 100 000) and seizures have also been seen with pentazocine alone. It is not clear what part the disease itself, or watching television, had in the development of this adverse reaction.²⁰

No interaction between **diclofenac** and pentazocine is established, but be aware of this case if concurrent use is being considered, particularly in patients who are known to be seizure-prone.

Opioids + NSAIDs; Coxibs

Parecoxib had no effect on the pharmacokinetics of alfentanil or fentanyl, and celecoxib and rofecoxib appeared not to affect the pharmacokinetics of tramadol. Coxibs can reduce the perioperative opioid requirement, but adverse effects are not necessarily reduced.

Clinical evidence, mechanism, importance and management

(a) Pharmacokinetic studies

In a crossover study in 12 healthy subjects intravenous **parecoxib** 40 mg, given one hour before and 12 hours after an infusion of **alfentanil** 15 micrograms/kg or **fentanyl** 5 micrograms/kg, had no effect on the pharmacokinetics of these opioids.¹ Pupil diameter versus time curves were not affected by **parecoxib**. This interaction was investigated because both **valdecoxib** (the main metabolite of **parecoxib**) and **alfentanil** are substrates of the cytochrome P450 isoenzyme CYP3A4. The study suggests there should be no interaction during concurrent use. In a study in patients receiving stable doses of **celecoxib** or **rofecoxib**, the pharmacokinetics of **tramadol** (given with paracetamol) did not appear to be affected by the coxibs. **Tramadol** is metabolised by CYP2D6 and CYP3A4, but there appeared to be no difference in the clearance of tramadol given with **celecoxib** (potential to interact with CYP2D6 substrates and is itself metabolised in part by CYP3A4).²

(b) Pharmacodynamic studies

Many studies have reported reduced opioid requirements and reduced opioid-related adverse effects when coxibs including **celecoxib**,³ **parecoxib**,⁴ and **rofecoxib**⁵ are given perioperatively or postoperatively with various opioids including **hydrocodone**³ and **morphine**.⁵ The timing of the coxib administration appears to affect the opioid-induced analgesia and post-infusion increases in sensitivity to pain. One study in healthy subjects found that pretreatment with **parecoxib** increased the analgesic effects of a **remifentanyl** infusion and significantly diminished the increased sensitivity to pain after remifentanyl was withdrawn. Giving **parecoxib** at the start of the **remifentanyl** infusion did not alter its analgesic effects.⁶ In another study, patients given preoperative and postoperative rofecoxib, or placebo, found that rofecoxib reduced morphine requirements and pain scores. In another group of patients given placebo preoperatively and rofecoxib postoperatively, rofecoxib did not significantly affect morphine requirements or pain score at 24 hours after the operation compared to those given placebo pre- and postoperatively, but did show improvement at 48 hours and 72 hours after the operation. However, preoperative rofecoxib was considered to provide only moderate benefit and possibly offered little benefit over early postoperative administration.⁵

In a double-blind, placebo-controlled study in 72 patients undergoing laparoscopic cholecystectomy, oral **etoricoxib** 120 mg given 1.5 hours before surgery reduced the need for postoperative patient controlled analgesia (PCA) with **fentanyl**, but opioid-related adverse effects were not reduced.⁷ Furthermore, the safety of short-term perioperative use of coxibs has been questioned, as some studies have reported more adverse effects (including myocardial infarction, cardiac arrest, stroke, and pulmonary embolism) with **parecoxib** or **valdecoxib** compared with placebo.⁸

Opioids + Opioids

The concurrent use of two opioid agonists may have enhanced effects, although acute opioid tolerance may also occur. Opioids with mixed agonist/antagonist properties (e.g. buprenorphine, butorphanol, nalbuphine, pentazocine) may precipitate opioid withdrawal symptoms in patients taking pure opioid agonists (e.g. fentanyl, methadone, morphine).

Clinical evidence, mechanism, importance and management

Many of the opioids used clinically act primarily at μ receptors including **morphine**, **codeine**, **fentanyl**, **methadone** and **diamorphine**, but they often have pharmacological differences, and patients tolerant to one opioid can frequently be switched to another opioid (opioid rotation) at doses lower than predicted by relative potencies.¹ Studies *in animals* have found synergistic or additive effects between μ -opioids.¹ The majority of studies in patients have reported enhanced analgesic effects with opioid combinations,^{2,3} although combined opioids are not always beneficial;⁴ in some cases adverse effects were increased and acute opioid tolerance has also occurred.³ For example, a study in 69 patients who had undergone abdominal surgery and were receiving **morphine** found that the addition of a **tramadol** infusion was associated with improved patient-controlled analgesia and smaller **morphine** requirement with no increase in adverse effects.² However, another study found that the effects of this combination were less than additive.⁵ Furthermore, the incidence of dry mouth occurred more frequently and it was concluded that the use of two μ -opioid agonists in combination might only increase the number of adverse effects.⁵ Other studies have found that transdermal **fentanyl** reduced **morphine** requirements after hysterectomy^{6,7} without affecting sedation scores.⁶ However, the combination of **fentanyl** and **morphine** resulted in more pronounced respiratory depression than morphine alone.^{6,7} In contrast, in a study of 49 patients undergoing major abdominal surgery, relatively large doses of intraoperative **remifentanyl** (mean remifentanyl infusion rate 300 nanograms/kg per minute) was reported to almost double **morphine** requirements in the first 24 hours postoperatively. The results suggested that **remifentanyl** caused the development of acute opioid tolerance and excessive sensitivity to pain.⁸ Therefore, although some opioid combinations are useful, clinical studies are needed to ascertain benefits and safety of specific combinations.⁴

Opioids with mixed agonist/antagonist properties (e.g. **buprenorphine**, **butorphanol**, **nalbuphine**, **pentazocine**) may precipitate opioid withdrawal symptoms in patients taking pure opioid agonists such as **fentanyl**, **methadone** and **morphine** (see 'Table 6.1', (p.134), for a classification). An example of this occurred in a 60-year-old woman who was taking slow-release **morphine** 90 mg twice daily for cancer pain and was additionally given **nalbuphine** 30 mg intravenously in an ambulance following a fractured femur. She became agitated and experienced involuntary movements, tachycardia, hypertension and sweating (typical of opioid withdrawal). Her management was further complicated by resistance to intravenous **morphine**, necessitating a femoral nerve block. The agitation, which lasted for about 4 hours after she was given the nalbuphine, was controlled with lorazepam.⁹

Opioids + Phenothiazines

Chlorpromazine has been reported to increase the analgesic effect of pethidine, but increased respiratory depression, sedation, CNS toxicity and hypotension can also occur. Other phenothiazines such as levomepromazine, promethazine, prochlorperazine, propiomazine and thioridazine may also interact with pethidine to cause some of these effects. Additive CNS depressant effects would be expected when opioids are given with phenothiazines.

Clinical evidence

(a) Pethidine (Meperidine)

Chlorpromazine 25 mg/70 kg given alone had no consistent effect on respiratory function in 6 healthy subjects but the respiratory depression produced by pethidine 100 mg/70 kg was exacerbated when the two drugs were given together. One subject showed marked respiratory depression, beginning about 30 minutes after both drugs were given and lasting 2 hours.¹ No change in the pharmacokinetics of pethidine was found when **chlorpromazine** was given in a single-dose study in healthy subjects, but the excretion of the metabolites of pethidine was increased. The symptoms of light-headedness, dry mouth and lethargy were significantly increased and 4 subjects experienced such marked debilitation that they required assistance to continue the study. Systolic and diastolic blood pressures were also reduced.²

The respiratory depressant effects of pethidine can be increased by **promethazine** with pentobarbital,³ **propiomazine**^{4,5} and **levomepromazine**⁶, but the effects of **prochlorperazine**⁷ with pethidine on respiration were not statistically significant. A 12-year-old patient taking long-term **thioridazine** 50 mg twice daily, given premedication with pethidine, diphenhydramine and glycopyrrolate, was very lethargic after surgery and stopped breathing. He responded to naloxone.⁸ For the effects of promethazine see below.

(b) Other opioids

There have been conflicting data as to whether or not phenothiazines potentiate narcotic analgesia,⁹ and it has been suggested that some patients treated with an opioid and a phenothiazine are merely too sedated to report pain.¹⁰ However, some studies have shown that **promethazine** reduces opioid requirements. The maintenance doses of a variety of opioid analgesics (**morphine**, **pethidine**, **oxymorphone**, **hydromorphone**, **fentanyl**, **pentazocine**) required during surgical anaesthesia were reduced by 28% to 46% when 132 patients were premedicated with intramuscular **promethazine**, 50 mg/70 kg, when compared with control patients. Similarly, on-demand **pentazocine** requirements post-caesarean section were reduced by 32% in women given **promethazine** as soon as the cord was clamped.¹¹ In a randomised, placebo-controlled study in 90 patients undergoing abdominal hysterectomy, the preoperative use of intravenous **promethazine** 100 micrograms/kg (given over 30 minutes, starting 30 minutes before induction), reduced the 24-hour postoperative **morphine** consumption by about 30%, when compared with placebo or postoperative **promethazine** use. Postoperative nausea and vomiting was reduced by both pre- and postoperative **promethazine** compared with placebo.¹²

Mechanism

There is evidence that chlorpromazine can increase the activity of the liver microsomal enzymes so that the metabolism of pethidine to norpethidine and norpethidinic acid are increased. These metabolites are toxic and probably account for the lethargy and hypotension seen in one study.² The effects of the phenothiazines on pethidine-induced respiratory depression may be related. Both the opioids and the phenothiazines are CNS depressants, and their effects may be additive.

Importance and management

The manufacturers of many opioids note that they can enhance the hypotensive, sedative, and respiratory depressant effects of phenothiazines. Patients should be monitored carefully, and dosage reductions made if necessary. One manufacturer of **methadone** contraindicates the use of the injection, but not the oral solution, with other CNS depressants including phenothiazines.^{13,14} Although lower analgesic doses of pethidine have been used with chlorpromazine,¹⁵ a marked increase in respiratory depression can occur in some susceptible individuals¹ and the authors of one study² suggested that the risks of using the combination of pethidine with chlorpromazine outweighed the advantages. Information about other adverse interactions with pethidine and phenothiazines seems to be very limited: the interaction with thioridazine seems to be the only one reported. Increased analgesia may occur but it may be accompanied by increased respiratory depression, which is undesirable in patients with existing respiratory insufficiency. The US manufacturer suggests that the dose of pethidine should be proportionally reduced (usually by 25 to 50%) when it is given with phenothiazines.¹⁶

For mention of myoclonus associated with high doses of morphine and chlorpromazine, see 'Opioids; Morphine + Miscellaneous', p.190.

Opioids + Protease inhibitors

Ritonavir decreases pethidine (meperidine) and increases norpethidine levels, which may possibly increase toxicity on long-term use. Similarly, ritonavir and other protease inhibitors increase buprenorphine levels. Ritonavir may increase the metabolism of morphine, and decrease the metabolism of dextropropoxyphene (CYP3A4 substrate) and tramadol or other CYP2D6 substrates (such as codeine).

Clinical evidence

(a) Buprenorphine

One report describes 3 HIV-positive patients who experienced increased buprenorphine adverse effects (e.g. daytime sleepiness, dizziness, and reduced mental function) within about 2 days of starting to take **atazanavir** boosted by low-dose **ritonavir**. When the dose of buprenorphine was reduced there was a reduction in sedative symptoms within a week.¹

In a study in opioid-dependent patients treated with sublingual buprenorphine and naloxone, patients were given an antiretroviral (**nelfinavir**, **lopinavir/ritonavir**, or **ritonavir**) for 5 to 15 days to investigate the effect of these drugs on the QT interval. Buprenorphine/naloxone alone did not significantly alter the QT interval, but when combined with an antiretroviral there was a statistically, but probably not clinically, significant increase in the QT interval. The greatest increase in QTc interval was seen in patients receiving buprenorphine/naloxone with **ritonavir** 100 mg twice daily (low booster dose).²

(b) Pethidine (Meperidine)

Ritonavir 500 mg twice daily for 10 days decreased the AUC of a single 50-mg dose of oral pethidine by 62% and increased the AUC of norpethidine by 47% in 8 healthy subjects.^{3,4} Norpethidine is pharmacologically active, and is possibly less effective an analgesic than the parent compound, and more likely to cause CNS effects such as seizures.

Mechanism

In vitro and *in vivo* studies have demonstrated that ritonavir is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 and to a lesser extent CYP2D6, and may also induce glucuronidation.⁴ An *in vitro* study suggested that buprenorphine metabolism may be inhibited by **ritonavir** and to a lesser extent by **indinavir** and **saquinavir**,⁵ which would be expected to lead to increased buprenorphine levels. Other opioids metabolised by CYP3A4 include **dextropropoxyphene** (propoxyphene), 'fentanyl and related drugs', (below), and 'methadone', (p.182). Substrates of CYP2D6 include **codeine**, **dihydrocodeine**, **oxycodone**, and **tramadol**. Morphine undergoes glucuronidation, and the morphine metabolite M6G [morphine-6 beta-glucuronide] is believed to contribute to the analgesic effects of morphine. Buprenorphine, and to some extent, **codeine** also undergo glucuronidation.⁶

Importance and management

Most of these interactions remain theoretical, but they are consistent with the way the protease inhibitors and the opioids interact with other drugs. The consequences of inhibition of CYP2D6 are most pronounced for **codeine**, and CYP2D6 inhibition will lead to decreased levels of the morphine metabolite of codeine and therefore, perhaps contrary to expectation, a reduced effect. The levels of other CYP2D6 substrates **dihydrocodeine**, **oxycodone**, and **tramadol** would be expected to be raised, and dose reductions may be necessary. This has been suggested for tramadol.⁷ It would seem prudent to monitor for adverse effects such as sedation. However, note that *low-dose* ritonavir (i.e. the dose used as a pharmacokinetic enhancer with other protease inhibitors) has a less potent effect on CYP2D6 and dose reductions of drugs metabolised by CYP2D6 would not generally be required if this dose of ritonavir is given concurrently.⁸

Ritonavir is a potent inhibitor of CYP3A4 and therefore the UK manufacturer of ritonavir contraindicates its use with **dextropropoxyphene** as extremely raised dextropropoxyphene levels may occur, which would increase the risk of serious respiratory depression or other serious adverse events.⁴ However, the US manufacturer only suggests that a dose decrease may be needed.⁷

The outcome of taking ritonavir with **morphine** is less clear, but it is expected that its levels will be decreased.^{4,9} It would seem prudent to monitor closely to ensure morphine is effective in patients taking ritonavir. More study is needed.

It has been suggested that the starting dose of buprenorphine should be halved in patients taking CYP3A4 inhibitors, such as the protease inhibitors, when it is used for opioid dependence.¹⁰ However, it has also been suggested that, since the magnitude of an inhibitory effect is unknown, such drug combinations should be avoided when buprenorphine is used parenterally or sublingually as a strong analgesic.^{11,12}

The manufacturers of pethidine oral preparations and injection contraindicate or advise against its use with ritonavir because of the risk of norpethidine toxicity.^{13,14} Long-term use of pethidine with other protease inhibitors e.g. tipranavir, which are given with low-dose ritonavir is also not recommended.^{15,16}

Opioids; Fentanyl and related drugs + Protease inhibitors

Ritonavir markedly increases the levels of fentanyl, and markedly increases alfentanil-induced miosis. Other protease inhibitors such as nelfinavir may have a similar effect. Care should also be taken if ritonavir is used with other protease inhibitors as a pharmacokinetic enhancer.

Clinical evidence*(a) Alfentanil*

The miosis caused by oral and intravenous alfentanil was markedly increased by the short-term (1 to 3 days) and longer-term (14 days) use of **ritonavir** in healthy subjects.¹

(b) Fentanyl

Ritonavir 200 mg increased to 300 mg three times daily for a total of 7 doses increased the AUC of a single 5-mg/kg intravenous dose of fentanyl by 83%, decreased its clearance by 67%, and increased the elimination half-life twofold in healthy subjects.²

Mechanism

Both fentanyl and alfentanil are metabolised by the cytochrome P450 isoenzyme CYP3A4. Ritonavir, and other protease inhibitors, are potent inhibitors of CYP3A4 and they therefore reduce the metabolism of these opioids, which results in increased levels and effects.

Importance and management

The evidence is limited, but is consistent with the way protease inhibitors and fentanyl or alfentanil interact with other drugs. The UK manufacturer of alfentanil warns that potent CYP3A4 inhibitors such as ritonavir could increase the risk of prolonged or delayed respiratory depression, and says the combination should be used with special care, and that a reduced dose of alfentanil may be necessary.³ Similarly, caution is required in patients taking **ritonavir** given fentanyl by any route (oral, parenteral, or transdermal). In particular, the manufacturers suggest avoiding the combination of **ritonavir** and transdermal fentanyl, unless the patient is closely monitored.^{4,5} Fentanyl dose reductions may be needed on long-term treatment to avoid fentanyl accumulation.⁶ The US manufacturer also warns that other potent CYP3A4 inhibitors including **nelfinavir** may have a similar effect.⁵ In addition, the manufacturers of saquinavir warn that, although specific studies have not been performed, the use of **saquinavir** or **saquinavir** with **ritonavir** may raise the levels of fentanyl and alfentanil and therefore these combinations should be given with caution.^{7,8}

Opioids; Methadone + Protease inhibitors

Methadone serum levels can be reduced by amprenavir, nelfinavir, lopinavir/ritonavir, saquinavir/ritonavir, tipranavir/ritonavir, and possibly ritonavir. In addition, amprenavir levels may be reduced by methadone. No interaction appears to occur between methadone and indinavir, or possibly atazanavir or saquinavir, alone.

Clinical evidence

(a) Amprenavir

A study involving 16 opioid-dependent subjects found that amprenavir 1.2 g twice daily for 10 days decreased the AUCs for both *R*-methadone (active enantiomer) and *S*-methadone (inactive enantiomer) by 13% and 40%, respectively. No clinically significant changes were noted in opioid effects and there was no evidence of opioid withdrawal.¹ However, in another study methadone levels were reduced by 35% (range 28% to 87%) in 5 patients within 17 days of starting to take amprenavir 1.2 g twice daily and abacavir 600 mg twice daily. Two patients reported nausea before their daily methadone dose, which can be a sign of opiate withdrawal.² Note that 'abacavir', (p.175), may modestly reduce methadone levels, and could therefore have contributed to this effect.

The first study also found that amprenavir and methadone resulted in a 30% decrease in amprenavir AUC compared with non-matched historical controls.¹

(b) Atazanavir

Atazanavir, given for 14 days, had little effect on the steady-state pharmacokinetics of methadone in 16 patients treated for opiate addiction, and symptoms of opiate withdrawal or excess were not detected.³

(c) Indinavir

A randomised, crossover study in 12 patients taking methadone found that the pharmacokinetics of methadone were unchanged by indinavir 800 mg every 8 hours for 8 days. A small decrease in indinavir peak levels and a small increase in trough levels were noted, when compared with historical controls.⁴ Another study in 6 HIV-positive patients taking methadone and two nucleoside analogues similarly found that methadone serum levels remained unchanged when indinavir was added.^{5,6}

There are also clinical reports about 2 patients whose methadone levels appeared to be unaltered while taking indinavir, but who later had reduced levels when treated with nelfinavir or ritonavir (see (e) and (g) below).^{7,8} This would seem to confirm that indinavir does not have a clinically relevant effect on methadone levels.

(d) Lopinavir/ritonavir

A study in healthy subjects found that lopinavir/ritonavir 400 mg/100 mg twice daily for 10 days reduced the AUC of a single 5-mg dose of methadone by about 50%.⁹ Similarly, in 15 healthy subjects taking methadone lopinavir/ritonavir 400 mg/100 mg twice daily for 7 days decreased the AUC of methadone by 26% and increased its clearance by 42%. Four of the subjects had clinically important increases in opioid-withdrawal scores, and were all found to have subtherapeutic trough methadone levels.¹⁰ [Note that the same dose of ritonavir alone had no effect on methadone levels, see (f) below]. In another study in 8 HIV-positive patients taking methadone a lopinavir/ritonavir based antiretroviral regimen reduced the AUC of methadone by 36% after 14 days of treatment. However, none of these patients experienced methadone withdrawal during the study or during 6 weeks of follow-up.¹¹ In yet another study (that did not measure methadone levels), none of 18 patients experienced methadone withdrawal during the 28 days after starting lopinavir/ritonavir.¹²

In a further study, methadone appeared to have no effect on the pharmacokinetics of lopinavir or ritonavir (given as a combined preparation).¹³

(e) Nelfinavir

An HIV-positive man who had been taking methadone 100 mg daily for several years with indinavir 800 mg and zalcitabine 750 micrograms three times daily, developed opioid withdrawal symptoms within 6 weeks of starting to take stavudine and nelfinavir 750 mg three times daily. His methadone dosage was increased to 285 mg daily before therapeutic serum levels were achieved. When his antiretroviral treatment was withdrawn, his methadone dosage was successfully reduced to 125 mg daily.⁸ Two other patients taking nucleoside analogues had a 40 to 50% fall in

their serum methadone levels when nelfinavir was added.^{5,6} Similarly, in another study, 4 of 6 patients developed symptoms of methadone withdrawal within 5 to 7 days of starting nelfinavir-based therapy. The mean AUC of methadone was reduced by 56% and the subjects required a mean increase in methadone dose of 15%.¹⁴

The manufacturers of nelfinavir say that in a pharmacokinetic study nelfinavir reduced the concentrations of methadone by 47%.^{15,16} However, despite this reduction none of the subjects developed withdrawal symptoms, although due to the pharmacokinetic changes, it should be expected that some patients might experience withdrawal symptoms.¹⁵ A retrospective study of HIV-positive patients taking methadone reported that 5 out of 30 patients (17%) required methadone adjustments (mean 26 mg). The use of nelfinavir with methadone was effective and well tolerated.¹⁷

A patient receiving methadone experienced torsades de pointes after starting treatment with nelfinavir.¹⁸ Raised methadone levels are associated with QT-prolongation, and this case therefore suggests that nelfinavir raises methadone levels.

In a study looking at the levels of nelfinavir and its active metabolite M8, methadone had no significant effect on the AUC of nelfinavir, but the AUC₀₋₁₂ of M8 was reduced by 48%.¹⁹

(f) Ritonavir

A patient taking lamivudine and zidovudine had a marked decrease in methadone serum levels when ritonavir was added.^{5,6} Another patient receiving methadone experienced an opioid withdrawal syndrome when ritonavir was added to a similar antiretroviral regimen.²⁰

Ritonavir (dose not stated) was given to 11 healthy subjects for 14 days, with a single 5-mg dose of methadone on day 11. Ritonavir reduced the maximum serum levels of methadone by 37.8% and the AUC by 36.3%.²¹ However, in another study in 15 healthy subjects receiving methadone, ritonavir 100 mg twice daily for 7 days had no significant effect on methadone pharmacokinetics.¹⁰

In a further study, methadone apparently increased ritonavir exposure by 60%, when given alone, but had no effect on ritonavir pharmacokinetics when it was given with lopinavir.¹³

In healthy subjects the miosis caused by oral and intravenous methadone was increased by the acute use of ritonavir for 3 days but returned to below baseline after longer-term use for 14 days. It appeared that acute ritonavir inhibited, but chronic ritonavir mildly increased methadone elimination.²²

(g) Ritonavir/saquinavir

An HIV-positive patient taking methadone 90 mg daily with indinavir, lamivudine and zidovudine, developed withdrawal symptoms and was hospitalised within a week of stopping these HIV drugs and starting ritonavir 400 mg, saquinavir 400 mg and stavudine 40 mg twice daily. The patient was eventually re-stabilised taking methadone 130 mg daily.⁷

A later study in 12 HIV-positive subjects taking methadone maintenance found that ritonavir/saquinavir 400 mg/400 mg twice daily decreased the *S*-methadone AUC by 40% and the *R*-methadone AUC by 32%. However, when these decreases were corrected for changes in protein binding, the free *R*-methadone AUC was decreased by only 19.6%, and the free *S*-methadone AUC by 24.6%. None of the subjects experienced methadone withdrawal or required a change in their methadone dosage.²³ Similarly, in another study ritonavir/saquinavir 100 mg/1600 mg daily for 14 days caused no clinically relevant changes in total or free levels of either enantiomer of methadone in 12 HIV-negative subjects taking methadone. None of the subjects experienced methadone withdrawal.²⁴

(h) Saquinavir

A study in an HIV-positive patient taking methadone and two nucleoside analogues found that methadone serum levels remained unchanged when saquinavir was added.^{5,6}

(i) Tipranavir/ritonavir

The manufacturers of tipranavir state that use of methadone with tipranavir boosted by low-dose ritonavir (200 mg) can result in a decrease in methadone levels of about 50%, which may require dose increase in some patients.^{25,26}

Mechanism

Not known. The findings are the opposite of those originally predicted based on *in vitro* data showing *inhibition* of methadone metabolism (principally mediated by the cytochrome P450 isoenzyme CYP3A).²⁷ One study found a slight increase in methadone elimination,²² but this was not mediated by CYP3A. It is possible that these protease inhibitors induce the

activity of other isoenzymes or act via other mechanisms (e.g. glucuronyl-transferases). The reduction in methadone levels has not always correlated with clinical effects, and it has been suggested that this may be because the pharmacokinetics of the enantiomers (one of which is inactive) are affected differently, and/or altered protein binding occurs.¹⁹

Importance and management

Information is limited but the interactions with amprenavir, nelfinavir, lopinavir/ritonavir, saquinavir/ritonavir, tipranavir/ritonavir and probably ritonavir would appear to be established. However the picture seems to be that not all patients experience withdrawal symptoms if given these drugs. Therefore, in methadone-maintained patients, care should be taken if any of these protease inhibitors is started or stopped. It has been suggested that patients taking methadone who are given a protease inhibitor should be screened for opioid withdrawal beginning on the fourth day of the new medication. If symptoms develop, the methadone dose should be increased by 10 mg every 2 to 3 days until symptoms abate.²⁸ However, others have suggested dose increments should be made at one-week intervals to avoid overdose, as methadone has a long half-life (reported to range from 13 to 47 hours).¹⁸ If the protease inhibitor is stopped the methadone dose should be gradually reduced to pretreatment levels over the course of 1 to 2 weeks.²⁸

Indinavir appears not to interact with methadone, and very limited evidence suggests that atazanavir and saquinavir alone do not interact either.

Note that amprenavir plasma levels may also be reduced by methadone. The US manufacturer says that amprenavir may be less effective if taken concurrently with narcotic analgesics and alternative antiretroviral therapy should be considered.²⁹

Opioids + Quinidine

Quinidine appears to increase the oral absorption and effects of fentanyl, methadone, and morphine, but does not significantly alter the opioid-induced miosis when these opioids are given intravenously. Care should be taken if high-dose methadone is used with quinidine as cardiac conduction might possibly be affected.

Clinical evidence, mechanism, importance and management

(a) Fentanyl

Quinidine sulfate 600 mg given one hour before an infusion of fentanyl 2.5 micrograms/kg did not alter the fentanyl-induced miosis in healthy subjects. However, the same dose of quinidine given before oral fentanyl 2.5 micrograms/kg (with ondansetron as an antiemetic) did increase fentanyl-induced miosis. This increase was considered proportionate to the increase in the AUC of fentanyl (160%). There was no change in the elimination half-life of fentanyl.¹ It was suggested that quinidine inhibits the intestinal P-glycoprotein and so allows an increase in oral fentanyl absorption, and a consequent increase in its effects. The effects on miosis indicate that quinidine did not alter brain access of fentanyl.¹

The clinical importance of this finding to the use of buccal fentanyl citrate (of which a significant proportion is swallowed) remains to be determined, but be aware that effects may be increased.

(b) Hydromorphone

An *in vitro* study suggested that quinidine did not significantly affect the metabolism of hydromorphone to norhydromorphone. Hydromorphone appears to be mainly metabolised by CYP3A, and to a lesser extent CYP2C9, but the inhibition of CYP2D6 by quinidine does not appear to affect norhydromorphone formation.²

(c) Methadone

Quinidine sulfate 600 mg, given one hour before intravenous methadone hydrochloride 10 mg, did not alter methadone-induced miosis in healthy subjects. However, the same dose of quinidine given before oral methadone hydrochloride 10 mg (with ondansetron as an antiemetic) increased the peak methadone-induced miosis by 34% and increased the plasma levels of oral methadone in the absorption phase, but had no effect on the maximum plasma level or AUC of methadone.³ Methadone is primarily metabolised by CYP3A and quinidine does not affect the hepatic metabolism of methadone. However, quinidine can inhibit P-glycoprotein and this may affect methadone intestinal transport and absorption.³

The absorption of oral methadone may possibly be affected by quinidine, but the clinical relevance is not known. However, note that both high doses of methadone and quinidine can affect the QT interval, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

(d) Morphine

Quinidine sulfate 600 mg, given one hour before intravenous morphine sulfate 150 micrograms/kg, did not alter morphine-induced miosis in healthy subjects. However, the same dose of quinidine given before oral morphine sulfate 30 mg (with ondansetron as an antiemetic) increased morphine-induced miosis by 56%. This increase was considered proportionate to the increase in morphine AUC (60%) and maximum level (88%). There was no change in the elimination half-life of morphine.⁴ Similarly, in another study in healthy subjects, quinidine 800 mg, given one hour before intravenous morphine 7.5 mg did not alter the respiratory depressant nor mitotic effects of morphine, and there was no change in plasma morphine or morphine glucuronide levels.⁵

It was suggested that quinidine inhibits P-glycoprotein and so allows an increase in oral morphine absorption.⁴ In addition, the effects on miosis suggest that quinidine has no effect on the brain distribution of morphine.^{4,5}

The clinical importance of these findings remains to be determined, but it appears that quinidine may increase the effects of oral morphine.

(e) Tramadol

A placebo-controlled study in 12 healthy subjects found that quinidine 50 mg had virtually no effect on the analgesic effects of tramadol 100 mg but it inhibited its effect on pupil size.⁶ The manufacturers say that quinidine increases the tramadol AUC and maximum level by 25%, but this is within the normal pharmacokinetic variation seen with tramadol.⁷ Tramadol is partially metabolised to the active metabolite *O*-desmethyltramadol (which affects opioid receptors), by the cytochrome P450 isoenzyme CYP2D6, and it is this enzyme that is inhibited by quinidine. Blockade of the production of this metabolite appears to have little effect on the analgesic effect of tramadol.⁶ No special precautions seem to be needed.

Opioids; Codeine and related drugs + Quinidine

The analgesic effects of codeine, and probably also hydrocodone, are reduced or abolished by quinidine. Quinidine alters the pharmacokinetics of dihydrocodeine and oxycodone, but this does not appear to alter their effects.

Clinical evidence

(a) Codeine

Codeine 100 mg was given to 16 extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6 with and without a single 200-mg dose of quinidine. The quinidine reduced the peak morphine levels by about 80% (from a mean of 18 nanomol/L to less than 4 nanomol/L). Codeine given alone increased the pain threshold (pin-prick pain test using an argon laser) but no significant analgesic effects were detectable when quinidine was also present.¹ Another study found that the effects of codeine in extensive metabolisers of CYP2D6 who were given quinidine were virtually the same as codeine alone in poor metabolisers of CYP2D6.²

These studies confirm the preliminary findings of an earlier study using codeine 100 mg and quinidine 50 mg.³ The quinidine reduced the peak morphine plasma levels by more than 90% (by 92% in 7 extensive metabolisers, and by 97% in one poor metaboliser) and similarly abolished the analgesic effects.³

(b) Dihydrocodeine

A study in which 4 extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6 were given dihydrocodeine 40 or 60 mg found that when they were pretreated with quinidine 200 mg almost none of the morphinoid metabolites of dihydrocodeine normally present in the serum could be detected.⁴ The same authors found essentially the same results in a later study in 10 extensive metabolisers of CYP2D6 given dihydrocodeine 60 mg and quinidine 50 mg.⁵ However, a single-dose study involving 10 healthy subjects who were extensive metabolisers of CYP2D6 investigated the effect of quinidine on the visceral and somatic analgesic effects of dihydrocodeine and its metabolite, dihydromorphone. It was found that although quinidine reduced dihydromorphone plasma levels (by inhibition of CYP2D6 reducing the metabolism of dihydrocodeine to dihydromorphone), this did not result in diminished pain tolerance thresholds. This suggested that the metabolism of dihydrocodeine to dihydromorphone may not be clinically important for analgesia.⁶ Further study is needed.

(c) Hydrocodone

In a comparative study, 5 extensive metabolisers and 6 poor metabolisers of the cytochrome P450 isoenzyme CYP2D6 were given hydrocodone, and another 4 extensive metabolisers of CYP2D6 were given hydrocodone after pre-treatment with quinidine. The metabolism of the hydrocodone to its active metabolite hydromorphone was found to be high in the extensive metabolisers who described 'good opiate effects' but poor in the poor metabolisers and the extensive metabolisers pre-treated with quinidine who described 'poor opiate effects'.⁷ For the effect of quinidine on hydromorphone metabolism, see 'Opioids + Quinidine', p.183.

(d) Oxycodone

Quinidine, given as 200 mg 3 hours before and 100 mg 6 hours after a single 20-mg dose of oxycodone almost completely inhibited the formation of the metabolite, oxymorphone in 10 healthy extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6. Despite this, the psychomotor and subjective effects of oxycodone were not altered (note that analgesia was not assessed). The AUC of the metabolite noroxycodone was increased about 85%, and the oxycodone AUC was slightly increased by 13%.⁸ Similar results were found in the preliminary report of another study.⁹

Mechanism

The evidence available shows that the conversion of codeine, dihydrocodeine and hydrocodone to their active analgesic metabolites in the body (morphine, morphinoid metabolites and hydromorphone, respectively) probably depends upon the activity of the cytochrome P450 isoenzyme CYP2D6 in the liver. If this isoenzyme is inhibited by quinidine, these conversions largely fail to occur and the analgesic effects may be reduced or lost. This interaction is only likely to occur in extensive metabolisers, and not in poor metabolisers, who have minimal CYP2D6 activity and who therefore may only derive minimal benefit from analgesics such as codeine, whose principal pharmacological effect appears to depend on this metabolism.² However, one study in healthy subjects has suggested that the analgesic effect of dihydrocodeine does not necessarily depend on its systemic metabolism to dihydromorphone.⁶ Similarly, although quinidine also blocks conversion of oxycodone to oxymorphone, it appears that this is not important for the pharmacodynamic effects of this drug.

Importance and management

The interaction between codeine and quinidine is well established and clinically important. Codeine will be virtually ineffective as an analgesic in extensive metabolisers of CYP2D6 (most patients) taking quinidine. An alternative analgesic should be used (possibly dihydrocodeine, see below, or tramadol, see 'Opioids + Quinidine', p.183). No interaction would be expected in poor metabolisers (about 7% of Caucasians), but codeine is probably unlikely to be effective in these patients in any case. Whether the antitussive effects of codeine are similarly affected is not established, but it seems likely. Note that this interaction has been used clinically in an attempt to treat codeine dependence.¹⁰

The interaction of hydrocodone is less well established, but the evidence suggests that the analgesic effect will similarly be reduced or lost if quinidine is given. Further study is needed.

The available evidence suggests that the efficacy of dihydrocodeine, hydromorphone, or oxycodone may not be significantly affected by quinidine, but this needs confirmation.

Opioids + Rifampicin (Rifampin)

Rifampicin markedly increases the metabolism of codeine and morphine, and reduces their effects. Rifampicin dramatically reduced the effects of oxycodone in one patient.

Clinical evidence, mechanism, importance and management

(a) Codeine

A study in 9 extensive metabolisers and 6 poor metabolisers of the cytochrome P450 isoenzyme CYP2D6 found that after taking rifampicin 600 mg daily for 3 weeks, the metabolism of a single 120-mg oral dose of codeine phosphate was markedly increased in both phenotypes. The AUC of codeine was decreased by 79.4% in extensive metabolisers and 83.5% in poor metabolisers and in both the *N*-demethylation and glucuronidation metabolic pathways were induced. However, the *O*-demethylation of codeine (mediated by CYP2D6) was induced only in extensive metabolisers, and in these subjects there was a 56% reduction in the AUC of morphine (the main active metabolite of codeine), and a 173% increase in the AUC normorphine (another active metabolite). Note that morphine and its metabolites were not detected in poor metabolisers, either before or after rifampicin was given because the pathway that leads to these metabolites is deficient or absent in these subjects. Rifampicin reduced the respiratory and psychomotor effects of the codeine in extensive metabolisers, but not in poor metabolisers. In contrast, rifampicin did not alter the pupillary effect of codeine in extensive metabolisers, but decreased it in poor metabolisers. The clinically more relevant question of whether, and to what extent, the analgesic effects of the codeine were reduced by this interaction was not addressed by this study.¹ However, some reduction in effect might be expected. Therefore, if these drugs are used concurrently, be alert for the need to raise the codeine dosage. More study is needed.

(b) Morphine

In a randomised study, 10 healthy subjects were given a single 10-mg oral dose of morphine sulfate with rifampicin 600 mg daily. It was found that the rifampicin increased the clearance of the morphine by 49% and its analgesic effects (using a modified cold pressor test) were abolished.² The mechanism of this interaction is uncertain since morphine is principally metabolised by glucuronidation (see 'opioids', (p.133)), but the findings of this study could not be attributed to rifampicin induction of glucuronosyltransferases (UGTs).² Be alert for the need to use an increased dosage of morphine in patients taking rifampicin. More study is needed.

(c) Oxycodone

A 60-year-old man who was taking rifampicin as well as oxycodone had 3 consecutive negative urine oxycodone screens in a 2-month period, which would normally suggest that he was not taking the oxycodone. However, oxycodone metabolites were found in his urine confirming compliance with his medication. An interaction between rifampicin and oxycodone was suspected and his oxycodone dose was increased to optimise his pain control.³

Opioids; Fentanyl and related drugs + Rifampicin (Rifampin)

The serum levels and effects of transdermal fentanyl were decreased when one patient took rifampicin. Studies in healthy subjects have shown that the bioavailability of transmucosal fentanyl is reduced, and the clearance of intravenous alfentanil is markedly increased, by rifampicin.

