Metrifonate + Antacids or H₂-receptor antagonists

The pharmacokinetics of a single dose of metrifonate were not altered by an antacid containing aluminium/magnesium hydroxide, nor by pretreatment with cimetidine or ranitidine.

Clinical evidence, mechanism, importance and management

(a) Antacids

The AUC and maximum level of metrifonate and its pharmacologically active metabolite were not altered by concurrent use of an **aluminium/magnesium hydroxide**-containing antacid in a single-dose study in healthy subjects.¹

(b) H₂-receptor antagonists

The AUC and maximum level of metrifonate and its pharmacologically active metabolite were not altered by pretreatment with either **cimetidine** or **ranitidine** in a study in healthy subjects.¹ Based on these results it seems unlikely that other H₂-receptor antagonists will interact with metrifonate.

- Heinig R, Boettcher M, Herman-Gnjidic Z, Pierce CH. Effects of magnesium/aluminium hydroxide-containing antacid, cimetidine or ranitidine on the pharmacokinetics of metrifonate and its metabolite DDVP. *Clin Drug Invest* (1999) 17, 67–77.

Piperazine + Chlorpromazine

An isolated case of convulsions in a child was attributed to the use of piperazine followed by chlorpromazine.

Clinical evidence, mechanism, importance and management

A child given piperazine for pin worms developed convulsions when treated with chlorpromazine several days later.¹ In a subsequent *animal* study using chlorpromazine 4.5 or 10 mg/kg, many of the *animals* died from respiratory arrest after severe clonic convulsions.¹ However, a later study did not confirm these findings² and it is by no means certain whether the adverse reaction in the child was due to an interaction or not. Given that both drugs may cause convulsions, there is probably enough evidence to warrant caution if they are used concurrently.

Praziquantel + Antiepileptics

Phenytoin, phenobarbital and carbamazepine markedly reduce the serum levels of praziquantel, but whether this results in neurocysticercosis treatment failures is unclear. A case report suggests that the addition of 'cimetidine', (p.236) may control this interaction.

Clinical evidence

(a) Carbamazepine, Phenobarbital or Phenytoin

A comparative study of patients, taking long-term phenytoin or carbamazepine, and healthy subjects (10 in each group), both given a single

25-mg/kg oral dose of praziquantel, found that **phenytoin** and **carbamazepine** reduced the AUC of praziquantel by about 74% and 90%, respectively, and reduced the maximum serum levels by 76% and 92%, respectively, when compared with the controls.¹ Another study also reported low praziquantel levels (maximum levels of 42 to 540 nanograms/mL with undetectable trough levels) in 4 patients taking **phenytoin** and 8 patients taking **phenobarbital**. However, in this study praziquantel 45 mg/kg daily in 3 divided doses for 15 days was very effective for neurocysticercosis, with all patients showing a marked improvement.²

(b) Phenytoin/Phenobarbital and Cimetidine

A patient with neurocysticercosis taking phenytoin and phenobarbital for a seizure disorder had no response to praziquantel (four courses in doses of up to 50 mg/kg daily). Praziquantel 50 mg/kg daily and dexamethasone 12 mg daily were started and, after one week, cimetidine 400 mg four times daily was added. The patient's serum praziquantel levels more than doubled with the addition of cimetidine (maximum serum levels raised from 350 to 826 nanograms/mL) and the AUC rose about fourfold, and became similar to that found in control subjects taking praziquantel alone. The patient showed marginal improvement, and continued to slowly improve over the following 4 months.³

Mechanism

Not established, but the probable reason is that these anticonvulsants and 'dexamethasone', (p.236) have enzyme-inducing effects and can therefore increase the metabolism of praziquantel. 'Cimetidine', (p.236) (an enzyme inhibitor) appears to oppose this effect. However, the fact that praziquantel was still effective in one study suggests that metabolites of praziquantel might be active.²

Importance and management

Direct information appears to be limited to the reports cited, but the pharmacokinetic interactions appear to be established. However, the clinical relevance of the interaction is uncertain. When treating systemic worm infections such as neurocysticercosis some authors advise increasing the praziquantel dosage from 25 to 50 mg/kg if potent enzyme inducers such as carbamazepine or phenytoin are being used, in order to reduce the risk of treatment failure.¹ A 45 mg/kg daily dose was effective in one study in 11 patients taking antiepileptics, despite low praziquantel levels,² but a 50 mg/kg daily dose was not effective in another case.³ Note that the manufacturer recommends giving praziquantel 50 mg/kg daily in 3 divided doses for neurocysticercosis, and they suggest that the use of drugs to prevent or alleviate convulsions should be decided on a case to case basis.⁴ Adding cimetidine may reduce the effect of enzyme-inducing anticonvulsants. However, the authors of the case above³ were not sure whether the improvement they saw was in fact due to the cimetidine or simply part of the natural history of the disease. It is clear that 'cimetidine', (p.236), alone can markedly increase praziquantel levels. The interaction with anticonvulsants is of no importance when praziquantel is used for intestinal worm infections (where its action is a local effect on the worms in the gut).

- Cysticide (Praziquantel). Merck. UK package insert, January 2000.

Praziquantel + Chloroquine

Chloroquine reduces the bioavailability of praziquantel, which would be expected to reduce its efficacy in systemic worm infections such as schistosomiasis.

Clinical evidence, mechanism, importance and management

A single 40-mg/kg oral dose of praziquantel was given to 8 healthy subjects alone, and 2 hours after chloroquine 600 mg. The chloroquine reduced the praziquantel AUC by 65% and the maximum serum levels by 59%. The reasons for this effect are not understood. There were large individual variations in levels, and one subject was not affected. The effect of this interaction could be that some patients will not achieve high enough

serum praziquantel levels to treat systemic worm infections such as schistosomiasis. After taking the chloroquine, the praziquantel serum levels of 4 out of the 8 subjects (50%) did not reach the threshold of 0.3 micrograms/mL for about 6 hours (which is required to effectively kill schistosomes), compared with only 2 of 8 (25%) during the control period. The authors conclude that an increased dosage of praziquantel should be considered if chloroquine is given (they do not suggest how much), particularly in anyone who does not respond to initial treatment with praziquantel.¹ More study of this interaction is needed.

The interaction is of no importance when praziquantel is used for intestinal worm infections (where its action is a local effect on the worms in the gut).

1. Masimirembwa CM, Naik YS, Hasler JA. The effect of chloroquine on the pharmacokinetics and metabolism of praziquantel in rats and in humans. *Biopharm Drug Dispos* (1994) 15, 33–43.

Praziquantel + Cimetidine

Cimetidine can double the serum levels of praziquantel, and may improve its efficacy in neurocysticercosis.

Clinical evidence

In a randomised crossover study 8 healthy subjects were given three 25-mg/kg oral doses of praziquantel at 2-hourly intervals with cimetidine 400 mg given 1 hour before each dose of praziquantel. Cimetidine was found to have roughly doubled the praziquantel serum levels and AUC.^{1,2} A further study in patients with neurocysticercosis found that this short regimen of praziquantel with cimetidine (which increased plasma levels of praziquantel by about threefold), had similar efficacy to the traditional regimen of 50 mg/kg daily in divided doses for 15 days.³ Of 6 patients receiving praziquantel with cimetidine, the clinical cure rate was 83% compared with only 50% in 6 patients receiving praziquantel while fasting.³

Mechanism

Cimetidine probably inhibits the metabolism of praziquantel.

Importance and management

Direct information appears to be limited to the reports cited, but the interaction appears to be established. It is clear that cimetidine can markedly increase praziquantel levels, and the authors say that concurrent use can reduce treatment for neurocysticercosis from 2 weeks to 1 day.^{1,3} Cimetidine has been tried to reverse the effects of 'antiepileptics', (p.235) and 'corticosteroids', (below) on praziquantel.

Praziquantel + Corticosteroids

The continuous use of dexamethasone can halve serum praziquantel levels. Two case reports suggest that this may reduce its efficacy in systemic worm infections, whereas another study suggests that efficacy is not affected.

Clinical evidence

Eight patients with parenchymal brain cysticercosis taking praziquantel 50 mg/kg (in three divided doses, taken every 8 hours) had a 50% reduction in steady-state serum levels, from 3.13 to 1.55 micrograms/mL, when given dexamethasone 8 mg every 8 hours.¹ Another patient with recurrent neurocysticercosis, who did not respond to praziquantel 50 mg/kg daily, was successfully treated with high-dose praziquantel 100 mg/kg

daily, dexamethasone 12 mg daily and cimetidine 800 mg daily. As dexamethasone was thought to reduce the plasma levels of praziquantel, cimetidine was added to try to reverse this effect, as it has been reported to increase the bioavailability of praziquantel.² However, some patients have responded well to praziquantel, despite low serum levels.³

Mechanism

Uncertain. Dexamethasone is an inducer of the cytochrome P450 isoenzyme CYP3A4, and might therefore be expected to reduce levels of praziquantel. 'Cimetidine', (above) may reverse this effect.

Importance and management

Information seems to be limited but the pharmacokinetic interaction would appear to be established. Just how much it affects the outcome of treatment for systemic worm infections such as cysticercosis is unknown because the optimum praziquantel levels are still uncertain, and it is possible that the metabolites of praziquantel might be active.³ The authors of one report suggest that dexamethasone should not be given continuously with praziquantel but only used transiently to resolve inflammatory reactions to praziquantel treatment.¹ Alternatively, limited information suggests the addition of cimetidine may allow dexamethasone to be used.²

Intravenous methylprednisolone has also been used for acute corticosteroid therapy with praziquantel, and oral prednisone has been used long-term to prevent further tissue damage associated with inflammation^{4,5} but the effect of these corticosteroids on the plasma levels of praziquantel do not appear to have been studied.

The interaction with dexamethasone is of no importance when praziquantel is used for intestinal worm infections (where its action is a local effect on the worms in the gut).

Praziquantel + Food

Food increases the bioavailability of praziquantel.

Clinical evidence, mechanism, importance and management

The maximum plasma levels and AUC of a single 1.8-g dose of praziquantel were increased by 243% and 180% when it was given following a high-fat diet and by 515% and 271% after a high-carbohydrate diet, respectively.¹ In another study in healthy Sudanese men, when praziquantel was given with food the AUC was 2.6-fold higher than when it was given in the fasted state.²

A further study in patients with neurocysticercosis found that treatment with a short regimen of praziquantel 25 mg/kg every 2 hours for 3 doses with a high-carbohydrate diet, which increased plasma levels of praziquantel, provided an adequate clinical alternative to the traditional regimen of 50 mg/kg daily in divided doses for 15 days.³ In 6 patients who took praziquantel with food, the clinical cure rate was 83%, compared with only 50% in 6 patients who took praziquantel while fasting.³

On the basis of the above studies, if praziquantel is used for systemic worm infections, administration with food is advisable, and this is recommended by the manufacturers.^{4,5}

5. Cysticide (Praziquantel). Merck. UK package insert, January 2000.

Praziquantel + Grapefruit juice

Grapefruit juice increases the AUC of praziquantel.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects the maximum plasma level of a single 1.8-g dose of praziquantel was increased by about 63% and the AUC by 90% when given with 250 mL of **grapefruit juice** rather than with water.¹ The authors suggested that grapefruit juice probably increased the absorption of praziquantel. The clinical effect of this interaction has not been assessed, but it may lead to improved efficacy. When compared with other studies, the authors noted that the effect of grapefruit juice was comparable to that of 'cimetidine', (p.236) and less than that of 'food', (p.236).

1. Castro N, Jung H, Medina R, González-Esquivel D, Lopez M, Sotelo J. Interaction between grapefruit juice and praziquantel in humans. *Antimicrob Agents Chemother* (2002) 46, 1614–16.

Praziquantel + Rifampicin (Rifampin)

The plasma levels of praziquantel were markedly reduced by rifampicin pretreatment, to undetectable levels in over half of the subjects in one study. It is predicted that rifampicin will reduce the efficacy of praziquantel.

Clinical evidence, mechanism, importance and management

Pretreatment with rifampicin 600 mg once daily for 5 days markedly reduced the AUC and maximum level of a single 40-mg/kg dose of praziquantel in 10 subjects. Seven of the subjects had undetectable praziquantel levels (less than 12.5 nanograms/mL), and the other 3 had an 85% reduction in the AUC of praziquantel. The same subjects were then given three doses of praziquantel 25 mg/kg at intervals of 8 hours, alone, and after pretreatment with rifampicin. In this multiple-dose study, 5 of the 10 subjects had undetectable praziquantel levels, and the remainder had an 80% reduction in AUC.¹ It was suggested that rifampicin induced the metabolism of praziquantel via cytochrome P450 isoenzyme CYP3A4. Although efficacy has not been assessed, the authors concluded that the levels of praziquantel after rifampicin pretreatment were less than those considered necessary for anthelmintic activity. They therefore recommend that the combination should be avoided,¹ a stance which is also taken by one of the manufacturers of praziquantel.²

2. Biltricide (Praziquantel). Bayer Healthcare. US Prescribing information, October 2004.

Primaquine + Mepacrine (Quinacrine)

Theoretically, mepacrine would be expected to elevate the serum levels of primaquine, because it increased levels of a formerly used drug pamaquine, but there do not seem to be any reports confirming or disproving this.

Clinical evidence, mechanism, importance and management

Patients given pamaquine (a formerly used antimalarial that was a predecessor of primaquine, and almost identical in structure), had grossly elevated pamaquine serum levels when they were also given mepacrine.^{1,2} The reason is unknown. On theoretical grounds primaquine might be expected to interact with mepacrine similarly, but there seem to be no reports confirming that a clinically important interaction actually takes place.

1. Zubrod CG, Kennedy TJ, Shannon JA. Studies on the chemotherapy of the human malarial. VIII. The physiological disposition of pamaquine. *J Clin Invest* (1948) 27 (Suppl), 114–120.
2. Earle DP, Bigelow FS, Zubrod CG, Kane CA. Studies on the chemotherapy of the human malarial. IX. Effect of pamaquine on the blood cells of man. *J Clin Invest* (1948) 27, (Suppl), 121–9.

Primaquine + Quinine

Quinine does not appear to affect the pharmacokinetics of primaquine.

Clinical evidence, mechanism, importance and management

Quinine 10 mg/kg three times daily had no effect on the pharmacokinetics of a single 45-mg dose of primaquine in 7 subjects, except for a 50% increase in the AUC of the carboxyprimaquine metabolite. The combination was effective for the treatment of malaria with no complications and no adverse effects reported.¹

Usually quinine is used only for the treatment of falciparum malaria, and primaquine is used only to eliminate the liver stages of vivax and ovale malarial, and therefore the drugs are generally unlikely to be taken together. However, quinine may be used when the infective species is unknown or the infection mixed, when subsequent primaquine may then be required. The limited data from the above study suggest that no special precautions would be required.

Proguanil + Antacids

The absorption of proguanil is markedly reduced by magnesium trisilicate, and therefore the efficacy of proguanil may be reduced.

Clinical evidence

Magnesium trisilicate reduced the AUC of a 200-mg dose of proguanil by about 65% in 8 healthy subjects, as assessed by salivary proguanil levels.¹

Mechanism

In vitro tests showed that magnesium trisilicate adsorbed proguanil. Two other antacids, **aluminium hydroxide** and light **magnesium carbonate**, had lesser effects.¹

Importance and management

The interaction between proguanil and magnesium trisilicate appears to be established, but its clinical importance does not seem to have been assessed. Given the extent of reduction in levels, the antimalarial effects of proguanil might be expected to be reduced. One way to minimise the interaction is to separate the dosage of proguanil and magnesium trisilicate as much as possible (2 to 3 hours) to reduce admixture in the gut. There do not appear to be any studies to see if other antacids behave similarly. The manufacturers of proguanil recommend taking proguanil and antacids at least 2 to 3 hours apart.²

2. Paludrine (Proguanil hydrochloride). AstraZeneca UK Ltd. UK Summary of product characteristics, April 2005.

Proguanil + Chloroquine

Chloroquine appears to increase the incidence of mouth ulcers by 1.5-fold in those taking prophylactic proguanil.

Clinical evidence, mechanism, importance and management

Following the observation that mouth ulcers appeared to be common in those taking prophylactic antimalarials, an extensive study was undertaken in 628 servicemen in Belize. Of those taking proguanil 200 mg daily, 24% developed mouth ulcers, and in those also taking chloroquine base 150 to 300 mg weekly, 37% developed mouth ulcers. The incidence of diarrhoea was also increased from 63% among those who did not develop ulcers to 83% in those that did develop ulcers (any treatment). The reasons are not understood. The authors of the study suggested that these two

drugs should not be given together unnecessarily for prophylaxis against *Plasmodium falciparum*.¹ Nevertheless, chloroquine plus proguanil is an established prophylactic regimen that is commonly recommended in regions where there is some chloroquine resistance.

1. Drysdale SF, Phillips-Howard PA, Behrens RH. Proguanil, chloroquine, and mouth ulcers. *Lancet* (1990) 1, 164.

Proguanil + Cimetidine or Omeprazole

There is some evidence that omeprazole and cimetidine can moderately reduce the production of the active metabolite of proguanil, but also some evidence to suggest that this may not be clinically relevant.

Clinical evidence

(a) Cimetidine

In one study, 4 patients with peptic ulcer disease and 6 healthy subjects were given a single 200-mg dose of proguanil on the last day of a 3-day course of cimetidine 400 mg twice daily. In both groups the half-life and AUC of proguanil were significantly increased, but only the healthy subjects had an increase in the maximum serum concentration of 89%. In both groups these pharmacokinetic changes resulted in lower levels of the active metabolite, cycloguanil.¹ This decrease in cycloguanil supported the findings of an earlier study, which had found a 30% decrease in the urinary recovery of cycloguanil when proguanil and cimetidine were given together.²

(b) Omeprazole

In a steady-state study in 12 healthy subjects taking proguanil 200 mg daily it was found that omeprazole 20 mg daily roughly halved the AUC of the active metabolite of proguanil, cycloguanil.³ However, an earlier study found that omeprazole 20 mg had no effect on the urinary recovery of cycloguanil (or proguanil) following a single 200-mg dose of proguanil.²

Mechanism

Cimetidine and omeprazole increase the gastric pH, which may lead to an increase in the absorption of proguanil. Cimetidine^{1,2} and omeprazole³ are also thought to inhibit the metabolism of proguanil, due to their inhibitory effects on cytochrome P450 isoenzyme CYP2C19.

Importance and management

The differences between the healthy subjects and patients with peptic ulcer disease seen in one study may have been because the disease itself alters the effects of the cimetidine in some way.¹ Patients with peptic ulcer disease are also likely to have an increased gastric pH, which will lead to altered proguanil absorption. The clinical relevance of all these findings is still unclear, although the implication is that decreased cycloguanil levels may lead to inadequate malaria prophylaxis. However, a subsequent clinical study reported that subjects who were poor metabolisers of proguanil (who had relatively low cycloguanil levels) did not have an increased risk of failure of proguanil prophylaxis.⁴ Similarly, treatment of malaria with proguanil was as effective in 62 patients with CYP2C19 poor metaboliser genotype as in 33 patients with extensive metaboliser genotype, independent of cycloguanil levels.⁵ This suggests that any interaction with omeprazole or cimetidine via this mechanism would be unlikely to be clinically relevant.

Proguanil + Fluvoxamine

The conversion of proguanil to its active metabolite is markedly inhibited by fluvoxamine in those who are CYP2C19 extensive metabolisers. However, there is some evidence this may not be of any clinical relevance.

Clinical evidence

Twelve healthy subjects, 6 of whom were of CYP2C19 extensive metaboliser genotype and 6 of whom were CYP2C19 poor metabolisers, were given proguanil 200 mg daily for 8 days. This was followed by fluvoxamine 100 mg for 8 days, with a single 200-mg dose of proguanil on day 6. In the group of extensive metabolisers it was found that fluvoxamine reduced the total clearance of proguanil by about 40%. The partial clearance of proguanil via its two metabolites was reduced, by 85% for cycloguanil, and by 89% for 4-chlorophenylbiguanide. The concentrations of these two metabolites in the plasma were hardly detectable while fluvoxamine was being taken. No pharmacokinetic interaction occurred in the poor metabolisers.¹

Mechanism

Proguanil, which is thought to be a prodrug, is metabolised to its active metabolite, cycloguanil by the cytochrome P450 isoenzyme CYP2C19. This isoenzyme is inhibited by fluvoxamine and so proguanil does not become activated.² Note that subjects with decreased CYP2C19 activity show slower metabolism of proguanil to cycloguanil,³ but they may still respond to proguanil.⁴

Importance and management

Information appears to be limited to the studies cited, the purpose of which was to confirm that fluvoxamine is an inhibitor of CYP2C19. However, they also demonstrate that proguanil, which is a prodrug, will not be effectively converted into its active form in patients who are extensive metabolisers if fluvoxamine is also being taken, making them effectively poor metabolisers. There are as yet no reports of treatment failures due to this interaction, but if the activity of proguanil is virtually abolished by fluvoxamine, as the authors suggest,² then proguanil would also be expected to be ineffective in the proportion of the population that are poor metabolisers. However, a subsequent clinical study reported that subjects who were poor metabolisers of proguanil did not have an increased risk of failure of proguanil prophylaxis.⁵ Similarly, treatment of malaria with proguanil was as effective in 62 patients with CYP2C19 poor metaboliser genotype as in 33 patients with extensive metaboliser genotype, independent of cycloguanil levels.⁴ This suggests any interaction with fluvoxamine, or other CYP2C19 inhibitors, may not be clinically relevant.

Pyrantel + Piperazine

Piperazine opposes the anthelmintic actions of pyrantel.

Clinical evidence, mechanism, importance and management

Pyrantel acts as an anthelmintic because it depolarises the neuromuscular junctions of some intestinal nematodes causing the worms to contract. This paralyses the worms so that they are dislodged by peristalsis and expelled in the faeces. Piperazine also paralyses nematodes but it does so by causing hyperpolarisation of the neuromuscular junctions. These two pharmacological actions oppose one another, as was shown in two *in vitro* pharmacological studies. Strips of whole *Ascaris lumbricoides*, which

contracted when exposed to pyrantel failed to do so when also exposed to piperazine.¹ Parallel electrophysiological studies using *Ascaris* cells confirmed that the depolarisation due to pyrantel (which causes the paralysis) was opposed by piperazine.¹

In practical terms this means that piperazine does not add to the anthelmintic effect of pyrantel on *Ascaris* as might be expected, but opposes it. For this reason it is usually recommended that concurrent use should be avoided, but direct clinical evidence confirming that combined use is ineffective seems to be lacking. It seems reasonable to extrapolate the results of these studies on *Ascaris lumbricoides* (roundworm) to the other gastrointestinal parasites for which pyrantel is used, i.e. *Enterobius vermicularis* (threadworm or pinworm), *Ancylostoma duodenale*, *Necator americanus* (hookworm) and *Trichostrongylus* spp. However, no one seems to have studied this.

Pyrimethamine + Artemether

Artemether raises pyrimethamine plasma levels, but this does not appear to cause an increase in adverse effects.

Clinical evidence, mechanism, importance and management

In a three-way single-dose crossover study, 8 healthy subjects were given either artemether 300 mg, pyrimethamine 100 mg, or both drugs together. Although there was large inter-individual variation in the pharmacokinetics of pyrimethamine, its maximum plasma levels were raised by 44%. As there was no corresponding increase in adverse effects the authors suggest that the interaction may be of benefit.¹ More study is warranted to confirm this result.

1. Tan-ariya P, Na-Bangchang K, Ubalee R, Thanavibul A, Thipawangkosol P, Karbwang J. Pharmacokinetic interaction of artemether and pyrimethamine in healthy male Thais. *South-east Asian J Trop Med Public Health* (1998) 29, 18–23.

Pyrimethamine + Co-trimoxazole or Sulfonamides

Serious pancytopenia and megaloblastic anaemia have occasionally occurred in patients given pyrimethamine and either co-trimoxazole or other sulfonamides.

Clinical evidence

A woman taking pyrimethamine 50 mg weekly as malaria prophylaxis, developed petechial haemorrhages and widespread bruising within 10 days of starting to take co-trimoxazole (trimethoprim 320 mg with sulfamethoxazole 800 mg) daily for a urinary-tract infection. She was found to have gross megaloblastic changes and pancytopenia in addition to being obviously pale and ill. After withdrawal of the two drugs she responded rapidly to hydroxocobalamin and folic acid, and the pyrimethamine was changed to chloroquine for malaria prophylaxis.¹

Similar cases have been described in other patients taking pyrimethamine with co-trimoxazole,^{2–4} sulfafurazole (sulfisoxazole),⁵ or other sulfonamides.⁶

Mechanism

Uncertain, but a reasonable surmise can be made. Pyrimethamine and trimethoprim are both **folate antagonists** and both selectively inhibit the actions of the enzyme dihydrofolate reductase, which is concerned with the eventual synthesis of the nucleic acids needed for the production of new cells. The sulfonamides inhibit another part of the same synthetic chain. The adverse reactions seen would seem to reflect a gross reduction of the normal folate metabolism caused by the combined actions of both drugs. Megaloblastic anaemia and pancytopenia are among the adverse reactions of pyrimethamine and, more rarely, of co-trimoxazole taken alone.

Importance and management

Information seems to be limited to the reports cited, but the interaction appears to be established. Its incidence is unknown. Pyrimethamine is usu-

ally given with a sulfonamide for toxoplasmosis and malaria. Caution should be used in prescribing these combinations, especially in the presence of other drugs, such as folate antagonists, or disease states that may predispose to folate deficiency. Note that the manufacturer of sulfadoxine/pyrimethamine (*Fansidar*), which is indicated for the prophylaxis and treatment of malaria, recommends that concomitant treatment with folate antagonists such as other sulfonamides, trimethoprim, co-trimoxazole and some antiepileptics should be avoided.^{7,8} When high-dose pyrimethamine is used for the treatment of toxoplasmosis, the manufacturer recommends that all patients should receive a folate supplement, preferably calcium folinate, to reduce the risk of bone marrow depression.^{9,10}

Pyrimethamine ± Sulfadoxine + Zidovudine

Pyrimethamine does not appear to alter zidovudine pharmacokinetics, and zidovudine does not appear to alter the prophylactic efficacy of sulfadoxine/pyrimethamine for toxoplasmosis. The combination of pyrimethamine and zidovudine may increase the risk of myelosuppression.

Clinical evidence, mechanism, importance and management

The addition of pyrimethamine (200 mg loading dose then 50 mg daily) and folic acid 10 mg daily to zidovudine had no effect on zidovudine pharmacokinetics, based on data from 10 HIV positive patients for whom zidovudine pharmacokinetics were available before and after starting pyrimethamine. Of 26 patients receiving the combination, 5 developed leucopenia and one discontinued treatment because of anaemia.¹

A study in patients with AIDS found that zidovudine 250 mg four times daily did not adversely affect the prevention of toxoplasma encephalitis with pyrimethamine/sulfadoxine (*Fansidar*), one tablet twice weekly for up to 8 months.² *In vitro* and animal data have shown that the combination of zidovudine and pyrimethamine caused synergistic decreases in lymphocyte and neutrophil numbers.³

The manufacturers of pyrimethamine note that the concurrent use of zidovudine may increase the risk of bone marrow depression.^{4,5} They say that if signs of folate deficiency develop, then pyrimethamine should be discontinued and folic acid given. Note that the prophylactic use of a folate supplement, preferably folic acid, is recommended for all patients with toxoplasmosis taking high-dose pyrimethamine, to reduce the risk of bone marrow suppression.^{4,5} See also 'NRTIs; Zidovudine + Myelosuppressive drugs', p.809

Quinine + Colestyramine

Colestyramine does not appear to alter the pharmacokinetics of quinine.

Clinical evidence, mechanism, importance and management

Colestyramine 8 g did not alter the pharmacokinetics of quinine 600 mg, given concurrently to 8 healthy subjects. The authors warn that this lack of interaction may have been because only single doses were used, and suggest continuing to separate the administration of the two drugs until a lack of interaction is demonstrated in a multiple dose study.¹ It is usually recommended that other drugs are taken 1 hour before or 4 to 6 hours after colestyramine.

1. Ridditid W, Wongnawa M, Kleeaew A, Mahathanatrakul W, Sunbhanich M. Cholestyramine does not significantly decrease the bioavailability of quinine in healthy volunteers. *Asia Pac J Pharmacol* (1998) 13, 123–7.

Quinine + Fluvoxamine

Fluvoxamine had no effect on the pharmacokinetics of quinine.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, fluvoxamine 25 mg was given both 12-hours and 1-hour before a single 500-mg dose of quinine hydrochloride, followed by a further 4 doses of fluvoxamine, given every 12 hours.¹ Fluvoxamine had no effect on the apparent oral clearance of quinine and caused a minor 6% increase in the AUC of 3-hydroxyquinine, with no effect on the AUC of various other metabolites.^{1,2}

Fluvoxamine is a known inhibitor of the cytochrome P450 isoenzyme CYP2C19, and it appears that this has little effect on the pharmacokinetics of quinine and therefore no dose adjustments would be necessary on concurrent use.

2. Mirghani RA, Hellgren U, Bertilsson L, Gustafsson LL, Ericsson Ö. Metabolism and elimination of quinine in healthy volunteers. *Eur J Clin Pharmacol* (2003) 59, 423–7.

Quinine + Grapefruit juice

Grapefruit juice had no effect on the pharmacokinetics of quinine.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects 200 mL full-strength grapefruit juice, half-strength grapefruit juice, or orange juice was given twice daily for 11 doses with a single 600-mg dose of quinine sulfate, given on day 6 with the last dose of grapefruit juice. There were no significant differences in the pharmacokinetics of quinine between the three treatments, although the maximum level of the 3-hydroxymetabolite was slightly reduced (by 19%) with full-strength grapefruit juice compared with orange juice or half-strength grapefruit juice.¹

Grapefruit juice is a known inhibitor of intestinal cytochrome P450 isoenzyme CYP3A4, and it appears that this has little effect on the pharmacokinetics of quinine, which has a high oral bioavailability and is metabolised in the liver.

Grapefruit juice does not alter the pharmacokinetics of quinine, suggesting that patients requiring quinine may safely drink grapefruit juice if they wish.¹

1. Ho PC, Chalcraft SC, Coville PF, Wanwimolruk S. Grapefruit juice has no effect on quinine pharmacokinetics. *Eur J Clin Pharmacol* (1999) 55, 393–8.

Quinine + H₂-receptor antagonists

Quinine clearance is reduced by cimetidine, but not ranitidine.

Clinical evidence, mechanism, importance and management

In a study in 6 healthy subjects **cimetidine** 200 mg three times daily and 400 mg at night for one week reduced the clearance of quinine by 27%, increased the half-life by 49% (from 7.6 to 11.3 hours), and increased the

AUC by 42%. Peak levels were unchanged. No interaction was seen when **cimetidine** was replaced by **ranitidine** 150 mg twice daily.¹ The probable reason for this effect is that **cimetidine** (a recognised enzyme inhibitor) reduces the metabolism of the quinine by the liver, whereas **ranitidine** does not. It therefore seems likely that other H₂-receptor antagonists will not interact, although this needs confirmation. The clinical importance of this is uncertain, but prescribers should be alert for any evidence of quinine toxicity if cimetidine is also given.

Quinine + Isoniazid

A study in 9 healthy subjects found that the clearance of a single 600-mg dose of quinine sulfate was not significantly affected by pretreatment with isoniazid 300 mg daily for a week.¹

1. Wanwimolruk S, Kang W, Coville PF, Viriyayudhakorn S, Thitiarchakul S. Marked enhancement by rifampicin and lack of effect of isoniazid on the elimination of quinine in man. *Br J Clin Pharmacol* (1995) 40, 87–91.

Quinine + Ketoconazole

Ketoconazole modestly decreases the clearance of quinine, but this is probably not clinically relevant.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects ketoconazole 100 mg twice daily was given for 3 days with a single 500-mg dose of quinine hydrochloride one hour after the second dose of ketoconazole. Ketoconazole decreased the apparent oral clearance of quinine by 31% and decreased the AUC of 3-hydroxyquinine by 30%,¹ with increases in the AUC of various other metabolites.²

It is likely that ketoconazole inhibits the metabolism of quinine to its major metabolite 3-hydroxyquinine via the cytochrome P450 isoenzyme CYP3A4. This pharmacokinetic interaction would appear to be established, but of unknown clinical relevance. The modest increase in quinine levels seen is probably unlikely to be of much significance.

2. Mirghani RA, Hellgren U, Bertilsson L, Gustafsson LL, Ericsson Ö. Metabolism and elimination of quinine in healthy volunteers. *Eur J Clin Pharmacol* (2003) 59, 423–7.

Quinine + Miscellaneous

Urinary alkalinisers can increase the retention of quinine in man, and antacids can reduce the absorption of quinine in animals. None of these interactions appears to be of general clinical importance.

Clinical evidence, mechanism, importance and management

(a) Antacids

Aluminium/magnesium hydroxide gel reduces the absorption of quinine from the gut of *rats* and reduces quinine blood levels by 50 to 70%.¹ This appears to occur because **aluminium hydroxide** slows gastric emptying, which reduces absorption, and also because **magnesium hydroxide** forms an insoluble precipitate with quinine. However, there seem to be no clinical reports of a reduction in the therapeutic effectiveness of quinine due to the concurrent use of antacids.

(b) Urinary alkalinisers and acidifiers

The excretion of unchanged quinine is virtually halved (from 17.4 to 8.9%) if the urine is alkalinised. This is because in alkaline urine more of the quinine exists in the non-ionised (lipid soluble) form, which is more

easily reabsorbed by the kidney tubules.² However, there seem to be no reports of adverse effects arising from changes in excretion due to this interaction, and no special precautions seem to be necessary.

2. Haag HB, Larson PS, Schwartz JJ. The effect of urinary pH on the elimination of quinine in man. *J Pharmacol Exp Ther* (1943) 79, 136–9.

Quinine + Rifampicin (Rifampin)

Rifampicin induces the metabolism of quinine, which may result in subtherapeutic quinine levels.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects found that the clearance of a single 600-mg dose of quinine sulfate was increased more than sixfold by pretreatment with rifampicin 600 mg daily for 2 weeks. The elimination half-life of quinine was decreased from about 11 hours to 5.5 hours.¹

A report describes a patient with myotonia, controlled with quinine, whose symptoms worsened within 3 weeks of starting to take rifampicin for the treatment of tuberculosis. Peak quinine levels were found to be low, but rose again when the rifampicin was stopped. Control of the myotonia was regained 6 weeks later.²

The effect of adding rifampicin to quinine was investigated in patients with uncomplicated falciparum malaria. They were taking quinine sulfate 10 mg/kg three times daily either alone (30 patients) or with rifampicin 15 mg/kg daily (29 patients) for 7 days. Peak plasma levels of quinine during monotherapy were attained within 2 days of treatment and remained within the therapeutic range for the 7-day treatment period. Levels of the main metabolite of quinine, 3-hydroxyquinine, followed a similar pattern. In patients taking quinine with rifampicin, quinine was more extensively metabolised and, after the second day of treatment, quinine levels were sharply reduced to below therapeutic levels. Acute malaria reduces the metabolic clearance of quinine (by a reduction in hepatic mixed function oxidase activity, mainly by the cytochrome P450 isoenzyme CYP3A4) and recovery is associated with a sharp decline in quinine levels. Rifampicin induces the cytochrome P450 isoenzymes and this probably more than countered their inhibition during acute malaria and resulted in increased metabolism of quinine. Although patients who received rifampicin with quinine had shorter parasite clearance times than those who received quinine alone, suggesting rifampicin may enhance the antimalarial activity of quinine, recrudescence rates were 5 times, higher suggesting increased resistance. [Note, recrudescence is the reappearance of the disease after a period of inactivity.] The authors suggest that rifampicin should not be given with quinine for the treatment of malaria. Patients receiving rifampicin who also require quinine for malaria may need increased doses of quinine.³

Quinine + Tetracyclines

Doxycycline does not appear to alter the pharmacokinetics of quinine. Tetracycline increases quinine levels and has been found to improve efficacy.

Clinical evidence, mechanism, importance and management

(a) Doxycycline

In a study in 13 patients with acute falciparum malaria, the addition of intravenous **doxycycline** to treatment with intravenous quinine did not affect quinine pharmacokinetics, when compared with 13 patients taking

quinine alone.¹ In contrast, *in vitro*, **doxycycline** appears to be a potent inhibitor of quinine metabolism.² However, given the above evidence from their use in patients, no special precautions would seem to be necessary on concurrent use.

(b) Tetracycline

A study in patients with acute falciparum malaria found that quinine levels were about doubled in those taking quinine 600 mg every 8 hours with **tetracycline** 250 mg every 6 hours, when compared with those taking quinine alone. Quinine levels were above the MIC for malaria with the combination but not for quinine alone. Two of 8 patients treated with quinine alone had malaria recrudescence (the reappearance of the disease after a period of inactivity) compared with none of 8 patients receiving the combination.³ *In vitro* **tetracycline** is also a potent inhibitor of quinine metabolism.² The authors considered that this pharmacokinetic interaction might be part of the explanation why the combination has been found to be more effective.³

3. Karbwang J, Molunto P, Bunnag D, Harinasuta T. Plasma quinine levels in patients with falciparum malaria given alone or in combination with tetracycline with or without primaquine. *Southeast Asian J Trop Med Public Health* (1991) 22, 72–6.

Quinine + Tobacco

Smokers cleared quinine from the body much more quickly than non-smokers in a single-dose study in healthy subjects. However, quinine metabolism is reduced in patients with falciparum malaria, which may negate this effect. Quinine pharmacokinetics and efficacy were unchanged by smoking in one study.

Clinical evidence

A comparative study in 10 smokers (averaging 17 cigarettes daily) and 10 non-smokers found that the AUC of a single 600-mg dose of quinine sulfate was reduced by 44%, the clearance was increased by 77% and the half-life was shortened (from 12 to 7.5 hours), when compared with the non-smokers.¹ In contrast, in a study in patients with uncomplicated falciparum malaria taking quinine sulfate 10 mg/kg three times daily for 7 days, there was no significant difference in fever clearance time, parasite clearance time, and cure rate between 10 regular smokers and 12 non-smokers. In addition pharmacokinetic parameters did not differ significantly between the smokers and non-smokers.²

Mechanism

Tobacco smoke contains polycyclic aromatic compounds and other substances, which are potent inducers of the liver enzymes that metabolise quinine. It is not yet clear which cytochrome P450 isoenzymes are affected. Smoking induces CYP1A, but the formation of the major metabolite of quinine, 3-hydroxyquinine, is catalysed by CYP3A, which suggests that other metabolic pathways of quinine are affected by smoking.³

Importance and management

Information seems to be limited but the pharmacokinetic interaction would appear to be established in healthy subjects. However, the clinical study in patients with falciparum malaria suggests that any pharmacokinetic differences are more limited probably due to the additional effect the disease has on quinine metabolism, and that smoking status does not appear to affect the clinical outcome of quinine treatment for malaria. The systemic clearance of quinine in acute falciparum malaria may be reduced by up to two-thirds, when compared to healthy subjects as malaria reduces hepatic microsomal enzyme activity. The authors say that this reduction in the clearance of quinine outweighs the possible effects of smoking-induced clearance.²

3. Wanwimolruk S, Wong S-M, Zhang H, Coville PF, Walker RJ. Metabolism of quinine in man: identification of a major metabolite, and effects of smoking and rifampicin pretreatment. *J Pharm Pharmacol* (1995) 47, 957–63.

Terbinafine + H₂-receptor antagonists

Cimetidine modestly increases the AUC of terbinafine. However, no clinically relevant interactions appear to have been reported between terbinafine and cimetidine or ranitidine.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects **cimetidine** 400 mg twice daily for 5 days increased the AUC of a single 250-mg dose of terbinafine by 34% and reduced its clearance by 30%.¹ The likely reason is that **cimetidine** (a known enzyme inhibitor) reduces the metabolism of terbinafine by the liver. However, it seems that this modest increase in the serum levels of terbinafine is of little or no clinical relevance, because in a large scale post-marketing survey of patients taking terbinafine no interactions were reported in patients also taking **cimetidine** or **ranitidine** [number un-

known].² Nevertheless, the manufacturer of terbinafine recommends that the dosage of terbinafine may need adjusting (presumably reduced) if cimetidine is given.³

2. Hall M, Monka C, Krupp P, O'Sullivan D. Safety of oral terbinafine. Results of a postmarketing surveillance study in 25 884 patients. *Arch Dermatol* (1997) 133, 1213–19.
3. Lamisil Tablets (Terbinafine hydrochloride). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, February 2007.

Terbinafine + Rifampicin (Rifampin)

The serum levels of terbinafine are reduced by rifampicin.

Clinical evidence, mechanism, importance and management

In 12 subjects, rifampicin 600 mg daily for 6 days halved the AUC of terbinafine and roughly doubled its clearance.¹ Rifampicin is a potent enzyme inducer, which increases the metabolism of many drugs. Be alert, therefore, for the need to increase the dosage of terbinafine if rifampicin is given.

9

Antiarrhythmics

This section is mainly concerned with the class I antiarrhythmics, which also possess some local anaesthetic properties, and with class III antiarrhythmics. Antiarrhythmics that fall into other classes are dealt with under 'beta blockers', (p.833), 'digitalis glycosides', (p.903), and 'calcium-channel blockers', (p.860). Some antiarrhythmics that do not fit into the Vaughan Williams classification (see 'Table 9.1', (below)) are also included in this section (e.g. adenosine). Interactions in which the antiarrhythmic drug is the affecting substance, rather than the drug whose activity is altered, are dealt with elsewhere.

Predicting interactions between two antiarrhythmics

It is difficult to know exactly what is likely to happen if two antiarrhythmics are used together. The hope is always that a combination will work better than just one drug, and many drug trials have confirmed that hope, but sometimes the combinations are unsafe. Predicting unsafe combinations is difficult, but there are some very broad general rules that can be applied if the general pharmacology of the drugs is understood.

If drugs with similar effects are used together, whether they act on the myocardium itself or on the conducting tissues, the total effect is likely to be increased (additive). The classification of the antiarrhythmics in 'Table 9.1', (see below) helps to predict what is likely to happen, but remember that the classification is not rigid so drugs in one class can share some characteristics with others. The following sections deal with some examples.

(a) Combinations of antiarrhythmics from the same class

The drugs in class Ia can prolong the QT interval so combining drugs from this class would be expected to show an increased effect on the QT interval. This prolongation carries the risk of causing torsade de pointes arrhythmias (see the monograph, 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257). It would also be expected that the negative inotropic effects of quinidine would be additive with procainamide or any of the other drugs within class Ia. For safety therefore it is sometimes considered best to avoid drugs that fall into the same subclass or only to use them together with caution.

(b) Combinations of antiarrhythmics from different classes

Class III antiarrhythmics such as amiodarone can also prolong the QT interval, so they would also be expected to interact with drugs in other classes that do the same, namely class Ia drugs (see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257). Verapamil comes into class IV and has negative inotropic effects, so it can interact with other drugs with similar effects, such as the beta blockers, which fall into class III. For safety you should always look at the whole drug profile and take care with any two drugs, from any class, that share a common pharmacological action.

Table 9.1 Antiarrhythmics (modified Vaughan Williams classification)

Class I: Membrane stabilising drugs

- (a) Ajmaline, Cibenzoline (Cifenline),* Disopyramide, Procainamide, Quinidine
 - (b) Aprindine, Lidocaine, Mexiletine, Tocainide
 - (c) Flecainide, Propafenone
- Class I, but not easily fitting the above subgroups – Moracizine

Class II: Beta blocker activity

Atenolol, Bretylium,† Propranolol

Class III: Inhibitors of depolarisation

†Bretylium has class II and III activity

Adenosine + Dipyridamole

Dipyridamole reduces the bolus dose of adenosine necessary to convert supraventricular tachycardia to sinus rhythm by about fourfold. Profound bradycardia occurred in one patient taking dipyridamole when an adenosine infusion was given for myocardial stress testing.

Clinical evidence

(a) Adenosine bolus for supraventricular tachycardia

Adenosine by rapid intravenous bolus (10 to 200 micrograms/kg in step-wise doses) was found to restore sinus rhythm in 10 of 14 episodes of tachycardia in 7 patients with supraventricular tachycardia (SVT). The mean dose was 8.8 mg compared with only 1 mg in two patients also taking oral dipyridamole.¹ Another study in 6 patients found that dipyridamole (560 microgram/kg intravenous bolus, followed by a continuous infusion of 5 micrograms/kg/minute) reduced the minimum effective bolus dose of intravenous adenosine required to stop the SVT from 68 to 17 micrograms/kg in 5 patients. In the other patient, dipyridamole alone stopped the SVT.²

Other studies in healthy subjects have clearly shown that dipyridamole reduces the dose of adenosine required to produce an equivalent cardiovascular effect by fourfold³ or six- to sixteenfold.⁴ A brief report describes a woman with paroxysmal SVT who lost ventricular activity for 18 seconds when given adenosine 6 mg intravenously. She was also taking dipyridamole [dose unstated], which was considered to have contributed to the loss of ventricular function.⁵ Another report describes 3 of 4 patients who had heart block of 3, 9 and 21-second duration respectively when given adenosine 3 to 6 mg by central venous bolus. The patient with the most profound heart block was also being treated with dipyridamole, which was thought to have contributed to the reaction.⁶

(b) Adenosine infusion for myocardial stress testing

A 79-year-old woman taking a combination of low-dose aspirin and extended-release dipyridamole (*Aggrenox*) became profoundly bradycardic (36 bpm), dizzy and almost fainted 2 minutes after the start of an adenosine infusion for radionuclide myocardial imaging. Adenosine was stopped, and she recovered within 2 minutes. The last dose of *Aggrenox* had been taken 12 hours previously.⁷ However, note that bradycardia is a known adverse effect of adenosine.^{8,9}

Mechanism

Not fully understood. Part of the explanation is that dipyridamole increases plasma levels of endogenous adenosine by inhibiting its uptake into cells.^{2,4,10}

Importance and management

An established interaction.

(a) Patients will need much less adenosine to treat arrhythmias while taking dipyridamole. It has been suggested that the initial dose of adenosine should be reduced by twofold⁵ or fourfold.² The UK manufacturers actually advise the avoidance of adenosine in patients taking dipyridamole. If it must be used for supraventricular tachycardia in a patient taking dipyridamole, they recommend that the adenosine dose should be reduced about fourfold.⁸

(b) The UK manufacturers advise the avoidance of adenosine in patients taking dipyridamole. If adenosine is considered necessary for myocardial imaging in a patient taking dipyridamole, they suggest that the dipyridamole should be stopped 24 hours before, or the dose of adenosine should be greatly reduced.⁹ This may be insufficient for extended-release dipyridamole preparations: the authors of the above report recommend several days.⁷ Xanthines, such as intravenous aminophylline, have been used to terminate persistent adverse effects of adenosine infusion given for myocardial imaging.⁹ Consider also 'Adenosine + Xanthines', below.

Adenosine + Nicotine

Nicotine appears to enhance the effects of adenosine, but the clinical relevance of this is unclear.

Clinical evidence, mechanism, importance and management

Nicotine chewing gum 2 mg (approximately equal to one cigarette) increased the circulatory effects of a 70 microgram/kg/minute infusion of adenosine in 10 healthy subjects. The increase in heart rate due to nicotine (5.5 bpm) was further increased to 14.9 bpm by the adenosine, and the diastolic blood pressure rise due to nicotine (7 mmHg) was reduced to 1.1 mmHg.¹ In another study, **nicotine chewing gum** 2 mg increased chest pain and the duration of AV block when it was given to 7 healthy subjects with intravenous bolus doses of adenosine.² What this means in practical terms is uncertain, but be aware that the effects of adenosine may be modified to some extent by nicotine-containing products (**tobacco smoking, nicotine gum**, etc).

Adenosine + Xanthines

Caffeine and theophylline can inhibit the effects of adenosine infusions used in conjunction with radionuclide myocardial imaging. Xanthines should be withheld 12 to 24 hours prior to the procedure or they will interfere with test results. Aminophylline has been used to terminate persistent adverse effects of adenosine infusions. Adenosine may still be effective for terminating supraventricular tachycardia in patients taking xanthines.

Clinical evidence

(a) Adenosine bolus for supraventricular tachycardia

It is usually considered that an adenosine bolus for the termination of paroxysmal supraventricular tachycardia will be ineffective in patients taking xanthines. However, one case describes a man taking **theophylline** (serum level 8 nanograms/mL) in whom adenosine 9 mg terminated supraventricular tachycardia. Two previous adenosine doses, one of 3 mg and one of 6 mg had not been effective.¹ Another report found that high adenosine doses, of 400 to 800 micrograms/kg (usual dose 50 to 200 micrograms/kg), were required to revert supraventricular tachycardia in a preterm infant receiving **theophylline**.²

(b) Adenosine infusion

Experimental studies in healthy subjects, on the way xanthine drugs possibly interact with adenosine, have shown that **caffeine** and **theophylline** (but not **enprofylline**) reduced the increased heart rate and the changes in blood pressure caused by infusions of adenosine,^{3–6} and attenuated adenosine-induced vasodilatation.^{7,8} **Theophylline** also attenuated adenosine-induced respiratory effects and chest pain.^{5,6} Similarly, an adenosine infusion antagonised the haemodynamic effects of a single dose of **theophylline** in healthy subjects, but did not reduce the metabolic effects (reductions in plasma potassium and magnesium).⁵

Mechanism

Caffeine and theophylline have an antagonistic effect on adenosine receptors.⁹ They appear to have opposite effects on the circulatory system: caf-

feine and theophylline cause vasoconstriction whereas adenosine infusions generally cause vasodilatation.³ Consequently their concurrent use is likely to result in an interaction.

Importance and management

(a) Adenosine bolus injection for the termination of paroxysmal supraventricular tachycardia may still be effective in patients on xanthines. The usual dose schedule should be followed. However, note that adenosine has induced bronchospasm. The US manufacturers^{10,11} state that adenosine preparations, whether used for supraventricular tachycardia or myocardial imaging, should be avoided in patients with bronchoconstriction or bronchospasm (e.g. asthma), and used cautiously in those with obstructive pulmonary disease not associated with bronchospasm (e.g. emphysema, bronchitis). The UK manufacturers similarly recommend that the product used for supraventricular tachycardia¹² should be avoided in asthma, and warn that adenosine may precipitate or aggravate bronchospasm. They also contraindicate the use of adenosine for diagnostic imaging¹³ in both asthma and other obstructive pulmonary disease associated with bronchospasm. Whether an adenosine bolus can stop theophylline-induced supraventricular tachycardia appears not to have been studied.

(b) The manufacturers of adenosine state that theophylline, aminophylline and other xanthines should be avoided for 24 hours before using an adenosine infusion for radionuclide myocardial imaging, and that xanthine-containing drinks (tea, coffee, chocolate, cola drinks etc.) should be avoided for at least 12 hours before imaging.¹³ In a recent study in 70 patients, measurable caffeine serum levels were found in 74% of patients after 12 hours of self-reported abstinence from caffeine-containing products. Patients with caffeine serum levels of at least 2.9 mg/L had significantly fewer stress symptoms (chest tightness, chest pain, headache, dyspnoea, nausea, dizziness) than those with lower serum levels. The authors suggest that a 12-hour abstinence from caffeine-containing products may be insufficient, and could result in false-negative results.¹⁴ Xanthines, such as intravenous aminophylline, have been used to terminate persistent adverse effects of adenosine infusion given for myocardial imaging.¹³

Ajmaline + Miscellaneous

An isolated report describes cardiac failure in a patient given ajmaline with lidocaine. Quinidine causes a very considerable increase in the plasma levels of ajmaline, and phenobarbital appears to cause a marked reduction.

Clinical evidence, mechanism, importance and management

A woman had a marked aggravation of her existing cardiac failure when she was given ajmaline orally and lidocaine intravenously for repeated ventricular tachycardias.¹

A study² in 4 healthy subjects found that if a single 200-mg oral dose of quinidine was given with a single 50-mg oral dose of ajmaline, the AUC of ajmaline was increased 10- to 30-fold and the maximum plasma concentrations increased from 18 to 141 nanograms/mL. Another single-dose

study in 5 healthy subjects found that the metabolism of ajmaline was inhibited by quinidine, possibly because the quinidine becomes competitively bound to the enzymes that metabolise ajmaline.³

The clearance of intravenous ajmaline was almost twice as high in 3 patients also taking phenobarbital when compared with 5 patients who were not taking phenobarbital. Therefore the clinical effects of ajmaline would be expected to be markedly diminished in those taking phenobarbital.⁴

The clinical importance of all of these interactions is uncertain but concurrent use should be well monitored.

Amiodarone + Anaesthesia

There is some evidence that the presence of amiodarone possibly increases the risk of complications (atropine-resistant bradycardia, hypotension, decreased cardiac output) during general anaesthesia. All cases were with fentanyl-based anaesthesia, but some other studies have shown no problems with fentanyl-based anaesthesia.

Clinical evidence

(a) Evidence for complications

Several case reports^{1–4} and two studies^{5,6} suggest that severe intra-operative complications (atropine-resistant bradycardia, myocardial depression, hypotension) may occur in patients receiving amiodarone. One of the studies, a comparative retrospective review of patients (16 receiving amiodarone 300 to 800 mg daily and 30 controls) having operations under anaesthesia (mainly open-heart surgery), showed that the incidence of slow nodal rhythm, complete heart block or pacemaker dependency rose from 17% in controls to 66% in amiodarone-treated patients. Intra-aortic balloon pump augmentation (reflecting poor cardiac output) was 50% in the amiodarone group compared with 7% in the control group, and a state of low systemic vascular resistance with normal to high cardiac output occurred in 13% of the amiodarone-treated patients, but none of the controls. Overall there were 3 fatalities; all of these patients had received amiodarone and had been on cardiopulmonary bypass during surgery. Fentanyl was used for all of the patients, often combined with diazepam, and sometimes also isoflurane, enflurane or halothane.⁵

Another study of 37 patients receiving amiodarone (mean dose about 250 mg daily) found no problems in 8 undergoing non-cardiac surgery. Of the 29 undergoing cardiac surgery, 52% had postoperative arrhythmias and 24% required a pacemaker, which was not considered exceptional for the type of surgery. However, one patient having coronary artery bypass surgery had fatal vasoplegia (a hypotensive syndrome), which was considered to be amiodarone-related. This occurred shortly after he was taken off of cardiopulmonary bypass. Anaesthesia in all patients was fentanyl-based.⁶ It was suggested in one case report that serious hypotension in two patients on amiodarone undergoing surgery may have been further compounded by ACE inhibitor therapy.³ For the interactions of ACE inhibitors and anaesthetics see 'Anaesthetics, general + Antihypertensives', p.94.