Clinical evidence, mechanism, importance and management

(a) Alfentanil

A study in 9 healthy subjects found that when they were given intravenous alfentanil 20 micrograms/kg after taking rifampicin 600 mg orally for 5 days, alfentanil clearance was increased almost threefold.¹ This increased clearance probably occurs because rifampicin increases the activity of the cytochrome P450 isoenzyme CYP3A4 in the liver, which is concerned with the metabolism of alfentanil (see 'opioids', (p.133)). This study was primarily designed to investigate the role of CYP3A4 in the metabolism of alfentanil, but it also provides good evidence that alfentanil is likely to be much less effective in patients taking rifampicin. A much larger dose of alfentanil will almost certainly be needed.

(b) Fentanyl

A 61-year-old man with lung metastases was given transdermal fentanyl (1.67 mg patch every 3 days). Serum fentanyl levels were measured 48 and 72 hours after the first day of treatment were 0.9 and 0.77 nanograms/mL, respectively (within the reported minimal effective therapeutic range of 0.2 to 1.2 nanograms/mL). On day 5, due to insufficient pain control, the fentanyl patch was increased to 2.5 mg every 3 days. However, on day 7, oral rifampicin 300 mg daily, isoniazid and ethambutol were started for pulmonary tuberculosis. The following day severe pain developed and fentanyl serum levels 48 and 72 hours after treatment on day 8 were 0.53 and 0.21 nanograms/mL, respectively (i.e. in the presence of rifampicin a higher dose of fentanyl had led to lower levels). Even after the dose was titrated up to 7.5 mg every 3 days, the patient still complained of moderate pain and the fentanyl serum level 72 hours after treatment was only 0.69 nanograms/mL (i.e. less than the level achieved with the 1.67 mg dose).²

In a study in 12 healthy subjects, peak levels and maximum miosis after oral, transmucosal fentanyl 10 micrograms/kg were minimally affected by oral rifampicin 600 mg daily for 5 days, but the AUC of fentanyl was decreased by 63%; the AUC of its metabolite, norfentanyl, was increased by 73%, and the AUC_{0–10} of miosis was decreased by 54%.³

Fentanyl is metabolised by the cytochrome P450 isoenzyme CYP3A4 and rifampicin, a potent inducer of CYP3A4, appears to reduce its serum levels and pharmacological efficacy. Thus an increase in fentanyl dosage may be needed in patients taking rifampicin.²

Opioids; Methadone + Rifamycins

Serum methadone levels can be markedly reduced by rifampicin, and withdrawal symptoms have occurred in some patients. Rifabutin appears to interact similarly, but to a lesser extent.

Clinical evidence

(a) Rifabutin

A study in 24 HIV-positive patients taking methadone found that after taking rifabutin 300 mg daily for 13 days the pharmacokinetics of the methadone were minimally changed. However 75% of the patients reported at least one mild symptom of methadone withdrawal, but this was not enough for any of them to withdraw from the study. Only 3 of them asked for and received an increase in their methadone dosage. The authors offered the opinion that over-reporting of withdrawal symptoms was likely to be due to the warnings that the patients had received.¹

(b) Rifampicin

The observation that former diamorphine (heroin) addicts taking methadone complained of withdrawal symptoms when given rifampicin, prompted a study² in 30 patients taking methadone. Withdrawal symptoms developed in 21 of the 30 within 1 to 33 days of starting rifampicin 600 to 900 mg daily and isoniazid daily. In 6 of the 7 most severely affected, the symptoms developed within a week, and their plasma methadone

levels fell by 33 to 68%. Of 56 other patients taking methadone with other antitubercular treatment (which included isoniazid but not rifampicin), none developed withdrawal symptoms.²⁻⁴

Other cases of this interaction have been reported.⁵⁻⁹ Some patients needed two to threefold increases in the methadone dosage while taking rifampicin to control the withdrawal symptoms.^{6,7,9}

Mechanism

Rifampicin is a potent enzyme-inducer, which increases the activity of the intestinal and liver enzymes concerned with the metabolism of methadone, resulting in a marked decrease in its levels.¹⁰ In 4 patients in the study cited, the urinary excretion of the major metabolite of methadone rose by 150%.² Rifabutin has only a small enzyme-inducing effect and therefore the effects are not as great.

Importance and management

The interaction between methadone and rifampicin is established, adequately documented and of clinical importance. The incidence is high. Two-thirds (21) of the narcotic-dependent patients in one study² developed this interaction, 14 of whom were able to continue treatment. Withdrawal symptoms may develop within 24 hours. The analgesic effects of methadone would also be expected to be reduced. Concurrent use need not be avoided, but the effects should be monitored and appropriate dosage increases (as much as two to threefold) made where necessary.

Rifabutin appears to interact to a very much lesser extent so that fewer, if any, patients are likely to need a methadone dosage increase.

(a) Codeine

The metabolism of a single 25-mg dose of codeine did not differ between 9 heavy smokers (greater than 20 cigarettes daily) and 9 non-smoking control subjects, except that smokers had a slightly higher rate of codeine glucuronidation.³ This is unlikely to be clinically important. Another study found no clinically important differences in the systemic availability of single 60-mg oral or intramuscular doses of codeine between 10 smokers and 12 non-smokers. There was no significant difference in the plasma half-life of codeine or in the conversion of codeine to morphine, however, there was a slightly higher plasma clearance of codeine in smokers than in non-smokers.⁴ No differences in the efficacy of codeine are expected between smokers and non-smokers.

(b) Dextropropoxyphene (Propoxyphene)

A study in 835 patients who were given dextropropoxyphene for mild or moderate pain or headache found that its efficacy as an analgesic was decreased by smoking. The drug was rated as ineffective in about 10% of 335 non-smokers, 15% of 347 patients who smoked up to 20 cigarettes daily, and 20% of 153 patients who smoked more than 20 cigarettes daily.⁵

(c) Morphine

A study in 7 women during acute post-caesarean recovery found that intravenous morphine use (as patient-controlled analgesia; PCA), was significantly higher in smokers compared with non-smokers: weight-adjusted morphine use was 1.8 mg/kg per 24 hours compared with 0.64 mg/kg per 24 hours, respectively. It was suggested that a history of nicotine use and/or short-term nicotine abstinence could modulate morphine use and analgesia during postoperative recovery.⁶ Similarly, another retrospective study found increased morphine PCA requirements in smokers compared with non-smokers.⁷

(d) Pentazocine

A study in which pentazocine was used to supplement nitrous oxide relaxant anaesthesia found that patients who came from an urban environment needed about 50% more pentazocine than those who lived in the country (3.6 micrograms/kg per minute compared with 2.4 micrograms/kg per minute). Roughly the same difference was seen between those who smoked and those who did not (3.8 micrograms/kg per minute compared with 2.5 micrograms/kg per minute).⁸ In another study it was found that pentazocine metabolism was 40% higher in smokers than in non-smokers.⁹

Mechanism

It is thought that tobacco smoke contains compounds that increase the activity of the liver enzymes concerned with the metabolism of dextropropoxyphene, pentazocine and other opioids, which increases their metabolism, decreases their levels and diminishes their effectiveness as analgesics.^{2,5} However, former smokers have also been found to have increased opioid requirements and it has been suggested that smoking might have an effect on pain perception and/or opioid response, or that nicotine addiction and opioid requirements may be genetically linked.²

Importance and management

The interaction appears to be well established. Prescribers should be aware that smokers may require a greater amount of opioids postoperatively than non-smokers. In contrast, codeine metabolism does not appear to be affected to a clinically important extent by smoking.

Opioids + Tobacco

Smokers who discontinue smoking appear to require more opioid analgesics for postoperative pain control than non-smokers; this has been seen with both fentanyl and morphine patient controlled analgesia. Atmospheric pollution has a similar effect on pentazocine. Codeine metabolism was not affected to a clinically relevant extent by smoking in one study.

Clinical evidence

A retrospective study of coronary artery bypass graft patients found that 20 patients who had abruptly discontinued smoking prior to surgery required more postoperative opioid analgesics than 69 non-smokers. The opioid analgesics included dextropropoxyphene (propoxyphene), fentanyl, hydrocodone, oxycodone, morphine, nalbuphine and pethidine (meperidine), but the most commonly used postoperative opioid analgesic was fentanyl (used in approximately two-thirds of the patients) given by patient controlled analgesia (PCA). Smokers deprived of nicotine had an increase in opioid requirement (converted to morphine equivalents), during the first 48 hours after surgery, ranging from 29 to 33% (when normalised for body weight or body mass index).¹ Similarly, another retrospective study in 171 women found that average postoperative narcotic use (expressed as equivalent doses of morphine) was 10.9 mg/12 hours for patients who had never smoked, 13 mg/12 hours for former smokers, and 13.1 mg/12 hours for current smokers.²

Opioids + Tricyclic and related antidepressants

In general, the concurrent use of most opioids and tricyclics is uneventful, although lethargy, sedation, and respiratory depression have been reported. Tramadol should be used with caution with tricyclic antidepressants because of the possible risk of seizures and the serotonin syndrome. Dextropropoxyphene may cause moderate rises in the serum levels of amitriptyline and nortriptyline, and methadone may moderately raise desipramine levels. The bioavailability and the degree of analgesia of oral morphine is increased by clomipramine, desipramine and possibly amitriptyline.

Clinical evidence

(a) Buprenorphine

A study in 12 healthy subjects found that both sublingual buprenorphine 400 micrograms and oral amitriptyline 50 mg impaired the performance of a number of psychomotor tests (digit symbol substitution, flicker fusion, Maddox wing, hand-to-eye coordination, reactive skills), and the subjects felt drowsy, feeble, mentally slow and muzzy. When amitriptyline 30 mg, increased to 75 mg daily was given for 4 days before a single dose of buprenorphine, the psychomotor effects were not significantly increased, but the respiratory depressant effects of the buprenorphine were enhanced.¹

(b) Dextropropoxyphene (Propoxyphene)

An elderly man taking doxepin 150 mg daily developed lethargy and daytime sedation when he started to take dextropropoxyphene 65 mg every 6 hours. His plasma doxepin levels rose by almost 150% (from 20 to 48.5 nanograms/mL) and desmethyldoxepin levels were similarly increased (from 8.8 to 20.7 nanograms/mL).²

The amitriptyline concentration/dose ratio in 12 patients given amitriptyline and dextropropoxyphene was raised by about 20% (suggesting raised amitriptyline levels), when compared with other patients taking amitriptyline alone. Similarly, the plasma levels of the amitriptyline metabolite nortriptyline was raised by about 30% in 14 patients given dextropropoxyphene;³ and in another study nortriptyline plasma levels were raised by 16% by dextropropoxyphene.³

Fifteen patients with rheumatoid arthritis given a single 25-mg dose of amitriptyline and dextropropoxyphene (up to 65 mg three times daily) experienced some drowsiness and mental slowness. They complained of being clumsier and had more pain, but these effects were said to be mild.⁴

(c) Methadone

The mean serum levels of desipramine 2.5 mg/kg daily were approximately doubled in 5 men who took methadone 500 micrograms/kg daily for 2 weeks. Previous observations in patients given both drugs had shown that desipramine levels were higher than expected and adverse effects developed at relatively low doses.⁵ Further evidence of an increase in plasma desipramine levels due to methadone is described in another study.⁶

(d) Morphine

Clomipramine or amitriptyline, in doses of 20 or 50 mg daily, increased the AUC of oral morphine by 28 to 111% in 24 patients with cancer pain. The half-life of morphine was also prolonged.⁷ A previous study⁸ found that desipramine, but not amitriptyline, increased and prolonged morphine analgesia, and a later study by the same group confirmed the value of desipramine.⁹

(e) Oxycodone

Pretreatment with amitriptyline 10 mg increased to 50 mg daily for 4 days caused no major changes in the psychomotor effects of a single 280-microgram/kg oral dose of oxycodone in 9 healthy subjects.¹⁰ Respiratory effects were not assessed.

(f) Pentazocine

Both pentazocine and amitriptyline given alone caused 11 healthy subjects to feel drowsy, muzzy and clumsy, and reduced the performance of a number of psychomotor tests. However, when the same subjects were

given intramuscular pentazocine 30 mg after taking amitriptyline 50 mg daily for a week, the combination of drugs appeared not to impair driving or occupational skills more than either drug given alone.¹¹ Respiratory depression was increased more by the combination than either drug alone. Amitriptyline modestly decreased pentazocine plasma levels by about 20% at 1.5 and 3.5 hours.¹¹

(g) Tramadol

The CSM in the UK has publicised 27 reports of convulsions and one of worsening epilepsy with tramadol, a reporting rate of 1 in 7000 patients. Some of the patients were given doses well in excess of those recommended, and 8 patients were also taking tricyclic antidepressants, which are known to reduce the convulsive threshold.¹² Similarly, the FDA in the US has received 124 reports of seizures associated with tramadol, 28 of which included the concurrent use of tricyclic antidepressants,¹³ and the Australian Adverse Drug Reaction Advisory Committee (ADRAC) has received 26 cases of convulsions associated with tramadol, some of which included the concurrent use of tricyclic antidepressants.¹⁴ ADRAC have also received reports of the serotonin syndrome, which were associated with the use of tramadol and tricyclic antidepressants.¹⁴ Furthermore two case reports suggest that tramadol may have contributed to the development of the serotonin syndrome, one in a patient abusing tramadol, moclobemide and clomipramine,¹⁵ and the other in a 79-year-old patient taking morphine (MST), co-proxamol (dextropropoxyphene with paracetamol) and amitriptyline, after she started to take tramadol.^{16,17} In both of these cases the patient died. For this reason tramadol should be used with caution with tricyclic antidepressants.

Similarly, seizures and the serotonin syndrome have been reported in a woman who took mirtazapine with tramadol, but this may have been due to over-use of the tramadol rather than an interaction.¹⁸ Lethargy, confusion, hypotension, bronchospasm and hypoxia has also been seen following the use of tramadol and mirtazapine, which resolved within hours of both drugs being stopped.¹⁹

Mechanism

The CNS depressant effects of opioids and the tricyclic antidepressants are expected to be additive. The reasons for the increased morphine levels and analgesic effects that occur with some tricyclics are not understood. The increased analgesia may be due not only to the increased serum levels of morphine, but possibly also to some alteration in the way the morphine affects its receptors. Dextropropoxyphene probably inhibits liver metabolism of some tricyclic antidepressants³ by inhibiting the activity of the cytochrome P450 isoenzyme CYP2D6, and as a result the serum levels of the tricyclic antidepressants rise. It is suggested that the methadone may possibly inhibit the hydroxylation of the desipramine, thereby raising its levels.⁶

Importance and management

The majority of the evidence, and general clinical experience suggests that, in most cases, the use of opioids with tricyclic antidepressants is uneventful. Furthermore, limited evidence suggests that concurrent use may be beneficial in pain management. However, the CNS depressant effects of both these classes of drugs should be considered when prescribing the combination, especially as there is some evidence to suggest that the respiratory depressant effects are increased: this may be clinically important in patients with a restricted respiratory capacity.¹¹ Certain opioids appear to have a greater propensity to interact. Both tramadol and the tricyclics can lower the seizure threshold and cause the serotonin syndrome. Therefore particular caution is warranted with this combination, especially in epileptic patients or those taking other drugs that affect serotonin. Mirtazapine appears to interact in the same way as the tricyclics. Be aware that as dextropropoxyphene and methadone may raise tricyclic levels: however, the general clinical significance of these interactions is uncertain but be alert for any evidence of increased CNS depression and increased tricyclic antidepressant adverse effects. In this context it is worth noting that one study reported that the incidence of hip fractures in the elderly was found to be increased by a factor of 1.6 in those taking dextropropoxyphene, and further increased to 2.6 when antidepressants, benzodiazepines or antipsychotics were added.²⁰

For mention of the suggestion that antidepressants and antipsychotics may increase the incidence of myoclonus with high-dose morphine, see 'Opioids; Morphine + Miscellaneous', p.190.

Opioids + Urinary acidifiers or alkalinisers

Urinary methadone clearance is increased if the urine is made acid (e.g. by giving ammonium chloride) and reduced if it is made alkaline (e.g. by giving sodium bicarbonate). The urinary clearance of dextropropoxyphene (propoxyphene) and pethidine (meperidine) may also be increased by acidification of the urine.

Clinical evidence

(a) Dextropropoxyphene (Propoxyphene)

A study in 6 healthy subjects found that the cumulative 72-hour urinary excretion of unchanged dextropropoxyphene was increased sixfold by acidification of the urine with oral **ammonium chloride** and reduced by 95% by alkalinisation with **sodium bicarbonate**; the half-life of dextropropoxyphene was also shortened by ammonium chloride. The excretion of the active metabolite norpropoxyphene was much less dependent on urinary pH. However, the cumulative excretion of dextropropoxyphene and norpropoxyphene, even into acidic urine, accounted for less than 25% of the dose during 72 hours.¹

(b) Methadone

A study in patients taking methadone found that the urinary clearance in those with urinary pHs of less than 6 was greater than those with higher urinary pHs.² When the urinary pH of one subject was lowered from 6.2 to 5.5, the loss of unchanged methadone in the urine was nearly doubled.³

A pharmacokinetic study in 5 healthy subjects given a 10-mg intramuscular dose of methadone found that the plasma half-life was 19.5 hours when the urine was made acidic (pH 5.2) with **ammonium chloride**, compared with 42.1 hours when the urine was made alkaline (pH 7.8) with **sodium bicarbonate**. The clearance of the methadone fell from 134 to 91.9 mL/minute when the urine was changed from acidic to alkaline.⁴

For isolated reports of respiratory depression when cimetidine or ranitidine were given with opioids, see 'H₂-receptor antagonists', (p.171).

(c) Pethidine (Meperidine)

A study in 6 healthy subjects given intravenous pethidine 21.75 mg found that urinary acidification with **ammonium chloride** increased the 48-hour urinary recovery of pethidine and norpethidine from about 7% and 12%, respectively, with no control of urinary pH, to about 20% and 24%, respectively. Urinary alkalinisation reduced the urinary recovery of pethidine and norpethidine to less than 1% and 7%, respectively. These pronounced effects had negligible effects on the blood concentration/time profiles.⁵ A study in 10 healthy Chinese subjects given intravenous pethidine 150 micrograms/kg found large variations in the 48-hour urinary recovery of pethidine and norpethidine depending on urinary pH; mean urinary recovery values under acidic conditions were 24.3% and 33.0%, respectively, and under alkaline conditions were 0.4% and 3.8%, respectively. The bioavailability was slightly lower under acidic urinary conditions due to the greater renal clearance of the drug.⁶

Mechanism

Methadone is eliminated from the body both by liver metabolism and excretion of unchanged methadone in the urine. Above pH 6 the urinary excretion is less important, but with urinary pH below 6 the half-life becomes dependent on both excretion (30%) and metabolism (70%).^{3,4,7} Methadone is a weak base (pKa 8.4) so that in acidic urine little of the drug is in the un-ionised form and little is reabsorbed by simple passive diffusion. On the other hand, in alkaline solution most of the drug is in the un-ionised form, which is readily reabsorbed by the kidney tubules, and little is lost in the urine.

Acidification of the urine may also increase the renal clearance of unchanged pethidine and norpethidine again probably due to reduced reabsorption in the renal tubule.⁶ Dextropropoxyphene appears to be similarly affected.

Importance and management

The effect of urinary pH on the clearance of methadone is an established interaction, but of uncertain importance. Be alert for any evidence of reduced methadone effects in patients whose urine becomes acidic because they are taking large doses of ammonium chloride. Lowering the urinary pH to 5 with ammonium chloride to increase the clearance can also be used to treat toxicity. Theoretically, urinary alkalinisers such as sodium bicarbonate and **acetazolamide** may increase the effect of methadone.

Similarly, the urinary clearance of dextropropoxyphene and pethidine appear to be increased to some extent by acidification of the urine, although their bioavailabilities do not appear to be significantly affected and the clinical effect is probably small. However, be aware of the potential for increased urinary excretion.

Opioids; Alfentanil + Reserpine

An isolated report describes ventricular arrhythmias when a patient taking reserpine was given alfentanil during anaesthesia.

Clinical evidence, mechanism, importance and management

A hypertensive woman taking reserpine 250 micrograms daily was given intravenous alfentanil 800 micrograms over 5 minutes, before anaesthesia with thiopental and suxamethonium (succinylcholine). During surgery she was given nine 100-microgram doses of alfentanil and 70% N₂O/O₂. Bradycardia developed and frequent unifocal premature ventricular con-

tractions occurred throughout the surgery, but they disappeared 3 to 4 hours afterwards. The arrhythmia was attributed to an interaction between reserpine and alfentanil, but just why this should occur is not understood.¹

1. Jahr JS, Weber S. Ventricular dysrhythmias following an alfentanil anesthetic in a patient on reserpine for hypertension. *Acta Anaesthesiol Scand* (1991) 35, 788–9.

Opioids; Alfentanil + Terbinafine

Terbinafine 250 mg daily for 3 days had no statistically significant effect on alfentanil pharmacokinetics and no adverse effects were reported.¹

1. Saari TI, Laine K, Leino K, Valtonen M, Neuvonen PJ, Olkkola KT. Voriconazole, but not terbinafine, markedly reduces alfentanil clearance and prolongs its half-life. *Clin Pharmacol Ther* (2006) 80, 502–8.

Opioids; Codeine + Kaolin

An isolated report describes patients suffering from chronic diarrhoea, who were stabilised taking codeine phosphate, but who experienced a relapse when the codeine was added to *Kaolin Mixture*. An *in vitro* study suggested the bioavailability of codeine may be reduced by adsorption onto kaolin.¹

1. Yu SKS, Oppenheim RC, Stewart NF. Codeine phosphate adsorbed by kaolin. *Aust J Pharm* (1976) 57, 468.

Opioids; Codeine + Somatostatin analogues

Lanreotide and octreotide partially inhibit the metabolism of codeine, which may possibly reduce its analgesic effects.

Clinical evidence, mechanism, importance and management

A study in 6 patients with gastrointestinal carcinoid tumours found that **lanreotide** or **octreotide** 750 micrograms subcutaneously three times daily for 3 days decreased the partial metabolic clearance of **codeine** by *N*-demethylation (by the cytochrome P450 isoenzyme CYP3A) by an average of 44% and the *O*-demethylation (by CYP2D6) by 35%. However, the partial clearance by 6-glucuronidation and the total systemic clearance of **codeine** were not consistently changed. The effects of the somatostatins were thought to be mediated by a suppression of growth hormone secretion. The reduction in *O*-demethylation can reduce the active metabolite of codeine, morphine, which could reduce the analgesic effect of the drug.¹

Opioids; Dextropropoxyphene (Propoxyphene) + Orphenadrine

An alleged adverse interaction between dextropropoxyphene and orphenadrine, which is said to cause mental confusion, anxiety, and tremors, seems to be very rare, if indeed it ever occurs.

Clinical evidence, mechanism, importance and management

The manufacturers of orphenadrine used to state in their package insert that mental confusion, anxiety and tremors have been reported in patients receiving both orphenadrine and dextropropoxyphene. The manufacturers of dextropropoxyphene issued a similar warning. However, in correspondence with both manufacturers, two investigators¹ of this interaction were told that the basis of these statements consisted of 6 anecdotal reports from clinicians to one manufacturer and 7 to the other (some could represent the same cases). Of the 7 cases to one manufacturer, 4 occurred where patients had received twice the recommended dose of orphenadrine. In every case the adverse reactions seen were similar to those reported with either drug alone. A brief study in 5 patients given both drugs to investigate this al-

leged interaction failed to reveal an adverse interaction.² One case has been reported separately.³

The documentation is therefore sparse, and no case of interaction has been firmly established. The investigators calculated that the two drugs were probably being used together on 300 000 prescriptions a year, and that these few cases would be less than significant.¹ There seems therefore little reason for avoiding concurrent use.

Opioids; Diamorphine + Pyrithyldione

A single case report describes a fatality due to the combined CNS depressant effects of diamorphine and pyrithyldione.

Clinical evidence, mechanism, importance and management

A diamorphine (heroin) addict was found dead after taking pyrithyldione (a sedative and hypnotic) with diamorphine. His blood pyrithyldione and brain morphine levels were found to be 590 nanograms/mL and 0.06 nanograms/g respectively, suggesting that he had taken only a therapeutic dose of the pyrithyldione and a moderate dose of diamorphine. The presumed cause of death was the combined CNS depressant effects of both drugs. The authors of the report draw the conclusion that the pyrithyldione potentiated the effects of the diamorphine.¹

Opioids; Levacetylmethadol + Miscellaneous

Levacetylmethadol has been withdrawn in Europe and the USA because of cases of life-threatening cardiac arrhythmias associated with QT prolongation.^{1,2} Its use was contraindicated with MAOIs and drugs that prolong the QT interval.^{3,4} In addition, the manufacturers warned about the possible effects of inducers or inhibitors of the cytochrome P450 isoenzyme CYP3A4, which may increase or reduce its activity, respectively;^{3,5} the additive effects of alcohol or other CNS depressants; and the possible risk of oral contraceptive failure.³ They also advised the avoidance of pethidine (meperidine), dextropropoxyphene (propoxyphene) or naloxone (except when used for overdose).³

Opioids; Methadone + Ciprofloxacin

An isolated case describes sedation, confusion and respiratory depression, which was attributed to the inhibition of methadone metabolism by ciprofloxacin.

Clinical evidence

A woman taking methadone 140 mg daily for 6 years to manage pain due to chronic intestinal pseudo-obstruction was admitted to hospital because of a urinary tract infection and given ciprofloxacin 750 mg twice daily. Two days later she became sedated and confused. Ciprofloxacin was replaced with co-trimoxazole and the patient recovered within 48 hours. She was treated with ciprofloxacin for recurrent urinary-tract infections a further three times and on each occasion the patient became sedated, with her normal alertness regained on discontinuing ciprofloxacin. On the last oc-

casation, when the venlafaxine that she had also been taking was replaced by fluoxetine, she also developed respiratory depression, which was reversed with naloxone.¹

Mechanism

The cytochrome P450 isoenzymes CYP1A2, CYP2D6 and CYP3A4 are involved in the metabolism of methadone. Ciprofloxacin is a potent inhibitor of CYP1A2 and possibly has some effect on CYP3A4. It is therefore probable that the confusion and sedation seen in the patient were due to the inhibition of methadone metabolism. The use of 'fluoxetine', (p.1221) and the fact that the patient was a smoker, may also have contributed.

Importance and management

This seems to be the only report of this interaction but it would appear to be of clinical importance. Care is needed if ciprofloxacin and methadone are given concurrently, especially if there are other factors such as smoking or the use of other enzyme inhibitors, which may also contribute to the interaction. Be alert for the need to change the methadone dosage. Consider also 'Quinolones + Opioids', p.338.

- Herrlin K, Segerdahl M, Gustafsson LL, Kalso E. Methadone, ciprofloxacin, and adverse drug reactions. *Lancet* (2000) 356, 2069–70.

Opioids; Methadone + Disulfiram

No adverse interaction was seen when patients taking methadone were given disulfiram.

Clinical evidence, mechanism, importance and management

Seven opioid addicts, without chronic alcoholism or liver disease, and who were receiving methadone maintenance treatment (45 to 65 mg daily) had an increase in the urinary excretion of the major pyrrolidine metabolite of methadone (an indicator of increased *N*-demethylation) when given disulfiram 500 mg daily for 7 days. However, there was no effect on the degree of opioid intoxication, nor were withdrawal symptoms experienced.¹ No special precautions would seem to be necessary if both drugs are given.

- Tong TG, Benowitz NL, Kreek MJ. Methadone-disulfiram interaction during methadone maintenance. *J Clin Pharmacol* (1980) 20, 506–13.

Opioids; Methadone + Fusidic acid

There is evidence that long-term fusidic acid may modestly reduce the effects of methadone.

Clinical evidence, mechanism, importance and management

A drug abuser with AIDS needed an increase in his levomethadone (*R*-methadone) dosage from 60 to 80 mg daily within 6 months of starting to take fusidic acid 1.5 g daily.¹ The patient showed evidence of liver enzyme induction (using antipyrine as a marker), from which it was concluded that fusidic acid increases the metabolism and loss of methadone from the body.¹ A subsequent study confirmed that fusidic acid 500 mg daily for 28 days increased antipyrine clearance in 10 patients taking levomethadone, and some of them developed clinical signs of underdosage. In contrast, fusidic acid 500 mg daily for 14 days had no effect in another 10 patients taking levomethadone.²

Information appears to be limited to these reports. Bear them in mind in the event of any unexpected reduction in efficacy of methadone in a patient taking long-term fusidic acid.

Opioids; Morphine + Miscellaneous

Some limited evidence suggests that antidepressants, antipsychotics, NSAIDs and thiethylperazine may increase the myoclonus caused by high doses of morphine.

Clinical evidence, mechanism, importance and management

In 19 patients with malignant disease taking high doses of morphine (daily doses of 500 mg or more orally or 250 mg or more parenterally), an analysis was made of the relationship between myoclonus and the use of supplemental drugs. In the 12 patients with myoclonus, 8 patients were taking antidepressants (**amitriptyline, doxepin**) or antipsychotics (**chlorpromazine, haloperidol**) compared with none of 6 patients without myoclonus. In addition, there was a higher use of NSAIDs (**indometacin, naproxen, piroxicam, aspirin**) and an antiemetic (**thiethylperazine**).¹ The reasons are not understood, and the findings of this paper have been questioned.²

Opioids; Pethidine (Meperidine) + Aciclovir

An isolated report describes pethidine toxicity associated with the use of high-dose aciclovir.

Clinical evidence, mechanism, importance and management

A man with Hodgkin's disease was treated with high-dose intravenous aciclovir for localised herpes zoster, and with intramuscular pethidine, oral methadone and carbidopa-levodopa. On the second day he experienced nausea, vomiting and confusion, and later dysarthria, lethargy and ataxia. Despite vigorous treatment he later died. It was concluded that some of the adverse effects were due to pethidine toxicity arising from norpethidine accumulation, associated with renal impairment caused by the aciclovir.¹ The US manufacturer of pethidine says that plasma concentrations of pethidine, and its metabolite norpethidine may be increased by aciclovir, thus caution should be used if both drugs are given.²

- Demerol (Meperidine hydrochloride). Sanofi-Aventis US LLC. US Prescribing information, July 2007.

Opioids; Tramadol + Pseudoephedrine

An isolated report describes ischaemic colitis when a patient taking tramadol took a decongestant containing pseudoephedrine.

Clinical evidence, mechanism, importance and management

Acute, self-limiting ischaemic colitis occurred in a 46-year-old patient taking regular tramadol, celecoxib and diazepam for back pain, who had self-medicated with an oral decongestant containing pseudoephedrine. He had taken the maximum recommended dose of pseudoephedrine (240 mg daily) for 7 days. A similar, but milder abdominal discomfort had occurred 3 months earlier when he had used the same medication for one week. The colitis was thought to be due to the pseudoephedrine, but the concurrent use of the tramadol might possibly have contributed by increasing adrenergic vasoconstriction.¹ The general significance of this isolated case is unclear.

- Traino AA, Buckley NA, Bassett ML. Probable ischemic colitis caused by pseudoephedrine with tramadol as a possible contributing factor. *Ann Pharmacother* (2004) 38, 2068–70.

Paracetamol (Acetaminophen) + Amantadine

Amantadine had no clinically significant effect on the pharmacokinetics of paracetamol.

Clinical evidence, mechanism, importance and management

A single 650-mg dose of paracetamol was given to 5 healthy subjects who had taken amantadine 200 mg daily for 42 days, and also after a single dose of amantadine. Although the apparent volume of distribution of paracetamol was very slightly larger following long-term amantadine use, no

other pharmacokinetic parameters were altered. Therefore, from this limited information it appears that no change in paracetamol dose is necessary if these two drugs are given together.¹

Paracetamol (Acetaminophen) + Antiemetics

Metoclopramide increases the rate of absorption of paracetamol and raises its maximum plasma levels. Similarly, domperidone may increase the rate of absorption of paracetamol.

Clinical evidence, mechanism, importance and management

Intravenous metoclopramide 10 mg increased the peak plasma levels of a single 1.5-g dose of paracetamol by 64% in 5 healthy subjects (slow absorbers of paracetamol), and increased its rate of absorption (peak levels reached in 48 minutes instead of 120 minutes), but the total amount absorbed remained virtually unaltered.¹ Oral metoclopramide also increases the rate of paracetamol absorption,² probably because the rate of gastric emptying is increased. Similarly, the speed of absorption of paracetamol may also be increased by domperidone.³ This interaction is exploited in *Paramax* (a proprietary oral preparation containing both paracetamol and metoclopramide) to increase the effectiveness and onset of analgesia for the treatment of migraine. This is obviously an advantageous interaction in this situation.

Paracetamol (Acetaminophen) + Antiepileptics

The metabolism of paracetamol is increased in patients taking enzyme-inducing antiepileptics (carbamazepine, phenytoin, phenobarbital, primidone). Isolated reports describe unexpected hepatotoxicity in patients taking phenobarbital, phenytoin, or carbamazepine after taking paracetamol. Valproate does not appear to affect paracetamol metabolism. Paracetamol modestly reduces the AUC of lamotrigine but appears not to affect phenytoin or carbamazepine.

Clinical evidence

(a) Enzyme-inducing antiepileptics

The AUC of oral paracetamol 1 g was found to be 40% lower (and when given intravenously, 31% lower) in 6 epileptic subjects than in 6 healthy subjects. Five of the epileptic patients were taking at least two of the following drugs: **carbamazepine, phenobarbital, primidone, phenytoin**, and one was taking **phenytoin** alone.¹ Similar findings (a 38% decrease in AUC) were reported in another study in 13 patients taking enzyme-inducing antiepileptics and 2 patients taking rifampicin. In these patients, the amount of glucuronide, but not sulfate, metabolites of paracetamol were higher than controls, but the potentially hepatotoxic metabolite (assessed by mercapturic acid and cysteine conjugates) was not raised.² Similar changes in paracetamol metabolites were reported in Chinese patients taking **phenytoin** alone. However, in those taking **carbamazepine** alone there was no change in the paracetamol metabolites, when compared with control subjects.³ Other studies have also reported a greater rate of paracetamol glucuronidation and unchanged sulfation in patients taking **phenytoin** alone⁴ and patients taking **phenytoin** and/or **carbamazepine**.⁵ In contrast, this latter study also found an increase in clearance of the glutathione-derived conjugates (mercapturic and cysteine conjugates), which may indicate an increased risk of paracetamol hepatotoxicity.⁵

An epileptic woman taking **phenobarbital** 100 mg daily developed hepatitis after taking paracetamol 1 g daily for 3 months for headaches. Within 2 weeks of stopping the paracetamol her serum transaminase levels had

fallen within the normal range, which implied drug-induced liver damage.⁶ Another patient taking **phenobarbital** developed liver and kidney toxicity after taking only 9 g of paracetamol over 48 hours.⁷ **Phenobarbital** also appeared to have increased the toxic effects of paracetamol in an adolescent who took an overdose of both drugs, which resulted in fatal hepatic encephalopathy.⁸

Other case reports describe unexpected paracetamol hepatotoxicity in three patients taking **phenytoin**,^{9–11} three patients taking **carbamazepine**,^{12–14} and a patient taking **phenytoin** and **primidone**.¹⁵ Another analysis of patients with paracetamol-induced fulminant hepatic failure suggested that mortality was higher in the group of patients receiving antiepileptics (including **phenytoin, phenobarbital, carbamazepine, primidone** and **valproate** alone or in combination).¹⁶

The serum levels of **phenytoin** and **carbamazepine** in 10 epileptics were not significantly affected by paracetamol 1.5 g daily for 3 days.¹⁷

(b) Lamotrigine

A study in 8 healthy subjects found that paracetamol 2.7 g daily reduced the AUC of a 300-mg dose of lamotrigine by 20% and reduced its half-life by 15%.¹⁸

(c) Valproate

Valproate is extensively metabolised in man and a significant proportion of the metabolism occurs via glucuronide conjugation. A study designed to determine whether valproate affected the disposition of drugs that are largely dependent on conjugation found that it did not affect the pharmacokinetics of paracetamol in 3 epileptic patients.¹⁹

Mechanism

The increased paracetamol clearance is due to the well-recognised enzyme inducing effects of the antiepileptics, which increase its metabolism (glucuronidation and oxidation) and loss from the body. It has been suggested that this could result in an increase in the production of the hepatotoxic oxidative metabolite of paracetamol, *N*-acetyl-*p*-benzoquinone imine. If this toxic metabolite then exceeds the normal glutathione binding capacity, liver damage may occur (see 'paracetamol', (p.133)). The production of the toxic metabolite *in vitro* in animals and humans seems to depend on several isoenzymes, but the available evidence indicates that the cytochrome P450 isoenzyme CYP2E1 is the primary enzyme in humans.²⁰ Therefore, since these enzyme-inducing antiepileptics do not induce this isoenzyme, some consider the few possible cases described merely represent idiosyncratic effects.²⁰ However, others have suggested that, when several drugs, including phenobarbital or phenytoin are taken, inhibition of uridine diphosphate glucuronosyltransferase (UGT) enzymes by one of these drugs can lead to decreased glucuronidation and increased systemic exposure and toxicity of the paracetamol.²¹

Importance and management

Information is limited. The clinical importance of these interactions is not established and further study is needed. However, paracetamol is possibly a less effective analgesic in patients taking enzyme-inducing antiepileptics as plasma-paracetamol levels may be reduced. However, levels of the potentially hepatotoxic metabolites may be increased. Some believe that the evidence indicates that the risk of liver damage after paracetamol overdose is increased, and they suggest that patients taking enzyme-inducing antiepileptics should be treated with antidotes at lower plasma levels of paracetamol.^{9,11,12,15} In addition, some suggest that therapeutic doses of paracetamol should be used with caution in patients receiving these drugs.^{10,11,16} Conversely, others consider that therapeutic doses of paracetamol are not associated with an increased risk of toxicity when used with enzyme-inducers. Moreover, phenytoin, by increasing glucuronidation, may actually have some hepato-protective effects.^{20,22} The differences stem from different understandings of which mechanism and isoenzyme(s) are important in the production of the hepatotoxic metabolite of paracetamol^{10,20} (see Mechanism, above).

It is unlikely that the interaction between lamotrigine and paracetamol is of practical importance, but this needs confirmation.

(usual maximum is 2 hours).³ In this situation there is a danger that early paracetamol levels could be incorrectly assessed. Therefore, when assessing paracetamol overdoses, it is important to consider whether any concurrent drugs could delay the absorption of paracetamol.

Paracetamol (Acetaminophen) + Caffeine

Caffeine has been variously reported to increase, decrease, and have no effect on the absorption of paracetamol.

Clinical evidence, mechanism, importance and management

Caffeine citrate 120 mg increased the AUC of a single 500-mg dose of paracetamol in 10 healthy subjects by 29%, increased the maximum plasma levels by 15% and decreased the total body clearance by 32%. The decrease in time to maximum level and increase in absorption rate did not reach statistical significance.¹ However, in another study, although caffeine slightly increased the rate of absorption of paracetamol, it had no effect on the extent of absorption.² Moreover, a third study states that caffeine decreased plasma paracetamol levels and AUC and increased paracetamol elimination in healthy men.³ Caffeine is commonly included in paracetamol preparations as an analgesic adjuvant. Its potential benefit and the mechanisms behind its possible effects remain unclear.

Paracetamol (Acetaminophen) + Chloroquine

Although modest pharmacokinetic effects occur when paracetamol and chloroquine are given together this is not thought to be clinically significant.

Clinical evidence, mechanism, importance and management

In a single-dose study, intravenous chloroquine increased the peak plasma paracetamol levels and the AUC by 47% and 22%, respectively.¹ Another single-dose study in 8 healthy subjects found that paracetamol 500 mg increased the maximum plasma level and AUC of chloroquine 600 mg by 17% and 24%, respectively.² These changes were thought unlikely to be clinically significant in therapeutic doses.¹ A further study in 5 healthy subjects found that the pharmacokinetics of a single 300-mg dose of chloroquine were not affected by a single 1-g dose of paracetamol.³ This evidence therefore suggests that no dosage adjustments would be expected to be necessary when paracetamol is given with chloroquine.

Paracetamol (Acetaminophen) + Colestyramine

The absorption of paracetamol may be reduced if colestyramine is given at the same time, but the reduction in absorption is small if colestyramine is given an hour later.

Paracetamol (Acetaminophen) + Antimuscarinics

Propantheline reduced the rate, but not the extent, of paracetamol absorption. This would be expected to reduce the rate of onset of analgesia. Other antimuscarinic drugs that delay gastric emptying would be expected to interact similarly. In one case, the diphenhydramine component of a paracetamol product delayed paracetamol absorption after an overdose, and complicated the evaluation of the risk of toxicity.

Clinical evidence, mechanism, importance and management

Propantheline 30 mg intravenously delayed the peak serum levels of paracetamol 1.5 g in 6 convalescent patients from about 1 hour to 3 hours. Peak levels were lowered by about one-third, but the total amount of paracetamol absorbed was unchanged.¹ This effect occurs because **propantheline** is an antimuscarinic drug that slows the rate at which the stomach empties, so that the rate of absorption in the gut is reduced. The practical consequence of this is likely to be that rapid pain relief with single doses of paracetamol may be delayed and reduced by antimuscarinics (see 'Table 18.1', (p.672), and 'Table 18.2', (p.674) for a list) but this needs clinical confirmation. If the paracetamol is being taken in repeated doses over extended periods this seems unlikely to be an important interaction because the total amount absorbed is unchanged.

One study in 10 healthy subjects reported that **diphenhydramine** 250 mg taken with paracetamol 5 g (simulated paracetamol overdose) had little effect on the absorption of paracetamol.² However, a case has been described where the **diphenhydramine** component of a paracetamol product (**Tylenol PM**) taken in overdose (paracetamol 7.5 g and **diphenhydramine** 375 mg) delayed the absorption of paracetamol, so that the peak serum-paracetamol level did not occur until 8 hours after ingestion

Clinical evidence

When 4 healthy subjects took colestyramine 12 g and paracetamol 2 g together, the absorption of the paracetamol was reduced by 60% (range 30 to 98%) at 2 hours, but the results were said not to be statistically significant. When the colestyramine was given 1 hour after the paracetamol, the absorption was reduced by only 16%.¹

Mechanism

Colestyramine reduces absorption, presumably because it binds with the paracetamol in the gut. Separating the dosages minimises mixing in the gut.

Importance and management

Although information is limited, it suggests that colestyramine should not be given within 1 hour of paracetamol if maximal analgesia is to be achieved. It is normally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine.

1. Dordoni B, Willson RA, Thompson RPH, Williams R. Reduction of absorption of paracetamol by activated charcoal and colestyramine: a possible therapeutic measure. *BMJ* (1973) 3, 86–7.

Paracetamol (Acetaminophen) + Disulfiram

Disulfiram had no important effect on the metabolism of paracetamol in one study, but decreased the production of the glutathione (hepatotoxic) metabolites in another.

Clinical evidence, mechanism, importance and management

After taking disulfiram 200 mg daily for 5 days, the clearance of a single 500-mg intravenous dose of paracetamol was slightly reduced (by about 10%) in 5 healthy subjects without liver disease and 5 others with alcoholic liver cirrhosis. The fractional clearance of paracetamol to its glucuronide, sulfate and glutathione metabolites was not altered.¹ In contrast, another study found that pretreatment of healthy subjects with a single 500-mg dose of disulfiram 10 hours before a single 500-mg oral dose of paracetamol reduced the recovery of glutathione metabolites (a measure of the production of the hepatotoxic metabolite, see 'paracetamol', (p.133)) by 69%.²

Disulfiram is an inhibitor of the cytochrome P450 isoenzyme CYP2E1, which is involved in the metabolism of paracetamol. Previously, the authors of the first study¹ had shown that in *rats*, high doses of disulfiram protected against the hepatotoxicity of paracetamol. Therefore, it was suggested that disulfiram might be useful in reducing the risks of paracetamol overdose. However, the authors of the first study concluded that disulfiram at doses used clinically is unlikely to have any beneficial (or adverse) effect on paracetamol metabolism.¹ In contrast, the authors of the second study consider that disulfiram may be useful in reducing the formation of the hepatotoxic metabolite of paracetamol in some situations.² Further study is needed.

Paracetamol (Acetaminophen) + Erythromycin

Erythromycin accelerates gastric emptying and increases paracetamol absorption but this does not appear to result in a clinically significant interaction.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, intravenous erythromycin 0.75 to 3 mg/kg accelerated gastric emptying in a dose-dependent manner and increased paracetamol absorption.¹ However, another study found that erythromycin 200 mg intravenously, given to promote gastrointestinal motility, did not alter the pharmacokinetics of an extended-release oral dose of paracetamol.² A further study in 7 healthy subjects reported that the pharmacokinetics of a single 1-g oral dose of paracetamol were not significantly

affected by pretreatment with oral erythromycin 250 mg four times daily for 7 days.³ It was suggested that the concurrent use of erythromycin and paracetamol is unlikely to result in a clinically significant interaction.³

Paracetamol (Acetaminophen) + Food

Food slows the rate of absorption of paracetamol, but the overall bioavailability is not usually affected. However, in some individuals food may delay and reduce peak paracetamol-plasma levels. A high fat meal may slightly reduce the extent of paracetamol absorption and certain foods, such as cabbage and brussels sprouts, may affect the metabolism of paracetamol, but this is unlikely to be clinically significant.

Consider also the food preservative 'sodium nitrate', (p.198).

Clinical evidence, mechanism, importance and management

(a) Absorption of paracetamol (acetaminophen)

Several studies have demonstrated that food slows the rate of absorption of paracetamol, but the overall bioavailability is not affected^{1–5} and some studies have also reported that food has no effect on the analgesic effect of paracetamol⁶ or its onset.⁷ The absorption of paracetamol is affected by the rate of gastric emptying and most foods delay gastric emptying. **Carbohydrate,**² **fat,**² **guar gum** and **pectin,**⁵ **protein,**¹ and particularly **fibre,**^{2,4} may delay the absorption of paracetamol. Furthermore, the rate and extent of absorption, and peak plasma levels of a single dose of paracetamol have been found to be impaired in vegetarians compared with non-vegetarians.⁸ A **high fat** diet has also been reported to slightly reduce the extent of absorption.²

Although overall bioavailability is not usually affected by food, there may be a delay in reaching therapeutic plasma paracetamol levels, particularly following a single dose of paracetamol. A reduction in the maximum plasma paracetamol level has been reported when it is given after food, when compared with the fasted state;^{3,9} in one study the maximum plasma paracetamol level in some individuals did not reach the level reported to be required for effective analgesia.⁹ The dosage form will also affect the absorption; many of the studies have used conventional paracetamol tablets, but some formulations (for example paracetamol with sodium bicarbonate)^{3,7} are more rapidly absorbed and, although food may reduce the rate of absorption,^{3,4} one study found that there was no difference in the onset of analgesia between the fed and fasted states.⁷ Another study found that diet composition did not affect the systemic availability of paracetamol in a liquid dosage form, whereas absorption of the tablet form was delayed by a **fibre-enriched diet.**⁴

The clinical importance of these findings is uncertain. It appears that rapid pain relief with single doses of paracetamol tablets may possibly be delayed and reduced by food in some individuals, but liquid or rapidly absorbed preparations are less likely to be affected. If paracetamol is being taken in repeated doses, the interaction with food is unlikely to be clinically important as the total amount absorbed is usually unchanged.

(b) Fasting and hepatotoxicity of paracetamol

A prospective study found that, of 49 patients with paracetamol hepatotoxicity, all had taken more than the recommended limit of 4 g of paracetamol daily. Paracetamol hepatotoxicity after a dose of 4 to 10 g daily was associated with fasting and less commonly with alcohol use, and it was suggested that paracetamol hepatotoxicity after an overdose appears to be enhanced by fasting in addition to alcohol ingestion.¹⁰ The metabolism of a lower 2-g dose of paracetamol was not, however, affected by food restriction in obese patients.¹¹ Fasting may possibly contribute to paracetamol toxicity by shunting paracetamol detoxification from the conjugative to the potentially toxic oxidative pathways.¹¹ See also, 'Alcohol + Paracetamol (Acetaminophen)', p.73.

(c) Metabolism of paracetamol

In a crossover study in 10 healthy subjects, a 10-day balanced diet including **cabbage** 100 g and **brussels sprouts** 150 g at lunch and dinner was found to stimulate the metabolism of paracetamol, at least in part by en-

hanced glucuronidation. Compared with a control diet (which included instead, lettuce, cucumber, green beans and peas), **cabbage** and **brussels sprouts** induced a 16% decrease in the mean AUC of paracetamol, a 17% increase in the mean metabolic clearance rate, and an 8% increase in the mean 24-hour urinary recovery of the glucuronide metabolite.¹² Consumption of **watercress** caused a decrease in the levels of plasma and urinary oxidative metabolites of paracetamol, but the urinary excretion of paracetamol, or its glucuronide and sulfate were not significantly altered.¹³ However, **charcoal-broiled beef** (which accelerates the oxidative metabolism of some drugs) did not affect paracetamol metabolism.¹⁴ It seems unlikely that these foods would have a significant clinical effect, except perhaps **cabbage** and **brussels sprouts** if eaten to excess.

Paracetamol (Acetaminophen) + H₂-receptor antagonists

Cimetidine, nizatidine, and ranitidine do not appear to alter the pharmacokinetics of paracetamol to a clinically relevant extent.

Clinical evidence

(a) Cimetidine

Cimetidine (given as a single 200-mg dose or as 1 g daily in divided doses for 7 days) had no statistically significant effect on the pharmacokinetics of a single 750-mg dose of paracetamol in 4 healthy subjects.¹ Similarly, in another study, a single 800-mg dose of cimetidine given one hour before paracetamol 1 g had no effect on paracetamol half-life or plasma clearance, and no effect on urinary excretion of its principal metabolites (glucuronide, sulfate, mercapturate) in 10 healthy subjects.² Furthermore, the pharmacokinetics of a single 1-g dose of paracetamol were not altered by 2 months of treatment with cimetidine 400 mg twice daily in 10 patients. The only difference in urinary metabolites was a modest 37% decrease in paracetamol mercapturate (indicating a reduction in the hepatotoxic metabolite).² Other studies have shown that cimetidine does not alter the clearance^{3–5} or metabolic pathways of paracetamol.^{3,5}

In contrast, one study reported that cimetidine 300 mg every 6 hours decreased the fractional clearance of the oxidised metabolites (mercapturate and cysteine conjugates) of paracetamol in healthy subjects.⁶ Another study showed that a single 400-mg dose of cimetidine given one hour be-

fore paracetamol 1 g in fasting subjects delayed the absorption of paracetamol (for instance, there was a 37% reduction in peak salivary level and a 63% increase in time to peak level). This effect was not seen when the two drugs were given simultaneously.⁷

(b) Nizatidine

Nizatidine 300 mg given to 5 healthy subjects with paracetamol 1 g modestly increased the paracetamol AUC in the first 3 hours by 25%. Over this time period, there was also a nonsignificant 4% reduction in formation of paracetamol glucuronide, but this did reach statistical significance at 30 and 45 minutes. Nizatidine 150 mg had a similar, but smaller, effect.⁸

(c) Ranitidine

In one study, ranitidine 300 mg twice daily for 4 days had no effect on the clearance and half-life of single 1-g intravenous and oral doses of paracetamol in 8 healthy subjects. In addition, there was no difference in the urinary excretion of paracetamol metabolites. In this study, ranitidine was given one hour before paracetamol.^{9,10} Another study reported similar findings when ranitidine 300 mg was given one hour before paracetamol 1 g. However, when the two drugs were given simultaneously, there was a change in paracetamol pharmacokinetics. The AUC_{0–3} of paracetamol was increased by 63%, and there was a 35% decrease in the AUC_{0–3} of paracetamol glucuronide, but no change occurred in sulfate levels.¹¹ An isolated case describes a man who noted his urine was dark 3 weeks after starting ranitidine 150 mg twice daily and paracetamol 1.3 to 2 g daily. He was found to have raised liver enzyme levels (alkaline phosphatase 708 units/L; AST 196 mIU/mL), which returned to normal on discontinuing ranitidine.¹²

Mechanism

Cimetidine may inhibit the oxidative metabolism of paracetamol by cytochrome P450 isoenzymes, resulting in a reduction in the hepatotoxic metabolite, see 'paracetamol', (p.133). It was suggested that cimetidine delayed paracetamol absorption by reducing gastric emptying.⁷ Nizatidine may cause a minor inhibition of glucuronyltransferases.⁸ Ranitidine may also inhibit paracetamol glucuronyltransferases when given simultaneously, but this was not seen when given one hour apart.

Importance and management

Any changes in the pharmacokinetics of paracetamol with these H₂-receptor antagonists appear to be clinically unimportant. Thus, no special precaution would seem to be necessary when paracetamol is used with cimetidine, nizatidine or ranitidine. The effect of cimetidine on the oxidative metabolism of paracetamol has been investigated as a means of reducing paracetamol hepatotoxicity. However, it appears that cimetidine is not effective for this purpose.¹³

Paracetamol (Acetaminophen) + Herbal medicines

Studies in healthy subjects found that garlic and hibiscus extracts did not affect the pharmacokinetics of single-dose paracetamol to a clinically relevant extent, although the clearance of paracetamol was increased by hibiscus extract. Similarly, single-dose studies in healthy subjects found that Kakkonto did not affect the pharmacokinetics of paracetamol, but animal studies found increased paracetamol levels.

Clinical evidence, mechanism, importance and management

(a) Garlic

A study in 16 healthy subjects found that the use of an aged garlic extract (approximately equivalent to 6 to 7 cloves of garlic daily) for 3 months had little effect on the metabolism of a single 1-g oral dose of paracetamol. There was a very slight increase in glucuronidation after the long-term use of garlic, and some evidence that sulfate conjugation was enhanced, but no effect on oxidative metabolism.¹ No clinically significant interaction would therefore be expected if paracetamol is taken with garlic.

(b) Hibiscus

A study in 6 healthy subjects found that Zobo drink (*Hibiscus sabdariffa* water extract), given 78 minutes before a single 1-g dose of paracetamol did not affect the absorption or AUC of paracetamol, but the total body clearance increased by 12%.² This is not expected to be clinically significant.

(c) Kakkonto

A study in 6 healthy subjects found that 5 g of Kakkonto extract, a Chinese herbal medicine containing extracts of *Puerariae*, *Ephedrae*, *Zingiberis*, *Cinnamomi*, *Glycyrrhizae*, *Paeoniae* and *Zizphi* spp. had no effects on the pharmacokinetics of a single 12-mg/kg dose of paracetamol. A further study in 19 healthy subjects found that 1.25 g of Kakkonto had no effect on the pharmacokinetics of paracetamol 150 mg (from a preparation also containing salicylamide, caffeine and promethazine methylene disalicylate). Because in animal studies high doses of Kakkonto for 7 days were found to significantly increase serum levels of paracetamol, the authors concluded that further investigations were required to assess safety and efficacy of concurrent use.³

Paracetamol (Acetaminophen) + Hormonal contraceptives or HRT

Paracetamol clearance is increased in women taking oral contraceptives, although the clinical relevance of this is uncertain. Paracetamol also increases the absorption of ethinylestradiol from the gut by about 20%. HRT appears not to interact with paracetamol.

Clinical evidence

(a) Effect on paracetamol

In 7 healthy women taking combined oral contraceptives (containing ethinylestradiol), the plasma clearance of a single 1.5-g dose of paracetamol was 64% higher and the elimination half-life 30% lower, when compared with 7 healthy women not taking oral contraceptives. The fractional clearance by glucuronidation and of the cysteine conjugate increased, but that of sulfation and the mercapturic acid conjugate were unchanged.¹ Similarly, other studies have found higher paracetamol clearances of 30 to 49%, and corresponding lower paracetamol half-lives, in women taking oral contraceptives, when compared with control subjects.^{2–4}

One study found that the pharmacokinetics of a single 650-mg intravenous dose of paracetamol did not differ between women who had taken conjugated oestrogens for at least 3 months and control subjects.⁵

(b) Effect on oral contraceptives

A single 1-g oral dose of paracetamol increased the AUC of ethinylestradiol by 22% in 6 healthy women, and decreased the AUC of ethinylestradiol sulfate by 41%. Plasma levels of levonorgestrel were not affected.⁶

Mechanism

The evidence suggests that oral contraceptives increase the metabolism (both oxidation and glucuronidation) of paracetamol by the liver so that it is cleared from the body more quickly.³ The increased absorption of the ethinylestradiol probably occurs because the paracetamol reduces its metabolism by the gut wall during absorption.⁶ It has been suggested that the differences between the effects of oral contraceptives and conjugated oestrogens on paracetamol may be attributable to the influence of progestogens on glucuronide and sulfate conjugation.⁵ This needs confirmation.

Importance and management

The modest pharmacokinetic interaction between the oral contraceptives and paracetamol appears to be established, but its clinical importance has not been directly studied. The clinical importance of the modest increased ethinylestradiol absorption is also uncertain, but likely to be minor. HRT appears not to interact with paracetamol.

Paracetamol (Acetaminophen) + 5-HT₃-receptor antagonists

A placebo-controlled, crossover study in 26 healthy subjects found that both intravenous granisetron 3 mg and tropisetron 5 mg blocked the analgesic effect of a single 1-g oral dose of paracetamol given 90 minutes later. The pharmacokinetics of paracetamol were unaffected by the two drugs. The interaction was thought to involve the serotonergic system,¹ see *Mechanism*, in 'Opioids + Antiemetics; Ondansetron', p.161.

Paracetamol (Acetaminophen) + Isoniazid

A number of reports suggest that the toxicity of paracetamol may be increased by isoniazid so that normal analgesic dosages (4 g daily) may not be safe in some individuals. Pharmacokinetic studies suggest that isoniazid usually inhibits the metabolism of paracetamol, but that metabolism to toxic metabolites may be induced shortly after stopping isoniazid, or late in the isoniazid dose-interval in fast acetylators of isoniazid.

Clinical evidence

A 21-year-old woman who had been taking isoniazid 300 mg for 6 months took 3.25 g of paracetamol for abdominal cramping. Within about 6 hours she developed marked evidence of liver damage (prolonged prothrombin time, elevated ammonia, transaminases, hyperbilirubinaemia).¹

A young woman taking isoniazid who had taken up to 11.5 g of paracetamol in a suicide gesture, developed life-threatening hepatic and renal toxicity despite the fact that her serum paracetamol levels 13 hours later were only 15 micromol/L (toxicity normally associated with levels above 26 micromol/L).²

Three other similar cases were reported in patients taking isoniazid, rifampicin and pyrazinamide who had taken only 2 to 6 g of paracetamol daily.³ Three other possible cases of this toxic interaction have been described.⁴

However, in a pharmacokinetic study in 10 healthy subjects of both slow and fast acetylator status, isoniazid 300 mg daily for 7 days modestly decreased the total clearance of a single 500-mg dose of paracetamol by 15%. Moreover, the clearance of paracetamol to oxidative metabolites was *decreased*.⁵ Similarly, in a further study in 10 healthy slow acetylators of isoniazid, the formation of paracetamol thioether metabolites and oxidative metabolites was reduced by 63% and 49%, respectively, by isoniazid 300 mg daily. However, one day after stopping isoniazid, the formation of thioether metabolites was *increased* by 56%, and this returned to pretreatment values 3 days after the discontinuation of isoniazid.⁶ In yet another study in 10 healthy subjects taking isoniazid prophylaxis, the formation clearance of paracetamol to *N*-acetyl-*p*-benzoquinone imine (NAPQI) was inhibited by 56% when the paracetamol was given simultaneously with the daily isoniazid dose, but when the paracetamol was taken 12 hours after the isoniazid, there was no difference in NAPQI formation clearance, compared with the control phase (1 to 2 weeks after isoniazid had been discontinued). However, when the results were analysed by acetylator status, it appeared that the NAPQI formation clearance was *increased* in fast acetylators taking paracetamol 12 hours after the isoniazid dose.⁷

Mechanism

Not established. A possible reason is that isoniazid induces the cytochrome P450 isoenzyme CYP2E1 by stabilisation.⁸ This means that while the isoniazid is still present, the metabolism of substrates such as paracetamol is inhibited. However, when isoniazid levels drop sufficiently (as may be the case late in the dosing interval in fast acetylators), metabolism may be induced resulting in a greater proportion of the paracetamol being converted into toxic metabolites than would normally occur.⁷

Importance and management

Information is limited, but it would now seem prudent to consider warning patients taking isoniazid to limit their use of paracetamol because it seems that some individuals risk possible paracetamol-induced liver toxicity, even with normal recommended doses. Pharmacokinetic studies suggest that it is possible that the risk is greatest shortly after stopping isoniazid. The risk may also be higher if paracetamol is taken late in the isoniazid dosing interval, particularly in fast acetylators of isoniazid. More study is needed to clarify the situation.

Clinical evidence

(a) Codeine

In 6 healthy subjects paracetamol 1 g every 8 hours for 7 doses had no effect on the pharmacokinetics of a single 30-mg oral dose of codeine, or its metabolites.¹ Similarly in other studies, codeine had no effect on the pharmacokinetics of paracetamol.^{2,3} Paracetamol and codeine are often combined because the combination is more effective than either drug given alone. However, note that not all studies have found this. For example, in one clinical study of surgical removal of impacted third molar teeth, there was no difference in analgesic efficacy between patients given paracetamol alone (800 mg given 3, 6, and 9 hours after surgery, then 400 mg four times daily for 2 days) and those given the same dose of paracetamol with the addition of codeine phosphate 30 mg. Moreover, patients given codeine experienced more adverse effects (nausea, dizziness, drowsiness).⁴

(b) Diamorphine, Pethidine (Meperidine) and Pentazocine

In 8 healthy subjects the absorption of a single 20-mg/kg oral dose of paracetamol solution given 30 minutes after an intramuscular injection of either pethidine 150 mg or diamorphine 10 mg was markedly delayed and reduced. Peak plasma paracetamol levels were reduced by 31% and 74%, respectively, and delayed from 22 minutes to 114 minutes and 142 minutes, respectively.⁵ This interaction was also observed, by the same study group, in women in labour who had been given paracetamol tablets after receiving pethidine, diamorphine or pentazocine.⁶

(c) Fentanyl

An *in vitro* study found that paracetamol inhibited the oxidation of fentanyl to norfentanyl, but the concentrations of paracetamol used were greater than those found therapeutically. A potential interaction was thought possible because fentanyl is metabolised by the cytochrome P450 isoenzyme CYP3A4 and paracetamol is also partially metabolised by the CYP3A family.⁷

(d) Morphine

A study in healthy subjects, who remained in the supine position, investigated the effect of morphine syrup (4 doses of 10 mg given every 4 hours) on the absorption of paracetamol. The time to the maximum plasma paracetamol level, for conventional tablets, was increased from 51 minutes to 160 minutes by morphine, whereas the time to the maximum plasma paracetamol level for dispersible tablets was only increased from 14 to 15 minutes.⁸

(e) Oxycodone

A crossover study in 10 healthy subjects investigated the effect of oxycodone 500 micrograms/kg on the absorption kinetics of a simulated paracetamol overdose (5 g). The maximum serum paracetamol level was reduced by 40%, the time to maximum level was increased by 68%, and the AUC₀₋₈ was 27% lower, when compared with paracetamol alone.⁹

Mechanism, importance and management

The underlying mechanism of these interactions is that the opioid analgesics delay gastric emptying so that the rate of absorption of paracetamol is reduced, but the total amount absorbed is not affected. These were largely investigational studies in healthy subjects, where paracetamol was used as a measure of gastric emptying, and any clinical relevance has not been determined. Reducing the rate of paracetamol absorption would be expected to reduce the onset of analgesic effect, but this is probably not relevant in patients who are receiving regular doses of paracetamol. However, if speed of onset of action is important, one study⁸ suggested that the use of dispersible paracetamol might help to reduce the delay in reaching therapeutic plasma levels.

In paracetamol overdose, it has been suggested that when an opioid is present there may be a potential role for the use of activated charcoal beyond the one-hour post ingestion, because of the delay in the absorption of paracetamol.⁹ It is also worth noting that maximum plasma levels may be delayed when assessing treatment options.

Paracetamol (Acetaminophen) + Opioids

Diamorphine, morphine, oxycodone, pentazocine and pethidine delay gastric emptying so that the rate of absorption of paracetamol given orally is reduced. There is no pharmacokinetic interaction between codeine and paracetamol, but the combination may not always result in increased analgesia.

Paracetamol (Acetaminophen) + Proton pump inhibitors

Lansoprazole modestly increased the rate, but not the extent, of absorption of paracetamol solution. Omeprazole does not appear to have any effect on the metabolism of phenacetin or paracetamol.

Clinical evidence

(a) Lansoprazole

In a study in 6 healthy subjects, lansoprazole 30 mg once daily for 3 days increased the peak level of paracetamol (given as a single 1-g dose in solution) by 43%, and decreased the time to peak paracetamol levels by half (from about 35 to 17.5 minutes). However, lansoprazole had no effect on the AUC and elimination half-life of paracetamol.¹

(b) Omeprazole

Omeprazole 20 mg daily for 8 days had no effect on the pharmacokinetics of **phenacetin**, or paracetamol derived from **phenacetin**, in 10 healthy subjects, except that the peak plasma level of **phenacetin** was higher. There was no change in the metabolism (oxidative and conjugative) of phenacetin or derived paracetamol.² In another study, omeprazole 40 mg daily for 7 days had no effect on the formation of thioether metabolites of paracetamol in 5 rapid and 5 slow metabolisers of *S*-mephenytoin [a probe drug for CYP2C19 activity, see 'Genetic factors in drug metabolism', (p.4)].³

Mechanism

Lansoprazole may increase the absorption of paracetamol by indirectly increasing the rate of gastric emptying.¹ Phenacetin is metabolised to paracetamol by the cytochrome P450 isoenzyme CYP1A2, and it has been suggested that omeprazole can induce CYP1A2, and possibly increase the formation of hepatotoxic metabolites of paracetamol. However, the findings here suggest that omeprazole has no important effect on CYP1A2, or on phenacetin or paracetamol metabolism.

Importance and management

The findings from these studies suggest that neither lansoprazole nor omeprazole cause any clinically important changes in the pharmacokinetics of paracetamol. No special precautions appear to be needed on concurrent use.

Paracetamol (Acetaminophen) + Rifampicin (Rifampin)

Rifampicin increases the metabolism of paracetamol. An isolated report describes hepatic failure, which may have been due to an interaction between paracetamol and rifampicin.

Clinical evidence, mechanism, importance and management

The metabolite to paracetamol ratio for glucuronides was twice as high in 10 patients treated with rifampicin 600 mg daily than in 14 healthy control subjects. In contrast the ratio for sulfates did not differ between the two groups.¹ In a crossover study in healthy subjects, rifampicin 600 mg daily for 1 week, given before paracetamol 500 mg, had no effect on the formation of *N*-acetyl-*p*-benzoquinone imine (NAPQI) or the recovery of thiol

Paracetamol (Acetaminophen) + Probenecid

Probenecid reduces the clearance of paracetamol.

Clinical evidence, mechanism, importance and management

A metabolic study in 10 healthy subjects found that the clearance of paracetamol 1.5 g was almost halved (from 6.23 to 3.42 mL/minute per kg) when it was taken 1 hour after a 1-g dose of probenecid. The amount of unchanged paracetamol in the urine stayed the same, but the glucuronide metabolite fell sharply.¹ Another study in 11 subjects also found that probenecid 500 mg every 6 hours almost halved (from 329 to 178 mL/minute) the clearance of a 650-mg intravenous dose of paracetamol. The urinary excretion of the glucuronide metabolite was decreased by 68% and the excretion of the sulfate metabolite increased by 49%.² These studies suggest that probenecid inhibits paracetamol glucuronidation, possibly by inhibiting glucuronyltransferase. See also 'paracetamol', (p.133). The practical consequences of this interaction are uncertain but there seem to be no adverse reports.

Paracetamol (Acetaminophen) + Propranolol

Propranolol may slightly increase the bioavailability of paracetamol, but this is unlikely to be clinically significant.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects, propranolol 80 mg twice daily for 4 days increased the half-life of a single 1.5-g dose of paracetamol by 25% and lowered its clearance by 14%. The partial clearance of paracetamol to its cysteine and mercapturate derivatives was decreased by 16% and 32%, respectively, and the clearance to the glucuronide conjugate was decreased by 27%, but the sulfate was not significantly affected.¹ Similarly, an earlier study found that propranolol 40 mg four times daily for one week increased the maximum plasma level of a single 1.5-g dose of paracetamol and reduced the time to peak plasma level. However, the increased rate of absorption of paracetamol was not thought to be clinically important.² In contrast, a study in 6 subjects found that a relatively small dose of propranolol (80 mg daily for 6 days) did not affect the pharmacokinetics of paracetamol.³ Another study found that long-term propranolol use in patients with chronic liver disease did not influence the clearance of total or unconjugated paracetamol.⁴

The changes described here appear to be small, and therefore unlikely to be clinically significant. Note that, it has been postulated, based on studies in *animals*, that propranolol may have a protective effect on paracetamol hepatic toxicity by inhibiting the oxidative metabolism of paracetamol to toxic metabolites.^{1,5}

metabolites formed by conjugation of NAPQI with glutathione.² These studies suggest that rifampicin induces the glucuronidation of paracetamol, but that it does not increase the formation of hepatotoxic metabolites of 'paracetamol', (p.133).

However, a 32-year-old woman, who had taken paracetamol 2 to 4 g daily for several weeks, and who had not responded to doxycycline or clarithromycin for suspected cat scratch fever, became confused and agitated 2 days after starting to take rifampicin 600 mg twice daily. Her INR increased from 1.1 to 5.2 and her liver enzymes became raised. Rifampicin and paracetamol were stopped, and she was treated with vitamin K and acetylcysteine, and liver function returned to normal. Paracetamol hepatotoxicity, in doses not normally associated with such effects, occurred only after the addition of rifampicin. It was suggested that rifampicin, which alone may cause hepatitis, had in this case induced the metabolism of paracetamol to hepatotoxic metabolites.³

The clinical importance of the studies awaits further study, but they suggest that rifampicin may reduce the efficacy of paracetamol.

Paracetamol (Acetaminophen) + Sodium nitrate

An isolated report describes severe methaemoglobinaemia in a patient who had taken paracetamol after a meal consisting of 'yuke' (raw beef preserved with sodium nitrate). Both paracetamol and sodium nitrate may cause methaemoglobinaemia, so an interaction resulting in additive effects may have occurred, but a genetic cause was also considered to be a possibility.¹

1. Kobayashi T, Kawabata M, Tanaka S, Maehara M, Mishima A, Murase T. Methemoglobinemia induced by combined use of sodium nitrate and acetaminophen. *Intern Med* (2000) 39, 860.

Paracetamol (Acetaminophen) + Sucralfate

The bioavailability of paracetamol 1 g (using salivary paracetamol levels over 4 hours as a measure of paracetamol absorption) was found to be unchanged in 6 healthy subjects given sucralfate 1 g.¹

1. Kamali F, Fry JR, Smart HL, Bell GD. A double-blind placebo-controlled study to examine effects of sucralfate on paracetamol absorption. *Br J Clin Pharmacol* (1985) 19, 113–14.

Paracetamol (Acetaminophen) + Sulfinpyrazone

Sulfinpyrazone modestly increases the clearance of paracetamol.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, sulfinpyrazone 200 mg given every 6 hours for one week, increased the clearance of a single 1-g dose of paracetamol by 23%. There was a 26% increase in metabolic clearance of the glucuronide

conjugate, and a 43% increase in the glutathione-derived conjugates (indicating an increased production of the hepatotoxic metabolite), but no change in sulfation.¹ It has therefore been suggested that, in patients taking sulfinpyrazone, the risk of liver damage may be increased after paracetamol overdosage and perhaps during prolonged consumption,¹ (see also 'paracetamol', (p.133)) but there seem to be no adverse reports. The clinical importance of these findings awaits further study.

Paracetamol (Acetaminophen) + Tobacco

Heavy, but not moderate, smoking may increase the metabolism of paracetamol. The clearance of phenacetin is also increased in smokers. There is some evidence that smokers are at risk of a poorer outcome after paracetamol overdose.

Clinical evidence, mechanism, importance and management

There was no difference in the clearance of a single 1-g dose of paracetamol in 6 healthy smokers (more than 15 cigarettes per day) and 6 healthy non-smokers in one study, and no difference in the paracetamol metabolites.¹ Similarly, another study found no difference in the pharmacokinetics of a single 650-mg intravenous dose of paracetamol in 14 healthy smokers (range 8 to 35 cigarettes per day) and 15 non-smokers.² In contrast, in another study, the metabolite to paracetamol ratio for glucuronides was 83% higher in 9 heavy smokers (about 40 cigarettes daily), suggesting increased paracetamol metabolism, than in 14 healthy non-smokers. However, it was not higher in moderate smokers (about 10 cigarettes daily).³

A further study in 36 healthy Chinese subjects given a single 900-mg dose of phenacetin found that subjects who smoked cigarettes (7 to 40 daily; mean 20) had a 2.5-fold higher phenacetin apparent oral clearance, compared with non-smokers. Paracetamol plasma levels were also moderately lower in the smokers (phenacetin is metabolised to paracetamol). Cigarette smoke appears to induce the metabolism of phenacetin by the cytochrome P450 isoenzyme CYP1A2, and also appears to increase the metabolism of paracetamol either by stimulating a minor pathway involving CYP1A2 oxidation or by stimulating the conversion of phenacetin to compounds other than paracetamol.⁴

A retrospective study of patients treated for paracetamol poisoning found that there was a much higher proportion of smokers than in the general population (70% versus 31%). Moreover, smoking was independently associated with an increased risk of hepatic encephalopathy (odds ratio 2.68) and death (odds ratio 3.64) following paracetamol overdose.⁵

No interaction is established, but the above studies suggest that heavy smoking may increase the metabolism of paracetamol. The retrospective study also suggests that smoking is associated with a poorer outcome after paracetamol overdose. Further study is needed.

7

Anorectics and Stimulants

This section covers the drugs used in the management of obesity (such as orlistat and sibutramine) as well as the older drugs, such as the amfetamines, which are now no longer widely indicated for this condition, and are now more generally considered as drugs of abuse. However, it should not be forgotten that the amfetamines (largely dexamfetamine) still have a limited therapeutic role in the management of narcolepsy. Ecstasy (MDMA, methylenedioxymethamphetamine), a drug of abuse that is struc-

turally related to amfetamine, is also included in this section. The amfetamines are sympathomimetics, a diverse group, which have a number of interactions. The mechanism of action and classification of sympathomimetics is discussed in 'Cardiovascular drugs, miscellaneous', (p.878). Other stimulant drugs (such as atomoxetine; and methylphenidate, another sympathomimetic) have a role in attention deficit hyperactivity disorder (ADHD) and are also discussed in this section.

Amfetamines + Cocaine

An ischaemic stroke occurred in a patient who was abusing amfetamine and cocaine. *In vitro*, cocaine inhibits the demethylation of ecstasy (MDMA, methylenedioxyamfetamine), but the clinical significance of this is unknown.

Clinical evidence, mechanism, importance and management

A 16-year-old boy developed unsteadiness and double vision 5 minutes after intranasal inhalation of a small amount of amfetamine 'cut' with cocaine. Cranial MRI (magnetic resonance imaging) revealed a mesencephalic lesion that was seen to have decreased 12 days later, and he became symptom-free after 3 weeks. The ischaemic lesion was thought to be due to vasospasm caused by synergistic stimulation of the sympathetic nervous system: amfetamine causes the release of adrenaline (epinephrine) and noradrenaline (norepinephrine), while cocaine prevents their reuptake.¹

An *in vitro* study showed that cocaine (a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6) inhibited the CYP2D6-mediated demethylation of **ecstasy** (MDMA, methylenedioxyamfetamine). Therefore, theoretically, the use of cocaine would be expected to increase plasma and CNS concentrations of **ecstasy**,² but it is not known if this is significant in practice.

Amfetamines and related drugs + Lithium

The stimulant and/or cardiovascular effects of the amfetamines have been shown to be opposed by lithium in some, but not other studies.