(b) Evidence for no complications

The preliminary report of one study in 21 patients taking amiodarone (mean dose 538 mg daily) and undergoing defibrillator implantation suggested that haemodynamic changes during surgery were not significantly different from those in matched controls not taking amiodarone.⁷ Similarly, another study found no difference in haemodynamic status or pacemaker dependency between patients on short-term amiodarone 600 mg daily for 1 week then 400 mg daily for 2 weeks prior to surgery and a control group during valve replacement surgery with thiopental-fentanyl anaesthesia.⁸ In a double-blind trial, there was no significant difference in haemodynamic instability during fentanyl-isoflurane anaesthesia between patients randomised to receive short-term amiodarone (3.4 g over 5 days or 2.2 g over 24 hours) or placebo before cardiac surgery. In this

study, haemodynamic instability was assessed by fluid balance, use of dopamine or other vasopressors, and use of a phosphodiesterase inhibitor or intra-aortic balloon pump.⁹ A case report describes the successful use of epidural anaesthesia with **fentanyl** then **chloroprocaine** during labour and caesarean section in a woman who had been taking amiodarone long-term for arrhythmia control. The only haemodynamic change of possible note was that the patient had a drop in systemic vascular resistance from high to almost normal levels shortly after receiving **fentanyl** during the first stage of labour, and again when **fentanyl** was given for postoperative pain relief.¹⁰

Mechanism

In vitro and *in vivo* studies in *animals* suggest that amiodarone has additive cardiodepressant and vasodilator effects with volatile anaesthetics such as halothane, enflurane and isoflurane.^{2,11} The manufacturer notes that fentanyl is a substrate for the cytochrome P450 isoenzyme CYP3A4, and that amiodarone might inhibit CYP3A4, thereby increasing the toxicity of fentanyl.¹²

Importance and management

The assessment of this interaction is complicated by the problem of conducting studies in anaesthesia, most being retrospective and using matched controls. The only randomised study used short-term amiodarone to assess its safety in the prevention of post-operative atrial fibrillation, and its findings may not be relevant to patients taking long-term amiodarone.⁹ It appears that potentially severe complications may occur in some patients taking amiodarone undergoing general anaesthesia, including bradycardia unresponsive to atropine, hypotension, conduction disturbances, and decreased cardiac output. Anaesthetists should take particular care in patients taking amiodarone who undergo surgery on cardiopulmonary bypass.¹³ Amiodarone persists in the body for many weeks, which usually means it cannot be withdrawn before surgery, especially if there are risks in delaying surgery,⁶ or the amiodarone is being used for serious arrhythmias.¹³ A possible pharmacokinetic interaction exists between fentanyl and amiodarone, which could contribute to the interactions seen, and further study is needed on this.

Amiodarone + Antihistamines

A case of torsade de pointes occurred in an elderly woman taking amiodarone when she was also given loratadine, an antihistamine generally viewed as unlikely to have clinically relevant effects on the QT-interval. Combined effects on the QT interval would be expected if amiodarone was given with terfenadine or astemizole, and possibly also mizolastine.

Clinical evidence, mechanism, importance and management

A 73-year-old woman taking amiodarone for atrial fibrillation was given **loratadine** and developed syncope and multiple episodes of torsade de pointes arrhythmia.¹

Amiodarone alone is known to cause QT prolongation and torsade de pointes arrhythmia, but **loratadine** is not usually considered to have a clinically relevant effect on the QT interval, see 'Table 15.2', (p.583). Amiodarone may have inhibited the metabolism of loratadine by the cytochrome P450 isoenzyme CYP3A4.

The general clinical relevance of this one case is uncertain, but the authors consider that the QT interval should be monitored if **loratadine** is given with other drugs that may potentially prolong the QT interval. Note that it is recommended that antihistamines with known potential for QT prolongation such as **terfenadine** and **astemizole** (see 'Table 15.2', (p.583)) should not be used with amiodarone, and although there appear to be no cases of clinically relevant QT-prolongation with **mizolastine**, the manufacturers contraindicate concurrent amiodarone.^{2,3}

Amiodarone + Beta blockers

Hypotension, bradycardia, ventricular fibrillation and asystole have been seen in a few patients given amiodarone with propranolol, metoprolol or sotalol (for sotalol, see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257). However, analysis of clinical trials suggests that the combination can be beneficial. Amiodarone may inhibit the metabolism of beta blockers metabolised by CYP2D6, such as metoprolol, which might be a factor in the interaction.

Clinical evidence

(a) Case reports of problems

A 64-year-old woman was treated for hypertrophic cardiomyopathy with amiodarone 1.2 g daily and **atenolol** 50 mg daily. Five days later the **atenolol** was replaced by **metoprolol** 100 mg daily. Within 3 hours she complained of dizziness, weakness and blurred vision. On examination she was found to be pale and sweating with a pulse rate of 20 bpm. Her systolic blood pressure was 60 mmHg. Atropine 2 mg did not produce chronotropic or haemodynamic improvement. She responded to isoprenaline (isoproterenol).¹ Severe hypotension has been reported in another patient taking **sotalol** when intravenous amiodarone (total dose 250 mg) was given.² Another report describes cardiac arrest in one patient on amiodarone, and severe bradycardia and ventricular fibrillation (requiring defibrillation) in another, within 1.5 and 2 hours of starting to take **propranolol**.³

(b) Clinical studies showing benefits

In contrast to the above case reports, an analysis of data from two large clinical studies of the use of amiodarone for post-myocardial infarction arrhythmias found that the combination of **beta blockers** [unnamed] and amiodarone was beneficial (reduced cardiac deaths, arrhythmic deaths and resuscitated cardiac arrest) compared with either drug alone, or neither drug. Discontinuation of amiodarone because of excessive bradycardia was no more frequent when beta blockers were also given, although more patients taking amiodarone discontinued beta blockers than those taking placebo.⁴ Similarly, in the analysis of another study in ischaemic heart failure, the benefits of **carvedilol** were still apparent in those patients already receiving amiodarone, and the combination was not associated with a greater incidence of adverse effects (worsened heart failure, hypotension/dizziness, bradycardia/atrioventricular block) than either drug alone.⁵

(c) Pharmacokinetics

In one study, 10 elderly patients (9 with symptomatic atrial fibrillation and one with an implanted defibrillator and frequent ventricular tachycardia) taking **metoprolol** (mean daily dose 119 mg) were also given amiodarone 1.2 g daily for 6 days. The **metoprolol** AUC and plasma levels were increased by about 80% and 75%, respectively, by the amiodarone, the extent varying by CYP2D6 genotype.⁶ None of the patients included in the study were poor metabolisers.

Mechanism

Not understood. The clinical picture is that of excessive beta-blockade, and additive pharmacodynamic effects are possible. In addition, amiodarone increases the levels of metoprolol via inhibition of the cytochrome P450 isoenzyme CYP2D6, and this may be significant in fast metabolisers.⁶ See 'Genetic factors', (p.4), for more information about fast metabolisers. Other beta blockers that are also substrates of CYP2D6, and which could therefore be similarly affected, include carvedilol and propranolol.

Importance and management

The isolated reports of adverse reactions cited here (they seem to be the only ones so far documented) emphasise the need for caution when amiodarone is used with beta blockers. The manufacturers of amiodarone recommend that the combination should not be used⁷ or used with caution⁸ because potentiation of negative chronotropic properties and conduction-slowing effects may occur. However, the concurrent use of beta blockers and amiodarone is not uncommon and may be therapeutically useful. The authors of one of the analyses suggest that post-myocardial infarction, if possible, beta blockers should be continued in patients for whom amiodarone is indicated.⁴ A pharmacokinetic interaction between amiodarone and beta blockers that are substrates of CYP2D6, such as metoprolol, also appears to be established. Although this interaction with other inhibitors of CYP2D6 is generally not thought to be clinically relevant (e.g. see 'Beta blockers + SSRIs', p.855), it is possible that this pharmacokinetic interaction plays some part in the adverse reactions sometimes seen, or even in the clinical benefits.⁶ See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257, which deals with the possible risks of using amiodarone with sotalol.

Amiodarone + Calcium-channel blockers

Increased cardiac depressant effects would be expected if amiodarone is used with diltiazem or verapamil. One case of sinus arrest and serious hypotension occurred in a woman taking diltiazem when she was given amiodarone.

Clinical evidence, mechanism, importance and management

A woman with compensated congestive heart failure, paroxysmal atrial fibrillation and ventricular arrhythmias was treated with furosemide and **diltiazem** 90 mg every 6 hours. Four days after amiodarone, 600 mg every 12 hours was added, she developed sinus arrest and a life-threatening low cardiac output state (systolic blood pressure 80 mmHg) with oliguria. **Diltiazem** and amiodarone were stopped and she was treated with pressor drugs and ventricular pacing. She had previously had no problems when taking **diltiazem** or **verapamil** alone, and later she took amiodarone 400 mg daily alone without incident. This reaction is thought to be caused by the additive effects of both drugs on myocardial contractility, and on sinus and atrioventricular nodal function.¹ Before this isolated case report was published, another author predicted this interaction with **diltiazem** or **verapamil** on theoretical grounds, and warned of the risks if dysfunction of the sinus node (bradycardia or sick sinus syndrome) is suspected, or if partial AV block exists.² The manufacturers state that amiodarone should not be used,³ or used with caution,⁴ with certain calcium-channel blockers (**diltiazem**, **verapamil**) because potentiation of negative chronotropic

properties and conduction-slowing effects may occur. Note that **diltiazem** has been used for rate control in patients developing postoperative atrial fibrillation despite the use of prophylactic amiodarone.⁵ There do not appear to be any reports of adverse effects attributed to the use of amiodarone with the dihydropyridine class of calcium-channel blockers (e.g. **nifedipine**), which typically have little or no negative inotropic activity at usual doses.

Amiodarone + Cimetidine

Cimetidine possibly causes a modest rise in the serum levels of amiodarone in some patients.

Clinical evidence, mechanism, importance and management

The preliminary report of one study in 12 patients notes that the mean serum levels of amiodarone 200 mg twice daily rose by an average of 38%, from 1.4 to 1.93 micrograms/mL, when cimetidine 1.2 g daily was given for a week. The desethyl-amiodarone levels rose by 54%. However, these increases were not statistically significant, and only 8 of the 12 patients had any rise.¹ It is possible that cimetidine may inhibit the metabolism of amiodarone. Information seems to be limited to this study but this interaction may be clinically important in some patients. Monitor the effects when cimetidine is started, being alert for amiodarone adverse effects. Remember that amiodarone has a very long half-life of 25 to 100 days, so that the results of the one-week study cited here may possibly not adequately reflect the magnitude of this interaction. There does not appear to have been anything further published on this.

Amiodarone + Colestyramine

Colestyramine appears to reduce the serum levels of amiodarone.

Clinical evidence

When 4 doses of colestyramine 4 g were given to 11 patients at 1-hour intervals starting 1.5 hours after a single 400-mg dose of amiodarone, the serum amiodarone levels 7.5 hours later were reduced by about 50%.¹ In a further study, the amiodarone half-life was shorter in 3 patients given colestyramine 4 g daily after discontinuing long-term amiodarone (23.5, 29 and 32 days, respectively) compared with that in 8 patients discontinuing amiodarone and not given colestyramine (35 to 58 days).¹

Mechanism

This interaction probably occurs because colestyramine binds with amiodarone in the gut, thereby reducing its absorption. It may also affect the enterohepatic recirculation of amiodarone.¹ This is consistent with the way colestyramine interacts with other drugs.

Importance and management

Information is very limited but a reduced response to amiodarone may be expected. Separating the dosages to avoid admixture in the gut would reduce or prevent any effects on absorption from the gut, but not the effects due to reduced enterohepatic recirculation. Monitor concurrent use closely and consider an alternative to colestyramine, or raise the amiodarone dosage if necessary.

Amiodarone + Disopyramide

The risk of QT interval prolongation and torsade de pointes is increased if amiodarone is given with disopyramide.

Clinical evidence

A brief report describes 2 patients who developed torsade de pointes when they were given amiodarone with disopyramide. Their QT intervals became markedly prolonged to somewhere between 500 and 600 milliseconds.¹ In another study, 2 patients who had been taking disopyramide 300 mg daily for a number of months developed prolonged QT intervals from 450 to 640 milliseconds and from 390 to 680 milliseconds respectively, and developed torsade de pointes 2 and 5 days respectively, after starting amiodarone 800 mg daily.² However, one early report also described the successful and apparently safe use of amiodarone 100 to 600 mg daily with disopyramide 300 to 500 mg daily,³ although the results on long-term follow-up were not reported in all cases.

Mechanism

Amiodarone is a class III antiarrhythmic and can prolong the QT interval. Disopyramide is a class Ia antiarrhythmic and also prolongs the QT interval. Their additive effects can result in the development of torsade de pointes arrhythmias.

Importance and management

An established and potentially serious interaction. In general, class Ia antiarrhythmics such as disopyramide (see 'Table 9.2', (p.257)) should be avoided or used with great caution with amiodarone because of their additive effects in delaying conduction. The manufacturers of amiodarone contraindicate⁴ or urge caution⁵ if it is used with class Ia antiarrhythmics. If amiodarone is started in a patient taking disopyramide, they suggest the dose of disopyramide should be reduced by 30 to 50% several days after the addition of amiodarone, and that the continued need for disopyramide should be monitored, and withdrawal attempted. If disopyramide is added to amiodarone, the initial dose of disopyramide should be about half of the usual recommended dose.⁵ See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257, and for the interactions of other class Ia antiarrhythmics see 'Procainamide + Amiodarone', p.271, and 'Quinidine + Amiodarone', p.276.

Amiodarone + Grapefruit juice

Grapefruit juice inhibited the metabolism of oral amiodarone, and decreased its effects on the PR and QTc interval.

Clinical evidence, mechanism, importance and management

A single 17-mg/kg oral dose of amiodarone was given to 11 healthy subjects on two occasions, once with water and once with grapefruit juice (300 mL taken three times on the same day). Grapefruit juice completely inhibited the metabolism of amiodarone to its major metabolite *N*-desethylamiodarone (N-DEA) and increased the amiodarone AUC by 50% and the peak serum level by 84%. The effect of amiodarone on the PR and QTc intervals was decreased.¹ It is likely that grapefruit juice inhibits the cytochrome P450 isoenzyme CYP3A4 in the intestinal mucosa, thus inhibiting the formation of N-DEA from oral, but probably not intravenous, amiodarone.

This interaction appears to be established, but its clinical consequences remain to be determined. N-DEA is known to be active, so this could possibly result in decreased activity.¹ In addition, high amiodarone concentrations may increase toxicity.¹ Conversely, a reduction in QT prolongation is potentially beneficial.¹ Further study is needed. However, the US man-

ufacturer recommends that grapefruit juice should not be taken during treatment with oral amiodarone.²

2. Cordarone (Amiodarone hydrochloride). Wyeth Pharmaceuticals. US Prescribing information, May 2007.

Amiodarone + Lithium

Hypothyroidism developed very rapidly in two patients taking amiodarone when lithium was added.

Clinical evidence, mechanism, importance and management

A patient who had taken amiodarone 400 mg daily for more than a year developed acute manic depression. He was started on 600 mg of lithium daily [salt unknown], but within 2 weeks he developed clinical signs of hypothyroidism, which were confirmed by clinical tests. He made a complete recovery within 3 weeks of stopping amiodarone while continuing lithium.¹ Similarly, another patient rapidly developed hypothyroidism, when taking amiodarone with lithium [dose and salt unknown]. It resolved when the amiodarone was stopped.¹ Both lithium and amiodarone on their own can cause hypothyroidism, (note that amiodarone can also cause hyperthyroidism). In these two cases the effects appear to have been additive, and very rapid.

These two cases appear to be the first and only reports of this interaction. Its general importance is therefore still uncertain. Note that lithium has been tried for the treatment of amiodarone-induced hyperthyroidism,² and regular monitoring of thyroid status is recommended throughout amiodarone treatment.^{3,4} It would therefore seem prudent to be extra vigilant for any signs of hypothyroidism (lethargy, weakness, depression, weight gain, hoarseness) in any patient given both drugs.

Lithium therapy has rarely been associated with cardiac QT prolongation, and consequently the UK manufacturer of amiodarone contraindicates combined use.³ However, note that QT-prolongation associated with lithium is usually as a result of lithium toxicity. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Amiodarone + Macrolides

Torsade de pointes occurred in a man taking amiodarone when he was also given intravenous erythromycin. QT prolongation occurred in another patient when azithromycin was added to established amiodarone therapy.

Clinical evidence

A 76-year-old man taking amiodarone 200 mg daily had a prolonged QT interval and a syncopal episode with torsade de pointes 24 hours after starting a course of intravenous **erythromycin lactobionate**. This occurred on rechallenge.¹ Marked QT prolongation and increased QT dispersion occurred when **azithromycin** was started in a patient on long-term amiodarone therapy, and resolved when it was stopped.²

Mechanism

Amiodarone alone can prolong the QT interval and increase the risk of torsade de pointes. Of the macrolides, *intravenous* erythromycin is known to prolong the QT interval, and there is also some evidence that clarithromycin may prolong the QT interval.³ Amiodarone and these macrolides may therefore have additive effects on the QT interval.

Importance and management

In general the concurrent use of two or more drugs that prolong the QT interval should be avoided, because this increases the risk of torsade de

pointes arrhythmias (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257). For this reason, the UK manufacturer of amiodarone contraindicates the concurrent use of *intravenous* erythromycin.⁴ The authors of the above report suggest that the combination of azithromycin and amiodarone should be used with caution,² and this should probably also apply to **clarithromycin** until more is known. The US manufacturer recommends that a careful risk assessment should be done if amiodarone is to be given with a macrolide.⁵

5. Cordarone (Amiodarone hydrochloride). Wyeth Pharmaceuticals. US Prescribing information, May 2007.

Amiodarone + Orlistat

Orlistat modestly reduces the absorption of amiodarone, but this is unlikely to be clinically important.

Clinical evidence, mechanism, importance and management

A randomised placebo-controlled study in 16 healthy subjects found that orlistat 120 mg three times daily reduced the AUC and peak serum level of a single 1.2-g dose of amiodarone by 23% and 27%, respectively. Levels of its active metabolite, desethylamiodarone, were similarly reduced. The half-life and time to maximum serum level were not significantly altered. It was suggested that orlistat, which inhibits dietary fat absorption, may also reduce the absorption of amiodarone, which is a lipophilic drug.¹

Although the clinical effect of this modest reduction in amiodarone levels is not known, it is almost certainly unlikely to be clinically relevant.

Amiodarone + Oxygen

High-dose oxygen may increase the risks of amiodarone-induced postoperative adult respiratory distress syndrome.

Clinical evidence, mechanism, importance and management

A retrospective review of 20 patients who underwent cardiac surgery found that pulmonary complications were more common in those receiving amiodarone (73% versus 25%). Moreover, the incidence of pulmonary complications in patients taking amiodarone was higher in those exposed to 100% oxygen (6 of 7) than those not (2 of 4).¹

Four other patients taking amiodarone (without preoperative amiodarone pulmonary toxicity), developed postoperative toxicity, and 2 patients died). The common intraoperative factor in the 4 patients was exposure to high inspired oxygen concentrations.² A further two reports describe 3 patients taking amiodarone who developed acute onset unilateral adult respiratory syndrome after receiving 100% oxygen ventilation of one lung during surgery. These reports also suggest that high-dose oxygen may be a risk factor in patients receiving amiodarone.^{3,4}

Life-threatening pulmonary complications occurred in 4 patients with diagnosed amiodarone pulmonary toxicity who subsequently underwent cardiothoracic surgery: 2 patients died. These 4 patients were compared with 13 other patients taking amiodarone (only one of whom had preoperative amiodarone pulmonary toxicity) who were undergoing similar surgery and who did not develop pulmonary complications. The comparison indicated that *preoperative* amiodarone pulmonary toxicity appears to be a risk factor in the development of pulmonary complications, but other additional factors could include pump-oxygenator time and oxygen toxicity.⁵

Increased pulmonary toxicity (pulmonary oedema) with the combination of amiodarone and 100% oxygen has been confirmed in *mice*.⁶

The UK manufacturer of amiodarone suggests caution in patients receiving high-dose oxygen therapy.⁷ Others have suggested that the concentration of oxygen should be maintained at the lowest possible level consistent with adequate oxygenation.^{1,3,4,6}

Amiodarone + Protease inhibitors

A case report describes increased amiodarone levels in a patient given indinavir. Other protease inhibitors are predicted to act similarly.

Clinical evidence

A patient taking amiodarone 200 mg daily was also given zidovudine, lamivudine, and **indinavir** for 4 weeks, as post HIV-exposure prophylaxis after a needlestick injury. Amiodarone serum levels increased, from 0.9 mg/L before antiretroviral prophylaxis, to 1.3 mg/L during therapy, and gradually decreased to 0.8 mg/L during the 77 days after stopping prophylaxis. Although the reference range for amiodarone levels is not established, these levels were not outside those usually considered to achieve good antiarrhythmic control.¹

Mechanism

Protease inhibitors such as indinavir are inhibitors of cytochrome P450 enzymes and pharmacokinetic interactions are therefore possible. It was considered that the increase in serum amiodarone in this case was due to decreased metabolism of amiodarone, although no decrease in the serum levels of desethylamiodarone were observed.¹

Importance and management

Although in the case cited the interaction was not clinically relevant, the authors considered that it could be in patients with higher initial amiodarone levels. They recommend monitoring amiodarone therapy if indinavir is also given.¹ In general the UK manufacturers of protease inhibitors suggest that they may increase amiodarone levels, and contraindicate concurrent use. The exception is **atazanavir**,² where caution is recommended. Similarly the US manufacturers of the protease inhibitors generally contraindicate concurrent use. The exceptions are **amprenavir**,³ **atazanavir**,⁴ **fosamprenavir**⁵ and **lopinavir**,⁶ where the manufacturers recommend increased monitoring, including taking amiodarone levels, where possible.

Amiodarone + Quinolones

Torsade de pointes has been reported in two patients taking amiodarone and levofloxacin. Post-marketing surveillance identified two cases with amiodarone and sparfloxacin. An increased risk of this arrhythmia would also be expected if amiodarone is used with gatifloxacin or moxifloxacin.

Clinical evidence, mechanism, importance and management

Torsade de pointes arrhythmia occurred in a patient taking **levofloxacin** and amiodarone.¹ The same authors subsequently encountered a second case of this reaction.² The FDA Adverse Events Reporting System database up to May 2001 was reviewed for cases of torsade de pointes associated with quinolones. Four cases [possibly including the two mentioned above] were noted in patients taking amiodarone and a quinolone (unspecified, but **ciprofloxacin**, **gatifloxacin**, **levofloxacin**, **moxifloxacin**, and **ofloxacin** were assessed). In total, 37 cases of torsade de pointes were identified, and 19 occurred in patients also taking other drugs known to prolong the QT interval.³

During post-marketing surveillance of **sparfloxacin** in France over a period of 8 months (about 750 000 patients) serious adverse cardiovascular effects were reported in 7 patients. All 7 patients had underlying risk factors including 3 patients who were also receiving amiodarone. Of these, 2 patients had documented QT prolongation and ventricular tachycardia.⁴

Amiodarone can prolong the QT interval and increase the risk of torsade de pointes. Of the quinolones used clinically, **gatifloxacin**, **moxifloxacin**, and **sparfloxacin** are known to prolong the QT interval (see 'Table 9.2', (p.257)). There is also evidence that **levofloxacin** may prolong the QT interval.^{2,3}

In general the concurrent use of two or more drugs that prolong the QT interval should be avoided, because this increases the risk of torsade de pointes arrhythmias (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257). The above quinolones should probably be avoided in patients on amiodarone. **Ciprofloxacin** appears to have less effect on the QT interval.³

Amiodarone + Rifampicin (Rifampin)

An isolated case report suggests that rifampicin may decrease the serum levels of amiodarone and its metabolite *N*-desethylamiodarone.

Clinical evidence, mechanism, importance and management

A woman with congenital heart disease and atrial and ventricular arrhythmias managed by an implanted cardioverter defibrillator, epicardial pacing and amiodarone 400 mg daily, experienced deterioration in the control of her condition. She developed palpitations and experienced a shock from the defibrillator. Her amiodarone serum levels were 40% lower than 2 months previously, and her *N*-desethylamiodarone levels were undetectable. It was noted that 5 weeks earlier rifampicin 600 mg daily had been started to treat an infection of the pacing system. The amiodarone dose was doubled, but the palpitations continued. Amiodarone and *N*-desethylamiodarone levels increased after rifampicin was discontinued.¹ Rifampicin is a potent enzyme inducer and it may have increased the metabolism and clearance of amiodarone. This case suggests that combined use of amiodarone and rifampicin should be well monitored.

1. Zaremski DG, Fischer SA, Santucci PA, Porter MT, Costanzo MR, Trohman RG. Impact of rifampin on serum amiodarone concentrations in a patient with congenital heart disease. *Pharmacotherapy* (1999) 19, 249–51.

Amiodarone + Sertraline

In an isolated report, a slight to moderate rise in plasma amiodarone levels was attributed to the concurrent use of sertraline.

Clinical evidence, mechanism, importance and management

A depressed patient taking amiodarone 200 mg twice daily had his treatment with carbamazepine 200 mg twice daily and sertraline 100 mg daily stopped, just before ECT treatment. After 4 days it was noted that his plasma amiodarone levels had fallen by nearly 20%. The authors of the report

drew the conclusion that while taking all three drugs, the amiodarone levels had become slightly raised due to the enzyme inhibitory effects of the sertraline, despite the potential enzyme-inducing activity of the carbamazepine.¹ The patient had no changes in his cardiac status while amiodarone levels were reduced, suggesting that this interaction (if such it is) is of limited clinical importance.¹

1. DeVane CL, Gill HS, Markowitz JS, Carson WH. Awareness of potential drug interactions may aid avoidance. *Ther Drug Monit* (1997) 19, 366–7.

Amiodarone + Trazodone

An isolated report describes the development of torsade de pointes when a woman taking amiodarone was also given trazodone.

Clinical evidence, mechanism, importance and management

A 74-year-old woman with a pacemaker, taking nifedipine, furosemide, aspirin and amiodarone 200 mg daily, began to have dizzy spells but no loss of consciousness soon after starting trazodone (initially 50 mg and eventually 150 mg daily by the end of 2 weeks). Both the amiodarone and trazodone were stopped when she was hospitalised. She had prolonged QT, QTc and JTc intervals on the ECG and recurrent episodes of torsade de pointes arrhythmia, which were controlled by increasing the ventricular pacing rate. The QTc and other ECG intervals shortened and she was later discharged on amiodarone without the trazodone, with an ECG similar to that seen 4 months before hospitalisation.¹ No general conclusions can be drawn from this apparent interaction, but prescribers should be aware of this case. The manufacturer notes that trazodone does have the potential to be arrhythmogenic.² See also, 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

2. Molipaxin (Trazodone hydrochloride). Sanofi-Aventis. UK Summary of product characteristics, July 2005.

Aprindine + Amiodarone

Serum aprindine levels can be increased by amiodarone. Toxicity may occur unless the dosage is reduced.

Clinical evidence, mechanism, importance and management

The serum aprindine levels of two patients rose, accompanied by signs of toxicity (nausea, ataxia, etc.), when they were also given amiodarone. One of them, taking aprindine 100 mg daily, had a progressive rise in trough serum levels from 2.3 to 3.5 mg/L over a 5-week period, when given 1.2 g and later 600 mg of amiodarone daily. Even when the aprindine dosage was reduced, serum levels remained higher than before amiodarone was started.¹ The authors say that those given both drugs generally need less aprindine than those on aprindine alone. This interaction has been briefly reported elsewhere.² Its mechanism is not understood. Monitor the effects of concurrent use and reduce the dosage of aprindine as necessary.

2. Zhang Z, Wang G, Wang H, Zhang J. Effect of amiodarone on the plasma concentration of aprindine [Abstract 115: 197745u in Chemical Abstracts (1991) 115, 22]. *Zhongguo Yao Xue Za Zhi* (1991) 26, 156–9.

Azimilide + Miscellaneous

There was no important pharmacokinetic interaction between azimilide and digoxin, and digoxin did not appreciably alter azimilide-induced QTc prolongation. Ketoconazole did not alter the pharmacokinetics of azimilide to a clinically relevant extent, and therefore other CYP3A4 inhibitors are also unlikely to affect azimilide pharmacokinetics. Azimilide did not alter the pharmacokinetics of omeprazole to a clinically relevant extent, and is therefore unlikely to interact with other substrates of CYP2C19.

***In vitro* studies suggest pharmacokinetic interactions between azimilide and drugs metabolised by CYP1A2, CYP2C9 and CYP2D6 are also unlikely. Azimilide was found to maintain its class III antiarrhythmic effect in the presence of isoprenaline.**

Clinical evidence, mechanism, importance and management

(a) Digoxin

A study in 18 healthy subjects found that, except for an increase in renal clearance of 36%, azimilide pharmacokinetics were not affected by digoxin. The pharmacokinetics of digoxin were unaffected by azimilide except for a 21% increase in maximum serum levels and a 10% increase in the AUC. In this study, azimilide dihydrochloride 175 mg was given orally once daily for 4 days then 100 mg on day 5 and digoxin was given as a loading dose of 750 micrograms on day one then as 250 micrograms daily for 4 days. Drugs were given alone, and then combined. Azimilide alone increased the QTc, whereas digoxin did not. The combination showed that digoxin caused about a 2 to 4% decrease in QTc when compared with azimilide alone. Neither the pharmacokinetic changes nor the effect of digoxin on the azimilide-induced QTc prolongation are likely to be clinically important.¹

(b) Isoprenaline (Isoproterenol)

In a study, patients with cardiovascular disorders were given isoprenaline infusion titrated from 0.5 micrograms/minute up to a maximum of 4 micrograms/minute until the heart rate reached 125% of baseline (up to a maximum 120 bpm). Patients were then given azimilide infusion as a loading dose of 4.5 mg/kg over 15 minutes followed by a continuous infusion of 0.625 mg/kg per hour plus either a second dose of isoprenaline at the same final dose as the first then a saline infusion or *vice versa*. In the presence of isoprenaline, azimilide prolonged the action potential duration at 90% repolarisation by a mean of 8.7 milliseconds (isoprenaline alone shortened action potential duration by 2.6 milliseconds). Isoprenaline alone shortened the right ventricular effective period by 13.6 seconds, but in the presence of azimilide this period was essentially unaffected. Azimilide maintained its class III antiarrhythmic effect in the presence of isoprenaline and at increased heart rate.²

(c) Ketoconazole and other CYP3A4 inhibitors

In a randomised placebo-controlled study in 21 healthy subjects, ketoconazole 200 mg daily slightly increased the AUC and maximum blood levels of a single 125-mg dose of azimilide dihydrochloride given on day 8 by 16% and 12%, respectively. Azimilide half-life was prolonged by 13% and clearance was decreased by 14%. Azimilide is partly metabolised by the cytochrome P450 isoenzyme CYP3A4, which is inhibited by ketoconazole. The minor changes in azimilide pharmacokinetics with ketoconazole are not considered to be clinically important, and clinically significant pharmacokinetic interactions with other inhibitors of CYP3A4 are not expected.³

(d) Omeprazole

A randomised placebo-controlled study in 40 healthy subjects (extensive metabolisers of the cytochrome P450 isoenzyme CYP2C19) given azimilide dihydrochloride 125 mg every 12 hours for 3 days, then daily for 5 days found that the AUC of a single 20-mg dose of omeprazole given on day 8 was reduced by 12%. There were no significant changes in the pharmacokinetics of 5-hydroxyomeprazole. There was no change in the metabolite-to-parent AUC suggesting that azimilide had no effect on the CYP2C19-mediated metabolism of omeprazole.⁴ The change in omeprazole AUC described would not be clinically significant.

The authors note that *in vitro* studies suggested that of the cytochrome P450 isoenzymes, azimilide had the lowest inhibitory concentration against CYP2C19. On this basis they suggest that azimilide is also unlikely to interact with drugs metabolised by CYP1A2, CYP2C9, CYP2D6 and CYP3A4.⁴

Bretylium + Sympathomimetics

The pressor effects of adrenaline (epinephrine) and noradrenaline (norepinephrine) are increased in the presence of bretylium. Amphetamine and protriptyline antagonise the blood pressure lowering effect of bretylium.

Clinical evidence

(a) Adrenaline (epinephrine) or Noradrenaline (norepinephrine)

A dose of bretylium sufficient to produce postural hypotension enhanced the pressor effect of noradrenaline in 4 healthy subjects. A similar effect was found with adrenaline.¹

(b) Amphetamine

When 7 patients with hypertension, taking bretylium 600 mg to 4 g daily were given a single 25-mg dose of amphetamine, 6 patients had a rise in blood pressure.²

(c) Protriptyline

An experimental study found that protriptyline can return the blood pressure to normal in patients taking bretylium, without reducing its antiarrhythmic efficacy.³

Mechanism

Animal studies have shown that bretylium reduces blood pressure via its blocking effects on adrenergic neurones similar to guanethidine.^{4,5} Bretylium therefore enhances the effects of directly-acting sympathomimetics such as noradrenaline, and is antagonised by drugs with indirect sympathomimetic activity such as the amphetamines and tricyclic antidepressants.

Importance and management

Although documentation is limited, based on the known pharmacology of bretylium, these interactions would appear to be established. The use of bretylium is now limited to the short-term control of ventricular arrhythmias. In this situation, if directly-acting sympathomimetics such as noradrenaline are required to reverse bretylium-induced hypotension, this should be undertaken with caution since their effects may be enhanced.

Bretylium is no longer used for the treatment of hypertension, therefore the interactions with amphetamines and tricyclics described above are unlikely to be of much clinical relevance.

Cibenzoline (Cifenline) + H₂-receptor antagonists

Cimetidine increases the plasma levels of cibenzoline, but ranitidine does not interact.

Clinical evidence, mechanism, importance and management

Cimetidine 1.2 g daily raised the maximum plasma levels of a single 160-mg dose of cibenzoline in 12 healthy subjects by 27%, increased the AUC by 44%, and prolonged its half-life by 30%. **Ranitidine** 300 mg daily had no effect.¹ The probable reason is that **cimetidine**, an enzyme inhibitor, reduces the metabolism of the cibenzoline by the liver, whereas **ranitidine**, which has little enzyme inhibiting effect, does not. The clinical importance of this interaction is not known but be alert for increased cibenzoline effects.

- Massarella JW, Defeo TM, Liguori J, Passe S, Aogaichi K. The effects of cimetidine and ranitidine on the pharmacokinetics of cifenline. *Br J Clin Pharmacol* (1991) 31, 481–3.

Disopyramide + Antacids

There is some inconclusive evidence that aluminium phosphate may possibly cause a small reduction in the absorption of disopyramide.

Clinical evidence, mechanism, importance and management

A single 11-g dose of an **aluminium phosphate** antacid had no statistically significant effect on the pharmacokinetics of a single 200-mg oral dose of disopyramide in 10 patients. However the antacid appeared to reduce the absorption of disopyramide to some extent in individual subjects.¹ The clinical importance of this interaction is uncertain, but probably small.

1. Albin H, Vincon G, Bertolaso D, Dangoumau J. Influence du phosphate d'aluminium sur la biodisponibilité de la procaïnamide et du disopyramide. *Thérapie* (1981) 36, 541–6.

Disopyramide + Beta blockers

Severe bradycardia has been described after the use of disopyramide with beta blockers including practolol (3 cases, 1 fatal) pindolol (1 case, fatal) and metoprolol (1 case). Another patient given disopyramide and intravenous sotalol developed asystole (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257). Atenolol modestly decreased disopyramide clearance in one study. Oral propranolol and disopyramide have been combined without any increase in negative inotropic effects or pharmacokinetic changes in healthy subjects.

Clinical evidence

Two patients with supraventricular tachycardia (180 bpm) were treated, firstly with intravenous **practolol** (20 and 10 mg respectively) and shortly afterwards with disopyramide (150 and 80 mg respectively). The first patient rapidly developed sinus bradycardia of 25 bpm, lost consciousness and became profoundly hypotensive. He did not respond to 600 micrograms of atropine, but later his heart rate increased to 60 bpm while a temporary pacemaker was being inserted.¹ He was successfully treated with disopyramide 150 mg alone for a later episode of tachycardia. The second patient also developed severe bradycardia and asystole, despite the use of atropine. He was resuscitated with adrenaline (epinephrine) but later died.¹

Severe bradycardia has been reported in another patient, similarly treated with intravenous **practolol** and then disopyramide.² Another patient developed severe bradycardia and died when treated for supraventricular tachycardia with **pindolol** 5 mg and disopyramide 250 mg (both orally).³ Another patient taking oral disopyramide 250 mg twice daily developed asystole when given a total of 60 mg of intravenous **sotalol**.⁴

A patient with hypertrophic obstructive cardiomyopathy and paroxysmal atrial fibrillation taking disopyramide 450 mg daily developed hypotension, bradycardia and cardiac conduction disturbances 5 days after starting **metoprolol** 50 mg daily.⁵

Atenolol 100 mg daily has been shown to increase the serum disopyramide steady-state levels from 3.46 to 4.25 micrograms/mL and reduce the clearance of disopyramide by 16% in healthy subjects and patients with ischaemic heart disease.⁶ None of the subjects developed any adverse reactions or symptoms of heart failure, apart from one of the subjects who had transient first degree heart block.⁶

In contrast, studies in healthy subjects have shown that the negative inotropic effect was no greater when oral **propranolol** and disopyramide were used concurrently,⁷ nor were the pharmacokinetics of either drug affected.⁸

Mechanism

Not understood. Both disopyramide and the beta blockers can depress the contractility and conductivity of the heart muscle.

Importance and management

The general clinical importance of this interaction is uncertain. A clear risk seemed to exist in patients who were treated with disopyramide and practolol. Considerable caution should be exercised in patients treated

with disopyramide and intravenous sotalol. More study is needed to find out what contributes to the development of this potentially serious interaction. The US manufacturers of disopyramide suggest that the combination of disopyramide and beta blockers should generally be avoided, except in the case of life-threatening arrhythmias unresponsive to a single drug.⁹

The UK manufacturer of sotalol also warns that both sotalol and disopyramide can prolong the QT interval, which may increase the risk of torsade de pointes arrhythmia if both are used together.¹⁰ The US manufacturer recommends that this combination should be avoided.¹¹ See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Disopyramide + H₂-receptor antagonists

A single-dose study has shown that cimetidine can slightly increase the serum levels of oral disopyramide. Cimetidine did not affect the pharmacokinetics of intravenous disopyramide. Ranitidine appears not to interact with disopyramide.

Clinical evidence, mechanism, importance and management

Oral cimetidine 400 mg twice daily for 14 days did not alter the pharmacokinetics of a single 150-mg intravenous dose of disopyramide in 7 healthy subjects.¹ Another study in 6 healthy subjects found that a single 400-mg dose of **cimetidine** increased the AUC of a single 300-mg oral dose of disopyramide by 8.5% and increased the maximum serum levels by 18.5%, but did not significantly affect the metabolism of disopyramide. **Ranitidine** 150 mg was found not to interact significantly.² The reasons are not known, but the authors of the report suggest that **cimetidine** may have increased disopyramide absorption.² **Cimetidine** is only a weak inhibitor of disopyramide metabolism *in vitro*.³ The changes described are unlikely to be clinically important, but this should probably be confirmed in a more clinically realistic situation, using multiple oral doses of both drugs.

Disopyramide + Macrolides

The serum disopyramide levels of two patients rose when they were given erythromycin, and QT prolongation and cardiac arrhythmias developed. Another patient given both drugs developed heart block. One patient developed ventricular fibrillation and two patients developed torsade de pointes when given clarithromycin with disopyramide. Two other patients developed severe hypoglycaemia. Ventricular fibrillation occurred in a patient given azithromycin with disopyramide. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Clinical evidence

(a) Azithromycin

A patient taking disopyramide 150 mg three times daily developed ventricular tachycardia requiring cardioversion 11 days after starting azithromycin 250 mg daily.¹ Her disopyramide level was found to have risen from 2.6 to 11.1 micrograms/mL.

(b) Clarithromycin

A 74-year-old woman who had been taking disopyramide 200 mg twice daily for 7 years collapsed with ventricular fibrillation 6 days after starting to take omeprazole 40 mg, metronidazole 800 mg and clarithromycin 500 mg daily. After successful resuscitation, her QTc interval, which had never previously been above 440 milliseconds, was found to have risen to 625 milliseconds. Her disopyramide plasma level was also elevated (4.6 micrograms/mL) and the half-life was markedly prolonged (40 hours). The QTc interval normalised as her plasma disopyramide levels fell.² A 76-year old woman taking disopyramide developed torsades de pointes when given clarithromycin 200 mg twice daily. Hypokalaemia (potassium 2.8 mmol/L) probably contributed to this case.³

An episode of torsade de pointes occurred in another elderly woman taking disopyramide 5 days after starting clarithromycin 250 mg twice daily.⁴

A haemodialysis patient, receiving disopyramide 50 mg daily because of paroxysmal atrial fibrillation, was hospitalised with hypoglycaemic coma after also taking clarithromycin 600 mg daily. Serum disopyramide levels increased from 1.5 to 8 micrograms/mL during treatment with clarithromycin. QT and QTc intervals were prolonged, but torsade de pointes did not occur.⁵ Hypoglycaemic coma has also been reported in another patient taking disopyramide with clarithromycin.⁶

(c) Erythromycin

A woman with ventricular ectopy taking disopyramide (300 mg alternating with 150 mg every 6 hours) developed new arrhythmias (ventricular asystoles and later torsade de pointes) within 36 hours of starting erythromycin lactobionate 1 g intravenously every 6 hours, and cefamandole. Her QTc interval had increased from 390 to 600 milliseconds and her serum disopyramide level was found to be 16 micromol/L. The problem resolved when the disopyramide was stopped and bretylium given, but it returned when the disopyramide was restarted. It resolved again when the erythromycin was stopped.⁷ Another patient with ventricular tachycardia, well controlled over 5 years with disopyramide 200 mg four times daily, developed polymorphic ventricular tachycardia within a few days of starting erythromycin 500 mg four times daily. His QTc interval had increased from 430 to 630 milliseconds and serum disopyramide levels were found to be elevated at 30 micromol/L. The problem resolved when both drugs were withdrawn and antiarrhythmics given.⁷ Heart block is said to have developed in another patient treated with both drugs.⁸

Mechanism

Not fully established. An *in vitro* study using human liver microsomes indicated that erythromycin inhibits the metabolism (mono-*N*-dealkylation) of disopyramide which, *in vivo*, would be expected to reduce its loss from the body and increase its serum levels.⁹ Clarithromycin and azithromycin probably do the same. The increased serum levels of disopyramide can result in adverse effects such as QT prolongation and torsade de pointes, and may result in enhanced insulin secretion and hypoglycaemia.^{5,6} Both intravenous erythromycin¹⁰ and clarithromycin¹¹ alone have been associated with prolongation of the QT interval and torsade de pointes. Therefore, disopyramide and macrolides may have additive effects on the QT interval in addition to the pharmacokinetic interaction.

Importance and management

An established interaction, although it is probably rare. Even so the effects of concurrent use should be well monitored if azithromycin, clarithromycin or erythromycin is added to disopyramide, being alert for the development of raised plasma disopyramide levels and prolongation of the QT interval. The manufacturer of disopyramide recommends¹² avoiding the combination of disopyramide and macrolides that inhibit the cytochrome P450 isoenzyme CYP3A, and this would certainly be prudent in situations where close monitoring is not possible. Although direct clinical information is lacking, *in vitro* studies with human liver microsomes⁹ indicate that **josamycin** is likely to interact similarly, and **telithromycin** (an erythromycin derivative) might also be expected to interact in the same way. See

also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Disopyramide + Phenobarbital

Serum disopyramide levels are reduced by phenobarbital.

Clinical evidence

After taking phenobarbital 100 mg daily for 21 days, the half-life and AUC of a single 200-mg dose of disopyramide were reduced by about 35%. The apparent metabolic clearance more than doubled, and the fraction recovered in the urine as metabolite increased. Sixteen healthy subjects took part in the study and no significant differences were seen between those who smoked and those who did not.¹

Mechanism

It seems probable that phenobarbital (a known enzyme inducer) increases the metabolism of disopyramide by the liver, and thereby increases its loss from the body.

Importance and management

This interaction appears to be established, but its clinical importance is uncertain. The extent to which it would reduce the control of arrhythmias by disopyramide is unknown, but monitor the effects and the serum levels of disopyramide if phenobarbital is added or withdrawn. The manufacturer of disopyramide² recommends avoiding using it in combination with inducers of the cytochrome P450 isoenzyme CYP3A, such as phenobarbital. Other barbiturates would be expected to interact similarly.

2. Rythmodan Capsules (Disopyramide). Sanofi-Aventis. UK Summary of product characteristics, November 2005.

Disopyramide + Phenytoin

Serum disopyramide levels are reduced by phenytoin and may fall below therapeutic levels. Loss of arrhythmic control may occur.

Clinical evidence

Eight patients with ventricular tachycardia treated with disopyramide 600 mg to 2 g daily had a 54% fall in their serum disopyramide levels (from a mean of 3.99 to 1.82 micrograms/mL) when they were also given phenytoin 200 to 600 mg daily for a week. Two of the patients who responded to disopyramide and underwent Holter monitoring showed a 53- and 2000-fold increase in ventricular premature beat frequency as a result of this interaction.¹

In other reports, 3 patients who had low levels of disopyramide and high levels of its metabolite were noted to be taking phenytoin,² and one patient

receiving both drugs required an unusually high dose of disopyramide.³ A marked fall in serum disopyramide levels (75% in one case) was seen in 2 patients who took phenytoin 300 to 400 mg daily for up to 2 weeks.⁴ Pharmacokinetic studies^{3,5} in a total of 12 healthy subjects confirm this interaction. In addition, one healthy epileptic taking phenytoin had a disopyramide AUC and elimination half-life that were 50% lower than those in control subjects.⁵

Mechanism

Phenytoin, which is a known enzyme-inducer, increases the metabolism of the disopyramide by the liver. Although, the major metabolite (*N*-dealkyldisopyramide) also possesses antiarrhythmic activity the net effect is a reduction in arrhythmic control.¹

Importance and management

An established interaction of clinical importance. Some loss of arrhythmic control can occur during concurrent use. Disopyramide adverse effects (because of the potential for high metabolite levels) and the antiarrhythmic response should be well monitored. An increase in the dosage of disopyramide may be necessary. The interaction appears to resolve fully within 2 weeks of withdrawing the phenytoin. Note that the manufacturer of disopyramide⁶ recommends avoiding using it in combination with inducers of the cytochrome P450 isoenzyme CYP3A, such as phenytoin.

Disopyramide + Quinidine

Disopyramide serum levels may be slightly raised by quinidine. Both drugs prolong the QT interval, and this effect may be additive on combined use.

Clinical evidence, mechanism, importance and management

After taking quinidine 200 mg four times daily, the peak serum levels of disopyramide, given as a single 150-mg dose to 16 healthy subjects, were raised by 20% from 2.68 to 3.23 micrograms/mL, and by 14% when given long-term, as 150 mg four times a day. Serum quinidine levels were decreased by 26%. However, there was no change in the half-life of either drug. Both quinidine and disopyramide caused a slight lengthening of the QTc interval, and when quinidine was added to disopyramide therapy additional lengthening of the QT interval occurred. The frequency of adverse effects such as dry mouth, blurred vision, urinary retention and nausea were also somewhat increased.¹ The mechanism of the effect on serum levels is not understood. The antimuscarinic adverse effects of disopyramide may be increased. Disopyramide and quinidine are both class Ia antiarrhythmics that prolong the QT interval, and, in general, such combinations should be avoided (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257).

1. Baker BJ, Gammill J, Massengill J, Schubert E, Karin A, Doherty JE. Concurrent use of quinidine and disopyramide: evaluation of serum concentrations and electrocardiographic effects. *Am Heart J* (1983) 105, 12–15.

Disopyramide + Rifampicin (Rifampin)

The plasma levels of disopyramide can be reduced by rifampicin.

Clinical evidence

After taking rifampicin for 14 days the plasma levels of disopyramide were approximately halved in 11 patients with tuberculosis who had taken a single 200- or 300-mg dose of disopyramide.¹ The disopyramide AUC was reduced by about two-thirds and the half-life was reduced from 5.9 to

3.25 hours by rifampicin. A woman who had been receiving rifampicin for 2 weeks started taking disopyramide 100 mg every 8 hours but only achieved subtherapeutic levels of 0.9 micromol/L. The dosage of disopyramide was increased to 300 mg every 8 hours, and the rifampicin was discontinued. Three days after discontinuing rifampicin the disopyramide level was 3.6 micromol/L and after 5 days it was 8.1 micromol/L. The patient was eventually maintained on disopyramide 250 mg every 8 hours.²

Mechanism

The most probable explanation is that rifampicin (a well-known enzyme inducer) increases the metabolism of the disopyramide by the liver so that it is cleared from the body much more quickly.

Importance and management

Information seems to be limited to these studies, but they indicate that the dosage of disopyramide will need to be increased in most patients taking rifampicin.

Disopyramide + Verapamil

Profound hypotension and collapse has occurred in a small number of patients taking verapamil who were also given disopyramide.

Clinical evidence, mechanism, importance and management

A group of clinicians who had used single 400-mg oral doses of disopyramide successfully and with few adverse effects for reverting acute supraventricular arrhythmias, reported 5 cases of profound hypotension and collapse. Three of the patients developed severe epigastric pain. All 5 had previous myocardial disease and/or were taking myocardial depressants, either beta blockers or verapamil in small quantities [not specified].¹

On the basis of this report, and on reports of studies in *animals*,² and from the known risks associated with the concurrent use of beta blockers (see 'Disopyramide + Beta blockers', p.252), the UK manufacturer warns about combining disopyramide and other drugs [such as verapamil] that may have additive negative inotropic effects.³ However, they do point out that in some specific circumstances combinations of antiarrhythmic drugs (they specifically name digoxin, beta blockers and verapamil for the control of atrial fibrillation) may be beneficial.³ They note that severe hypotension caused by disopyramide has usually been associated with cardiomyopathy or uncompensated congestive heart failure.³ However, the US manufacturer advises that until more data is available, disopyramide should not be given within 48 hours before or 24 hours after verapamil.⁴

Dofetilide + Antacids

Antacids (aluminium/magnesium hydroxide) appear not to interact with dofetilide.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that pretreatment with **aluminium/magnesium hydroxide** (*Maalox*) 30 mL (10, 2 and 0.5 hours before dofetilide) did not affect the pharmacokinetics of a single 500-microgram dose of dofetilide, nor the dofetilide-induced change in QTc interval.¹ No special precautions appear to be necessary.

1. Vincent J, Gardner MJ, Baris B, Willavize SA. Concurrent administration of omeprazole and antacid does not alter the pharmacokinetics and pharmacodynamic of dofetilide in healthy subjects. *Clin Pharmacol Ther* (1996) 59, 182.

Dofetilide + Diuretics

Hydrochlorothiazide and hydrochlorothiazide/triamterene modestly increased dofetilide plasma levels, and caused a marked increase in the QT interval.

Clinical evidence

The manufacturer notes that the concurrent use of dofetilide 500 micrograms twice daily with **hydrochlorothiazide** 50 mg daily for 7 days increased the dofetilide AUC by 14% and increased the QTc interval by 47.6 milliseconds.¹ Similar results were seen with the same dose of dofetilide combined with **hydrochlorothiazide/triamterene** 50/100 mg daily (18% increase in AUC, and 38.1 millisecond increase in QTc).¹

Mechanism

Triamterene might be expected to increase dofetilide plasma levels by competing for its renal tubular secretion (see 'Dofetilide + Miscellaneous', p.255), but the effect of its combination with hydrochlorothiazide was no greater than with hydrochlorothiazide alone. Why hydrochlorothiazide should increase dofetilide levels is unclear. An increase in dofetilide levels would be expected to increase the QT interval, but the increase seen here was much greater than expected by the change in plasma levels. The manufacturer suggests that a reduction in serum potassium could have contributed to the extent of QT prolongation.¹ This makes sense for hydrochlorothiazide (a potassium-depleting diuretic), but the combination with triamterene (a potassium-sparing diuretic) might therefore have been expected to have less effect on the QT interval.

Importance and management

On the basis of the above findings, the manufacturer contraindicates the use of dofetilide with **hydrochlorothiazide** alone or in combination with **triamterene**.² Given the increase in QT interval, a risk factor for torsade de pointes arrhythmia, this appears a prudent precaution. Further study is needed. Any diuretic that depletes serum potassium (such as the **loop diuretics**) might be expected to increase the risk of QT prolongation and torsade de pointes with dofetilide, and serum potassium should be monitored.²

Dofetilide + H₂-receptor antagonists

Cimetidine markedly increases plasma dofetilide levels, and hence increases dofetilide-induced QT prolongation and the risk of torsade de pointes arrhythmias. Its combined use with dofetilide should be avoided. Dofetilide appears not to interact with ranitidine.

Clinical evidence

A placebo-controlled study in 24 healthy subjects indicated that **cimetidine** 400 mg twice daily given with dofetilide 500 micrograms twice daily for 7 days significantly decreased the renal clearance of dofetilide by 44%, increased its AUC by 58%, and increased its peak blood levels by 50%, without significantly altering the QTc interval.¹ In a further study it was found that **cimetidine** 100 mg twice daily (non-prescription dose) or 400 mg twice daily (a common prescription dose) for 4 days reduced the renal clearance of a single 500-microgram dose of dofetilide by 13 and 33%, respectively. In addition, the respective **cimetidine** doses increased the QTc interval by 22 and 33%. Conversely, **ranitidine** 150 mg twice daily did not significantly affect the pharmacokinetics or pharmacodynamics of dofetilide.²

Mechanism

At least 50% of a dofetilide dose is eliminated unchanged in the urine by an active renal tubular secretion mechanism.^{3,4} Drugs that inhibit this mechanism, such as cimetidine, increase dofetilide plasma levels.^{2,3} There

is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which increases the risk of torsade de pointes arrhythmias.³

Importance and management

An established interaction. Because of the likely increased risk of torsade de pointes, the manufacturer contraindicates the use of cimetidine in patients on dofetilide. This would seem to be a prudent precaution. This applies equally to cimetidine at over-the-counter doses, and patients on dofetilide should be warned to avoid this. No special precautions appear to be necessary with ranitidine. Note that 'omeprazole', (p.256) and 'antacids', (p.254) also appear not to interact with dofetilide.