Clinical evidence, mechanism, importance and management

Two depressed patients stopped abusing **metamfetamine** and cannabis, or **phenmetrazine** and 'other diet pills' because, while taking lithium carbonate, they were unable to get 'high'. Another patient complained that she felt no effects from amfetamines taken for weight reduction, including no decrease in appetite, until lithium carbonate was withdrawn.¹ A controlled study in 9 depressed patients confirmed that lithium carbonate taken for 10 days attenuated the subjective stimulant effects of **dexamfetamine** or **L-amfetamine**.² Another study found similar results with **dexamfetamine** in schizophrenic patients.³ However, in a further study, only 4 of 8 subjects had an attenuation of the stimulant effects of **amfetamine**.⁴ In this study, lithium attenuated the increase in systolic blood pressure caused by amfetamine (from an average increase of 31/15 mmHg down to 20/9 mmHg).⁴ In contrast, in a controlled study in healthy subjects, there was no difference in subjective or cardiovascular effects of a single 20-mg dose of **dexamfetamine** between those receiving lithium 1.2 g daily for 7 days and those receiving placebo.⁵ In yet another controlled study, in 9 subjects, the only significant effect of pretreatment with lithium 900 mg for 14 days was to attenuate the feeling of happiness after **dexamfetamine**.⁶

The reasons for these reactions, when they occur, are not known, but one suggestion is that amfetamines and lithium have mutually opposing pharmacological actions on noradrenaline (norepinephrine) release and uptake at adrenergic neurones.¹

Information is contradictory, therefore an interaction is not established. Nevertheless, it may be prudent to be alert for evidence of reduced amfetamine effects in the presence of lithium.

Amfetamines and related drugs + Phenothiazines

The appetite suppressant and other effects of amfetamines, chlorphentermine and phenmetrazine are opposed by chlorpromazine. It seems possible that other phenothiazine will interact similarly. The antipsychotic effects of chlorpromazine can be opposed by dexamfetamine.

Clinical evidence

In a placebo-controlled study 10 obese schizophrenic patients who were taking drugs including **chlorpromazine**, **thioridazine**, imipramine and chlorthalidoxepoxide did not respond to treatment with **dexamfetamine** for obesity. The expected sleep disturbance in response to **dexamfetamine** was also not seen.¹ In a double-blind, placebo-controlled study in 76 patients, **chlorpromazine** was found to diminish the weight-reducing effect of **phenmetrazine**,² and, in another study, patients taking **chlorpromazine** did not experience the expected weight loss when they were given **phenmetrazine** or **chlorphentermine**.³ Similarly, antagonism of the effects of **amfetamines** by **chlorpromazine** has been described in other reports.^{4,5}

A study in 462 patients taking **chlorpromazine** 200 to 600 mg daily indicated that the addition of **dexamfetamine** 10 to 60 mg daily had a detrimental effect on the control of their schizophrenic symptoms.⁶

This interaction has been deliberately exploited, with success, in the treatment of 22 children poisoned with various amfetamines or related compounds (**amfetamine**, **dexamfetamine**, **metamfetamine**, **phenmetrazine**).⁴

Mechanism

Not understood. It is known that chlorpromazine can inhibit adrenergic and dopaminergic activity, which could explain some part of the antagonism of the amfetamines, the euphoriant effects of which are said to be mediated by central dopamine receptors.

Importance and management

Established interactions. These reports suggest that it is not beneficial to attempt to treat patients taking chlorpromazine with amfetamines, such as dexamfetamine, or other central stimulants such as phenmetrazine. In one study, thioridazine also appeared to interact. However, it is not clear whether this interaction takes place with antipsychotics other than chlorpromazine, but it seems possible with the phenothiazines, especially if the suggested mechanism is correct. Note that central stimulants are no longer recommended for the treatment of obesity.

Amfetamines + Phenylpropanolamine

The effects of levamfetamine were attenuated in a hyperactive child by a nasal decongestant containing chlorphenamine and phenylpropanolamine.

Clinical evidence, mechanism, importance and management

The use of **levamfetamine succinate** 42 mg daily in was found to be ineffective a 12-year-old hyperactive boy on two occasions when he took **Contac** cold capsules and **Allerest** tablets for colds. Both of these proprietary nasal decongestants contain phenylpropanolamine and chlorphenamine.¹ The reason for this interaction is not understood and there is too little information to make any statement about the general importance of this reaction.

1. Huestis RD, Arnold LE. Possible antagonism of amphetamine by decongestant-antihistamine compounds. *J Pediatr* (1974) 85, 579.

Amfetamines and related drugs + Protease inhibitors

A man taking ritonavir suffered a fatal serotonergic reaction after taking ecstasy (MDMA, methylenedioxyamfetamine). A similar fatal reaction occurred with metamfetamine and ritonavir.

Clinical evidence

(a) *Ecstasy (MDMA, Methylenedioxyamfetamine)*

An HIV-positive man taking lamivudine and zidovudine was additionally given **ritonavir** 600 mg twice daily. About a fortnight later he went to a club and took ecstasy, in a dose estimated to be about 180 mg. He soon became unwell, and when seen by a nurse in the club was hypertonic, tachypnoeic (45 breaths per minute), tachycardic (more than 140 bpm), cyanosed and diaphoretic. He had a tonic-clonic seizure, his pulse rose to 200 bpm, he then vomited, had a cardiorespiratory arrest and died. A post mortem showed blood-alcohol concentrations of 24 mg% and an ecstasy level of 4.56 micrograms/mL, which was almost 10 times greater than might have been expected from the dose he had taken. The authors say that death was consistent with a severe serotonergic reaction.¹ Another report verifies that high ecstasy levels (4.05 micrograms/mL) result in these life-threatening symptoms.²

A patient with AIDS, taking **ritonavir** and **saquinavir**, experienced agitation that lasted for over a day, following a small dose of ecstasy. He then experienced a nearly fatal reaction to a small dose of **sodium oxybate (GHB, gamma-hydroxybutyrate, γ -hydroxybutyrate)**, becoming unresponsive within 20 minutes of ingestion of the drug and exhibiting a brief episode of repetitive clonic contractions.³

(b) *Metamfetamine*

A 49-year-old HIV-positive man taking protease inhibitors was found dead after injecting himself twice with metamfetamine as well as sniffing **amyl nitrate**. He had been taking an antiretroviral regimen of **ritonavir** 400 mg twice daily, soft gel **saquinavir** 400 mg twice daily and stavudine 40 mg twice daily for 4 months. Toxicology detected metamfetamine 500 nanograms/mL in the blood (considered to be in the fatal range, especially when used with other unnamed drugs). Cannabinoids and traces of diazepam and nordiazepam were also found in this patient.⁴

Mechanism

Ritonavir inhibits the cytochrome P450 isoenzyme CYP2D6, which is responsible for the demethylation of ecstasy, so concurrent use leads to a sharp rise in ecstasy plasma levels. Poor liver function (due to alcoholism) may have been a contributory factor in one patient,¹ and further CYP inhibition by nitric oxide (the metabolite of amyl nitrate) may have contributed to another case.⁴ An additional factor is that ecstasy may show non-linear pharmacokinetics.⁵ Metamfetamine is also metabolised by CYP2D6 and its levels would therefore similarly be raised by ritonavir.

Importance and management

Although there are few reported cases, what happens is consistent with the known toxic effects and pharmacology of the drugs concerned. In addition, protease inhibitors may theoretically inhibit the metabolism of ecstasy via other isoenzymes (CYP3A4, CYP2B6), which could therefore also lead to increased levels.

It has been suggested that patients who are prescribed any protease inhibitor should be made aware of the potential risks of using any form of recreational drugs metabolised by CYP2D6.⁴ In particular, some authors recommend that patients taking ritonavir should avoid using ecstasy, metamfetamine and other amfetamines.⁶ Open discussions of illicit drug use would enable carers to warn patients that the use of these drugs may be even more dangerous while taking protease inhibitors. Appropriate precautions, apart from avoidance, include a reduction of the usual dose of ecstasy to about 25%, taking breaks from dancing, checking that a medical team are on site, maintaining adequate hydration by avoiding alcohol, and replenishing fluids regularly.⁶

Amfetamines and related drugs + SSRIs

The psychological effects of ecstasy (MDMA, methylenedioxyamfetamine) may be reduced if citalopram has previously been given. It seems likely that other SSRIs will also reduce or block some of the effects of ecstasy, but increased serotonin effects may, in theory, also be possible. An isolated report describes a neurotoxic reaction in a man taking citalopram when he took unknown amounts of ecstasy. Fluoxetine and paroxetine may decrease the metabolism of ecstasy.

Clinical evidence

A double-blind, placebo-controlled psychometric study in 16 healthy subjects found that **ecstasy (MDMA, methylenedioxyamfetamine)** 1.5 mg/kg produced an emotional state with heightened mood, increased self-confidence and extroversion, moderate derealisation and an intensification of sensory perception. Most of these effects were found to be markedly reduced by pretreatment with **citalopram** 40 mg by intravenous infusion, although their duration was prolonged by up to 2 hours.¹ Similarly a case report describes 2 patients taking **citalopram** 20 mg daily or **paroxetine** 20 mg daily who did not experience any effects from **ecstasy** after starting the SSRI. One patient continued to experience a 'high' from **amfetamines**.² However, an account of 4 **ecstasy** users who had taken **fluoxetine** 20 mg before taking **ecstasy** 100 to 250 mg, reported that they still experienced the subjective effects of euphoria, but one commented that the overall acute experience was "slightly calmer". Some of the adverse effects such as jaw clenching and insomnia were also attenuated and recovery was more rapid.³

When a man taking **citalopram** 60 mg daily additionally took unknown amounts of **ecstasy** he became aggressive, agitated, severely grandiose, restless and performed compulsive movements in a peculiar and joyless dance-like manner. He lacked normal movement control and said he could see little bugs. He was treated with haloperidol and chlordiazepoxide, and improved within 2 days of replacing the **citalopram** with promazine.⁴

In a placebo-controlled, randomised, crossover study, 7 healthy subjects were given **ecstasy** 100 mg on the last day of taking **paroxetine** 20 mg daily for 3 days. **Paroxetine** raised the maximum serum levels and AUC of **ecstasy** by 17% and 27%, respectively.⁵

Mechanism

Complex. It has been suggested that the psychological and neurotoxic effects of ecstasy may be caused by serotonin release in the brain.^{3,6} This could potentially be blocked by serotonin reuptake inhibitors (such as citalopram) resulting in reduced ecstasy effects. However, ecstasy is also thought to inhibit serotonin reuptake,⁶ so its use with the SSRIs could increase serotonin effects, which could result in neurotoxicity.⁷ Furthermore, the SSRIs (to varying degrees) inhibit the cytochrome P450 isoenzyme CYP2D6, by which ecstasy is metabolised, so concurrent use could result in increased ecstasy levels.^{5,8}

Importance and management

The study of ecstasy with citalopram was primarily undertaken to find out how ecstasy works, but on the basis of these results and *animal* studies it seems likely that patients already taking citalopram may not be able to get as 'high' on usual doses of ecstasy, and some adverse effects may also be reduced. Furthermore, if the proposed mechanism of interaction is correct, the same is also likely to be true if they are taking any other SSRI and some cases have been reported. However, be aware of possible pharmacokinetic interactions with some SSRIs that are potent CYP2D6 inhibitors (e.g. fluoxetine, paroxetine), which may increase ecstasy levels. There is also a risk of increased serotonergic activity and there have been a few reports of interactions involving other sympathomimetics and SSRIs or related drugs, see 'Phentermine + Fluoxetine', p.205.

The neurotoxic reaction cited seems to be an isolated case but it illustrates some of the risks attached to using 'recreational' drugs by patients already taking other medications, particularly antidepressants and psychotropic drugs that affect the same receptors in the CNS.

Amfetamines + Urinary acidifiers or alkalinisers

The urinary excretion of amfetamines is increased by urinary acidifiers (ammonium chloride) and reduced by urinary alkalinisers (sodium bicarbonate).

Clinical evidence

A study in 6 healthy subjects given dexamfetamine 10 to 15 mg found that when the urine was made alkaline (pH of about 8) by giving sodium bicarbonate, only 3% of the original dose of amfetamine was excreted over a 16-hour period, compared with 55% when the urine was made acidic (pH of about 5) by taking ammonium chloride.¹ Similar results have been reported elsewhere for amfetamine, dexamfetamine and metamfetamine.^{2–4} A further study found that the effects of amfetamine were increased and prolonged in subjects with alkaline urine.⁵ Psychoses resulting from amfetamine retention in patients with alkaline urine has been described.⁶

Mechanism

Amfetamines are bases, which are excreted by the kidneys. If the urine is alkaline most of the drug exists in the unionised form, which is readily reabsorbed by the kidney tubules so that little is lost. In acid urine, little of the drug is in the unionised form so that little can be reabsorbed and much of it is lost. For more detail on this mechanism see 'Changes in urinary pH', (p.7).

Importance and management

A well established and well understood interaction but reports of problems in practice seem rare. The interaction has been exploited to increase the clearance of amfetamines in cases of overdose by acidifying the urine with ammonium chloride. Conversely it can represent an undesirable interaction if therapeutic doses of amfetamines are excreted too rapidly. Care is needed to ensure that amfetamine toxicity does not develop if the urine is made alkaline with sodium bicarbonate or another urinary alkaliniser, acetazolamide.

Atomoxetine + CYP2D6 inhibitors

Paroxetine markedly increases atomoxetine levels in extensive metabolisers of CYP2D6. Fluoxetine also raises atomoxetine levels. There is a possibility that this may increase adverse effects, and a slower titration of atomoxetine dose is suggested for patients taking paroxetine and other CYP2D6 inhibitors.

Clinical evidence

Paroxetine 20 mg daily for 17 days, with atomoxetine 20 mg twice daily on days 12 to 17, was given to 22 healthy subjects who were extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6 (most common phenotype). **Paroxetine** increased the AUC of atomoxetine 6.5-fold, increased the maximum plasma level by 3.5-fold, and increased the elimination half-life by 2.5-fold, when compared with atomoxetine alone. No changes in paroxetine pharmacokinetics were seen.¹ The pharmacokinetics of atomoxetine with **paroxetine** in these subjects was similar to that previously seen with atomoxetine alone in poor metaboliser subjects.^{1,2}

Following a small-scale study in which atomoxetine was given with **fluoxetine** without any adverse effects, 127 children with attention deficit hyperactivity disorder were randomised to receive **fluoxetine** 20 mg daily and 46 to placebo. After 3 weeks atomoxetine (starting at 0.5 mg/kg daily, increasing over 5 weeks to a maximum of 1.8 mg/kg daily) was also given to both groups. The **fluoxetine** group had 3.3-fold higher peak atomoxetine levels than the placebo group (1177 nanograms/mL compared with 351 nanograms/mL). However, despite a trend towards a greater incidence of decreased appetite with the combination (20% versus 6.8%), there was no significant difference in adverse events between the two groups.³

Mechanism

Atomoxetine is extensively metabolised by CYP2D6,⁴ an isoenzyme that shows polymorphism, with up to 10% of the population lacking an active form (poor metabolisers). Paroxetine inhibits CYP2D6, and thereby increases atomoxetine levels in those with an extensive metaboliser phenotype. It would not be expected to have any effect in poor metabolisers. Fluoxetine can similarly inhibit CYP2D6.

Importance and management

An established pharmacokinetic interaction. Paroxetine effectively changes patients from an extensive metaboliser phenotype to a poor metaboliser phenotype, markedly raising atomoxetine levels. Although the clinical relevance has not been directly assessed, the manufacturer notes that some adverse effects of atomoxetine were up to twice as frequent in poor metaboliser patients in clinical studies.² Because of this, they suggest that patients already taking CYP2D6 inhibitors should undergo a slower titration of atomoxetine dose than usual,³ with the dose only increased if symptoms fail to improve and if the initial dose is well tolerated.² This seems a sensible precaution. Note that in the fluoxetine study, which found that the concurrent use of atomoxetine was generally well-tolerated, dosage increases were made on a weekly basis, with a dose of 1.2 mg/kg daily achieved in 2 weeks.³ The US manufacturers suggest a starting dose of atomoxetine 0.5 mg/kg daily and only increasing the dose to 1.2 mg/kg daily if symptoms fail to improve over 4 weeks and the initial dose is well tolerated.² The UK manufacturers say that the initial dose should be maintained for a minimum of 7 days before increasing it, if necessary, and that slower titration may be necessary in patients taking CYP2D6 inhibitors.⁵

It would also seem prudent to be alert to the possibility of an increase in adverse effects if CYP2D6 inhibitors are added to established atomoxetine

treatment, and the US manufacturers specifically name fluoxetine, paroxetine and **quinidine**.² For a list of inhibitors of CYP2D6, see 'Table 1.3', (p.6).

Extra caution may be prudent with this combination in those with epilepsy, as both atomoxetine and SSRIs may lower the seizure threshold, and this risk appears to be increased by higher atomoxetine levels.²

5. Strattera (Atomoxetine hydrochloride). Eli Lilly and Company Ltd. UK Summary of product characteristics, January 2007.

Atomoxetine + Miscellaneous

The manufacturer contraindicates the concurrent use of atomoxetine and MAOIs on theoretical grounds. Atomoxetine is predicted to have additive effects with pressor drugs and other sympathomimetics and has been seen to potentiate the increase in heart rate and blood pressure seen with intravenous salbutamol. However, no increase in cardiovascular effects was seen when atomoxetine was given with methylphenidate.

Atomoxetine did not alter desipramine pharmacokinetics and would therefore not be expected to affect other substrates of CYP2D6. Atomoxetine did not alter midazolam pharmacokinetics and would therefore not be expected to affect other substrates of CYP3A4. Antacids and omeprazole do not alter atomoxetine bioavailability.

Clinical evidence, mechanism, importance and management

Atomoxetine is a sympathomimetic that acts as a noradrenaline reuptake inhibitor. As such, it causes a modest increase in pulse and/or blood pressure in many patients.^{1,2} It can also cause hypotension.^{1,2}

(a) Antacids or Omeprazole

In a study in 20 extensive metabolisers of atomoxetine, **aluminium/magnesium hydroxide (Maalox)** and omeprazole did not affect the bioavailability of atomoxetine 40 mg.³ No special precautions appear to be necessary on concurrent use.

(b) CYP2D6 substrates

Atomoxetine 40 or 60 mg twice daily for 13 days was given to 21 subjects who were extensive metabolisers of CYP2D6 (most common phenotype), with a single 50-mg dose of **desipramine** on day 4. Atomoxetine had no effect on **desipramine** pharmacokinetics.⁴

Desipramine is extensively metabolised by CYP2D6, and can be used as a probe drug for assessment of the effect of drugs on this isoenzyme in extensive metabolisers (see 'Genetic factors', (p.4)). It was concluded that atomoxetine, even at the maximum recommended dose, does not cause clinically relevant inhibition of CYP2D6 *in vivo*, and so will not affect the pharmacokinetics of other CYP2D6 substrates.⁴ For a list of CYP2D6 substrates, see 'Table 1.3', (p.6).

(c) CYP3A4 substrates

Atomoxetine 60 mg twice daily for 12 days was given to 6 subjects who were poor metabolisers of CYP2D6, with a single 5-mg oral dose of **midazolam** on days 6 and 12. Atomoxetine increased the maximum level and AUC of midazolam by about 16%, which was not statistically or clinically significant.⁴

Midazolam is extensively metabolised by CYP3A4, and can be used as a probe drug for assessment of the effect of drugs on this isoenzyme. Poor metabolisers of CYP2D6 were chosen for this study, because they have much higher levels of atomoxetine than extensive metabolisers of CYP2D6. It was concluded that atomoxetine, even at the maximum recommended dose, does not cause clinically relevant inhibition of CYP3A4 *in vivo*, and so will not affect the pharmacokinetics of other CYP3A4 substrates.⁴ For a list of CYP3A4 substrates, see 'Table 1.4', (p.6).

(d) MAOIs

The manufacturer contraindicates the concurrent use of atomoxetine with MAOIs, or within 2 weeks of stopping an MAOI,^{1,2} because other drugs that affect brain monoamine levels have caused serious reactions (similar to the neuroleptic malignant syndrome) when taken with MAOIs.²

(e) Methylphenidate

A placebo-controlled, crossover study in 12 healthy subjects examined the effects of giving either atomoxetine 60 mg twice daily or and methylphenidate 60 mg daily for 5 days, with the other drug added for the final 2 days. No additional changes in blood pressure or heart rate were seen when the drugs were given together, and concurrent use did not increase the frequency of adverse effects.⁵

(f) Pressor drugs

The manufacturer recommends caution if atomoxetine is given concurrently with pressor drugs, because of the possible additive effects on blood pressure.^{1,2}

(g) Salbutamol (Albuterol)

The manufacturer notes that atomoxetine 60 mg twice daily for 5 days potentiated the increase in heart rate and blood pressure caused by an infusion of salbutamol 600 micrograms over 2 hours.² Because of this, they recommend caution when atomoxetine is used in patients receiving intravenous or oral salbutamol or other beta₂ agonists^{1,2} (for a list, see 'Table 33.1', (p.1159)). The UK manufacturer also extends this precaution to high-dose nebulised salbutamol.¹

(h) Miscellaneous

The manufacturer recommends caution when atomoxetine is given concurrently with other drugs that affect noradrenaline, because of the potential for additive or synergistic pharmacological effects. Examples they name are antidepressants such as **imipramine**, **venlafaxine** and **mirtazapine**, and the decongestants **pseudoephedrine** or **phenylephrine**.¹ Until more is known, this would seem a sensible precaution.

Dexfenfluramine or Fenfluramine + Other anorectics

Fenfluramine and dexfenfluramine have generally been withdrawn worldwide because of the occurrence of serious and sometimes fatal valvular heart disease (aortic, mitral, tricuspid or mixed valve disease). Pulmonary hypertension has also sometimes been seen. These serious adverse effects occurred when these drugs were taken alone, and when combined with phentermine as *Fen-phen* and *Dexfen-phen*, but not with phentermine alone.^{1–5}

There is also an isolated case of cardiomyopathy attributed to the use of fenfluramine with mazindol.⁶ Before the withdrawal of the drug from the market, the manufacturer of fenfluramine recommended that concurrent use with other centrally acting anorectics should be avoided.⁷

Methylphenidate + Carbamazepine

Carbamazepine may reduce methylphenidate levels.

Clinical evidence, mechanism, importance and management

A 7-year-old boy with attention deficit disorder taking carbamazepine 1 g daily for grand mal epilepsy was referred because of unmanageable behaviour. He failed to respond to methylphenidate in doses of up to 30 mg every 4 hours, and his blood levels of both methylphenidate and its metabolites were undetectable. The authors of the report attributed this to an interaction with the carbamazepine.¹ Similarly, symptoms of attention deficit hyperactivity disorder worsened in a 13-year-old girl taking methylphenidate after she also took carbamazepine. Methylphenidate serum levels decreased markedly and the dose of methylphenidate had to be increased from 20 to 60 mg three times daily to regain a benefit similar to that achieved before the addition of carbamazepine.² However, another report describes 4 out of 7 children taking methylphenidate and carbamazepine in whom the combination was successful. Blood levels of methylphenidate were apparently not measured.³ Despite the sparsity of the information, and the cases of apparently successful use, it would seem wise to consider carbamazepine as a possible cause if patients do not respond adequately to methylphenidate. If this occurs, consider increasing the methylphenidate dose.

Methylphenidate + Clonidine

Much publicised fears about the serious consequences of using methylphenidate with clonidine appear to be unfounded. There is limited evidence to suggest that concurrent use can be both safe and effective.

Clinical evidence, mechanism, importance and management

There have been fears about serious adverse events when methylphenidate is taken with clonidine,¹ due to reports of 3 deaths in children taking both drugs. One child died from ventricular fibrillation due to cardiac abnormalities, one from cardiac arrest attributed to an overdose of fluoxetine, and the third death was unexplained. Studies of these 3 cases and one other failed to establish any link between the use of methylphenidate with clonidine and these deaths, the final broad conclusion being that the event was largely a media-inspired scare story built on inconclusive evidence.^{2,3} A small scale pilot study in 24 patients suggested that the combination is both safe and effective for the treatment of attention deficit hyperactivity disorder,⁴ and the manufacturers of one formulation of methylphenidate¹ said that, as of 2002, they were not aware of any reports describing adverse events when *Concerta XL* (methylphenidate) was used with clonidine.

Modafinil + Dexamfetamine

No pharmacokinetic interaction appears to occur between modafinil and dexamfetamine.

Clinical evidence, mechanism, importance and management

In a steady-state study, 23 healthy subjects were given modafinil 200 mg daily for 7 days, followed by 400 mg daily for 3 weeks. During the last week, 10 of the subjects were also given dexamfetamine 20 mg daily, 7 hours after their modafinil dose. Dexamfetamine caused no significant change in the pharmacokinetics of modafinil and the combination was well tolerated. In addition, the pharmacokinetics of dexamfetamine did not appear to be affected by modafinil, when compared with values reported in the literature.¹ Similar results were found in a single dose study.² No additional precautions appear to be necessary on concurrent use.

- Hellriegel ET, Arora S, Nelson M, Robertson P. Steady-state pharmacokinetics and tolerability of modafinil administered alone or in combination with dextroamphetamine in healthy volunteers. *J Clin Pharmacol* (2002) 42, 448–58.

Modafinil + Methylphenidate

No pharmacokinetic interaction appears to occur between modafinil and methylphenidate.

Clinical evidence, mechanism, importance and management

In a single-dose study in healthy subjects, modafinil 200 mg and methylphenidate 40 mg were given together without any clinically relevant changes in the pharmacokinetics of either drug.¹ In a steady-state study, 30 healthy subjects were given modafinil 200 mg daily for 7 days, followed by 400 mg daily for 3 weeks. During the last week, 16 of the subjects were also given methylphenidate 20 mg daily, taken 8 hours after their modafinil dose. Methylphenidate caused no significant change in the pharmacokinetics of modafinil. In addition, the pharmacokinetics of methylphenidate did not appear to be affected by modafinil, when compared with values reported in the literature.² No special precautions would appear to be necessary on concurrent use.

- Wong YN, King SP, Laughton WB, McCormick GC, Grebow PE. Single-dose pharmacokinetics of modafinil and methylphenidate given alone or in combination in healthy male volunteers. *J Clin Pharmacol* (1998) 38, 276–82.
- Hellriegel ET, Arora S, Nelson M, Robertson P. Steady-state pharmacokinetics and tolerability of modafinil given alone or in combination with methylphenidate in healthy volunteers. *J Clin Pharmacol* (2001) 41, 895–904.

Modafinil + Miscellaneous

The manufacturers caution if enzyme-inducing anticonvulsants, particularly phenytoin, are used with modafinil. There is speculation, based on *in vitro* studies, about some possible interactions with other drugs, such as warfarin. Modafinil is an inducer of CYP3A4 and therefore may be expected to interact with substrates of this isoenzyme.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers and inhibitors

Animal studies suggest that **phenobarbital** reduces the serum levels of modafinil; both drugs are inducers of the cytochrome P450 isoenzyme CYP3A4.¹ The manufacturers similarly suggest that this is a possibility.^{2,3}

There is no clinical evidence of interactions with other potent enzyme inducers, but the manufacturers suggest that **carbamazepine**^{2,3} and **rifampicin (rifampin)**³ may reduce modafinil levels. Also, inhibitors of CYP3A4 (**itraconazole**, **ketoconazole** are specifically named) are predicted to possibly increase modafinil levels. However, clinically relevant interactions with either CYP3A4 inducers or inhibitors seem unlikely because CYP3A4 is not the only cytochrome P450 isoenzyme that is involved in the metabolism of modafinil.

(b) CYP3A4 substrates

Modafinil is an inducer of the cytochrome P450 isoenzyme CYP3A4. The manufacturers therefore predict that it may reduce the levels of drugs that are CYP3A4 substrates. They specifically name the protease inhibitors, **buspirone**, **calcium-channel blockers**, ciclosporin, **midazolam**, and the **statins** [note that only some statins, namely **atorvastatin**, **lovastatin** and

simvastatin, are CYP3A4 substrates], and triazolam.^{2,3} Interactions have been seen with 'ciclosporin', (p.1039), and 'triazolam', (p.732).

(c) Phenytoin

Due to the enzyme inhibiting potential of modafinil, the manufacturers say that care should be taken if phenytoin is also given.² There is *in vitro* evidence to indicate that modafinil may possibly inhibit the metabolism of phenytoin by the cytochrome P450 isoenzymes CYP2C9 and CYP2C19, and so there is some reason for monitoring concurrent use for evidence of increased phenytoin effects and toxicity.^{2,3}

(d) Warfarin

There is no clinical evidence of an interaction between warfarin and modafinil, but because warfarin is, in part, metabolised by the cytochrome P450 isoenzyme CYP2C9 (which is inhibited by modafinil) the manufacturers suggest that concurrent use should be monitored for the first 2 months of concurrent use.^{2,3}

Orlistat + Sucrose polyesters

A single case report suggests that the concurrent use of orlistat and sucrose polyesters (*Olestra* – used in some foods as a fat substitute) can result in additive gastrointestinal adverse effects (soft, fatty/oily stools, increased flatulence and abdominal pain). In the case in question, symptoms resolved when the patient stopped eating *Olestra*-containing food while continuing to take orlistat.¹

1. Heck AM, Calis KA, McDuffie JR, Carobene SE, Yanovski JA. Additive gastrointestinal effects with concomitant use of *olestra* and orlistat. *Ann Pharmacother* (2002) 36, 1003–5.

Phenmetrazine + Barbiturates

The CNS adverse effects and the weight-reducing effects of phenmetrazine are reduced by amobarbital.

Clinical evidence, mechanism, importance and management

A comparative study in 50 overweight adults, of the effects of phenmetrazine 25 mg three times daily with or without amobarbital 30 mg three times daily, found that although the adverse CNS effects, particularly insomnia, headache and nervousness, were decreased by the presence of the barbiturate, the weight-reducing effects were also decreased (by 65%).¹

1. Hadler AJ. Phenmetrazine vs. phenmetrazine with amobarbital for weight reduction: a double-blind study. *Curr Ther Res* (1969) 11, 750–4.

Phentermine + Fluoxetine

An isolated report describes phentermine toxicity, which occurred in a woman several days after she stopped taking fluoxetine.

Clinical evidence, mechanism, importance and management

A 22-year-old woman who had successfully and uneventfully taken fluoxetine 20 mg daily for 3 months, stopped the fluoxetine and then 8 days later took a single 30-mg tablet of phentermine. Within a few hours she experienced racing thoughts, stomach cramps, palpitations (pulse 84 bpm), tremors, dry eyes and diffuse hyper-reflexia. The problems had all resolved the following day after she took lorazepam 1.5 mg. The authors of this report suggested that the residual inhibitory effects of the fluoxetine on liver cytochrome P450 enzymes led to decreased phentermine metabolism, resulting in increased phentermine levels and sympathetic hyperstimulation. It is known that fluoxetine and its active metabolite have a long half-life and can persist for weeks. The authors also alternatively wondered whether some of the symptoms might have fitted those of the serotonin syndrome.¹

Although this is an isolated case and its general importance is unknown, the authors of the report draw attention to the possible risks of taking SSRIs and sympathomimetic drugs used for controlling diet.

A neurotoxic reaction has also been reported with ecstasy and citalopram, see 'Amfetamines and related drugs + SSRIs', p.201.

1. Bostwick JM, Brown TM. A toxic reaction from combining fluoxetine and phentermine. *J Clin Psychopharmacol* (1996) 16, 189–90.

Rimonabant + Miscellaneous

Ketoconazole doubled the AUC of rimonabant, and other potent CYP3A4 inhibitors are also expected to raise rimonabant levels. Potent CYP3A4 inducers are expected to lower rimonabant levels. Due to a lack of information the manufacturers suggest that rimonabant should not be taken with antidepressants. Rimonabant does not appear to affect the levels of oral contraceptives, digoxin, midazolam or warfarin, and alcohol, lorazepam, and orlistat do not appear to alter rimonabant levels.

Clinical evidence, mechanism, importance and management

(a) Antidepressants

Depressive disorders and mood alterations are common in patients taking rimonabant. The manufacturers say that as there is limited experience in using rimonabant with antidepressants, and concurrent use is not recommended.¹

(b) CYP3A4 inducers and inhibitors

Rimonabant is partly metabolised by the cytochrome P450 isoenzyme CYP3A4. **Ketoconazole**, a potent CYP3A4 inhibitor, doubles the AUC of rimonabant. The manufacturers therefore expect that other potent CYP3A4 inhibitors (they name **clarithromycin**, **itraconazole**, **nefazodone**, **ritonavir**, and **telithromycin**) will also raise rimonabant levels, and they therefore advise caution on concurrent use.¹ They similarly suggest that potent CYP3A4 inducers (such as **carbamazepine**, **phenobarbital**, **phenytoin**, **rifampicin** (**rifampin**) and **St John's wort**) may lower rimonabant levels. If concurrent use is necessary monitor to ensure that rimonabant remains effective.¹ See 'Table 1.4', (p.6), for a list of clinically relevant CYP3A4 inducers and inhibitors.

(c) Miscellaneous

Digoxin, **midazolam**, and **warfarin** were given with rimonabant in clinical studies to assess the effect of rimonabant on P-glycoprotein, CYP3A4 and CYP2C9, respectively. As rimonabant did not interact with these drugs, the manufacturers say this confirms *in vitro* evidence that it has no effect on these isoenzymes or transporter, and would not be expected to interact with other substrates of P-glycoprotein, CYP3A4 and CYP2C9. The manufacturers also note that rimonabant had no effect on the pharmacokinetics of an oral contraceptive containing **ethinylestradiol** and **levonorgestrel**, and that **alcohol**, **lorazepam**, and **orlistat** did not affect the plasma levels of rimonabant.¹

1. Acomplia (Rimonabant), Sanofi-Aventis. UK Summary of product characteristics, June 2006.

Sibutramine + Azoles

Ketoconazole modestly increases steady-state levels of sibutramine and its active metabolites. The UK manufacturers recommend caution when sibutramine is used with itraconazole or ketoconazole.

Clinical evidence, mechanism, importance and management

Twelve obese patients were given sibutramine hydrochloride monohydrate 20 mg daily for 14 days, with **ketoconazole** 200 mg twice daily for the last 7 days. **Ketoconazole** caused moderate increases in the serum levels of sibutramine and its two metabolites (AUC and maximum serum level increases of 58% and 36%, respectively, for metabolites M1, and 20% and 19%, respectively, for M2, probably through inhibition of the cytochrome P450 isoenzyme CYP3A4). Small increases in heart rates were seen (2.5 bpm at 4 hours and 1.4 bpm at 8 hours), while ECG parameters were unchanged.¹ Sibutramine alone can cause an increase in heart rate, and a rate increase of 10 bpm is an indication to withdraw the drug. There-

fore, the manufacturers in the UK² suggest caution should be exercised when sibutramine is used with **ketoconazole**. They also suggest that due to its ability to inhibit CYP3A4 **itraconazole** should also be used with caution.

2. Reductil (Sibutramine hydrochloride monohydrate). Abbott Laboratories Ltd. UK Summary of product characteristics, November 2005.

Sibutramine + Macrolides

Although no interaction appears to occur between sibutramine and erythromycin, the UK manufacturers still caution the use of sibutramine with clarithromycin, erythromycin and troleandomycin.

Clinical evidence, mechanism, importance and management

Twelve obese patients were given sibutramine 20 mg daily for 14 days, with **erythromycin** 500 mg three times daily for the last 7 days. It was found that, apart from some slight and unimportant changes in the pharmacokinetics of the metabolites of sibutramine (probably caused by some inhibition of the cytochrome P450 isoenzyme CYP3A4), the pharmacokinetics of sibutramine were not significantly altered by **erythromycin**. No blood pressure changes were seen and only very small and clinically irrelevant increases in the QTc interval and heart rate occurred.¹ The extent of any interaction appears to be too small to matter,¹ and there would seem to be no reason for avoiding the concurrent use of these two drugs. Despite this the UK manufacturers still say that caution should be exercised, probably because sibutramine is principally metabolised by CYP3A4.² They also extrapolate their caution to the CYP3A4 inhibitors **clarithromycin** and **troleandomycin**.

1. Hinson JL, Leone MB, Leese PT, Moulton JT, Carter FJ, Faulkner RD. Steady-state interaction study of sibutramine (Meridia) and erythromycin in uncomplicated obese subjects. *Pharm Res* (1996) 13 (9 Suppl), S116.
2. Reductil (Sibutramine hydrochloride monohydrate). Abbott Laboratories Ltd. UK Summary of product characteristics, November 2005.

Sibutramine + Miscellaneous

On theoretical grounds the manufacturers contraindicate the concurrent use of sibutramine with MAOIs, and they say that it should not be given with serotonergic drugs because of the risk of the serious serotonin syndrome. The manufacturers say that the use of sibutramine with other centrally acting appetite suppressants is contraindicated and they caution the use of cold and flu remedies. No clinically relevant interactions have been seen between sibutramine and cimetidine, and no interaction occurs with oral contraceptives.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

When cimetidine 400 mg twice daily was given with sibutramine 15 mg once daily to 12 healthy subjects the maximum serum levels and AUCs of the combined sibutramine metabolites were increased by 3.4% and 7.3%, respectively.¹ These changes are too small to be of clinical significance, and there is no reason for avoiding the concurrent use of these two drugs.

(b) Centrally acting appetite suppressants, and drugs that raise blood pressure or heart rate

The UK manufacturers say that the concurrent use of sibutramine and other centrally acting appetite suppressants is contraindicated. No work appears to have been done to see what happens if sibutramine is given with **decongestants, cough, cold and allergy medications**, but the manufacturers advise caution because of the risk of raised blood pressure or heart rate. The manufacturers in the UK and US both list **ephedrine** and **pseudoephedrine**,^{1,2} while in the UK **xylometazoline** is also specifically named.²

(c) CYP3A4 inducers

The UK manufacturers point out that **carbamazepine, dexamethasone, phenobarbital, phenytoin** and **rifampicin** are all inducers of CYP3A4, an isoenzyme involved in the metabolism of sibutramine.² These drugs might therefore increase the metabolism of sibutramine resulting in a fall in its serum levels. However, this has not been studied experimentally and, at the present time, the existence, the extent and the possible clinical relevance of any such interaction is unknown.

(d) MAOIs

There are no reports of adverse reactions between sibutramine and the MAOIs. However, sibutramine inhibits serotonin reuptake, and because the serious serotonin syndrome can occur when MAOIs and SSRIs are used together, the manufacturers warn that concurrent use of sibutramine and MAOIs is contraindicated. They say that 14 days should elapse between stopping either drug and starting the other.^{1,2} The US manufacturers included **selegiline** in this warning.¹

(e) Oral contraceptives

A crossover study in 12 subjects found that sibutramine 15 mg daily, given for 8 weeks, had no clinically significant effect on the inhibition of ovulation caused by an oral contraceptive, and it was concluded that there is no need to use alternative contraceptive methods while taking sibutramine.¹

(f) Serotonergic drugs

Because sibutramine inhibits serotonin uptake, and because the serious serotonin syndrome has been seen when serotonergic drugs were taken with SSRIs, the manufacturers say that sibutramine should not be taken with any serotonergic drugs.^{1,2} They name **dextromethorphan, dihydroergotamine, fentanyl, pentazocine, pethidine (meperidine)**, SSRIs, **sumatriptan**, and **tryptophan**. Possible cases have been reported for sibutramine and 'SSRIs', (below). The US manufacturers also include **lithium** in their list.¹ Note that this list is not exhaustive (see MAOIs under (d) above) and a case of the serotonin syndrome has been seen when **venlafaxine** was given with sibutramine.³

The extent of the risk with these serotonergic drugs is not known, but because of the potential severity of the reaction this warning would seem to be a prudent precaution. For more information on the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

2. Reductil (Sibutramine hydrochloride monohydrate). Abbott Laboratories Ltd. UK Summary of product characteristics, November 2005.
3. Trakas K, Shear NH. Serotonin syndrome risk with antiobesity drug. *Can J Clin Pharmacol* (2000) 7, 216.

Sibutramine + SSRIs

Two case reports suggest that the concurrent use of sertraline or citalopram with sibutramine may cause the serotonin syndrome.

Clinical evidence, mechanism, importance and management

A 43-year-old woman taking **citalopram** 40 mg daily was also given sibutramine hydrochloride monohydrate 10 mg daily. Within a few hours of taking the first dose of sibutramine she developed racing thoughts, hyperactivity, psychomotor agitation, shivering and diaphoresis, which continued for the 3 days that she continued to take sibutramine. The authors suggested that one of the reasons for the hypomania may have been the serotonin syndrome, which could have been caused by the use of two drugs with serotonergic action.¹ A letter briefly mentions another possible case of the serotonin syndrome, following the use of sibutramine and **sertraline**.² The manufacturers of sibutramine^{3,4} say that concurrent use of any other drug that has serotonergic actions should be avoided where possible, or only undertaken with appropriate monitoring. For more information about the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

Anthelmintics, Antifungals and Antiprotozoals

'Table 8.1', (p.208) lists the drugs covered in this section by therapeutic group and drug class. If the anti-infective is the drug causing the interaction, the interaction is generally dealt with under the affected drug. Also note that drugs such as the 5-nitroimidazoles (e.g. metronidazole), which have actions against more than one type of organism (e.g. bacteria and protozoa) are covered under Antibacterials.

(a) Amphotericin B

Intravenous amphotericin B causes important pharmacodynamic interactions via additive nephrotoxicity and myelotoxicity, and may increase the cardiotoxicity of other drugs because of amphotericin-induced hypokalaemia. No important pharmacokinetic interactions are known. Lipid formulations such as liposomal amphotericin are less nephrotoxic than conventional amphotericin, and would therefore be expected to interact less frequently. Orally administered amphotericin is not absorbed systemically, and no interactions are known.

(b) Azole antifungals

The most important interactions affecting and caused by the azole antifungals are those resulting from inhibition and induction of cytochrome P450 isoenzymes.

Fluconazole is principally (80%) excreted unchanged in the urine, so is less affected by enzyme inducers and inhibitors than some other azoles. Fluconazole is a potent inhibitor of CYP2C9 and CYP2C19, and generally only inhibits CYP3A4 at high doses (greater than 200 mg daily). Interactions are less likely with single doses used for genital candidiasis than with longer term use.

Itraconazole is extensively metabolised by CYP3A4, and its metabolism may become saturated with multiple dosing. Itraconazole and its major metabolite, hydroxy-itraconazole are potent inhibitors of CYP3A4.

Ketoconazole is extensively metabolised, particularly by CYP3A4. It is also a potent inhibitor of CYP3A4.

Miconazole is a potent inhibitor of CYP2C9. Because this azole is generally used topically as pessaries, skin cream, or an oral gel, it is less likely to cause interactions, although it should be noted that interactions with 'warfarin', (p.388), have been reported, particularly for the oral gel.

Posaconazole is metabolised via UDP glucuronidation, and may also be a substrate for P-glycoprotein. Posaconazole is an inhibitor of CYP3A4.

Voriconazole is metabolised by CYP2C19, CYP2C9, and to a lesser extent by CYP3A4. Voriconazole is an inhibitor of CYP2C9, CYP2C19 and CYP3A4.

An number of other azole antifungals are only used topically in the form of skin creams or intravaginal preparations, and have not been associated with drug interactions, presumably since their systemic absorption is so low, see 'Azoles; Topical + Miscellaneous', p.222.

Fluconazole, ketoconazole and voriconazole have been associated with prolongation of the QT interval, although generally not to a clinically relevant extent. However, they may also raise the levels of other drugs that prolong the QT interval, and these combinations are often contraindicated, see 'Antihistamines + Azoles', p.584.

Albendazole or Mebendazole + Antiepileptics

Phenytoin, carbamazepine and phenobarbital lower the plasma levels of albendazole and mebendazole, and they therefore might reduce their efficacy for systemic infections. Valproate does not lower plasma mebendazole levels.

Clinical evidence

(a) Albendazole

In one study, 32 patients with intraparenchymatous neurocysticercosis were given albendazole 7.5 mg/kg every 12 hours for 8 days. These patients were also taking either **phenytoin** 200 to 300 mg daily (9 patients), **carbamazepine** 600 to 1200 mg daily (9 patients), or **phenobarbital** 100 to 300 mg daily (5 patients) all for at least 3 months, and a control group consisting of 9 patients who did not receive any antiepileptics. The AUCs for (+)-albendazole sulfoxide were 66%, 49%, and 61% lower than the control group for the **phenytoin**, **carbamazepine**, and **phenobarbital** groups respectively. The maximum plasma levels of (+)-albendazole sulfoxide were 50 to 63% lower and the half lives about 3 to 4 hours shorter. The AUCs, peak plasma levels and half-life of (–)-albendazole sulfoxide (present in much lower levels than the (+)-isomer) were similarly reduced by the antiepileptics.¹

(b) Mebendazole

A retrospective analysis found that patients with echinococcosis taking mebendazole and **phenytoin** or **carbamazepine** tended to have lower plasma mebendazole levels than patients not taking these antiepileptics.² **Valproic acid** tended to increase mebendazole levels, and some patients had a clinically important rise in mebendazole levels when they were switched from **phenytoin** or **carbamazepine** to **valproic acid**.²

Mechanism

Phenytoin, carbamazepine and phenobarbital appear to induce the oxidative metabolism of albendazole by the cytochrome P450 isoenzyme CYP3A to roughly the same extent, resulting in significantly reduced levels of albendazole sulfoxide. Phenytoin, and to a lesser extent carbamazepine, may also induce the metabolism of albendazole sulfone by CYP2C. Mebendazole is similarly affected.

Importance and management

These pharmacokinetic interactions are established, and are likely to be clinically important when these anthelmintics are used to treat systemic worm infections. For these infections it may be necessary to increase the albendazole or mebendazole dosage in patients taking phenytoin, carbamazepine or phenobarbital. Monitor the outcome of concurrent use. The interactions are of no importance when these anthelmintics are used for intestinal worm infections (where their action is a local effect on the worms in the gut), which is the most common use of mebendazole in particular.

2. Luder PJ, Siffert B, Witassek F, Meister F, Bircher J. Treatment of hydatid disease with high oral doses of mebendazole. Long-term follow-up of plasma mebendazole levels and drug interactions. *Eur J Clin Pharmacol* (1986) 31, 443–8.

Albendazole or Mebendazole + Cimetidine

Cimetidine raises serum mebendazole levels, and prolongs the half-life of albendazole sulfoxide. In some cases cimetidine appeared to increase the effectiveness of these anthelmintics against systemic infection.

Clinical evidence

(a) Albendazole

A study in 6 healthy subjects given albendazole 20 mg/kg and cimetidine 10 mg/kg twice daily found that cimetidine significantly inhibited the metabolism of albendazole sulfoxide as indicated by an increase in its elimination half-life from 7.4 to 19 hours. Cimetidine also reduced inter-

individual variability in plasma albendazole levels.¹ Another study in patients with cystic echinococcosis given albendazole 20 mg/kg daily, for three 4-week courses separated by intervals of 10 days, found that levels of the active metabolite albendazole sulfoxide were higher in bile and hydatid cyst fluid in 7 patients who also received cimetidine 10 mg/kg daily. The therapeutic benefit of the combined treatment was reported to be greater than that with albendazole alone.²

(b) Mebendazole

A study in 8 patients (5 with peptic ulcers and 3 with hydatid cysts) taking mebendazole 1.5 g three times daily found that cimetidine 400 mg three times daily for 30 days raised the maximum plasma mebendazole levels by 48%. The previously unresponsive hepatic hydatid cysts resolved totally.³ However, a previous study had found smaller increases in serum mebendazole levels with cimetidine 1 g daily in divided doses, which were considered too small to be clinically useful.⁴

Mechanism

It is suggested that the interaction is caused by the enzyme inhibitory actions of cimetidine, which result in a reduction in the metabolism of albendazole and mebendazole.^{1,3} Cimetidine may also reduce albendazole absorption and minimise inter-patient variability by reducing gastric acidity,¹ but the reduction in absorption appears to be outweighed by the enzyme-inhibitory effects.

Importance and management

These pharmacokinetic interactions would appear to be established, but their clinical relevance is uncertain. Increased efficacy has been shown in some studies for systemic worm infections. There would seem to be no reason for avoiding concurrent use, but increased monitoring for efficacy and toxicity might be prudent.

3. Bekhti A, Pirotte J. Cimetidine increases serum mebendazole concentrations. Implications for treatment of hepatic hydatid cysts. *Br J Clin Pharmacol* (1987) 24, 390–2.
4. Luder PJ, Siffert B, Witassek F, Meister F, Bircher J. Treatment of hydatid disease with high oral doses of mebendazole. Long-term follow-up of plasma mebendazole levels and drug interactions. *Eur J Clin Pharmacol* (1986) 31, 443–8.

Albendazole + Corticosteroids

Dexamethasone can raise levels of albendazole sulfoxide by 50%, which might increase its efficacy in systemic worm infections.

Clinical evidence

In one study albendazole 15 mg/kg daily in three divided doses was given to 8 patients with cysticercosis. The plasma levels of the active metabolite of albendazole (albendazole sulfoxide) were found to be increased by about 50% by the use of **dexamethasone** 8 mg every 8 hours.¹ Another study did not detect significantly increased maximum plasma levels of albendazole sulfoxide, when **dexamethasone** was given, but the AUC was increased twofold, and there was a decrease in its clearance.²

Mechanism

Uncertain. Dexamethasone is an inducer of the cytochrome P450 isoenzyme CYP3A4, and might therefore be expected to reduce levels of albendazole, so the finding is unexpected. Dexamethasone appears not to alter the rate of formation of albendazole sulfoxide, but decreases its elimination.²

Importance and management

Information about albendazole seems to be limited but the interaction would appear to be established. It would appear that albendazole can be given concurrently with dexamethasone without compromising treatment, and combined use may actually be beneficial.³

1. Jung H, Hurtado M, Tulio Medina M, Sanchez M, Sotelo J. Dexamethasone increases plasma levels of albendazole. *J Neurol* (1990) 237, 279–80.

- Takayanagui OM, Lanchote VL, Marques MPC, Bonato PS. Therapy for neurocysticercosis: pharmacokinetic interaction of albendazole sulfoxide with dexamethasone. *Ther Drug Monit* (1997) 19, 51–5.
- Sotelo J, Jung H. Pharmacokinetic optimisation of the treatment of neurocysticercosis. *Clin Pharmacokinetics* (1998) 34, 503–15.

Albendazole + Diethylcarbamazine

There appears to be no pharmacokinetic interaction between albendazole and diethylcarbamazine.

Clinical evidence, mechanism, importance and management

There was no difference in the pharmacokinetics of single doses of diethylcarbamazine 6 mg/kg or albendazole 400 mg between groups of 14 amicrofilaraemic subjects given either drug alone and another group of 14 subjects given both drugs.¹ This study suggests there is no pharmacokinetic interaction between these two anthelmintic drugs, and the lack of adverse events¹ suggests that concurrent use is safe.

- Shenoy RK, Suma TK, John A, Arun SR, Kumaraswami V, Fleckenstein LL, Na-Bangchang K. The pharmacokinetics, safety and tolerability of the co-administration of diethylcarbamazine and albendazole. *Ann Trop Med Parasitol* (2002) 96, 603–14.

Albendazole + Food

Giving albendazole with a fatty meal markedly increases the levels of its active metabolite. Albendazole should be taken with a meal.

Clinical evidence, mechanism, importance and management

A study in Sudanese men found that giving a single 400-mg dose of albendazole with a meal resulted in a 7.9-fold higher level of the active metabolite, albendazole sulfoxide, than when albendazole was given in the fasted state.¹ Similarly, a further study in healthy subjects found that when albendazole 10 mg/kg was given with a fatty meal, rather than with water, the peak plasma levels of the active metabolite were increased by more than sixfold and the half-life decreased from 8.8 to 8.2 hours.² Albendazole absorption is poor, and if it is being used for systemic infections, it is advisable to take it with a meal.

- Homeida M, Leahy W, Copeland S, Ali MMM, Harron DWG. Pharmacokinetic interaction between praziquantel and albendazole in Sudanese men. *Ann Trop Med Parasitol* (1994) 88, 551–9.
- Nagy J, Schipper HG, Koopmans RP, Butter JJ, Van Boxtel CJ, Kager PA. Effect of grapefruit juice or cimetidine coadministration on albendazole bioavailability. *Am J Trop Med Hyg* (2002) 66, 260–3.

Albendazole + Grapefruit juice

Grapefruit juice increases the plasma levels of albendazole.

Clinical evidence, mechanism, importance and management

Grapefruit juice increased albendazole sulfoxide levels by about threefold and shortened its half-life by 46%.¹ When albendazole was given with grapefruit juice and cimetidine the peak plasma level was reduced from 760 to 410 micrograms/L. However, the level achieved with cimetidine and grapefruit juice was still greater than that achieved when albendazole was given with water.

It was suggested that grapefruit juice inhibits the metabolism of albendazole by the cytochrome P450 isoenzyme CYP3A4 in the intestinal mucosa, and so albendazole levels are raised. The addition of cimetidine may decrease this effect by reducing albendazole absorption by affecting gastric pH.¹ (See also 'Albendazole or Mebendazole + Cimetidine', p.209.) The clinical relevance of the change with grapefruit juice is uncertain. For systemic infections, increased absorption might be beneficial, but the decrease in half-life might be detrimental.

- Nagy J, Schipper HG, Koopmans RP, Butter JJ, Van Boxtel CJ, Kager PA. Effect of grapefruit juice or cimetidine coadministration on albendazole bioavailability. *Am J Trop Med Hyg* (2002) 66, 260–3.

Albendazole + Ivermectin

No pharmacokinetic interaction occurs between albendazole and ivermectin.

Clinical evidence, mechanism, importance and management

In a double-blind placebo-controlled study, 42 patients with onchocerciasis were given single doses of either ivermectin 200 micrograms/kg, albendazole 400 mg or both drugs together. There was no significant pharmacokinetic interaction, and although the combination seemed to offer no advantage over ivermectin alone for the treatment on onchocerciasis, the combination appeared safe. No dosage adjustments would be required during concurrent use.¹

Albendazole + Levamisole

Levamisole may markedly decrease the bioavailability of albendazole sulfoxide, but albendazole has no clinically significant effects on levamisole pharmacokinetics.

Clinical evidence, mechanism, importance and management

A study in 28 healthy subjects given levamisole 2.5 mg/kg alone or with albendazole 400 mg found that albendazole produced a modest reduction in the AUC of levamisole but no other pharmacokinetic parameters were affected. However, the AUC of albendazole sulfoxide (the active metabolite) was 75% lower when given with levamisole than historical values in subjects who had received levamisole alone.¹ An associated study in 44 patients found that levamisole with or without albendazole was not effective against *Onchocerca volvulus* infections. Both treatments caused a similar number of adverse effects.¹ The clinical relevance of these findings is unclear, but they suggest that caution is needed if both drugs are to be given for systemic worm infections.

The safety, tolerability and pharmacokinetics of levamisole alone, levamisole plus ivermectin, and levamisole plus albendazole, and their efficacy against *Onchocerca volvulus*. *Ann Trop Med Parasitol* (2004) 98, 595–614.

Albendazole + Praziquantel

Albendazole does not alter the bioavailability of praziquantel. Praziquantel markedly increases the bioavailability of albendazole sulfoxide in fasted subjects, but much less so when albendazole is given with a meal, as recommended. None of these changes appears to have adverse consequences.

Clinical evidence, mechanism, importance and management

(a) Effect on albendazole

In a study in Sudanese men, the AUC of albendazole sulfoxide (the active metabolite of albendazole), was increased 4.5-fold when a single 400-mg dose of albendazole was given with praziquantel 40 mg/kg to fasting subjects. However, this difference was much less marked (only a 1.5-fold increase) when the drugs were given with food.¹ The reasons for these changes and their practical consequences are not known, but the increases in albendazole sulfoxide levels seemed not to cause any problems.¹ If both drugs are given with food, as may be advisable (see 'Albendazole + Food', above), any interaction is modest. On the basis of these studies there do not seem to be any obvious reasons why the concurrent use of these two drugs should be avoided.

(b) Effect on praziquantel

In a study, 21 children treated for giardiasis were given a single 400-mg dose of albendazole either alone or with a single 20-mg/kg dose of praziquantel. It was found that the pharmacokinetics of albendazole were not significantly affected by praziquantel when the drugs were given with 200 mL of milk, one hour after breakfast. There were wide inter-individual

ual variations in the plasma levels and AUC of the active metabolite, albendazole sulfoxide, but these were similar whether albendazole was given alone or with praziquantel.²

Amphotericin B + Antineoplastics

Use of conventional amphotericin B with nephrotoxic antineoplastics such as cisplatin and ifosfamide may increase the risk of renal impairment, and should generally be avoided. Liposomal amphotericin B may be an alternative, but renal function should still be closely monitored.

Clinical evidence, mechanism, importance and management

A multivariate analysis in patients receiving high-dose cisplatin with saline hydration and mannitol diuresis found that the concurrent use of amphotericin B was a predictor of renal failure.¹ Both cisplatin and amphotericin B are nephrotoxic, and their effects might be expected to be additive.

The manufacturer of conventional amphotericin B states that nephrotoxic antineoplastics should not be given concurrently except with great caution.² Of the antineoplastics, cisplatin, ifosfamide and methotrexate are well known for their nephrotoxicity. Amphotericin also reduces the renal clearance of 'methotrexate', (p.642).

Liposomal amphotericin B is licensed for use in the empirical treatment of presumed fungal infections in febrile neutropenic patients. It is therefore likely to be used in patients who have received antineoplastics and who may have antineoplastic-induced renal impairment. The manufacturer notes that it has been used successfully in a large number of patients with pre-existing renal impairment. Nevertheless, renal function should be closely monitored in these patients.³

Amphotericin B + Azoles

The effects of amphotericin B and azole antifungals would be expected to be antagonistic, and there is some clinical evidence to support this suggestion of reduced efficacy, and even increased adverse effects. However, other studies suggest that the combination of amphotericin B and fluconazole may be beneficial.

Clinical evidence

Studies in a few patients and *in vitro* experiments suggest that the antifungal effects of amphotericin B and miconazole used together may be antagonistic.^{1,2} In another study, 4 out of 6 patients did not respond to amphotericin B treatment while also taking ketoconazole, whereas treatment was successful in 6 others, 5 of whom had stopped taking prophylactic miconazole or ketoconazole. The authors suggested that the numbers are too small to draw any definite conclusions, but antagonism is certainly a possibility.³ A comparative study found that patients given itraconazole and amphotericin B had serum itraconazole levels of less than 1 microgram/mL, whereas those given itraconazole alone had serum itraconazole levels of 3.75 micrograms/mL, which suggests that amphotericin B may reduce itraconazole levels.⁴ There are numerous *in vitro* and *animal* studies of the potential interaction of azoles with amphotericin B, which show conflicting results from antagonism to additive or synergistic effects, some of which have been the subject of a review.⁵ In a recent large randomised study in 219 patients with candidaemia who were not neutropenic, high-dose fluconazole plus amphotericin B tended to be more ef-

fective than fluconazole plus placebo (69% versus 56% success rate). The combination was not antagonistic compared with fluconazole alone.⁶ Similarly, in a randomised study in HIV-positive patients with cryptococcal meningitis, fluconazole plus amphotericin B was found to be more effective in reducing CSF fungal levels than amphotericin B alone. However, it was not as effective as amphotericin B plus flucytosine. All treatments were well tolerated.⁷

A retrospective study of itraconazole use found that 11 of 12 leukaemic patients given amphotericin B and itraconazole had raised liver enzymes. These abnormalities resolved in 7 patients when the amphotericin B was discontinued. Itraconazole alone, given to another 8 patients did not cause liver enzyme abnormalities, even though it was used in high doses.⁸ Amphotericin B has only rarely been associated with adverse effects on the liver and increases in liver enzymes may occur in patients treated with itraconazole.

Mechanism

Uncertain. In theory, the combination of an antifungal that binds to ergosterol in fungal cell membranes (amphotericin B) with one that inhibits the synthesis of ergosterol (azoles) would be expected to exert antagonistic effects.^{5,9,10} *In vitro* studies with *Candida albicans* found that azole exposure may allow the generation of cells that are unaffected by subsequent exposure to amphotericin B. The degree of resistance appears to depend on concentration and the azole involved, with itraconazole causing more resistance than fluconazole.¹¹ Resistance of *Candida* species to amphotericin B appears to depend on the duration of pre-exposure to fluconazole and is also greater when amphotericin B is subsequently used in combination with fluconazole rather than alone.^{10,12} Resistance may also depend on the organism involved and its sensitivity to azoles.^{13,14}

Importance and management

Despite extensive *in vitro* and *animal* data, it is not entirely clear whether or not azoles inhibit the efficacy of amphotericin B.^{9,15,16} The emergence of resistant strains of fungi and the fact that antifungal therapy for invasive fungal infections remains suboptimal, has meant that combinations of antifungals have continued to be tried. Critically ill patients are often given empirical treatment with amphotericin B, with a subsequent change to fluconazole if the organism is sensitive. The Infectious Disease Society of America advises that a combination of amphotericin B and fluconazole may be an option in selected patients.¹⁷ However, combinations of azoles and amphotericin B should not be considered as routine practice, and until more is known it may be better to limit concurrent use to specific cases. The outcome of combined use should be well monitored for both a reduced antifungal response and an increase in adverse effects, such as a worsening of liver function tests.⁸ Some recent reviews have usefully discussed the topic of antifungal combinations.^{18–20}

Amphotericin B + Corticosteroids

Both amphotericin B and corticosteroids can cause potassium loss and salt and water retention, which can have adverse effects on cardiac function.

Clinical evidence

Four patients treated with amphotericin B and **hydrocortisone** 25 to 40 mg daily developed cardiac enlargement and congestive heart failure. The cardiac size decreased and the heart failure disappeared within 2 weeks of stopping the **hydrocortisone**. The amphotericin B was continued successfully with the addition of potassium supplements.¹

Mechanism

Amphotericin B causes potassium to be lost in the urine. Hydrocortisone can cause potassium to be lost, and salt and water to be retained, and occasional instances of hypernatraemia with amphotericin B have also been seen. Working in concert these could account for the hypokalaemic cardiopathy and the circulatory overload that was seen.

Importance and management

Information is limited but the interaction would seem to be established. Monitor electrolytes (especially potassium, which should be closely monitored in patients receiving amphotericin B in any case) and fluid balance if amphotericin B is given with corticosteroids. The elderly would seem to be particularly at risk. Note that hypokalaemia increases the risk of adverse interactions with ‘digitalis glycosides’, (p.923) and ‘QT-interval prolonging drugs’, (p.257). The manufacturer of conventional amphotericin B advises that corticosteroids should not be used concurrently unless necessary to control drug reactions.² However, in clinical practice, it is sometimes deemed necessary to use both drugs together. In this situation, close monitoring of the patient’s fluid balance, potassium level and cardiovascular parameters is required.

- Fungizone Intravenous (Amphotericin B). E. R. Squibb & Sons Ltd. UK Summary of product characteristics, May 2006.

Amphotericin B + Diuretics

Amphotericin B commonly causes hypokalaemia. Loop diuretics or thiazides and related diuretics increase the risk of hypokalaemia when given with amphotericin.¹ In turn, this might increase the risk of interactions with ‘digitalis glycosides’, (p.923) and ‘QT-interval prolonging drugs’, (p.257). Conversely, potassium-sparing diuretics such as amiloride might reduce the incidence of hypokalaemia with amphotericin.²

Amphotericin B + Low salt diet

The renal toxicity of amphotericin B can be associated with sodium depletion. When the sodium is replaced the renal function improves.^{1,2}

Amphotericin B + Pentamidine

There is some evidence to suggest that acute renal failure may develop in patients taking amphotericin B if they are also given parenteral pentamidine.

Clinical evidence, mechanism, importance and management

A retrospective study between 1985 and 1988 identified 101 patients with AIDS who had been given amphotericin B for various systemic mycoses. The patients were given amphotericin 0.6 to 0.8 mg/kg daily for 7 to 10 days, then a dose three times a week for about 9 weeks. Nine patients were concurrently treated for *Pneumocystis carinii* pneumonia, and of these the 4 who had been given pentamidine parenterally developed acute and rapid reversible renal failure. In all 4 cases, renal function returned to normal when the drugs were withdrawn. No renal failure was seen in 2 others given pentamidine by inhalation or 3 given intravenous co-trimoxazole.¹

Both amphotericin B and pentamidine are known to be nephrotoxic and the renal impairment was attributed to additive effects of these drugs. The reason no toxicity occurred when the pentamidine was given by inhalation is probably because the serum levels achieved were low.

In general, conventional amphotericin B should not be used with other nephrotoxic drugs such as parenteral pentamidine. Renal function should be monitored closely with either drug (daily in the case of parenteral pentamidine), and it is essential that this recommendation is adhered to if both drugs are given. Anticipate the likelihood of renal failure and the need to withdraw the drugs.

- Antoniskis D, Larsen RA. Acute, rapidly progressive renal failure with simultaneous use of amphotericin B and pentamidine. *Antimicrob Agents Chemother* (1990) 34, 470–2.

Amphotericin B; Oral + Miscellaneous

The manufacturer of amphotericin B¹ notes that its absorption from the gastrointestinal tract is negligible, and that no interactions have been noted with amphotericin B lozenges, or other oral formulations. For a theoretical interaction with sucralfate, see ‘sucralfate’, (below).

- Fungilin Lozenge, Oral Suspension, Oral Tablets (Amphotericin B). E. R. Squibb & Sons Ltd. UK Summary of product characteristics, May 2006.

Amphotericin B; Oral + Sucralfate

An *in vitro* study with amphotericin B found that it became markedly and irreversibly bound to sucralfate at the pH values found in the gut. This suggests that efficacy for intestinal candidiasis or gut decontamination might be decreased, but no study appears to have been conducted to establish this.

Clinical evidence, mechanism, importance and management

To simulate what might happen in the gut, amphotericin B 25 mg/L was mixed with sucralfate 500 mg in 40 mL of water at pH 3.5 and allowed to stand for 90 minutes at 25°C. Analysis of the solution found that the amphotericin B concentration fell rapidly and progressively over 90 minutes to about 20%. When the pH of the mixture was then raised to about 6.5 to 7 for 90 minutes, there was no change in the concentration of amphotericin

B, suggesting that the interaction was irreversible.¹ The reason for this change is not known, but the suggestion is that sucralfate forms insoluble chelates with amphotericin B.¹

It is not known how important this interaction is likely to be in practice, but the efficacy of amphotericin B for intestinal candidiasis or gut decontamination may be decreased. Separating the dosages might not be effective in some postoperative patients because their gastric function may not return to normal for up to 5 days, and some sucralfate might still be present when the next dose is given.¹ This study was conducted more than a decade ago, and nobody appears to have conducted a clinical study to establish its hypothesis. If both sucralfate and oral amphotericin are required, it would seem prudent to monitor concurrent use carefully, being alert for any evidence of reduced effects.

1. Feron B, Adair CG, Gorman SP, McClurg B. Interaction of sucralfate with antibiotics used for selective decontamination of the gastrointestinal tract. *Am J Hosp Pharm* (1993) 50, 2550–3.

Atovaquone + Co-trimoxazole

In one small study co-trimoxazole did not alter atovaquone levels, and atovaquone caused a minor decrease in co-trimoxazole levels, which was not considered clinically relevant.

Clinical evidence, mechanism, importance and management

As part of a larger study, 6 HIV-positive subjects received atovaquone 500 mg once daily, co-trimoxazole 960 mg (trimethoprim/sulfamethoxazole 160/800 mg) twice daily, or the combination, taken with food. There was no change in steady-state atovaquone levels but there was a minor 17% decrease in steady-state trimethoprim levels and a minor 8% decrease in sulfamethoxazole levels when both drugs were given together.¹

This study shows there is no important pharmacokinetic interaction between atovaquone and co-trimoxazole. No dosage adjustments of either drug would be required on concurrent use.

1. Falloon J, Sargent S, Piscitelli SC, Bechtel C, LaFon SW, Sadler B, Walker RE, Kovacs JA, Polis MA, Davey RT, Lan HC, Masur H. Atovaquone suspension in HIV-infected volunteers: pharmacokinetics, pharmacodynamics, and TMP-SMX interaction study. *Pharmacotherapy* (1999) 19, 1050–6.

Atovaquone + Food

Taking atovaquone with fatty food markedly increases its AUC by two to threefold. Atovaquone/proguanil tablets should be taken with food or a milky drink, and atovaquone suspension should be taken with food, to maximise absorption and efficacy.

Clinical evidence

(a) Suspension

In a pharmacokinetic study in HIV-positive subjects designed to determine the dose of atovaquone suspension that would achieve specific steady-state plasma levels, administration with **high-fat** food increased the bioavailability of atovaquone by 1.4-fold when compared with the fasted state.¹ In another similar study, administration of atovaquone suspension with food (23 g of fat) increased average steady-state levels by 1.3-fold to 1.7-fold with different dosage regimens (using 500 mg to 1.5 g of atovaquone).²

In a single-dose study in healthy subjects, a **high-fat breakfast** (21 g of fat) increased the AUC of atovaquone by 2.4-fold, and an **enteral nutritional supplement** (*Sustacal Plus*, containing 28 g of fat) increased the AUC by 2.7-fold compared with the fasted state.³

(b) Tablets

In a crossover study in 18 healthy subjects after an overnight fast, administration of atovaquone 500 mg after a **high-fat standard breakfast** (23 g of fat) increased the AUC by 3.3-fold when compared with the fasted state.⁴ In a further study of similar design, 2 slices of **toast** alone had no effect on atovaquone AUC, 2 slices of **toast with 23 g of butter** increased the AUC by threefold, and 2 slices of **toast with 56 g of butter** increased the AUC by 3.9-fold.⁴

Mechanism

Atovaquone is a highly lipophilic compound, which shows considerable inter-individual variability in absorption. Dietary fat increases the rate and extent of atovaquone absorption from both the suspension and the tablets, probably by increasing its solubility in the gut. The suspension has about a twofold higher oral bioavailability than the tablets when given with food or when fasting.

Importance and management

Established interactions of clinical importance. Atovaquone suspension used for the treatment or prevention of *Pneumocystis pneumonia* must be taken with food, since this is likely to increase the likelihood of successful treatment and survival.^{5,6} Alternatively, an enteral nutritional supplement with a high-fat content appears to be suitable.³ In the US, the manufacturer says that, for patients who have difficulty taking atovaquone suspension with food, parenteral therapy for *Pneumocystis pneumonia* should be considered.⁶

Similarly, atovaquone/proguanil tablets used for the treatment or prophylaxis of malaria should be taken with a milky drink or with food to maximise absorption.^{7,8} Be aware that if patients are unable to tolerate food, the systemic exposure to atovaquone will be reduced.^{7,8} In this situation, monitoring of parasitaemia to ensure efficacy would seem prudent.

Atovaquone + Miscellaneous

Preliminary evidence suggested that, of a number of drugs given with atovaquone in clinical trials, only metoclopramide caused any marked change (decreases) in the atovaquone serum levels. Until more is known, it may be prudent to monitor efficacy if metoclopramide is used with atovaquone.

Clinical evidence, mechanism, importance and management

An analysis of 191 patients with AIDS, given atovaquone as part of efficacy studies, found that when normalised for plasma albumin, body-weight, and the absence of other drugs, the expected steady-state plasma levels of atovaquone were 14.8 micrograms/mL. Steady-state atovaquone plasma levels achieved in the presence of other drugs were examined in an attempt to identify possible interactions. **Fluconazole** and **prednisone** were associated with increases of 2.5 and 2.3 micrograms/mL, respectively, whereas **paracetamol (acetaminophen)**, **aciclovir**, **opioids**, **antidiarrhoeals**, **cephalosporins**, **benzodiazepines** and **laxatives** were associated with decreases of greater than 3.4 micrograms/mL. **Metoclopramide** was associated with a decrease of 7.2 micrograms/mL. **U plasma binders** [not defined], **erythromycin**, **clofazimine**, **antacids**, **clotrimazole**, **NSAIDs**, **ketoconazole**, **hydroxyzine**, **megestrol**, **antiemetics** (other than **metoclopramide**), **other systemic steroids**, and **H₂-receptor antagonists** were not associated with any change in steady-state atovaquone serum levels. **U plasma binders**, **erythromycin** and **clofazimine** were represented by fewer than 5 subjects.^{1,2}

The kind of analysis described above^{1,2} provides only the very broadest indication that interactions might or might not occur between atovaquone and these drugs, but it highlights the need to be vigilant if an apparently interacting drug is used concurrently. Only the changes caused by **metoclopramide** seem likely to have any potential clinical importance and the manufacturers recommend caution in its use with atovaquone/pro-

guanil.^{2,3} If an antiemetic is required in patients taking atovaquone/proguanil, they suggest that **metoclopramide** should be given only if other antiemetics are unavailable,³ and that parasitaemia should be closely monitored.⁴ In the UK, the manufacturers also say that **metoclopramide** should be given with caution to patients taking atovaquone suspension for Pneumocystis pneumonia, until the interaction has been further studied,² whereas the US manufacturers of atovaquone suspension do not mention **metoclopramide**.⁵

Atovaquone + Proguanil

There appears to be no clinically relevant pharmacokinetic interaction between atovaquone and proguanil.

Clinical evidence, mechanism, importance and management

Atovaquone did not affect the pharmacokinetics of proguanil in a comparative study of 4 patients taking proguanil 200 mg twice daily for 3 days and 12 patients taking proguanil 200 mg twice daily with atovaquone 500 mg twice daily for 3 days.¹ A similar lack of interaction was seen in 18 healthy subjects given proguanil 400 mg daily with atovaquone 1 g daily for 3 days.²

In contrast, in a longer study 13 healthy subjects were given a single 250/100-mg dose of atovaquone/proguanil, then after an interval of one week they were given daily doses for 13 days. There was no change in the AUC of atovaquone from single dose to steady state, indicating that accumulation did not occur. However, the AUC of proguanil was modestly increased at steady state, and the AUC of the active metabolite cycloguanil was modestly decreased, in the 9 subjects who were extensive metaboliser phenotypes for the cytochrome P450 isoenzyme CYP2C19 (see 'Genetic factors', (p.4)). It was suggested that atovaquone may have inhibited the production of cycloguanil by CYP3A4. However, since this study had no arm with each drug alone, it is impossible to determine whether these changes in pharmacokinetics were due to an interaction or not.³

A pharmacokinetic interaction is not established, and is anyway of little clinical relevance, since the efficacy of the combination product for malaria prophylaxis up to 12 weeks is established. The enhanced activity of the combination may, in part, be due to proguanil lowering the effective concentration at which atovaquone collapses the mitochondrial potential in malaria parasites.⁴

Atovaquone + Rifamycins

Rifampicin reduces serum atovaquone levels by about 50% whereas atovaquone modestly raises serum rifampicin levels. The combination should be avoided because of the likelihood of sub-therapeutic atovaquone levels. Rifabutin caused a lesser 34% decrease in atovaquone levels, which the manufacturer considers may also reduce efficacy.

Clinical evidence

(a) Rifabutin

In 24 healthy subjects given atovaquone 750 mg twice daily and rifabutin 300 mg once daily for 14 days, there was a modest 34% decrease in the AUC of atovaquone and a small 19% decrease in the rifabutin levels.¹

(a) Rifampicin (Rifampin)

A steady-state study in 13 HIV-positive subjects found that the use of atovaquone 750 mg twice daily with rifampicin 600 mg four times daily for 14 days resulted in a more than 50% reduction in the atovaquone AUC and serum levels, but a more than 30% rise in rifampicin AUC and serum levels.^{2,3}

Mechanism

Uncertain. Atovaquone is predominantly excreted (greater than 90%) as unchanged drug in the faeces,^{3,4} and would not therefore be expected to be affected by cytochrome P450 enzyme induction.

Importance and management

Information is limited but these pharmacokinetic interactions appear to be established. Their clinical importance is unknown, but it seems highly likely that the efficacy of atovaquone will be reduced in the presence of rifampicin. The combination should therefore be avoided.

The effect of rifabutin is less than rifampicin, and the authors of the above report suggested that no atovaquone dosage adjustment is needed.¹ However, in the UK, the manufacturer of atovaquone still considers that rifabutin use could result in subtherapeutic atovaquone levels in some patients, and they also advise against the concurrent use of this combination.⁴

Atovaquone + Tetracyclines

Tetracycline reduces the plasma levels of atovaquone by about 40%. The effect of doxycycline does not appear to have been studied.