Dofetilide + Ketoconazole

Ketoconazole markedly increases the plasma levels of dofetilide. This is likely to be associated with an increased risk of dofetilide-induced QT prolongation and torsade de pointes arrhythmias.

Clinical evidence

The manufacturer of dofetilide notes that ketoconazole 400 mg daily, given with dofetilide 500 micrograms twice daily for 7 days, increased the dofetilide peak levels by 53% in men and 97% in women, and the AUC by 41% in men and 69% in women.¹ Ketoconazole decreased the renal clearance of dofetilide by 31.3% and the non-renal clearance by 40.3%, resulting in a reduction in total clearance of 34.7%.²

Mechanism

Ketoconazole may inhibit the active renal tubular secretion mechanism by which dofetilide is eliminated, so reducing its loss from the body (see also 'Dofetilide + H₂-receptor antagonists', above).^{1,2} Ketoconazole also inhibits the metabolism of dofetilide² by the cytochrome P450 isoenzyme CYP3A4. Both of these mechanisms contribute to the increase in dofetilide plasma levels. There is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which increases the risk for torsade de pointes.¹

Importance and management

An established interaction. Because of the likely increased risk of torsade de pointes, the manufacturer contraindicates the use of ketoconazole in patients on dofetilide. This would seem to be a prudent precaution.

Dofetilide + Miscellaneous

The manufacturer of dofetilide cautions about the use of various drugs that may have the potential to increase dofetilide plasma levels, so increasing the risk of QT prolongation and arrhythmias. Use with other drugs that prolong the QT interval should be avoided.

Clinical evidence, mechanism, importance and management

(a) Inhibitors/substrates for renal secretion

At least 50% of a dofetilide dose is eliminated unchanged in the urine by an active renal tubular secretion mechanism.^{1,2} Some drugs that inhibit this mechanism have been shown to increase dofetilide plasma levels (e.g. see 'Dofetilide + H₂-receptor antagonists', above). The manufacturer contraindicates their concurrent use since there is a linear relationship between plasma dofetilide concentrations and prolongation of the QT

interval, which is a risk factor for torsade de pointes arrhythmias.¹ The manufacturer also contraindicates the use of other drugs that inhibit the renal mechanism by which dofetilide is eliminated, such as **prochlorperazine** and **megestrol**,¹ although these have not been directly studied. Furthermore, the manufacturer suggests¹ that there is a potential for dofetilide plasma levels to be increased by other drugs undergoing active renal secretion (e.g. **amiloride**, **metformin** and **triamterene**), but this needs confirmation in direct studies (see also 'Dofetilide + Diuretics', p.255). Until then, these drugs should be used cautiously with dofetilide.

(b) *Inhibitors of hepatic metabolism*

Dofetilide is partially metabolised by the liver, primarily by the cytochrome P450 isoenzyme CYP3A4.³ The manufacturer suggests¹ that there is a potential for dofetilide plasma levels to be increased by inhibitors of CYP3A4, and this has been shown for 'ketoconazole', (p.255). They recommend caution with other CYP3A4 inhibitors.

(c) *Other drugs that prolong the QT interval*

Dofetilide is a class III antiarrhythmic that prolongs the QT interval and can cause torsade de pointes arrhythmia. In general, use of two or more drugs that prolong the QT interval should be avoided. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Dofetilide + Omeprazole

Omeprazole appears not to interact with dofetilide.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that pretreatment with omeprazole 40 mg (10 or 2 hours before dofetilide) did not affect the pharmacokinetics of a single 500-microgram dose of dofetilide nor the dofetilide-induced change in QTc interval.¹ No special precautions appear to be necessary.

1. Vincent J, Gardner MJ, Baris B, Willavize SA. Concurrent administration of omeprazole and antacid does not alter the pharmacokinetics and pharmacodynamic of dofetilide in healthy subjects. *Clin Pharmacol Ther* (1996) 59, 182.

Dofetilide + Phenytoin

There does not appear to be any interaction between dofetilide and phenytoin.

Clinical evidence, mechanism, importance and management

In one study, 24 healthy subjects were stabilised on phenytoin to achieve steady-state plasma levels of 8 to 20 micrograms/mL and then either dofetilide 500 micrograms twice daily or placebo was given. No changes in phenytoin pharmacokinetics or cardiac effects were seen.¹ Another study by the same researchers in 24 subjects given dofetilide 500 micrograms every 12 hours found that phenytoin 300 mg daily did not have a clinically important effect on either the pharmacokinetics of the dofetilide or on its cardiovascular pharmacodynamics (QTc, PR, QRS, RR intervals).² These findings confirm those of an *in vitro* study³ showing that dofetilide did not inhibit the cytochrome P450 isoenzyme CYP2C9, thus suggesting that dofetilide is unlikely to affect the metabolism of phenytoin.

Dofetilide + Theophylline

There does not appear to be any interaction between theophylline and dofetilide.

Clinical evidence, mechanism, importance and management

Studies in healthy subjects found that the concurrent use of theophylline 450 mg every 12 hours and dofetilide 500 micrograms every 12 hours did not alter the steady-state pharmacokinetics of either drug.^{1,2} In addition, the increase in the QTc interval was no greater with the combination than with dofetilide alone.¹ No special precautions appear to be necessary.

2. Gardner MJ, Ashton HM, Willavize SA, Vincent J. The effects of orally administered theophylline on the pharmacokinetics and pharmacodynamics of dofetilide. *Clin Pharmacol Ther* (1996) 59, 182.

Dofetilide + Trimethoprim

Trimethoprim markedly increases the plasma levels of dofetilide. This is likely to be associated with an increased risk of dofetilide-induced QT prolongation and torsade de pointes.

Clinical evidence, mechanism, importance and management

The manufacturer of dofetilide notes that trimethoprim 160 mg (in combination with **sulfamethoxazole** 800 mg) twice daily given with dofetilide 500 micrograms twice daily for 4 days increased dofetilide peak levels by 93% and AUC by 103%.¹ Trimethoprim inhibits the active renal tubular secretion mechanism by which dofetilide is eliminated, so reducing its loss from the body (see also 'Dofetilide + H₂-receptor antagonists', p.255). There is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which increases the risk of torsade de pointes arrhythmia.¹ For this reason, the manufacturer contraindicates the use of trimethoprim in patients on dofetilide. This would seem to be a prudent precaution.

1. Tikosyn (Dofetilide). Pfizer Labs. US Prescribing information, March 2004.

Dofetilide + Verapamil

Verapamil transiently increases dofetilide plasma levels and QTc prolongation, and has been associated with an increased risk of torsade de pointes arrhythmia. Its use with dofetilide is contraindicated.

Clinical evidence

A study in 12 healthy subjects found that verapamil 80 mg three times daily given with dofetilide 500 micrograms twice daily for 3 days caused a 42% increase in the peak plasma levels of dofetilide from 2.4 to 3.43 nanograms/mL. There was a 26% increase in the AUC₀₋₄, which was associated with a transient simultaneous increase in QTc of 20 milliseconds for dofetilide alone and 26 milliseconds for the combination. However, the AUC₀₋₈ was not significantly different.¹ The manufacturer notes that an analysis of clinical trial data for dofetilide revealed a higher occurrence of torsade de pointes when verapamil was used with dofetilide.²

Mechanism

Verapamil is postulated to interact with dofetilide by increasing its rate of absorption by increasing hepatic blood flow.¹ There is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which is a risk factor for torsade de pointes.²

Importance and management

The use of verapamil with dofetilide appears to be associated with a transient increase in dofetilide plasma concentrations, and an increased risk of torsade de pointes. For this reason, the combination is contraindicated.

Table 9.2 Drugs causing QT prolongation and torsade de pointes

High risk	Some risk
Amisulpride	Clarithromycin (increase in QTc interval less than 5 milliseconds; rare case reports of torsade de pointes)
Antiarrhythmics, class Ia (ajmaline, cibenzoline, disopyramide, hydroquinidine, procainamide, quinidine)	Chlorpromazine (rare case reports of torsade de pointes)
Antiarrhythmics, class III (amiodarone, azimilide, cibenzoline, dofetilide, [†] ibutilide, [†] sotalol [†])	Erythromycin oral (see also high risk)
Arsenic trioxide (40% of patients had a QTc interval greater than 500 milliseconds)	Gatifloxacin (increase in QTc interval less than 10 milliseconds)
Artemisinin derivatives (artemisinin, artemether/lumefantrine - 5% of patients had an asymptomatic prolongation of QTc intervals by greater than 30 milliseconds, with an actual QTc of greater than 450 milliseconds in males and greater than 470 milliseconds in females)	Levofloxacin (rare case reports of torsade de pointes)
Astemizole [†] (if metabolism inhibited)	Lithium (greater risk if levels raised)
Cisapride [†] (if metabolism inhibited)	Methadone (in doses greater than 100 mg)
Droperidol [†]	Moxifloxacin (increase in QTc interval less than 10 milliseconds)
Erythromycin intravenous (see also some risk)	Pentamidine intravenous (case reports of torsade de pointes)
Halofantrine [†]	Quinine (greater risk with higher doses and intravenous use)
Haloperidol (also increased in high doses and with intravenous use)	Spiramycin
Ketanserin (30% of patients had an increase of greater than 30 milliseconds in a clinical trial)	Tricyclics (prolongation of QTc interval greater than 10 milliseconds, most notable risk occurs with clomipramine, risk with other tricyclics largely seems to be in overdose)
Mesoridazine [†]	
Pimozide [†]	
Ranolazine (dose-related QTc interval prolonged by up to 15 milliseconds, or more if metabolism inhibited)	
Sertindole [†]	
Sparfloxacin (10 millisecond increase in clinical trials)	
Terfenadine [†] (if metabolism inhibited)	
Thioridazine [†]	

[†]indicates drug suspended/restricted in some countries because of this effect
This list is not exhaustive

Drugs that prolong the QT interval + Drugs that lower potassium levels

The combined use of drugs that can cause hypokalaemia (e.g. amphotericin B, corticosteroids, thiazide and loop diuretics, and stimulant laxatives) and drugs that prolong the QT interval (e.g. class Ia and class III antiarrhythmics; see 'Table 9.2', (above)) should be well monitored because hypokalaemia increases the risk of torsade de pointes arrhythmias. There appear to be only a few reports of this interaction, for example, see 'Beta blockers + Potassium-depleting drugs', p.852.

Drugs that prolong the QT interval + Other drugs that prolong the QT interval

The consensus of opinion is that the concurrent use of drugs that have a high risk of prolonging the QTc interval should be avoided because of the risk of additive effects, leading to the possible development of serious and potentially life-threatening torsade de pointes cardiac arrhythmia. With drugs that have some risk of prolonging the QTc interval, some caution is appropriate, particularly in patients with other risk factors for QTc prolongation.

Clinical evidence, mechanism, importance and management

If the QT interval on the ECG becomes excessively prolonged, ventricular arrhythmias can develop, in particular a type of polymorphic tachycardia known as 'torsade de pointes'. On the ECG this arrhythmia can appear as an intermittent series of rapid spikes during which the heart fails to pump effectively, the blood pressure falls and the patient will feel dizzy and may possibly lose consciousness. Usually the condition is self-limiting but it may progress and degenerate into ventricular fibrillation, which can cause sudden death.

There are a number of reasons why QT interval prolongation can occur. These include:

- increasing age
- female sex
- congenital long QT syndrome
- cardiac disease
- thyroid disease
- some metabolic disturbances (hypocalcaemia, hypokalaemia, hypomagnesaemia)

Another important cause is the use of various QT-prolonging drugs including some antiarrhythmics, antipsychotics, antihistamines, antimalarials and others.^{1,2} These drugs all appear to cause this effect by blocking the rapid component of the delayed rectifier (repolarisation) potassium channel.

At what degree of prolongation of corrected QT (QTc) interval torsade de pointes arrhythmia is likely to develop is uncertain. However a QTc interval exceeding 500 milliseconds is generally considered of particular concern, but this is not an exact figure. In addition, there is uncertainty about what constitutes an important change in QTc interval from baseline, although, in general, increases of 30 to 60 milliseconds should raise concern, and increases of over 60 milliseconds raise clear concerns about the potential for arrhythmias. Because of these uncertainties, many drug manufacturers and regulatory agencies contraindicated the concurrent use of drugs known to prolong the QT interval, and a 'blanket' warning was often issued because the QT prolonging effects of the drugs are expected to be additive. Regulatory guidance for the assessment of risk of a non-antiarrhythmic drug states that drugs causing an increase in mean QT/QTc interval of around 5 milliseconds or less do not appear to cause torsade de pointes. Data on drugs causing mean increases of around 5 and less than 20 are inconclusive, and some drugs causing this have been associated with proarrhythmic risk. Drugs with an increase of more than 20 milliseconds have a substantially increased likelihood of being proarrhythmic.^{3,4} The extent of the drug-induced prolongation usually depends on the dosage of the drug and the particular drugs in question.

'Table 9.2', (p.257) is a list of drugs that are known to prolong the QT interval and cause torsade de pointes. Note that this list is not exhaustive of all the drugs that have ever been reported to be associated with QT interval prolongation and torsade de pointes. For some of the drugs listed, QT prolongation is a fairly frequent effect when the drug is used alone, and it is well accepted that use of these drugs requires careful monitoring (e.g. a number of the antiarrhythmics). For other drugs, QT prolongation is rare, but because of the relatively benign indications for these drugs, the risk-benefit ratio is considered poor, and use of these drugs has been severely restricted or discontinued (e.g. astemizole, terfenadine, cisapride). For others there is less clear evidence of the risk of QT prolongation (e.g. clarithromycin, chlorpromazine). Specific reports of additive QT prolonging effects with or without torsade de pointes are covered in individual monographs.

Drugs that do not themselves prolong the QT interval, but potentiate the effect of drugs that do (e.g. by pharmacokinetic mechanisms, lowering serum potassium, or by causing bradycardia) are not included in 'Table 9.2', (p.257). The interactions of these drugs (e.g. azole antifungals with cisapride, astemizole, or terfenadine, and potassium-depleting diuretics with sotalol) are dealt with in individual monographs. However, note that some drugs, for example the macrolide antibacterials, may cause QT prolongation by dual mechanisms—they appear to have both the intrinsic ability to prolong the QT interval, and they may inhibit the metabolism of drugs that prolong the QT interval.⁵

Flecainide + Amiodarone

Serum flecainide levels are increased by amiodarone. The flecainide dosage should be reduced by between one-third and one-half. An isolated report describes a patient on amiodarone who developed torsade de pointes when given flecainide.

Clinical evidence

Amiodarone 1.2 g daily for 10 to 14 days then 600 mg daily was given to 7 patients taking oral flecainide 200 to 500 mg daily. The trough plasma levels of flecainide were increased by about 50%, and the flecainide dosage was reduced by one-third (averaging a reduction from 325 to 225 mg daily) to keep the flecainide levels constant. Observations in two patients suggest that the interaction begins soon after the amiodarone is added, and it takes 2 weeks or more to develop fully.¹

Other authors have reported this interaction, and suggest reducing the flecainide dosage by between one-third to one-half when amiodarone is added.²⁻⁵ Another study found that amiodarone raised steady-state flecainide plasma levels by 37% in extensive metabolisers, and 55% in poor metabolisers of dextromethorphan (a probe drug for CYP2D6 activity).⁶ In a later report of this study the authors concluded that these differences were not clinically important, and that CYP2D6 phenotype does not affect the extent of the flecainide-amiodarone interaction.⁷ An isolated report describes torsade de pointes in a patient on amiodarone when given flecainide.⁸

Mechanism

Amiodarone inhibits the cytochrome P450 isoenzyme CYP2D6, so that the flecainide is metabolised by the liver more slowly. Amiodarone also inhibits CYP2D6-independent mechanisms of flecainide elimination.⁷

Importance and management

An established interaction, but the documentation is limited. Reduce the flecainide dosage by one-third to one-half if amiodarone is added.^{1-5,7} The manufacturers of flecainide recommend a 50% reduction in dose if amiodarone is given, and advise that adverse effects and plasma flecainide levels should be monitored.^{9,10} There seems to be no need to treat extensive metabolisers differently from poor metabolisers.⁷ Remember that the interaction may take 2 weeks or more to develop fully, and also that amiodarone is cleared from the body exceptionally slowly so that this interaction may persist for some weeks after it has been withdrawn.

Flecainide + Antacids or Food

The absorption of flecainide is not significantly altered if it is taken with food or an aluminium hydroxide antacid in adults, but it may possibly be reduced by milk in infants.

Clinical evidence, mechanism, importance and management

Neither food nor three 15-mL doses of *Aldrox* (280 mg of aluminium hydroxide per 5 mL) had any significant effect on the rate or extent of absorption of a single 200-mg dose of flecainide in healthy adult subjects.¹ No special precautions seem necessary if they are taken together.

A premature baby being treated for refractory atrio-ventricular tachycardia with high doses of flecainide (40 mg/kg daily or 25 mg every 6 hours) developed flecainide toxicity (seen as ventricular tachycardia) when his **milk feed** was replaced by **dextrose 5%**. His serum flecainide levels approximately doubled, the conclusion being that the **milk** had reduced the absorption.² **Milk**-fed infants on high doses of flecainide may therefore possibly need a reduced dosage if **milk** is reduced or stopped. Monitor the effects.

2. Russell GAB, Martin RP. Flecainide toxicity. *Arch Dis Child* (1989) 64, 860–2.

Flecainide + Antiepileptics

Limited data suggests that phenytoin or phenobarbital may modestly increase flecainide clearance, but this may not be clinically important.

Clinical evidence, mechanism, importance and management

Preliminary findings of a controlled study in 6 epileptic patients taking **phenytoin** or **phenobarbital** showed that the pharmacokinetics of a single 2-mg/kg intravenous dose of flecainide were not statistically different from those in a group of 7 healthy subjects. A 25 to 30% shorter flecainide half-life and urine clearance of unchanged drug was noted.¹ The authors say that this change may not require any adjustment in the flecainide dosage.

Flecainide + Benziodarone

A single case report describes ECG changes in a patient taking flecainide with benziodarone.

Clinical evidence, mechanism, importance and management

A 71-year-old woman who had undergone kidney transplantation 7 years earlier and who was taking amlodipine, losartan, furosemide, chlortalidone, calcitriol, aspirin, prednisone, ciclosporin, cyclophosphamide and insulin was also treated with flecainide, which controlled her paroxysmal atrial fibrillation. Atorvastatin was then restarted for hypercholesterolaemia and benziodarone 100 mg daily (because of intolerance to allopurinol) was added to treat hyperuricaemia. Three days later she presented with asthenia and poor overall condition and later an ECG showed QRS prolongation of 169 milliseconds (21% increase) caused by complete right bundle branch block with a previous anterior hemiblock, QTc interval prolongation of 482 milliseconds (22% increase) and PR interval prolongation of 203 milliseconds (18% increase). Creatinine levels were about 127 micromol/L, creatine phosphokinase 354 units/L and urea 155 mg/dL. Atorvastatin was stopped because of mild rhabdomyolysis. Flecainide and benziodarone were discontinued because an interaction was also suspected and symptoms resolved within 48 hours, with the ECG then showing values close to baseline. Flecainide was restarted and the dose gradually increased to 100 mg daily.¹

It was suggested that benziodarone may inhibit the cytochrome P450 isoenzyme CYP2D6 which is concerned with the metabolism of flecainide.¹ Note that benziodarone is chemically related to amiodarone, which has a similar effect, see 'Flecainide + Amiodarone', p.258. Mild renal

insufficiency in the patient may also have contributed to reduced flecainide elimination. More study is needed.

Flecainide + Cimetidine

Cimetidine can increase flecainide plasma levels.

Clinical evidence

After taking cimetidine 1 g daily for a week, the AUC of a single 200-mg dose of flecainide was increased by 28% in 8 healthy subjects. The fraction of flecainide excreted unchanged in the urine was increased by 20%, but the total renal clearance was not altered.¹ In another study in 11 patients, cimetidine 1 g daily for 5 days almost doubled the plasma levels of flecainide 200 mg daily measured 2 hours after the morning dose.²

Mechanism

Uncertain, but it is thought that the cimetidine reduces the hepatic metabolism of flecainide.^{1,2}

Importance and management

An established but not extensively documented interaction. The clinical importance appears not to have been assessed, but be alert for the need to reduce the flecainide dosage if cimetidine is added. Caution is recommended in patients with impaired renal function, as the interaction is likely to be enhanced.¹

Flecainide + Colestyramine

An isolated report describes reduced plasma flecainide levels in a patient given colestyramine. However, studies in other subjects have not found an interaction.

Clinical evidence, mechanism, importance and management

A patient taking flecainide 100 mg twice daily had unusually low trough plasma levels (100 nanograms/mL) while taking colestyramine 4 g three times daily. When he stopped taking the colestyramine his plasma flecainide levels rose. However, a later study in 3 healthy subjects given flecainide 100 mg once daily and colestyramine 4 g three times daily, found little or no evidence of an interaction (steady-state flecainide levels of 63.1 and 59.1 nanograms/mL without and with colestyramine respectively). *In vitro* studies also did not find any binding between flecainide and colestyramine that might result in reduced absorption from the gut.¹ The authors however postulate that the citric acid contained in the colestyramine formulation might have altered the urinary pH, which could have increased the renal clearance of the flecainide.¹

Information seems to be limited to this preliminary report. Its general importance seems to be minor, nevertheless the outcome of concurrent use should be monitored so that any unusual cases can be identified.

Flecainide + Quinidine or Quinine

Quinidine and quinine cause a modest reduction in the clearance of flecainide.

Clinical evidence, mechanism, importance and management

(a) Quinidine

A single 50-mg oral dose of quinidine given to 6 healthy subjects the night before a single 150-mg intravenous dose of flecainide decreased the flecainide clearance by 23%. The flecainide half-life was increased by 22%

and its AUC by 28%.¹ In another study, 5 patients who were 'extensive metabolisers', (p.4), of the cytochrome P450 isoenzyme CYP2D6 and taking long-term flecainide were given quinidine 50 mg every 6 hours for 5 days. The plasma levels and clearance of S-(+)-flecainide were unchanged, but plasma levels of R-(-)-flecainide increased by about 15% and its clearance reduced by 15%. The effects of the flecainide were slightly but not significantly increased.² Quinidine inhibits CYP2D6, which is concerned with the metabolism of flecainide. The clinical importance of this interaction is uncertain, but it is probably minor.

(b) Quinine

Three 500-mg doses of quinine given to 10 healthy subjects over 24 hours increased the AUC of a single 150-mg intravenous infusion of flecainide (given over 30 minutes) by 21% and reduced the systemic clearance by 16.5%. Renal clearance remained unchanged. The increases in the PR and QRS intervals caused by flecainide were slightly, but not significantly, increased by quinine.³ The evidence suggests that quinine reduces the metabolism of flecainide.³ The clinical importance of this interaction is uncertain but a slight increase in the serum levels of flecainide would be expected, accompanied by some, probably minor, changes in its effects.

Flecainide + SSRIs

Paroxetine is an inhibitor of CYP2D6 and may, therefore, increase the plasma levels of flecainide, which is metabolised via this isoenzyme. The manufacturers suggest that escitalopram may have similar effects.

Clinical evidence, mechanism, importance and management

(a) Escitalopram

Although studies *in vitro* did not reveal an inhibitory effect of escitalopram on CYP2D6, limited *in vivo* data with 'desipramine', (p.1241) and 'metoprolol', (p.855) suggest a modest inhibitory effect.¹ The UK manufacturer recommends caution if escitalopram is given with drugs that are mainly metabolised by this enzyme, and that have a narrow therapeutic index. They specifically name flecainide.¹

(b) Paroxetine

The manufacturer² states that paroxetine is an inhibitor of CYP2D6 and it may increase the plasma levels of drugs that are metabolised via this enzyme, such as flecainide. Several similarly metabolised drugs have been shown to interact (e.g. 'metoprolol', (p.855), and 'propafenone', (p.275)).

Flecainide + Tobacco

Tobacco smokers need larger doses of flecainide than non-smokers to achieve the same therapeutic effects.

Clinical evidence

Prompted by the chance observation that smokers appeared to have a reduced pharmacodynamic response to flecainide than non-smokers, a meta-analysis¹ was undertaken of the findings of 7 premarketing pharmacokinetic studies and 5 multicentre efficacy trials in which flecainide had been studied and in which the smoking habits of the subjects/patients had been also recorded. In the pharmacokinetic studies, the clearance of flecainide was found to be about 50% higher in smokers than in non-smokers. In the efficacy studies, average clinically effective

flecainide doses were found to be 338 mg daily for smokers and 288 mg daily for non-smokers, while trough plasma concentrations of flecainide were 1.74 and 2.18 nanograms/mL per mg dose for the smokers and non-smokers, respectively. This confirmed that smokers needed higher doses of flecainide to achieve the same steady-state serum levels.¹

Mechanism

The probable reason for this interaction is that some components of the tobacco smoke stimulate the cytochrome P450 enzymes in the liver concerned with the *O*-dealkylation of flecainide, so that it is cleared from the body more quickly.¹

Importance and management

An established interaction. Smokers seem likely to need higher doses of flecainide than non-smokers, but the way in which this interaction was identified suggests that in practice no specific action needs to be taken to accommodate it.

Flecainide + Urinary acidifiers or alkalinisers

The excretion of flecainide is increased if the urine is made acidic (e.g. with ammonium chloride) and reduced if the urine is made alkaline (e.g. with sodium bicarbonate). The clinical importance of these changes is not known.

Clinical evidence

Six healthy subjects were given single 300-mg oral doses of flecainide on two occasions. On the first occasion flecainide was taken after **ammonium chloride** 1 g orally every 3 hours, and 2 g at bedtime, for a total of 21 hours to make the urine acidic (pH range 4.4 to 5.4). On the second occasion flecainide was taken after **sodium bicarbonate** 4 g every 4 hours for a total of 21 hours (including night periods) to make the urine alkaline (pH range 7.4 to 8.3). Over the next 32 hours, 44.7% of unchanged flecainide appeared in the acidic urine, but only 7.4% in alkaline urine.¹ This compares with 25% found by other researchers when urinary pH was not controlled.¹ A later similar study from the same research group broadly confirmed these findings; the elimination half-life of the flecainide was 10.7 hours in acidic urine and 17.6 hours in alkaline urine.² Another study also confirmed the effect of urinary pH on the excretion of flecainide, and found that the fluid load and the urinary flow rate had little effect on flecainide excretion.³

Mechanism

In alkaline urine at pH 8, much of the flecainide exists in the kidney tubules in the non-ionised form (non-ionised fraction 0.04), which is therefore more readily reabsorbed. In acidic urine at pH 5 more exists in the ionised form (non-ionised fraction 0.0001), which is less readily reabsorbed and is therefore lost in the urine.³

Importance and management

Established interactions, but their clinical importance is still uncertain. The effects of these changes on the subsequent control of arrhythmias by flecainide in patients seem not to have been studied, but the outcome should be well monitored if patients are given drugs that alter urinary pH to a significant extent (such as ammonium chloride, sodium bicarbonate). Large doses of some **antacids** may possibly do the same, but nobody seems to have studied this.

Flecainide + Verapamil

Although flecainide and verapamil have been used together successfully, serious and potentially life-threatening cardiogenic shock and asystole have been seen in a few patients, because the cardiac depressant effects of the two drugs can be additive.

Clinical evidence

A man with triple coronary vessel disease and taking flecainide 200 mg daily for recurrent ventricular tachycardia, developed severe cardiogenic shock within 2 days of increasing the flecainide dosage to 300 mg daily and one day of starting verapamil 80 mg daily. His blood pressure fell to 60/40 mmHg and he had an idioventricular rhythm of 88 bpm.¹ Another patient with atrial flutter and fibrillation was given digitalis and verapamil 120 mg three times daily. He was also given flecainide 150 mg daily for 10 days, but 3 days after the dosage was raised to 200 mg daily he fainted, and later developed severe bradycardia (15 bpm) and asystoles of up to 14 seconds. He later died.¹

Another report describes atrioventricular block in a patient with a pacemaker when treated with digoxin, flecainide and verapamil.²

Two earlier studies in patients³ and healthy subjects⁴ had found that the pharmacokinetics of flecainide and verapamil were only minimally affected by concurrent use, but the PR interval was increased by both drugs and additive depressant effects were seen on heart contractility and AV conduction. No serious adverse responses occurred.

Mechanism

Flecainide and verapamil have little or no effects on the pharmacokinetics of each other,^{3,4} but they can apparently have additive depressant effects on the heart (negative inotropic and chronotropic) in both patients and healthy subjects.^{1,3,4} Verapamil alone^{5,6} and flecainide alone^{7,8} have been responsible for asystole and cardiogenic shock in a few patients. In the cases cited above¹⁻³ the cardiac depressant effects were particularly serious because the patients already had compromised cardiac function.

Importance and management

An established interaction, but the incidence of serious adverse effects is probably not great. The additive cardiac depressant effects are probably of little importance in many patients, but may represent 'the last straw' in a few who have seriously compromised cardiac function. The authors of one of the reports cited¹ advise careful monitoring if both drugs are used and emphasise the potential hazards of combining **class Ic antiarrhythmics** and verapamil.

Ibutilide + Amiodarone

The concurrent use of ibutilide and amiodarone would be expected to further prolong the QT interval and increase the risk of torsade de pointes, but, despite this, one report describes their successful use for cardioversion.

Clinical evidence, mechanism, importance and management

When intravenous ibutilide 2 mg was used for cardioversion of atrial fibrillation or flutter in 70 patients taking long-term amiodarone the QT interval was further prolonged (from 371 to 479 milliseconds). However, only one patient had an episode of non-sustained torsade de pointes. Ibutilide was effective within 30 minutes of infusion in 39% of patients with atrial flutter, and 54% of patients with fibrillation.¹ Both amiodarone and ibutilide are class III antiarrhythmics and prolong the QT interval, with the consequent risk of torsade de pointes. The manufacturer recommends that they should not be used concurrently.² However, the authors of the above report suggest that ibutilide may be useful for cardioversion in those already taking amiodarone. Combined use should be very well monitored.

2. Corvert (Ibutilide fumarate). Pharmacia & Upjohn. US Prescribing information. July 2002.

Ibutilide + Calcium-channel blockers

Calcium-channel blockers (predominantly non-dihydropyridine type) have not altered the safety or efficacy of ibutilide in clinical trials.

Clinical evidence, mechanism, importance and management

Retrospective analysis of three clinical trials showed that calcium-channel blockers did not alter the ECG effects (QT prolongation) or the efficacy of ibutilide. In these three studies, 68 of the 130 patients treated with ibutilide were also taking calcium-channel blockers. The report did not specify which calcium-channel blockers were used, except to say that only 12 of the 68 (19%) were taking a dihydropyridine-type.¹

In vitro studies have shown that **nifedipine** (a dihydropyridine) attenuated the effects of ibutilide.² The findings of the above report¹ suggest that this may not be clinically important. However, since so few patients were taking a dihydropyridine, an effect specific to dihydropyridines cannot be excluded. Further study is needed.

2. Lee KS, Lee EW. Ionic mechanism of ibutilide in human atrium: evidence for a drug-induced Na⁺ current through a nifedipine inhibited inward channel. *J Pharmacol Exp Ther* (1998) 286, 9–22.

Ibutilide + Class Ic antiarrhythmics

Some evidence suggests that patients taking ibutilide have a less marked increase in QT interval, without a change in efficacy, when they are also given propafenone or flecainide.

Clinical evidence, mechanism, importance and management

The increase in QTc interval after intravenous ibutilide 2 mg was less in patients treated with **propafenone** (5 patients) or **flecainide** (1 patient) than in 85 other patients who had taken ibutilide alone (34 versus 65 milliseconds). The effect appeared to be dose-related, with higher propafenone doses causing the largest attenuation in the ibutilide-induced QT prolongation. The efficacy of ibutilide was unaltered.¹ In a further study, 71 patients with atrial fibrillation or atrial flutter receiving either propafenone 300 to 900 mg daily or flecainide 100 to 300 mg daily underwent cardioversion with a single intravenous dose of ibutilide 1 mg over 10 minutes, followed if necessary by a further dose after an interval of 10 minutes. Torsade de pointes occurred in one patient with profound sinus node suppression after cardioversion, but the mean ibutilide-induced QTc interval was attenuated (20 ± 54 milliseconds compared to reported range of 47 to 90 milliseconds) without a decrease in efficacy. However, the authors note that the risk of sustained torsade de pointes in this study appears to be similar to that seen in other studies of ibutilide.²

Ibutilide, a class III antiarrhythmic, is known to increase the QT interval, so increasing the risk of torsade de pointes arrhythmia. Class Ic antiarrhythmics such as **propafenone** and **flecainide** generally shorten the QT interval. It is possible that class Ic antiarrhythmics may usefully attenuate the risk of torsade de pointes with ibutilide,¹ and ibutilide may be

useful in restoring sinus rhythm in patients taking class Ic antiarrhythmics,² but further study is needed.

Ibutilide + Miscellaneous

Ibutilide can prolong the QT interval, therefore caution has been advised about the concurrent use of other drugs that can do the same. Ibutilide is reported not to interact with beta blockers or digoxin.

Clinical evidence, mechanism, importance and management

No specific drug interaction studies appear to have been undertaken with ibutilide, which is a class III antiarrhythmic, but because it can prolong the QT interval it has been recommended that other drugs that can do the same should be administered with caution, because of the potential additive effects.¹ The manufacturer of ibutilide specifically recommends that **class Ia** and other **class III antiarrhythmics** should not be given within 4 hours of an ibutilide infusion, and that ibutilide should not be given within five half-lives of these antiarrhythmics (but see also, 'Ibutilide + Amiodarone', p.261).² The concern is that a prolongation of the QT interval is associated with an increased risk of torsade de pointes arrhythmia, which is potentially life-threatening. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

The concurrent use of **beta blockers** and **digoxin** during clinical trials is reported not to affect the safety or efficacy of ibutilide.^{1,2} Ibutilide is said not to affect the cytochrome P450 isoenzymes CYP3A4 or CYP2D6 and so metabolic interactions with drugs affected by these enzymes would not be expected.¹ Study is needed to confirm all of these predictions and findings.

2. Corvert (Ibutilide fumarate). Pharmacia & Upjohn. US Prescribing information. July 2002.

Lidocaine + Amiodarone

One man receiving intravenous lidocaine had a seizure about two days after starting treatment with amiodarone, and another man with sick sinus syndrome taking amiodarone had a sinoatrial arrest during placement of a pacemaker under local anaesthesia with lidocaine. There is conflicting evidence as to whether or not amiodarone affects the pharmacokinetics of intravenous lidocaine.

Clinical evidence

(a) Effects on lidocaine levels, seizure

An elderly man taking digoxin, enalapril, amitriptyline and temazepam was treated for monomorphic ventricular tachycardia, firstly with procainamide, later replaced by a 2-mg/minute infusion of lidocaine, to which oral amiodarone 600 mg twice daily was added. After 12 hours his lidocaine level was 5.4 mg/L (therapeutic levels 1.5 to 5 mg/L), but 53 hours later he developed a seizure and his lidocaine level was found to have risen to 12.6 mg/L. A tomography brain scan showed no abnormalities that could have caused the seizure and it was therefore attributed to the toxic lidocaine levels.¹

Six patients with symptomatic cardiac arrhythmias took part in a two-phase study. Initially, lidocaine 1 mg/kg was given intravenously over 2 minutes. In phase I, loading doses of amiodarone 500 mg daily for 6 days were given, followed by the same lidocaine dose. After 19 to 21 days, when the total cumulative amiodarone dose was 13 g, the same lidocaine dose was given again (phase II). The lidocaine AUC increased by about 20% and the systemic clearance decreased by about 20%. The elimination half-life and distribution volume at steady-state were unchanged. The pharmacokinetic parameters of lidocaine in phase II were the same as those in phase I, indicating that the interaction occurs early in

the loading phase of amiodarone use.² This is in contrast to an earlier study, in which the pharmacokinetics of a bolus dose of lidocaine 1 mg/kg over 2 minutes were not altered in 10 patients who had taken amiodarone 200 to 400 mg daily (following an loading dose of 800 or 1200 mg) for 4 to 5 weeks.³

(b) Sinoatrial arrest

An elderly man with long standing brady-tachycardia was successfully treated for atrial flutter firstly with a temporary pacemaker (later withdrawn) and 600 mg amiodarone daily. Ten days later, and 25 minutes after a permanent pacemaker was inserted under local anaesthesia with 15 mL of 2% lidocaine, severe sinus bradycardia and long sinoatrial arrest developed. He was effectively treated with atropine plus isoprenaline, and cardiac massage.⁴

Mechanism

An *in vitro* study has demonstrated that amiodarone may inhibit lidocaine metabolism competitively and *vice versa*. The interaction *in vivo* may be due to inhibition of the cytochrome P450 isoenzyme CYP3A4 by amiodarone and/or its main metabolite desethylamiodarone.³ CYP3A4 is partially involved in the metabolism of lidocaine.

The authors of the report describing the sinoatrial arrest suggest a synergistic depression by both drugs of the sinus node.

Importance and management

Evidence of a pharmacokinetic interaction between lidocaine and amiodarone is conflicting. However, the two reports of adverse interactions and the study in patients with arrhythmias illustrate the importance of good monitoring if both drugs are used.

Lidocaine + Barbiturates

Plasma lidocaine levels following slow intravenous injection may be modestly lower in patients who are taking barbiturates.

Clinical evidence

A single 2-mg/kg dose of lidocaine was given by slow intravenous injection (rate about 100 mg over 15 minutes) to 7 epileptic patients, firstly while taking their usual antiepileptic drugs and sedatives (including phenytoin, barbiturates, phenothiazines, benzodiazepines) and secondly after taking only **phenobarbital** 300 mg daily for 4 weeks. The same lidocaine dose was also given to 6 control subjects who had not received any drugs. When compared with the levels in the 6 control subjects, plasma lidocaine levels were somewhat lower when the patients took their standard antiepileptic treatment (18 and 29% lower at 30 and 60 minutes, respectively). When plasma lidocaine levels achieved during the **phenobarbital** phase were compared with those achieved during the standard antiepileptic treatment they were found to be 10 to 25% higher, suggesting that the effect of combined treatment caused a greater reduction in lidocaine levels than **phenobarbital**.¹

Mechanism

Not fully understood. One suggestion is that the barbiturates increase the activity of the liver microsomal enzymes, thereby increasing the rate of metabolism of the lidocaine.¹

Importance and management

Direct information is very limited. It may be necessary to increase the dosage of lidocaine to achieve the desired therapeutic response in patients on phenobarbital or other barbiturates.

1. Heinonen J, Takki S, Jarho L. Plasma lidocaine levels in patients treated with potential inducers of microsomal enzymes. *Acta Anaesthesiol Scand* (1970) 14, 89–95.

Lidocaine + Beta blockers

The plasma levels of lidocaine after intravenous, and possibly oral, use can be increased by propranolol. Isolated cases of toxicity attributed to this interaction have been reported. Nadolol and penbutolol possibly interact similarly, but there is uncertainty about metoprolol. Atenolol and pindolol appear not to interact.

Clinical evidence

(a) Atenolol

A study with oral atenolol 50 mg daily found that it did not affect the clearance of lidocaine after oral or intravenous use.¹

(b) Metoprolol

In 6 healthy subjects, metoprolol 100 mg twice daily for 2 days did not affect the pharmacokinetics of a single intravenous dose of lidocaine.² Similarly, another study in 7 healthy subjects failed to find any changes in the pharmacokinetics of a single oral or intravenous dose of lidocaine after treatment with metoprolol 100 mg every 12 hours for a week.¹ In contrast, another study found that the clearance of a single intravenous dose of lidocaine was reduced by 31% by pretreatment with metoprolol 50 mg every 6 hours for a day.³

(c) Nadolol

A study in 6 healthy subjects receiving 30-hour infusions of lidocaine at a rate of 2 mg/minute found that pretreatment with nadolol 160 mg daily for 3 days raised the steady-state plasma lidocaine levels by 28% (from 2.1 to 2.7 micrograms/mL) and reduced the plasma clearance by 17%.⁴

(d) Penbutolol

In 7 healthy subjects, penbutolol 60 mg daily significantly increased the volume of distribution of a single 100-mg intravenous dose of lidocaine, thus prolonging its elimination half-life. However, the reduction in clearance of lidocaine did not reach significance.⁵

(e) Pindolol

A study with intravenous pindolol 23 micrograms/kg found that it did not affect the clearance of intravenous lidocaine.⁶

(f) Propranolol

A study in 6 healthy subjects receiving 30-hour infusions of lidocaine at a rate of 2 mg/minute found that pretreatment with propranolol 80 mg every 8 hours for 3 days raised the steady-state plasma lidocaine levels by 19% (from 2.1 to 2.5 micrograms/mL) and reduced the plasma clearance by 16%.⁴ Other similar studies have found a 22.5 to 30% increase in steady-state serum lidocaine levels and a 14.7 to 46% fall in plasma clearance due to the concurrent use of propranolol.^{3,6,7} Two cases of lidocaine toxicity attributed to a lidocaine-propranolol interaction were revealed by a search⁸ of the FDA adverse drug reaction file in 1981. A further case of lidocaine toxicity (seizures) has been described in a man on propranolol after accidental oral ingestion of lidocaine for oesophageal anaesthesia. High serum levels of lidocaine were detected.⁹

(g) Unnamed beta blockers

A matched study in 51 cardiac patients taking a variety of beta blockers (including propranolol, metoprolol, timolol, pindolol) found no significant differences in either total or free concentrations of lidocaine during a lidocaine infusion, but there was a trend towards an increase in the adverse effects of lidocaine (bradycardias) with concurrent beta blocker treatment.¹⁰

Mechanism

Not fully agreed. There is some debate about whether the increased serum lidocaine levels largely occur because of the decreased cardiac output caused by the beta blockers, which decreases the flow of blood through the liver thereby reducing the metabolism of the lidocaine,⁴ or because of direct liver enzyme inhibition.¹¹ There may also be a pharmacodynamic interaction, with an increased risk of myocardial depression.¹⁰

Importance and management

The lidocaine/propranolol interaction is established and of clinical importance. Monitor the effects of concurrent use and reduce the intravenous lidocaine dosage if necessary to avoid toxicity. The situation with other

beta blockers is less clear. Nadolol appears to interact like propranolol, but it is uncertain whether metoprolol interacts or not. Atenolol and pindolol are reported not to interact pharmacokinetically. It has been suggested that a higher intravenous loading dose (but not a higher maintenance dose) of lidocaine may be needed if penbutolol is used.⁵ The suggestion has been made that a significant pharmacokinetic interaction is only likely to occur with non-selective beta blockers without intrinsic sympathomimetic activity¹¹ e.g. nadolol or propranolol. Aside from the pharmacokinetic interactions, a pharmacodynamic interaction is possible, and so it would be prudent to monitor the effects of concurrent use with any beta blocker.

Note that local anaesthetic preparations of lidocaine often contain adrenaline (epinephrine), which may interact with beta blockers, see 'Beta blockers + Inotropes and Vasopressors', p.848.

Lidocaine + Cocaine

Limited evidence suggests intravenous lidocaine use in patients with cocaine-associated myocardial infarction is not associated with significant toxicity.

Clinical evidence, mechanism, importance and management

A retrospective study, covering a 6-year period in 29 hospitals, identified 29 patients (27 available for review) who received lidocaine for prophylaxis or treatment of cocaine-associated myocardial infarction. No patient exhibited bradycardia, sustained ventricular tachycardia or ventricular fibrillation, and no patients died.¹

Both lidocaine and cocaine exhibit class I antiarrhythmic effects and are proconvulsants. Lidocaine may potentiate the cardiac and CNS adverse effects of cocaine. Therefore the use of lidocaine for cocaine-associated myocardial infarction is controversial. The lack of adverse effects in this study may have been due to delays of more than 5 hours between last exposure to cocaine and lidocaine therapy. These authors¹ and others^{2,3} consider that the cautious use of lidocaine does not appear to be contraindicated in patients with cocaine-associated myocardial infarction who require antiarrhythmic therapy. However, extra care should be taken in patients who receive lidocaine shortly after cocaine.¹

Lidocaine + Dextromethorphan

Intravenous lidocaine does not inhibit the activity of CYP2D6, as assessed by its lack of effect on dextromethorphan pharmacokinetics, and is therefore unlikely to interact with drugs that are metabolised by this isoenzyme.

Clinical evidence, mechanism, importance and management

Although *in vitro* data suggested that lidocaine inhibited oxidative metabolism reactions mediated by the cytochrome P450 isoenzyme CYP2D6, a

later *in vivo* study in 16 patients found that, while being given an infusion of lidocaine (serum level range 3.2 to 55.9 micromol/L), the metabolism of a single 30-mg dose of dextromethorphan remained unchanged. All of the patients were of the extensive metaboliser phenotype. Since dextromethorphan is a well-established marker of CYP2D6 activity, it was concluded that lidocaine is unlikely to interact with drugs that are extensively metabolised by this isoenzyme.¹

Lidocaine + Disopyramide

***In vitro* studies show that disopyramide can increase the levels of unbound lidocaine, but it is not known whether their combined effects have a clinically important cardiac depressant effect in practice.**

Clinical evidence, mechanism, importance and management

An *in vitro* study using serum taken from 9 patients receiving intravenous lidocaine for severe ventricular arrhythmias showed that there was an average 20% increase in its free (unbound) fraction when disopyramide in a concentration of 14.7 micromol/L was added.¹ This appears to occur because disopyramide can displace lidocaine from its binding sites on plasma proteins (alpha-1-acid glycoprotein).

The importance of this possible displacement interaction in clinical practice is uncertain. The suggestion made by the authors¹ is that, although lidocaine has only a minor cardiac depressant effect, a transient 20% increase in levels of free and active lidocaine plus the negative inotropic effects of the disopyramide might possibly be hazardous in patients with reduced cardiac function.

Lidocaine + Erythromycin

Erythromycin may markedly increase plasma levels of oral lidocaine, but causes only a minor increase after intravenous lidocaine.

Clinical evidence

In a randomised double-blind crossover study 9 healthy subjects were given erythromycin 500 mg three times daily or placebo daily for 4 days. Erythromycin increased the AUC and peak plasma levels of a single 1-mg/kg *oral* dose of lidocaine by 50 and 40% respectively. Erythromycin also markedly increased the AUC of the metabolite of lidocaine, monoethylglycinexylidide (MEGX) by 60%.¹

In a similar study,² erythromycin had no effect on the AUC or peak plasma level of a single 1.5-mg/kg intravenous dose of lidocaine, but still increased the AUC of MEGX by 70%. In yet another study, erythromycin ethylsuccinate 600 mg three times daily for 5 doses had a minor effect on the pharmacokinetics of a single 1-mg/kg intravenous dose of lidocaine (an 18% decrease in clearance), and caused a 33% increase in the AUC of MEGX. There was no difference in the results from the 10 healthy subjects and the 20 patients with biopsy proven cirrhosis.³ In another study, 9 healthy subjects were given fluvoxamine 100 mg daily alone or with erythromycin 500 mg three times daily for 5 days before the administration of a single intravenous dose of lidocaine 1.5 mg/kg on day 6. The clearance of lidocaine was reduced 41% by fluvoxamine and 53% by concurrent fluvoxamine and erythromycin.⁴

Mechanism

Erythromycin is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, the isoenzyme partially involved in the metabolism of lidocaine. Erythromycin appears to markedly reduce the first-pass metabolism of oral lidocaine so that its plasma levels rise.¹ The increase in MEGX could be due to either an increase in the production of this metabolite, or the inhibition of its further metabolism. Fluvoxamine, is an inhibitor of CYP1A2 which

is also involved in lidocaine metabolism. Lidocaine clearance is reduced by fluvoxamine and further decreased by concurrent erythromycin.

Importance and management

Information seems limited, and since lidocaine is not usually given orally the practical importance is minor. However, lidocaine is used for oro-pharyngeal topical anaesthesia, and there have been cases of toxicity after accidental ingestion. Thus, in a patient on erythromycin, the toxicity of *oral* lidocaine may be markedly increased. Further study is required to assess the significance of the increase in MEGX during prolonged intravenous lidocaine infusions.

4. Olkkola KT, Isohanni MH, Hamunen K, Neuvonen PJ. The effect of erythromycin and fluvoxamine on the pharmacokinetics of intravenous lidocaine. *Anesth Analg* (2005) 100, 1352–6.

Lidocaine + Fluvoxamine

Fluvoxamine reduces the clearance of intravenous lidocaine.

Clinical evidence, mechanism, importance and management

In a study, 9 healthy subjects were given fluvoxamine 100 mg daily alone or with erythromycin 500 mg three times daily for 5 days before the administration of a single intravenous dose of lidocaine 1.5 mg/kg on day 6. The clearance of lidocaine was reduced 41% by fluvoxamine and 53% by concurrent fluvoxamine and erythromycin.¹

The study found lidocaine clearance was reduced by fluvoxamine and further decreased by concurrent erythromycin. The cytochrome P450 isoenzymes CYP1A2 and CYP3A4 are involved in lidocaine metabolism. An *in vitro* study found that fluvoxamine (a CYP1A2 inhibitor) was a more potent inhibitor of lidocaine metabolism than erythromycin (a CYP3A4 inhibitor).² See also 'Lidocaine + Erythromycin', above and 'Anaesthetics, local + Fluvoxamine', p.110.

Lidocaine + H₂-receptor antagonists

Cimetidine modestly reduces the clearance of intravenous and possibly oral lidocaine, and raises its serum levels in some patients. Lidocaine toxicity may occur if the dosage is not reduced. Ranitidine appears to interact minimally. See also 'Anaesthetics, local + H₂-receptor antagonists', p.111.

Clinical evidence

(a) Cimetidine in cardiac patients

In one study, 15 patients were given a 1-mg/kg intravenous loading dose of lidocaine followed by a continuous infusion of 2 or 3 mg/minute over 26 hours. At 6 hours the patients were started on cimetidine (initial dose 300 mg intravenously, then 300 mg every 6 hours by mouth). After 26 hours (20 hours after cimetidine was started) the serum levels of lidocaine were 30% higher (5.6 micrograms/mL) than in a control group of 6 patients (4.3 micrograms/mL). The most substantial rise in levels occurred in the first 6 hours after cimetidine was started. Six patients developed toxic serum levels (over 5 micrograms/mL) and two (with levels of 10 and 11 micrograms/mL) experienced lethargy and confusion attributed to lidocaine toxicity, which disappeared when the lidocaine was stopped.¹

A study in patients with suspected myocardial infarction given two 300-mg oral doses of cimetidine 4 hours apart, starting 11 to 20 hours after a 2 mg/minute infusion of lidocaine began, showed that total lidocaine serum levels had risen by 28%, and unbound levels by 18%, 24 hours after the initial cimetidine dose. In three of these patients whose diagnosis of myocardial infarction was subsequently confirmed, rises in total and unbound lidocaine

serum levels of 24% and 9% occurred by 24 hours.² In contrast, a study in 6 patients with suspected myocardial infarction given lidocaine infusions, followed later by a cimetidine infusion, failed to find a significant increase in the plasma accumulation of lidocaine.³

An 89-year-old man with congestive heart failure taking oral cimetidine had two seizures 10 to 15 minutes after accidental oral ingestion of lidocaine solution for oesophageal anaesthesia. He had a high serum lidocaine level of 7.8 micrograms/mL.⁴

(b) Cimetidine in healthy subjects

In a study in 6 healthy subjects cimetidine 300 mg every 6 hours for one day raised the peak serum levels of intravenous lidocaine by 50%. Systemic clearance fell by about 25% (from 766 to 576 mL/minute) and 5 of the 6 experienced toxicity (light-headedness, paraesthesia).⁵ Similarly, in another study, oral cimetidine 300 mg four times daily caused a 30% fall in the clearance of intravenous lidocaine.⁶ In contrast, in other studies, oral cimetidine 300 mg four times daily caused only 18% and 15% falls in the clearance of intravenous lidocaine under both single-dose and steady-state conditions, which did not reach statistical significance.^{7,8} In one study, the effect of intravenous cimetidine 300 mg four times daily was less than that of the oral cimetidine.⁸

Cimetidine pretreatment increased the oral bioavailability of lidocaine by 35% in healthy subjects, and reduced the apparent oral clearance by 42%.⁹ Another study showed that 2 days of cimetidine pretreatment increased the AUC of lidocaine by 52% after aerosol application of lidocaine 120 mg (12 sprays of *Xylocaine* 10%) to the oropharynx.¹⁰

(c) Ranitidine in healthy subjects

A study in 10 healthy subjects given 150 mg ranitidine twice daily for 5 days found that it increased the systemic clearance of lidocaine by 9%, but did not alter the oral clearance.¹¹ In two other studies, ranitidine 150 mg twice daily for 1 to 2 days did not change the clearance of intravenous lidocaine.^{7,12}

Mechanism

Not established. It seems possible that the metabolism of lidocaine is reduced both by a fall in blood flow to the liver and by direct inhibition of the activity of the liver microsomal enzymes. As a result its clearance is reduced and its serum levels rise.

Importance and management

The lidocaine/cimetidine interaction is well studied but controversial. It is confused by the differences between the studies (healthy subjects, patients with different diseases, different modes of drug administration, etc). A fall in the clearance of lidocaine (15% or more) and a resultant rise in the serum levels should be looked for if cimetidine is used, but a clinically significant alteration may not occur in every patient. It may possibly be of less importance in patients following a myocardial infarction because of the increased amounts of alpha-1-acid glycoprotein, which alters the levels of bound and free lidocaine.² Monitor all patients closely for evidence of toxicity and, where possible, check serum lidocaine levels regularly. A reduced infusion rate may be needed. Ranitidine would appear to be a suitable alternative to cimetidine. See also 'Anaesthetics, local + H₂-receptor antagonists', p.111.

Lidocaine + Itraconazole

Itraconazole may markedly increase the plasma levels of lidocaine after oral administration, but not after intravenous administration or inhalation via a nebuliser.

Clinical evidence

Nine healthy subjects were given either itraconazole 200 mg once daily or placebo for 4 days, in a randomised double-blind crossover study. Itraconazole increased the AUC and peak plasma levels of a single 1-mg/kg oral dose of lidocaine by 75 and 55% respectively. Itraconazole did not affect the concentration of the lidocaine metabolite, monoethylglycinexylidide (MEGX).¹ In similar studies, itraconazole had no effect on the AUC and peak plasma levels of lidocaine or MEGX after 1.5-mg/kg intravenous² or nebulised³ doses of lidocaine.