Clinical evidence, mechanism, importance and management

The manufacturer of atovaquone/proguanil^{1,2} notes that **tetracycline** may reduce plasma levels of atovaquone by about 40%.¹

An *in vitro* study found that **doxycycline** potentiated the antimalarial activity of atovaquone,³ but there appears to be no information on the effect of **doxycycline** on the absorption of atovaquone. A study looking at the population pharmacokinetics of atovaquone in 24 Thai patients found that neither the oral clearance nor the volume of distribution of atovaquone were significantly affected by the concurrent use of tetracycline.⁴

The manufacturers suggest that parasitaemia should be closely monitored in patients taking atovaquone/proguanil tablets with **tetracycline**.^{1,2} In the UK, they also say that **tetracycline** should be given with caution to patients taking atovaquone suspension for Pneumocystis pneumonia, until the interaction has been further studied,⁵ whereas the US manufacturers of atovaquone suspension do not mention **tetracycline**.⁶

Atovaquone/Proguanil + Artesunate

Artesunate does not appear to affect the pharmacokinetics of atovaquone/proguanil.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, a single dose of atovaquone/proguanil 1 g/400 mg was given to 12 healthy subjects with and without artesunate 250 mg. No change was noted in the pharmacokinetics of either atovaquone or proguanil and no unexpected adverse events were seen.¹ Although artesunate does not therefore appear to interact pharmacokinetically with atovaquone/proguanil, this needs confirmation in a multiple-dose study. A study to investigate whether the addition of artesunate to atovaquone/proguanil increased the risk of cardiotoxicity found that the QT_c interval was not significantly different in those receiving all three drugs, when compared with those receiving atovaquone/proguanil alone.²

Azoles + Antacids

The gastrointestinal absorption of ketoconazole is markedly reduced by antacids. Itraconazole may also be modestly affected. However, the absorption of fluconazole and posaconazole appears not to be significantly affected by antacids. Similarly, voriconazole is not expected to be affected.

Clinical evidence

(a) Fluconazole

Maalox forte (aluminium/magnesium hydroxide) 20 mL did not affect the absorption of a single 100-mg dose of fluconazole in 14 healthy subjects.¹

(b) Itraconazole

For mention of a study in which some patients needed an increase in itraconazole dose when treated with ranitidine and an antacid [not named], see 'Azoles + H₂-receptor antagonists', p.217.

(c) Ketoconazole

A haemodialysis patient did not respond to treatment with ketoconazole 200 mg daily while taking cimetidine, sodium bicarbonate 2 g daily and aluminium oxide 2.5 g daily. Only when the ketoconazole dosage was increased to 200 mg four times daily did her serum levels rise. A later study in 3 healthy subjects found that when ketoconazole 200 mg was taken 2 hours after cimetidine 400 mg, the absorption was considerably reduced (AUC reduced by about 60%). When this was repeated with the addition of sodium bicarbonate 500 mg, the absorption was reduced by about 95%. In contrast, when this was again repeated, but with the ketoconazole in an acidic solution, the absorption was increased by about 50%.²

A study in 4 patients found that the concurrent use of *Maalox* reduced the absorption of ketoconazole but this was not statistically significant.³ An anecdotal report suggested that giving ketoconazole 2 hours before a stomatitis cocktail containing *Maalox* seemed to prevent the cocktail reducing ketoconazole effectiveness.⁴

(d) Posaconazole

A study in 12 healthy subjects found that *Mylanta* (aluminium/magnesium hydroxide) 20 mL did not significantly affect the bioavailability of a single 200-mg dose of posaconazole, either when taken with food or when fasting.⁵

Mechanism

Ketoconazole is a poorly soluble base, which must be transformed by the acid in the stomach into the soluble hydrochloride salt. Agents that reduce gastric acidity, such as antacids, 'H₂-receptor antagonists', (p.217), and 'proton pump inhibitors', (p.218), raise the pH in the stomach so that the dissolution of the ketoconazole and its absorption are reduced. Conversely,

anything that increases the gastric acidity (e.g. 'cola drinks', (p.215)) increases the dissolution and the absorption of ketoconazole. The absorption of itraconazole is also affected by changes in gastric pH, but fluconazole and posaconazole are minimally affected.

Importance and management

The interaction of antacids with ketoconazole is clinically important, but not extensively documented. Advise patients to take antacids not less than 2 to 3 hours before or after the ketoconazole so that absorption can take place with minimal changes in the pH of the gastric contents.² Monitor the effects to confirm that the ketoconazole is effective.

The situation with itraconazole is not entirely clear, but based on the data with 'H₂-receptor antagonists', (p.217), some reduction in its absorption might be expected with antacids, and it would therefore be prudent to separate administration.

Antacids do not significantly affect posaconazole or fluconazole levels, and, based on the data with 'H₂-receptor antagonists', (p.217), would not be expected to affect voriconazole levels.

Azoles + Cola drinks

Some cola drinks can temporarily lower the stomach pH of patients with achlorhydria or hypochlorhydria due to disease or acid-suppressing drugs. This improves the bioavailability of itraconazole and ketoconazole.

Clinical evidence

Eight healthy subjects were given itraconazole 100 mg with either 325 mL of water or *Coca-Cola* (pH 2.5). Their peak serum itraconazole levels were more than doubled by the *Coca-Cola* and the itraconazole AUC was increased by 80%. Two of the subjects did not show this effect.¹

Another study in 18 fasted AIDS patients who absorbed itraconazole poorly, found that the absorption was restored to that of fasted healthy subjects when the itraconazole was given with a cola drink.² A study in 30 healthy subjects compared the bioavailability of itraconazole alone or after ranitidine, both with and without a cola drink. Ranitidine reduced the absorption of itraconazole but this effect was countered by the cola drink.³

Yet another study used omeprazole to raise the pH and *Coca-Cola Classic* to lower it. Absorption was greatest when ketoconazole was given alone, and least when given with omeprazole. However, *Coca-Cola* increased the absorption of ketoconazole in the presence of omeprazole to 65% of that seen with ketoconazole alone.⁴

Mechanism

Itraconazole and ketoconazole are poorly soluble bases, which must be transformed by the acid in the stomach into a soluble hydrochloride salt. Therefore any condition that reduces gastric acidity (or any drug that raises stomach pH, see 'H₂-receptor antagonists', (p.217) and 'proton pump inhibitors', (p.218)) can reduce the dissolution and the absorption of these antifungals. Acidic drinks, which lower the pH, can increase the absorption.

Importance and management

The interactions of itraconazole and ketoconazole with cola drinks that lower the gastric pH are established. The interaction can be exploited to improve the absorption of these antifungals in patients with achlorhydria or hypochlorhydria, and those taking gastric acid suppressants (see 'H₂-receptor antagonists', (p.217) and 'proton pump inhibitors', (p.218)), and this is recommended by some manufacturers of ketoconazole⁵ and itraconazole.^{6,7} For a brief mention of the use of cola to increase itraconazole

levels and thereby increase ciclosporin levels, see 'Ciclosporin + Azoles', p.1023. *Coca-Cola Classic*, *Pepsi* and *Canada Dry Ginger Ale* can be used because they can achieve stomach pH values of less than 3, but none of the other beverages examined in one study produced such a low pH. The authors suggest that these would be less effective, although they were not actually studied. They included *Diet Coca-Cola*, *Diet Pepsi*, *Diet 7-Up*, *Diet Canada Dry Ginger Ale*, *Diet Canada Dry Orange juice*, *7-Up* and *Canada Dry Orange juice*.⁴ For mention that **glutamic acid** did not increase the absorption of itraconazole in fasted or fed subjects, or ketoconazole in subjects pre-treated with cimetidine, see 'Azoles + Food', below, and 'Azoles + H₂-receptor antagonists', p.217, respectively.

Azoles + Food

Itraconazole capsules should be taken with or after food to improve absorption, whereas itraconazole solution should be taken at least one hour before food. Food increases the absorption of posaconazole suspension, and this should be taken with a meal or nutritional supplement. Some manufacturers advise taking ketoconazole with food, but two studies have shown little effect of food on absorption, and one actually showed a decrease. The bioavailability of voriconazole is modestly reduced by food, and the manufacturer recommends it be taken at least one hour before or after a meal. Food does not appear to affect the bioavailability of fluconazole capsules.

Clinical evidence

(a) Fluconazole

A study in 12 healthy subjects found that food had no therapeutically relevant effect on the pharmacokinetics of a single 100-mg dose of fluconazole in capsule form.¹

(b) Itraconazole

A study in 24 patients with superficial dermatophyte, *Candida albicans* and pityriasis versicolor infections, given itraconazole 50 or 100 mg daily, found that taking the drug with or after breakfast produced higher serum levels and gave much better treatment results than taking it before breakfast.² A later study found that the relative bioavailability of itraconazole was 54% on an empty stomach, 86% after a light meal and 100% after a full meal.¹ Similar results were found in other studies.^{3,4}

In contrast, studies with itraconazole oral solution give different results. A study in 30 healthy males given itraconazole solution 200 mg daily, either on an empty stomach or with a standard breakfast, found that the bioavailability was 29% higher when itraconazole was taken in the fasted state.⁵

In another study of 20 HIV positive patients, **glutamic acid** 1360 mg, given to acidify the stomach, either with or without food did not enhance itraconazole absorption.³

(c) Ketoconazole

One study found that the AUC and peak serum concentrations of a single 200-mg dose of ketoconazole tablets were *reduced* by about 40% (levels reduced from 4.1 to 2.3 micrograms/mL) when given to 10 healthy subjects after a standardised meal.⁶

In contrast, another study found that high carbohydrate and fat diets tended to reduce the rate, but not the overall amount of ketoconazole absorbed from tablets.⁷ Similarly, a third study found that the absorption of single 200- or 800-mg doses of ketoconazole in 8 healthy subjects was

not altered when they were taken after a standardised breakfast, although the peak serum levels were delayed. The absorption of single 400- and 600-mg doses were increased by about up to 50% with food, but this was not statistically significant.⁸

(d) Posaconazole

A study in 24 healthy subjects found that the maximum plasma levels and AUC of a single 400-mg dose of posaconazole oral suspension were increased 3.4- and 2.6-fold, respectively, when given with a **nutritional supplement** (*Boost Plus*) rather than in the fasting state.⁹ In a further study in 20 healthy subjects, single 200-mg doses of posaconazole (as oral suspension) were given with either a high-fat meal, a non-fat breakfast or after a 10-hour fast. The AUC of the suspension was increased fourfold when given with a high-fat meal, and 2.7-fold when given with a non-fat breakfast when compared with fasting.¹⁰

(e) Voriconazole

In a study 12 healthy subjects were given voriconazole capsules 200 mg twice daily either with food or in the fasted state (2 hours before or after food). Food delayed the oral absorption of voriconazole by about one hour and reduced the AUC by 22%.¹¹

Mechanism

Not understood.

Importance and management

Itraconazole absorption from the capsule formulation is best when it is taken with or after food, whereas absorption from the acidic liquid formulation appears to be better when it is taken at least one hour before food. Similarly, **posaconazole** absorption from the oral suspension is improved by food, and the manufacturer recommends that posaconazole should be taken with food.

A confusing and conflicting picture is presented by the studies with **ketoconazole**, two showing no significant change in absorption with food, and one showing a decrease. However, one manufacturer of ketoconazole says that the absorption of ketoconazole is maximal when it is taken during a meal, as it depends on stomach acidity, and it should therefore always be taken with meals.¹²

The manufacturers of **voriconazole** tablets and the US manufacturers of voriconazole suspension recommend that it should be taken at least 1 hour before or at least 1 hour after a meal. The UK manufacturers of voriconazole suspension suggest that it should be taken at least 1 hour before or at least 2 hours after a meal.^{13,14}

There appears to be no relevant interaction between food and **fluconazole** capsules.

Azoles + H₂-receptor antagonists

The gastrointestinal absorption of ketoconazole is markedly reduced by cimetidine and ranitidine. The absorption of itraconazole is reduced (possibly halved) by H₂-receptor antagonists, and, similarly, the absorption of posaconazole is reduced by about 40% by cimetidine. The absorption of fluconazole and voriconazole is not significantly affected by H₂-receptor antagonists.

Clinical evidence

(a) Fluconazole

The AUC₀₋₄₈ of fluconazole 100 mg was reduced by only 13% when it was given to 6 healthy subjects with a single 400-mg dose of cimetidine.¹ Two other studies found that cimetidine² and famotidine³ did not affect fluconazole absorption.

(b) Itraconazole

Twelve healthy subjects were given cimetidine 400 mg twice daily or ranitidine 150 mg twice daily for 3 days before and after a single 200-mg dose of itraconazole. The AUC and maximum serum levels of the itraconazole were reduced, but not significantly. The largest changes were 20% reductions in the AUC and maximum serum levels with ranitidine.⁴ In contrast, another study in 30 healthy subjects found that ranitidine 150 mg twice daily for 3 days reduced the AUC of a single 200-mg dose of itraconazole by 44%, and reduced the maximum serum levels by 52%.⁵ A study of the bioavailability of itraconazole in 12 lung transplant patients also given ranitidine 150 mg twice daily and an antacid four times daily found that the serum levels of itraconazole were highly variable. Half of the patients required the dose of itraconazole to be increased from 200 to 400 mg daily to achieve satisfactory serum levels.⁶

Famotidine 40 mg was found to reduce the serum levels of a 200-mg dose of itraconazole by about 50% in 12 healthy subjects.³ Famotidine 20 mg twice daily was given with itraconazole 200 mg daily for 10 days to 16 patients undergoing chemotherapy for haematological malignancies. The minimum plasma levels of itraconazole were reduced by about 39%, and 8 patients did not achieve the levels considered necessary to protect neutropenic patients from fungal infections.⁷

A study in 8 healthy subjects found that itraconazole 200 mg twice daily for 3 days increased the AUC of intravenous cimetidine (loading dose 0.2 mg/kg followed by an infusion of 36 mg/hour for 4 hours) by 25%.⁸

(c) Ketoconazole

A haemodialysis patient did not respond to treatment with ketoconazole 200 mg daily while taking cimetidine, sodium bicarbonate 2 g daily and aluminium oxide 2.5 g daily. Only when the ketoconazole dosage was increased to 200 mg four times daily did her serum levels rise. A later study in 3 healthy subjects found that when ketoconazole 200 mg was taken 2 hours after cimetidine 400 mg, the absorption was considerably reduced (AUC reduced by about 60%). When this was repeated with the addition of sodium bicarbonate 500 mg, the absorption was reduced by about 95%. In contrast, when this was again repeated but with the ketoconazole in an acidic solution, the absorption was increased by about 50%.⁹

The AUC of a single 200-mg oral dose of ketoconazole was reduced by 91% in 12 fasting subjects who received cimetidine 300 mg two hours prior to ketoconazole, followed by sodium bicarbonate 2 g one hour prior to the ketoconazole. This effect was only slightly reversed by the use of glutamic acid.¹⁰ Another study² in 24 healthy subjects found that intravenous cimetidine titrated to give a gastric pH of 6 or more reduced the absorption of ketoconazole by 95%. A study¹¹ in 6 healthy subjects found that ranitidine 150 mg given 2 hours before ketoconazole 400 mg reduced its AUC by about 95%.

(d) Posaconazole

A placebo-controlled study in 12 healthy subjects found that cimetidine 400 mg every 12 hours, given with posaconazole 200 mg once daily for 10 days, reduced the AUC and maximum plasma levels of posaconazole by about 40%.¹²

(e) Voriconazole

A study in 12 healthy subjects found that cimetidine 400 mg twice daily given with voriconazole 200 mg twice daily increased the maximum plasma levels and AUC of voriconazole by about 20%, but this is not consid-

ered sufficient to warrant a dosage adjustment.¹³ Ranitidine 150 mg twice daily had no significant effect on the AUC and maximum plasma levels of voriconazole.¹³

Mechanism

Ketoconazole is a poorly soluble base, which must be transformed by the acid in the stomach into the soluble hydrochloride salt. Agents that reduce gastric acidity, such as H₂-receptor antagonists, 'proton pump inhibitors', (p.218) or 'antacids', (p.215), raise the pH in the stomach so that the dissolution of the ketoconazole and its absorption are reduced. Conversely, anything that increases the gastric acidity increases the dissolution and the absorption (e.g. 'cola drinks', (p.215)). The absorption of itraconazole is also affected by changes in gastric pH, but fluconazole is minimally affected. The manufacturer of posaconazole says that the reduced absorption is possibly secondary to a reduction in gastric acid.¹⁴ The slight increase in cimetidine levels in the presence of itraconazole may be due to inhibition of P-glycoprotein mediated renal tubular secretion of cimetidine.⁸

Importance and management

The interactions with ketoconazole are clinically important but not extensively documented. Monitor the effects to confirm that the ketoconazole is effective. The situation with itraconazole is not entirely clear, but some reduction in its absorption apparently occurs and it would also therefore be prudent to confirm that it remains effective in the presence of H₂-receptor antagonists. It has been suggested⁵ that the reduction in bioavailability due to H₂-receptor antagonists can be minimised by giving itraconazole and ketoconazole with an acidic drink such as 'cola', (p.215), and this is recommended by some manufacturers.¹⁵⁻¹⁷

The bioavailability of posaconazole also appears to be reduced by cimetidine. If this is due to the reduction in gastric acid, it could be minimised by taking posaconazole with a cola drink, as for ketoconazole and itraconazole. However, the manufacturer currently recommends that the use of posaconazole with cimetidine or other H₂-receptor antagonists be avoided if possible, unless the benefit to the patient outweighs the risk.¹⁴ Further study is needed.

Fluconazole only interacts to a small and clinically irrelevant extent with H₂-receptor antagonists and is therefore a possible alternative to ketoconazole and itraconazole. Similarly, no dosage adjustments are necessary if voriconazole is used with any of the H₂-receptor antagonists.¹⁸

Azoles + Proton pump inhibitors

The bioavailability of ketoconazole is reduced by both omeprazole and rabeprazole. Other proton pump inhibitors are expected to behave similarly. Omeprazole also markedly reduces the absorption of itraconazole capsules, but not the oral solution. Proton pump inhibitors are predicted to reduce the bioavailability of posaconazole. The bioavailabilities of fluconazole and voriconazole are not significantly affected by omeprazole. Esomeprazole levels may also be increased by voriconazole. Omeprazole levels are increased by ketoconazole, and markedly increased by fluconazole and voriconazole.

Clinical evidence

(a) Esomeprazole

Based on data for omeprazole (see below), and the known acid-lowering effect of esomeprazole,¹ the manufacturers predict that esomeprazole might reduce the absorption of **itraconazole** and **ketoconazole**, which depend on a low pH for optimal dissolution and absorption.¹ **Voriconazole** may more than double the levels of esomeprazole.²

(b) Omeprazole

1. *Fluconazole*. A study in 12 healthy subjects found that omeprazole 20 mg daily for 7 days did not affect the pharmacokinetics of a single 100-mg dose of fluconazole given after a standard breakfast.³

In another study in 18 healthy subjects, fluconazole 100 mg daily for 5 days markedly increased the peak plasma levels and AUC of a single 20-mg dose of omeprazole by 2.4- and 6.3-fold, respectively.⁴

2. *Itraconazole*. Itraconazole 200 mg [capsule] was given after a standard breakfast to 11 healthy subjects after 14 days pre-treatment with omeprazole 40 mg daily. The AUC and maximum serum level of itraconazole were both reduced by about 65%.⁵ In contrast, another study in 15 healthy subjects found that omeprazole 40 mg daily did not significantly affect the pharmacokinetics of single 400-mg doses of itraconazole or its metabolite hydroxyitraconazole when given as an oral solution. However, there was a large interpatient variation in mean serum levels.⁶ Another study similarly reported that omeprazole had little effect on the pharmacokinetics of itraconazole oral solution.⁷

3. *Ketoconazole*. A three-way crossover study in 9 healthy fasting subjects found that omeprazole 60 mg reduced the AUC of ketoconazole 200 mg by about 80%.⁸

Another study was carried out in 10 healthy subjects (both 'extensive' and 'poor' metabolisers) to find the extent to which cytochrome P450 isoenzyme CYP3A4 is involved in the metabolism (sulfoxidation) of omeprazole. This revealed that ketoconazole 100 to 200 mg, a known inhibitor of CYP3A4, reduced the formation of the omeprazole sulfone in both groups, and doubled the serum omeprazole levels in the poor metabolisers.⁹

4. *Posaconazole*. Based on the 40% reduction in posaconazole AUC when given with 'cimetidine', (p.217), the manufacturers consider that **proton pump inhibitors** might interact similarly.¹⁰

5. *Voriconazole*. A study in 18 healthy subjects found that omeprazole 40 mg daily for 7 days increased the maximum plasma levels and AUC of voriconazole by 15 and 41%, respectively. Food was prohibited within one hour before and after each dose.¹¹

However, voriconazole 200 mg twice daily increased the maximum plasma levels and AUC of omeprazole 40 mg once daily by about twofold and fourfold respectively.¹²

(c) Rabeprazole

In a randomised placebo-controlled study 18 healthy subjects were given **ketoconazole** 400 mg before and after taking rabeprazole 20 mg daily or a placebo for 7 days. Significant decreases in the **ketoconazole** AUC and maximum serum levels were found,¹³ representing about a 30% reduction in its bioavailability.¹⁴ There was no evidence that **ketoconazole** affected rabeprazole metabolism.

Mechanism

Ketoconazole and itraconazole are poorly soluble bases, which must be transformed by the acid in the stomach into the soluble hydrochloride salt. Agents that reduce gastric secretions, such as proton pump inhibitors, 'H₂-receptor antagonists', (p.217), or 'antacids', (p.215), raise the pH in

the stomach so that the dissolution and absorption of drugs such as itraconazole or ketoconazole are reduced. Conversely, anything that increases the gastric acidity increases their dissolution and absorption.⁸

Fluconazole and voriconazole almost certainly cause a rise in omeprazole and esomeprazole levels by inhibiting their metabolism by the cytochrome P450 isoenzymes CYP2C19 and CYP3A4. As esomeprazole is an inhibitor of and also a substrate for CYP2C19, it is likely to have the same effect as omeprazole.¹ Ketoconazole only inhibits CYP3A4 and therefore causes a less marked rise in omeprazole levels. Itraconazole would be expected to interact similarly to ketoconazole.

Importance and management

The interaction between **ketoconazole** and omeprazole appears to be established and of clinical importance. Direct evidence seems to be limited to this study, but other drugs that raise the gastric pH have a similar effect (see 'Azoles + Antacids', p.215 or 'H₂-receptor antagonists', p.217). Such a large reduction in the absorption of ketoconazole would be expected to result in the failure of treatment. Separating the dosages of the two drugs is unlikely to be the answer because the effect of omeprazole is so prolonged. An alternative would simply be to monitor for any inadequate response to ketoconazole if omeprazole or esomeprazole is also given and to raise the dosage if necessary. However, bear in mind that ketoconazole can double omeprazole levels, although the clinical relevance of this is uncertain. Giving ketoconazole with an acidic drink⁸ such as 'cola', (p.215), appears to minimise the interaction, and is recommended by some manufacturers of ketoconazole for patients taking proton pump inhibitors.¹⁵

The interaction between ketoconazole and rabeprazole is also established, but the reduction in the bioavailability is only moderate (30%) and it may be possible to accommodate this by raising the antifungal dosage.

There seem to be no reports about ketoconazole and other proton pump inhibitors but they are also expected to interact to reduce the bioavailability of the ketoconazole, but the extent is not known.

The interaction between **itraconazole** and omeprazole also appears to be established, but it appears that this can be minimised by using an oral itraconazole solution. As with ketoconazole, giving itraconazole with an acidic drink such as 'cola', (p.215) would minimise the interaction, and is recommended by some manufacturers of itraconazole for patients taking proton pump inhibitors.^{16,17} Monitor patients taking itraconazole if proton pump inhibitors are also given. The effect of itraconazole on omeprazole is unknown, but it might be expected to increase omeprazole levels similarly to ketoconazole.

The interaction between **voriconazole** and omeprazole is established but no adjustment to the dose of voriconazole is required.^{12,18} The clinical importance of the marked rise in serum omeprazole levels caused by voriconazole is not established, but the manufacturers recommend that the omeprazole dose be halved,^{12,18} although the US manufacturers restrict this to patients taking omeprazole 40 mg or more.¹² The increase in levels of esomeprazole by voriconazole does not routinely require a dose adjustment of esomeprazole. However, patients taking esomeprazole in doses of more than 240 mg daily (e.g. for Zollinger-Ellison syndrome) may require a dose adjustment.²

Fluconazole is not affected by omeprazole, and is unlikely to be affected by other proton pump inhibitors. However, fluconazole markedly increases omeprazole levels. The clinical relevance of these changes is uncertain, but not likely to be important for single-dose fluconazole regimens. More study is needed to establish whether it is advisable to reduce the omeprazole dose in those given both drugs longer-term.

Because of the possibility that **posaconazole** levels might be reduced by proton pump inhibitors, the manufacturer currently recommends that concurrent use be avoided if possible.¹⁰ Further study is needed.

Azoles + Rifabutin

Rifabutin levels are increased by fluconazole, posaconazole, voriconazole, and possibly itraconazole. Patients taking this combination are at increased risk of rifabutin toxicity, specifically uveitis, and should be closely monitored. Rifabutin markedly reduces the plasma levels of itraconazole, posaconazole, and voriconazole. These azoles should be used cautiously with rifabutin, if at all. Rifabutin does not affect the metabolism of fluconazole.

Clinical evidence

(a) Fluconazole

Twelve HIV positive patients were given zidovudine 500 mg daily from day 1 to 44, fluconazole 200 mg daily from days 3 to 30 and rifabutin 300 mg daily from days 17 to 44. Rifabutin did not significantly affect the pharmacokinetics of fluconazole,¹ but fluconazole increased the AUC of rifabutin by 82%, and the AUC of the rifabutin metabolite LM565 was increased by 216%.¹ In another study in 10 patients with HIV infection, fluconazole 200 mg daily increased the AUC of rifabutin 300 mg daily by 76% and the maximum level by 91%. When the patients were also given clarithromycin 500 mg daily, the AUC of rifabutin was further increased to 152%.² There is some evidence that fluconazole increases the prophylactic efficacy of rifabutin against *M. avium* complex disease, although there was also an increase in incidence of leucopenia.³ Uveitis developed in 6 HIV positive patients taking rifabutin 450 to 600 mg daily and fluconazole, 5 of whom were also taking clarithromycin,⁴ which is also known to increase rifabutin levels, see 'Macrolides + Rifamycins', p.316. Uveitis has been attributed to the concurrent use of rifabutin and fluconazole in other reports.^{5,6} Rifabutin does not appear to significantly affect the metabolism of fluconazole.^{7,8}

(b) Itraconazole

1. *Itraconazole serum levels reduced.* In a three-period study, 6 HIV positive patients were given itraconazole 200 mg daily for 14 days, rifabutin 300 mg daily for 10 days, and then both drugs for 14 days. It was found that the rifabutin reduced the peak plasma levels of the itraconazole by 71% and reduced its AUC by 74%.⁹

2. *Rifabutin serum levels raised.* A 49-year-old HIV positive man taking rifabutin 300 mg daily was also given itraconazole 600 mg daily. Because of low plasma levels after 3 weeks the itraconazole dose was increased to 900 mg daily. A week later the patient developed anterior uveitis. It was found that the itraconazole trough serum levels were normal but rifabutin trough serum levels were raised to 153 nanograms/mL (expected to be less than 50 nanograms/mL after 24 hours). Rifabutin was stopped and the uveitis was treated. Symptoms resolved after 5 days.¹⁰

(c) Posaconazole

In a study in healthy subjects the concurrent use of posaconazole 200 mg once daily and rifabutin 300 mg once daily for 10 days increased the AUC of rifabutin by 72% and decreased the AUC of posaconazole by 51% when compared with either drug alone.¹¹

(d) Voriconazole

Rifabutin 300 mg daily decreased the AUC and maximum plasma levels of voriconazole 200 mg twice daily by 79% and 67%, respectively. Increasing the dose of voriconazole to 350 mg twice daily in the presence of ri-

fabutin gave an AUC of 68% of that achieved with voriconazole 200 mg twice daily alone while maximum plasma levels were more or less the same.^{12,13} At a dose of 400 mg twice daily, voriconazole increased the maximum plasma level and AUC of rifabutin 300 mg twice daily by about threefold and fourfold, respectively.^{12,13}

Mechanism

Rifabutin increases the metabolism of itraconazole, posaconazole and voriconazole, probably, at least in part, by inducing their metabolism by the cytochrome P450 CYP3A subfamily. Fluconazole is largely excreted unchanged in the urine and so it is not affected. The azoles apparently increase rifabutin levels by inhibiting its metabolism, probably by CYP3A4. Raised rifabutin levels can cause uveitis.

Importance and management

The interaction between rifabutin and **fluconazole** is established, the general picture being that concurrent use can be advantageous. However, because of the increased risk of uveitis, the UK Committee on Safety of Medicines says that full consideration should be given to reducing the dosage of rifabutin to 300 mg daily. The rifabutin should be stopped if uveitis develops and the patient referred to an ophthalmologist.¹⁴ A later review suggests this 300 mg dose is associated with a reduced risk of uveitis and maintains efficacy.¹⁵ The combination should be well monitored. Note that the effects of 'clarithromycin', (p.316), are additive with those of fluconazole.

Information on the interaction between **itraconazole** and rifabutin is very limited, but monitor for reduced antifungal activity, raising the itraconazole dosage as necessary, and watch for increased rifabutin levels and toxicity (in particular uveitis). More study is needed. Note that the manufacturers recommend that the combination should be avoided.^{16,17}

The manufacturer of **ketoconazole** suggests that the levels of both drugs may be affected if rifabutin is also taken. They suggest that the rifabutin dose may need to be reduced.¹⁸

On the basis of the interaction between rifabutin and **posaconazole**, the manufacturer suggests that the combination be avoided unless the benefit to the patient outweighs the risk.¹⁹ If the combination is used, monitor the efficacy of posaconazole and the toxicity of rifabutin, particularly full blood counts and uveitis.

The manufacturer in the US contraindicates the combination of **voriconazole** and rifabutin.¹³ However, the UK manufacturer permits concurrent use if the benefits outweigh the risks.¹² If used together, it is recommended that the oral dose of voriconazole be increased from 200 mg twice daily to 350 mg twice daily (and from 100 to 200 mg twice daily in patients under 40 kg). The intravenous dose should also be increased from 4 to 5 mg/kg twice daily. Importantly, the manufacturer advises careful monitoring for rifabutin adverse effects (e.g. check full blood counts, monitor for uveitis).¹²

Azoles + Rifampicin (Rifampin) and/or Isoniazid

Although rifampicin causes only a modest increase in fluconazole clearance, the reduction in its effects may possibly be clinically important. Fluconazole does not appear to affect rifampicin pharmacokinetics. There is an isolated report of hypercalcaemia in a patient taking both fluconazole and rifampicin.

Rifampicin very markedly reduces serum itraconazole levels. This can reduce or abolish the antifungal effects of the itraconazole, possibly depending on the infection being treated.

The serum levels of ketoconazole can be reduced by 50 to 90% by rifampicin and/or isoniazid. Serum rifampicin levels can also be halved by ketoconazole, but are possibly unaffected if the drugs are given 12 hours apart.

Rifampicin markedly reduces voriconazole levels, and the combination should be avoided. Posaconazole is predicted to be similarly affected.

Clinical evidence

(a) Fluconazole

1. *Fluconazole levels reduced.* In a study in healthy subjects, rifampicin 600 mg daily for 19 days reduced the AUC of a single 200-mg dose of oral fluconazole by 23% and decreased the half-life by 19%.¹

Similarly, a study in two groups of 12 patients with AIDS found that the AUC and peak plasma level of fluconazole 400 mg daily given for cryptococcal meningitis were reduced by 22% and 17% by rifampicin 600 mg daily when compared with the 12 patients not given rifampicin. The elimination rate constant of fluconazole was increased by 39% and the elimination half life was reduced by 28%. There were no significant changes in clinical outcome although the subsequent use of a lower prophylactic dose of fluconazole 200 mg with rifampicin was found to result in levels of fluconazole below the MIC of the infecting organism.² Also, 3 patients with AIDS being treated for cryptococcal meningitis with fluconazole 400 mg daily relapsed when rifampicin was added.³ Another report briefly states that one of 5 patients taking fluconazole needed an increased dosage or a replacement antifungal when given rifampicin.⁴

In yet another study, the AUC of *intravenous* fluconazole was 52% lower in 2 patients also taking rifampicin than in 3 other patients not taking rifampicin.⁵

2. *Rifampicin (Rifampin) levels unchanged.* A study in 11 AIDS patients with cryptococcal meningitis found that fluconazole 200 mg twice daily for 14 days had no effect on the pharmacokinetics of rifampicin 300 mg daily.⁶ Five AIDS patients with tuberculosis, taking rifampicin and fluconazole, had normal rifampicin levels compared with 14 similar patients taking rifampicin alone, but in both groups rifampicin levels were only about 28% of those predicted.⁷

3. *Hypercalcaemia.* There is an isolated report of severe hypercalcaemia attributed to the use of rifampicin and fluconazole in a patient with tuberculosis and pneumocystosis.⁸ The clinical relevance of this case is uncertain.

(b) Itraconazole

A patient receiving antitubercular treatment including rifampicin 600 mg and isoniazid 300 mg daily was also given itraconazole 200 mg daily. After 2 weeks his serum itraconazole levels were negligible (0.011 mg/L). Even when the dosage was doubled the levels only reached a maximum of 0.056 mg/L. When the antitubercular drugs were stopped his serum itraconazole level was 3.23 mg/L with a 300 mg daily dose, and 2.35 to 2.6 mg/L with a 200 mg daily dose.⁹

A later study in 8 other patients confirmed that itraconazole levels were reduced by rifampicin but the clinical outcome depended on the mycosis being treated. Four out of 5 patients responded to treatment for a *Cryptococcus neoformans* infection, despite undetectable itraconazole levels, apparently because *in vitro* there is synergy between the two drugs. In contrast, 2 patients with coccidioidomycosis failed to respond, and 2 others with cryptococcosis suffered a relapse or persistence of seborrhoeic dermatitis (possibly due to *M. furfur*) while taking both drugs.¹⁰ In a pa-

tient with AIDS the serum levels of itraconazole 400 to 600 mg daily in divided doses were undetectable in the presence of rifampicin, and took 3 to 5 days to recover after the rifampicin was stopped.¹¹ Undetectable itraconazole levels occurred in another patient given rifampicin who was treated for histoplasmosis.¹² In contrast, a study found that the AUC of a single 100-mg dose of itraconazole was reduced by 80% after 6 healthy subjects took rifampicin 600 mg daily for 3 days.¹³ Very markedly reduced serum itraconazole levels (undetectable in some instances) have been seen in other healthy subjects and AIDS patients when given rifampicin.¹⁴ Retrospective review of the medical records of 2 patients given itraconazole and rifampicin indicated that itraconazole was not effective until rifampicin was stopped, based on the finding of continued weight loss while on the combination, and a clear weight gain after rifampicin was stopped.¹⁵

(c) Ketoconazole

1. *Ketoconazole levels.* Rifampicin 600 mg daily reduced the AUC of ketoconazole 200 mg by 80% in a study in 6 healthy subjects.¹⁶ Similarly, the serum levels of ketoconazole 200 mg daily were roughly halved by rifampicin 600 mg in one patient. After 5 months of concurrent use with rifampicin and **isoniazid** 300 mg daily, there was a ninefold decrease in peak serum levels and the AUC was reduced by nearly 90%.¹⁷

A study in a 3-year-old child who had responded poorly to treatment found that peak serum levels and AUC of ketoconazole were reduced by about 65 to 80% by rifampicin and/or **isoniazid**. The interaction also occurred when the dosages were separated by 12 hours. When all three drugs were given together the ketoconazole serum levels were undetectable.¹⁸ Other reports confirm these reports of decreased ketoconazole levels with rifampicin.¹⁹⁻²³

2. *Rifampicin levels.* The addition of ketoconazole 200 mg twice daily for one day then 200 mg once daily for 2 days to rifampicin 600 mg daily had little effect on the peak level and AUC of rifampicin in a study in 6 healthy subjects.¹⁶ In contrast, the rifampicin serum levels of a child were roughly halved by ketoconazole, but when the rifampicin was given 12 hours after the ketoconazole, the serum levels of rifampicin were unaffected.¹⁸ Other studies also show a reduction in rifampicin levels caused by ketoconazole,²¹⁻²³ one confirming that separation of the drugs by 12 hours minimised the interaction.²¹

(d) Voriconazole

The manufacturer²⁴ notes that rifampicin 600 mg once daily decreased the maximum plasma levels and AUC of voriconazole 200 mg twice daily by about 95%. Even doubling the dose of voriconazole did not give adequate exposure.²⁴ The concurrent use of voriconazole and rifampicin is therefore contraindicated.^{24,25}

Mechanism

Rifampicin increases the metabolism of the azole antifungals by the liver. However, as fluconazole (unlike ketoconazole, itraconazole and voriconazole) is mainly excreted unchanged in the urine, changes to its metabolism would not be expected to have as marked an effect as on these other azoles.

The absorption of antitubercular drugs may be reduced in patients with AIDS and an increase in rifampicin levels may be due to increased absorption in the presence of fluconazole.⁷ In contrast, it is suggested that ketoconazole impairs the absorption of rifampicin from the gut. Just how isoniazid interacts is uncertain.

Importance and management

The interaction between rifampicin and **fluconazole** appears to be established and of clinical importance. Although rifampicin has only a modest effect on fluconazole, the cases of relapse cited above³ and the need for an increased dosage⁴ indicate that this interaction can be clinically important. Monitor concurrent use and increase the fluconazole dosage if necessary. One study suggests a 30% increase in fluconazole dose may be considered for serious infections during concurrent rifampicin therapy. This may be especially important during prophylaxis of cryptococcal meningitis with lower doses of fluconazole, such as 200 mg daily.²

The interaction between **itraconazole** and rifampicin is established and clinically important. Monitor the effects of concurrent use, being alert for the need to increase the itraconazole dosage. The effect on serum itraconazole levels can be very marked indeed. The clinical importance of this interaction can apparently depend on the mycosis being treated. Note that the manufacturer considers that itraconazole should not be used with rifampicin, since its levels are so markedly reduced.^{26,27}

The interactions between **ketoconazole** and rifampicin appear to be established and of clinical importance, but there is very much less information about the interaction with isoniazid. The effects on rifampicin can apparently be avoided by giving the ketoconazole at a different time (12 hours apart seems to be effective) but this does not solve the problem of the effects on ketoconazole. The dosage of at least one of the drugs will need to be increased to achieve both good antitubercular and antifungal responses. Concurrent use should be well monitored and dosage increases made if necessary. One manufacturer suggests that the combination should be avoided.²⁸

The manufacturer predicts that **posaconazole** levels may be significantly lowered when used with rifampicin. They suggest that the combination be avoided unless the benefit to the patient outweighs the risk.²⁹

Voriconazole levels are very markedly reduced by rifampicin and concurrent use is contraindicated.^{24,25}

Azoles + Sucralfate

The gastrointestinal absorption of ketoconazole is modestly reduced by sucralfate. The absorption of fluconazole appears not to be significantly affected by sucralfate.