Mechanism

Itraconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, which is partially involved in the metabolism of lidocaine. Itraconazole appears to markedly reduce the first-pass metabolism of orally administered lidocaine so that its plasma levels rise.¹

Importance and management

Information seems to be limited, and since lidocaine is not usually given orally the practical importance is minor. However, lidocaine is used for oro-pharyngeal topical anaesthesia, and there have been cases of toxicity after accidental ingestion. There is also a possibility of accidental oral ingestion during inhalation of lidocaine. In patients on itraconazole, the toxicity of oral lidocaine may be markedly increased.

Lidocaine + Mexiletine

Mexiletine may increase the toxicity of lidocaine.

Clinical evidence, mechanism, importance and management

A patient with cardiomyopathy taking mexiletine 300 mg twice daily developed lidocaine CNS toxicity within one hour of receiving a total of 600 mg of oral lidocaine for oesophageal burning. Her lidocaine concentration was raised at 26.9 micrograms/mL.¹ Similarly, involuntary motion and muscular stiffness occurred in a man treated with oral mexiletine and an intravenous infusion of lidocaine for one day.² Studies in animals have shown that the concurrent use of mexiletine and intravenous lidocaine resulted in a decrease in the total clearance of lidocaine and an increase in plasma levels. It appeared that this was due to mexiletine displacing the tissue binding of lidocaine and reducing its distribution.³ Mexiletine is an oral lidocaine analogue, so it is perhaps not surprising the two drugs may interact. The combination should be used with caution, especially during the initial stages of treatment. Where possible, lidocaine levels should be closely monitored.

Lidocaine + Omeprazole

Omeprazole does not appear to alter the pharmacokinetics of intravenous lidocaine.

Clinical evidence, mechanism, importance and management

Omeprazole 40 mg daily for one week did not affect the AUC or half-life of lidocaine or its metabolite methylglycinexylidene when a single 1-mg/kg intravenous dose of lidocaine was given to 10 healthy subjects.¹ This study suggests that no special precautions are required during concurrent use.

1. Noble DW, Bannister J, Lamont M, Andersson T, Scott DB. The effect of oral omeprazole on the disposition of lignocaine. *Anaesthesia* (1994) 49, 497–500.

Lidocaine + Phenytoin

The incidence of central toxic adverse effects may be increased following the concurrent intravenous infusion of lidocaine and phenytoin. Sinoatrial arrest has been reported in one patient. In patients taking phenytoin, serum lidocaine levels may be slightly reduced when given intravenously, but markedly reduced if given orally.

Clinical evidence

(a) Cardiac depression and increased adverse effects

A study in 5 patients with suspected myocardial infarction, given lidocaine 0.5 to 3 mg/minute intravenously for at least 24 hours, followed by additional intravenous injections or infusions of phenytoin, found that plasma levels of both drugs remained unchanged but the incidence of adverse effects (vertigo, nausea, nystagmus, diplopia, impaired hearing) were unusually high.¹

Sinoatrial arrest occurred in a man with heart block following a suspected myocardial infarction, after he received intravenous lidocaine 1 mg/kg over 1 minute, followed 3 minutes later by phenytoin 250 mg given over 5 minutes. The patient lost consciousness and his blood pressure could not be measured, but he responded to a 200-microgram dose of isoprenaline (isoproterenol).²

(b) Serum lidocaine levels

In the study described above,¹ intravenous phenytoin had no effect on plasma lidocaine levels during continuous infusion. However, in another study, lidocaine 2 mg/kg was given intravenously to 7 epileptic patients taking their usual anticonvulsants (including phenytoin, barbiturates, phenothiazines, benzodiazepines), and to 6 control subjects. Plasma lidocaine levels were 27 and 43% lower in the epileptic patients at 30 and 60 minutes, respectively.³ Another study found that the clearance of intravenous lidocaine was slightly greater in patients taking anticonvulsants than in healthy subjects (850 compared with 770 mL/minute) but this difference was not statistically significant.⁴ Other studies in epileptic patients and healthy subjects have shown that phenytoin halves the bioavailability of oral lidocaine.^{4,5}

Mechanism

Phenytoin and lidocaine appear to have additive cardiac depressant actions.

The reduced lidocaine serum levels are possibly due to liver enzyme induction; when lidocaine is given orally the marked reduction in levels results from the stimulation of hepatic first-pass metabolism by phenytoin.^{4,5} In addition, patients taking antiepileptics including phenytoin had higher plasma concentrations of alpha-1-acid glycoprotein, which may result in a lower free fraction of lidocaine in the plasma.⁶

Importance and management

Information is limited and the importance of this interaction is not well established. The case of sinoatrial arrest emphasises the need to exercise caution when giving two drugs that have cardiac depressant actions.

The reduction in serum lidocaine levels after intravenous use in patients taking antiepileptics, including phenytoin, is small and appears not to be of any clinical significance. Since lidocaine is not usually given orally, the practical importance of the marked reduction in bioavailability would also seem to be small.

Lidocaine + Procainamide

An isolated case of delirium has been described in a patient given intravenous lidocaine with procainamide.

Clinical evidence, mechanism, importance and management

A man with paroxysmal tachycardia, treated with oral procainamide 1 g every 5 hours and increasing doses of lidocaine by intravenous infusion (550 mg within 3.5 hours), became restless, noisy and delirious when given a further 250 mg intravenous dose of procainamide.¹ The symptoms disappeared within 20 minutes of discontinuing the lidocaine. The reason is not understood but the symptoms suggest that the neurotoxic effects of the two drugs might be additive. Other studies in patients have shown that lidocaine plasma levels are unaffected by intravenous or oral procainamide.²

2. Karlsson E, Collste P, Rawlins MD. Plasma levels of lidocaine during combined treatment with phenytoin and procainamide. *Eur J Clin Pharmacol* (1974) 7, 455–9.

Lidocaine + Propafenone

Propafenone has minimal effects on the pharmacokinetics of intravenous lidocaine, but the severity and duration of the CNS adverse effects of lidocaine are increased.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects, who had been taking 225 mg propafenone every 8 hours for 4 days, were given a continuous infusion of lidocaine 2 mg/kg/hour for 22 hours. Propafenone increased the AUC of lidocaine by 7% and reduced the clearance by 7%. One poor metaboliser of propafenone had an increase in lidocaine clearance. Increases in the PR and QRS intervals of 10 to 20% were also seen. Combined use increased the severity and duration of adverse effects (lightheadedness, dizziness, paraesthesia, lethargy, somnolence). One subject withdrew from the study as a result.¹ In another study, the combined infusion of lidocaine (100 mg bolus then a 2 mg/minute infusion) and propafenone (1 or 2 mg/kg) produced a minor additional negative inotropic effect (which was not statistically significant) and reversed the prolongation in atrial and ventricular refractoriness produced by propafenone alone.²

There would therefore appear to be no marked or important pharmacokinetic interaction between these two drugs, but the increased CNS adverse effects may be poorly tolerated by some individuals, and cardiac depressant effects may be additive.

Lidocaine + Rifampicin (Rifampin)

Rifampicin may reduce the serum levels of lidocaine given intravenously.

Clinical evidence, mechanism, importance and management

Rifampicin 600 mg daily for 6 days increased the clearance of a 50-mg intravenous dose of lidocaine by 15% in 10 healthy subjects. In addition, plasma concentrations of the lidocaine metabolite monoethylglycinexylidide (MEGX) increased by 34%, although this did not reach statistical significance.¹ Using cultured human hepatocytes it was found that rifampicin increases the metabolism of lidocaine, probably because it induces the cytochrome P450 isoenzyme CYP3A4, which is partially concerned with the metabolism of lidocaine to MEGX.² These modest changes in lidocaine pharmacokinetics are unlikely to be of much importance, particularly as the intravenous lidocaine dose is usually titrated to effect.

1. Reichel C, Skodra T, Nacke A, Spengler U, Sauerbruch T. The lignocaine metabolite (MEGX) liver function test and P-450 induction in humans. *Br J Clin Pharmacol* (1998) 46, 535–9.
2. Li AP, Rasmussen A, Xu L, Kaminski DL. Rifampicin induction of lidocaine metabolism in cultured human hepatocytes. *J Pharmacol Exp Ther* (1995) 274, 673–7.

Lidocaine + Tobacco

Tobacco smoking reduces the bioavailability of oral but not intravenous lidocaine.

Clinical evidence, mechanism, importance and management

A study in healthy subjects found that the bioavailability of oral lidocaine was markedly lower in smokers (mean AUCs of 15.2 and 47.9 micrograms/mL per minute in 4 smokers and 5 non-smokers respectively), but when the lidocaine was given intravenously only moderate differences were seen.¹ The reason for the differences is probably due to liver enzyme induction caused by components of tobacco smoke. With oral lidocaine this could result in increased first-pass hepatic clearance. In the case of intravenous lidocaine, first-pass clearance is bypassed, and the enzyme induction was opposed by a smoking-related decrease in hepatic flow. In practical terms this interaction is unlikely to be of much importance since lidocaine is not usually given orally.

1. Huet P-M, Leloir J. Effects of smoking and chronic hepatitis B on lidocaine and indocyanine green kinetics. *Clin Pharmacol Ther* (1980) 28, 208–15.

Lidocaine + Tocainide

A report describes a tonic-clonic seizure in a man during the period when his treatment was being changed from intravenous lidocaine to oral tocainide.

Clinical evidence, mechanism, importance and management

An elderly man taking furosemide and co-trimoxazole experienced a tonic-clonic seizure while his treatment with intravenous lidocaine was being changed to oral tocainide, although the serum levels of both antiarrhythmics remained within their therapeutic ranges. The patient became progressively agitated and disorientated about 8 hours after starting oral tocainide 600 mg every 6 hours while still receiving lidocaine 2 mg/minute intravenously. About 1 hour later he had a seizure. The patient subsequently tolerated each drug separately, at concentrations similar to those that preceded the seizure, without problems.¹ A study in animals² showed that tocainide reduces the lidocaine serum levels at which seizures occur by about 45%. Tocainide is no longer widely available, but the manufacturer previously noted that concurrent use of lidocaine and tocainide may cause an increased incidence of adverse effects, including CNS adverse reactions such as seizure, since the two drugs have similar pharmacodynamic effects.³ Great care must therefore be exercised if tocainide is given during lidocaine use.

Mexiletine + Amiodarone

Amiodarone does not affect the clearance of mexiletine. The concurrent use of mexiletine and amiodarone can be clinically useful.

Clinical evidence, mechanism, importance and management

The clearance of mexiletine in 10 patients did not differ before and after 1, 3 and 5 months concurrent use of amiodarone. In addition, the clearance of mexiletine did not differ between these patients and 155 other patients not taking amiodarone.¹

Torsade de pointes has been described in a patient taking amiodarone and mexiletine (a class Ib antiarrhythmic).² The manufacturers of mexiletine say that this seems to be an isolated case.³

Class Ib antiarrhythmics are usually associated with shortening of the QT interval, and could therefore be expected to reduce the QT prolongation and risk of torsade de pointes seen with amiodarone alone (for examples of this effect of mexiletine see also 'Mexiletine + Beta blockers', p.268 and 'Mexiletine + Quinidine', p.269). However, note that the UK manufacturer of mexiletine⁴ says that it may exacerbate arrhythmias [as all antiarrhythmics may], but also that it may be used concurrently with amiodarone. The two drugs have been used together successfully.^{5,6}

Mexiletine + Antacids, Atropine or Metoclopramide

The rate of absorption of mexiletine is slowed by the antacid almasilate and atropine and hastened by metoclopramide, but the extent of the absorption is unaltered.

Clinical evidence, mechanism, importance and management

The antacid almasilate (*Gelusil*), given one hour before a single 400-mg dose of mexiletine, resulted in a slight delay in absorption (time to maximum concentration prolonged from 1.7 to 2.9 hours), but had no effect on the extent of absorption in healthy subjects.¹

A study in 8 healthy subjects found that a single 600-microgram dose of intravenous atropine reduced the rate of absorption of a single 400-mg oral dose of mexiletine, but the mexiletine AUC remained unaffected. Intravenous metoclopramide 10 mg hastened the absorption of mexiletine but similarly did not affect the AUC. Metoclopramide tended to reverse the effect of diamorphine on plasma mexiletine levels in one clinical trial² (see also 'Mexiletine + Opioids', p.268).

Since the achievement of steady-state mexiletine levels depends on the extent of absorption, not on its rate, it seems very unlikely that these drugs will affect the antiarrhythmic effects of mexiletine during chronic dosing.³ However, these drugs may cause variations in the antiarrhythmic effects of initial oral mexiletine doses, which may be a problem if rapid control of the arrhythmia is essential. In general, no special precautions would appear necessary.

Mexiletine + Beta blockers

The concurrent use of mexiletine and beta blockers can be clinically useful. Mexiletine may reduce the QT prolonging effects of sotalol.

Clinical evidence, mechanism, importance and management

A study in 4 patients found that a combination of mexiletine and **propranolol** 240 mg daily was more effective in blocking ventricular premature depolarisation (VPD) and ventricular tachycardia than mexiletine alone, and did not increase adverse effects. Plasma mexiletine concentrations were not changed significantly by **propranolol**.¹ Similar efficacy was reported for **metoprolol** with mexiletine.² Success in decreasing VPDs was noted in 30% of 44 patients taking mexiletine plus a beta blocker [unspecified] compared with only 14% of 185 subjects taking mexiletine alone.³ The UK manufacturer of mexiletine states that it may be used concurrently with beta blockers.⁴

A study in *animals* showed that mexiletine reduced the QT prolonging effect of **sotalol** and reduced the risk of torsade de pointes.⁵

Mexiletine + Ciprofloxacin

Ciprofloxacin slightly reduces the clearance of mexiletine, but this is unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

A study in healthy subjects found that the oral clearance of mexiletine was reduced by about 8 to 20% when a single dose was given on day 3 of a 5-day course of ciprofloxacin 750 mg twice daily. This was due to a decrease in the metabolic clearance of mexiletine, presumed to occur as a result of ciprofloxacin-induced inhibition of the cytochrome P450 isoenzyme CYP1A2, which is involved in the metabolism of mexiletine.¹ It is unlikely that changes of this magnitude would be clinically relevant.

1. Labbé L, Robitaille NM, Lefez C, Potvin D, Gilbert M, O'Hara G, Turgeon J. Effects of ciprofloxacin on the stereoselective disposition of mexiletine in man. *Ther Drug Monit* (2004) 26, 492–8.

Mexiletine + Fluconazole

Fluconazole does not affect the pharmacokinetics of mexiletine.

Clinical evidence, mechanism, importance and management

Six healthy subjects were given a single 200-mg dose of mexiletine before and after taking fluconazole 200 mg daily for 7 days. Two of the subjects were given fluconazole 400 mg daily for a further 7 days. No significant changes in the pharmacokinetics of mexiletine were seen.¹ The clinical outcome of concurrent use in patients was not studied, but there appear to be no adverse reports in the literature. No special precautions appear to be necessary if these drugs are used concurrently.

Mexiletine + H₂-receptor antagonists

The pharmacokinetics of mexiletine were not altered by cimetidine or ranitidine. Cimetidine can reduce the gastric adverse effects of mexiletine.

Clinical evidence, mechanism, importance and management

The peak and trough plasma mexiletine levels of 11 patients were unaltered when they were given **cimetidine** 300 mg four times daily for a week, and the frequency and severity of the ventricular arrhythmias for which they were being treated remained unchanged. Moreover the gastric adverse effects of mexiletine were reduced in half of the patients.¹ This study in patients confirms the findings of two other studies using **cimetidine** or **ranitidine** in healthy subjects.^{2,3} There would seem to be no problems associated with giving these drugs concurrently, and some advantages.

Mexiletine + Omeprazole

Omeprazole does not appear to affect the pharmacokinetics of mexiletine.

Clinical evidence, mechanism, importance and management

A crossover study in 9 healthy Japanese men found that when they were given mexiletine 200 mg after taking omeprazole 40 mg daily for 8 days, the mexiletine serum concentrations and its AUCs remained unchanged. It was concluded that omeprazole does not affect the metabolism of mexiletine,¹ and no special precautions would seem to be needed if these drugs are used concurrently.

1. Kusumoto M, Ueno K, Tanaka K, Takeda K, Mashimo K, Kameda T, Fujimura Y, Shibakawa M. Lack of pharmacokinetic interaction between mexiletine and omeprazole. *Ann Pharmacother* (1998) 32, 182–4.

Mexiletine + Opioids

The absorption of mexiletine is reduced following myocardial infarction, and very markedly reduced and delayed if diamorphine or morphine is used concurrently. A higher loading dose may be needed if oral mexiletine is required during the first few hours following a myocardial infarction.

Clinical evidence

A pharmacokinetic study showed that the mean plasma levels of mexiletine (400 mg orally followed by 200 mg 2 hours later) in the first 3 hours were more than 50% lower in 6 patients who had suffered a myocardial infarction and who had been given **diamorphine** 5 to 10 mg or **morphine** 10 to 15 mg than in 4 patients who had not been given opioids. In addition, the AUC_{0–8} was 38.6% lower in those who had received opioids.¹

In a further study about the prophylactic use of mexiletine, the same authors found that plasma mexiletine levels 3 hours after the first oral dose were 31% lower in 10 patients who had received opioids than in 6 patients who had not. These patients were from a subset who were subsequently shown not to have had a myocardial infarction.¹ In another similar trial of mexiletine in acute myocardial infarction, use of **diamorphine** was associated with low plasma mexiletine levels at 3 hours, and possible reduced efficacy of mexiletine. In this study, pretreatment with intravenous metoclopramide tended to reduce the effect of **diamorphine** on mexiletine absorption,² although this was not noted in the other report.¹

Mechanism

The reduced absorption of mexiletine would seem to result from inhibition of gastric emptying by the opioids. Other mechanisms probably contribute to the delayed clearance of mexiletine.

Importance and management

An established interaction although information is limited. The delay and reduction in the absorption would seem to limit the value of oral mexiletine during the first few hours after a myocardial infarction, particularly if opioid analgesics are used. The manufacturer suggests that a higher load-

ing dose of oral mexiletine may be preferable in this situation. Alternatively, an intravenous dose of mexiletine may be given. In addition, they note that it may be necessary to titrate the dose against therapeutic effects and adverse effects.³

3. Mexitil (Mexiletine). Boehringer Ingelheim Ltd. UK Summary of product characteristics, May 2003.

Mexiletine + Phenytoin

Plasma mexiletine levels are reduced by phenytoin. An increase in the dosage may be necessary.

Clinical evidence

The observation that 3 patients had unusually low plasma mexiletine levels while taking phenytoin prompted a pharmacokinetic study in 6 healthy subjects. After taking phenytoin 300 mg daily for a week, the mean AUC and half-life of a single 400-mg dose of mexiletine were reduced by an average of about 50% (half-life reduced from 17.2 to 8.4 hours).¹

Mechanism

The most likely explanation is that phenytoin increases the metabolism of mexiletine by the cytochrome P450 isoenzyme CYP1A2.

Importance and management

Information seems to be limited to this report¹ but the interaction appears to be established. It seems likely that the fall in mexiletine levels will be clinically important in some individuals. Monitor for mexiletine efficacy, and where possible levels. Raise the dosage if necessary.

1. Begg EJ, Chinwah PM, Webb C, Day RO, Wade DN. Enhanced metabolism of mexiletine after phenytoin administration. *Br J Clin Pharmacol* (1982) 14, 219–23.

Mexiletine + Propafenone

Propafenone raises mexiletine serum levels in extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6.

Clinical evidence, mechanism, importance and management

In one study in healthy subjects, propafenone reduced mexiletine clearance and increased plasma mexiletine concentrations in those subjects with extensive cytochrome P450 isoenzyme CYP2D6 activity, but had no effect in those of the poor metaboliser phenotype. The pharmacokinetics of mexiletine in extensive metabolisers after propafenone treatment became the same as those in poor metabolisers.¹ Mexiletine did not affect propafenone pharmacokinetics.¹ In this study, overall changes in ECG parameters were minor during the concurrent use of mexiletine and propafenone.¹ Propafenone is an inhibitor of CYP2D6, and inhibits the metabolism of mexiletine by this pathway.¹ Although the use of the combination was not associated with significant ECG changes, the potentiation of drug effects could predispose to proarrhythmias in patients with ischaemic heart disease. The authors suggest that slow dose titration of the combination may decrease the risk of adverse effects.¹ The UK manufacturer² notes that it may be necessary to reduce the dose of mexiletine when it is given with drugs causing inhibition of hepatic enzymes, especially CYP1A2 and CYP2D6.

1. Labbé L, O'Hara G, Lefebvre M, Lessard É, Gilbert M, Adedoyin A, Champagne J, Hamelin B, Turgeon J. Pharmacokinetic and pharmacodynamic interaction between mexiletine and propafenone in human beings. *Clin Pharmacol Ther* (2000) 68, 44–57.
2. Mexitil (Mexiletine). Boehringer Ingelheim Ltd. UK Summary of product characteristics, May 2003.

Mexiletine + Quinidine

The concurrent use of mexiletine and quinidine can be clinically useful. Mexiletine appears to limit the quinidine-induced increase in QT interval. Quinidine raises mexiletine serum levels in extensive metabolisers of cytochrome P450 isoenzyme CYP2D6.

Clinical evidence, mechanism, importance and management

Mexiletine and quinidine given concurrently were reported to be more effective than either drug alone, and the incidence of adverse effects was reduced. Mexiletine limited the quinidine-induced increase in QT interval.¹ A study in *animals* concluded that the benefit of combined use may be due to prolonged refractoriness and conduction time in the peri-infarct zone.² Two studies^{3,4} in healthy subjects have shown that quinidine reduces the metabolism and excretion of mexiletine in extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6 (total clearance reduced by 24%⁴), but not poor metabolisers. Quinidine is an inhibitor of CYP2D6, and inhibits the metabolism of mexiletine by this pathway. Thus, a pharmacokinetic mechanism may also contribute to the increased efficacy of the combination.⁴ The UK manufacturer of mexiletine states that it may be used concurrently with quinidine.⁵ They also note that it may be necessary to reduce the dose of mexiletine when used concurrently with drugs causing inhibition of hepatic enzymes, particularly the cytochrome P450 isoenzymes CYP1A2 and CYP2D6.⁵

5. Mexitil (Mexiletine). Boehringer Ingelheim Ltd. UK Summary of product characteristics, May 2003.

Mexiletine + Rifampicin (Rifampin)

The clearance of mexiletine is increased by rifampicin. An increase in the dosage of mexiletine may be necessary.

Clinical evidence, mechanism, importance and management

After taking rifampicin 600 mg daily for 10 days, the half-life of a single 400-mg dose of mexiletine was reduced by 40% (from 8.5 to 5 hours) and the AUC fell by 39% in 8 healthy subjects.¹ The probable reason is that the rifampicin (a known, potent enzyme-inducer) increases the metabolism and clearance of mexiletine. It seems likely that the mexiletine dosage will need to be increased during concurrent use. Monitor concurrent use well.

1. Pentikäinen PJ, Koivula IH, Hiltunen HA. Effect of rifampicin treatment on the kinetics of mexiletine. *Eur J Clin Pharmacol* (1982) 23, 261–6.

Mexiletine + SSRIs

Fluvoxamine markedly increases the AUC of mexiletine by inhibiting CYP1A2. Fluoxetine and paroxetine might also be expected to interact, albeit by inhibiting CYP2D6, but sertraline is possibly unlikely to interact.

Clinical evidence, mechanism, importance and management

Fluvoxamine 50 mg twice daily for 7 days increased the AUC of a single 200-mg dose of mexiletine by 55%, and decreased the clearance by 37% in 6 healthy subjects.¹ It is likely that **fluvoxamine** decreases the metabolism of mexiletine by inhibiting the cytochrome P450 isoenzyme CYP1A2, which is partially responsible for the metabolism of mexiletine.¹ The large changes in mexiletine AUC suggest that concurrent therapy should be well monitored.

Mexiletine is also metabolised by CYP2D6 (e.g. see 'Mexiletine + Propafenone', p.269). In an *in vitro* study using human liver microsomes, **paroxetine**, **fluoxetine**, and **sertraline** extensively inhibited the metabolism of mexiletine. Using a model to predict *in vivo* interactions, it was suggested that both **fluoxetine** and **paroxetine** may interact with mexiletine to a clinically relevant extent, whereas **sertraline** is less likely to interact.²

The UK manufacturer notes that it may be necessary to reduce the dose of mexiletine when used concurrently with drugs causing inhibition of hepatic enzymes, in particular the cytochrome P450 isoenzymes CYP1A2 and CYP2D6,³ which is consistent with the proposed mechanism of the interaction.

Mexiletine + Urinary acidifiers or alkalinisers

Large changes in urinary pH caused by acidifying or alkalinising drugs can have a marked effect on the plasma levels of mexiletine in some patients.

Clinical evidence

In 4 healthy subjects, a single 200-mg intravenous dose of mexiletine was given, once when the urine was acidic (pH 5) after administration of **ammonium chloride**, and once when the urine was alkaline (pH 8) after administration of **sodium bicarbonate**. The plasma elimination half-life was significantly shorter when the urine was acidic (2.8 hours) compared with when it was alkaline (8.6 hours). In addition, the percentage of mexiletine excreted unchanged in the urine was 57.5% when acidic and just 0.6% when alkaline.¹ Similar results were found in another study.² A further study in patients with uncontrolled urine pH (range 5.04 to 7.86) given mexiletine orally for 5 days found that the plasma concentration of mexiletine correlated with urine pH. In addition, it was predicted that a normal variation in pH could cause more than a 50% variation in plasma mexiletine levels.³ A later comprehensive pharmacokinetic study in 5 healthy subjects confirmed that renal clearance of mexiletine was 4 mL/minute in alkaline urine (pH 8) compared with 168 mL/minute in acidic urine (pH 5.2). In two subjects, this resulted in an increase in plasma concentrations of 61% and 96%, but in the other three the increase was less than 20%. Non-renal clearance (metabolic clearance) increased in the three subjects with little change in plasma concentrations, but was unaffected in the two with marked changes.⁴

Mechanism

Mexiletine is a basic drug, and undergoes greater reabsorption by the kidneys when in the non-ionised form in alkaline urine. Mexiletine is also extensively cleared from the body by liver metabolism and only about 10% is excreted unchanged in the urine at physiological pH, although this is variable. Any changes in the renal clearance of mexiletine that occur as a result of urinary pH changes might therefore be expected to be compensated by an increase in metabolic clearance, but this does not seem to occur in all patients.⁴

Importance and management

Although changes in urinary pH can affect the amount of mexiletine lost in the urine, the effect of diet or the concurrent use of alkalinisers (sodium bicarbonate, **acetazolamide**) or acidifiers (ammonium chloride etc.) on the plasma concentrations of mexiletine does not appear to be predictable. There appear to be no reports of adverse interactions but concurrent use should be monitored. The UK manufacturer of mexiletine recommends that the concomitant use of drugs that markedly acidify or alkalinise the urine should be avoided.⁵

Moracizine + Cimetidine

Cimetidine increases the plasma levels of moracizine but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects cimetidine 300 mg four times daily for 7 days, halved the clearance of a single 500-mg dose of moracizine and increased both its half-life and AUC by 39%. It is believed that this is because the cimetidine reduces moracizine metabolism by the liver.¹ Despite the increase in plasma moracizine levels, the PR and QRS intervals were not further prolonged. One possible explanation (so it is postulated) is that some of the metabolites of moracizine, whose production is inhibited by cimetidine, could also be pharmacologically active. Concurrent use should be well monitored, but measuring plasma moracizine levels may be of limited value because of the potential effects of the moracizine metabolites.

1. Biollaz J, Shaheen O, Wood AJJ. Cimetidine inhibition of ethmozine metabolism. *Clin Pharmacol Ther* (1985) 37, 665–8.

Moracizine + Diltiazem

A pharmacokinetic interaction occurs between moracizine and diltiazem resulting in increased systemic availability of moracizine and decreased systemic availability of diltiazem.

Clinical evidence, mechanism, importance and management

After 16 healthy subjects took both diltiazem 60 mg and moracizine 250 mg every 8 hours for 7 days, the maximum plasma concentration of moracizine was increased by 89%, the AUC was increased by 121%, and clearance was decreased by 54%. In contrast, the maximum plasma concentration and AUC of diltiazem decreased by 36% and clearance was increased by 52%. The AUCs for the diltiazem metabolites were not significantly affected. No clinically significant changes in ECG parameters were seen. However, the frequency of adverse events (e.g. headache, dizziness, paraesthesia) was greater on concurrent use (76%) than with either drug alone (54 and 45% for moracizine and diltiazem respectively).¹ Diltiazem probably inhibits the hepatic metabolism of moracizine while moracizine increases that of diltiazem. The clinical significance of this interaction is not known. However, particular caution is advised if diltiazem and moracizine are given concurrently, in light of the increase in adverse events. Dose adjustments may also be required to obtain optimum therapeutic responses.¹

Moracizine + Propranolol

Moracizine appears not to interact adversely with propranolol.

Clinical evidence, mechanism, importance and management

The efficacy and tolerability of the combination of propranolol and moracizine was compared with either drug alone in patients with ventricular arrhythmias in controlled trials. The combination was well tolerated, with no evidence of any adverse interactions, nor any beneficial interactions.

However, the dose of propranolol used was fairly low at 120 mg daily.^{1,2} Further study is needed.

Pirmenol + Cimetidine

Cimetidine 300 mg four times daily for 8 days had no significant effect on the pharmacokinetics of single 150-mg oral doses of pirmenol in 8 healthy subjects.¹ No clinically important interaction would therefore be expected in patients given both drugs.

1. Stringer KA, Lebsack ME, Cetnarowski-Cropp AB, Goldfarb AL, Radulovic LL, Bockbrader HN, Chang T, Sedman AJ. Effect of cimetidine administration on the pharmacokinetics of pirmenol. *J Clin Pharmacol* (1992) 32, 91–4.

Pirmenol + Rifampicin (Rifampin)

Rifampicin markedly increases the loss of pirmenol from the body. A reduction in its antiarrhythmic effects is likely to occur.

Clinical evidence, mechanism, importance and management

Treatment with rifampicin 600 mg daily for 14 days markedly affected the pharmacokinetics of a single 150-mg dose of pirmenol in 12 healthy subjects.¹ The apparent plasma clearance increased sevenfold and the AUC decreased by 83%.¹ The probable reason is that rifampicin increases the hepatic metabolism of pirmenol. Monitor well and anticipate the need to increase the dosage of pirmenol if rifampicin is used concurrently.

Procainamide + Amiodarone

When procainamide and amiodarone are used together the QT interval prolonging effects are increased, therefore the combination should generally be avoided. Serum procainamide levels are increased by about 60% and N-acetylprocainamide levels by about 30% by amiodarone. If the combination is used, the dosage of procainamide will need to be reduced to avoid toxicity.

Clinical evidence

Twelve patients were stabilised on procainamide (2 to 6 g daily, or about 900 mg every 6 hours). When amiodarone (600 mg loading dose every 12 hours for 5 to 7 days, then 600 mg daily) was also given their mean serum procainamide levels rose by 57% (from 6.8 to 10.6 micrograms/mL) and their serum levels of the metabolite N-acetylprocainamide (NAPA) rose by 32% (from 6.9 to 9.1 micrograms/mL). Procainamide levels increased by more than 3 micrograms/mL in 6 patients. The increases usually occurred within 24 hours, but in other patients they occurred as late as 4 or 5 days. Toxicity was seen in 2 patients. Despite lowering the procainamide dosages by 20%, serum procainamide levels were still higher (at 7.7 micrograms/mL) than before the amiodarone was started.¹

In another study, intravenous procainamide was given once before (at a mean dose of 13 mg/kg), and once during (at a 30% reduced dose: mean 9.2 mg/kg) the use of amiodarone 1.6 g daily for 7 to 14 days. Amiodarone decreased the clearance of procainamide by 23% and increased its elimination half-life by 38%. Both drugs prolonged the QRS and QTc intervals, and the extent of prolongation was significantly greater with the combination than either drug alone.²

Mechanism

The mechanism behind the pharmacokinetic interaction is not understood. The QT prolonging effects of the two drugs would be expected to be additive.

Importance and management

Information appears to be limited to these studies, but the interaction would seem to be established and clinically important. The use of amiodarone with procainamide further prolongs the QTc interval, which can increase the risk of torsade de pointes. Therefore, the combination should generally be avoided. The UK manufacturers of amiodarone contraindicate its use with class Ia antiarrhythmics such as procainamide,³ whereas the US manufacturers of amiodarone recommend that such combined therapy should be reserved for life-threatening ventricular arrhythmias incompletely responsive to either drug alone and recommend that the procainamide dosage should be reduced by one-third.⁴ See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257. This is similar to the recommendation made by the authors of the pharmacokinetic studies, who suggest that the dosage of procainamide may need to be reduced by 20 to 50%. They also suggest that serum levels should be monitored and patients observed for adverse effects.^{1,2} Remember that the interaction can develop within 24 hours.

Procainamide + Antacids or Antidiarrhoeals

There is some inconclusive evidence that aluminium phosphate may possibly cause a small reduction in the absorption of procainamide. Kaolin-pectin appears to reduce the bioavailability of procainamide.

Clinical evidence, mechanism, importance and management

A single 11-g dose of an aluminium phosphate antacid modestly reduced the AUC of a single 750-mg oral dose of procainamide by 14.6%.¹ The clinical importance of this interaction is uncertain, but probably small.

Kaolin-pectin was found to reduce the peak saliva concentrations and AUC of a single 250-mg dose of procainamide by about 30% in 4 healthy subjects. **Kaolin-pectin** and a variety of antacids (*Pepto-bismol*, *Simeco*, and **magnesium trisilicate**) absorbed procainamide *in vitro*.² The clinical importance of this is also uncertain.

Procainamide + Beta blockers

The pharmacokinetics of procainamide are little changed by either propranolol or metoprolol. Both sotalol and procainamide have QT-interval prolonging effects, which may be additive if they are used together.

Clinical evidence, mechanism, importance and management

Preliminary results of a study in 6 healthy subjects found that long-term treatment with **propranolol** [period and dosage not stated] increased the procainamide half-life from 1.71 to 2.66 hours and reduced the plasma clearance by 16%.¹ However, a later study in 8 healthy subjects found that the pharmacokinetics of a single 500-mg dose of procainamide were only slightly altered by **propranolol** 80 mg three times daily or **metoprolol** 100 mg twice daily. The procainamide half-life of 1.9 hours increased to 2.2 hours with **propranolol**, and to 2.3 hours with **metoprolol**, but no significant changes in total clearance occurred. No changes in the AUC of the metabolite N-acetylprocainamide were seen.² It seems unlikely that a clinically important adverse interaction normally occurs between these drugs.

A clinical study describes the successful use of procainamide with **sotalol**.³ However, both **sotalol** and procainamide can prolong the QT interval, and there may be an increased risk of torsade de pointes arrhythmias if

they are used together. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Procainamide + H₂-receptor antagonists

Serum procainamide levels can be increased by cimetidine and toxicity may develop, particularly in those who have a reduced renal clearance, such as the elderly. Ranitidine and famotidine appear to interact only minimally or not at all.

Clinical evidence

(a) Cimetidine

In one study, 36 elderly patients (65 to 90 years old) taking sustained-release oral procainamide every 6 hours had rises in mean steady-state serum levels of procainamide and its metabolite *N*-acetylprocainamide of 55 and 36% respectively, after taking cimetidine 300 mg every 6 hours for 3 days. This was tolerated in 24 patients without adverse effects (serum procainamide and *N*-acetylprocainamide less than 12 mg/L and less than 15 mg/L respectively) but the other 12 had some adverse effects (nausea, weakness, malaise PR interval increases of less than 20%), which was dealt with by stopping one or both drugs.¹ Another report describes an elderly man who developed procainamide toxicity when given cimetidine 1.2 g daily. His procainamide dosage was roughly halved (from 937.5 to 500 mg every 6 hours) to bring his serum procainamide and *N*-acetylprocainamide levels into the accepted therapeutic range.²

Four studies in healthy subjects have found that cimetidine increased the procainamide AUC by 24 to 43%, and decreased the renal clearance by 31 to 40%,³⁻⁶ these changes occurring even with single doses of cimetidine.⁵ A steady-state procainamide serum level increase of 43% has been seen when cimetidine 1.2 g daily was also given.⁶

(b) Famotidine

Famotidine 40 mg daily for 5 days did not affect the pharmacokinetics or pharmacodynamics of a single 5-mg/kg intravenous dose of procainamide in 8 healthy subjects.⁷

(c) Ranitidine

One study⁸ found that ranitidine 150 mg twice daily for one day reduced the absorption of procainamide from the gut by 10% and reduced its renal excretion by 19%, increasing the procainamide and *N*-acetylprocainamide AUC by about 14%. However, no change in the steady-state pharmacokinetics of procainamide was found with ranitidine 150 mg twice daily in another study, except that ranitidine delayed the time to maximum plasma concentration (from 1.4 to 2.7 hours).⁶ In a further study, ranitidine 150 mg twice daily for 4 days caused no significant changes in the mean pharmacokinetics of oral procainamide 1 g in 13 healthy subjects. However, it appeared that subjects had either a modest 20% increase or decrease in procainamide clearance, with the direction of change related to their baseline procainamide clearance: the higher the baseline clearance the greater the decrease caused by ranitidine.⁹

Mechanism

Procainamide levels in the body are increased because cimetidine reduces its renal excretion by about one-third or more, but the precise mechanism is uncertain. One suggestion is that it interferes with the active secretion of procainamide by the kidney tubules.^{3,4}

Importance and management

The interaction between procainamide and cimetidine is established. Concurrent use should be undertaken with care because the safety margin of procainamide is low. Reduce the procainamide dosage as necessary. This is particularly important in the elderly because they have a reduced ability to clear both drugs. Ranitidine and famotidine appear not to interact to a

clinically important extent, but it should be appreciated that what is known is based on studies in healthy subjects rather than patients.

Procainamide + Para-aminobenzoic acid (PABA)

A single case report found that para-aminobenzoic acid (PABA) increased the serum levels of procainamide and reduced the serum levels of the procainamide metabolite *N*-acetylprocainamide. In contrast, a later pharmacokinetic study in healthy subjects found that PABA had no effect on serum procainamide levels, and increased serum *N*-acetylprocainamide levels.

Clinical evidence, mechanism, importance and management

A 61-year-old man who had sustained ventricular tachycardia, which did not respond adequately to oral procainamide, was found to be a fast acetylator of procainamide, which resulted in particularly high serum levels of the procainamide metabolite (*N*-acetylprocainamide) when compared with the procainamide levels. When he was also given para-aminobenzoic acid (PABA) 1.5 g every 6 hours for 30 hours, to suppress the production of this metabolite, the serum level of procainamide increased, that of *N*-acetylprocainamide decreased, and control of his arrhythmia improved.¹ However, a later study in 10 healthy subjects, who were also fast acetylators, found that PABA did not significantly affect the pharmacokinetics of procainamide. In addition, although PABA inhibited the production of *N*-acetylprocainamide, it also inhibited renal excretion, so that the AUC and elimination half-life were increased. This suggests that PABA may in fact not be useful for increasing the efficacy and safety of procainamide.²

These contradictory findings are difficult to explain, but neither report suggests that concurrent use need be avoided.

Procainamide + Probenecid

The pharmacokinetics of a single 750-mg intravenous dose of procainamide and its effects on the QT interval were not altered by the prior administration of probenecid 2 g in 6 healthy subjects.¹ No special precautions appear to be necessary.

- Lam YWF, Boyd RA, Chin SK, Chang D, Giacomini KM. Effect of probenecid on the pharmacokinetics and pharmacodynamics of procainamide. *J Clin Pharmacol* (1991) 31, 429-32.

Procainamide + Quinidine

A single case report describes a marked increase in the plasma procainamide levels of a patient when he was also given quinidine. The combination prolongs the QT interval, and should generally be avoided because of the increased risk of torsade de pointes.

Clinical evidence

A man with sustained ventricular tachycardia taking high-dose intravenous procainamide 2 g every 8 hours had a 70% increase in his steady-state plasma procainamide levels, from 9.1 to 15.4 nanograms/mL, when he also took quinidine gluconate 324 mg every 8 hours. The procainamide half-life increased from 3.7 to 7.2 hours and its clearance fell from 27 to 16 L/hour. His QTc interval increased from 648 to 678 milliseconds.¹ In another study in patients with ventricular arrhythmias, quinidine was combined with procainamide. The doses were adjusted based in part on the QT interval. The QTc interval was longer with the combination (499 milliseconds) than each drug alone (quinidine 470 milliseconds, procainamide 460 milliseconds) despite using reduced doses in the combination (mean quinidine dose reduced by 28%; mean procainamide dose reduced by 32%).²

Mechanism

It has been suggested that the quinidine interferes with one or more of the renal pathways by which procainamide is cleared from the body.¹

Importance and management

Information on the possible pharmacokinetic interaction seems to be limited to this report. Both quinidine and procainamide are class Ia antiarrhythmics and prolong the QT interval, an effect that is increased with the combination. Such combinations should generally be avoided because of the increased risk of torsade de pointes. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Procainamide + Quinolones

Ofloxacin and levofloxacin cause moderate increases in the serum levels of procainamide, whereas ciprofloxacin has a lesser effect. However, the ECG appears to be unaltered in studies in healthy subjects given these quinolones with procainamide. An increased risk of torsade de pointes would be expected if procainamide is used with gatifloxacin, moxifloxacin, or sparfloxacin, and possibly levofloxacin.

Clinical evidence

Nine healthy subjects were given a single 1-g oral dose of procainamide alone, then again with the fifth dose of **ofloxacin** (400 mg given twice daily for five doses). **Ofloxacin** increased the AUC of procainamide by 27%, increased the maximum plasma levels by 21% (from 4.8 to 5.8 micrograms/L) and reduced the total clearance by 22%, whereas the pharmacokinetics of the active metabolite of procainamide (*N*-acetylprocainamide) were not significantly altered.¹ In another study 10 healthy subjects were given **levofloxacin** 500 mg once daily or **ciprofloxacin** 500 mg twice daily and a single 15-mg/kg intravenous dose of procainamide on day 5. **Levofloxacin** increased the AUC of procainamide by 21% and prolonged the half-life by about 19% (from 2.7 to 3.2 hours). The clearance of procainamide was reduced by 17% (range 4 to 46%) with renal clearance reduced by 26% (range 11 to 58%) by **levofloxacin**. The pharmacokinetics of *N*-acetylprocainamide were similarly affected. **Ciprofloxacin** caused only minor changes in procainamide and *N*-acetylprocainamide pharmacokinetics, although the renal clearance of procainamide was reduced by 15% (range 3 to 26%).²

Despite the pharmacokinetic changes, no ECG changes were detected. However, these studies^{1,2} involved only single doses of procainamide with average maximum serum levels (about 4 to 6 micrograms/mL) in the lower end of the therapeutic range for procainamide, although in one study individual levels of up to 8.5 micrograms/mL were found.¹

One case of torsade de pointes was noted in a patient taking procainamide with a quinolone [unspecified] in an analysis of cases of torsade de pointes associated with quinolones on the FDA Adverse Events Reporting

System database up to May 2001. The quinolones included were **ciprofloxacin, ofloxacin, levofloxacin, gatifloxacin, and moxifloxacin**, and in total there were 37 cases identified, of which 19 occurred in patients also taking other drugs known to prolong the QT interval.³

Mechanism

The probable reason for the interaction is that levofloxacin, ofloxacin and to a lesser extent ciprofloxacin, inhibit the secretion of unchanged procainamide by the kidney tubules via renal drug transporters. Levofloxacin also appears to inhibit the secretion of *N*-acetylprocainamide.

Importance and management

These results suggest that ofloxacin and levofloxacin interact to a modest extent and ciprofloxacin to a lesser extent with procainamide. The large interpatient variation found in these studies suggests it is possible that many patients will not experience a clinically significant interaction. However, in slow acetylators, in whom renal clearance contributes to a larger fraction of total clearance, and those on higher doses of procainamide (serum levels greater than 10 micrograms/mL), the use of quinolones could result in pharmacodynamic changes. Therefore, it would be prudent to monitor the outcome if procainamide and ofloxacin or ciprofloxacin are given together in patients. Monitoring has been recommended if procainamide is given with levofloxacin.² However, as there is also evidence that levofloxacin may prolong the QT interval (see 'Amiodarone + Quinolones', p.249) it may be best to avoid concurrent use of this quinolone and procainamide.

Of the quinolones used clinically, gatifloxacin, moxifloxacin, and **sparfloxacin** are known to prolong the QT interval (see 'Table 9.2', (p.257)) and would be expected to increase the risk of torsade de pointes arrhythmias when used with procainamide. These quinolones should probably be avoided in patients on procainamide (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257).

3. Frothingham R. Rates of torsades de pointes associated with ciprofloxacin, ofloxacin, levofloxacin, gatifloxacin, and moxifloxacin. *Pharmacotherapy* (2001) 21, 1468-72.

Procainamide + Sucralfate

Sucralfate does not appear to affect the absorption of procainamide.

Clinical evidence, mechanism, importance and management

In 4 healthy subjects sucralfate 1 g taken 30 minutes before a single 250-mg dose of procainamide reduced the mean maximum salivary level of procainamide by 5.3%, but did not significantly affect either the AUC or the rate of absorption.¹ These results suggest that a clinically significant interaction is unlikely.

1. Turkistani AAA, Gaber M, Al-Meshal MA, Al-Shora HI, Gouda MW. Effect of sucralfate on procainamide absorption. *Int J Pharmaceutics* (1990) 59, R1-R3.

Procainamide + Trimethoprim

Trimethoprim causes a marked increase in the plasma levels of procainamide and its active metabolite, *N*-acetylprocainamide, which increases the risk of toxicity.

Clinical evidence

Eight healthy subjects were given procainamide 500 mg every 6 hours for 3 days. The concurrent use of trimethoprim 200 mg daily increased the AUC₀₋₁₂ of procainamide and its active metabolite, *N*-acetylprocainamide (NAPA), by 63% and 51%, respectively. The renal clearance of procainamide and NAPA decreased by 47% and 13%, respectively. The QTc prolonging effects of procainamide were increased to a significant, but slight, extent by trimethoprim.¹ Another study found that trimethoprim 200 mg

daily reduced the renal clearance of a single 1-g dose of procainamide by 45% and of NAPA by 26%. The QTc interval was increased from 400 to 430 milliseconds.²

Mechanism

Trimethoprim decreases the renal clearance of both procainamide and its active metabolite by competing for active tubular secretion. It may also cause a small increase in the conversion of procainamide to *N*-acetylprocainamide.¹

Importance and management

An established interaction but its documentation is limited. The need to reduce the procainamide dosage should be anticipated if trimethoprim is given to patients already controlled on procainamide. In practice the effects may be greater than the studies cited suggest because the elderly lose procainamide through the kidneys more slowly than young healthy subjects. Remember too that the daily dosage of trimethoprim in **co-trimoxazole** (trimethoprim 160 mg with sulfamethoxazole 800 mg) may equal or exceed the dosages used in the studies cited.

Propafenone + Barbiturates

Phenobarbital increases the metabolism of propafenone and reduces its serum levels.

Clinical evidence, mechanism, importance and management

In a preliminary report of a study in 7 non-smoking subjects who were fast metabolisers of propafenone, **phenobarbital** 100 mg daily for 3 weeks reduced the levels of a single 300-mg dose of propafenone by 26 to 87% and the AUC by 10 to 89%. The intrinsic clearance increased by 11 to 84%. The results in a further 4 heavy smokers were similar.¹ These changes probably occur because **phenobarbital** (a potent stimulator of liver enzymes) increases the metabolism of the propafenone. The clinical importance of this awaits assessment, but check that propafenone remains effective if **phenobarbital** is added, and that toxicity does not occur if it is stopped. If the suggested mechanism is correct, other barbiturates would be expected to interact similarly.

1. Chan GL-Y, Axelson JE, Kerr CR. The effect of phenobarbital on the pharmacokinetics of propafenone in man. *Pharm Res* (1988) 5, S153.

Propafenone + Cimetidine

Cimetidine appears to interact minimally with propafenone.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects (10 extensive metabolisers and 2 poor metabolisers of propafenone) given propafenone 225 mg every 8 hours found that the concurrent use of cimetidine 400 mg every 8 hours caused some changes in the pharmacokinetics and pharmacodynamics of the propafenone, with wide intersubject variability. Raised mean peak and steady-state plasma levels were seen (24 and 22%, respectively), but these did not reach statistical significance. A slight increase in the QRS duration also occurred.¹ However, none of the changes were considered clinically important.

1. Pritchett ELC, Smith WM, Kirsten EB. Pharmacokinetic and pharmacodynamic interactions of propafenone and cimetidine. *J Clin Pharmacol* (1988) 28, 619–24.

Propafenone + Erythromycin

Limited evidence suggests that erythromycin may inhibit the metabolism of propafenone.

Clinical evidence, mechanism, importance and management

The preliminary results of a study in 12 healthy subjects given a single 300-mg dose of propafenone with or without erythromycin 250 mg showed that the increase in propafenone AUC with erythromycin was greater in those with lower cytochrome P450 isoenzyme CYP2D6 activity. It was suggested¹ that low CYP2D6 activity shifts propafenone metabolism to the CYP3A4/1A2-mediated *N*-depropylpropafenone pathway increasing the interaction with erythromycin, which is an inhibitor of CYP3A4. This appears to be the only documentation of a possible interaction with erythromycin and its clinical significance is not certain. More study is needed.

Propafenone + Grapefruit juice

Limited evidence suggests that grapefruit juice may inhibit the metabolism of propafenone.

Clinical evidence, mechanism, importance and management

Preliminary results of a study in 12 healthy subjects given a single 300-mg dose of propafenone with or without 250 mL of grapefruit juice showed that the increase in propafenone AUC with grapefruit juice was greater in those with lower cytochrome P450 isoenzyme CYP2D6 activity. It was suggested¹ that in the presence of low CYP2D6 activity a greater proportion of propafenone is eliminated by metabolism by CYP3A4 and CYP1A2 and the effect of grapefruit juice is increased since it is an inhibitor of CYP3A4. The clinical significance of this finding is not certain. Further study is needed.

Propafenone + Ketoconazole

An isolated case report describes a man taking propafenone who had a seizure two days after taking a dose of ketoconazole. Limited evidence suggests ketoconazole may inhibit the metabolism of propafenone.

Clinical evidence

A man who had been taking captopril and hydrochlorothiazide for 6 years and propafenone 300 mg daily for 4 years, without problems, and without any history of convulsive episodes, experienced a tonic-clonic seizure while watching television. It was later found that he had started to take two capsules of ketoconazole daily 2 days previously for the treatment of a candidal infection.¹ The preliminary results of another study in 12 healthy subjects given a single 300-mg dose of propafenone with or without ketoconazole 200 mg found that the increase in propafenone AUC with ketoconazole was greater in those with lower cytochrome P450 isoenzyme CYP2D6 activity.²

Mechanism

The authors of the case report postulate that the ketoconazole may have inhibited the metabolism of the propafenone so that this patient, in effect, may have developed an overdose.¹ However, convulsions with propafenone, even in overdose, are extremely rare.³ Ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which propafenone is metabolised to *N*-depropylpropafenone. Propafenone is also extensively metabolised by CYP2D6 to 5-hydroxypropafenone but it was suggested that if CYP2D6 activity is low, propafenone metabolism may be shifted to the CYP3A4 pathway increasing the possibility of an interaction with ketoconazole.² The manufacturer states that drugs that inhibit CYP2D6 and CYP3A4, such as ketoconazole, might lead to increased levels of propafenone.⁴

Importance and management

The general importance of this interaction is uncertain. As of 2006, there had been no other cases reported to the manufacturer of propafenone.⁴ As

available data suggest that an interaction can occur, it would seem prudent to keep this interaction in mind during concurrent use. There seems to be nothing documented about the effects of other azole antifungals.

Propafenone + Quinidine

Quinidine doubles the plasma levels of propafenone and halves the levels of its active metabolite in CYP2D6 extensive metabolisers. This interaction has been utilised clinically.

Clinical evidence

Nine patients taking propafenone for frequent isolated ventricular ectopic beats, firstly had their dosage reduced to 150 mg every 8 hours and then 4 days later the steady-state pharmacokinetics of propafenone were determined at this new dose. Quinidine was then added at a dose of 50 mg every 8 hours, and after a further 4 days the steady-state plasma propafenone levels in 7 CYP2D6 extensive metabolisers had more than doubled from 408 to 1100 nanograms/mL, and 5-hydroxypropafenone concentrations had approximately halved, but the ECG intervals and arrhythmia frequency were unaltered. The steady-state plasma propafenone levels remained unchanged in the other 2 patients with low levels of CYP2D6 ('poor' metabolisers).¹ Consider 'Genetic factors', (p.4), for more information on metaboliser status. The same research group conducted a similar study in healthy subjects, which confirmed that quinidine increased the plasma levels of propafenone in 'extensive' but not 'poor' metabolisers. In addition, it was found that quinidine increased the extent of the beta-blockade caused by the propafenone in 'extensive' metabolisers to approach that seen in 'poor' metabolisers.² Another study has shown that the inhibition of propafenone metabolism by low-dose quinidine also occurs in Chinese as well as Caucasian patients.³ [CYP2D6 shows pronounced interethnic differences in expression.] A further study showed that combining low-dose quinidine (150 mg daily) with standard dose propafenone in patients with atrial fibrillation resulted in a similar control of the arrhythmia as increasing the propafenone dose, but caused less gastrointestinal adverse effects.⁴

Mechanism

Quinidine inhibits the CYP2D6-dependent 5-hydroxylation of propafenone by the liver in those who are 'extensive' metabolisers so that it is cleared more slowly. Its plasma levels are doubled as a result, but the overall antiarrhythmic effects remain effectively unchanged, possibly because the production of its active antiarrhythmic metabolite (5-hydroxypropafenone) is simultaneously halved.¹ Quinidine increases the beta-blocking effects of propafenone in extensive metabolisers because only the parent drug, and not the metabolites, has beta-blocking activity.²

Importance and management

Quinidine appears to raise propafenone levels, and may also affect the beta-blocking properties of propafenone in some patients. In one study the concurrent use of propafenone and quinidine was said to have an effect similar to increasing the propafenone dose.⁴ The importance of CYP2D6 metaboliser status is unclear, and more study is needed to clarify this.

Propafenone + Rifampicin (Rifampin)

Propafenone serum levels and therapeutic effects can be markedly reduced by rifampicin.

Clinical evidence

A man with ventricular arrhythmias successfully treated with propafenone had a marked fall in his plasma propafenone level from 993 to 176 nanograms/mL within 12 days of starting to take rifampicin 450 mg twice daily. Levels of the two active metabolites of propafenone, 5-hydroxypropafenone and *N*-depropylpropafenone, changed from 195 to 64 nanograms/mL and from 110 to 192 nanograms/mL, respectively. His arrhythmias returned, but 2 weeks after stopping the rifampicin his arrhythmias had disappeared and the propafenone and its 5-hydroxy and *N*-depropyl metabolites had returned to acceptable levels (1411, 78 and 158 nanograms/mL respectively).¹ In a study in young healthy subjects, rifampicin 600 mg daily for 9 days reduced the bioavailability of a single 300-mg oral dose of propafenone from 30 to 10% in CYP2D6 extensive metabolisers, and from 81 to 48% in those with low levels of CYP2D6 ('poor' metabolisers). Consider 'Genetic factors', (p.4), for more information on metaboliser status. QRS prolongation decreased during enzyme induction. In contrast, in this study, rifampicin had no substantial effect on the pharmacokinetics of propafenone given intravenously.² Similar findings were reported in a further study by the same research group in healthy elderly subjects.³

Mechanism

Rifampicin induces the CYP3A4/1A2-mediated metabolism and phase II glucuronidation of propafenone. The effect of rifampicin on gastrointestinal clearance of propafenone was greater than that of its hepatic clearance. Rifampicin had no effect on CYP2D6-mediated metabolism of propafenone (the usual main metabolic route in 'extensive' metabolisers).^{2,3}

Importance and management

An established and clinically relevant metabolic drug interaction. The dosage of oral propafenone will need increasing during concurrent use of rifampicin.³ Alternatively, if possible, the authors of the case report¹ advise the use of another antibacterial, where possible, because of the probable difficulty in adjusting the propafenone dosage.

Propafenone + SSRIs

Fluoxetine markedly inhibits the metabolism of propafenone by 5-hydroxylation, and paroxetine would be expected to behave similarly, but the clinical consequences of this are unknown. Fluvoxamine would be expected to inhibit the metabolism of propafenone by *N*-dealkylation. Sertraline, citalopram (and probably escitalopram) would not be expected to interact to a significant extent.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects **fluoxetine** 20 mg daily for 10 days decreased the oral clearance of a single 400-mg dose of propafenone by 34% for both the *R*- and *S*-enantiomers. The peak plasma levels increased by 39% for *S*-propafenone and by 71% for *R*-propafenone. However, there were no differences in the changes to the PR and QRS intervals.¹ **Fluoxetine** is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, which is responsible for the metabolism of propafenone to its primary active metabolite 5-hydroxypropafenone (for more detail see mechanism under 'Propafenone + Quinidine', above). *In vitro* data have shown that, of the SSRIs, **fluoxetine** is the most potent inhibitor of propafenone 5-hydroxylation, and that **paroxetine** would also be expected to interact.² As with

'quinidine', (p.275), inhibition of 5-hydroxylation would be expected to increase the beta-blocking effects of propafenone.² Until more is known, it would be prudent to use caution when giving **fluoxetine** or **paroxetine** with propafenone. **Sertraline** and **citalopram** did not interact *in vitro*.² Similarly, **escitalopram** would not be expected to interact significantly because evidence with other drugs ('desipramine', (p.1241) and 'metoprolol', (p.855)) suggest that **escitalopram** has only a modest inhibitory effect on CYP2D6. However, the manufacturers³ still warn about a possible interaction with propafenone.

Although **fluvoxamine** had no effect on propafenone 5-hydroxylation *in vitro*,² it did inhibit propafenone *N*-dealkylation² via its inhibitory effects on the cytochrome P450 isoenzyme CYP1A2. This isoenzyme has only a minor role in the metabolism of propafenone, but it may assume greater importance in those who have low levels of CYP2D6 ('poor' metabolisers).² Further study is needed.

Quinidine + Amiloride

A single study has shown that the antiarrhythmic activity of quinidine can be opposed by amiloride.

Clinical evidence

A study in 10 patients with inducible sustained ventricular tachycardia was carried out to see whether a beneficial interaction occurred between quinidine and amiloride. Patients were given oral quinidine until their trough serum levels reached 10 micromol/L, or the maximum well-tolerated dose was reached. After electrophysiological studies, oral amiloride was added at a dosage of 5 mg twice daily, increased up to 10 mg twice daily (if serum potassium levels remained normal) for 3 days. The electrophysiological studies were then repeated. Unexpectedly, 7 of the 10 patients demonstrated adverse responses while taking both drugs. Three developed sustained ventricular tachycardia and 3 others had somatic adverse effects (hypotension, nausea, diarrhoea), which prevented further studies being carried out. One patient had 12 episodes of sustained ventricular tachycardia while taking both drugs. Amiloride had no effect on quinidine levels.¹

Mechanism

Not understood. The combination of quinidine and amiloride increased the QRS interval, but did not prolong the QT interval more than quinidine alone.

Importance and management

So far the evidence seems to be limited to this single study but it suggests that amiloride can oppose the antiarrhythmic activity of quinidine. The full clinical implications of this interaction are not yet known, but it would now clearly be prudent to consider monitoring to confirm that the quinidine continues to be effective if amiloride is present.

1. Wang L, Sheldon RS, Mitchell B, Wyse DG, Gillis AM, Chiamvimonvat N, Duff HJ. Amiloride-quinidine interaction: adverse outcomes. *Clin Pharmacol Ther* (1994) 56, 659–67.

Quinidine + Amiodarone

The QT interval prolonging effects of quinidine and amiodarone are increased when they are used together, and torsade de pointes has occurred. Therefore the combination should generally be avoided. However, if the combination is used, note that amiodarone increases quinidine levels and dosage reductions are likely to be needed.

Clinical evidence

Eleven patients were stabilised on quinidine (daily doses of 1.2 to 4.2 g). When they were also given amiodarone (600 mg every 12 hours for 5 to 7 days, then 600 mg daily) their mean serum quinidine levels rose by an average of 32%, from 4.4 to 5.8 micrograms/mL and 3 of them had a substantial increase of 2 micrograms/mL. Signs of toxicity (diarrhoea, nausea, vomiting, hypotension) were seen in some, and the quinidine dosage was reduced in 9 of the patients by an average of 37%. Despite the dose reduction, the quinidine serum levels were still higher at 5.2 micrograms/mL than before the amiodarone was started.¹

A test in a healthy subject showed that 3 days after amiodarone 600 mg was added to quinidine 1.2 g daily, the serum quinidine levels doubled and the relative QT interval was prolonged from 1 (no drugs) to 1.2 (quinidine alone) to 1.4 (quinidine plus amiodarone).² This report also described two patients with minor cardiac arrhythmias who developed QT prolongation and torsade de pointes when given both drugs.² A Russian study of the use of the combination in atrial fibrillation reported that one of 52 patients had a 50% increase in the QT interval resulting in torsade de pointes and subsequently ventricular fibrillation, which required repeated defibrillation over 6 hours.³ A 76-year-old man taking quinidine and amiodarone had a number of episodes of loss of consciousness, and subsequently QT prolongation and torsade de pointes, which stopped when the quinidine was discontinued.⁴

Mechanism

The mechanism behind the pharmacokinetic interaction is not understood. The QT prolonging effects of the two drugs would be expected to be additive.

Importance and management

An established and clinically important pharmacokinetic and pharmacodynamic interaction. The use of amiodarone with quinidine further prolongs the QT interval and increases the risk of torsade de pointes. Therefore, the combination should generally be avoided. The UK manufacturer of amiodarone contraindicates its use with class Ia antiarrhythmics such as quinidine.⁵ See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257. The pharmacokinetic component appears to occur in most patients, and to develop rapidly. The US manufacturer⁶ of amiodarone considers such combination therapy should be reserved for life-threatening ventricular arrhythmias incompletely responsive to either drug alone and recommend that the dose of quinidine should be reduced by one-third. Others suggest that if the two drugs are considered essential, the dosage of quinidine should be reduced by about 30 to 50% and the serum levels should be monitored.¹ The ECG should also be monitored for evidence of changes in the QT interval when combined therapy is started or stopped.⁷ Successful and uneventful concurrent use has been described in a report of 4 patients taking quinidine [dose not stated] and amiodarone 200 mg five times weekly.⁸ Another describes the successful use of a short course of quinidine to convert chronic atrial fibrillation to sinus rhythm in 9 of 15 patients on long-term amiodarone therapy. Patients were hospitalised and continuously monitored. No proarrhythmias occurred and the QT interval remained within acceptable limits.⁹

Quinidine + Antacids or Urinary alkalinisers

Large rises in urinary pH due to the concurrent use of some antacids, diuretics or alkaline salts can cause quinidine retention, which could lead to quinidine toxicity, but there seems to be only one case on record of an adverse interaction (with an aluminium/magnesium hydroxide antacid). Aluminium hydroxide alone appears not to interact.

Clinical evidence

The renal clearance of oral quinidine in 4 subjects taking 200 mg every 6 hours was reduced by an average of 50% (from 53 to 26 mL/minute) when their urine was made alkaline (i.e. changed from pH 6 to 7, up to pH 7 to 8) with **sodium bicarbonate** and **acetazolamide** 500 mg twice daily. Below pH 6 their urinary quinidine level averaged 115 mg/L, whereas when urinary pH values rose above 7.5 the average quinidine level fell to 13 mg/L. The quinidine urinary excretion rate decreased from 103 to 31 micrograms/minute. In 6 other subjects the rise in serum quinidine levels was reflected in a prolongation of the QT interval. Raising the urinary pH from about 6 to 7.5 in one individual increased serum quinidine levels from about 1.6 to 2.6 micrograms/mL.¹

A patient on quinidine who took eight *Mylanta* tablets daily (**aluminium hydroxide** gel 200 mg, **magnesium hydroxide** 200 mg and simeticone 20 mg) for a week and a little over 1 litre of fruit juice (orange and grapefruit) each day developed a threefold increase in serum quinidine levels (from 8 to 25 mg/L) and toxicity. However, note that the 'grapefruit juice', (p.280) may have contributed. In 6 healthy subjects, this dose of *Mylanta* for 3 days produced consistently alkaline urine in 4 subjects, and in 5 subjects when combined with fruit juice.²

In 4 healthy subjects, 30 mL of **aluminium hydroxide** gel (*Amphogel*) given with, and one hour after, a single 200-mg dose of quinidine sulphate had no effect on serum quinidine levels, AUC or excretion (urine pH ranged from 5 to 6.2).³ Two similar single-dose studies in healthy subjects found that the absorption and elimination of 400 mg of quinidine sulphate⁴ or 648 mg of quinidine gluconate⁵ was unaffected by 30 mL **aluminium hydroxide** gel, although the change in quinidine AUC did vary from a decrease of 18% to an increase of 35% in one study.⁵ Urinary pH was unaffected in both studies.^{4,5}

Mechanism

Quinidine is excreted unchanged in the urine. In acid urine much of the quinidine excreted by the kidney tubules is in the ionised (lipid-insoluble) form, which is unable to diffuse freely back into the cells and so is lost in the urine. In alkaline urine more of the quinidine is in the non-ionised (lipid-soluble) form, which freely diffuses back into the cells and is retained. In this way the pH of the urine determines how much quinidine is lost or retained and thereby governs the serum levels. *In vitro* data suggest that changes in pH and adsorption effects within the gut due to antacids could also affect the absorption of quinidine.^{6,7}

Importance and management

An established interaction, but with the exception of the one isolated case cited,² there seem to be no reports of problems in patients given quinidine and antacids or urinary alkalinisers. However, in this case quinidine was given with grapefruit juice, which may potentially have had an effect of its own, see 'Quinidine + Grapefruit juice', p.280. Nevertheless you should monitor the effects if drugs that can markedly change urinary pH are started or stopped. Reduce the quinidine dosage as necessary.

It is difficult to predict which antacids, if any, are likely to increase the serum levels of quinidine. As noted above, aluminium hydroxide gel and magnesium hydroxide (*Mylanta*) alkalinises urine and can interact. Similarly, magnesium and aluminium hydroxide (*Maalox*) can raise the urinary pH by about 0.9 and could possibly interact.⁸ Magnesium hydroxide (*Milk of magnesia*) and **calcium carbonate-glycine** (*Titrinalc*) in normal doses raise the urinary pH by about 0.5, so that a smaller effect is likely.⁸ Aluminium hydroxide gel (*Amphogel*) and **dihydroxyaluminium glycinate** (*Robalate*) are reported to have no effect on urinary pH,⁸ and the studies above confirm aluminium hydroxide gel does not generally interact.

Quinidine + Antiepileptics

Serum quinidine levels can be reduced by phenytoin, phenobarbital or primidone. Loss of arrhythmia control is possible if the quinidine dosage is not increased.

Clinical evidence

A man taking long-term **primidone** 500 mg daily was given quinidine 300 mg every 4 hours, but only attained a plasma quinidine level of 0.8 micrograms/mL with an estimated half-life of 5 hours. When **primidone** was discontinued, his quinidine level rose to 2.4 micrograms/mL and the half-life was 12 hours. **Phenobarbital** 90 mg daily was then started, and the quinidine level fell to 1.6 micrograms/mL with a half-life of 7.6 hours. In another case, a woman required doses of quinidine sulfate of up to 800 mg every 4 hours to achieve therapeutic levels while taking **phenytoin**. When the **phenytoin** was stopped, quinidine toxicity occurred, and the dose was eventually halved. Further study was then made in 4 healthy subjects. After 4 weeks of treatment with either **phenytoin** (in dosages adjusted to give levels of 10 to 20 micrograms/mL) or **phenobarbital**, the elimination half-life of a single 300-mg dose of quinidine sulphate was reduced by about 50% and the total AUC was reduced by about 60%.¹

Similar results were found with **phenytoin** in another study in 3 healthy subjects.² Other cases have also been reported with **phenytoin**, **primidone**, **pentobarbital** and **phenobarbital**.³⁻⁶ In one case, quinidine levels fell by 44% when **phenytoin** was given with quinidine to a patient with recurrent ventricular tachycardia.⁵ In another report quinidine levels increased from a mean of 0.8 to 2.2 micrograms/mL 15 days after **pentobarbital** was discontinued.⁴ Interestingly, in this case the patient was also on **digoxin**, and stopping phenobarbital precipitated **digoxin** toxicity by causing an increase in quinidine levels.

A 3-year-old child taking both **phenobarbital** and **phenytoin** required quinidine 300 mg every 4 hours to achieve therapeutic serum quinidine levels, and had an estimated quinidine half-life of only 1.4 hours.⁵ Difficulty in achieving adequate serum quinidine levels was also reported in a woman taking **phenytoin** and **primidone**. Her quinidine half-life was 2.7 hours, about half that usually seen in adults.⁶

Quinidine 200 mg had no effect on the metabolism (4-hydroxylation) of **mephenytoin** 100 mg in 10 healthy subjects.⁷

Mechanism

The evidence suggests that phenytoin, primidone or phenobarbital (all known enzyme-inducers) increase the hepatic metabolism of quinidine and thereby reduce its levels.²

Importance and management

Established interactions of clinical importance although the documentation is limited. The concurrent use of phenytoin, primidone, phenobarbital or any other barbiturate need not be avoided, but be alert for the need to increase the quinidine dosage. If the anticonvulsants are withdrawn the quinidine dosage may need to be reduced to avoid quinidine toxicity. Where possible, quinidine serum levels should be monitored.

Quinidine + Aspirin

A patient and two healthy subjects given quinidine and aspirin had a two- to threefold increase in bleeding times. The patient developed petechiae and gastrointestinal bleeding.

Clinical evidence, mechanism, importance and management

A patient with a prolonged history of paroxysmal atrial tachycardia was given quinidine 800 mg daily and aspirin 325 mg twice daily. After a week he developed generalised petechiae and blood in his faeces. His prothrombin and partial prothrombin times were normal but the template bleeding time was more than 35 minutes (normal 2 to 10 minutes). Further study in two healthy subjects showed that quinidine 975 mg daily given alone for 5 days and aspirin 650 mg three times a day given alone for 5 days prolonged bleeding times by 125% and 163% respectively; given together for 5 days the bleeding times were prolonged by 288%.¹ The underlying mechanism is not totally understood but it is believed to be the outcome of the additive effects of two drugs, both of which can reduce platelet aggregation,¹ although with quinidine this antiplatelet effect usually only occurs as the result of a hypersensitivity reaction.

This seems to be the only study of this adverse interaction, and its general importance is uncertain. It may be prudent to monitor concurrent use to check that bleeding does not occur.

Quinidine + Calcium-channel blockers

A few patients have shown increased serum quinidine levels when stopping nifedipine, but in others no interaction has occurred and one study even suggests that quinidine serum levels may be slightly raised by nifedipine. Nifedipine levels may be modestly raised by quinidine. Verapamil reduces the clearance of quinidine and in one patient the serum quinidine levels doubled and quinidine toxicity developed. Acute hypotension has also been seen in three patients taking quinidine when they were given verapamil intravenously. Felodipine and nisoldipine appear not to interact, and the situation with diltiazem is unclear.

Clinical evidence

(a) Diltiazem

A study in 10 healthy subjects given quinidine 600 mg twice daily and diltiazem 120 mg daily for 7 days found that the pharmacokinetics of neither drug was affected by the presence of the other.¹ These findings contrast with another crossover study in 12 healthy subjects in which a single 60-mg dose of diltiazem was given before and after quinidine 100 mg twice daily for 5 doses, and a single 200-mg dose of quinidine was given before and after diltiazem 90 mg twice daily for 5 doses. The pharmacokinetics of diltiazem were unaffected by quinidine, but the AUC of quinidine was increased by 51% by diltiazem.² When quinidine was given after diltiazem pretreatment, there were significant increases in QTc and PR intervals, and a significant decrease in heart rate and diastolic blood pressure. Pretreatment with quinidine did not significantly alter the effects of diltiazem.²

(b) Felodipine

Felodipine 10 mg daily for 3 days was found to have no clinically significant effect on the pharmacokinetics or haemodynamic and ECG effects of a single 400-mg dose of quinidine in 12 healthy subjects. Felodipine did cause a modest 22% decrease in the AUC of the quinidine metabolite 3-hydroxyquinidine.³

(c) Nifedipine

1. Quinidine serum levels. The quinidine serum levels of 2 patients taking quinidine sulfate 300 or 400 mg every 6 hours and nifedipine 10 or 20 mg every 6 or 8 hours doubled (from a range of 2 to 2.5 up to 4.6 micrograms/mL and from 1.6 to 1.8 up to 3.5 micrograms/mL respectively) when the nifedipine was withdrawn. The increased serum quinidine levels were reflected in a prolongation of the QTc interval. However, in the first patient there had been no change in quinidine levels when nifedipine was initially added to his existing quinidine therapy. Further, 4 other patients did not develop this interaction.⁴ Two other reports^{5,6} describe a similar response: the quinidine serum level doubled in one patient when the nifedipine was stopped,⁵ and in the other it was found difficult to achieve adequate serum quinidine levels when nifedipine was added, even when the quinidine dosage was increased threefold. When the nifedipine was withdrawn, the quinidine levels rose once again.⁶ A study in 12 patients found no significant change in serum quinidine levels in the group as a whole when given nifedipine, but one patient had a 41% decrease in quinidine levels.⁷ Two other studies in healthy subjects found that the quinidine AUC was unchanged by nifedipine.^{3,8} A further study in 12 healthy subjects found that the AUC of a single 200-mg oral dose of quinidine sulphate was increased by 16% by nifedipine 20 mg. The quinidine clearance was reduced by 14% and the maximum serum level was raised by almost 20%. These modest changes were not considered clinically relevant.⁹

2. Nifedipine serum levels. In a study in 10 healthy subjects quinidine sulfate 200 mg every 8 hours increased the AUC of nifedipine by 37%, and heart rates were significantly increased. Quinidine levels were unchanged.⁸ Another study found that quinidine had a modest inhibitory effect on the metabolism of nifedipine (half-life prolonged by 40%).¹⁰ A further study in 12 healthy subjects found that the AUC of a single 20-mg dose of nifedipine was increased 16% by quinidine 200 mg and its clearance was reduced by 17%, but these modest changes were not considered clinically relevant.⁹

(d) Nisoldipine

An open crossover study in 20 healthy subjects found that nisoldipine 20 mg had no effect on the bioavailability of quinidine gluconate 648 mg.¹¹

(e) Verapamil

After taking verapamil 80 mg three times daily for 3 days, the clearance of a single 400-mg dose of quinidine sulphate in 6 healthy subjects was decreased by 32% and the half-life was increased by 35% from 6.87 to 9.29 hours.¹²

A patient given quinidine gluconate 648 mg every 6 hours had an increase in serum quinidine levels from 2.6 to 5.7 micrograms/mL when given verapamil 80 mg every 8 hours for a week. He became dizzy and had blurred vision and was found to have atrioventricular block (heart rate 38 bpm) and a systolic blood pressure of 50 mmHg. In a subsequent study in this patient it was found that the verapamil halved the quinidine clearance and almost doubled the serum half-life.¹³

Three other patients given quinidine orally developed marked hypotension when given intravenous verapamil 2.5 or 5 mg (blood pressure fall from 130/70 to 80/50 mmHg, systolic pressure fall from 140 to 85 mmHg and a mean arterial pressure fall from 100 to 60 mmHg, in the 3 patients respectively). In two of the patients, after quinidine was discontinued, the same dose of verapamil did not cause a drop in blood pressure.¹⁴

Mechanism

Suggestions for how nifedipine could alter quinidine levels include changes in cardiovascular haemodynamics,⁴ and effects on metabolism.⁷ Quinidine probably inhibits the metabolism of nifedipine by competing for metabolism by the cytochrome P450 isoenzyme CYP3A4.¹⁰ The interaction with verapamil is probably due to an inhibitory effect of verapamil on the metabolism of quinidine (inhibition of cytochrome P450 isoenzyme CYP3A).^{12,15} The marked hypotension observed may be related to the antagonistic effects of the two drugs on catecholamine-induced alpha-receptor induced vasoconstriction.¹⁴

Importance and management

The results of studies of the interaction between quinidine and nifedipine are inconsistent and contradictory, so that the outcome of concurrent use is uncertain. Monitor the response, being alert for the need to modify the

dosage. More study of this interaction is needed. Quinidine appears to increase nifedipine levels, but the importance of this is uncertain.

What is known about the interaction between quinidine and verapamil suggests that a reduction in the dosage of the quinidine may be needed to avoid toxicity. If the verapamil is given intravenously, use with caution and be alert for evidence of acute hypotension. Monitor the effects of concurrent use closely. There is actually a fixed dose preparation containing verapamil and quinidine (*Cordichin*) available in Germany, which is used for the management of atrial fibrillation. No interaction apparently occurs between quinidine and felodipine or nisoldipine. The situation with diltiazem is as yet uncertain but be alert for the need to reduce the quinidine dosage.

Quinidine + Colesevelam

A single 4.5-g dose of colesevelam had no significant effect on the pharmacokinetics of a single 324-mg dose of quinidine in 25 healthy subjects.¹ This suggests that colesevelam does not reduce the absorption of quinidine. No special precautions appear to be needed during concurrent use.

Quinidine + Co-phenotrope (Atropine/Diphenoxylate)

Co-phenotrope slightly reduced the rate, but not the extent, of absorption of a single dose of quinidine.

Clinical evidence, mechanism, importance and management

In one study, 8 healthy subjects were given a single 300-mg dose of quinidine sulfate alone and after taking two tablets of co-phenotrope (atropine sulfate 25 micrograms, diphenoxylate 2.5 mg; *Lomotil*) at midnight on the evening before and another two tablets the next morning an hour before the quinidine.¹ It was found that the maximum plasma quinidine levels were reduced by 21% from 2.1 to 1.65 micrograms/mL by the co-phenotrope, the time to maximum level was prolonged from 0.89 to 1.21 hours, and there was a slight increase in elimination half-life from 5.7 to 6.8 hours. While these results were statistically significant, the changes

were relatively small and it seems doubtful if they are clinically relevant, particularly as the extent of absorption was unchanged. However it needs to be emphasised that because the quinidine formulation used was an immediate-release preparation, these results may not necessarily apply to sustained-release preparations, and also may not apply if multiple doses of quinidine are used.

Quinidine + Diazepam

A single dose study suggests that diazepam does not affect the pharmacokinetics of quinidine.

Clinical evidence, mechanism, importance and management

A comparative study in 8 healthy subjects found that the pharmacokinetics of a single 250-mg dose of quinidine sulfate was unaltered by a single 10-mg dose of diazepam.¹ This suggests that no interaction between these drugs is likely but it needs confirmation by further studies using multiple doses of both drugs.

1. Rao BR, Rambhau D. Absence of a pharmacokinetic interaction between quinidine and diazepam. *Drug Metabol Drug Interact* (1995) 12, 45–51.

Quinidine + Diclofenac

Diclofenac inhibits the metabolism (N-oxidation) of quinidine but does not affect other pharmacokinetic parameters. *In vitro* and animal data suggest that quinidine may increase the metabolism of diclofenac.

Clinical evidence, mechanism, importance and management

In an open study, 6 healthy subjects were given a single 200-mg dose of quinidine sulfate before and on day 5 of a 6-day course of diclofenac 100 mg daily. Diclofenac reduced the N-oxidation of quinidine by 33%, but no other pharmacokinetic changes were found.¹ Diclofenac is a substrate for, and therefore a possible competitive inhibitor of the cytochrome P450 isoenzyme CYP2C9. These results suggest that CYP2C9 does not appear to have a major role in quinidine metabolism,¹ and so clinically relevant changes in quinidine pharmacokinetics with diclofenac would seem unlikely.

A study in *monkeys* found that plasma levels of diclofenac were approximately halved when diclofenac was given with quinidine (both by portal vein infusion).² *In vitro* study³ has shown that quinidine stimulates the metabolism of diclofenac to its 5-hydroxylated derivative, via its effects on CYP3A4. Further study is required to assess the clinical relevance of these findings.

Quinidine + Disulfiram

Disulfiram does not affect the pharmacokinetics of quinidine.

Clinical evidence, mechanism, importance and management

In an open study, 6 healthy subjects were given a single 200-mg dose of quinidine sulfate before and on day 5 of a 6-day course of disulfiram 200 mg daily. There were no changes in quinidine pharmacokinetics during disulfiram administration.¹ Disulfiram is thought to be an inhibitor of the cytochrome P450 isoenzyme CYP2E1, but this isoenzyme does not

appear to have a major role in quinidine metabolism.¹ Clinically relevant pharmacokinetic interactions between quinidine and disulfiram therefore seem unlikely. Concurrent use need not be avoided.

1. Damkier P, Hansen LL, Brøsen K. Effect of diclofenac, disulfiram, itraconazole, grapefruit juice and erythromycin on the pharmacokinetics of quinidine. *Br J Clin Pharmacol* (1999) 48, 829–38.

Quinidine + Erythromycin

Erythromycin can increase quinidine levels and cause a small further increase in the QTc interval. An isolated report describes a moderate rise in serum quinidine levels in an elderly man attributed to the concurrent use of intravenous erythromycin, which was possibly a factor in an episode of torsade de pointes. Another isolated report describes the development of torsade de pointes arrhythmia in a very elderly man when he was given quinidine and erythromycin orally. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Clinical evidence

A 74-year-old man with a history of cardiac disease (coronary artery bypass graft surgery, ventricular tachycardia) treated with quinidine sulfate 200 mg every 6 hours and several other drugs (mexiletine, hydralazine, dipyridamole, aspirin and paracetamol (acetaminophen)), was hospitalised with suspected implantable cardioverter defibrillator infection. Within 2 days of starting to take erythromycin lactobionate 500 mg every 6 hours and ceftriaxone 1 g daily, both given intravenously, his trough serum quinidine levels had risen by about one-third from about 2.8 to 4.2 mg/L. On day 7 metronidazole 500 mg every 8 hours was added and the erythromycin dosage was doubled, and the patient experienced an episode of torsade de pointes. By day 12 his serum quinidine levels had further risen to 5.8 mg/L, whereupon the quinidine dosage was reduced by 25%. Because an interaction between quinidine and erythromycin had by then been suspected, the antibacterials were replaced by doxycycline and ciprofloxacin. By day 21 the quinidine serum levels had fallen to their former levels. The patient had a prolonged QTc interval of 504 milliseconds on admission, and this did not change.¹

A 95-year-old man developed QT interval prolongation, torsade de pointes arrhythmia and subsequent cardiac arrest when given quinidine and erythromycin, both orally.²

Preliminary results of a randomised, placebo-controlled crossover study in 12 subjects found that when a single 400-mg dose of quinidine was given after oral erythromycin 500 mg three times daily or a placebo for 5 days, the total QTc AUC was significantly prolonged by about 6% during the erythromycin phase.³ In a parallel study by the same group, peak levels of quinidine were increased by 39%, from 587 to 816 nanograms/mL, and the AUC by 62%, by day 5 of the erythromycin phase. Peak levels of the main metabolite of quinidine, 3-hydroxyquinidine, were significantly reduced.⁴ Another study in 6 healthy subjects found that oral erythromycin 250 mg four times daily for 6 days reduced the total clearance of a single 200-mg dose of quinidine sulfate by 34% and increased its maximum serum concentration by 39%.⁵

Mechanism

Not fully understood, but erythromycin inhibits the metabolism of quinidine,⁴ possibly by inhibition of the cytochrome P450 isoenzyme CYP3A4,⁵ thereby reducing its clearance from the body and increasing its effects. There are also a number of cases on record of prolongation of the QT interval and torsade de pointes associated with the use of intravenous erythromycin alone.⁶ Therefore, quinidine and erythromycin may have additive effects on the QT interval in addition to the pharmacokinetic interaction.

Importance and management

Information about this interaction appears to be limited to these reports, but it would appear to be established. If erythromycin is essential in a patient taking quinidine, the effects of concurrent use should be well moni-

tored, being alert for the development of raised plasma quinidine levels and prolongation of the QT interval (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257).

Quinidine + Fluvoxamine

Fluvoxamine appears to inhibit the metabolism and clearance of quinidine.

Clinical evidence, mechanism, importance and management

Six healthy subjects were given a single 250-mg dose of quinidine sulfate before and on day 5 of a 6-day course of fluvoxamine 100 mg daily.¹ The total apparent oral clearance of quinidine was reduced by 29%, and *N*-oxidation and 3-hydroxylation were reduced by 33 and 44% respectively. Renal clearance and the elimination half-life were unchanged. It was concluded that fluvoxamine inhibited the metabolism of quinidine by the cytochrome P450 isoenzyme CYP3A4, although a role for CYP1A2 and CYP2C19 was not excluded. The clinical relevance of these findings is unclear. However, it would seem prudent to monitor the concurrent use of quinidine with fluvoxamine. More study is needed to assess the effect of multiple dosing and to establish the clinical significance of this interaction.

1. Damkier P, Hansen LL, Brøsen K. Effect of fluvoxamine on the pharmacokinetics of quinidine. *Eur J Clin Pharmacol* (1999) 55, 451–6.

Quinidine + Grapefruit juice

Grapefruit juice delays the absorption of quinidine and reduces its metabolism to some extent, but no clinically relevant adverse interaction seems to occur.

Clinical evidence, mechanism, importance and management

In one study, 12 healthy subjects were given quinidine sulfate 400 mg orally on two occasions, once with 240 mL of water and once with grapefruit juice. The pharmacokinetics of the quinidine were unchanged, except that its absorption was delayed (the time to reach maximum plasma concentrations was doubled from 1.6 to 3.3 hours), for reasons that are not understood. The AUC of its metabolite (3-hydroxyquinidine) was decreased by one-third, suggesting that the grapefruit juice inhibits the metabolism of the quinidine.¹ No important changes in the QTc interval were seen.¹ Similarly, another study in 6 healthy subjects found the total clearance of a single 200-mg dose of quinidine sulfate was reduced by 15% by 250 mL of grapefruit juice, with no change in maximum level. There was a small reduction in metabolite formation suggesting only minor inhibition of metabolism.² Grapefruit is known to inhibit the cytochrome P450 isoenzyme CYP3A4, which is involved with the metabolism of quinidine, so it seems likely that any interaction would occur via this pathway.^{1,2} These studies suggest that it is not necessary for patients on quinidine to avoid grapefruit juice. Nevertheless, grapefruit juice may have contributed to raised quinidine levels and toxicity in a woman who took an antacid and one litre of fruit juice daily for a week, see ‘Quinidine + Antacids or Urinary alkalinisers’, p.277.

Quinidine + H₂-receptor antagonists

Quinidine serum levels can rise and toxicity may develop in some patients when they take cimetidine. An isolated case of ventricular bigeminy (a form of arrhythmia) occurred in a patient taking quinidine and ranitidine.

Clinical evidence

Cimetidine 300 mg four times daily for 7 days prolonged the elimination half-life of a single 400-mg dose of quinidine sulfate by 55%, from 5.8 to 9 hours, and decreased its clearance by 37% in 6 healthy subjects. Peak plasma levels were raised by 21%. These changes were reflected in ECG changes, with 51% and 28% increases in the mean areas under the QT and QTc time curves, respectively, but these were not considered to be statistically significant.¹

A later study in healthy subjects, prompted by the observation of two patients who developed toxic quinidine levels when given **cimetidine**, found essentially the same effects. The AUC and half-life of quinidine were increased by 14.5 and 22.6% respectively, and the clearance was decreased by 25% by **cimetidine** 300 mg four times daily.² A further study in 4 healthy subjects found that **cimetidine** 300 mg four times daily for 5 days prolonged the elimination half-life of quinidine by 54% and decreased its total clearance by 36%.^{3,4} **Cimetidine** prolonged the QT interval by 30% more than the effect of quinidine alone.⁴ A case report describes marked increases in both quinidine and digitoxin concentrations in a woman also given **cimetidine**.⁵ Similarly, quinidine levels increased by up to 50%, without causing any adverse effects, when a man taking quinidine was given **cimetidine**.⁶

Ventricular bigeminy (a form of arrhythmia) occurred when a man taking quinidine was given **ranitidine**. His serum quinidine levels remained unchanged.⁷

Mechanism

It was originally suggested that the cimetidine inhibits the metabolism of the quinidine by the liver so that it is cleared more slowly.² However, further data suggest that cimetidine successfully competes with quinidine for its excretion by the kidneys.⁸

Importance and management

The interaction between quinidine and cimetidine is established and of clinical importance. The incidence is unknown. Be alert for changes in the response to quinidine if cimetidine is started or stopped. Ideally the quinidine serum levels should be monitored and the dosage reduced as necessary. Reductions of 25% (oral) and 35% (intravenous) have been suggested.³ Those at greatest risk are likely to be patients with impaired renal function, patients with impaired liver function, the elderly, and those with serum quinidine levels already at the top end of the therapeutic range.² The situation with ranitidine is uncertain.

Quinidine + Itraconazole

Itraconazole increases the plasma levels of quinidine.

Clinical evidence

In a double-blind, randomised, two-phase crossover study, 9 healthy subjects were given a single 100-mg dose of quinidine sulfate on the final day

of a 4-day course of either itraconazole 200 mg daily or placebo. The itraconazole caused a 1.6-fold increase in the peak plasma quinidine levels, a 2.4-fold increase in its AUC, a 1.6-fold increase in its elimination half-life and a 50% decrease in its renal clearance.¹ Similarly, another study in 6 healthy subjects found that itraconazole 100 mg daily for 6 days reduced the total clearance of a single 200-mg dose of quinidine sulfate by 61%, increased its elimination half-life by 35%, and decreased its renal clearance by 60%.²

Mechanism

The most likely explanation is that itraconazole not only inhibits the metabolism of quinidine by the cytochrome P450 isoenzyme CYP3A4 in the gut wall and liver, but possibly also inhibits the active secretion of quinidine by the kidney tubules.^{1,2}

Importance and management

Direct information appears to be limited to these studies, but the evidence suggests that this interaction is clinically important. What happens is consistent with the way that itraconazole interacts with other drugs. If larger doses of itraconazole were to be used and for longer periods, it seems likely that the effects would be even greater. The concurrent use of these drugs should therefore be well monitored and the dosage of quinidine reduced accordingly. More study is needed. Consider also 'Quinidine + Ketoconazole', below.

Quinidine + Kaolin-pectin

There is some evidence that kaolin-pectin can reduce the absorption of quinidine and lower its serum levels.

Clinical evidence, mechanism, importance and management

When 4 patients were given 30 mL of kaolin-pectin (*Kaopectate*), after a single 100-mg oral dose of quinidine, the maximal salivary quinidine concentration was reduced by 54% and the AUC by 58%, without any effect on absorption rate.¹ There is a correlation between salivary and serum concentrations after a single (but not repeated) doses of quinidine.² This is consistent with *in vitro* data showing quinidine is adsorbed onto kaolin,³ pectin,³ and kaolin-pectin.¹ Documentation appears to be limited to these two studies, but be alert for the need to increase the quinidine dosage if kaolin-pectin is used concurrently.

Quinidine + Ketoconazole

An isolated report describes a temporary marked increase in plasma quinidine levels in man when he was also given ketoconazole.

Clinical evidence, mechanism, importance and management

An elderly man with chronic atrial fibrillation, treated with quinidine sulfate 300 mg four times daily, was also given ketoconazole 200 mg daily, for candidal oesophagitis after antineoplastic therapy. Within 7 days his plasma quinidine levels had risen from a range of 1.4 to 2.7 mg/L up to 6.9 mg/L (normal range 2 to 5 mg/L) but he showed no evidence of toxicity. The elimination half-life of quinidine was found to be 25 hours (normal values in healthy subjects 6 to 7 hours). The quinidine dosage was reduced to 200 mg twice daily, but it needed to be increased to the former

dose by the end of a month, even though ketoconazole was continued at the same dosage. The reasons for this reaction are not understood, but may be that the ketoconazole initially inhibits the metabolism of quinidine, causing the plasma levels to rise, and then later induces the metabolism of quinidine, causing the levels to fall.¹ This is an isolated case so that its general importance is uncertain. See also 'Quinidine + Itraconazole', p.281.

1. McNulty RM, Lazor JA, Sketch M. Transient increase in plasma quinidine concentrations during ketoconazole-quinidine therapy. *Clin Pharm* (1989) 8, 222–5.

Quinidine + Laxatives

Quinidine plasma levels can be reduced by the anthraquinone laxative senna.

Clinical evidence, mechanism, importance and management

A study in 7 patients with cardiac arrhythmias taking quinidine bisulfate 500 mg every 12 hours found that the anthraquinone laxative **senna** (*Liquedepur*) reduced plasma quinidine levels, measured 12 hours after the last dose of quinidine, by about 25%.¹ This might be of clinical importance in patients whose plasma levels are barely adequate to control their arrhythmia.

1. Guckenbiehl W, Gilfrich HJ, Just H. Einfluß von Laxantien und Metoclopramid auf die Chinidin-Plasmakonzentration während Langzeittherapie bei Patienten mit Herzrhythmusstörungen. *Med Welt* (1976) 27, 1273–6.

Quinidine + Lidocaine

A single case report describes a man taking quinidine who had sinoatrial arrest when he was given intravenous lidocaine.

Clinical evidence, mechanism, importance and management

A man with Parkinson's disease was given quinidine 300 mg every 6 hours for the control of ventricular ectopic beats. After receiving two doses he was given lidocaine as well, initially as a bolus of 80 mg, followed by an infusion of 4 mg/minute because persistent premature ventricular beats developed. Within 2.5 hours the patient complained of dizziness and weakness, and was found to have sinus bradycardia, sinoatrial arrest and atrioventricular escape rhythm. Normal sinus rhythm resumed when the lidocaine was stopped. Whether quinidine was a contributing factor in this reaction is uncertain.¹ However, this case emphasizes the need to exercise caution when giving two drugs that have cardiac depressant actions.

1. Jeresaty RM, Kahn AH, Landry AB. Sinoatrial arrest due to lidocaine in a patient receiving quinidine. *Chest* (1972) 61, 683–5.

Quinidine + Metoclopramide

Metoclopramide slightly reduced the absorption of quinidine from a sustained-release formulation in one study, but modestly increased quinidine levels in another.

Clinical evidence

A study of this interaction was prompted by the case of a patient who was taking sustained-release quinidine (*Quinidex*) and whose arrhythmia became uncontrolled when metoclopramide was added. In a crossover study, 9 healthy subjects were given either metoclopramide 10 mg every 6 hours for 24 hours before, and 48 hours after, a single 600- or 900-mg oral dose of quinidine sulfate or quinidine alone. It was found that metoclopramide caused a mean 10% decrease in the AUC of quinidine, although two subjects had decreases of 22.5 and 28.1%, respectively. The elimination rate constant was unaffected.¹ Another study in patients taking a sustained-re-

lease formulation of quinidine bisulfate 500 mg every 12 hours found that metoclopramide 10 mg three times daily increased the mean plasma levels measured 3.5 hours after the last dose of quinidine by almost 20%, from 1.6 to 1.9 micrograms/mL, and at 12 hours by about 16%, from 2.4 to 2.8 micrograms/mL.²

Mechanism

Not understood. Metoclopramide alters both the gastric emptying time and gastrointestinal motility, which can affect quinidine absorption.

Importance and management

Direct information seems to be limited to these studies using different quinidine preparations. The outcome of concurrent use is uncertain, but generally seems small.

1. Yuen GJ, Hansten PD, Collins J. Effect of metoclopramide on the absorption of an oral sustained-release quinidine product. *Clin Pharm* (1987) 6, 722–5.
2. Guckenbiehl W, Gilfrich HJ, Just H. Einfluß von Laxantien und Metoclopramid auf die Chinidin-Plasmakonzentration während Langzeittherapie bei Patienten mit Herzrhythmusstörungen. *Med Welt* (1976) 27, 1273–6.

Quinidine + Omeprazole

Omeprazole does not appear to alter the pharmacokinetics or QT-interval prolonging effects of quinidine.

Clinical evidence, mechanism, importance and management

Omeprazole 40 mg daily for one week had no effect on the pharmacokinetics of a single 400-mg dose of quinidine sulfate in 8 healthy subjects. In addition, the corrected QT interval was not significantly changed.¹ There would not appear to be the need for any special precautions during concurrent use.

1. Ching MS, Elliott SL, Stead CK, Murdoch RT, Devenish-Meares S, Morgan DJ, Smallwood RA. Quinidine single dose pharmacokinetics and pharmacodynamics are unaltered by omeprazole. *Aliment Pharmacol Ther* (1991) 5, 523–31.

Quinidine + Quinolones

Ciprofloxacin normally appears not to interact with quinidine to a clinically relevant extent. An increased risk of torsade de pointes might be expected if quinidine is used with gatifloxacin, moxifloxacin, or sparfloxacin, and possibly levofloxacin.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of a single 400-mg oral dose of quinidine sulfate and QRS and QTc prolongation were not significantly changed in 7 healthy subjects after they took **ciprofloxacin** 750 mg daily for 6 days. The decrease in clearance ranged from a decrease of 10% to an increase of 20%, with a mean 1% increase, which is unlikely to be clinically relevant.¹ However an isolated case report describes a woman who started taking quinidine gluconate 324 mg every 8 hours while she was taking **ciprofloxacin** and metronidazole. Her first trough serum quinidine levels was raised a little above normal at 6.3 micrograms/mL compared with the normal range of 2 to 5 micrograms/mL, without evidence of toxicity. Quinidine therapy was continued unchanged, and her next trough serum quinidine level was only 2.3 micrograms/mL, 3 days after finishing the course of antibacterials. This was tentatively attributed to the possible enzyme inhibitory effects of **ciprofloxacin** and metronidazole. This case is far from clear and so no firm conclusions can be reached.² There would seem to be little reason for avoiding concurrent use.

Some quinolones can prolong the QT interval, and would be expected to increase the risk of torsade de pointes arrhythmias when used with quinidine. Of the quinolones used clinically, **gatifloxacin**, **moxifloxacin**, and **sparfloxacin** are known to prolong the QT interval (see 'Table 9.2', (p.257)). There is also evidence that **levofloxacin** may prolong the QT interval (see 'Amiodarone + Quinolones', p.249). These quinolones should

probably be avoided in patients taking quinidine (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257).

Quinidine + Rifampicins

The serum levels and therapeutic effects of quinidine can be markedly reduced by rifampicin.

Clinical evidence

It was noted that the control of ventricular arrhythmia deteriorated in a patient taking quinidine sulfate 800 mg daily within a week of starting to take **rifampicin** 600 mg daily. His serum quinidine level fell from 4 to 0.5 micrograms/mL, and remained low despite doubling the quinidine dose to 1.6 g daily. The **rifampicin** was discontinued, and quinidine levels gradually increased over a week. Some signs of quinidine toxicity then occurred, and the quinidine dose was reduced back to 800 mg daily.¹ Further study in 4 healthy subjects found that treatment with **rifampicin** 600 mg daily for 7 days reduced the mean half-life of a single 6-mg/kg oral dose of quinidine sulfate by about 62% (from 6.1 to 2.3 hours) and the AUC by 83%.² Similar findings were reported in 4 other subjects receiving the same dose of quinidine intravenously.²

Another case report describes a patient taking **rifampicin** who did not achieve adequate serum quinidine levels despite large daily doses of up to 3.2 g of quinidine. When the **rifampicin** was stopped, ultimately, a reduced quinidine dosage of 1.8 g daily achieved a serum level of 2 micrograms/mL, reflecting a 44% decrease in dose and a 43% increase in level.³ In a further case, a 'double interaction' was seen when a patient taking quinidine and digoxin was given **rifampicin**: the quinidine levels fell, resulting in a fall in digoxin levels.⁴

Mechanism

Rifampicin is a potent enzyme-inducer, which markedly increases the metabolism of the quinidine by 3-hydroxylation and N-oxidation, thereby reducing its levels and effects.⁵ It has been suggested that two of the quinidine metabolites (3-hydroxyquinidine and 2-oxoquinidinone) may be active, which might, to some extent, offset the effects of this interaction.⁴

Importance and management

An established and clinically important interaction, although documentation is limited. The dosage of quinidine will need to be increased if rifampicin is given concurrently. Monitor the serum levels. Doubling the dose may not be sufficient.^{2,4} An equivalent dosage reduction will be needed if the rifampicin is stopped. There does not seem to be any information regarding the other rifamycins, **rifabutin** (a weak enzyme inducer) and **rifapentine** (a moderate enzyme inducer). However, the manufacturers and the CSM in the UK warn that **rifabutin** may possibly reduce the effects of a number of drugs, including quinidine.^{6,7}

Quinidine + Sucralfate

An isolated report describes a marked reduction in serum quinidine levels, which was attributed to the concurrent use of sucralfate.

Clinical evidence, mechanism, importance and management

An elderly woman was found to have subtherapeutic levels of warfarin, digoxin and sustained-release quinidine (serum quinidine level 0.31 micromol/L), even though they were given 2 hours apart from sucralfate. On hospitalisation, a variety of other medications were then started for chest pain (glyceryl trinitrate, diltiazem, pethidine, promethazine), and on day 4 the sucralfate was stopped. On day 5, her serum quinidine level was 5.55 micromol/L.¹ The patient denied noncompliance, and the suggestion was that sucralfate can bind with quinidine within the gut and reduce its absorption. However, a study in *dogs* found sucralfate did not alter quinidine bioavailability.² This isolated case report is of doubtful general importance.

Tocainide + Antacids or Urinary alkalinisers

Raising the pH of the urine (e.g. with some antacids, diuretics or alkaline salts) can modestly reduce the loss of tocinide from the body.

Clinical evidence

Preliminary findings of a study found that when 5 healthy subjects took 30 mL of an unnamed antacid four times a day for 48 hours before and 58 hours after a single 600-mg dose of tocinide, the urinary pH rose from 5.9 to 6.9, the total clearance of tocinide fell by 28%, the peak serum levels fell by 19% from 4.2 to 3.4 micrograms/mL, the AUC rose by 33% and the half-life was prolonged from 13.2 to 15.4 hours.¹

Mechanism

Tocainide is a weak base so that its loss in the urine will be affected by the pH of the urine. Alkalinisation of the urine increases the number of non-ionised molecules available for passive reabsorption, thereby reducing the urinary loss and raising the serum levels.

Importance and management

An established interaction of uncertain but probably limited clinical importance. There seem to be no reports of adverse reactions in patients as a result of this interaction, but be alert for any evidence of increased tocinide effects if other drugs are given that can raise the urinary pH significantly (e.g. **sodium bicarbonate** and **acetazolamide**). Reduce the tocinide dosage if necessary. Of the antacids,² **aluminium/magnesium hydroxide** (*Maalox*) can raise urinary pH by about 0.9 whereas **magnesium hydroxide** (*Milk of magnesia*) and **calcium carbonate-glycine** (*Titrilac*) in normal doses raise the pH by about 0.5. **Aluminium hydroxide** (*Amphogel*) and **dihydroxyaluminium glycinate** (*Robalate*) are reported to have no effect on urinary pH.²

2. Gibaldi M, Grundhofer B, Levy G. Effect of antacids on pH of urine. *Clin Pharmacol Ther* (1974) 16, 520–5.

Tocainide + H₂-receptor antagonists

There is some evidence that cimetidine can reduce the bioavailability and serum levels of tocinide, but ranitidine appears not to interact.

Clinical evidence, mechanism, importance and management

In a preliminary report of a study, 4 days of treatment with **cimetidine** [dose not stated] in 11 healthy subjects had a small effect on the pharmacokinetics of tocinide 500 mg given intravenously over 15 minutes, which was not considered clinically important.¹ In another study, **cimetidine** 300 mg four times daily for 2 days reduced the AUC of a single 400-mg oral dose of tocinide in 7 healthy subjects by about one-third. The peak

serum levels were also reduced, from 2.81 to 1.7 micrograms/mL, but no changes in the half-life or renal clearance occurred.² The reasons for this, and its clinical importance are uncertain, but be alert for evidence of a reduced response to tocinide in the presence of **cimetidine**. **Ranitidine** 150 mg twice daily has been found not to interact.²

1. Price BA, Holmes GI, Antonello J, Yeh KC, Demetriades J, Irvin JD, McMahon FG. Intravenous tocinide (T) maintains safe therapeutic levels when administered concomitantly with cimetidine (C). *Clin Pharmacol Ther* (1987), 41, 237.
2. North DS, Mattern AL, Kapil RP, Lalonde RL. The effect of histamine-2 receptor antagonists on tocinide pharmacokinetics. *J Clin Pharmacol* (1988) 28, 640–3.

Tocainide + Phenobarbital

Phenobarbital does not appear to alter the pharmacokinetics of tocinide.

Clinical evidence, mechanism, importance and management

Phenobarbital 100 mg daily for 15 days did not alter the AUC of a single 600-mg dose of tocinide in 6 healthy subjects. In addition, the percentage of the dose excreted unchanged in the urine and as the glucuronide metabolite did not differ.¹ Phenobarbital at this dosage does not appear to alter

the metabolism of tocinide. No special precautions appear to be necessary.

1. Elvin AT, Lalka D, Stoeckel K, du Souich P, Axelson JE, Golden LH, McLean AJ. Tocainide kinetics and metabolism: effects of phenobarbital and substrates of glucuronyl transferase. *Clin Pharmacol Ther* (1980) 28, 652–8.

Tocainide + Rifampicin (Rifampin)

The loss of tocinide from the body is increased by rifampicin.

Clinical evidence, mechanism, importance and management

The AUC of a single 600-mg oral dose of tocinide was reduced by almost 30% and the half-life was also reduced by about 30%, from 13.2 to 9.4 hours, in 8 healthy subjects given rifampicin 300 mg twice daily for 5 days.¹

This response is consistent with the well-recognised enzyme inducing effects of rifampicin. Information is limited to this single dose study, but the interaction would seem to be established and may be of clinical importance. Monitor any patients given rifampicin for evidence of reduced tocinide serum levels and reduced effects. Increase the dosage as necessary. Reduce the tocinide dosage if the rifampicin is withdrawn. More study is needed.

10

Antibacterials

This section deals with interactions where the effects of the antibacterial are altered. In many cases the antibacterial drugs interact by affecting other drugs, and these interactions are dealt with elsewhere in this publication. Some of the macrolides and the quinolones are potent enzyme inhibitors; the macrolides exert their effects on the cytochrome P450 isoenzyme CYP3A4, whereas many quinolones inhibit CYP1A2. Rifampicin (rifampin) is a potent non-specific enzyme inducer and therefore lowers the levels of many drugs.

Many of the interactions covered in this section concern absorption interactions, such as the ability of the tetracyclines and quinolones to chelate with divalent cations. More information on the mechanism of these interactions can be found in 'Drug absorption interactions', (p.3).

Many monographs concern the use of multiple antibacterials. One of the great difficulties with these interactions is the often poor correlation between *in vitro* and *in vivo* studies, so that it is difficult to get a thoroughly reliable indication of how antibacterial drugs will behave together in clinical practice. Two antibacterials may actually be less effective than one on its own, because, in theory, the effects of a bactericidal drug, which requires actively dividing cells for it to be effective, may be reduced by a bacteriostatic drug. However, in practice this seems to be less important than might be supposed and there are relatively few well-authenticated clinical examples.

The antibacterials covered in this section are listed in 'Table 10.1', (see below).