Clinical evidence

(a) Fluconazole

Sucralfate 2 g was found to have no significant effect on the pharmacokinetics of a single 200-mg dose of fluconazole in 10 healthy subjects, confirming the results of an *in vitro* study.¹

(b) Ketoconazole

A study² in 6 fasting healthy subjects found that sucralfate 1 g given 2 hours before ketoconazole 400 mg reduced its AUC by about 20%. Another study in fasting healthy subjects found that sucralfate 1 g given with glutamic acid hydrochloride reduced the AUC and maximum serum levels of a single 100-mg dose of ketoconazole by about 25%, but no significant changes were seen when the ketoconazole was given 2 hours after the sucralfate.³

Mechanism

There is *in vitro* evidence that an electrostatic interaction occurs between ketoconazole and sucralfate to form an ion pair that cannot pass through the gut wall.⁴

Importance and management

The interaction of sucralfate with ketoconazole is modest and of uncertain clinical importance. Any interaction may be minimised by taking sucralfate not less than 2 to 3 hours before or after the ketoconazole.

Fluconazole does not interact with sucralfate.

Azoles; Fluconazole + Hydrochlorothiazide

Hydrochlorothiazide modestly increases the levels of fluconazole, but this is unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

The manufacturer notes that, in 13 healthy subjects, hydrochlorothiazide 50 mg daily increased the AUC and plasma levels of fluconazole 100 mg daily for 10 days by about 40%.^{1,2} They attribute these changes to a reduction in the renal clearance of fluconazole.² However they say it is unlikely that a change in the fluconazole dosage will be needed in patients taking diuretics, but that the interaction should be borne in mind.¹ Any interaction is almost certainly of no relevance in patients taking a single dose of fluconazole for genital candidiasis.

2. Diflucan (Fluconazole). Pfizer Inc. US Prescribing information, August 2004.

Azoles; Itraconazole + Grapefruit and other fruit juices

Grapefruit juice impaired the absorption of itraconazole capsules in one study, but not in another. Grapefruit juice had no effect on the absorption of itraconazole oral solution. Orange juice impaired the absorption of itraconazole capsules in one study.

Clinical evidence

(a) Capsules

In one study, either 240 mL of double-strength **grapefruit juice** or water were given with, and 2 hours after a single 200-mg dose of itraconazole (*Sporanox capsules*, Janssen) to 11 healthy subjects immediately after a standard breakfast. **Grapefruit juice**, unexpectedly decreased the AUC of itraconazole on average by 43% (range 81% reduction to 105% increase), with a similar decrease in hydroxy-itraconazole levels.¹ However, another

similar study found that **grapefruit juice** had no effect on the pharmacokinetics of itraconazole capsules (*Itrizole, Janssen*). The only apparent differences in this study were that itraconazole was given at the lower dose of 100 mg, and that 350 mL of single-strength **grapefruit juice** was used.² Furthermore, in this study,² **orange juice** reduced the AUC of itraconazole by an average of 41%.

(b) Oral solution

A small 17% increase in the AUC of itraconazole was seen in 20 healthy subjects when given grapefruit juice. In this study, regular strength grapefruit juice 240 mL was given three times daily for 2 days, then together with itraconazole oral solution 200 mg on the morning of the third day in the fasted state, then again 2 hours later.³

Mechanism

As grapefruit juice is an inhibitor of intestinal cytochrome P450 isoenzyme CYP3A4, the major enzyme involved in itraconazole metabolism, it was predicted that it would enhance itraconazole absorption. Appearing to confirm this, a small increase in itraconazole levels was seen with itraconazole oral solution. However, with itraconazole capsules, one study showed decreased levels and one no change. The mechanism is not known, but grapefruit juice may impair the absorption of itraconazole capsules either by affecting P-glycoprotein or lowering the duodenal pH.¹

Importance and management

The 40% reduction in itraconazole levels from itraconazole capsules seen with grapefruit juice would be anticipated to be clinically relevant in some situations, but it was seen in only one of two single-dose studies. Similarly, the reduction in levels with orange juice might be clinically relevant. However, at present, there is insufficient evidence to recommend avoiding concurrent use. Until more is known, in the event of unexpected inefficacy or low levels of itraconazole, bear the possibility in mind that grapefruit juice or orange juice may be a factor. Itraconazole oral solution, which is better absorbed than the capsules, did not appear to be affected by grapefruit juice.

Azoles; Topical + Miscellaneous

Butoconazole, clotrimazole and fenticonazole are absorbed very poorly from the vagina so that the risk of an interaction with other drugs given systemically is small. Similarly, econazole, oxiconazole and sertaconazole are minimally absorbed through the skin, and would not be expected to cause drug interactions. However, note that there have been a few cases of miconazole cream or pessaries interacting with oral anticoagulants, see ‘Coumarins and related drugs + Azoles; Miconazole’, p.388.

Clinical evidence, mechanism, importance and management

(a) Intravaginal application

The manufacturer notes that 1.3% to 2.2% of the dose of intravaginal **butoconazole** cream 2% was absorbed in a study in three women.¹

Early studies with intravaginal **clotrimazole** revealed that only a small fraction (3 to 10% of the dose) was absorbed systemically, and that this was rapidly metabolised.²

A study in 14 women (5 of them healthy, 4 with relapsing vulvovaginal candidiasis, and 5 with cervical carcinoma) found that the systemic absorption of **fenticonazole** nitrate from a single 1-g pessary was very small indeed. The amount absorbed, based on the amount recovered from the urine and faeces over 5 days, ranged from 0.58 to 1.81% of the original dose.³

The risk of a clinically relevant interaction with other drugs that may be present in the body would therefore seem to be very small with these an-

tifungals used vaginally. However, for a few reports of raised INRs in women taking oral anticoagulants while using intravaginal miconazole, see ‘Coumarins and related drugs + Azoles; Miconazole’, p.388.

(b) Topical application to the skin

After topical application to the skin of normal subjects, systemic absorption was extremely low and less than 1% of the applied dose of **econazole** was recovered in the urine and faeces.⁴ Systemically administered econazole does inhibit cytochrome P450 isoenzymes, but because of the low systemic availability after topical application, one manufacturer notes that clinically relevant interactions are rare.⁵

The manufacturer of **oxiconazole** notes that systemic absorption is low, and in healthy subjects less than 0.3% of the applied dose was recovered in the urine after topical application of the cream.⁶

Plasma levels of **sertaconazole** were below the limit of detection (2.5 nanograms/mL) when 5 patients with interdigital tinea pedis applied sertaconazole cream 2% every 2 hours for a total of 13 doses.⁷

Based on this information the risk of a clinically relevant drug interaction with systemically administered drugs and these topical azoles would seem to be very small. However, for a case report of raised INR in a man taking warfarin while using miconazole cream for a groin infection, see ‘Coumarins and related drugs + Azoles; Miconazole’, p.388.

Azoles; Voriconazole + St John's wort (*Hypericum perforatum*)

St John's wort, taken for two weeks, halved the levels of a single dose of voriconazole, which may be clinically relevant.

Clinical evidence, mechanism, importance and management

A single 400-mg dose of oral voriconazole was given alone and on the first and last day of St John's wort (*Jarsin, Lichtwer Pharma*) given at a dose of 300 mg three times daily for 15 days to 17 healthy subjects. One day of St John's wort had no effect on the voriconazole AUC_{0-∞}, but slightly increased the maximum serum level and AUC₀₋₁₀ by 22%. However, when voriconazole was given on day 15, the AUC of voriconazole was decreased by 59% and there was a 2.4-fold increase in oral clearance.¹

These results suggest that the short-term effect of St John's wort is to slightly enhance the absorption of voriconazole, whereas the longer-term effect is to induce absorption-limiting transport proteins and intestinal metabolism via cytochrome P450 isoenzymes.¹

The slight increase in voriconazole absorption with a single dose of St John's wort is not clinically relevant. However, the reduction in voriconazole levels after 15 days of St John's wort could impact on clinical efficacy. This suggests that patients requiring voriconazole should be asked about current or recent use of St John's wort, since this may indicate the need to use an increased voriconazole dose, at least initially. Patients taking voriconazole should be advised not to take St John's wort.

Chloroquine or Hydroxychloroquine + Antacids or Kaolin

The absorption of chloroquine is moderately reduced by magnesium trisilicate and kaolin. Hydroxychloroquine is predicted to be similarly affected.

Clinical evidence

Six healthy subjects were given chloroquine phosphate 1 g (equivalent to 620 mg of chloroquine base) with either **magnesium trisilicate** 1 g or

kaolin 1 g after an overnight fast. The **magnesium trisilicate** reduced the AUC of the chloroquine by 18.2% and the **kaolin** reduced it by 28.6%.¹

Related *in vitro* studies by the same authors using segments of *rat* intestine found that the absorption of chloroquine was decreased as follows: **magnesium trisilicate** 31.3%, **kaolin** 46.5%, **calcium carbonate** 52%, and **gerdiga** 36.1%. **Gerdiga** is a clay containing hydrated silicates with sodium and potassium carbonates and bicarbonates. It is used as an antacid and is similar to **attapulgit**.²

Mechanism

These antacid and antidiarrhoeal compounds adsorb chloroquine thereby reducing the amount available for absorption by the gut. Dissolution of chloroquine from tablets may also be delayed by adsorbent antacids.³

Importance and management

The modest pharmacokinetic interactions between chloroquine and magnesium trisilicate or kaolin are established, but their clinical importance does not seem to have been assessed. One way to minimise any interaction is to separate the dosages of the antimalarials and magnesium trisilicate or kaolin as much as possible (at least 2 to 3 hours) to reduce admixture in the gut. There do not appear to be any studies to see if other antacids behave similarly.

The manufacturer of **hydroxychloroquine** predicts that, as with chloroquine, antacids might decrease hydroxychloroquine absorption, and they recommend separating administration by 4 hours.⁴

4. Plaquenil (Hydroxychloroquine sulfate). Sanofi-Aventis. UK Summary of product characteristics, March 2003.

Chloroquine + Colestyramine

Colestyramine can modestly reduce the absorption of chloroquine, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

Colestyramine 4 g reduced the absorption of chloroquine 10 mg/kg by about 30% in 5 children aged 6 to 13. Considerable inter-individual differences were seen.¹ This reduced absorption is consistent with the way colestyramine interacts with other drugs by binding to them in the gut. The clinical importance is uncertain but separating the dosages is effective in minimising this interaction with other drugs. It is generally advised that other drugs are given 1 hour before or 4 to 6 hours after colestyramine.

1. Gendrel D, Verdier F, Richard-Lenoble D, Nardou M. Interaction entre colestyramine et chloroquine. *Arch Fr Pediatr* (1990) 47, 387–8.

Chloroquine or Hydroxychloroquine + H₂-receptor antagonists

Cimetidine reduces the metabolism and clearance of chloroquine, but the clinical importance of this is uncertain. Hydroxychloroquine is predicted to interact in the same way as chloroquine. Ranitidine appears not to interact with chloroquine.

Clinical evidence, mechanism, importance and management

Cimetidine 400 mg daily for 4 days approximately halved the clearance of a single 600-mg dose of chloroquine base in 10 healthy subjects. The elimination half-life was prolonged from 3.11 to 4.62 days.¹ It was suggested that these effects occurred because **cimetidine** inhibits the metabolism of chloroquine by the liver. The clinical importance of this interaction is uncertain, but it would seem prudent to be alert for any signs

of chloroquine toxicity during concurrent use. A similar study by the same authors found that **ranitidine** does not interact with chloroquine.²

On the basis of these data for chloroquine and cimetidine, the manufacturer of **hydroxychloroquine** states that, even though specific reports have not appeared, **cimetidine** might inhibit **hydroxychloroquine** metabolism.³

3. Plaquenil (Hydroxychloroquine sulfate). Sanofi-Aventis. UK Summary of product characteristics, March 2003.

Chloroquine + Imipramine

No pharmacokinetic interaction was seen in 6 healthy subjects given single doses of chloroquine 300 mg and imipramine 50 mg.¹ See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

1. Onyeji CO, Toriola TA, Ogunbona FA. Lack of pharmacokinetic interaction between chloroquine and imipramine. *Ther Drug Monit* (1993) 15, 43–6.

Chloroquine + Methylthioninium chloride (Methylene blue)

Methylthioninium chloride caused a small 20% reduction in exposure to chloroquine, which was not considered to be clinically relevant.

Clinical evidence, mechanism, importance and management

Methylthioninium chloride 130 mg twice daily given orally to 12 healthy subjects with a 3-day course of chloroquine tended to decrease the AUC of chloroquine (by 20%), without affecting renal clearance when compared with a control group of 12 patients receiving chloroquine alone. This small reduction would not be expected to be clinically relevant.¹

1. Rengelshausen J, Burhenne J, Fröhlich M, Tayrouz Y, Kumar Singh S, Riedel K-D, Müller O, Hoppe-Tichy T, Haefeli WE, Mikus G, Walter-Sack I. Pharmacokinetic interaction of chloroquine and methylene blue combination against malaria. *Eur J Clin Pharmacol* (2004) 60, 709–15.

Chloroquine + Promethazine

Promethazine appears to increase the levels of intramuscular chloroquine and its metabolites.

Clinical evidence, mechanism, importance and management

A study in healthy subjects found that intramuscular promethazine hydrochloride 25 mg, given with intramuscular chloroquine phosphate 200 mg increased the AUC of chloroquine and its metabolites by 85%. This may be due to promethazine enhancing the absorption of chloroquine from the injection site or displacing it and its metabolites from binding sites in the blood. The initial rate of excretion of chloroquine and the total drug excreted within 3 hours was unaffected by promethazine.¹ The increased bioavailability of chloroquine may improve its therapeutic effects but could also increase toxicity. *In vitro* and *animal* studies suggest the combination may be effective in the treatment of uncomplicated chloroquine-resistant malaria.^{2,3} More study is needed. For mention that chloroquine may increase chlorpromazine levels, see 'Phenothiazines + Antimalarials', p.759.

Co-artemether + CYP2D6 substrates

The manufacturer of co-artemether¹ notes that *in vitro* data indicate that lumefantrine significantly inhibits CYP2D6. As a consequence, they contraindicate the use of co-artemether in patients taking any drug that is metabolised by CYP2D6, and they give flecainide, metoprolol, imipramine, amitriptyline, clomipramine as examples (for a list of CYP2D6 substrates, see 'Table 1.3', (p.6)). These contraindications seem unnecessarily restrictive, especially since none of the drugs they give as examples are contraindicated with other established inhibitors of CYP2D6. Until more is known, it would be prudent to closely monitor the effects of any CYP2D6 substrate in patients for whom co-artemether is considered the antimalarial drug of choice.

1. Riamet (Artemether/Lumefantrine). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, December 2006.

Co-artemether + CYP3A4 inhibitors

Ketoconazole doubles the AUC of artemether and lumefantrine, and other potent inhibitors of CYP3A4 are predicted to interact similarly. Although the clinical relevance of this is uncertain, the manufacturers of co-artemether currently advise against concurrent use.

Clinical evidence, mechanism, importance and management

In one study, 16 healthy subjects were given ketoconazole 400 mg on day one then 200 mg daily for 4 days increased the AUC of artemether 2.4-fold, its metabolite dihydroartemisinin 1.7-fold and lumefantrine 1.7-fold after a single dose of co-artemether 80/480 mg given with a high-fat breakfast.¹ The maximum levels of the drugs were increased to a similar extent. No changes in ECG parameters or increases in adverse events were noted.

It was suggested that ketoconazole probably increases the levels of artemether and lumefantrine via its effects on intestinal and/or hepatic cytochrome P450 isoenzyme CYP3A4.

A pharmacokinetic interaction with ketoconazole seems to be established, and would be predicted for other similar potent CYP3A4 inhibitors. However, the clinical relevance of a twofold increase in artemether and lumefantrine levels is unclear. The authors of this drug company-supported study suggest that this change is within the between subject variability in the pharmacokinetics of these drugs, and is therefore unlikely to be clinically relevant. They suggest that no dosage adjustment would appear necessary.¹ Nevertheless, the manufacturer of co-artemether contraindicates the use of co-artemether in patients who are taking any drug that inhibits CYP3A4, and they give erythromycin, ketoconazole, itraconazole, cimetidine and protease inhibitors as examples. They base this advice on the lack of clinical data and unknown effects on safety.² Given the data with ketoconazole, in the setting of acute *Plasmodium falciparum* malaria, when co-artemether is considered the appropriate treatment, this advice seems unnecessarily restrictive. If it is deemed necessary to use co-artemether in a patient on a CYP3A4 inhibitor, it may be prudent to closely monitor the ECG and potassium levels, since artemether may prolong the QT interval. Further study is needed.

Co-artemether + Food

High-fat food markedly increases the absorption of lumefantrine and moderately increases the absorption of artemether. As soon as patients can tolerate food they should be encouraged to take co-artemether with meals.

Clinical evidence, mechanism, importance and management

In a study in healthy Chinese subjects a single dose of artemether/lumefantrine 80/480 mg was taken after a high fat meal and in the fasted state. The relative bioavailabilities of artemether and its active metabolite dihydroartemisinin were increased by more than twofold, and the bioavailability of lumefantrine was increased 16-fold by the meal.¹ Based on these data, the manufacturer notes that if 100% absorption is assumed for lumefantrine taken with a high fat meal, then absorption in the fasted state is less than 10% of the dose.²

In a clinical trial in patients with malaria, intake of a light meal within one hour of lumefantrine increased the bioavailability by 48%, and intake of a normal meal increased absorption twofold, when compared with liquids alone. After 24 to 48 hours in this study, most patients were eating normally.³ Artemether/lumefantrine should be taken with food. However, patients with acute uncomplicated malaria are unlikely to tolerate food. The manufacturer notes that patients should be encouraged to take artemether/lumefantrine with food as soon as this can be tolerated. They say that patients who remain averse to food during treatment should be closely monitored since they may be at greater risk of recrudescence (reappearance of the disease after a period of inactivity).²

Co-artemether + Grapefruit juice

Grapefruit juice doubles the AUC of artemether. Although the clinical relevance of this is uncertain, the manufacturers of co-artemether advise against concurrent use.

Clinical evidence, mechanism, importance and management

In a crossover study, healthy subjects were given a single 100-mg dose of artemether after breakfast with water, then after a 7-day washout period the study was repeated with 350 mL of double-strength grapefruit juice. Grapefruit juice increased the AUC of artemether by almost twofold, and the maximum level by more than twofold. The pharmacokinetics of the metabolite dihydroartemisinin were unaffected.¹ In a further multiple-dose study, artemether 100 mg was taken with water or 350 mL of double-strength grapefruit juice once daily for 5 days. Grapefruit juice increased the AUC and maximum level of artemether twofold on both day one and day 5, but the AUC of artemether was markedly lower on day 5, due to autoinduction of its metabolism.² This suggests that grapefruit juice might increase the levels of artemether via inhibition of intestinal CYP3A4, but that autoinduction does not affect this process.

The clinical relevance of a twofold increase in artemether levels is unclear. The authors suggest that the use of grapefruit juice might improve clinical efficacy in malaria, and might theoretically reduce the recrudescence (the reappearance of a disease after a period of inactivity) rate of artemether monotherapy.² However, artemether is used with lumefantrine to limit recrudescence. Further study is needed.

Co-artemether + Mefloquine

The levels of lumefantrine were modestly reduced by mefloquine pretreatment, but the levels of artemether and of mefloquine were not affected. No adverse effects on the QT interval were seen. These data indicate that co-artemether may be used after mefloquine prophylaxis or treatment.

Clinical evidence, mechanism, importance and management

In a study, 6 doses of co-artemether 80/480 mg were given over 60 hours to 42 healthy subjects, starting 12 hours after a short course of mefloquine (3 doses totalling 1 g given over 12 hours). The pharmacokinetics of the mefloquine and the artemether were unaffected by sequential use, but the lumefantrine maximum plasma concentrations and AUC were reduced by 29 and 41% respectively. However, given that the plasma levels of lumefantrine are usually highly variable, these changes were not thought large enough to affect the efficacy of treatment.¹

In another study, similar sequential use of these drugs did not affect the QT interval, and drug levels were also considered adequate for treatment.² The authors considered that adverse effects on the QT interval are unlikely to occur if co-artemether is used after mefloquine prophylaxis or treatment.

These data indicate that sequential use of mefloquine then co-artemether is unlikely to require any special precautions. The manufacturer of co-artemether notes that prolongation of the QT interval was seen in about 5% of patients in clinical trials (although they say this could be disease related). They state that, due to the limited data on safety and efficacy, co-artemether should not be given concurrently with any other antimalarial.³ For mention of a study where artemether pretreatment modestly reduced mefloquine levels, see 'Mefloquine + Artemisinin derivatives', p.231.

Co-artemether + Quinine

No clinically significant pharmacokinetic interaction appears to occur between quinine and co-artemether. Quinine-induced QTc prolongation may be enhanced by artemether.

Clinical evidence, mechanism, importance and management

In a double-blind placebo-controlled study in healthy subjects, 6 doses of co-artemether 80/480 mg were given to 14 subjects, over a period of 60 hours, followed 2 hours after the last dose by intravenous quinine 10 mg/kg (to a maximum of 600 mg) over 2 hours. Another two groups, each containing 14 subjects, received quinine or co-artemether, with placebo. The pharmacokinetics of lumefantrine and quinine were unaffected by combined use but the AUC and plasma levels of artemether and its active metabolite dihydroartemisinin appeared to be lower when co-artemether was given with quinine. However, the levels prior to quinine use in this group were also lower and the reduction in the presence of quinine was not considered clinically significant. The transient prolongation of the QTc interval noted with quinine (average and peak increases of 3 and 6 milliseconds, respectively) was slightly greater when quinine was given after co-artemether (average and peak increases 7 and 15 milliseconds respectively).¹ Both quinine and artemether are known to prolong the QT interval. In general, it is advised that the concurrent use of drugs that prolong the QT interval should be avoided (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257). However, the authors of this study considered that the modest increased risk of QTc prolongation was outweighed by the potential benefit of the combined treatment in complicated or multidrug-resistant falciparum malaria.¹ If the combination is used, careful cardiac monitoring is recommended.

Diethylcarbamazine + Urinary acidifiers or alkalinisers

Urinary alkalinisers can reduce the loss of diethylcarbamazine in the urine, whereas urinary acidifiers can increase the loss. The clinical importance of this is unknown.

Clinical evidence

Two studies, one in healthy subjects¹ and the other in patients with onchocerciasis,² found that making the urine alkaline with **sodium bicarbonate** markedly increased the retention of the diethylcarbamazine. The urinary excretion of a 50-mg dose of diethylcarbamazine was 62.3% and its elimination half-life 4 hours when the urine was made acidic (pH less than 5.5) by giving ammonium chloride, compared with 5.1% and 9.6 hours respectively when the urine was made alkaline (pH more than 7.5) using sodium bicarbonate.¹

Mechanism

In alkaline urine most of the diethylcarbamazine is non-ionised and is therefore easily reabsorbed in the kidney by simple diffusion through the lipid membrane. However, the conclusion was reached that in practice there is no advantage in making the urine alkaline in order to be able to use smaller doses of diethylcarbamazine because the severity of the adverse reactions (the Mazzotti reaction) is not reduced, and the microfilarial counts at the end of a month are not significantly different.²

Importance and management

The clinical importance of any unsought for changes in the urinary pH brought about by the use of other drugs during diethylcarbamazine treatment has not been assessed, but be aware that its pharmacokinetics and possibly the severity of its adverse effects can be changed.

Echinocandins + Amphotericin B

Limited evidence suggests that amphotericin B does not alter the pharmacokinetics of anidulafungin. The pharmacokinetics of caspofungin and amphotericin B are not altered by concurrent use.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

The manufacturer notes that population pharmacokinetic analysis showed no difference in the pharmacokinetics of anidulafungin in 27 patients who were also given liposomal amphotericin B when compared with data from patients receiving anidulafungin alone. This suggests that no dosage adjustment of anidulafungin is required if it is given with amphotericin B.¹

(b) Caspofungin

The manufacturers of caspofungin say there were no pharmacokinetic interactions between caspofungin and amphotericin B in a study in healthy subjects.^{2,3}

2. Cancidas (Caspofungin acetate). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, January 2007.
3. Cancidas (Caspofungin acetate). Merck & Co., Inc. US Prescribing information, February 2005.

Echinocandins + Azoles

No pharmacokinetic interaction appears to occur between anidulafungin and voriconazole or between caspofungin and itraconazole. No dosage adjustment of these drugs is necessary if they are used in combination.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

In a crossover study in 17 healthy subjects the steady state maximum level and AUC of both anidulafungin and **voriconazole** were not significantly altered by concurrent use, when compared with either drug given with placebo. Intravenous anidulafungin was given at a dose of 200 mg on the first

day, then 100 mg daily for 3 days. **Voriconazole** was given orally, at a dose of 400 mg every 12 hours on the first day, then 200 mg every 12 hours for 3 days.¹ No dosage adjustment appears to be necessary with either drug when used together.

(b) Caspofungin

Caspofungin 70 mg on day 1 and 50 mg for the next 13 days did not alter the pharmacokinetics of **itraconazole** 200 mg daily.² The pharmacokinetics of caspofungin were also unaltered. No dosage adjustment of either drug appears to be necessary when they are used together.

Echinocandins + Ciclosporin

Ciclosporin appears to modestly increase caspofungin levels, and concurrent use can apparently result in raised liver enzymes. Ciclosporin slightly raised anidulafungin levels in one study, without any serious adverse events.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

Intravenous anidulafungin 200 mg on day one, then 100 mg daily for 7 days was given to 12 healthy subjects with concurrent oral ciclosporin solution (*Neoral*) 1.25 mg/kg twice daily on the last 4 days. Ciclosporin caused a small 22% increase in the steady-state AUC of anidulafungin, which was not considered to be clinically relevant. No dose-limiting toxicities or serious adverse events were noted. One patient had a mild increase in liver enzymes on day 6 (after 2 days of concurrent use), and the study drugs were withdrawn at this point.¹

Anidulafungin is not expected to alter ciclosporin levels based on an *in vitro* study where anidulafungin had no effect on the metabolism of ciclosporin.¹

The manufacturer states that no dosage adjustment of either drug is needed on concurrent use.²

(b) Caspofungin

The manufacturers report that in two studies in healthy subjects, ciclosporin (a single 4-mg/kg dose, or two 3-mg/kg doses 12 hours apart) increased the AUC of caspofungin by 35%. Moreover, 5 of 12 subjects (43%) had increases in AST and ALT of up to threefold. The liver enzymes returned to normal on discontinuation of both drugs, and during concurrent use the levels of ciclosporin were not affected.^{3–5} These findings led to the exclusion of patients receiving ciclosporin from phase II/III studies of caspofungin.⁵ Note that elevated liver enzymes (typically mild and rarely leading to discontinuation) are a common adverse effect of caspofungin alone.³ More recently, 3 studies have reported retrospective analyses of the clinical use of caspofungin in a total of 68 patients taking ciclosporin.^{6–8} All three found no serious hepatic adverse events. Two reported no clinically significant elevations of liver enzymes,^{6,8} but one found 2 of 40 patients had discontinued therapy because of abnormalities in hepatic enzymes, possibly related to caspofungin and/or ciclosporin.⁷

The manufacturers say that ciclosporin and caspofungin can be used together if the potential benefit outweighs the risk. If they are used together, close monitoring of liver enzymes is recommended.^{3,4}

Echinocandins + Rifampicin (Rifampin) and other enzyme inducers

Rifampicin modestly reduces the trough levels of caspofungin after 2 weeks of concurrent use, but this is not thought to be due to increased metabolism. One case of caspofungin treatment failure has been reported in a patient taking rifampicin. Other enzyme inducers (carbamazepine, dexamethasone, efavirenz, nevirapine, and phenytoin) also appeared to reduce caspofungin levels. Rifampicin and other unnamed enzyme inducers did not appear to alter anidulafungin clearance.

Clinical evidence

(a) Anidulafungin

A population pharmacokinetic analysis of anidulafungin in patients with serious fungal infections found that the clearance of anidulafungin did not differ between 27 patients also taking **rifampicin (rifampin)** and 77 patients taking no known interacting drugs.¹ Similarly, anidulafungin clearance was not different in 40 patients given **inducers of cytochrome P450** (including **rifampicin**, but others not specifically named).¹ These findings suggest that no dosage adjustment of anidulafungin is needed in patients taking **rifampicin** or other **enzyme inducers**.^{1,2}

(b) Caspofungin

A parallel-group study in healthy subjects looked at the effects of rifampicin on the pharmacokinetics of caspofungin. In the first group, **rifampicin** 600 mg daily was given with intravenous caspofungin 50 mg daily, started on the same day. It was found that the trough levels and AUC of caspofungin were increased by 170 and 61%, respectively, on day one. However, after 2 weeks the AUC had returned to normal, and, when compared to subjects not taking **rifampicin**, there was a trend to lower trough levels of caspofungin. In the second group of healthy subjects in this study, **rifampicin** 600 mg daily was given for 14 days alone and then for a further 14 days combined with caspofungin. In this study, no significant increase in the caspofungin AUC was seen on day one of concurrent use. On both day one and day 14, the trough levels of caspofungin were reduced by about 30%, without any change in the AUC, similar to the findings on day 14 in the first group. In this second group, caspofungin did not alter the pharmacokinetics of **rifampicin**.³

A case report describes a neutropenic patient with fungaemia who did not respond to intravenous caspofungin (70 mg on the first day then 50 mg daily) whilst taking **rifampicin** 600 mg daily. However, susceptibility testing showed that the isolate was not resistant to caspofungin and she was successfully treated with amphotericin B. Although this patient was treated with standard dose caspofungin, the authors note she weighed just 47 kg and showed not even an initial response. They suggest that caspofungin doses of more than 70 mg daily would have been required for efficacy in their patient.⁴

Mechanism

Caspofungin is a poor substrate for cytochrome P450 and is not a substrate for P-glycoprotein,⁵ therefore these mechanisms are not thought to be involved in the interaction with rifampicin. It is possible that the modest effect of rifampicin on caspofungin is due to induction of tissue uptake transport proteins at steady-state.³

Importance and management

The manufacturers recommend that consideration should be given to increasing the dose of caspofungin from 50 to 70 mg daily in patients taking **rifampicin**.^{5,6} This dose has been generally well tolerated in clinical studies.³ However, bear in mind the case report of possible caspofungin failure, even at this dose. The manufacturers also say that a population pharmacokinetic analysis suggested that the concurrent use of other met-

abolic inducers (**carbamazepine**, **dexamethasone**, **efavirenz**, **nevirapine** or **phenytoin**) may result in clinically meaningful reductions in caspofungin AUC.^{5,6} They suggest considering increasing the dose of caspofungin from 50 to 70 mg daily if it is used with enzyme inducers such as these. Further study is needed.

Echinocandins; Anidulafungin + Miscellaneous

A population pharmacokinetic analysis of anidulafungin in patients with serious fungal infections found that the clearance of anidulafungin did not differ between 140 patients taking drugs classified as cytochrome P450 isoenzyme inhibitors (none specifically named) and 77 patients who received no known interacting drugs.¹ For the lack of a pharmacokinetic interaction between anidulafungin and voriconazole, see 'Echinocandins + Azoles', p.225.

1. Dowell J, Knebel W, Ludden T, Stogniew M, Krause D, Henkel T. Population pharmacokinetic analysis of anidulafungin, an echinocandin antifungal. *J Clin Pharmacol* (2004) 44, 590–8.

Echinocandins; Caspofungin + Mycophenolate

The manufacturers of caspofungin say that the pharmacokinetics of caspofungin and mycophenolate are not altered by concurrent use.^{1,2}

1. Cancidas (Caspofungin acetate). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, January 2007.
2. Cancidas (Caspofungin acetate). Merck & Co., Inc. US Prescribing information, February 2005.

Echinocandins; Caspofungin + Nelfinavir

Nelfinavir does not have a clinically relevant effect on the pharmacokinetics of caspofungin.

Clinical evidence, mechanism, importance and management

In a parallel-group study healthy subjects were given nelfinavir 1250 mg every 12 hours, with intravenous caspofungin 50 mg daily, started on the same day. The AUC of caspofungin and the trough level were increased by 16 and 58%, respectively, on the first day when compared with subjects receiving caspofungin alone. However, after 2 weeks of combined use, there was no difference in the AUC or trough level of caspofungin.¹ The authors note that their previous population pharmacokinetic analysis had shown that nelfinavir might decrease the AUC and trough level of caspofungin, which in the light of the controlled study, they consider to be a spurious finding.

It appears that nelfinavir does not have a clinically significant effect on the pharmacokinetics of caspofungin, and no dosage adjustment of caspofungin is required on combined use.

1. Stone JA, Migoya EM, Hickey L, Winchell GA, Deutsch PJ, Ghosh K, Freeman A, Bi S, Desai R, Dilzer SC, Lasseter KC, Kraft WK, Greenberg H, Waldman SA. Potential for interactions between caspofungin and nelfinavir or rifampin. *Antimicrob Agents Chemother* (2004) 48, 4306–14.

Flucytosine + Amphotericin B

The combination of flucytosine with amphotericin B may be more effective than flucytosine alone for some fungal infections, but amphotericin B increases the toxicity of flucytosine. Close monitoring of flucytosine levels and renal function is required. Other drugs that impair glomerular filtration might also decrease flucytosine elimination and increase toxicity.

Clinical evidence, mechanism, importance and management

The combined use of flucytosine and amphotericin B is more effective than flucytosine alone in the treatment of cryptococcal meningitis, as demonstrated in an early study,¹ and is still the recommended treatment.^{2,3} However, amphotericin B can cause deterioration in renal function, which reduces flucytosine elimination, and may result in raised flucytosine blood levels. In addition, amphotericin may increase the cellular uptake of flucytosine.⁴ Whatever the exact mechanism, combined use increases flucytosine bone marrow toxicity. A study of 194 patients randomised to either a 4 or 6-week course of low-dose amphotericin B (initially 0.3 mg/kg daily) and maximal dose flucytosine (150 mg/kg daily, adjusted for renal function) found that severe adverse effects were common. These included azotaemia (51 patients), blood dyscrasias (52 patients), and hepatitis (13 patients).⁵

Flucytosine levels and renal function should be very closely monitored when the drugs are used concurrently. One manufacturer of flucytosine says that any drug that impairs glomerular filtration may prolong the half-life of flucytosine, which would increase the risk of toxicity.⁶

Flucytosine + Antacids

Aluminium/magnesium hydroxide delays the absorption of flucytosine from the gut, but the total amount absorbed remains unaffected.¹ No special precautions appear to be needed if this antacid is given with oral flucytosine.

1. Cutler RE, Blair AD, Kelly MR. Flucytosine kinetics in subjects with normal and impaired renal function. *Clin Pharmacol Ther* (1978) 24, 333–42.

Flucytosine + Cytarabine

Some very limited evidence suggests that cytarabine may oppose the antifungal effects of flucytosine, or reduce flucytosine levels. Theoretically, their bone marrow suppressant effects might be additive.

Clinical evidence, mechanism, importance and management

A man with Hodgkin's disease treated for cryptococcal meningitis with flucytosine 100 mg/kg daily had reduced flucytosine serum and CSF levels, from a range of 30 to 40 mg/L down to undetectable levels, when given cytarabine intravenously. When the cytarabine was replaced by procarbazine, the flucytosine levels returned to their former values. *In vitro* tests found that cytarabine 1 mg/L completely abolished the activity of up to 50 mg/L of flucytosine against the patient's strain of *Cryptococcus*, whereas procarbazine did not.¹ In another study in a patient with acute myeloid leukaemia, the predose flucytosine level fell from 65 to 42 mg/L and

the post-dose flucytosine level fell from and 80 to 53 mg/L when cytarabine and daunorubicin were given. However, these levels were still within the therapeutic range. The drop in levels was attributed to an improvement in renal function rather than antagonism between the two drugs.² In an *in vitro* study the antifungal effects of flucytosine against 14 out of 16 wild isolates of *Cryptococcus* were not changed in the presence of cytarabine. In the remaining two isolates, an increase in effect was seen in one and a decrease was seen the other.²

The evidence for any interaction is therefore very limited indeed and its general clinical importance remains uncertain. The manufacturers of flucytosine advise that strict monitoring of flucytosine levels is required if both drugs are given.³ Of equal concern is the fact that both drugs are bone marrow suppressants, and this effect might be additive.

Furazolidone + Omeprazole

Omeprazole modestly reduces the serum levels of furazolidone. Note that the two drugs have been successfully combined in *H. pylori* eradication regimens.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects found that omeprazole 20 mg twice daily for 5 days reduced the peak serum level of a single 200-mg dose of furazolidone by about 30%. The clinical relevance of this modest change is uncertain. Omeprazole may alter the bioavailability of furazolidone by reducing its dissolution or increasing its degradation before it reaches the intestine and/or inducing its first-pass metabolism.¹ Note that there are now a large number of clinical trials describing the successful combination of furazolidone with omeprazole in regimens to eradicate *H. pylori*. However, there is some evidence that success rates are unacceptable if low-dose furazolidone (100 mg twice daily) rather than standard dose (200 mg twice daily) is used.² It is possible that a pharmacokinetic interaction could play a part in this finding.

- Calafatti SA, Ortiz RAM, Deguer M, Martinez M, Pedrazzoli J. Effect of acid secretion blockade by omeprazole on the relative bioavailability of orally administered furazolidone in healthy volunteers. *Br J Clin Pharmacol* (2001) 52, 205–9.
- Fakheri H, Merat S, Hosseini C, Malekzadeh R. Low-dose furazolidone in triple and quadruple regimens for *Helicobacter pylori* eradication. *Aliment Pharmacol Ther* (2004) 19, 89–93.