Table 10.1 Antibacterials

Group	Drugs
Aminoglycosides	Amikacin, Astromicin, Dibekacin, Dihydrostreptomycin, Framycetin, Gentamicin, Isepamicin, Kanamycin, Micronomicin, Neomycin, Netilmicin, Paromomycin, Sisomicin, Streptomycin, Tobramycin
Antimycobacterials and related drugs	Aminosalicylic acid (PAS), Capreomycin, Clofazimine, Cycloserine, Dapsone, Ethambutol, Ethionamide, Isoniazid, Methanzide, Protonamide, Pyrazinamide, Rifabutin, Rifampicin (Rifampin), Rifamycin, Rifapentine, Rifaximin
Carbapenems	Biapenem, Ertapenem, Faropenem, Imipenem, Meropenem, Panipenem
Cephalosporins	Cefaclor, Cefadroxil, Cefalexin, Cefaloglycin, Cefaloridine, Cefalotin, Cefamandole, Cefapirin, Cefatrizine, Cefazolin, Cefbuperazone, Cefcapene, Cefdinir, Cefditoren, Cefepime, Cefetamet, Cefixime, Cefmenoxime, Cefmetazole, Cefminox, Cefodizime, Cefonicid, Cefoperazone, Ceforanide, Cefotaxime, Cefotetan, Cefotiam, Cefoxitin, Cefpiramide, Cefpirome, Cefpodoxime, Cefprozil, Cefradine, Cefsulodin, Ceftazidime, Cefteteram, Ceftazole, Cefitbuten, Ceftizoxime, Ceftriaxone, Cefuroxime, Flomoxef, Latamoxef
Macrolides	Azithromycin, Clarithromycin, Dirithromycin, Erythromycin, Flurithromycin, Josamycin, Midecamycin, Rokitomycin, Roxithromycin, Spiramycin, Telithromycin, Troleandomycin
Penicillins	Amoxicillin, Ampicillin, Azidocillin, Azlocillin, Bacampicillin, Benzylpenicillin (Penicillin G), Carbenicillin, Carindacillin, Ciclacillin, Clometocillin, Cloxacillin, Dicloxacillin, Flucloxacillin, Mecillinam, Meticillin, Mezlocillin, Nafcillin, Oxacillin, Phenethicillin, Phenoxymethylpenicillin (Penicillin V), Piperacillin, Pivampicillin, Pivmecillinam, Procaine benzylpenicillin (Procaine penicillin), Propicillin, Sulbenicillin, Temocillin, Ticarcillin
Polypeptides	Bacitracin, Colistimethate sodium, Colistin, Polymyxin B, Teicoplanin, Vancomycin
Quinolones	Cinoxacin, Ciprofloxacin, Enoxacin, Fleroxacin, Flumequine, Gatifloxacin, Gemifloxacin, Grepafloxacin, Levofloxacin, Lomefloxacin, Moxifloxacin, Nadifloxacin, Nalidixic acid, Norfloxacin, Ofloxacin, Oxolinic Acid, Pazufloxacin, Pefloxacin, Pipemidic Acid, Rosoxacin, Rufloxacin, Sparfloxacin, Temafloxacin, Tosufloxacin, Trovafloxacin
Sulfonamides	Co-trimoxazole, Phthalylsulfathiazole, Sulfadiazine, Sulfadimidine (Sulfamethazine), Sulfafurazole (Sulfisoxazole), Sulfaguanidine, Sulfamerazine, Sulfamethazole, Sulfamethoxazole, Sulfametopyrazine, Sulfametrole
Tetracyclines	Chlortetracycline, Demeclocycline, Doxycycline, Lymecycline, Methacycline, Minocycline, Oxytetracycline, Rolitetracycline, Tetracycline, Tigecycline
Miscellaneous	Aztreonam, Carumonam, Chloramphenicol, Cilastatin, Clindamycin, Daptomycin, Fosfomycin, Fusidic acid, Lincomycin, Linezolid, Loracarbef, Methenamine, Metronidazole, Mupirocin, Nitrofurantoin, Novobiocin, Pristinamycin, Quinupristin/Dalfopristin, Spectinomycin, Trimethoprim, Vancomycin

Aminoglycosides + Amphotericin B

One study suggested that amphotericin B decreased the clearance of amikacin and gentamicin. The concurrent use of aminoglycosides and amphotericin B can result in nephrotoxicity.

Clinical evidence, mechanism, importance and management

A study found that **amikacin** or **gentamicin** clearance was impaired in 12 of 17 children given amphotericin B. Serum creatinine increased by 50% or more in 3 of them, but there was no significant increase in creatinine levels in 7 others. As a result, the aminoglycoside dose was decreased or the dose interval lengthened in 7 children.¹

The renal function of 4 patients receiving moderate doses of **gentamicin** deteriorated when they were given amphotericin B. Both drugs are known to be nephrotoxic and it is suggested, on the basis of what was seen, that combined use may have had additive nephrotoxic effects.² A further retrospective analysis found that the use of **amikacin** tended to increase amphotericin B-related nephrotoxicity.³

A study assessing the risk factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of amphotericin B significantly increased the risk of nephrotoxicity.⁴

The nephrotoxicity of various combinations of antibiotics was assessed in 171 cancer patients (139 treated with a combination of aminoglycoside with penicillin or cephalosporin; 32 treated with amphotericin B or vancomycin with other antibacterials). The highest nephrotoxicity (based on changes in urea and electrolytes) was found in patients treated with amphotericin B with an aminoglycoside and a cephalosporin.⁵

Two other studies did not find aminoglycosides increased the risk of amphotericin B-associated toxicity (defined as a 100% or greater increase in serum creatinine),^{6,7} although in one of the studies⁷ the frequency of concurrent aminoglycoside use may have been too low to identify any evidence of increased nephrotoxic risk.

As aminoglycosides are generally considered to be nephrotoxic, avoidance of use with other nephrotoxic drugs (such as amphotericin B) is generally recommended. However, concurrent use may be essential. Renal function and drug levels should be routinely monitored during aminoglycoside therapy, and it may be prudent to increase the frequency of such monitoring in the presence of amphotericin B. Lipid formulations of amphotericin B are less nephrotoxic than the conventional formulation.⁸ One manufacturer notes there was significantly less nephrotoxicity in patients receiving concurrent aminoglycosides and liposomal amphotericin B (*Ambisome*) compared to aminoglycosides and conventional amphotericin B.⁹

Aminoglycosides + Cephalosporins

The nephrotoxic effects of gentamicin and tobramycin can be increased by cefalotin. This may also occur with other aminoglycosides and cephalosporins.

Clinical evidence

(a) Gentamicin and Cefaloridine

Acute renal failure has been reported in a patient given gentamicin and cefaloridine.¹ One study reported an increase in the incidence of nephrotoxicity when cefaloridine was given with gentamicin (or other unnamed aminoglycosides), although other factors such as excessive dosage or pre-existing renal impairment were also associated with the increase in cephalosporin nephrotoxicity in most cases.²

(b) Gentamicin or Tobramycin and Cefalotin

A randomised, double-blind study³ in patients with sepsis showed the following incidence of definite nephrotoxicity:

- **gentamicin** with **cefalotin** 30.4% (7 of 23 patients),
- **tobramycin** with **cefalotin** 20.8% (5 of 24),
- **gentamicin** with **methicillin** 10% (2 of 20),
- **tobramycin** with **methicillin** 4.3% (1 of 23).

A very considerable number of studies and case reports confirm an increase in the incidence of nephrotoxicity when **gentamicin**^{2,4–14} or **tobramycin**^{15,16} are used with **cefalotin**. However, some other studies have found no increase in nephrotoxicity with the combination.^{17–20}

(c) Aminoglycosides and other Cephalosporins

The nephrotoxicity of various combinations of antibiotics was assessed in 171 cancer patients. In those receiving an aminoglycoside with a third generation cephalosporin, the most nephrotoxic combinations were found to be **gentamicin** with **cefotaxime** (although another study did not find this combination to be nephrotoxic²¹) and **amikacin** with **ceftriaxone**, where 5 of 20 and 5 of 13 patients, respectively, had increased serum creatinine. The following combinations were found to be safer: **amikacin** with **cefoxitin** or **ceftazidime**, **gentamicin** with **cefoxitin**, and **netilmicin** with **cefotaxime**.²²

Another study assessing the risk factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of cephalosporins (including **cefazolin**, **cefotaxime**, **cefoxitin**, **cefamandole**, **cefuroxime**, **ceftriaxone**, and **ceftazidime**) significantly increased the risk of nephrotoxicity.²³

Hypokalaemia has also been described in patients taking cytotoxic drugs for leukaemia when they were given **gentamicin** and **cefalexin**.²⁴

A study in healthy subjects found that **ceftazidime** may increase the levels of **amikacin**.²⁵

Some studies have reported no adverse interactions between;

- **amikacin** and **cefepime**²⁶
- **gentamicin** and **cefuroxime**,²⁷ or **cefazolin**,²⁰
- **tobramycin** and **cefuroxime**,²⁸ **cefotaxime**,²⁹ **ceftazidime**³⁰ or **cefazolin**²⁰

Mechanism

Uncertain. The nephrotoxic effects of gentamicin and tobramycin are well documented, and some (mostly older) cephalosporins are known to be nephrotoxic, especially in high dose. However, it appears that doses that are well tolerated separately can be nephrotoxic when given together.¹¹

Importance and management

The interaction between gentamicin and cefalotin is very well documented and potentially serious, but there is less information about tobramycin with cefalotin. The risk of nephrotoxicity is probably greatest if high doses of antibacterials are used in those with some existing renal impairment. One study suggests that short courses of treatment are sometimes justified,¹² but renal function should be very closely monitored and dosages kept to a minimum. The combination of gentamicin or tobramycin and cefalotin is probably best avoided in high-risk patients wherever possible.

Whether other aminoglycosides or cephalosporins interact similarly is uncertain, but the possibility should be borne in mind. Risk factors for this interaction are said to include raised aminoglycoside trough levels, decreased albumin, male gender, advanced age, increased length of treatment, liver disease or ascites, and some other diseases, including

leukaemia,^{23,31} although their significance in practice has been questioned.²³

Aminoglycosides + Clindamycin

Three cases of acute renal failure have been tentatively attributed to the use of gentamicin with clindamycin, and another report identified the combination as a risk factor for nephrotoxicity. However, other reports note no increased nephrotoxicity when gentamicin or tobramycin was given with clindamycin.

Clinical evidence, mechanism, importance and management

Acute renal failure has been reported in 3 patients with normal renal function when they were given gentamicin 3.9 to 4.9 mg/kg daily and clindamycin 0.9 to 1.8 mg/kg daily for 13 to 18 days. They recovered within 3 to 5 days of discontinuing the antibacterials¹ but in one patient acute renal failure only developed after the clindamycin was stopped. The reasons for the renal failure are not known, but given the long courses of gen-

tamicin involved, the possibility that renal impairment occurred as an adverse effect of the aminoglycoside alone cannot be excluded. However, one report identified concurrent clindamycin as one of several factors that increased the risk of aminoglycoside-associated nephrotoxicity.²

Clindamycin with an aminoglycoside seems to be a fairly common antibacterial combination, especially following abdominal trauma. A study assessing the risk factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of clindamycin was not significantly associated with increased risk of nephrotoxicity.³ This suggests that treatment with the combination is without nephrotoxic risk above and beyond that seen with an aminoglycoside alone. A short report has also indicated that the combination of **tobramycin** and clindamycin is not nephrotoxic.⁴

As renal function should be routinely monitored during the use of aminoglycosides, no additional precautions should be necessary if clindamycin is also given.

Aminoglycosides + Loop diuretics

The concurrent use of aminoglycosides and etacrynic acid should be avoided because their damaging actions on the ear can be additive. Even sequential use may not be safe. Bumetanide and piretanide have been shown to interact similarly in animals. Although some patients have developed nephrotoxicity and/or ototoxicity while taking furosemide and an aminoglycoside, it has not been established that this was as a result of an interaction.

Clinical evidence

(a) Bumetanide

There seem to be no clinical reports of an interaction between aminoglycosides and bumetanide, but ototoxicity has been described in animals given kanamycin and bumetanide.^{1,2}

(b) Etacrynic acid

Four patients with renal impairment became permanently deaf after they were given intramuscular **kanamycin** 1 to 1.5 g and intravenous etacrynic acid 50 to 150 mg. One patient also received **streptomycin**, and another also received oral **neomycin**. Deafness took between 30 minutes and almost 2 weeks to develop. In some cases deafness developed despite the doses being given on separate days, and in all cases it appeared irreversible.³ A patient receiving **gentamicin** rapidly developed deafness when furosemide was replaced by intravenous etacrynic acid.⁴

There are other reports describing temporary, partial or total permanent deafness as a result of giving intravenous etacrynic acid with **gentamicin**,⁵ intramuscular **kanamycin**,^{5–7} oral **neomycin**,⁸ or **streptomycin**.^{6,9} This interaction has been extensively demonstrated in animals.

(c) Furosemide

An analysis of three, controlled, randomised, studies found that furosemide did not increase either aminoglycoside-induced nephrotoxicity, or ototoxicity (the aminoglycosides used were **amikacin**, **gentamicin**, and **tobramycin**). Nephrotoxicity developed in 20% (10 of 50 patients) given furosemide and 17% (38 of 222) not given furosemide. Auditory toxicity developed in 22% (5 of 23) given furosemide and 24% (28 of 119) not given furosemide.⁴

A study assessing the risk factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of furosemide significantly increased the risk of nephrotoxicity.¹⁰ A clinical study evaluating a possible interaction found that furosemide increased aminoglycoside-

induced renal damage,¹¹ whereas two other clinical studies found no interaction.^{12,13} There are clinical reports claiming that concurrent use results in ototoxicity, but usually only small numbers of patients were involved and control groups were not included.¹⁴⁻¹⁸ A retrospective study of neonates suggested the possibility of increased ototoxicity but no firm conclusions could be drawn.¹⁹ Studies in patients and healthy subjects have shown that furosemide reduces the renal clearance of **gentamicin**^{20,21} and can cause a rise in both serum **gentamicin**²¹ and **tobramycin** levels.²² Ototoxicity has been described in *animals* given **kanamycin** and furosemide.^{1,2}

(d) Piretanide

There seem to be no clinical reports of an interaction between aminoglycosides and piretanide, but ototoxicity has been described in *animals* given **kanamycin** and piretanide.²³

Mechanism

Aminoglycosides or etacrynic acid alone can damage the ear and cause deafness, the site of action of the aminoglycosides being the hair cell and that of etacrynic acid the stria vascularis. Other loop diuretics can similarly damage hearing.

Animal studies have shown that intramuscular neomycin can cause a fivefold increase in the concentration of etacrynic acid in cochlear tissues, and it is possible that the aminoglycoside has some effect on the tissues, which allows the etacrynic acid to penetrate more easily.²⁴ Similar results have been found with gentamicin.²⁵

Importance and management

The interaction between etacrynic acid and aminoglycoside is well established and well documented. The concurrent or sequential use of etacrynic acid with parenteral aminoglycosides should be avoided because permanent deafness may result. Patients with renal impairment seem to be particularly at risk, most likely because the drugs are less rapidly cleared. Most of the reports describe deafness after intravenous use, but it has also been seen when etacrynic acid is given orally alone.⁹ If it is deemed absolutely necessary to use etacrynic acid and intravenous aminoglycosides, minimal doses should be used and the effects on hearing should be monitored continuously. Not every aminoglycoside has been implicated, but their ototoxicity is clearly established and they may be expected to interact in a similar way. For this reason the same precautions should be used.

Although there is ample evidence of an adverse interaction between furosemide and aminoglycosides in *animals*,^{2,26} the weight of clinical evidence suggests that furosemide does not normally increase either the nephrotoxicity or ototoxicity of the aminoglycosides. Nevertheless as there is still some uncertainty about the safety of concurrent use it would be prudent to monitor for any evidence of changes in aminoglycoside serum levels, and renal or hearing impairment. The authors of the major study cited⁴ suggest that an interaction may possibly exist if high dose infusions of furosemide are used. The same precautions would seem to be appropriate with bumetanide and piretanide. Note that it is generally advised that aminoglycosides should not be used with other drugs that may cause ototoxicity or nephrotoxicity, such as etacrynic acid and furosemide.

Aminoglycosides + Magnesium compounds

A neonate with elevated serum magnesium levels had a respiratory arrest when given gentamicin.

Clinical evidence

An infant born to a woman whose pre-eclampsia had been treated with magnesium sulfate was found to have muscle weakness and a serum magnesium concentration of 1.77 mmol/L. The neonate was given ampicillin 100 mg/kg intravenously and **gentamicin** 2.5 mg/kg intramuscularly every 12 hours, starting 12 hours after birth. Soon after the second dose of **gentamicin** she stopped breathing and needed intubation. The **gentamicin** was stopped and the child improved.¹ *Animal* studies confirmed this interaction.¹

Mechanism

Magnesium ions and the aminoglycosides have neuromuscular blocking activity, which can be additive (see also 'Neuromuscular blockers + Magnesium compounds', p.125 and 'Neuromuscular blockers + Aminoglycosides', p.113). In the case cited here it seems that it was enough to block the actions of the respiratory muscles.

Importance and management

Direct information about this interaction is very limited, but it is well supported by the recognised pharmacological actions of magnesium and the aminoglycosides, and their interactions with conventional neuromuscular blockers. The aminoglycosides as a group should be avoided in hypermagnesaemic infants needing antibacterial treatment. If this is not possible, the effects on respiration should be closely monitored.

Aminoglycosides + Miconazole

A report describes a reduction in serum tobramycin levels, which was attributed to the use of miconazole.

Clinical evidence, mechanism, importance and management

Intravenous miconazole significantly lowered the peak serum **tobramycin** levels from 9.1 to 6.7 micrograms/mL in 9 patients undergoing bone marrow transplantation. Six of them needed **tobramycin** dosage adjustments.¹ Miconazole was stopped in 4 patients, and **tobramycin** pharmacokinetic parameters returned to normal 4 to 8 days later. The reasons for this interaction are not understood. Although the use of **tobramycin** should be well monitored it would be prudent to increase the frequency in patients also given systemic miconazole (note that miconazole oral gel can have significant systemic absorption). There does not appear to be any information about other aminoglycosides and azole antifungals.

- Hatfield SM, Crane LR, Duman K, Karanes C, Kiel RJ. Miconazole-induced alteration in tobramycin pharmacokinetics. *Clin Pharm* (1986) 5, 415–19.

Aminoglycosides + NSAIDs

There are conflicting reports as to whether or not serum gentamicin and amikacin levels are raised by indometacin or ibuprofen in premature infants.

Clinical evidence

(a) Amikacin

A study in 10 preterm infants with gestational ages ranging from 25 to 34 weeks, who were given amikacin, found that the use of **indometacin** 200 micrograms/kg every 8 hours, for up to 3 doses, caused a rise in the serum levels of amikacin. Trough and peak levels of amikacin were raised by 28% and 17%, respectively.¹

In another study, preterm infants were given amikacin 20 mg/kg every 36 hours (gestational age less than 30 weeks) or every 24 hours (gestational age 30 to 31 weeks) with either **ibuprofen lysine** 10 mg/kg within 6 hours of birth, then a further 5 mg/kg dose 24 and 48 hours later, or placebo. The half-life of amikacin was increased from 12.4 to 16.4 hours and its clearance was reduced by 40% in infants who also received intravenous **ibuprofen lysine**.² Reductions in amikacin clearance, independent of gestational age were found by the same authors in another study in which preterm infants with gestational ages of between 24 and 34 weeks were given amikacin and **ibuprofen**.³

In contrast, another study in preterm infants given amikacin found no changes in its pharmacokinetics when **ibuprofen** or **indometacin** were given.⁴

(b) Gentamicin

A study in 10 preterm infants with gestational ages ranging from 25 to 34 weeks, who were given gentamicin, found that the use of **indometacin** 200 micrograms/kg every 8 hours, for up to 3 doses, caused a rise in the serum levels of gentamicin. Trough and peak levels of gentamicin were raised by 48% and 33%, respectively.¹ A later study⁵ confirmed that **indometacin** (200 micrograms/kg given intravenously at 0 hours, then 100 micrograms/kg given at 12 and then 36 hours) decreased the clearance of 3-mg/kg daily doses of gentamicin by 23% in preterm infants weighing less than 1250 g.

In contrast, 8 out of 13 infants had no increase in their serum gentamicin levels when they were given **indometacin** 200 to 250 micrograms/kg every 12 hours for 3 doses. Of the remaining 5, slight to moderate rises occurred in 4, and a substantial rise occurred in just one.⁶ In another study no significant changes in serum gentamicin levels were seen in 31 preterm newborns given parenteral **indometacin** 200 micrograms/kg every 12 hours for 3 doses.⁷

Mechanism

Aminoglycosides are excreted by renal filtration, which can be inhibited by indometacin or ibuprofen. This may result in the retention of the aminoglycoside.

Importance and management

Information seems to be limited to these conflicting studies, although supporting evidence for indometacin comes from the fact that it also causes the retention of digoxin in premature infants. The authors of one of the studies⁶ suggest that the different results may be because aminoglycoside serum levels were lower in their study before the indometacin was given, and also because they measured the new steady-state levels after 40 to 60 hours instead of 24 hours. Whatever the explanation, concurrent use should be very closely monitored because toxicity is associated with raised aminoglycoside serum levels. It has been suggested that the aminoglycoside dosage should be reduced before giving indometacin and the serum levels and renal function well monitored during concurrent use.¹ It has also been suggested that the dose interval of amikacin should be increased by at least 6 to 8 hours if ibuprofen lysine is also given during the first days of life.² Other aminoglycosides possibly behave similarly. This interaction does not seem to have been studied in adults.

Aminoglycosides + Penicillins or Carbapenems

The use of piperacillin is reported to be a risk factor for aminoglycoside-associated nephrotoxicity. A reduction in serum aminoglycoside levels can occur if aminoglycosides and penicillins are given together to patients with severe renal impairment. No pharmacokinetic interaction of importance appears to occur with intravenous aminoglycoside and penicillins in those with normal renal function or between aminoglycosides and carbapenems. The serum levels of oral phenoxymethylpenicillin can be halved by oral neomycin.

Clinical evidence

A. Intravenous or intramuscular aminoglycosides

(a) With carbapenems

The suspicion that low **tobramycin** levels in one patient might have been due to an interaction with **imipenem/cilastatin** was not confirmed in a later *in vitro* study.¹ It has also been suggested that the nephrotoxic effects of **imipenem** and the **aminoglycosides** might possibly be additive but this awaits confirmation.² A study in healthy subjects given single intravenous doses of **imipenem** and **amikacin** found there was a transient increase in **imipenem** levels but no effects on other pharmacokinetic parameters of either drug.³ In a study in 12 healthy subjects the concurrent use of **tobramycin** and **biapenem** did not alter the pharmacokinetics of either drug.⁴ No inactivation occurred in an *in vitro* assessment of these two drugs in urine.⁵

(b) With penicillins in patients with renal impairment

A study in 6 patients with renal failure requiring dialysis, who were receiving intravenous **carbenicillin** 8 to 15 g daily in 3 to 6 divided doses, found that in the presence of the penicillin serum **gentamicin** levels did not exceed 4 micrograms/mL. When the **carbenicillin** was stopped, serum **gentamicin** levels rose.⁶

Other reports similarly describe unusually low **gentamicin** levels in patients with impaired renal function, given **carbenicillin**,^{7–10} **piperacillin**,¹¹ or **ticarcillin**.^{8,10,12} The half-life of **gentamicin** has been reported to be reduced by **carbenicillin** or **piperacillin** by about one-half or one-third.^{8,11,13} Similarly, unusually low **tobramycin** levels have been reported in patients with impaired renal function, who were given **carbenicillin**,⁶ **piperacillin**¹⁴ or **ticarcillin**.¹²

In 3 patients receiving long-term haemodialysis **piperacillin** doubled the clearance of **tobramycin** 2 mg/kg, and reduced its half-life from 73 to 22 hours.¹⁵ A patient showed a reduction in the half-life of **tobramycin** from an expected 70 hours to 10.5 hours after being given **piperacillin**.¹⁶ In contrast one study found that **piperacillin** or **piperacillin/tazobactam** did not change the pharmacokinetics of **tobramycin** in subjects with renal impairment.¹⁷

Piperacillin 4 g every 12 hours did not affect the pharmacokinetics of **netilmicin** 2 mg/kg in 3 patients receiving long-term haemodialysis.¹⁵

(c) With penicillins in patients with normal renal function

A patient with normal renal function was given **gentamicin** 80 mg intravenously, with and without **carbenicillin** 4 g. The serum **gentamicin** concentration profiles in both cases were very similar.⁷

No interaction was seen in 10 patients given **tobramycin** with **piperacillin**,¹⁸ or in another 10 healthy subjects given once daily **gentamicin** with **piperacillin/tazobactam**.¹⁹ Only minimal pharmacokinetic changes were seen in 9 healthy subjects given **tobramycin** with **piperacillin/tazobactam**,²⁰ and 18 cystic fibrosis patients (adults and children) given **tobramycin** with **ticarcillin**.²¹

However, a study assessing the risk factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients,

157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of **piperacillin**, but not **ticarcillin** or **carbenicillin** significantly increased the risk of nephrotoxicity.²²

B. Oral aminoglycosides

The serum concentrations of a 250-mg oral dose of **phenoxymethylpenicillin** were reduced by more than 50% in 5 healthy subjects after they took **neomycin** 3 g four times daily for 7 days. Normal penicillin pharmacokinetics were not seen until 6 days after the **neomycin** was withdrawn.²³

Mechanism

The nephrotoxic effects of gentamicin and tobramycin are well documented. The reason why piperacillin but not carbenicillin or ticarcillin should increase the risk of nephrotoxicity is not clear. One suggestion is that sodium loading may protect the kidney from tobramycin toxicity and piperacillin has only 40% as much sodium as ticarcillin.²²

In vitro, the amino groups on the aminoglycosides and the beta-lactam ring on the penicillins interact chemically to form biologically inactive amides.²⁴ It has been suggested that this reaction may also occur in the plasma, causing a drop in the levels of active antibacterial.¹³ The interaction occurs in those with poor renal function as the drugs persist in the plasma for longer, allowing a greater time for inactivation. This therefore means the drug is lost more rapidly than has been accounted for by the renal function, and consequently lower than expected levels of the antibacterial result. However, the lack of interaction found in one study led to the conclusion that reported interactions in renal impairment may be due to *in vitro* inactivation after sample collection.¹⁷

In the case of phenoxymethylpenicillin, the levels are probably lowered because oral neomycin can cause a reversible malabsorption syndrome (histologically similar to nontropical sprue).

Importance and management

The concurrent use of piperacillin and aminoglycosides is reported to be a risk factor for nephrotoxicity.^{22,25} The nephrotoxic effects of gentamicin and tobramycin are well documented. Risk factors for nephrotoxicity include raised aminoglycoside trough levels, decreased albumin, male gender, advanced age, increased length of treatment, liver disease or ascites, and some other diseases, including leukaemia,^{22,25} although their significance in practice has been questioned.²² Renal function and antibacterial serum levels should be monitored if piperacillin is given with an aminoglycoside.

Other reports suggest that a pharmacokinetic interaction between parenteral aminoglycosides and piperacillin or other penicillins, resulting in reduced levels of aminoglycoside, seems to occur in patients with renal impairment.

In those cases where concurrent use is thought necessary, it has been recommended that the serum levels of both antibacterials closely monitored.⁶ However, note that antibacterial inactivation can continue in the assay sample, and one author²⁶ suggests that rapid assay is necessary, while others¹⁷ note the importance of protecting samples against further inactivation.

There would seem to be no reason for avoiding concurrent use in patients with normal renal function because no significant *in vivo* inactivation appears to occur. Moreover there is good clinical evidence that concurrent use is valuable, especially in the treatment of *Pseudomonas* infections.^{7,27}

Evidence for the oral neomycin/penicillin interaction seems limited to this one report and its clinical significance is unclear. It seems possible that oral **kanamycin** and **paromomycin** might interact similarly, but this needs confirmation.

Aminoglycosides + Polygeline (Haemacel)

The incidence of acute renal failure appears to be increased in cardiac surgical patients given polygeline (Haemacel) with gentamicin.

Clinical evidence

The observation of a differing incidence of acute renal failure in patients undergoing coronary artery bypass surgery in two similar units, prompted a retrospective review of patient records. This showed that the only management differences were related to antibacterial prophylaxis and the bypass prime content (i.e. the solution used to prime the cardiopulmonary bypass circuit).

Acute renal failure was defined as a more than 50% rise in serum creatinine on the first postoperative day in those patients whose creatinine was also greater than 120 micromol/L.

Four groups of patients were identified, and the incidence of renal failure was as follows:

- A (polygeline plus **gentamicin** and flucloxacillin) 31% (28 of 91 patients);
- B (polygeline plus cefalotin) 12% (9 of 72 patients);
- C (crystalloid plus **gentamicin** and flucloxacillin) 7% (4 of 57 patients);
- D (crystalloid plus cefalotin) 2% (1 of 47 patients).

Polygeline (*Haemacel*) 1 litre, which is a urea linked gelatin colloid with a calcium concentration of 6.25 micromol/L, was used for groups A and B, with crystalloid - Hartmann's solution or Ringer's injection (calcium concentration 2 mmol/L) to make up the rest of the prime volume of 2 litres. Groups C and D received only crystalloid (no polygeline) in the prime. Albumin 100 mL was used in groups B and D.¹ However, the study has been criticised because other drugs affecting renal function (such as ACE inhibitors, cimetidine, NSAIDs or clonidine) which may have been taken by the patients were not considered.² This criticism has been refuted because of the large sample size involved.³

Mechanism

Not fully understood. It is thought that the relatively high calcium content of the polygeline may have potentiated gentamicin-associated nephrotoxicity. Hypercalcaemia has been shown in *animals* to increase aminoglycoside-induced nephrotoxicity.⁴

Importance and management

Information appears to be limited to this clinical study and *animal* studies, but the evidence available suggests that a clinically important adverse interaction occurs between these drugs. The incidence of acute renal failure in cardiac surgery patients is normally about 3 to 5%⁵ which is low compared with the 31% shown by those given polygeline and gentamicin. The authors of the study advise avoidance of these two drugs. More study is needed.

Aminoglycosides + Vancomycin

The nephrotoxicity of the aminoglycosides appears to be potentiated by vancomycin.

Clinical evidence, mechanism, importance and management

A retrospective review of 105 patients who had received an aminoglycoside with vancomycin for at least 5 days found that nephrotoxicity occurred in 27% of the patients. Of these, 6 had no other identifiable cause for nephrotoxicity.¹ A study assessing the risks factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of vancomycin significantly increased the risk of nephrotoxicity.²

A number of other studies,^{3–9} including those where patients have had individualised pharmacokinetic monitoring,³ and those using both once daily and multiple daily dosing,⁴ have all found that vancomycin independently increases the risk of nephrotoxicity in patients receiving aminoglycosides. In one meta-analysis of 8 studies, the incidence of nephrotoxicity with the combination was 4.3% greater than with aminoglycosides alone and 13.3% greater than with vancomycin alone.⁸

Risk factors are said to include vancomycin peak and trough levels,^{1,6} aminoglycoside trough levels,^{1,3,6} decreased albumin concentrations,² male gender,^{1–3} advanced age,^{1–3} increased length of treatment,^{1–3} liver disease or ascites,^{1,2} as well as a large number of other disease states (such as leukaemia,² peritonitis¹ or neutropenia),¹ although their significance in practice has been questioned.²

Concurrent use of these antibacterials is therapeutically useful, but the risk of increased nephrotoxicity should be borne in mind. Therapeutic drug monitoring and regular assessment of renal function is warranted, as is recommended with the use of either drug alone.

Aminoglycosides + Verapamil

Verapamil appears to protect the kidney from damage caused by gentamicin.

Clinical evidence, mechanism, importance and management

In a comparative study, 9 healthy subjects were given **gentamicin** alone (2 mg/kg loading dose, followed by doses every 8 hours to achieve a peak concentration of 5.5 mg/L and a trough concentration of 0.5 mg/L), and 6 other subjects were given the same dosage of **gentamicin** with sustained-release verapamil 180 mg twice daily. The **gentamicin** AUCs of the two groups were virtually the same but the 24-hour urinary excretion of alanine aminopeptidase (AAP) was modestly reduced, by 18%, in the group given verapamil. The reduction in AAP excretion was particularly marked during the first 6 days.¹ The significance of urinary AAP is that this enzyme is found primarily in the brush border membranes of the proximal renal tubules, and its excretion is an early and sensitive marker of renal damage. Thus it seems that verapamil may modestly protect the kidneys from damage by **gentamicin**, but using a drug as potentially toxic as verapamil to provide this protection, when the risks of renal toxicity can be minimised by carefully controlling the **gentamicin** dosage, is unwarranted. Information about other aminoglycosides and other calcium-channel blockers seems to be lacking.

Aminoglycosides; Tobramycin + Sucralfate

An *in vitro* study with tobramycin found that it became markedly and irreversibly bound to sucralfate at the pH values found in the gut. This suggests that the efficacy of tobramycin in gut decontamination might be decreased.

Clinical evidence, mechanism, importance and management

To simulate what might happen in the gut, tobramycin 50 mg/mL was mixed with sucralfate 500 mg in 40 mL of water at pH 3.5 and allowed to stand for 90 minutes at 25°C. Analysis of the solution showed that the tobramycin concentration fell rapidly and progressively over 90 minutes to about 1%. When the pH of the mixture was then raised to 6.5 to 7 for 90 minutes, there was no change in the concentration of tobramycin, suggesting that the interaction was irreversible.¹ The reason for this change is not known, but the suggestion is that sucralfate forms insoluble chelates with tobramycin.¹

It is not known how important this interaction is likely to be in practice, but the efficacy of tobramycin in gut decontamination may be decreased. Separating the dosages might not be effective in some postoperative patients because their gastric function may not return to normal for up to 5 days, and some sucralfate might still be present when the next dose is given.¹ More study is needed to find out whether this interaction is clinically important, but in the meanwhile it would seem prudent to monitor concurrent use carefully, being alert for any evidence of reduced effects.

- Feron B, Adair CG, Gorman SP, McClurg B. Interaction of sucralfate with antibiotics used for selective decontamination of the gastrointestinal tract. *Am J Hosp Pharm* (1993) 50, 2550–3.

Aminosalicic acid + Diphenhydramine

Diphenhydramine can cause a small reduction in the absorption of aminosalicic acid from the gut.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects¹ showed that diphenhydramine 50 mg given intramuscularly 10 minutes before a 2-g oral dose of aminosalicic acid, reduced the mean peak serum aminosalicic acid levels by about 15%.

This effect may occur because diphenhydramine reduces peristalsis in the gut, which in some way reduces aminosalicic acid absorption. The extent to which diphenhydramine or any other anticholinergic drug diminishes the therapeutic response to long-term treatment with aminosalicic acid is uncertain, but it is probably small.

1. Lavigne J-G, Marchand C. Inhibition of the gastrointestinal absorption of p-aminosalicylate (PAS) in rats and humans by diphenhydramine. *Clin Pharmacol Ther* (1973) 14, 404–12.

Aminosalicic acid + Probenecid

The plasma levels of aminosalicic acid can be raised up to four-fold by probenecid.

Clinical evidence, mechanism, importance and management

In a study in 7 patients, probenecid 500 mg every 6 hours increased the plasma levels of aminosalicic acid 4 g by as much as fourfold.¹ Similar results are described in another report.²

The reasons for this effect are uncertain but it seems probable that probenecid successfully competes with aminosalicic acid for active excretion by the kidney tubules, which results in the increased aminosalicic acid levels.

The documentation of this interaction is limited but it appears to be established. Such large increases in plasma aminosalicic acid levels would be expected to lead to toxicity. It also seems possible that the dosage of aminosalicic acid could be reduced without losing the required therapeutic response. This needs confirmation. Monitoring aminosalicic acid levels, where possible, would probably be useful. Concurrent use should be undertaken with caution.

2. Carr DT, Karlson AG, Bridge EV. Concentration of PAS and tuberculostatic potency of serum after administration of PAS with and without Benemid. *Proc Staff Meet Mayo Clin* (1952) 27, 209–15.

Antibacterials + Immunoglobulins

One animal study found that for severe infections antibacterials were less effective in the presence of high-dose immunoglobulin, but this was not seen in less severe infections. The clinical relevance of this is uncertain.

Clinical evidence, mechanism, importance and management

A study in an animal model of severe group B streptococcal infection found the following mortalities: 51% with **benzylpenicillin** 200 mg/kg alone, 88% with immunoglobulin and benzylpenicillin, and 100% with immunoglobulin 2 g/kg alone. A smaller dose of immunoglobulin 0.5 g/kg was not associated with an increase in mortality.¹ Roughly similar results were found when the penicillin was replaced by **ceftriaxone**.¹ In another study using a 1000-fold smaller inoculum of group B streptococci, there was no difference in mortality between **benzylpenicillin** 200 mg/kg daily alone and **benzylpenicillin** with immunoglobulin 0.25 to 2 g/kg, and there was some evidence of a lower incidence of bacteraemia with the combination.^{1,2}

Immunoglobulins are used with antibacterials in the successful prevention of infections in clinical practice, and no special precautions appear to be needed in this situation. However, their clinical use for treating established infection is unclear, and the above findings suggest some caution is warranted.

Aztreonam + Other antibacterials

There appear to be no clinically significant pharmacokinetic interactions between aztreonam and amikacin, cefradine, clindamycin, gentamicin, metronidazole or nafcillin.

Clinical evidence, mechanism, importance and management

A study in healthy subjects given a single 1-g intravenous dose of aztreonam found that maximum levels were reduced by 12.6% and 9.8% when it was given with **gentamicin** 80 mg and **metronidazole** 500 mg, respectively. Serum bound aztreonam fell by 5% when it was given with **nafcillin** 500 mg and increased by 5.1% when given with **cefradine** 1 g. When aztreonam 1 g and **clindamycin** 600 mg were given together, their renal excretion increased by 5.2% and 10.9%, respectively. None of these changes was statistically significant.¹ Another study in healthy subjects found that the AUC of a 1-g intravenous dose of aztreonam was reduced by 22% by amikacin 500 mg, and the AUC of amikacin was increased by 27% by aztreonam.²

Carbapenems + Probenecid

Probenecid increases the serum levels of meropenem, but does not appear to interact with ertapenem to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

(a) Ertapenem

The use of probenecid with ertapenem is reported to decrease the renal clearance of unbound ertapenem by about 50%, probably because probenecid inhibits the renal tubular secretion of ertapenem. Probenecid slightly increased the elimination half-life and AUC of ertapenem and therefore concurrent use is considered unlikely to increase the effects of ertapenem.¹

(b) Meropenem

In 6 healthy subjects probenecid (1 g given orally 2 hours before meropenem and 500 mg given orally 1.5 hours after meropenem) increased the AUC of meropenem 500 mg by 43%.² Another study in 6 healthy subjects found that probenecid (1.5 g in divided doses the day before and 500 mg one hour before meropenem) increased the AUC of meropenem 1 g by up to 55% and increased its half-life by 33% (from 0.98 to 1.3 hours).³ In both studies the serum levels of meropenem were modestly increased. This is possibly because meropenem and probenecid compete for active kidney tubular secretion.^{4,5} The manufacturers say that because the potency and duration of meropenem are adequate without probenecid, they do not recommend concurrent use.^{4,5}

Cephalosporins + Antacids

No clinically significant interactions appear to occur between an aluminium/magnesium hydroxide antacid and cefaclor AF, cefalexin, cefetamet pivoxil, cefixime or cefprozil; between Alka-Seltzer and cefixime; or between cefitibuten and Mylanta. In contrast, antacids reduce the bioavailability of cefpodoxime proxetil.

Clinical evidence, mechanism, importance and management

(a) Cefaclor

A study with cefaclor AF (a formulation with a slow rate of release) found that an **aluminium/magnesium hydroxide** antacid (*Maalox*) given one hour after the cefaclor AF to fed subjects reduced the AUC by 18%.¹ This reduction is small and unlikely to be clinically important.

(b) Cefalexin

An **aluminium/magnesium hydroxide** antacid (*Maalox*) given as 8 doses of 10 mL on day one and 2 doses on day 2, had only small and therapeutically unimportant effects on the pharmacokinetics of cefalexin 1 g.²

(c) Cefetamet pivoxil

Cefetamet pivoxil 1 g was given to 18 healthy subjects after breakfast with or without 80 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox 70*) given the evening before, 2 hours before, and after breakfast. The pharmacokinetics of the cefetamet were unaffected by the antacid.³

(d) Cefixime

An **aluminium/magnesium hydroxide** antacid (*Maalox*) and *Alka-Seltzer* (aspirin, calcium phosphate, citric acid and **sodium bicarbonate**) do not significantly affect the absorption of cefixime.^{4,5}

(e) Cefpodoxime proxetil

A study in 10 healthy subjects found that 10 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox*) reduced the bioavailability of cefpodoxime proxetil by about 40%. This was considered to be due to reduced dissolution at increased gastric pH values.⁶ These results confirm the findings of a previous study with **sodium bicarbonate** and **aluminium hydroxide**.⁷ It has been recommended that cefpodoxime is given at least 2 hours after antacids.⁶

(f) Cefprozil

An **aluminium/magnesium hydroxide** antacid (*Maalox*) does not affect the bioavailability of cefprozil.⁸

(g) Cefibuten

In 18 healthy subjects, 60 mL of an antacid containing **aluminium/magnesium hydroxide** plus **simeticone** (*Mylanta II*) was found not to affect the pharmacokinetics of cefibuten 400 mg.⁹

Cephalosporins + Calcium-channel blockers

Nifedipine increases the serum levels of cefixime but this is unlikely to be clinically important. Neither nifedipine nor diltiazem affect the pharmacokinetics of cefpodoxime proxetil.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects the AUC and peak serum levels of a single 200-mg dose of **cefixime** were increased by about 70% and 50%, respectively, when **cefixime** was taken 30 minutes after a 20-mg dose of **nifedipine**. The rate of absorption was also increased. One suggested reason for this interaction is that the **nifedipine** increases the absorption of the **cefixime** by affecting the carrier system across the epithelial wall of the gut.¹ It seems doubtful if this increased **cefixime** bioavailability is clinically important (the combination was well-tolerated) and no particular precautions would seem to be necessary on concurrent use.

The pharmacokinetics of a single 200-mg dose of **cefpodoxime proxetil** were found to be unchanged by single doses of either **diltiazem** 60 mg or **nifedipine** 20 mg in 12 healthy subjects.² No special precautions would seem necessary during concurrent use.

Information about other cephalosporins and calcium-channel blockers seems to be lacking, but there seems to be no particular reason to suspect an interaction.

Cephalosporins + Colestyramine

Colestyramine binds with cefadroxil and cefalexin in the gut, which delays their absorption. The importance of this is probably small.

Clinical evidence

The peak serum levels of a 500-mg oral dose of **cefadroxil** were reduced and delayed in 4 subjects when it was taken with 10 g of colestyramine, but the total amount absorbed was not affected.¹ Similar results were found in a study involving **cefixime** and colestyramine.²

Mechanism

Colestyramine is an ion-exchange resin, which binds with these two cephalosporins in the gut. This prevents the early and rapid absorption of the antibacterial, but as the colestyramine/cephalosporin complex passes along the gastrointestinal tract, the antibacterial is progressively released and eventually virtually all of it becomes available for absorption.¹

Importance and management

Direct information seems to be limited to the studies cited. The clinical significance is uncertain, but as the total amount of antibacterial absorbed is not reduced this interaction is probably of little importance. This needs confirmation. Information about other cephalosporins seems to be lacking.

- Marino EL, Vicente MT and Dominguez-Gil A. Influence of colestyramine on the pharmacokinetic parameters of cefadroxil after simultaneous administration. *Int J Pharmacokinetics* (1983) 16, 23–30.

Cephalosporins + Food

The bioavailabilities of cefadroxil, cefalexin, cefixime, cefprozil, and cefradine are not affected by food. Cefaclor may be given without regard to food but absorption of an extended-release preparation may be increased by food. The bioavailabilities of cefetamet pivoxil and cefuroxime axetil may be increased by administration with food.

Clinical evidence, mechanism, importance and management

(a) Cefaclor

A study in 18 healthy subjects given a single 250-mg capsule of cefaclor after an overnight fast or within 30 minutes of different meals found the bioavailability was not significantly affected by food. The rate of absorption and maximum plasma levels were decreased: a low-fat vegetarian diet produced the smallest decrease in maximum plasma levels (26%) and a high-fat non-vegetarian diet produced the largest decrease (47%) compared with levels achieved after an overnight fast. None of the diets significantly affected the AUC_{0-∞} of cefaclor. Therapeutic efficacy (measured by time levels were above MIC₅₀) was not significantly altered.¹ In a further study, healthy subjects were given a single 500-mg dose of cefaclor as an extended-release tablet. The rate of absorption was decreased by food but compared to the fasting state, the maximum levels were increased; by 52% for rice-based diets, by 33% for low-fat-vegetarian food, by 29% for high-fat non-vegetarian food, by 12.5% for high-fat-vegetarian food, and by 7% for low-fat non-vegetarian food. Compared with the fasting state, all the diets increased the time above MIC₉₀, with a significant increase of almost 42% with low-fat vegetarian (wheat-based) food.² The manufacturers of immediate-release cefaclor capsules state that total absorption is the same whether the drug is given with or without

food,³ but for the extended-release preparation since absorption is enhanced by administration with food, the manufacturers recommend that this preparation should be taken with meals.⁴

(b) *Cefadroxil*

The manufacturers of cefadroxil state that the bioavailability of cefadroxil is unaffected by food so it may be taken either with meals or on an empty stomach.⁵

(c) *Cefalexin*

The manufacturers of cefalexin state that it is acid stable and may be given without regard to meals.⁶

(d) *Cefetamet pivoxil*

A study found that the bioavailability of cefetamet pivoxil was up to 25% higher when it was given 10 minutes after a standard breakfast rather than in the fasting state.^{7,8} However, in another study, healthy subjects were given oral cefetamet pivoxil hydrochloride 1 g (equivalent to 693 mg of cefetamet free acid) either: 1 hour before food with 200 mL of water; with a standard breakfast and a cup of tea or coffee; or 1 hour after breakfast with 200 mL of water. The cefetamet maximum plasma levels were 5.5, 5.47, and 6.57 micrograms/mL, respectively, and the AUCs were 38, 35.7, and 42.8 micrograms.hour/mL, respectively, suggesting that bioavailability of cefetamet pivoxil is lowest when taken with food. The time to reach maximum plasma levels was increased from 3.3 hours when given before food to 4.3 hours when given with food, and 4.1 hours when given one hour after food.⁹ It was thought possible that the amount of fluid taken with cefetamet may have affected absorption, but a study in which cefetamet 1 g was given under fasting conditions with either 250 or 450 mL of water found that increasing fluid intake did not affect absorption. Further, the absorption when taken with food, with or without 200 mL of water was similar. It was recommended that cefetamet pivoxil should be taken within an hour of a meal to improve absorption. The delay in absorption was not considered to be of significance, especially during multiple dose therapy.⁹

(e) *Cefixime*

A study in healthy subjects given a single 400-mg dose of cefixime, either in the fasting state or immediately after a standard breakfast found that the time to peak serum levels was increased from about 3.8 to 4.8 hours when cefixime was given with food, probably because of delayed gastric emptying. Serum levels, AUC and 24 hour urinary recovery were similar for fasted and fed states.¹⁰ Cefixime may be given without regard to meals.^{10,11}

(f) *Cefpodoxime proxetil*

In a study in healthy subjects, cefpodoxime proxetil 400 mg tablets were given with 180 mL of water after an overnight fast, or either 1 hour before, with, or 2 hours after the start of a high-fat meal. Dosing 1 hour before the meal was similar to dosing in the fasting state. However, when cefpodoxime was taken with, or 2 hours after the meal its peak plasma levels were increased by about 45% and 46%, respectively, when compared with the peak levels achieved in the fasting state. The AUC was also increased, by 40%. The rate of cefpodoxime absorption was not greatly affected by food.¹² Studies with a 200-mg dose of cefpodoxime have also found that food increases the extent, but not the rate, of cefpodoxime absorption.¹³ However, the extent of the food effect appears to be greater with the 400 mg dose. This is possibly because the bioavailability of the 400-mg tablets is less than that of the 200-mg tablets, so food may have a greater effect on the higher strength preparation.¹² In another study by the same authors the AUC and urinary excretion of cefpodoxime proxetil 200 mg given as a suspension were higher (11% and 14%, respectively) when taken with a high-fat meal rather than in the fasting state. Maximum plasma levels were not affected by a high-fat meal but the time to achieve maximum levels was prolonged.¹⁴

The manufacturers state that the bioavailability of cefpodoxime proxetil 100 mg tablets and suspension is increased by food.^{15,16} The studies¹²⁻¹⁴ suggest the increased bioavailability of the tablets, but possibly not that of the suspension, when given with food may be clinically significant.

(g) *Cefprozil*

A study in healthy subjects found that, although food caused slight changes in the rate of absorption of a 1-g dose of cefprozil its pharmacokinetics (including total absorption) were not significantly affected.¹⁷

(h) *Cefradine*

A study in healthy subjects given cefradine 500 mg in the fasting state or immediately after a meal found the time to peak levels was increased from

0.8 hours to 2 hours by food. Peak serum levels of cefradine were reduced by 45% when it was given after food. However, the half-life and AUC were not affected.¹⁸ The manufacturers state that cefradine may be given without regard to meals.¹⁹

(i) *Cefuroxime axetil*

A study in healthy subjects given cefuroxime axetil 500 mg intravenously or oral doses of 125 mg to 1 g with or without food found that 36% and 52% of a 500-mg oral dose was absorbed in the fasting and fed states respectively.²⁰ In another study in healthy subjects, a single 1-g dose of cefuroxime axetil was given 2 hours before or 35 minutes after a standard cooked breakfast. The bioavailability of cefuroxime was markedly enhanced by food.²¹ The manufacturer notes that optimum absorption of cefuroxime axetil occurs when it is given after a meal.²² This is probably because of delayed gastric emptying and transit which allowed more complete dissolution and absorption.²¹

Cephalosporins + Furosemide

The nephrotoxic effects of cefaloridine and possibly cefalotin or cefacetrile appear to be increased by furosemide. Cefradine brain levels are reduced by furosemide. No important interactions appear to occur between furosemide and cefoxitin, ceftazidime, ceftriaxone, or cefuroxime.

Clinical evidence

(a) *Nephrotoxicity*

Nine out of 36 patients who developed acute renal failure while taking **cefaloridine** had also been taking a diuretic: furosemide was used in 7 cases. Other factors such as patient age and drug dosage may also have been involved. The authors of this report related their observations to previous *animal* studies, which showed that potent diuretics such as furosemide and etacrynic acid enhanced the incidence and extent of tubular necrosis.¹ Several other reports describe nephrotoxicity in patients given both **cefalori-**

dine and furosemide.²⁻⁴ There is a possibility that this effect also occurs with **cefalotin** and **cefacetrile** because *animal* studies found an increase in nephrotoxicity,^{5,6} and there is a single report describing nephrotoxicity in one patient taking **cefalotin** with furosemide.² **Cefoxitin** seems to be relatively free of nephrotoxicity alone or with furosemide.⁷

(b) *Changes in serum levels and clearance*

A clinical study⁸ found that furosemide 80 mg increased the serum half-life of **cefaloridine** by 25%, and in another study **cefaloridine** clearance was reduced by furosemide.⁹ A further study found that brain concentrations of **cefradine** are markedly reduced by furosemide.¹⁰ In a study in 6 healthy subjects, furosemide 40 mg, given 1 hour before a 1-g intramuscular dose of **ceftazidime**, raised the serum **ceftazidime** levels by about 20 to 40% over 8 hours and increased the AUC by 28%. Furosemide given 3 hours before **ceftazidime** had much smaller effects.¹¹ The serum half-lives of intravenous **cefoxitin** and **cefuroxime** were not affected by oral furosemide.¹² **Ceftriaxone** does not appear to interfere with the diuretic effects of furosemide.¹³

Mechanism

Cefaloridine is nephrotoxic, but why this should be increased by furosemide is not understood. It may possibly be related to a reduction in its clearance.⁹

Importance and management

The interaction between cefaloridine and furosemide is not well-established, but there is enough evidence to suggest that concurrent use should be undertaken with care. Age and/or renal impairment may possibly be predisposing factors. Renal function should be checked frequently if both drugs are given. A pharmacokinetic study suggests that the development of this adverse interaction may possibly depend on the time relationship of drug use, and it has been recommended that furosemide should be avoided for 3 or 4 hours before the cefaloridine.¹⁴

Although the manufacturers of ceftazidime issue a caution about the use of high doses of cephalosporins with other nephrotoxic drugs, they say that clinical experience has not shown this to be a problem with ceftazidime at the recommended doses.¹⁵ The rest of the information about other cephalosporins and furosemide is fairly sparse. Most appear not to interact adversely, with a few possible exceptions, namely cefalotin (nephrotoxicity in a single case² and *animal* studies⁵) and cefacetrile (nephrotoxicity in *animal* studies⁶). Care is clearly prudent with these two cephalosporins.

oavailability of cefuroxime axetil, but not to an important extent if cefuroxime is taken with food. No clinically significant pharmacokinetic interactions appear to occur between cefaclor AF and cimetidine, or between cefetamet pivoxil, cefalexin or ceftibuten and ranitidine.

Clinical evidence

(a) *Cefaclor*

A study using cefaclor AF (a formulation with a slow rate of release) found that **cimetidine** 800 mg taken the previous night reduced its maximum plasma concentration by 12%.¹

(b) *Cefalexin*

Ranitidine 150 mg for 3 doses had only small and therapeutically unimportant effects on the pharmacokinetics of cefalexin 1 g.² In another study in healthy subjects **ranitidine** 150 mg for 3 doses prolonged the time to attain peak serum levels of a single 500-mg dose of cefalexin from 1.19 to 1.48 hours. Other pharmacokinetic parameters were not significantly affected. Similar results were found when **omeprazole** was given instead of ranitidine.³

(c) *Cefetamet pivoxil*

Ranitidine 150 mg twice daily for 4 days did not affect the pharmacokinetics of cefetamet pivoxil 1 g given to 18 healthy subjects after breakfast.⁴

(d) *Cefpodoxime proxetil*

A study in 10 healthy fasted subjects showed that **famotidine** 40 mg reduced the bioavailability of cefpodoxime proxetil by about 40%.⁵ This confirms the findings of a previous study with **ranitidine**.⁶

(e) *Ceftibuten*

Ranitidine 150 mg every 12 hours for 3 days raised the maximum plasma levels and AUC of ceftibuten by 23% and 16%, respectively, in 18 healthy subjects. However these values lie within the normal ranges seen in healthy subjects and no dosage adjustment is therefore thought to be needed.⁷

(f) *Cefuroxime axetil*

Ranitidine 300 mg with sodium bicarbonate 4 g reduced the AUC of cefuroxime axetil 1 g by 43% when the combination was given to fasted subjects. However, when cefuroxime was given after food, its bioavailability was higher, and minimally affected by **ranitidine** plus sodium bicarbonate (10% reduction in AUC).⁸

Mechanism

The reduction in the bioavailability of some of the cephalosporins is thought to be due to reduced dissolution at increased gastric pH values.⁵

Importance and management

In most cases the interactions between the cephalosporins and H₂-receptor antagonists are not clinically significant. The clinical importance of the interaction with cefpodoxime has not been studied, but the manufacturer recommends that cefpodoxime is given at least 2 hours before H₂-receptor antagonists.⁹ As it is thought that a change in gastric pH is responsible for this interaction it would seem likely that **proton pump inhibitors** will interact similarly.

As long as cefuroxime is taken with food (as is recommended¹⁰), any interaction is minimal. The bioavailability of cefetamet pivoxil,⁴ and cefpodoxime proxetil,^{5,6} are also enhanced by food so it is probable that interaction with drugs which raise gastric pH may be similarly minimised.

Cephalosporins + Probenecid

The serum levels of many cephalosporins are raised by probenecid. Possible exceptions include ceforanide, ceftazidime, ceftriaxone and latamoxef. The rise in serum levels may possibly increase the risk of nephrotoxicity with some cephalosporins such as cefaloridine and cefalotin.

Clinical evidence

Ten healthy subjects given a single 500-mg oral dose of **cefradine** or **cefaclor** developed markedly raised serum antibacterial concentrations when they were also given probenecid (500-mg doses taken 25, 13 and 2 hours before the antibacterial). Peak serum levels of the antibacterial were very roughly doubled.¹ Similar results were obtained in another study in healthy subjects given **cefradine** by mouth or intramuscularly.²

Although some cephalosporins do not appear to interact, in general, most have their clearance reduced, their serum levels raised and sometimes their half-lives prolonged by probenecid, see 'Table 10.2', (p.297).

Mechanism

Probenecid inhibits the excretion of most cephalosporins by the kidney tubules by successfully competing for the excretory mechanisms. A fuller explanation of this mechanism is set out in 'Drug excretion interactions', (p.7). Thus the cephalosporin is retained in the body and its serum levels rise. The extent of the rise cannot always be fully accounted for by this mechanism alone and it is suggested that some change in tissue distribution may sometimes have a part to play.¹

Importance and management

An extremely well-documented interaction. The serum levels of many (but not all) cephalosporins will be higher if probenecid is given, but no special precautions are normally needed. The interaction has been used clinically. Elevated serum levels of some cephalosporins, in particular cefaloridine and cefalotin, might possibly increase the risk of nephrotoxicity.

Cephalosporins; Cefalexin + Pirenzepine

Pirenzepine (50 mg for 4 doses) had only small and therapeutically unimportant effects on the pharmacokinetics of a 1-g dose of cefalexin.¹

- Deppermann K-M, Lode H, Höffken G, Tschink G, Kalz C, Koeppel P. Influence of ranitidine, pirenzepine, and aluminum magnesium hydroxide on the bioavailability of various antibiotics, including amoxicillin, cephalixin, doxycycline and amoxicillin-clavulanic acid. *Antimicrob Agents Chemother* (1989) 33, 1901–1907.

Cephalosporins; Cefalotin + Colistin

Renal failure has been attributed to the concurrent use of cefalotin and colistin.

Clinical evidence, mechanism, importance and management

Four patients developed acute renal failure, which appeared to be reversible, during treatment with colistin. Three were given cefalotin concurrently and the fourth had previously been taking this antibacterial.¹ An increase in renal toxicity associated with concurrent use has been described in another report.² The reason for this reaction is not known. What is known suggests that renal function should be closely monitored if these drugs are given concurrently or sequentially.

Cephalosporins; Cefdinir + Iron compounds

Ferrous sulfate markedly reduces the absorption of cefdinir.

Clinical evidence

When 6 healthy subjects were given **ferrous sulfate** (1050 mg of *Ferro-Gradumet*, sustained release, equivalent to 210 mg of elemental iron) with cefdinir 200 mg the AUC of the cefdinir was reduced by 93%. When the **ferrous sulfate** was taken 3 hours after the cefdinir, the absorption of the cefdinir remained unchanged for 3 hours and then rapidly fell, the total AUC over 12 hours being reduced by 36%.¹

Mechanism

It is believed that the ferrous sulfate chelates with the cefdinir in the gut to produce a poorly absorbed complex.

Importance and management

An established interaction of clinical importance. Avoid ferrous sulfate and other iron compounds while taking cefdinir. It is not yet known how far apart these drugs must be separated to avoid this interaction, but 3 hours improves the situation considerably even if it does not totally solve it. There is no information to suggest that other cephalosporins interact in this way.

Cephalosporins; Cefotaxime + Penicillins

Azlocillin and mezlocillin may reduce the clearance of cefotaxime in subjects with normal or impaired renal function.

Clinical evidence, mechanism, importance and management

A patient with renal failure developed encephalopathy with focal motor status and generalised convulsions when given cefotaxime 2 g every 8 hours and **azlocillin** 5 g every 8 hours (high-dose).¹ In a study in subjects with either normal or impaired renal function, the clearance of a single dose of cefotaxime was reduced by 40 to 50% regardless of renal function.²

When intravenous cefotaxime 30 mg/kg and **mezlocillin** 50 mg/kg were given together over 30 minutes in 8 healthy subjects, the pharmacokinetics of the **mezlocillin** were unchanged but the clearance of the cefotaxime was reduced by about 40%. However, in a series of 5 patients with end-stage renal disease no significant decrease in cefotaxime clearance was seen when **mezlocillin** was given.³

Doses of cefotaxime may need to be reduced in the presence of either **azlocillin** or **mezlocillin**. One report suggests a dosage reduction of cefotaxime is advisable if the glomerular filtration rate is 20 to 40 mL/minute and **azlocillin** is also given.²

Table 10.2 Effect of probenecid on the pharmacokinetics of the cephalosporins

Drug	Route	Effect of probenecid	Refs
Cefacetrile	Intramuscular	Mean serum half-life increased from 52 to 90 minutes	1
Cefaclor	Oral	Serum level approximately doubled; renal excretion inhibited; renal excretion after 4 hours reduced by 61%	2,3
Cefadroxil	Oral	Probenecid 500 mg every 8 hours for 5 doses increased the half-life of cefadroxil from 1.13 to 1.63 hours and reduced its renal excretion by 58%; probenecid slightly increased and prolonged cefadroxil serum levels	4
Cefalexin	Oral	Reduced clearance	5
Cefaloglycin	Oral	Increased peak serum levels and duration of antibacterial activity	6
Cefaloridine	Intramuscular/Intravenous	Plasma levels increased by 20%. Clearance reduced by 24% (intravenous); increased serum levels; prolonged antibacterial activity (intramuscular)	7,8
Cefalotin	Intravenous	Plasma levels increased by 70%. Clearance reduced by 59%	7
Cefamandole	Intramuscular	Peak serum levels almost doubled; half-life prolonged from 1.1 to 2 hours	9
Cefazedone	Intravenous	AUC increased more than threefold; elimination half-life increased from 1.58 to 4.44 hours; total clearance reduced by 68%	10
Cefazolin	Intramuscular/Intravenous	At 6 hours serum levels of intramuscular dose doubled; after intravenous dose elimination half-life increased from 1.6 to 2.7 hour and mean serum level after 24 hours was increased from 1.1 to 2 mg/L; therapeutic levels at steady-state maintained by once daily rather than three times daily dose regimen	11-13
Cefditoren	Oral	Increased plasma half-life; decreased excretion and renal clearance	14
Cefmenoxime	Intravenous	Renal clearance of cefmenoxime reduced from 159 to 66 mL/minute; AUC almost doubled	15
Cefmetazole	Intravenous	Mean AUC increased by about 58%; clearance reduced by about 36%; half-life increased from 1.5 to 2.27 hours	16
Cefonicid	Intramuscular	Probenecid 1 g increased the maximum levels of cefonicid 500 mg by 52%, increased the AUC twofold, increased the half-life from 3.5 to 7.5 hours, reduced elimination rates and decreased renal clearance	17
Ceforanide	Intramuscular	No significant effect	18
Cefotaxime	Intramuscular/Intravenous	Oral probenecid 500 mg every 6 hours for 24 hours before, and 1 g 30 minutes before, intravenous cefotaxime 1 g reduced renal clearance by about half and almost doubled its AUC. Delayed excretion and increased plasma levels due to effects on renal tubular transfer. Clearance of cefotaxime and also its metabolites decreased by probenecid	19-21
Cefoxitin	Intramuscular/Intravenous	Serum half-life increased from 39 to 129 minutes and clearance halved (intravenous); greater increase in AUC when probenecid given 1 hour before rather than with cefoxitin (intravenous); increasing dose of probenecid from 1 to 2 g increased AUC of cefoxitin (intramuscular)	21-23
Cefprozil	Oral	Significant increase in half-life and maximum levels, AUC approximately doubled, and clearance decreased by about 60%	24
Cefradine	Oral/Intramuscular	Serum levels approximately doubled. Delay to time of peak from 1 to 2 hours (oral) and 1 to 1.5 hours (intramuscular); half-lives prolonged	2,25
Ceftazidime	Intravenous	Probenecid 500 mg every 6 hours for 24 hours before and 1 g immediately before a single intravenous dose of ceftazidime 1 g did not significantly affect ceftazidime clearance. Pharmacokinetics of single 50-mg/kg dose of ceftazidime in patients with cystic fibrosis not affected by pre-treatment with probenecid 2 g	19,26
Ceftizoxime	Intramuscular/Intravenous	AUC increased by 49% (both routes); half-life increased from 1.7 to 2.3 hours (intravenous) and 1.9 to 2.8 hours (intramuscular)	27
Ceftriaxone	Intravenous	No significant effect	28
Cefuroxime	Intravenous	AUC increased by 44 to 50%; half-life prolonged by 63%; clearance decreased by 29%	29
Latamoxef	Intravenous	Probenecid 500 mg every 6 hours for 24 hours before and 1 g immediately before a single 1-g intravenous dose of latamoxef did not significantly affect latamoxef clearance	19

Cephalosporins; Cefotaxime + Phenobarbital

A 30-month study noted a very marked increase in drug-induced reactions in children in intensive care who were given high-dose phenobarbital and beta-lactam antibacterials (mainly cefotaxime). Twenty-four out of 49 children developed drug-induced reactions, which were mainly exanthematous skin reactions.¹ The reasons are not known. It would seem prudent to consider this interaction in patients who develop skin reactions while taking both drugs.

1. Harder S, Schneider W, Bae ZU, Bock U, Zielen S. Unerwünschte Arzneimittelreaktionen bei gleichzeitiger Gabe von hochdosiertem Phenobarbital und Betalaktam-Antibiotika. *Klin Padiatr* (1990) 202, 404–7.

Cephalosporins; Cefpodoxime + Acetylcysteine

The pharmacokinetics of oral cefpodoxime proxetil are minimally affected by acetylcysteine and the interaction is unlikely to be of clinical importance.¹

1. Kees F, Wellenhofer M, Bröhl K, Grobecker H. Bioavailability of cefpodoxime proxetil with co-administered acetylcysteine. *Arzneimittelforschung* (1996) 46, 435–8.

Cephalosporins; Cefprozil + Metoclopramide or Propantheline

The pharmacokinetics of cefprozil are minimally affected by propantheline and metoclopramide, and an interaction of clinical importance is unlikely.¹

1. Shukla UA, Pittman KA, Barbhayia RH. Pharmacokinetic interactions of cefprozil with food, propantheline, metoclopramide, and probenecid in healthy volunteers. *J Clin Pharmacol* (1992) 32, 725–31.

Cephalosporins; Ceftazidime + Indometacin

The clearance of ceftazidime is significantly reduced by indometacin in neonates, and dosage adjustments are likely to be necessary.

Clinical evidence, mechanism, importance and management

A study found the prenatal use of indometacin reduced the clearance of ceftazidime 25 mg/kg by 17.5% in 12 premature neonates (born at about 29 weeks) who were 10 days old. Further, in similar neonates who had not received indometacin, the clearance of ceftazidime increased over the first 10 days of life, but this was not seen when indometacin had been given.¹ A further study by the same authors intended to establish an appropriate

dose of ceftazidime for premature neonates. This study found that in 25 subjects who had received indometacin prenatally, the clearance of ceftazidime was reduced by 31% and therefore the authors suggest that additional dose reductions are required. However, note that the effect of indometacin was cancelled out in neonates who had also received betamethasone prenatally.² *Animal* studies have shown that indometacin reduces ceftazidime excretion by decreasing its glomerular filtered load.³ Dosage of ceftazidime in preterm infants in the first week of life should be based on gestational age and glomerular filtration rate. Additional dosage adjustments are recommended in preterm infants who are also given indometacin.^{1,2}

Chloramphenicol + Cimetidine

Isolated reports describe fatal aplastic anaemia in two patients given intravenous chloramphenicol and cimetidine.

Clinical evidence, mechanism, importance and management

Pancytopenia and aplastic anaemia developed in a man taking cimetidine 1.2 g daily, within 18 days of being given intravenous chloramphenicol 1 g every 6 hours. It proved to be fatal.¹ Another patient, similarly treated, developed fatal aplastic anaemia after 19 days.² A drug interaction with cimetidine was suspected because the onset of pancytopenia was more rapid than in previous cases where chloramphenicol alone induced aplastic anaemia. This effect may occur because the bone marrow depressant effects of the two drugs are additive. There are at least 8 other cases of aplastic anaemia following the use of parenteral chloramphenicol in the absence of cimetidine.² The general importance of these observations is uncertain, but the authors of one of the reports suggest that these drugs should be used together with caution.

Chloramphenicol + Dapsone

Dapsone does not significantly affect the pharmacokinetics of oral chloramphenicol.

Clinical evidence, mechanism, importance and management

A comparison of the pharmacokinetics of oral chloramphenicol in 8 healthy subjects and 8 patients with uncomplicated lepromatous leprosy found that the half-life of a single 500-mg dose of chloramphenicol was prolonged from 4.3 to 6.4 hours in patients with leprosy, possibly due to changes in liver function. The elimination half-life of chloramphenicol was further increased, to about 8 hours, when the subjects were also given dapsone 100 mg daily for 8 days. However, this latter increase was not statistically significant. Although there was no clinically significant interaction between dapsone and chloramphenicol, the disposition of chloramphenicol may be altered in leprosy.¹

Chloramphenicol + Other antibacterials

An old report suggests that the use of chloramphenicol may antagonise the effects of ampicillin in bacterial meningitis. In contrast, no antagonism and even additive antibacterial effects have

been described in other infections. Chloramphenicol levels have been markedly lowered by rifampicin (rifampin) in 4 children.

Clinical evidence

(a) Antibacterial antagonism

A study in 264 patients (adults, and children over two months old) with acute bacterial meningitis showed that when they were given **ampicillin** 150 mg/kg daily alone, the case-fatality ratio was 4.3% compared with 10.5% in comparable subjects given a combination of **ampicillin**, chloramphenicol 100 mg/kg daily up to 4 g and **streptomycin** 40 mg/kg daily up to 2 g. The neurological sequelae (hemiparesis, deafness, cranial nerve palsies) were also markedly increased by the combined use of these drugs.¹ Antibacterial antagonism was clearly seen in a 10-week-old infant with *Salmonella enteritidis* meningitis, who was treated with chloramphenicol and **ceftazidime**.²

However, in contrast a report claims that antibacterial antagonism was not seen in 65 of 66 patients given chloramphenicol and **benzylpenicillin** for bronchitis or bronchopneumonia.³ **Ampicillin** with chloramphenicol is more effective than chloramphenicol alone in the treatment of typhoid,⁴ and in a study of 700 patients, **procaine benzylpenicillin** with chloramphenicol was shown to be more effective than chloramphenicol alone in the treatment of gonorrhoea (failure rates of 1.8% compared with 8.5%).⁵

(b) Pharmacokinetic interactions

In a study in premature and full-term neonates, infants and small children, it was found that the presence of **penicillin** markedly raised chloramphenicol levels.⁶

Two children, aged 2 and 5 years, with *Haemophilus influenzae* meningitis, were given chloramphenicol 100 mg/kg per day in four divided doses by infusion over 30 minutes. Within 3 days of starting **rifampicin** (**rifampin**) 20 mg/kg per day their peak serum chloramphenicol levels were reduced by 86 and 64%, respectively, and only returned to the therapeutic range when the chloramphenicol dosage was increased to 125 mg/kg per day.⁷

Two other children, of 5 and 18 months, with *Haemophilus influenzae* infections, are also reported to have shown reductions of 75% and 94%, respectively, in serum chloramphenicol levels when given **rifampicin** 20 mg/kg daily for 4 days. These reductions occurred despite 20 to 25% increases in the chloramphenicol dosage.⁸

Mechanism

By no means fully understood. Chloramphenicol inhibits bacterial protein synthesis and can change an actively growing bacterial colony into a static one. Thus the effects of a bactericide, such as penicillin, which interferes with cell wall synthesis, are blunted, and the death of the organism occurs more slowly. This would seem to explain the antagonism seen with some organisms.

It is thought that rifampicin, a potent enzyme inducer, markedly increases the metabolism of the chloramphenicol by the liver, thereby lowering its serum levels.^{7,8}

Importance and management

Proven cases of antibacterial antagonism of chloramphenicol in patients seem to be few in number, and there is insufficient evidence to impose a general prohibition, because, depending on the organism, penicillins and chloramphenicol have been used together with clear advantage.

So far only four cases of an interaction between rifampicin and chloramphenicol appear to have been reported. However, the evidence is of good quality and in line with the way rifampicin interacts with other drugs, so this interaction should be taken seriously. There is a risk that serum chloramphenicol levels will become subtherapeutic. The authors of the second report point out that raising the chloramphenicol dosage may possibly expose the patient to a greater risk of bone marrow aplasia. They suggest delaying rifampicin prophylaxis in patients with invasive *Haemophilus influenzae* infections until the end of chloramphenicol treatment.

Chloramphenicol + Paracetamol (Acetaminophen)

Although there is limited evidence to suggest that paracetamol may affect chloramphenicol pharmacokinetics its validity has been criticised. Evidence of a clinically relevant interaction appears to be lacking.

Clinical evidence, mechanism, importance and management

Three studies report alterations in the pharmacokinetics of chloramphenicol by paracetamol. The first was conducted in 6 adults in intensive care after an observation that the half-life of chloramphenicol was prolonged by paracetamol in children with kwashiorkor. The addition of 100 mg of intravenous paracetamol increased the half-life of chloramphenicol in the adults from 3.25 to 15 hours.¹ However, this study has been criticised because of potential errors in the method used to calculate the half-life,² the unusual doses and routes of administration used,^{2,3} and because the pharmacokinetics of the chloramphenicol with and without paracetamol were calculated at different times after the administration of chloramphenicol.⁴ It has also been pointed out that malnutrition (e.g. kwashiorkor) can increase the elimination rate and AUC of chloramphenicol independently of paracetamol.²

The second study demonstrated a different interaction, in that the clearance of chloramphenicol was *increased* and the half-life *reduced*.⁵ This study has also been criticised as it does not account for the fact that chloramphenicol clearance increases over the duration of a treatment course, which suggests that the changes seen in the pharmacokinetics of chloramphenicol may be independent of the paracetamol.⁶ The authors later admit this as a possibility.⁷ The third study found no differences in the pharmacokinetics of chloramphenicol after the first dose, but at steady state, the AUC and peak serum levels of chloramphenicol were lower in children who also received paracetamol.⁸

Three other studies have failed to confirm the existence of a pharmacokinetic interaction between chloramphenicol and paracetamol.^{2–4}

The clinical significance of these reports is unclear, and clinical evidence of toxicity or treatment failure of chloramphenicol appears to be lacking. It would seem prudent to remain aware of the potential for interaction, especially in malnourished patients, but routine monitoring would appear unnecessary without further evidence.

Chloramphenicol + Phenobarbital

Studies in children show that phenobarbital can markedly reduce serum chloramphenicol levels. There is a single report, in one adult, of markedly increased serum phenobarbital levels caused by chloramphenicol.

Clinical evidence

(a) Effects on chloramphenicol

A study in a group of infants and children (aged 1 month to 12 years) given chloramphenicol 25 mg/kg every 6 hours found that 6 of them, also taking phenobarbital, had reduced serum chloramphenicol levels, when compared with 17 controls. The peak levels were lowered by 34%, from 25.3 to 16.6 micrograms/mL, and the trough levels were lowered by 44%, from 13.4 to 7.5 micrograms/mL.¹ Two children aged 3 and 7 months were treated for *H. influenzae* meningitis with chloramphenicol 100 mg/kg daily, initially intravenously, and later orally. The chloramphenicol levels halved over the first 2 days of treatment, while the children were receiving phenobarbital 10 mg/kg/day to prevent convulsions. One child had serum chloramphenicol levels of only 5 micrograms/mL even though the initial doses used were expected to give levels of 15 to 25 micrograms/mL.²

Another study confirmed that this interaction occurred in 20 neonates, but no statistically significant effect was found in 40 infants.³ Decreased chloramphenicol levels have been described in a single case report of a child who was also being treated with phenytoin and phenobarbital. The serum chloramphenicol levels were 35.1 micrograms/mL prior to the antiepileptics, 19.1 micrograms/mL after 2 days of phenytoin and 13.2 micrograms/mL a month after the addition of phenobarbital.⁴ For more information on the interaction of chloramphenicol with phenytoin see 'Phenytoin + Chloramphenicol', p.555.

(b) Effects on phenobarbital

A man admitted to hospital on numerous occasions for pulmonary complications associated with cystic fibrosis, had average serum phenobarbital levels of 33 micrograms/mL while taking phenobarbital 200 mg daily and oral chloramphenicol 600 mg every 6 hours. One week after the antibacterial was withdrawn, his serum phenobarbital levels were 24 micrograms/mL even though the phenobarbital dosage was increased from 200 to 300 mg daily.⁵

Mechanism

Phenobarbital is a potent liver enzyme inducer, which can increase the metabolism and clearance of chloramphenicol (clearly demonstrated in *rats*⁶), so that its serum levels fall and its effects are reduced. Chloramphenicol inhibits the metabolism of the phenobarbital (also demonstrated in *animals*⁷) so that the effects of the barbiturate are increased.

Importance and management

This interaction appears to be established. The documentation is limited but what happened is consistent with the recognised enzyme-inducing actions of phenobarbital and the inhibitory actions of chloramphenicol. Concurrent use should be well monitored to ensure that chloramphenicol serum levels are adequate, and that phenobarbital levels do not become too high. Make appropriate dosage adjustments as necessary.

Clindamycin or Lincomycin + Food or Drinks

The serum levels of lincomycin are markedly reduced (by up to two-thirds) if taken in the presence of food, but clindamycin is not significantly affected. Cyclamate sweeteners can also reduce the absorption of lincomycin.

Clinical evidence

In a study in 10 healthy subjects the mean peak serum levels of a single 500-mg oral dose of lincomycin were about 3 micrograms/mL when taken 4 hours before **breakfast**, 2 micrograms/mL when taken 1 hour before breakfast, and less than 1 microgram/mL when taken after breakfast. The mean total amounts of lincomycin recovered from the urine were 40.4, 23.8, and 8.9 mg, respectively.¹

Reduced serum lincomycin levels due to the presence of **food** have been described in other reports,^{2,3} but the absorption of clindamycin is not affected.^{3,4}

Sodium cyclamate, an artificial sweetener found in diet foods, drinks and some pharmaceuticals, can also markedly reduce the absorption of lincomycin. The AUC of lincomycin 500 mg was reduced by about 75% by 1 Molar equivalent of **sodium cyclamate** (said to be an amount equal to only part of a bottle of diet drink, but exact quantity not stated).⁵

Mechanism

Not understood.

Importance and management

The food interaction with lincomycin is well established and of clinical importance. Lincomycin should not be taken with food or within several hours of eating a meal if adequate serum levels are to be achieved. An alternative is clindamycin, a synthetic derivative of lincomycin, which has the same antibacterial spectrum but is not affected by food.

Clindamycin or Lincomycin + Kaolin

Kaolin-pectin can markedly reduce the absorption of lincomycin. This can be avoided by giving the lincomycin two hours after the kaolin. The rate but not the extent of clindamycin absorption is altered by kaolin-pectin. However, note that diarrhoea is often an indication that these antibacterials should be withdrawn.

Clinical evidence

About 85 mL of *Kaopectate* (kaolin-pectin) reduced the absorption of lincomycin 500 mg by about 90% in 8 healthy subjects. Giving the *Kaopectate* 2 hours before the antibacterial had little or no effect on its absorption, whereas when *Kaopectate* was given 2 hours after lincomycin, the absorption was reduced by about 50%. The absorption rate of clindamycin is markedly prolonged by kaolin, but the extent of its absorption remains unaffected.¹

Mechanism

It seems probable that the lincomycin becomes adsorbed onto the kaolin, thereby reducing its bioavailability. The kaolin also coats the lining of the gut and acts as a physical barrier to absorption.²

Importance and management

Information seems to be limited to this study, but the interaction between lincomycin and kaolin appears to be established and of clinical importance. For good absorption and a good antibacterial response separate their administration as much as possible, ideally giving the kaolin at least 2 hours before the antibacterial. Clindamycin appears to be a suitable alternative to lincomycin.

However, note that marked diarrhoea is an indication that lincomycin or clindamycin should be stopped immediately. This is because it may be a sign of pseudomembranous colitis, which can be fatal.

Colistin + Sucralfate

An *in vitro* study with colistin sulfate found that it became markedly and irreversibly bound to sucralfate at the pH values found in the gut. This suggests that its efficacy for gut decontamination or gastrointestinal infections might be decreased by sucralfate.

Clinical evidence, mechanism, importance and management

To simulate what might happen in the gut, colistin sulfate 50 mg/L was mixed with sucralfate 500 mg in 40 mL of water at pH 3.5 and allowed to stand for 90 minutes at 25°C. Analysis of the solution showed that the colistin concentration fell rapidly and progressively over 90 minutes to about 40%. When the pH of the mixture was then raised to 6.5 to 7 for 90 minutes, there was no change in the concentration of colistin, suggesting that the interaction was irreversible.¹ The reason for this change is not known, but the suggestion is that sucralfate forms insoluble chelates with colistin.¹

It is not known how important this interaction is likely to be in practice, but the efficacy of colistin in gut decontamination and gut infections may be decreased. Separating the dosages might not be effective in some post-operative patients because their gastric function may not return to normal for up to 5 days, and some sucralfate might still be present when the next dose is given.¹ More study is needed to find out whether this interaction is clinically important, but in the meanwhile it would seem prudent to monitor concurrent use carefully, being alert for any evidence of reduced effects.

Co-trimoxazole + Azithromycin

Azithromycin does not alter the pharmacokinetics of co-trimoxazole.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given **co-trimoxazole** (trimethoprim and sulfamethoxazole) 960 mg daily for 7 days found that a single 1.2-g dose of azithromycin given on day 7 did not alter the pharmacokinetics of either trimethoprim or sulfamethoxazole to a clinically relevant extent.¹

1. Amsden GW, Foulds G, Thakker K. Pharmacokinetic study of azithromycin with fluconazole and cotrimoxazole (trimethoprim-sulfamethoxazole) in healthy volunteers. *Clin Drug Invest* (2000) 20, 135–42.

Co-trimoxazole + Cimetidine

Cimetidine has no significant effect on the pharmacokinetics of co-trimoxazole.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 6 healthy subjects were given cimetidine 400 mg every 6 hours for 6 days, with a single 960-mg dose of co-trimoxazole (trimethoprim with sulfamethoxazole) on day 6. Although trimethoprim levels were consistently slightly higher in the presence of cimetidine, they were not significantly different. Cimetidine had no effect on the pharmacokinetics sulfamethoxazole.¹

1. Rogers HJ, James CA, Morrison PJ, Bradbrook ID. Effect of cimetidine on oral absorption of ampicillin and co-trimoxazole. *J Antimicrob Chemother* (1980) 6, 297–300.

Co-trimoxazole + Kaolin-pectin

Kaolin-pectin can cause a small but probably clinically unimportant reduction in serum trimethoprim levels, and has no effect on sulfamethoxazole pharmacokinetics.

Clinical evidence, mechanism, importance and management

Co-trimoxazole suspension (trimethoprim 160 mg with sulfamethoxazole 800 mg) was given to 8 healthy subjects, with and without 20 mL of kaolin-pectin suspension. The kaolin-pectin reduced the AUC and the maximum serum levels of the trimethoprim by about 12% and 20%, respectively. Changes in the sulfamethoxazole pharmacokinetics were not significant.¹ The probable reason for this reduction in AUC is that trimethoprim is adsorbed onto the kaolin-pectin, which reduces the amount available for absorption. However, the reductions are small and unlikely to be clinically relevant.

1. Gupta KC, Desai NK, Satooskar RS, Gupta C, Goswami SN. Effect of pectin and kaolin on bioavailability of co-trimoxazole suspension. *Int J Clin Pharmacol Ther Toxicol* (1987) 25, 320–1.

Co-trimoxazole + Prilocaine/Lidocaine cream

Methaemoglobinaemia developed in a baby treated with co-trimoxazole when *Emla* (prilocaine/lidocaine) cream was applied to his skin.

Clinical evidence, mechanism, importance and management

A 12-week-old child, given co-trimoxazole for 2 months for pyelitis, was treated with 5 g of *Emla* cream (prilocaine 25 mg and lidocaine 25 mg per gram) applied to the back of his hands and the cubital regions. Unfortunately his operation was delayed, and 5 hours later, just before the operation began, his skin was noted to be pale and his lips had a brownish cyanotic colour. This was found to be due to the presence of 28% methaemoglobin (reference range: less than 3%).¹ The authors of the report suggest that the prilocaine together with the sulfamethoxazole (both known to be able to cause methaemoglobin formation) suppressed the activity of two enzymes (NADH-dehydrogenase and NADP-diaphorase), which normally keep blood levels of methaemoglobin to a minimum.¹ A study in 20 children² confirmed that *Emla* cream can increase methaemoglobin levels, although levels *decreased* in 6 of them. However, the maximum increase was 1.2% (from 0.7 to 1.9%), and the highest value was 2%, which was still within the reference range. Another study showed similar small increases in methaemoglobin levels, and found that these remained elevated after 24 hours. The authors concluded that daily application may lead to accumulation, and a greater risk of toxicity.³

The case report appears to be unusual, but it has been suggested that there may be a special risk of methaemoglobinaemia with *Emla* in children with pre-existing anaemia, reduced renal excretion of the metabolites of prilocaine, or the concurrent use of sulfonamides.³ It would seem prudent to keep *Emla* contact time to a minimum in these patients.

3. Fraying IM, Addison GM, Chatterjee K, Meakin G. Methaemoglobinaemia in children treated with prilocaine-lignocaine cream. *BMJ* (1990) 301, 153–4.

Co-trimoxazole or Trimethoprim + Rifamycins

The pharmacokinetics of trimethoprim are not significantly affected by rifabutin, and probably not by rifampicin (rifampin). Rifabutin does not affect the pharmacokinetics of sulfamethoxazole, but significantly increases exposure to its hydroxylamine metabolite and as a result may increase adverse reactions to sulfamethoxazole in HIV-positive patients.

A significant reduction in co-trimoxazole levels and a decrease in prophylactic efficacy has been seen in HIV-positive patients taking rifampicin. Limited evidence suggests that co-trimoxazole can increase rifampicin serum levels. Trimethoprim does not affect the pharmacokinetics of rifampicin.

Clinical evidence, mechanism, importance and management

(a) Rifabutin

Twelve HIV-positive patients taking co-trimoxazole (sulfamethoxazole and trimethoprim; strength not stated) twice daily for 7 days were also given

en rifabutin 300 mg daily for a further 14 days. The sulfamethoxazole component remained unaffected by rifabutin but the trimethoprim AUC was decreased by 22%. This small reduction is not expected to be clinically significant.¹ However, another study in HIV-positive patients given co-trimoxazole (sulfamethoxazole 800 mg with trimethoprim 160 mg daily) found that although rifabutin 300 mg daily had minimal effects on the disposition of sulfamethoxazole and its acetylated metabolite, it significantly increased the AUC, urinary recovery and formation clearance of its hydroxylamine metabolite by about 50%. As the hydroxylamine metabolite may be one of the factors associated with adverse reactions to sulfamethoxazole in HIV-positive patients, concurrent rifabutin may increase the rate of adverse reactions.²

(b) Rifampicin (Rifampin)

No significant pharmacokinetic interaction seems to occur when healthy subjects are given trimethoprim 240 mg daily with rifampicin 900 mg daily (both in divided doses). After 4 to 5 days, less trimethoprim is recovered in the urine, as more is metabolised prior to excretion due to the enzyme-inducing effects of rifampicin, but this does not appear to be of clinical importance.^{3,4} Another study also notes that no clinically significant pharmacokinetic interaction occurs between trimethoprim and rifampicin.⁵

However, a case-control study of the efficacy of co-trimoxazole in preventing toxoplasmosis in HIV-positive patients found a link between rifampicin use and co-trimoxazole failure,⁶ which prompted the authors to conduct a pharmacokinetic study. When rifampicin 600 mg daily was given to 10 HIV-positive patients with co-trimoxazole 960 mg daily, it was found that the AUCs of trimethoprim and sulfamethoxazole were reduced by 56% and 28%, respectively. These changes are sufficient to reduce the efficacy of co-trimoxazole treatment.⁷ It would therefore seem prudent to consider this interaction when giving rifampicin to HIV-positive patients taking co-trimoxazole prophylaxis.

In one study 15 patients with tuberculosis, who had taken rifampicin 450 mg daily for at least 15 days, were given co-trimoxazole (trimethoprim 320 mg and sulfamethoxazole 800 mg 12-hourly) for 5 to 10 days. Rifampicin levels were measured at 5 time points over 6 hours before and during co-trimoxazole treatment. At 4 and 6 hours, rifampicin levels were significantly higher (27% and 56%, respectively) during co-trimoxazole treatment, but peak levels were only increased by about 18%. Concurrent use did not result in any increase in adverse effects over the study period.⁸

Co-trimoxazole + Salbutamol (Albuterol)

Salbutamol reduces the rate but increases the extent of sulfamethoxazole absorption.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects, oral salbutamol 4 mg four times daily for 2 weeks had no effect on the pharmacokinetics of a single 400-mg oral dose of sulfamethoxazole (in co-trimoxazole), although the absorption rate constant was reduced by about 40% and the extent of absorption over 72 hours was increased by 22.6%.¹ A possible reason for these effects is that salbutamol stimulates the beta receptors in the gut, causing relaxation, which allows an increased contact time, and therefore increased absorption of sulfamethoxazole.¹ The clinical significance of this interaction is unknown, but it

seems unlikely to be of importance. No interaction would be expected with inhaled salbutamol.

Cycloserine + Ethionamide

Neurotoxic adverse effects may be potentiated by the concurrent use of cycloserine and ethionamide.

Clinical evidence, mechanism, importance and management

Three cases of encephalopathy have been reported in patients taking antitubercular regimens which included ethionamide (and in 2 cases, isoniazid): in one case symptoms occurred during treatment with ethionamide and cycloserine. All 3 patients recovered after withdrawal of either ethionamide (and isoniazid) or cycloserine, and treatment with nicotinamide and other vitamin B compounds.¹ The manufacturers note that the concurrent use of ethionamide can potentiate the neurotoxic adverse effects of cycloserine.^{2,3} The US manufacturer of ethionamide notes that convulsions have been reported in patients also taking cycloserine and they recommend special care when the treatment regimen includes both drugs.⁴

Cycloserine + Food or Antacids

Orange juice and an antacid (*Mylanta*) do not affect the pharmacokinetics of cycloserine, but a high-fat meal delays its absorption.

Clinical evidence, mechanism, importance and management

(a) Antacids

A study in 12 healthy subjects found that the bioavailability of a single 500-mg dose of cycloserine was not affected by 15 mL of *Mylanta* (aluminium hydroxide 400 mg, magnesium hydroxide 400 mg, simeticone 40 mg per 5 mL). *Mylanta* was given 9 hours before the cycloserine, at the same time as the cycloserine, immediately after meals, and at bedtime on the dosing day and following day.¹

(b) Food

A study in 12 healthy subjects found that the bioavailability of a single 500-mg dose of cycloserine was not significantly affected by 240 mL of orange juice.¹ When cycloserine 500 mg was given 15 minutes after the start of a high-fat meal, which was completed within 30 minutes, the AUC was not affected, but the maximum serum levels were reduced by about 16% and the time to maximum levels was increased from 0.75 to 3.5 hours. It is possible that patients with relatively low plasma levels or patients receiving once rather than a twice daily dosage that the delay in absorption could result in increased periods of subinhibitory levels.¹ However, there is no evidence to suggest that this is clinically significant.

1. Zhu M, Nix DE, Adam RD, Childs JM, Peloquin CA. Pharmacokinetics of cycloserine under fasting conditions and with high-fat meal, orange juice, and antacids. *Pharmacotherapy* (2001) 21, 891–7.

Cycloserine + Isoniazid

The adverse CNS effects of cycloserine are increased by isoniazid.

Clinical evidence, mechanism, importance and management

A report describes both an increase and a decrease in serum cycloserine levels in some subjects, which were apparently caused by isoniazid; however, the mean level of cycloserine was not significantly changed. Only one out of 11 patients taking cycloserine alone developed adverse effects (drowsiness, dizziness, unstable gait), but when isoniazid was added, 9 of the 11 developed these effects.¹ The manufacturers recommend monitor-

ing for these adverse effects and adjusting the doses as necessary to manage them.^{2,3}

3. Seromycin (Cycloserine). Eli Lilly and Company. US Prescribing information, April 2005.

Dapsone + Antacids

The absorption of dapsone is unaltered by an antacid containing aluminium/magnesium hydroxide and/or simeticone.

Clinical evidence, mechanism, importance and management

A study to see whether changes in gastric pH might affect the absorption of dapsone found that when a single 100-mg dose of dapsone was taken with the second of 11 doses of *Mylanta II* (hydrated aluminium hydroxide, magnesium hydroxide and simeticone), given every hour, the absorption of the dapsone remained unchanged. The mean gastric pH rose from 2.3 before using the antacid, to 4.5 or higher while taking dapsone and the antacid.¹ In another study, 8 subjects were given a single 100-mg dose of dapsone as a liquid oral preparation followed immediately by 12.5 mL of *Maalox TC* (aluminium/magnesium hydroxide). Peak plasma levels of dapsone were increased by about 11% and the time to peak levels was reduced from 1.9 to 1.3 hours. However, the dapsone AUC and elimination rate were not affected.² No special precautions would therefore seem to be needed if *Mylanta*, *Maalox TC* or any other similar antacid is used with dapsone. See also 'NRTIs + Dapsone', p.796, for a discussion of the effects of the buffer in didanosine tablets.

2. Mirochnick M, Breña A, McNamara ER, Clarke D, Pelton S. Effect of antacid on dapsone absorption. *Pediatr AIDS HIV Infect* (1993) 4, 13–16.

Dapsone + Clarithromycin

Clarithromycin does not alter the metabolism of dapsone.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given single 100-mg doses of dapsone before and after taking clarithromycin 1 g twice daily for 10 days, found that the clearance of dapsone was unchanged. Of equal importance was finding that the AUC of the *N*-hydroxylation metabolite of dapsone, which appears to be responsible for the haematological toxicity (methaemoglobinemia), was also unchanged.¹

In another study, 11 HIV-positive patients were given dapsone 100 mg daily then clarithromycin 500 mg twice daily for 2 weeks. Clarithromycin had no effect on dapsone clearance or the production of the hydroxylamine metabolite of dapsone.²

These results suggest that the cytochrome P450 isoenzyme CYP3A4, which is inhibited by clarithromycin, is not involved in dapsone metabolism.²

Clarithromycin would not be expected to alter the toxicity of dapsone, and no special precautions are required during concurrent use.

Dapsone + Clofazimine

Dapsone can reduce the anti-inflammatory effects of clofazimine. Clofazimine does not affect the pharmacokinetics of dapsone.

Clinical evidence, mechanism, importance and management

Fourteen out of 16 patients with severe recurrent erythema nodosum leprosum (ENL) failed to respond adequately when given dapsone and

clofazimine and needed additional treatment with corticosteroids. When the dapsone was stopped the patients responded to clofazimine alone, and in some instances the ENL was controlled by smaller doses.¹ Further evidence of this interaction comes from a laboratory study, which suggests that the actions of clofazimine may be related to its ability to inhibit neutrophil migration (resulting in decreased numbers of neutrophils in areas of inflammation), whereas dapsone can have the opposite effect.¹ Although the information is very limited, it would seem prudent to avoid the concurrent use of dapsone and clofazimine in the treatment of ENL. The authors of this report¹ are at great pains to emphasise that what they describe only relates to the effects of dapsone on the anti-inflammatory effects of clofazimine, and not to the beneficial effects of combined use when treating drug-resistant *Mycobacterium leprae*.

A study in patients taking clofazimine and dapsone² and 4 other studies in patients also taking isoniazid or rifampicin suggest that clofazimine does not affect the pharmacokinetics of dapsone.^{3–6} However, one earlier study⁷ found that clofazimine transiently increased the renal excretion of dapsone in 9 of 17 patients with leprosy who had recently discontinued dapsone.

Dapsone + Drugs that affect gastric pH

Cimetidine raises serum dapsone levels, and may reduce methaemoglobinaemia due to dapsone. Cimetidine, ranitidine and omeprazole do not appear to affect the outcome of dapsone prophylaxis against *Pneumocystis pneumonia*. The absorption of dapsone does not appear to be altered by nizatidine-induced increases in gastric pH.

Clinical evidence, mechanism, importance and management

The AUC of a single 100-mg dose of dapsone was increased by 40% in 7 healthy subjects after they took **cimetidine** 400 mg three times daily for 3 days.¹ The probable reason is that the **cimetidine** (a known enzyme inhibitor) inhibits the metabolism of the dapsone by the liver. Although this might be expected to increase the risk of haematological adverse effects of dapsone by raising its serum levels, **cimetidine** also apparently markedly reduces the production of the hydroxylamine metabolite of dapsone (the AUC fell by more than half). Dapsone hydroxylamine appears to be responsible for the methaemoglobinaemia and haemolysis that may occur with dapsone treatment.¹ These findings were later confirmed in 6 patients taking long-term dapsone 75 to 350 mg daily who were given **cimetidine** 1.2 g daily for 2 weeks. Steady-state serum dapsone levels rose by about 47%, accompanied by a fall in serum methaemoglobin levels from 7.1 to 5.2% (reference range less than 2%), in the first week.² Similar findings were reported in a further 3-month study in 8 patients.³ However, a sustained decrease in methaemoglobin was not seen, with levels returning to baseline at week 12, despite the continued use of **cimetidine**.³ Another report on a small number of patients, comparing those treated with **cimetidine**, **ranitidine** or **omeprazole** with those not taking acid suppression, found no difference in the outcome of dapsone prophylaxis for *Pneumocystis pneumonia* in HIV-positive patients.⁴ A study in healthy subjects found that the increase in pH produced by **nizatidine** did not result in any clinically significant changes in the rate or extent of dapsone absorption.⁵ It would therefore seem that no additional precautions are needed if H₂-receptor antagonists or proton pump inhibitors are given to patients taking dapsone. Dapsone + Fluconazole

Fluconazole decreases the production of the toxic metabolite of dapsone, and might therefore reduce the incidence of adverse reactions to dapsone.

Clinical evidence, mechanism, importance and management

Twelve HIV-positive patients were given dapsone 100 mg daily for 2 weeks and then in random order either fluconazole 200 mg daily, rifabutin 300 mg daily or fluconazole with rifabutin, each for 2 weeks. Dapsone pharmacokinetics were unaffected by fluconazole. However, fluconazole inhibited the production of the *N*-hydroxylamine metabolite of dapsone (AUC, urinary recovery, and formation clearance reduced by about 50%).¹

Hydroxylamine is assumed to be responsible for the haematological toxicity of dapsone (methaemoglobinaemia). The findings of this study suggest that the production of this metabolite is mediated via the cytochrome P450 isoenzyme CYP2C9, which fluconazole inhibits.

On the basis of these results, fluconazole would not be expected to alter the efficacy of dapsone, but might reduce its toxicity. Further study is needed to assess this potential.

Dapsone + Probenecid

The serum levels of dapsone can be markedly raised by probenecid.

Clinical evidence

Twelve patients with quiescent tuberculoid leprosy were given dapsone 300 mg with probenecid 500 mg, and 5 hours later another 300-mg dose of dapsone. At 4 hours, the dapsone serum levels were raised about 50%. The urinary excretion of dapsone and its metabolites were reduced.¹

Mechanism

Not fully examined. It seems probable that the probenecid inhibits the renal excretion of dapsone by the kidney.

Importance and management

The documentation is very limited. It is likely that the probenecid will raise the serum levels of dapsone given long-term. The importance of this is uncertain, but the extent of the rise and the evidence that the haematological toxicity of dapsone may be related to dapsone levels² suggests that it may well have some clinical importance. It would therefore seem prudent to monitor for dapsone adverse effects if probenecid is also given.

Dapsone + Proguanil

No pharmacokinetic interaction appears to occur between dapsone and proguanil, and they have been successfully used together for malaria prophylaxis.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects found that proguanil 200 mg daily had no effect on the pharmacokinetics of dapsone 10 mg daily, nor on its principal metabolite, monoacetyldapsone. However, the authors of this report are extremely cautious because, despite this lack of a pharmacokinetic interaction at these dosages, they say that increased dapsone toxicity cannot be ruled out.¹ Dapsone 25 mg was successfully used with proguanil 200 mg daily for malarial prophylaxis in the Vietnam war,² and the same regimen, but with the dapsone dosage every third day was successful as prophylaxis against proguanil-resistant falciparum malaria in Papua New Guinea.¹ Moreover, a different dosage (dapsone 4 or 12.5 mg with proguanil 200 mg daily), was well tolerated over a period of 80 days when used as malaria prophylaxis in Thailand.³

Dapsone + Pyrimethamine

Pyrimethamine does not significantly affect the pharmacokinetics of dapsone.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects given single doses of dapsone 100 mg, pyrimethamine 25 mg or both drugs together found that the peak plasma levels of dapsone fell by 17% and the half-life was unchanged, but the apparent volume of distribution was significantly increased from 1.53 to 1.93 L/kg. The pharmacokinetics of pyrimethamine were not affected by dapsone.¹ In another study HIV-positive patients were given dapsone 200 mg weekly (the maximum tolerated dose) either alone or with pyrimethamine 25 mg weekly. In contrast to the earlier study, there was a decrease in volume of distribution of dapsone when it was given with pyrimethamine, although dapsone levels were not significantly altered.² Furthermore, the tolerability of one-weekly dapsone plus pyrimethamine was found to be similar to that of once-weekly dapsone alone.²

Pharmacokinetics and safety of weekly dapsone and dapsone plus pyrimethamine for prevention of pneumocystis pneumonia. *Antimicrob Agents Chemother* (1994) 38, 1580–7.

Dapsone + Rifamycins

Rifampicin increases the urinary excretion of dapsone, lowers its serum levels and increases the risk of toxicity (methaemoglobinaemia). Similarly, rifabutin increases the clearance of dapsone, and may also increase its toxicity.

Clinical evidence

(a) Rifabutin

Twelve HIV-positive patients were given dapsone 100 mg daily for 2 weeks and then, in random order, either rifabutin 300 mg daily, fluconazole 200 mg daily, or fluconazole with rifabutin, each for 2 weeks. Rifabutin alone increased the clearance of dapsone by 67%. When combined with fluconazole, rifabutin increased the clearance of dapsone by 38%, which shows that fluconazole partially attenuated the enzyme-inducing effects of rifabutin. Rifabutin increased the formation clearance of dapsone by 92%, which was again attenuated by fluconazole. Rifabutin did not affect the AUC of the hydroxylamine metabolite of dapsone, which is thought to be associated with dapsone toxicity.¹

(b) Rifampicin (Rifampin)

A study in 7 patients with leprosy given single doses of dapsone 100 mg and rifampicin 600 mg, alone or together, found that while the pharmacokinetics of rifampicin were not significantly changed, the half-life of the dapsone was roughly halved and the AUC was reduced by about 20%.²

Other studies in patients given both drugs for several days, similarly found reduced dapsone serum levels and an increased urinary excretion.^{3–7} Another study in 12 healthy subjects given a single 100-mg dose of dapsone before and after taking rifampicin 600 mg daily for 10 days, found that the clearance of the dapsone was considerably increased (from 2.01 to 7.17 litres/hour). Of equal importance was finding that the production of the hydroxylamine metabolite of dapsone, which appears to be responsible for the haematological toxicity (methaemoglobinaemia), was markedly increased. The 24-hour AUC of methaemoglobin was increased by more than 60%,⁸ suggesting that this interaction increases dapsone toxicity.

Mechanism

Rifampicin and rifabutin increase the metabolism and clearance of dapsone. Rifampicin also increases the blood levels of the toxic hydroxylamine metabolite of dapsone. Similarly, rifabutin increased the formation of this metabolite, although increases in the AUC were not seen.

Importance and management

The interaction between dapsone and rifampicin is established but of uncertain clinical importance. Concurrent use should be well monitored to confirm that treatment is effective. It may be necessary to raise the dosage of dapsone. It has been pointed out that there is the risk of treatment failures for *Pneumocystis pneumonia* as well as for leprosy.⁹ Also be alert for any evidence of methaemoglobinaemia.

Although there is less information, rifabutin appears to interact similarly to rifampicin. When dapsone is given with rifabutin, the dosage of dapsone may need to be increased, but this may increase exposure to the potentially toxic hydroxylamine metabolite.¹

Dapsone + Trimethoprim

The serum levels of both drugs are possibly raised by concurrent use. Both increased efficacy and dapsone toxicity have been seen.

Clinical evidence

Eighteen patients with AIDS, treated for *Pneumocystis pneumonia* and taking dapsone 100 mg daily, were compared with 30 other patients taking dapsone with trimethoprim 20 mg/kg daily. The trimethoprim raised dapsone levels by 40%, from 1.5 to 2.1 micrograms/mL, at 7 days (steady-state). Dapsone toxicity (methaemoglobinaemia) was also increased.¹ Trimethoprim plasma levels were 48.4% higher in the 30 patients also taking dapsone when compared with another group of 30 patients given co-trimoxazole (trimethoprim with sulfamethoxazole), but the incidence of toxicity was higher in the co-trimoxazole group.¹ However, a later study by the same authors in 8 asymptomatic HIV-positive patients given dapsone 100 mg daily and trimethoprim 200 mg every 12 hours found that the steady-state pharmacokinetics of each drug was unaffected by the other, although the single dose pharmacokinetics showed higher serum levels than at steady state for both drugs.²

Mechanism

Not understood. Dapsone and trimethoprim appear to have mutually inhibitory effects on clearance.

Importance and management

Information is limited. The difference between the results of the two studies may be because the first was in AIDS patients with *Pneumocystis pneumonia* and the second was in asymptomatic HIV-positive patients whose drug metabolism may possibly be different. Concurrent use appears to be an effective form of treatment, but be alert for evidence of increased dapsone toxicity (methaemoglobinemia).

Dapsone + Ursodeoxycholic acid (Ursodiol)

A single case suggests that the effectiveness of dapsone in the treatment of dermatitis herpetiformis may be reduced by ursodeoxycholic acid.

Clinical evidence, mechanism, importance and management

A 61-year-old man taking dapsone 50 mg daily for dermatitis herpetiformis started taking ursodeoxycholic acid 450 mg twice daily for cholecystitis. Two weeks later the dermatitis herpetiformis worsened and the dose of dapsone was increased to 150 mg daily. However, his condition did not improve, so ursodeoxycholic acid was stopped and, as his condition improved, the dapsone dose was reduced to 100 mg, and then 50 mg daily. Two months later ursodeoxycholic acid was restarted and there was again an exacerbation of the dermatitis herpetiformis.¹ The general importance of this isolated report is unknown, but consider the possibility of reduced dapsone effects if ursodeoxycholic acid is also given.

- Stroubou E, Dawn G, Forsyth A. Ursodeoxycholic acid causing exacerbation of dermatitis herpetiformis. *J Am Acad Dermatol* (2001) 45, 319–20.

Daptomycin + Miscellaneous

The use of statins and probably fibrates should be suspended during daptomycin use because of the possible increased risk of muscle toxicity. Daptomycin does not appear to interact with warfarin, but its use may result in falsely elevated prothrombin times. NSAIDs may reduce daptomycin excretion and concurrent use may increase the risks of renal impairment.

Clinical evidence, mechanism, importance and management

(a) Drugs causing myopathy

The US manufacturers describe a study in 20 healthy subjects taking **simvastatin** 40 mg daily, in which the addition of daptomycin 4 mg/kg per day for 14 days did not result in an increase in adverse effects, when compared to subjects given placebo. In contrast, in a phase III study of patients with bacteraemia, 5 out of 22 patients who were currently, or had recently, been taking a **statin** developed raised creatinine phosphokinase levels.¹ Furthermore, a case report describes a patient who was given daptomycin 6.5 mg/kg daily, who developed muscle pain and a raised creatinine phosphokinase (20 771 units/L). He had been taking **simvastatin**, but this had been discontinued when the daptomycin was started.² It is difficult to know whether this was a result of an interaction as another case of rhabdomyolysis (creatinine phosphokinase 21 243 units/L) was attributed to daptomycin alone: the patient was taking no other drugs known to cause myopathy (fibrates and statins specifically mentioned).³ A review of patients with Gram-positive complicated skin and skin structure infections found that musculoskeletal pain or myalgia occurred in up to 0.4% of patients. In patients with similar infections treated with daptomycin the incidence of myopathy was slightly higher, at 0.2 to 0.9%,⁴ suggesting that daptomycin increases the risk of muscle toxicity.

The manufacturers note that experience of the concurrent use of daptomycin with statins is limited, and therefore the use of a statin should be suspended if daptomycin is given,^{1,5} unless the benefits of concurrent use

outweigh the risks, in which case the patient's creatine kinase should be monitored more frequently than weekly.⁵ See also 'muscle toxicity', (p.1086), for further guidance on monitoring for statin-associated myopathy, and risk factors for muscle toxicity. The UK manufacturers give the same guidance for **fibrates** and **ciclosporin**, both of which have been associated with myopathy.¹

(b) NSAIDs

The UK manufacturers note that NSAIDs (including coxibs) may reduce the renal excretion of daptomycin and have additive detrimental effects on renal function if used with daptomycin.⁵ They advise caution on concurrent use, which in practice probably means keeping a close eye on renal function and monitoring for possible daptomycin adverse effects.

(c) Warfarin

The US manufacturers describe a study in 16 healthy subjects in which daptomycin 6 mg/kg per day for 5 days did not affect either the pharmacokinetics or the INR in response to a single 25-mg dose of warfarin. The pharmacokinetics of daptomycin were also unchanged.¹ However, as experience is limited the manufacturers advise monitoring the INR for the first few days of concurrent use. Note that daptomycin causes a concentration-dependent false prolongation of prothrombin time.^{1,5} This only appears to occur with recombinant thromboplastin reagents. Blood for INR testing should therefore be drawn during the daptomycin trough (i.e. immediately before the next dose). If a raised INR is found it is recommended that the INR should be re-tested, and alternative methods of monitoring should be considered.¹

(d) Miscellaneous

The US manufacturers¹ briefly mention small studies in which daptomycin was given with **aztreonam** or **tobramycin** without any significant change in the pharmacokinetics of either drug. They also mention a study in which **probenecid** did not alter the pharmacokinetics of daptomycin.