Furazolidone + Sympathomimetics

After 5 to 10 days of use furazolidone has MAO-inhibitory activity about equivalent to that of the non-selective MAOIs. The concurrent use of furazolidone with indirectly-acting sympathomimetic amines (amfetamines, phenylpropanolamine, ephedrine, etc.) or with tyramine-rich foods and drinks may be expected to result in a potentially serious rise in blood pressure. However, direct evidence of accidental adverse reactions of this kind does not seem to have been reported. The pressor effects of noradrenaline (norepinephrine) are unchanged by furazolidone.

Clinical evidence

After 6 days of treatment with furazolidone 400 mg daily, the pressor responses to **tyramine** or **dexamfetamine** in 4 hypertensive patients had increased two to threefold, and after 13 days by about tenfold. These responses were about the same as those found in 2 other patients taking the MAOI **pargyline**.¹ The MAO-inhibitory activity of furazolidone was confirmed by measurements taken on jejunal specimens. The pressor effects of **noradrenaline (norepinephrine)** were unchanged by furazolidone.¹

Mechanism

The MAO-inhibitory activity of furazolidone is not immediate and may in fact be due to a metabolite of furazolidone.² It develops gradually so that after 5 to 10 days of use, indirectly-acting sympathomimetics will interact with furazolidone in the same way as they do in the presence of other

non-selective MAOIs.^{3,4} More details of the mechanisms of this interaction are to be found elsewhere. See 'MAOIs or RIMAs + Tyramine-rich foods', p.1153 and 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1147.

Importance and management

The MAO-inhibitory activity of furazolidone after 5 to 10 days of use is established, but reports of hypertensive crises either with sympathomimetics or **tyramine-containing foods** or drinks appear to be lacking. This may be, in part, a reflection of the fact that furazolidone may be given for just 2 to 5 days. Notwithstanding, it would seem prudent to warn patients given furazolidone not to take any of the drugs, foods or drinks that are prohibited with non-selective MAOIs. See the appropriate monographs on MAOIs for more detailed lists of these 'drugs', (p.1130), 'foods', (p.1153), and 'drinks', (p.1151). No adverse interaction would be expected with 'directly-acting sympathomimetics', (p.1146), such as noradrenaline (norepinephrine).

Griseofulvin + Food

The rate and probably extent of griseofulvin absorption is markedly increased if it is taken with a high-fat meal.

Clinical evidence, mechanism, importance and management

A study in 5 healthy subjects found that the absorption of micronised griseofulvin 125 mg (*Fulcin*) was enhanced if it was given with a fatty meal rather than in the fasting state, as assessed by a 37% increase in urinary excretion.¹ Other studies similarly found that the absorption of griseofulvin at 4 and 8 hours was about doubled when it was taken with a high-fat meal.^{2,3} A further study in 12 healthy subjects found that the higher the fat content of the meal the higher the bioavailability of griseofulvin (70% increase in bioavailability with a low-fat meal and 120% increase with a high-fat meal, when compared with fasting state absorption).⁴ However, another study found that although food increased the rate of absorption of micronised and PEG-ultramicrosized griseofulvin, the extent of absorption was not changed.⁵ Another report suggested that giving griseofulvin with food tended to reduce the differences in the bioavailability of griseofulvin from micronised and ultramicrosized tablets.⁶ Enhanced absorption was also found with a formulation of griseofulvin in a **corn oil** emulsion, when compared with tablets or an aqueous suspension.⁷

This interaction is established and of clinical importance. Some manufacturers advise that griseofulvin should be given after meals, otherwise absorption is likely to be inadequate.⁸

Griseofulvin + Phenobarbital

The antifungal effects of griseofulvin can be reduced or even abolished by phenobarbital.

Clinical evidence

Two epileptic children taking phenobarbital 40 mg daily did not respond to long-term treatment for tinea capitis with griseofulvin 125 mg three times daily until the barbiturate was withdrawn.¹

Five other patients (3 also taking phenytoin) similarly did not respond to griseofulvin while taking phenobarbital.²⁻⁴ Two studies, in a total of 14 healthy subjects, found that phenobarbital 30 mg three times daily reduced the serum levels of oral griseofulvin by about one-third,⁵ and the absorption was reduced from 58.1% without phenobarbital to 40.6% in the presence of phenobarbital.⁶

Mechanism

Not fully understood. Initially it was thought that the phenobarbital increased the metabolism and clearance of the griseofulvin,⁷ but it has also been suggested that it reduces the absorption of griseofulvin from the gut.⁶ One idea is that the phenobarbital increases peristalsis reducing the opportunity for absorption.⁶ Another suggestion is that phenobarbital forms a complex with griseofulvin, which makes an already poorly soluble drug even less soluble, and therefore less readily absorbed.⁸ A further suggestion is that phenobarbital may reduce the level of intestinal bile salts, which in turn may reduce the solubility and absorption of griseofulvin.⁹

Importance and management

An established interaction of clinical importance, although the evidence seems to be limited to the reports cited. If phenobarbital must be given, it has been suggested that the griseofulvin should be given in divided doses three times a day to give it a better chance of being absorbed.⁶ However, divided doses were used in one of the reports describing an interaction.¹ The effect of increasing the dosage of griseofulvin appears not to have been studied. An alternative, where possible, is to use a non-interacting anticonvulsant such as sodium valproate. This proved to be successful in one of the cases cited.¹

Halofantrine + Antacids

Magnesium carbonate halves the maximum plasma levels of halofantrine, which may be clinically relevant. Aluminium hydroxide and magnesium trisilicate seem less likely to interact.

Clinical evidence

Magnesium carbonate 1 g reduced the maximum plasma levels of halofantrine 500 mg by almost 50% in a single-dose study in healthy subjects. The AUC was also reduced by 28%, but this was not statistically significant. The active metabolite of halofantrine, which is equally potent, was similarly affected.¹

Mechanism

Magnesium carbonate might decrease the absorption of halofantrine. *In vitro* study showed that the halofantrine absorptive capacity of various antacids was highest for magnesium carbonate, intermediate for **aluminium hydroxide**, and least for **magnesium trisilicate**.¹

Importance and management

The pharmacokinetic interaction between halofantrine and magnesium carbonate appears to be established. Its clinical importance does not seem

to have been assessed, but the authors note that the clinical efficacy of halofantrine is related to peak levels, and therefore they consider that magnesium carbonate might affect antimalarial efficacy.¹ One way to minimise the interaction is to separate the dosages of halofantrine and magnesium carbonate as much as possible (at least 2 to 3 hours) to reduce admixture in the gut. There do not appear to be any studies to see if other antacids behave similarly, but the *in vitro* data with aluminium hydroxide and magnesium trisilicate (see Mechanism, above) suggest they are less likely to interact.¹

Halofantrine + Miscellaneous

Halofantrine prolongs the QT interval and therefore should not be used with other drugs that can prolong the QT interval because of the increased risk of cardiac arrhythmias. The concurrent and sequential use of halofantrine and mefloquine markedly increased the risk of clinically important increases in the QT interval.

Pyrimethamine/sulfadoxine and tetracycline have been shown to increase halofantrine levels, and may therefore increase its toxicity. Diltiazem, erythromycin, ketoconazole, mefloquine, quinine, and quinidine might also increase the toxicity of halofantrine because they have been shown to inhibit its metabolism *in vitro*. The manufacturer has therefore recommended caution with the concurrent use of potent CYP3A4 inhibitors. Fatty food markedly increases halofantrine levels, consequently it is recommended that halofantrine is taken on an empty stomach. Grapefruit juice has a similar effect. Note that halofantrine is no longer widely marketed.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inhibitors

A study in *animals* found that **ketoconazole** roughly doubled the AUC of halofantrine and inhibited its metabolism to the equipotent metabolite, desbutylhalofantrine.¹ *In vitro* studies, **ketoconazole** markedly inhibited the metabolism of halofantrine by CYP3A4.^{2,3} It has been suggested that the rise in halofantrine levels could reasonably be expected to increase toxicity.^{2,3} Other CYP3A4 inhibitors, **diltiazem** and **erythromycin**, also inhibited the metabolism of halofantrine *in vitro*, and might therefore do so clinically.³ The manufacturer recommended caution with the concurrent use of potent CYP3A4 inhibitors.⁴ Further study is needed of these potential pharmacokinetic interactions. **Mefloquine, quinine and quinidine** may also inhibit the metabolism of halofantrine by CYP3A4, see (b) below.

(b) Drugs that prolong the QT interval

Halofantrine, in therapeutic doses, can prolong the QT interval in the majority of patients, causing ventricular arrhythmias in a very small number. The effect is increased if halofantrine is taken with **fatty foods** because of the marked increase in absorption, see (d) below. By 1993, worldwide, 14 cases of cardiac arrhythmias associated with halofantrine had been reported, and 8 patients were known to have died. In order to reduce the likelihood of arrhythmias, in 1994 the UK Committee on Safety of Medicines advised that halofantrine should not be taken with **meals**, or with certain other drugs that may induce arrhythmias. They list **chloroquine, mefloquine, quinine, tricyclic antidepressants, antipsychotics, certain antiarrhythmics, terfenadine and astemizole**, as well as drugs causing electrolyte disturbances.⁵ Although not listed, it would seem prudent to avoid other drugs that prolong the QT interval. For a list, see 'Table 9.2', (p.257)'.⁵

In addition to possible additive QT-prolonging effects, **quinidine** and **quinine** have been shown *in vitro* to inhibit the metabolism of halofantrine by CYP3A4, and so may increase halofantrine levels, which could reasonably be expected to increase toxicity.^{2,3} *Animal* studies found that although **mefloquine** alone did not significantly alter the QTc interval, it enhanced the effects of halofantrine by increasing blood levels.⁶ Similarly, a study in patients with malaria found that the risk of clinically relevant QT prolongation was increased twofold when halofantrine was used after **mefloquine** failure (7 of 10 patients) when compared with use as primary

treatment (18 of 51 patients). However, the authors note that their population had longer baseline QT intervals than the average population, which may have made them more susceptible to the effects of halofantrine.⁷ The manufacturers of **mefloquine**^{8,9} and halofantrine,⁴ therefore contraindicated concurrent use, and the use of halofantrine after **mefloquine**.

(c) Food

A study in 6 healthy subjects found that the maximum plasma levels and AUC of a single 250-mg dose of halofantrine were increased by about 6.6-fold and 2.9-fold, respectively, when given with a **fatty meal** rather than in a fasting state. The AUC of the metabolite desbutylhalofantrine was also increased.¹⁰ *Animal* data suggest that **fats** may reduce the presystemic metabolism of halofantrine.¹ As this is likely to increase the risk of halofantrine-induced arrhythmias, halofantrine should not be taken with **meals**, but should be taken on an empty stomach.

(d) Grapefruit juice or Orange juice

A crossover study in 12 healthy subjects given halofantrine 500 mg with 250 mL of either water, orange juice or grapefruit juice (standard strength), found that grapefruit juice increased the AUC and peak plasma levels of halofantrine by 2.8-fold and 3.2-fold, respectively. The QTc interval increased by 17 milliseconds with halofantrine, and by 31 milliseconds when grapefruit juice was also given. Orange juice did not affect the pharmacokinetics or pharmacodynamics of halofantrine.¹¹ These data suggest that grapefruit juice should be avoided by patients taking halofantrine due to the increased risk of arrhythmias.¹¹

(e) Pyrimethamine/Sulfadoxine (Fansidar)

In a preliminary study in healthy subjects, **pyrimethamine/sulfadoxine (Fansidar)** raised the AUC₀₋₆ and peak plasma levels of halofantrine by about 1.6-fold, without changing the overall AUC. This might lead to an increased incidence of arrhythmias,¹² see also (b) above.

(f) Tetracyclines

A study in 8 healthy subjects found that tetracycline 500 mg twice daily for 7 days increased the maximum plasma levels, AUC and elimination half-life of a single 500-mg dose of halofantrine by 146%, 99%, and 73%, respectively. Increases in the major metabolite of halofantrine also occurred in the presence of tetracycline.¹³ As both halofantrine and tetracycline are excreted into the bile, competition for this elimination route may result in increased plasma levels. There may be an increased risk of halofantrine toxicity if it is used with higher doses of tetracycline.¹³ In contrast, *in vitro* studies found that **doxycycline** does not inhibit the metabolism of halofantrine.²

Hydroxychloroquine + Rifampicin (Rifampin)

A woman with discoid lupus, controlled by hydroxychloroquine, rapidly relapsed when rifampicin was started. Disease control was regained when the hydroxychloroquine dosage was doubled.

Clinical evidence, mechanism, importance and management

A woman with discoid lupus, which was controlled by hydroxychloroquine 200 mg daily, was also given rifampicin, isoniazid and pyrazinamide for tuberculosis. Within 1 to 2 weeks the discoid lupus flared-up again but it rapidly responded when the hydroxychloroquine dosage was doubled. The reason for this reaction is not known for certain but the authors of the report suggest that the rifampicin (a recognised and potent cytochrome P450 enzyme inducer) increased the metabolism and clearance of the hydroxychloroquine so that it was no longer effective.¹ It is already known that discoid lupus flare-ups can occur within 2 weeks of stopping hydroxychloroquine,² which gives support to this suggested mechanism. Neither isoniazid nor pyrazinamide is likely to have been responsible for what happened.

This seems to be the first and only report of this interaction, but what happened is consistent with the way rifampicin interacts with many other drugs. If rifampicin is added to hydroxychloroquine, the outcome should be well monitored. Be alert for the need to increase the hydroxychloroquine dosage.

Hydroxyquinoline (Oxyquinoline) + Zinc oxide

The presence of zinc oxide inhibits the therapeutic effects of hydroxyquinoline in ointments.

Clinical evidence

The observation that a patient had an allergic reaction to hydroxyquinoline in ointments with a paraffin base, but not a zinc oxide base, prompted further study of a possible incompatibility. The subsequent study in 13 patients confirmed that zinc oxide reduces the eczematogenic (allergic) properties of the hydroxyquinoline. However, it also inhibits its antibacterial and antimycotic effects, and appears to stimulate the growth of *Candida albicans*.¹

Mechanism

It seems almost certain that the zinc ions form chelates with hydroxyquinoline, which have little or no antibacterial properties.^{1,2}

Importance and management

The documentation is limited but the reaction appears to be established. There is no point in using zinc oxide to reduce the allergic properties of hydroxyquinoline if, at the same time, the therapeutic effects disappear.

Ivermectin + Food

The manufacturer notes that the bioavailability of ivermectin 30 mg was increased by about 2.5-fold when it was taken after a high-fat meal (48.6 g of fat) when compared with the fasted state.¹ They recommend that ivermectin is taken on an empty stomach with water.¹

1. Stromectol (Ivermectin). Merck & Co., Inc. US Prescribing information, March 2007.

Ivermectin + Levamisole

Levamisole may markedly increase the bioavailability of ivermectin. Ivermectin does not alter the pharmacokinetics of levamisole.

Clinical evidence, mechanism, importance and management

A study in 28 healthy subjects given levamisole 2.5 mg/kg, alone or with ivermectin 200 micrograms/kg, found that ivermectin had no effect on the AUC or maximum level of levamisole. However, the AUC of ivermectin was twofold higher when given with levamisole compared with historical values in subjects who had received ivermectin alone.¹ An associated study in 44 patients with *Onchocerca volvulus* infections found that levamisole given with ivermectin was neither macrofilaricidal nor more effective against microfilariae and adult worms than ivermectin alone. In addition, patients taking both drugs had a higher incidence of pruritus, arthralgia and fever than those on ivermectin alone.¹ Caution is recommended on concurrent use.

1. Awadzi K, Edwards G, Opoku NO, Ardrey AE, Favager S, Addy ET, Attah SK, Yamuah LK, Quarley BT. The safety, tolerability and pharmacokinetics of levamisole alone, levamisole plus ivermectin, and levamisole plus albendazole, and their efficacy against *Onchocerca volvulus*. *Ann Trop Med Parasitol* (2004) 98, 595–614.

Ivermectin + Orange juice

Orange juice modestly reduces the bioavailability of ivermectin.

Clinical evidence, mechanism, importance and management

A study in 16 healthy subjects found that the AUC and peak plasma levels of a single 150-micrograms/kg dose of ivermectin were reduced by 36% and 39%, respectively, when the ivermectin was given with orange juice (750 mL over 4 hours) rather than with water. The mechanism for the reduced bioavailability is not known but it does not seem related to P-glycoprotein activity.¹ The clinical relevance of these changes is uncertain.

1. Vanapalli SR, Chen Y, Ellingrod VL, Kitzman D, Lee Y, Hohl RJ, Fleckenstein L. Orange juice decreases the oral bioavailability of ivermectin in healthy volunteers. *Clin Pharmacol Ther* (2003) 73, P94.

Levamisole + Miscellaneous

There is some evidence that levamisole, taken with fluorouracil, can increase the effects of phenytoin, and that a disulfiram-like reaction can occur if patients taking levamisole drink alcohol.

Clinical evidence, mechanism, importance and management

The product information for levamisole states that levamisole, taken with fluorouracil, may increase in the plasma levels of **phenytoin**. Note that fluorouracil alone increases phenytoin levels, see 'Antiepileptics + Antineoplastics; Cytotoxic', p.518.

The information also notes that a disulfiram-like reaction has been reported with levamisole and **alcohol**.¹ The general importance of this interaction is uncertain, but bear it in mind when prescribing levamisole.

1. Ergamisol (Levamisole). Janssen Pharmaceutica Inc. US Prescribing information, August 1999.

Mefloquine + Ampicillin

Although ampicillin modestly increases the plasma levels of mefloquine and reduces its half-life, these effects are probably not clinically relevant.

Clinical evidence, mechanism, importance and management

In a study, 8 healthy subjects were given ampicillin 250 mg four times daily for 5 days, with a single 750-mg dose of mefloquine on day 2. The maximum plasma level and 5-day AUC of mefloquine were increased by 34% and 49%, respectively, although the AUC_{0-∞} was not significantly increased. The half-life and volume of distribution of mefloquine were reduced from 17.7 to 15.3 days and by 27%, respectively, by the ampicillin. No increase in adverse events was seen. The effects may be due to an increase in mefloquine bioavailability and a reduction in its enterohepatic recycling.¹ The clinical relevance of these changes is uncertain, but the au-

thors consider that the changes in elimination are unlikely to be clinically significant, since these occur after the resolution of infection.¹

1. Karbwang J, Na Bangchang K, Back DJ, Bunnag D. Effect of ampicillin on mefloquine pharmacokinetics in Thai males. *Eur J Clin Pharmacol* (1991) 40, 631–3.

Mefloquine + Artemisinin derivatives

Artemether pretreatment appears to modestly reduce mefloquine levels, whereas artemisinin and dihydroartemisinin do not affect the pharmacokinetics of mefloquine. If mefloquine is given shortly after artesunate its levels are lowered, but giving mefloquine two days in to artesunate treatment appears to raise mefloquine levels. The combined use of mefloquine with artemisinin derivatives might improve antimalarial activity. See also 'Co-artemether + Mefloquine', p.224

Clinical evidence, mechanism, importance and management

(a) Artemether

In a study in patients with acute uncomplicated falciparum malaria 15 patients were given a single 300-mg dose of artemether, with a single 750-mg dose of mefloquine 24 hours later. The AUC of mefloquine in these patients was found to be 27% lower than the AUC of 7 patients receiving mefloquine alone. However, the addition of artemether improved the rate of parasite clearance, and cure rates were similar between the groups.¹ For discussion of a study that found mefloquine pharmacokinetics did not appear to be altered when artemether/lumefantrine was given 12 hours after mefloquine treatment, see 'Co-artemether + Mefloquine', p.224. Note that co-artemether (artemether with lumefantrine) is one of the recommended treatment options in the WHO guidelines for the treatment of uncomplicated falciparum malaria.²

(b) Artemisinin or Dihydroartemisinin

In a single-dose three-way crossover study, 10 healthy subjects were given either mefloquine 750 mg, dihydroartemisinin 300 mg or both drugs together. The pharmacokinetics of the drugs were unchanged on concurrent use, except for the rate of absorption of mefloquine, which was increased. Also the activity of these drugs against *Plasmodium falciparum* was synergistic, rather than additive.³ Another study in patients with falciparum malaria found no significant pharmacokinetic interaction between artemisinin and mefloquine. In this study, patients received mefloquine 750 mg alone or artemisinin 500 mg daily for 3 days with a single 750-mg dose of mefloquine either on day 1 or day 4. There was no difference in overall efficacy between treatments, although those treated with artemisinin together with mefloquine on the first day of treatment had the fastest parasite clearance rates.⁴

(c) Artesunate

A study in 20 patients with acute uncomplicated falciparum malaria given mefloquine (750 mg followed after 6 hours by 500 mg) found that the levels of mefloquine were reduced by 27% and its clearance rate was increased 2.6-fold when the doses of mefloquine were given 6 and 12 hours after artesunate 200 mg. However, the patients who received the combination had shorter fever clearance and parasite clearance times than those given mefloquine alone, but the cure rate was lower for combined treatment than for mefloquine alone (66% versus 75%). To prevent the pharmacokinetic interaction resulting in a reduction in its efficacy, mefloquine should be given when artesunate and its metabolites have cleared the circulation (the authors suggest possibly 24 hours after a dose).⁵ This suggestion is supported by a study looking at the efficacy of mefloquine with artesunate. This study found that the AUC of mefloquine was about 30% higher in 22 children given mefloquine on day 2 of artesunate treatment, when compared with 24 children given mefloquine on day 0 (before artesunate was started). Both groups were given mefloquine without food.⁶

The combined use of artesunate and mefloquine is one of the recommended treatment options in the WHO guidelines for the treatment of uncomplicated falciparum malaria, and for uncomplicated vivax malaria in selected areas.² They say that mefloquine is usually given on day 2 of combined treatment.

Mefloquine + Cardioactive drugs

An isolated report describes cardiopulmonary arrest in a patient taking mefloquine with propranolol. The WHO have issued a warning about the concurrent use of mefloquine with antiarrhythmics, beta blockers, calcium-channel blockers, antihistamines, phenothiazines, and some related antimalarials. For mention that halofantrine should not be used with or after mefloquine, because of a clinically significant lengthening of the QT interval, see 'Halofantrine + Miscellaneous', p.229.

Clinical evidence, mechanism, importance and management

The WHO¹ warn that the use of mefloquine with **antiarrhythmics, beta blockers, calcium-channel blockers, antihistamines and phenothiazines** may contribute to the prolongation of the QTc interval, but do not specifically contraindicate the use of mefloquine with these drugs.¹ Note that, of the classes mentioned, class Ic and class III antiarrhythmics, sotalolol, astemizole and terfenadine are most frequently associated with QT-prolongation, and these drugs are therefore likely to present the greatest risk. It is also suggested that mefloquine and related drugs (e.g. **quinine** or **quinidine**) should only be given together under close medical supervision because of possible additive cardiotoxicity.¹ The manufacturers of mefloquine also give these warnings, pointing out that the interactions are theoretical, and that clinically significant QTc prolongation has not been found with mefloquine alone.^{2,3} Apart from 'quinine', (p.233) where two studies found minor QTc prolongation, no formal studies on the possible adverse effects of combining any of the above drugs with mefloquine seem to have been done. It remains to be confirmed whether the effects of mefloquine and these other drugs on cardiac function are normally additive, and whether the outcome is clinically important. However, until more is known it would seem prudent to err on the side of caution and to follow this cautionary advice. Drugs that prolong the QT interval are listed in 'Table 9.2', (p.257). There is also a theoretical interaction with QT-prolonging 'quinolones' (p.233). For mention that halofantrine should not be used with or after mefloquine, because of a clinically significant lengthening of the QT interval, which may be due to a pharmacokinetic interaction, see 'Halofantrine + Miscellaneous', p.229. One 1990 review⁴ and the US prescribing information³ briefly mention a single case of cardiopulmonary arrest (with full recovery³) when a patient taking **propranolol** was given a single dose⁴ of mefloquine. It has been suggested that the concurrent use of beta blockers and mefloquine may lead to bradycardia, which is an uncommon adverse effect of mefloquine,^{2,3} and a known effect of the beta blockers. However, there do not appear to be any reports of an adverse interaction in the literature.

Mefloquine + Cimetidine

Mefloquine levels may be modestly increased and/or its elimination modestly reduced by cimetidine. The clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

A single 500-mg dose of mefloquine was given to 10 healthy subjects before and after they took cimetidine 400 mg twice daily for 28 days. The cimetidine had no effect on the AUC or serum levels of mefloquine, but its half-life increased by 50% (from 9.6 to 14.4 days) and the oral clearance decreased by almost 40%.¹ In another study mefloquine was given to 6 healthy subjects and 6 patients with peptic ulcers, before and after cimetidine 400 mg twice daily for 3 days. In contrast to the first study, cimetidine increased the maximum plasma levels of mefloquine by about 42% and 20% and increased the AUC by about 37% and 32% in the healthy subjects and patients, respectively. The elimination half-life was increased, but not to a significant extent.²

The findings of the first study suggest that cimetidine (a recognised enzyme inhibitor) reduces the metabolism of the mefloquine by the liver.¹ However, the second study suggests that cimetidine may increase the rate of mefloquine absorption without significantly inhibiting its elimination.²

These two studies produced different findings, and an interaction is not therefore established. Nevertheless, the changes seen in both studies were modest, and unlikely to be clinically relevant in most patients taking lower doses of chloroquine for malaria prophylaxis. With higher doses of mefloquine used to treat malaria, to be on the safe side, prescribers should be alert for any evidence of increased mefloquine adverse effects (dizziness, nausea, vomiting, abdominal pain) and psychiatric or neurological reactions during concurrent use. Note that the UK Committee on Safety of Medicines say that any patient given mefloquine [for malaria prophylaxis] should be informed about its adverse effects, and advised that, if these occur, they should seek medical advice on alternative antimalarials before the next dose is due.³

Mefloquine + Ketoconazole

Ketoconazole increased the AUC of mefloquine by 79%. The clinical relevance of this is uncertain, but an increase in adverse events is possible.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects a single 500-mg dose of mefloquine, given on day 5 of a 10-day course of ketoconazole 400 mg daily, increased the mefloquine AUC by 79%, the maximum level by 64% and the half-life by 34%, when compared to mefloquine alone. A 28% decrease in the AUC of the carboxylic metabolite was also seen. No significant adverse effects were reported.¹ It is probable that ketoconazole inhibits the metabolism of mefloquine by cytochrome P450 isoenzyme CYP3A4. Although the clinical relevance of this increase in mefloquine levels is not known, it seems possible that it could increase the risk of adverse effects in some patients. Until more is known, it may be prudent to be cautious in the use of mefloquine in patients taking ketoconazole.

Mefloquine + Metoclopramide

Although metoclopramide increases the rate of absorption of a single-dose of mefloquine and increases mefloquine peak levels, its gastrointestinal adverse effects are possibly reduced.

Clinical evidence, mechanism, importance and management

When 7 healthy subjects took a 10-mg dose of metoclopramide 15 minutes before a single 750-mg dose of mefloquine, the absorption half-life of the mefloquine was reduced from 3.2 to 2.4 hours and the peak blood levels were raised by 31%. However, although the rate of absorption was increased, the total amount absorbed was unchanged. A possible rea-

son for these changes is that metoclopramide increases gastric emptying causing mefloquine to reach the small intestine more quickly, which would increase the rate of absorption. Despite these changes, the toxicity of mefloquine (dizziness, nausea, vomiting, abdominal pain) was noted to be reduced.¹ The modest increase in peak levels is probably not clinically relevant, especially with prophylactic mefloquine doses. More study is needed.

Mefloquine + Primaquine

Although one study suggested that primaquine can increase both the peak serum levels and adverse effects of mefloquine, other studies have generally found no important interaction. Primaquine may be used after mefloquine to effect a radical cure of *P. vivax* malaria without any special precautions.

Clinical evidence

A preliminary report of a randomised crossover study in 14 healthy subjects given mefloquine 1 g found that the addition of primaquine 15 or 30 mg raised the peak serum levels of mefloquine by 48% and 29%, respectively. Those taking the larger dose of primaquine had a transient increase in peak primaquine serum levels, and its conversion to its inactive carboxyl metabolite was also increased. Significant CNS symptoms were also experienced by those taking the larger dose of primaquine.¹

However, these results contrast with another single dose study in 8 healthy subjects, who were given mefloquine 750 mg with primaquine 45 mg. No increased adverse effects attributable to concurrent use were seen, and mefloquine pharmacokinetics (including the peak level) were not altered by primaquine.² Similarly, in a study in patients with malaria, there was no change in mefloquine pharmacokinetics when it was given with primaquine.³ In another group in this study, the only difference in mefloquine pharmacokinetics was an 11% shorter terminal elimination half-life in those taking primaquine with mefloquine and sulfadoxine/pyrimethamine, when compared with those taking mefloquine with sulfadoxine/pyrimethamine.³ Similarly, in another study in children given mefloquine with sulfadoxine/pyrimethamine, the addition of primaquine had no effect on the pharmacokinetics of mefloquine, and there was no serious adverse effects.⁴

The pharmacokinetics of a single 45-mg dose of primaquine were not altered by a single 10-mg/kg oral dose of mefloquine in healthy subjects.⁵

Mechanism

In vitro studies suggest that primaquine is a potent inhibitor of mefloquine metabolism.⁶

Importance and management

The bulk of the evidence suggests there is no important alteration in the pharmacokinetics or effect of mefloquine when it is given with primaquine. After treatment of vivax malaria, primaquine is used to eradicate hepatic parasites, so producing a radical cure, and the manufacturer of mefloquine specifically advises this.^{7,8}

Mefloquine + Quinine and related drugs

Mefloquine serum levels may possibly be increased by quinine. In theory there is an increased risk of convulsions if mefloquine is given with quinine or chloroquine.

Clinical evidence, mechanism, importance and management

Mefloquine 750 mg was given to 7 healthy subjects either alone, or followed 24 hours later by quinine 600 mg. The combination did not affect the pharmacokinetics of either drug, but the number of adverse effects and the period of prolongation of the QT interval was greater with the combination, although no symptomatic cardiotoxicity was seen.¹ This absence of a change in pharmacokinetics is contrary to earlier *in vitro* data and unpublished clinical observations,² which suggested that quinine may inhibit the metabolism of mefloquine, thereby raising its serum levels. Another study in 13 patients with uncomplicated falciparum malaria given quinine dihydrochloride 10 mg/kg as a one-hour infusion and simultaneous oral mefloquine 15 mg/kg found no evidence of a pharmacokinetic interaction, but postural hypotension was common. The QTc interval was prolonged by 12%, although a clinically significant cardiovascular interaction was not reported.³

The manufacturers of mefloquine say that it should not be given with quinine or related compounds (e.g. **quinidine**, **chloroquine**) since this could increase the risk of ECG abnormalities and convulsions. They suggest that patients initially given intravenous quinine for 2 to 3 days should delay mefloquine until at least 12 hours after the last dosing of quinine to minimise interactions leading to adverse events.^{4,5} However, there seem to be no documented adverse reports of this interaction leading to convulsions. Consider also 'Mefloquine + Cardioactive drugs' p.232, for further discussion of the potential for cardiotoxicity with these drugs.

Mefloquine + Quinolones

Three non-epileptic patients had convulsions when they were treated for fever with mefloquine and a quinolone. Also, some quinolones, such as moxifloxacin, prolong the QT interval and concurrent use with mefloquine might theoretically result in additive effects.

Clinical evidence, mechanism, importance and management

(a) Convulsions

A large scale survey in India of the adverse effects of mefloquine identified 3 cases of convulsions out of a total of 150 patients also taking **iprofloxacin**, **ofloxacin** or **sparfloxacin**. All 3 patients were not epileptic, and had no family history of epilepsy. All were being treated for fever, which was due to *Plasmodium vivax* in one case, *P. falciparum* in the second, and was not established in the third. None of the patients had severe or complicated malaria. The **ofloxacin** was given 2 days before the mefloquine, and the other two quinolones were given together with the mefloquine.¹ The reason for the seizures is not known, but seizures are among the recognised adverse effects of both mefloquine and these quinolones. These adverse, apparently additive, effects are rare, but prescribers should be

aware of the potential increased risk of convulsions when prescribing these drugs together.

(b) *Prolongation of the QT interval*

Gatifloxacin, moxifloxacin, and sparfloxacin may cause clinically relevant prolongation of the QT interval. Although mefloquine alone has not been shown to cause a clinically relevant lengthening of the QT interval, caution has still been recommended when it is combined with some other drugs that prolong the QT interval, see 'Mefloquine + Cardioactive drugs', p.232, and it may be prudent to extend this caution to these quinolones. The manufacturers of **moxifloxacin** note that an additive effect on QT prolongation between **moxifloxacin** and antimalarials cannot be excluded, and therefore contraindicates concurrent use, although they specifically mention only halofantrine.²

2. Avelox (Moxifloxacin). Bayer plc. UK Summary of product characteristics, July 2006.

Mefloquine + Rifampicin (Rifampin)

Rifampicin significantly reduces the plasma concentrations of mefloquine. Until more is known, it may be prudent to avoid the combination.

Clinical evidence, mechanism, importance and management

Rifampicin 600 mg daily was given to 7 healthy subjects for 7 days with a single 500-mg dose of mefloquine on day 7. The maximum plasma level of mefloquine decreased by 19% and the AUC decreased by 68%. Rifampicin, a potent enzyme-inducer, increases the metabolism of mefloquine by the cytochrome P450 isoenzyme CYP3A4 in the liver and gut wall. The clinical relevance of this reduction in mefloquine levels uncertain, but the authors suggest that simultaneous use of rifampicin and mefloquine should be avoided to prevent treatment failure and the risk of *Plasmodium falciparum* resistance to mefloquine.¹ Until more is known, this would seem a sensible precaution.

1. Ridditid W, Wongnawa M, Mahatthanatrakul W, Chaipol P, Sunbhanich M. Effect of rifampicin on plasma concentrations of mefloquine in healthy volunteers. *J Pharm Pharmacol* (2000) 52, 1265–9.

Mefloquine + Sulfadoxine/Pyrimethamine

Sulfadoxine/pyrimethamine caused a modest increase in exposure to mefloquine in healthy subjects, but not in a study in patients. Any changes seem unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

In healthy subjects, a comparison of the pharmacokinetic parameters of a single 750-mg dose of mefloquine given alone or in combination with sulfadoxine/pyrimethamine found that the only difference was a 33% increase in mean residence time and 27% increase in the half-life of mefloquine.¹ However, in a further study in patients with malaria, there was no difference in any pharmacokinetic parameter of mefloquine 750 mg between 15 patients taking mefloquine alone and 16 taking mefloquine with sulfadoxine/pyrimethamine.² In both of these studies there was considerable inter-individual variability in the pharmacokinetics of mefloquine.^{1,2} In another study in healthy subjects, the mefloquine AUC was increased by a non-significant 13% when mefloquine was given as a combination tablet containing mefloquine, sulfadoxine and pyrimethamine when compared with mefloquine given alone.³

These studies suggest that, at the most, a small increase in exposure to mefloquine may occur when it is given with sulfadoxine/pyrimethamine. It would seem that this is unlikely to be clinically relevant, especially in view of the inter-individual variability in mefloquine pharmacokinetics. No special precautions appear to be needed.

Mefloquine + Tetracycline

Mefloquine serum levels are modestly increased by tetracycline.

Clinical evidence, mechanism, importance and management

The maximum serum levels of a single 750-mg dose of mefloquine were increased by 38% (from 1.16 to 1.6 mg/mL) in 20 healthy Thai men who took tetracycline 250 mg four times daily for a week. The AUC was increased by 30% and the half-life reduced from 19.3 to 14.4 days, without any evidence of an increase in adverse effects. The suggested reason for the increased mefloquine levels is that its enterohepatic recycling is reduced because of competition with tetracycline for biliary excretion.¹ The authors of the report conclude that concurrent use may be valuable for treating multi-drug resistant falciparum malaria because higher mefloquine levels are associated with a more effective response. However, more study is needed to confirm these findings. There seems to be no reason for avoiding concurrent use.

1. Karbwang J, Na Bangchang K, Back DJ, Bunnag D, Rooney W. Effect of tetracycline on mefloquine pharmacokinetics in Thai males. *Eur J Clin Pharmacol* (1992) 43, 567–9.

Mefloquine + Typhoid vaccine; Oral

Some sources suggest that mefloquine should not be given at the same time as oral attenuated live typhoid vaccine, whereas others suggest that concurrent administration is acceptable. Note that this advice does not apply to the capsular polysaccharide typhoid vaccine for injection.

Clinical evidence

An *in vitro* study found that mefloquine killed a significant amount of *S. typhi* (Ty21a vaccine strain), which suggested that concurrent administration could possibly reduce the efficacy of the vaccine.¹ A study in healthy subjects investigated the use of mefloquine with a combination of cholera and oral typhoid vaccine (Ty21a vaccine strain). Cholera and typhoid vaccines had previously been shown not to affect each other, and the addition of mefloquine did not significantly reduce the serum antibody response to these vaccines. The authors therefore concluded that mefloquine could be given at the same time as oral typhoid vaccine without reducing its efficacy.²

Mechanism

Oral typhoid vaccine requires active replication of the attenuated *Salmonella typhi* strain in the ileum for the development of immunity. Mefloquine is thought to have some antibacterial effect, which may diminish the amount of *S. typhi* present, and therefore reduce the immune response produced by the vaccine.^{2,3}

Importance and Management

As mefloquine is rapidly absorbed it has been suggested that by 8 hours after a dose, the levels of mefloquine will be insufficient to inhibit live oral typhoid vaccine.⁴ Based on the results of the above study the US manufacturers note that mefloquine can be given at the same time as oral typhoid vaccine.^{2,5} The UK manufacturers of the oral typhoid vaccine recommend separating the dose of oral typhoid vaccine and mefloquine by at least 12 hours.⁶ However, the manufacturers of mefloquine say that immunisation with vaccines such as oral typhoid should be completed at least 3 days before the first dose of mefloquine.^{7,8} The UK Department of Health say that mefloquine can be given 12 hours before or after vaccination with oral typhoid vaccine.⁹ It would therefore seem acceptable to separate administration by 12 hours. Note that this advice does not apply to the capsular polysaccharide typhoid vaccine for injection.