Ethambutol + Antacids

Aluminium hydroxide and aluminium/magnesium hydroxide can cause a small but probably clinically unimportant reduction in the absorption of ethambutol in some patients.

Clinical evidence, mechanism, importance and management

A study in 13 patients with tuberculosis, given a single 50-mg/kg dose of ethambutol, found that when they were also given three 1.5-g doses of **aluminium hydroxide gel** (at the same time and 15 and 30 minutes later) their peak serum ethambutol levels were delayed and reduced. The average urinary excretion of ethambutol over a 10-hour period was reduced by about 15%, but there were marked variations between individual patients. Some showed no interaction, and others showed increased absorption.¹ No interaction was seen in 6 healthy subjects similarly treated.¹ A further study in 14 healthy subjects found that 30 mL of an **aluminium/magnesium hydroxide** antacid decreased the AUC and maximum serum levels of a 25-mg/kg dose of ethambutol by 10% and 29%, respectively.²

Just why this interaction occurs is not understood, but **aluminium hydroxide** can affect gastric emptying. The reduction in absorption is generally small and variable, and it seems doubtful if it will have a significant effect on the treatment of tuberculosis. However, the authors of the second study suggest avoiding giving antacid at the same time as ethambutol,² and the US manufacturer states that **aluminium hydroxide**-containing antacids should not be taken until 4 hours after a dose of ethambutol.³

- Mattila MJ, Linnoila M, Seppälä T, Koskinen R. Effect of aluminium hydroxide and glycyrrhonium on the absorption of ethambutol and alcohol in man. *Br J Clin Pharmacol* (1978) 5, 161–6.

- Myambutol (Ethambutol). Dura Pharmaceuticals. US Prescribing information, November 2003.

Ethambutol + Food

The pharmacokinetics of ethambutol given with a high-fat breakfast were only slightly different to its pharmacokinetics when it is given in the fasting state.¹ Therefore ethambutol may be given without regard to meals.

1. Peloquin CA, Bulpitt AE, Jaresko GS, Jelliffe RW, Childs JM, Nix DE. Pharmacokinetics of ethambutol under fasting conditions, with food, and with antacids. *Antimicrob Agents Chemother* (1999) 43, 568–72.

Ethambutol + Rifabutin

Rifabutin does not appear to affect the pharmacokinetics of ethambutol.

Clinical evidence, mechanism, importance and management

Ten healthy subjects were given a single 1.2-g dose of ethambutol before and after taking rifabutin 300 mg daily for a week. No clinically relevant changes in the pharmacokinetics of ethambutol were seen.¹ Although 5 of the subjects experienced moderate to severe chills, and one had transient thrombocytopenia these reactions are unlikely to have been due to an interaction. No special precautions would appear to be necessary during concurrent use.

1. Breda M, Benedetti MS, Bani M, Pellizzoni C, Poggessi I, Brianceschi G, Rocchetti M, Dolfi L, Sassella D, Rimoldi R. Effect of rifabutin on ethambutol pharmacokinetics in healthy volunteers. *Pharmacol Res* (1999) 40, 351–6.

Ethionamide + Isoniazid

Isoniazid may contribute to acute psychotic reactions associated with ethionamide, but evidence for this is limited.

Clinical evidence, mechanism, importance and management

Acute psychotic reactions occurring during treatment with either isoniazid or ethionamide are reported to be uncommon.¹ Acute mania occurred in a patient treated with streptomycin, isoniazid and prednisolone for 4 months, and ethionamide and pyrazinamide for 27 days. It was thought that ethionamide was probably responsible for the psychotic reaction but that isoniazid and prednisolone may have potentiated the reaction.² In another patient, ethionamide was considered to be responsible for psychological changes, which resolved when the drug was stopped. However, the contribution of alcohol and other concurrent drugs such as isoniazid was not ruled out.³ One study in patients found that ethionamide 750 mg increased serum levels of a single 10-mg/kg dose of isoniazid at 4 hours but not at 1 or 10 hours, but this was not considered to be of therapeutic significance⁴ and the toxic symptoms reported with the combination^{5,6} were considered not to be due to increased isoniazid levels.⁴

A clinically significant interaction therefore seems unlikely, but as both drugs can, rarely, cause psychotic reactions these tentative reports cannot entirely be dismissed.

6. Trendelenburg F. Antibakterielle chemotherapie der tuberkulose. *Fortschr Arzneimittelforsch* (1964) 7, 193–303.

Ethionamide + Miscellaneous

A study in 12 healthy subjects found that the bioavailability of a single 500-mg dose of ethionamide was not significantly affected by food, orange juice or antacids, when compared with ethiona-

mid bioavailability under fasting conditions. It was suggested that ethionamide may be given with food if tolerance is a problem.¹

1. Auclair B, Nix DE, Adam RD, James GT, Peloquin CA. Pharmacokinetics of ethionamide administered under fasting conditions or with orange juice, food, or antacids. *Antimicrob Agents Chemother* (2001) 45, 810–4.

Fosfomycin + Cimetidine

In a study in 9 healthy subjects the pharmacokinetics of a 50-mg dose of fosfomycin were not significantly altered by two 400 mg doses of cimetidine, given both the night before and 30 minutes before the fosfomycin.¹

1. Bergan T, Mastropalo G, Di Mario F, Naccarato R. Pharmacokinetics of fosfomycin and influence of cimetidine and metoclopramide on the bioavailability of fosfomycin trometamol. *New Trends in Urinary Tract Infections* (eds Neu and Williams) Int Symp Rome 1987, pp 157–66. Published in 1988.

Fosfomycin + Metoclopramide

Metoclopramide reduces fosfomycin bioavailability but the evidence suggests that this probably does not alter its efficacy in urinary tract infections.

Clinical evidence, mechanism, importance and management

Metoclopramide 20 mg given to 9 healthy subjects 30 minutes before fosfomycin 50 mg/kg reduced the peak serum levels of fosfomycin by 42% and reduced the AUC by 27%. These changes appear to occur because metoclopramide speeds the transit through the gut, so that less time is available for good absorption. However, despite these reductions, the urinary concentrations of fosfomycin remained above the minimum levels required for common urinary pathogens for at least 36 hours after the dose.¹ This suggests that the interaction is unlikely to be clinically important.

1. Bergan T, Mastropalo G, Di Mario F, Naccarato R. Pharmacokinetics of fosfomycin and influence of cimetidine and metoclopramide on the bioavailability of fosfomycin trometamol. *New Trends in Urinary Tract Infections* (eds Neu and Williams) Int Symp Rome 1987, pp 157–66. Published in 1988.

Isoniazid + Aminosalicic acid

Isoniazid serum levels are raised by aminosalicic acid.

Clinical evidence, mechanism, importance and management

A study found that aminosalicic acid significantly increased the plasma levels of isoniazid at 4 and 6 hours after administration by 32% and 114%, respectively in fast acetylators of isoniazid, and by 21% and 39%, respectively in slow acetylators. The half-life of isoniazid was increased from 1.32 to 2.89 hours in fast acetylators and from 3.05 to 4.27 hours in slow acetylators (see 'Genetic factors', (p.4), for more information about acetylator status). The effects were probably due to the inhibition of isoniazid metabolism by aminosalicic acid.¹ There seem to be no reports of isoniazid toxicity arising from this interaction, but the manufacturers of isoniazid warn that adverse effects are more likely in the presence of aminosalicic acid.²

2. Isoniazid. Celltech Manufacturing Services Ltd. UK Summary of product characteristics, November 2001.

Isoniazid + Antacids

The absorption of isoniazid from the gut is modestly reduced by aluminium hydroxide, less so by magaldrate, and not by affected by aluminium/magnesium hydroxide tablets or didanosine chewable tablets.

Clinical evidence

Aluminium hydroxide (Amphojel) 45 mL was given to 10 patients with tuberculosis at 6, 7 and 8 am, followed immediately by isoniazid and any other medication they were receiving. The plasma isoniazid levels at 1 hour were decreased, and peak plasma concentrations occurring between 1 and 2 hours after ingestion were reduced by about 25%, when adjusted for different dosages.¹ The effect of **magaldrate (hydrated magnesium aluminate)** was less,¹ and in another well-controlled study **aluminium/magnesium hydroxide (Mylanta)** had no effect.²

Didanosine chewable tablets contain antacids (**aluminium/magnesium hydroxide**) in the formulation, but it has been shown that they do not affect the bioavailability of isoniazid.³

Mechanism

Aluminium hydroxide delays gastric emptying,^{4,5} causing retention of the isoniazid in the stomach. Since isoniazid is largely absorbed from the intestine, this explains the slight decrease in plasma isoniazid concentrations. Aluminium hydroxide also appears to inhibit the absorption of isoniazid.

Importance and management

Information on this interaction is limited, and it is not established. The clinical importance of the modest reductions in isoniazid levels with aluminium hydroxide in one study is uncertain, but likely to be small. However, aluminium/magnesium hydroxide did not interact, and neither did didanosine chewable tablets.

- Hava M, Hurwitz A. The relaxing effect of aluminium and lanthanum on rat and human gastric smooth muscle in vitro. *Eur J Pharmacol* (1973) 22, 156–61.

Isoniazid + Ciprofloxacin

Ciprofloxacin may cause a modest increase in the bioavailability of isoniazid.

Clinical evidence, mechanism, importance and management

In a single-dose study ciprofloxacin 500 mg was found to increase the absorption of isoniazid 300 mg by about 15%. The time to reach maximum plasma levels was increased from 3 hours to 4 hours. The rate of elimination and plasma half-life of isoniazid were not significantly affected. The effects on isoniazid absorption may be due to inhibition of gastric motility and emptying by ciprofloxacin.¹ However, these effects are modest and unlikely to be clinically significant.

Isoniazid + Disulfiram

In most patients, the concurrent use of isoniazid and disulfiram is uneventful, but difficulties in co-ordination, with changes in mental status, behaviour, and drowsiness have been reported in a small number of patients.

Clinical evidence

Seven patients with tuberculosis who had been taking isoniazid for at least 30 days, without problems, experienced adverse reactions within 2 to 8 days of starting to take disulfiram 500 mg daily. Among the symptoms were dizziness, disorientation, a staggering gait, insomnia, irritability and querulous behaviour, listlessness, and lethargy. One patient became hypomanic. Most of them were also taking chlordiazepoxide, and other drugs included aminosalicylic acid, streptomycin and phenobarbital. The adverse reactions decreased or disappeared when the disulfiram was either

reduced to 250 or 125 mg daily, or withdrawn. These 7 patients represented less than one-third of those who received both drugs.¹ As disulfiram is known to inhibit the metabolism of chlordiazepoxide,² another 4 patients were given only isoniazid and disulfiram. Although their reaction was not as severe, all 4 developed drowsiness and depression.¹

In contrast, another report describes the concurrent use of both drugs, without problems, in 200 patients.³ A retrospective study in patients treated with isoniazid-containing regimens for tuberculosis found no difference in rates of toxicity in 13 patients taking disulfiram, when compared to a large group of patients not taking disulfiram. However, the small number of patients taking disulfiram in this study limits the strength of the negative finding.⁴ Another patient taking disulfiram with isoniazid and rifampicin (rifampin) also did not experience any problems.⁵

Mechanism

Not understood. One idea is that some kind of synergy occurs between the two drugs because both can produce similar adverse effects if given in high doses. The authors of one report¹ speculate that isoniazid and disulfiram together inhibit two of three biochemical pathways concerned with the metabolism of dopamine. This leaves a third pathway open, catalysed by COMT (catechol-*O*-methyl transferase), which produces a number of methylated products of dopamine. These methylated products may possibly have been responsible for the mental and physical reactions seen.

Importance and management

Information about this interaction appears to be limited to the reports cited. Its incidence is uncertain but apparently quite small. Two-thirds of the patients in one study, and at least 200 other patients showed no interaction. It would therefore seem that concurrent use need not be avoided, but the response should be monitored. If marked changes in mental status occur, or there is unsteady gait, the manufacturers recommend that the disulfiram should be withdrawn.⁶

Isoniazid + Ethambutol

Ethambutol does not appear to affect serum isoniazid levels. However, it seems that the optic neuropathy caused by ethambutol may be increased by isoniazid.

Clinical evidence, mechanism, importance and management

The mean serum levels of a 300-mg dose of isoniazid were not significantly changed in 10 patients with tuberculosis when they were given a single 20-mg/kg dose of ethambutol.¹ The possible effects of concurrent use over a period of time were not studied. However, there is some evidence that the optic neuropathy caused by ethambutol may be increased by isoniazid, and any effects resolve more slowly after the use of isoniazid.^{2–5} One group of authors recommends that both ethambutol and isoniazid should be stopped immediately if severe optic neuritis occurs. They further recommend that isoniazid should be stopped if less severe optic neuritis does not improve within 6 weeks after stopping ethambutol.⁶

Isoniazid + Fluconazole

A double-blind, crossover study in 16 healthy subjects (8 'fast' and 8 'slow' acetylators of isoniazid) found that fluconazole 400 mg daily for a week had no clinically significant effect on the pharmacokinetics of isoniazid.¹ No special precautions would appear necessary during concurrent use.

1. Buss DC, Routledge PA, Hutchings A, Brammer KW, Thorpe JE. The effect of fluconazole on the acetylation of isoniazid. *Hum Exp Toxicol* (1991) 10, 85–6.

Isoniazid + Food

The absorption of isoniazid is reduced by food. See also 'Isoniazid + Food; Cheese or Fish', below, for toxic reactions between isoniazid and specific foods.

Clinical evidence

In 9 healthy subjects the mean peak serum levels of isoniazid 10 mg/kg were delayed, and reduced by 79%, when isoniazid was given with **breakfast** rather than when fasting. The AUC was reduced by 43%.¹ In another study in 14 healthy subjects given isoniazid with a **full fat breakfast**, the maximum serum levels of isoniazid were decreased by 51%, the absorption was delayed, and the AUC was decreased by 12%.² Similar results have been found in another study.³

Mechanism

Uncertain. Food delays gastric emptying so that absorption further along the gut is also delayed, but the reduction in absorption is not understood.

Importance and management

Information is limited but the interaction seems to be established. For maximum absorption isoniazid should be taken without food, hence the manufacturer's guidance to take it at least 30 minutes before or 2 hours after food.⁴

4. Isoniazid. Celltech Manufacturing Services Ltd. UK Summary of product characteristics, November 2001.

Isoniazid + Food; Cheese or Fish

Patients taking isoniazid who eat some foods, particularly fish from the scombroid family (tuna, mackerel, salmon) that are not fresh, may experience an exaggerated histamine poisoning reaction. Cheese has also been implicated in this reaction, but the adverse effects may be due to the weak MAOI effects of isoniazid rather than histamine poisoning.

Clinical evidence

Three months after starting to take isoniazid 300 mg daily, a woman experienced a series of unpleasant reactions 10 to 30 minutes after eating cheese. These reactions included chills, headache (sometimes severe), itching of the face and scalp, slight diarrhoea, flushing of the face (and on one occasion the whole body), variable and mild tachycardia, and a bursting sensation in the head. Blood pressure measurements showed only a modest rise (from her normal level of 95/65 to 110/80 mmHg). No physical or biochemical abnormalities were found.¹

Headache, dizziness, blurred vision, tachycardia, flushing and itching of the skin, redness of the eyes, burning sensation of the body, difficulty in breathing, abdominal colic, diarrhoea, vomiting, sweating and wheezing have all been described after other patients taking isoniazid ate cheese.^{2–6} Certain tropical fish, including **tuna (skipjack or bonito — *Katsuwonus pelamis*)**,^{7–11} ***Sardinella (Amblygaster) sirm***,¹² ***Rastrigella kanagurta***,¹³

saury (skipper or bill-fish)¹⁴ and others¹⁵ are also implicated. There are a few hundred cases of this reaction on record.

Mechanism

The reaction appears to be an exaggeration of the histamine poisoning that can occur after eating some foods, such as members of the scombroid family of fish (tuna, mackerel, salmon, etc), if they are not fresh and adequately refrigerated. These fish (and some cheeses) have a high histidine content and under poor storage circumstances the histidine is decarboxylated by bacteria to produce unusually large amounts of histamine. Normally this is inactivated by histaminase in the body, but isoniazid is a potent inhibitor of this enzyme, which means that the histamine is absorbed largely unchanged and histamine poisoning develops.¹⁶ Histamine survives all but very prolonged cooking. Tuna fish can contain 180 to 500 mg histamine per 100 g, other types of fish may contain as little as 0.5 to 7.5 mg.¹⁰

Alternatively, it has been suggested that the cases of reactions to cheese are caused by tyramine content and the weak MAOI properties of isoniazid. See 'MAOIs or RIMAs + Tyramine-rich foods', p.1153 for more details of the mechanism of this interaction.

Importance and management

An established interaction of clinical importance. With the exception of one patient who appeared to have had a cerebrovascular accident,⁹ the reactions experienced by the others were unpleasant and alarming but usually not serious or life-threatening. They required little or no treatment, although 'scombroid poisoning' in the absence of isoniazid is sometimes more serious. Two reports say that treatment with antihistamines can be effective.^{10,15} Isoniazid has been in use since 1956 and there is little need to now introduce any general dietary restrictions, but if any of these reactions is experienced, examine the patient's diet and advise the avoidance of any probable offending foodstuffs. Very mature cheese and fish of the scombroid family (tuna, mackerel, salmon and other varieties of dark meat fish) that are not fresh are to be treated with suspicion, but the likely histamine or tyramine content of food cannot be assessed without undertaking a detailed analysis. See 'Table 32.2', (p.1152) and 'Table 32.3', (p.1154) for a list of tyramine rich foods and drinks.

Isoniazid + H₂-receptor antagonists

Pharmacokinetic evidence suggests that neither cimetidine nor ranitidine interact with isoniazid.

Clinical evidence, mechanism, importance and management

In 13 healthy subjects **cimetidine** 400 mg or **ranitidine** 300 mg, three times a day, for 3 days had no effect on the pharmacokinetics of a single 10-mg/kg dose of isoniazid. Neither the absorption nor the metabolism of

isoniazid were changed.¹ No special precautions would appear to be necessary on concurrent use. Although data about other H₂-receptor antagonists appears to be lacking, based on this study, they would not be expected to interact with isoniazid.

1. Paulsen O, Höglund P, Nilsson L-G, Gredeby H. No interaction between H₂ blockers and isoniazid. *Eur J Respir Dis* (1986) 68, 286–90.

Isoniazid + Laxatives

Sodium sulfate and castor oil used as laxatives can cause a modest but probably clinically unimportant reduction in isoniazid absorption.

Clinical evidence, mechanism, importance and management

In an experimental study of the possible effects of laxatives on isoniazid absorption, healthy subjects were given 10 to 20 g of oral **sodium sulfate** or 20 g of **castor oil** (doses sufficient to provoke diarrhoea). Absorption, measured by the amount of isoniazid excreted in the urine, was decreased by 50% with **castor oil** and by 41% with **sodium sulfate** at 4 hours. However, serum levels of isoniazid were relatively unchanged. The overall picture was that while these laxatives can alter the pattern of absorption, they do not seriously impair the total amount of drug absorbed.¹

1. Mattila MJ, Takki S, Jussila J. Effect of sodium sulphate and castor oil on drug absorption from the human intestine. *Ann Clin Res* (1974) 6, 19–24.

Isoniazid + Pethidine (Meperidine)

An isolated case report describes hypotension and lethargy in a patient after he took isoniazid with pethidine.

Clinical evidence, mechanism, importance and management

A patient became lethargic and his blood pressure fell from 124/68 to 84/50 mmHg within 20 minutes of being given pethidine 75 mg intramuscularly. An hour before, he had been given isoniazid. There was no evidence of fever or cardiac arrhythmias, and his serum electrolytes, glucose levels and blood gases were normal. His blood pressure returned to normal over the next 3 hours. He had previously had both pethidine and isoniazid separately without incident. He was subsequently uneventfully given intravenous morphine sulfate, 4 mg every 2 to 4 hours.¹ The authors of the report attribute this reaction to the MAO-inhibitory properties of the isoniazid and equate it with the severe and potentially fatal 'MAOI-pethidine interaction', (p.1140), but in reality this reaction was mild and lacked many of the characteristics of the more serious reaction. Moreover, isoniazid possesses only mild MAO-inhibitory properties and does not normally interact to the same extent as the potent antidepressant and antihypertensive MAOIs.

There is too little evidence to advise against concurrent use, but bear this interaction in mind in the case of an unexpected response to treatment.

Isoniazid + Prednisolone

Prednisolone can lower plasma isoniazid levels, but this may not be clinically important.

Clinical evidence, mechanism, importance and management

Isoniazid 10 mg/kg daily was given to 26 patients with tuberculosis. The 13 slow acetylators of isoniazid had a 23% fall in plasma isoniazid levels when they were given **prednisolone** 20 mg, while the 13 fast acetylators showed a 38% fall over 8.5 hours (see 'Genetic factors', (p.4), for an explanation of acetylator status). The reasons for these changes are not understood but changes in the metabolism, and/or the excretion of the isoniazid by the kidney, are possibilities. Despite these changes the response to treatment was excellent.¹ In another group of 49 patients, both slow and fast acetylators of isoniazid, rifampicin 12 mg/kg largely counteracted the isoniazid-lowering effects of **prednisolone**.¹

None of these interactions were of clinical importance, but the authors

point out that if the dosage of isoniazid had been lower, its effects might have been reduced. Be aware of the possibility of a reduced response during concurrent use, and raise the isoniazid dosage if necessary. There seems to be no information about other corticosteroids.

1. Sarma GR, Kailasam S, Nair NGK, Narayana ASL, Tripathy SP. Effect of prednisolone and rifampin on isoniazid metabolism in slow and rapid inactivators of isoniazid. *Antimicrob Agents Chemother* (1980) 18, 661–6.

Isoniazid + Propranolol

Propranolol causes a small reduction in the clearance of isoniazid, which seems unlikely to be of much practical importance.

Clinical evidence, mechanism, importance and management

The clearance of a single 600-mg intravenous dose of isoniazid was reduced by 21%, from 16.4 to 13 L/hour, in 6 healthy subjects after they took propranolol 40 mg three times daily for 3 days.¹ It is suggested that propranolol reduces the clearance of isoniazid by inhibiting its metabolism (acetylation) by the liver.¹ However, as the increase in isoniazid levels is likely to be only modest this interaction is probably of little clinical importance.

1. Santoso B. Impairment of isoniazid clearance by propranolol. *Int J Clin Pharmacol Ther Toxicol* (1985) 23, 134–6.

Isoniazid + Pyrimethamine

A study in 19 patients with tuberculosis found that pyrazinamide did not affect serum levels of isoniazid.¹

1. Levy D, Duysak S, Zylberberg B, Haapanen J, Russell WF, Middlebrook G. Effect of pyrazinamide on antimicrobially active serum isoniazid. *Dis Chest* (1960) 38, 148–51.

Isoniazid + Rifamycins

The concurrent use of a rifamycin and isoniazid is common and therapeutically valuable, but there is evidence that the incidence of hepatotoxicity may be increased, particularly in slow acetylators of isoniazid. One study suggests the bioavailability of rifampicin may be reduced by isoniazid but other studies found no pharmacokinetic interaction. Rifabutin and rifampicin do not alter the pharmacokinetics of isoniazid.

Clinical evidence, mechanism, importance and management

(a) Rifabutin

Rifabutin 300 mg, given daily for 7 days to 6 healthy subjects, had no significant effect on the pharmacokinetics of a single 300-mg dose of isoniazid or its metabolite acetylisoniazid.¹ Two of the 6 subjects were rapid acetylators of isoniazid (see 'Genetic factors', (p.4), for more information about acetylator status).

Although both drugs have been effectively used together in the treatment of tuberculosis, it is not clear whether concurrent use increases the incidence of hepatotoxicity, as occurs with isoniazid and rifampicin (see below). However, as regular monitoring of liver function is required for both isoniazid and rifabutin, no additional monitoring seems necessary on concurrent use. The manufacturer of rifabutin notes that haematological reactions of rifabutin could be increased by isoniazid, but, again, as regular monitoring of white blood cell and platelet counts is advised,² no additional monitoring seems necessary.

(b) Rifampicin (Rifampin)

Most studies have shown that the serum levels and half-lives of both drugs are not significantly affected by concurrent use,^{3–6} even in those with hepatic impairment.⁶ There was also no difference⁴ between rapid and slow acetylators of isoniazid, (see 'Genetic factors', (p.4), for more information about acetylator status). One single-dose study in healthy subjects found that isoniazid 12 mg/kg reduced the AUC of rifampicin 10 mg/kg by about 25%.⁷ There is some evidence that the incidence and severity of hepatotoxicity rises if both drugs are given together.⁸ Reports from India suggest that the incidence can be as high as 8 to 10%, while much lower figures of

2 to 3% are reported in the US.⁹ There is certainly one case report that appears to prove that hepatotoxicity can arise rapidly from the use of both drugs. The patient tolerated both drugs individually, but hepatotoxicity reappeared on concurrent use.¹⁰ Increased isoniazid hepatotoxicity caused by rifampicin has been demonstrated *in vitro*.¹¹

The reasons for the hepatotoxicity are not fully understood but rifampicin or isoniazid alone can cause liver damage by their own toxic action. One suggestion is that the rifampicin alters the metabolism of isoniazid, resulting in the formation of hydrazine, which has proven to be hepatotoxic.^{9,10,12} Higher plasma levels of hydrazine are said to occur in slow acetylators of isoniazid,⁹ but one study failed to confirm that this is so.¹³ There has certainly been at least one fatality caused by this combination.¹⁴ The manufacturers of rifampicin advise that caution is particularly needed in patients with impaired liver function, the elderly, malnourished patients, and children under two years of age. After baseline LFTs, further tests are only needed if fever, vomiting, or jaundice occur, or if the patient deteriorates.¹⁵ However, the manufacturers of isoniazid suggest that liver function tests should be reviewed regularly in patients on combined treatment.¹⁶

Isoniazid + SSRIs and related antidepressants

A few reports suggest that no important interaction occurs between isoniazid and the SSRIs or nefazodone. However, adverse reactions have been seen during concurrent use and one report found an increased discontinuation rate in patients taking an SSRI with isoniazid.

Clinical evidence

Two HIV-positive patients taking **fluoxetine** 20 mg daily were also given isoniazid. One of them tolerated the use of both drugs, but the other developed vomiting and diarrhoea, and after 10 days the **fluoxetine** was stopped.¹

A woman who had been hospitalised for serious depression was given **nefazodone** 300 mg daily. A few days later she began to take isoniazid 300 mg daily, and was later discharged on an increased **nefazodone** dose of 400 mg daily. She was reported to have had no problems while taking both drugs over a 5 month period.²

A woman with tuberculosis taking isoniazid 300 mg daily presented with depression and was given **sertraline** 50 mg daily, later raised to 150 mg daily, without problems. She responded well and was reported to have taken both drugs together for 8 months without problems.²

A retrospective review of HIV-positive patients who were taking either an SSRI, isoniazid, or both, found that the rate of discontinuation of the SSRI was higher in those also taking isoniazid (7 of 10 patients) than in the group of patients taking an SSRI alone (2 of 14). It is unclear why this rate was increased; little mention is made of the influence of other drugs or medical conditions.³

Mechanism, importance and management

Direct information about the concurrent use of isoniazid and SSRIs seems to be limited, but the case reports cited here^{1,2,4} would suggest that the combination of isoniazid and these SSRIs is normally without problems. However, also be aware that one report suggests the possibility of an increase in adverse effects with the combination of SSRIs and isoniazid.³

In theory isoniazid could interact with the SSRIs⁴ because it has some weak MAO inhibitory activity. However, isoniazid rarely interacts like the MAOIs. This is because isoniazid seems to lack activity on mitochondrial MAO even though it has activity on plasma MAO. Therefore no adverse MAOI/SSRI interaction would usually be expected.

Linezolid + Antacids

A study in healthy subjects found that *Maalox 70mVal* suspension 10 mL (aluminium/magnesium hydroxide) did not affect the pharmacokinetics of a single 600-mg dose of linezolid.¹

- Grunder G, Zysset-Aschmann Y, Vollenweider F, Maier T, Krähenbühl S, Drewe J. Lack of pharmacokinetic interaction between linezolid and antacid in healthy volunteers. *Antimicrob Agents Chemother* (2006) 50, 68–72.

Linezolid + Antidepressants

The serotonin syndrome has been reported in patients taking linezolid with an SSRI or venlafaxine. The serotonin syndrome is also predicted to occur if linezolid is given with tricyclic antidepressants.

Clinical evidence

(a) SSRIs

In an analysis of phase III studies, changes in vital signs did not differ between patients given linezolid and comparator drugs (i.e. antibiotics) when either were used with drugs known to interact with MAOIs, including unnamed SSRIs.^{1,2} One patient taking **fluoxetine** had a transient episode of asymptomatic hypertension after one dose of linezolid, but since this patient had no other symptoms of serotonin syndrome, it was not considered an interaction.² However, a 4-year-old girl given **fluoxetine** 5 mg daily developed symptoms of the serotonin syndrome 2 days after starting linezolid 140 mg every 12 hours, and after a procedure for which she was given fentanyl 200 micrograms. Fentanyl may have been a contributing factor.³ Another case report describes an 85-year-old woman taking **citalopram** who developed tremor, confusion, dysarthria, hyperreflexia, agitation, and restlessness after linezolid was started. **Citalopram** was stopped and the symptoms resolved over 72 hours.⁴ There are several other case reports of this interaction between linezolid and SSRIs^{5–8} including **citalopram**,^{5,6} **sertraline**^{6,7} and **paroxetine**.^{8,9}

(b) Tricyclics

In an analysis of phase III studies, changes in vital signs did not differ between patients given linezolid and comparator drugs (i.e. antibiotics) when either were used with drugs known to interact with MAOIs, including unnamed cyclic antidepressants.^{1,2} A case report describes the serotonin syndrome in an elderly patient treated with linezolid 600 mg every 12 hours, 21 days after amitriptyline 10 mg daily, paroxetine 20 mg daily and alprazolam 500 micrograms daily were started.⁹

(c) Other antidepressants

1. *Mirtazapine*. A patient taking linezolid 600 mg twice daily developed delirium, confusion and visual hallucinations 2 weeks after starting to take mirtazapine 15 or 30 mg daily and gabapentin 300 mg at night. Gabapentin was stopped and the delirium resolved. About 4 weeks later the delirium recurred and then resolved when the patient discontinued mirtazapine. Mirtazapine was restarted without recurrence of delirium. The patient subsequently took mirtazapine 15 mg daily with linezolid 600 mg twice daily without adverse effects.¹⁰

2. *Venlafaxine*. An 85-year-old man taking venlafaxine 150 mg daily was prescribed ciprofloxacin, rifampicin and linezolid 600 mg twice daily for a hip prosthesis infection. After 20 days he was found to be confused and disorientated, and 4 days later he was also drowsy, and suffering myoclonic jerks. Linezolid and venlafaxine were stopped and the symptoms resolved over 2 days.¹¹ However, another case report describes a 7-year-old boy treated with venlafaxine and methylphenidate who was prescribed linezolid for osteomyelitis. He was given all three drugs (doses not stated) for several days without any alterations in vital signs or evidence of the serotonin syndrome.¹²

Mechanism

Not fully understood. Linezolid has weak MAOI effects, and the serotonin syndrome is known to occur when MAOIs are given with 'SSRIs', (p.1142), 'tricyclics', (p.1149) and 'venlafaxine', (p.1156). In the case of the patient taking linezolid with amitriptyline and paroxetine, it is possible that an interaction between amitriptyline and paroxetine contributed to the development of the serotonin syndrome. Consider also 'Tricyclic and related antidepressants + SSRIs', p.1241.

Importance and management

Information on the reaction between linezolid and the SSRIs, tricyclics, mirtazapine or venlafaxine appears to be limited, but what is known suggests that the interaction is probably rare. The manufacturers of linezolid say that patients taking SSRIs and tricyclic antidepressants should have their blood pressure monitored and be closely observed if given linezolid. They say that if this is not possible, concurrent use should be avoided.¹³ If linezolid is used with a drug with serotonergic actions it would seem prudent to monitor for symptoms of the serotonin syndrome, which may take several weeks to manifest. See 'The serotonin syndrome', (p.9), for further details.

Linezolid + Aztreonam

The pharmacokinetics of intravenous aztreonam 1 g and intravenous linezolid 375 mg were not affected when they were given to-

gether in a single-dose study in healthy subjects. Therefore dose alterations are unlikely to be needed during concurrent use.¹

- Sisson TL, Jungbluth GL, Hopkins NK. A pharmacokinetic evaluation of concomitant administration of linezolid and aztreonam. *J Clin Pharmacol* (1999) 39, 1277–82.

Linezolid + Dextromethorphan

There is no important pharmacokinetic interaction between linezolid and dextromethorphan, but one case of concurrent use resulted in the serotonin syndrome.

Clinical evidence, mechanism, importance and management

In a study in 14 healthy subjects, two 20-mg doses of dextromethorphan given 4 hours apart, before and during the use of linezolid 600 mg every 12 hours, had no effect on linezolid pharmacokinetics. The AUC and maximum level of the dextromethorphan metabolite, dextroprhan was decreased by 30%, but this was not considered sufficient to warrant any dosing alterations. There was no evidence of the serotonin syndrome, as measured by changes in body temperature, alertness and mental performance.¹ However, the manufacturers describe one case where the concurrent use of linezolid and dextromethorphan resulted in the serotonin syndrome.² Linezolid has mild reversible MAOI activity, and the serotonin syndrome has been described when dextromethorphan was taken by patients also taking antidepressant MAOIs, see 'MAOIs or RIMAs + Dextromethorphan', p.1134. If the concurrent use of linezolid and dextromethorphan is considered necessary, it would seem prudent to monitor for symptoms of 'the serotonin syndrome', (p.9).

Linezolid + Food

Linezolid modestly increases the blood pressure response to oral tyramine, and as a consequence patients receiving linezolid should not consume excessive amounts of tyramine-rich foods and drinks. The bioavailability of linezolid is not affected by enteral feeds or food.

Clinical evidence, mechanism, importance and management*(a) Enteral feeds*

In a study a single 600-mg dose of linezolid was given as a suspension via a nasogastric tube or gastric tube to 9 patients receiving enteral feeds. The rate and extent of linezolid absorption was not significantly different to that found in another 6 patients not receiving enteral feeds. No dose adjustments are therefore thought to be required if linezolid is given with enteral feeds.¹

(b) Food

A study in healthy subjects found that the plasma levels following a single 375-mg oral dose of linezolid as a tablet were 23% higher when given to fasted subjects than when it was taken immediately after a high-fat meal. However, the AUCs were not significantly different, indicating that the extent of absorption was not affected by food.² Another study in healthy subjects found that food delayed the rate but not the extent of absorption and distribution of linezolid into tissues.³

(c) Tyramine-rich food

In a pharmacodynamic study in healthy subjects, the dose of oral tyramine required to raise the systolic blood pressure by 30 mmHg was decreased by a factor of about 3.5 (from a range of 300 to 600 mg without linezolid to 100 to 200 mg with linezolid) when the subjects were pretreated with linezolid 625 mg twice daily for 4 to 7 days. This increase in the pressor response to tyramine was similar to that seen with moclobemide 150 mg three times daily.⁴ Further, another placebo-controlled study in healthy subjects found that single doses of linezolid 600 mg and moclobemide 300 mg also caused similar increases in the pressor response to intravenous tyramine as measured by amount of tyramine required to raise the systolic blood pressure by 30 mmHg.⁵

Linezolid is a weak, non-selective inhibitor of MAO. As a consequence, it can inhibit the breakdown of the tyramine by MAO in the gut, and can also potentiate the effect of tyramine at nerve endings, therefore causing an increase in blood pressure (see Mechanism, under 'MAOIs or RIMAs + Tyramine-rich foods', p.1153). However, the extent of this rise was similar to that for moclobemide, which is much less than that seen with classical MAOIs.

The manufacturers of linezolid recommend that patients should avoid large amounts of tyramine-rich foods and drinks^{6,7} and should not consume more than 100 mg of tyramine per meal.⁷ For a list of the possible tyramine-content of various foods and drinks, see 'Table 32.2', (p.1152), 'Table 32.3', (p.1154) and 'Table 32.4', (p.1155). This is in line with the dietary restrictions recommended for RIMAs rather than the more stringent dietary recommendations required in patients taking non-selective MAOIs.

Linezolid + Other drugs with MAOI activity

The manufacturer of linezolid contraindicates its use with the MAOIs, including the selective MAO-B inhibitor selegiline and the RIMA moclobemide.

Clinical evidence, mechanism, importance and management

The UK manufacturer contraindicates the concurrent use of linezolid with or within 2 weeks of taking any other drug that inhibits MAO-A or MAO-B.¹ They specifically name the non-selective MAOIs **isocarboxazid** and **phenelzine**, the RIMA, **moclobemide**, and the MAO-B inhibitor, **selegiline**. Linezolid has reversible non-selective MAO-inhibitory activity, and this warning is based on the sometimes serious reactions that have occurred when non-selective MAOIs are given sequentially (see 'MAOIs + MAOIs or RIMAs', p.1137) or MAOIs are given with MAO-B inhibitors, see 'MAO-B inhibitors + MAOIs or RIMAs', p.692.

1. Zyvox (Linezolid). Pharmacia Ltd. UK Summary of product characteristics, July 2007.

Linezolid + Pethidine (Meperidine)

The UK manufacturer of linezolid¹ (a drug with weak, reversible, non-selective MAOI activity) contraindicates its use with pethidine, unless facilities are available for close observation and monitoring of blood pressure, because of the possibility of serious reactions, as have occurred with classical MAOIs and pethidine, see 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1140.

1. Zyvox (Linezolid). Pharmacia Ltd. UK Summary of product characteristics, July 2007.

Linezolid + Rifampicin (Rifampin)

Serum levels of intravenous linezolid are reduced by intravenous rifampicin.

Clinical evidence, mechanism, importance and management

A 31-year-old woman was given intravenous rifampicin 300 mg every 8 hours and linezolid 600 mg every 12 hours for an MRSA infection. During rifampicin treatment her linezolid peak and trough levels were

7.29 and 2.04 micrograms/mL, respectively. However, when the rifampicin was stopped the linezolid peak and trough levels were higher, at 12.46 and 5.03 micrograms/mL, respectively.¹

In an earlier study, healthy subjects were given a single 600-mg dose of intravenous linezolid either alone or with a single 600-mg dose of intravenous rifampicin. This study also found that rifampicin reduced the serum levels of linezolid by 10%, 20% and 35% at 6, 9 and 12 hours, respectively.

Linezolid is not metabolised by the cytochrome P450 enzyme system so the reduction in levels is unlikely to be due to increased metabolism associated with rifampicin enzyme induction. The reduction in linezolid serum levels may be attributable to the induction of P-glycoprotein by rifampicin, resulting in increased excretion of linezolid.^{1,2}

The clinical significance of this interaction is unclear and the concurrent use of rifampicin and linezolid is not established. The available evidence suggests that, where possible, linezolid levels should be monitored if both drugs are given. If this is not possible it would seem prudent to monitor concurrent use closely to ensure that the antibacterial treatment is effective.

Linezolid + Sympathomimetics

Because of its weak MAO-inhibitory properties, the manufacturers of linezolid contraindicate its use with sympathomimetics (such as adrenergic bronchodilators, phenylpropranolamine, pseudoephedrine, adrenaline (epinephrine), noradrenaline (norepinephrine), dopamine and dobutamine) unless facilities for close observation and blood pressure monitoring are available. In one study the use of linezolid with phenylpropranolamine or pseudoephedrine resulted in additive hypertensive effects.

Clinical evidence

In a placebo-controlled study, 14 healthy patients were given two 60-mg doses of pseudoephedrine or two 25-mg doses of phenylpropranolamine 4 hours apart, with and without linezolid. The mean maximum blood pressure rise was 11 mmHg with placebo, 15 mmHg with linezolid, 18 mmHg with pseudoephedrine and 14 mmHg with phenylpropranolamine. When the subjects were given linezolid with pseudoephedrine the rise was 32 mmHg, which was similar to the 38 mmHg rise seen with linezolid plus phenylpropranolamine. However, these rises were transient, resolving in about 2 hours. No effects were seen on linezolid pharmacokinetics.¹

Mechanism

Linezolid acts as a weak MAO-inhibitor, which allows the accumulation of some noradrenaline at adrenergic nerve endings associated with arterial blood vessels. Pseudoephedrine and phenylpropranolamine, both indirectly-acting sympathomimetics, can release these above-normal amounts of noradrenaline resulting in blood vessel constriction and a rise in blood pressure.

Importance and management

The manufacturers contraindicate the use of sympathomimetics (including adrenergic bronchodilators, pseudoephedrine, phenylpropranolamine, adrenaline (epinephrine), noradrenaline (norepinephrine), dopamine, dobutamine) with linezolid unless there are facilities available for close observation of the patient and monitoring of blood pressure.² Some indirectly-acting sympathomimetics occur in cough and cold remedies, which can be bought without prescription. To keep in line with the manufacturers recommendations, patients should be told to avoid these preparations. However, it should be said that the evidence available indicates that blood pressure rises are unlikely to be of the proportions seen with the antidepressant MAOIs, which result in hypertensive crises. Consider also 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1147.

Linezolid + Vitamins

The pharmacokinetics of linezolid are not affected by either vitamin C or vitamin E.

Clinical evidence, mechanism, importance and management

Healthy subjects were given vitamin C 1 g daily or vitamin E 800 units daily for 8 days with a single 600-mg dose of linezolid on the sixth day. As *in vitro* studies have indicated that endogenous reactive oxygen species (ROS) may affect linezolid clearance, it was considered possible that antioxidant supplements may affect the balance of ROS and linezolid clearance. However, the study found that antioxidants (vitamins C and E) given in doses far higher than the recommended daily intake did not affect linezolid pharmacokinetics. Therefore no dosage adjustments are considered necessary during concurrent use.¹

Loracarbef + Acetylcysteine

A study in healthy subjects found that acetylcysteine 200 mg had no effect on the absorption of loracarbef 400 mg.¹

1. Roller S, Lode H, Stelzer I, Deppermann KM, Boeckh M, Koeppel P. Pharmacokinetics of loracarbef and interaction with acetylcysteine. *Eur J Clin Microbiol Infect Dis* (1992) 11, 851–5.

Loracarbef + Food

Food reduces the maximum plasma levels of loracarbef, but does not alter its bioavailability.

Clinical evidence, mechanism, importance and management

Loracarbef 400 mg was given to 12 healthy subjects either in a fasting state or following a standard breakfast. Food slowed the rate of absorption, but not the total bioavailability of loracarbef.¹ In another study food was found to decrease the maximum plasma levels of a single 200-mg dose of loracarbef and increase the time to achieve maximum levels but the AUC of loracarbef was not significantly affected by food.² Loracarbef should be taken 1 hour before or 2 hours after food.³

3. Lorabid (Loracarbef). Monarch Pharmaceuticals, Inc. US Prescribing information, September 2002.

Loracarbef + Probenecid

Probenecid increases the half-life of loracarbef by about 50% but the clinical importance of this is unknown.¹

1. Force RW, Nahata MC. Loracarbef: a new orally administered carbacephem antibiotic. *Ann Pharmacother* (1993) 27, 321–9.

Macrolides + Antacids

Aluminium/magnesium hydroxide antacids may reduce the peak levels of azithromycin. *Mylanta* can prolong the absorption of erythromycin, but this is unlikely to be clinically important. Aluminium/magnesium hydroxide antacids do not appear to significantly alter the pharmacokinetics of clarithromycin, roxithromycin or telithromycin.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects the peak serum levels, but not the total absorption, of azithromycin was reduced by 30 mL *Maalox* (aluminium/magnesium hydroxide).¹ It is suggested therefore that azithromycin should not be given at the same time as antacids, but should be taken at least 1 hour before or 2 hours after.^{2,3}

In 8 healthy subjects *Mylanta* (aluminium/magnesium hydroxide, dimeticone) 30 mL had no significant effect on the AUC, peak serum concentration, or time to peak serum concentration of erythromycin stearate 500 mg, but the mean elimination rate constant was more than doubled. It was suggested that the effect on elimination may be due to a possible prolonging of absorption, although the reason for this effect is unclear.⁴ However, an *in vitro* study has suggested that the release and absorption of erythromycin stearate may be slowed in the presence of some antacids, including aluminium and magnesium hydroxides, aluminium and magnesium trisilicates, and simeticone because of adsorption of erythromycin by the antacids.⁵ The clinical relevance of this is uncertain, but likely to be small.

Aluminium/magnesium hydroxide antacids are reported not to affect the pharmacokinetics of clarithromycin,⁶ roxithromycin,⁷ or telithromycin.^{8,9}

Macrolides + Azoles

Moderate pharmacokinetic interactions appear to occur between several of the azoles and macrolides but many of these are unlikely to be of clinical significance. However, clarithromycin may almost double itraconazole levels, and ketoconazole may almost double telithromycin levels.

Clinical evidence, mechanism, importance and management

(a) Azithromycin

Single doses of fluconazole 800 mg and azithromycin 1200 mg were given to 18 healthy subjects alone and together without any significant change in the pharmacokinetics of either drug.¹

In healthy subjects, azithromycin 500 mg once daily for 3 days had no significant effect on the AUC and maximum plasma levels of voriconazole 200 mg twice daily.²

(b) Clarithromycin

Twenty healthy subjects were given clarithromycin 500 mg twice daily for 8 days. Fluconazole 400 mg daily was added on day 5, followed by 200 mg daily on days 6 to 8. The fluconazole increased the minimum plasma levels of the clarithromycin by 33% and the AUC_{0–12} by 18%.³ These relatively small changes in the pharmacokinetics of clarithromycin are almost certainly of little or no clinical importance.

A study in 8 AIDS patients taking itraconazole 200 mg daily found that when clarithromycin 500 mg twice daily was also given, for 14 days, the maximum serum levels and the AUC of the itraconazole were increased by 90% and 92%, respectively.⁴ Both clarithromycin and itraconazole are known to be metabolised by the hepatic cytochrome P450 isoenzyme CYP3A4 and it is therefore probable that competition for metabolism leads to a reduction in the clearance of itraconazole. This report does not comment on the outcome of this almost twofold increase in itraconazole levels, but it would seem prudent to be alert for the need to reduce its dosage. More study is needed.

(c) Erythromycin

The manufacturer notes that peak plasma levels and AUC of a single 200-mg dose of itraconazole were increased by 44% and 36%, respective-

ly, by a single 1-g dose of erythromycin ethyl succinate.⁵ However, no dosage adjustments are recommended.

In healthy subjects, erythromycin 1 g twice daily for 7 days had no significant effect on the AUC and maximum plasma levels of **voriconazole** 200 mg twice daily.²

(d) Telithromycin

In a study in which healthy subjects were given either telithromycin 800 mg, **ketoconazole** 800 mg or both drugs once daily, it was found that the AUC and peak plasma levels of telithromycin were increased by 94.5% and 51.3%, respectively. It may be prudent to monitor for telithromycin adverse effects on concurrent use. In a further related study healthy subjects were given **itraconazole** 200 mg daily instead of ketoconazole. **Itraconazole** was found to increase the AUC and peak plasma levels of telithromycin by 53.8% and 21.7%, respectively. No serious adverse effects were reported in either study and telithromycin did not increase the QTc intervals observed with either **ketoconazole** or **itraconazole** alone.⁶ Another study⁷ by the same authors, in subjects aged 60 years or older and with a creatinine clearance of 30 mL/minute or more, found that, when **ketoconazole** was given, levels of telithromycin were increased but only slightly higher than those found in younger healthy subjects⁶ in the earlier study.

Macrolides + Grapefruit juice

Grapefruit juice modestly increases the bioavailability of erythromycin, but does not affect the bioavailability of clarithromycin or telithromycin.

Clinical evidence

(a) Clarithromycin

In a study 12 healthy subjects were given a single 500-mg dose of clarithromycin and 240 mL of either water or freshly squeezed white grapefruit juice with and 2 hours after clarithromycin. Grapefruit juice increased the time to peak levels of both clarithromycin and its metabolite 14-hydroxy-clarithromycin from about 82 to 148 minutes and 84.5 to 172 minutes, respectively, but it did not affect the extent of clarithromycin absorption and had no significant effects on any other pharmacokinetic parameters.¹

(b) Erythromycin

A study in 6 healthy subjects given a single 400-mg dose of erythromycin with either water or grapefruit juice found that grapefruit juice increased the AUC and maximum plasma level of erythromycin by about 49% and 52%, respectively. The time to achieve maximum levels and the half-life of erythromycin were not affected.²

(c) Telithromycin

A study in 16 healthy subjects given telithromycin 800 mg daily found that grapefruit juice did not affect telithromycin pharmacokinetics.³

Mechanism

Some components of grapefruit juice, possibly flavonoids such as naringenin, or a psoralen, dihydroxybergamottin, may inhibit the activity of the cytochrome P450 isoenzyme CYP3A4 in the gut.¹ The levels of drugs metabolised by CYP3A4, such as the macrolides, may therefore be raised by grapefruit juice. Erythromycin levels, but not those of clarithromycin or telithromycin appear to be affected by grapefruit juice. It has been suggested that a drug with low or variable bioavailability may be more likely

to have its levels increased by grapefruit juice and it has been suggested that this may partly explain why the pharmacokinetics of clarithromycin (bioavailability of about 55%) and telithromycin (bioavailability of about 60%) are not significantly affected.¹

Importance and management

Information is very limited but it would appear that there is unlikely to be a clinically significant interaction between grapefruit juice and either clarithromycin or telithromycin. The increased bioavailability of erythromycin was found in a single-dose study and it has been suggested that more prolonged administration of erythromycin with grapefruit juice could increase levels further and potentially increase the risk of adverse effects.⁴ More study is needed.

Macrolides + H₂-receptor antagonists

Cimetidine doubled the serum levels of erythromycin in one single-dose study, and a single case report describes reversible deafness, which was attributed to this interaction. No clinically significant interaction appears to occur when cimetidine is given with azithromycin or clarithromycin, or when ranitidine is given with clarithromycin, roxithromycin, or telithromycin.

Clinical evidence

(a) Cimetidine

A 64-year-old woman was admitted to hospital with cough, dyspnoea and pleuritic pain and was found to have an atypical pneumonia and renal impairment. All her antihypertensive treatment (methyldopa, propranolol, co-amilofruse) was stopped, due to hypotension, and her treatment for duodenal ulcer was changed from ranitidine 150 mg twice daily to cimetidine 400 mg at night. She was then started on amoxicillin 500 mg three times daily and **erythromycin** stearate 1 g four times daily. Two days later she complained of 'fuzzy hearing' and audiometry showed a bilateral hearing loss. The **erythromycin** was stopped and her hearing returned to normal after 5 days.¹ This prompted a study of this possible interaction in 8 healthy subjects, which found that cimetidine 400 mg twice daily increased the AUC of a single 250-mg dose of **erythromycin** by 73%. Maximum serum **erythromycin** levels were doubled.¹

The pharmacokinetics of **azithromycin** were not affected by a single 800-mg dose of cimetidine in one study,² and although cimetidine prolongs the absorption of **clarithromycin**, this is unlikely to be of clinical significance.³

(b) Ranitidine

The pharmacokinetics of **clarithromycin**,⁴ **roxithromycin**⁵ and **telithromycin**^{6,7} are reported to be unaffected by ranitidine.

Mechanism

Cimetidine is known to inhibit the *N*-demethylation of erythromycin so that it is metabolised and cleared from the body more slowly and its serum levels rise. Deafness is known to be one of the adverse effects of erythromycin,¹ which usually occurs with high-doses or intravenous therapy, and was probably exacerbated by renal impairment⁴ in the patient described above.

Importance and management

Clinical information about an interaction between cimetidine and erythromycin seems to be limited to this case and the associated single-dose study. The manufacturers⁸ say that reversible hearing loss has been reported with erythromycin alone, usually in high doses (greater than 4 g daily⁹), usually when given by the intravenous route,⁹ and in patients with renal impairment.⁸ Most UK manufacturers do not include this interaction in their product information, and evidence for an interaction seems limited.

If deafness were to occur, the management would seem to be similar (withdraw the erythromycin) regardless of whether or not cimetidine was present, so no additional precautions seem necessary.

There is evidence that azithromycin and clarithromycin do not interact, and ranitidine does not interact with clarithromycin, roxithromycin or telithromycin. No interaction would be expected between the macrolides and other non-enzyme inducing H₂-receptor antagonists.

Macrolides + Penicillins

Some *in vitro* evidence suggests that antagonism may occur between erythromycin (a bacteriostatic drug) and penicillins (bactericidal drugs) when they are used against staphylococci¹ and *Streptococcus pneumoniae*.² However, another study has suggested that this *in vitro* antagonism against *S. pneumoniae* between ‘penicillin’ and erythromycin is minimal and dependent on the interpretative criteria applied.³ Clinical evidence for this interaction is apparently lacking, and the combination is generally used successfully for pneumonia.⁴ In the UK, the combination of amoxicillin and erythromycin or another macrolide (e.g. azithromycin or clarithromycin) has been recommended by the British Thoracic Society (BTS) for adult patients with non-severe community-acquired pneumonia who require hospital admission.⁵ More recently the BTS has recommended an intravenous combination of a beta-lactamase stable antibacterial such as co-amoxiclav (amoxicillin with clavulanic acid) with a macrolide (erythromycin or clarithromycin) for severe community-acquired pneumonia in hospitalised patients.⁶

Macrolides + Rifamycins

Rifabutin and azithromycin seem not to affect the serum levels of each other, but a very high incidence of neutropenia was seen in one study of the combination. Both rifabutin and rifampicin markedly reduce the serum levels of clarithromycin. Clarithromycin increases the serum levels of rifabutin and the combination is associated with an increased risk of uveitis and neutropenia. Rifampicin (rifampin) greatly reduces telithromycin levels and concurrent use is not recommended.

Clinical evidence

(a) Rifabutin

1. *Neutropenia*. A study in 12 healthy subjects was designed to investigate the safety and possible interactions between rifabutin 300 mg daily, and azithromycin 250 mg daily or clarithromycin 500 mg twice daily, for a course of 14 days. The subjects were matched against 18 healthy controls who received either of the macrolides or rifabutin alone. The study had to be abandoned after 10 days because 14 patients developed neutropenia; 2 taking rifabutin alone, and all 12 of those taking rifabutin with a macrolide. Eight subjects developed a fever, 5 required colony simulating factors, and 3 required hospitalisation.¹

2. *Pharmacokinetics*. In a study² investigating a possible regimen for the prophylaxis of *Mycobacterium avium* complex (MAC) disease, 12 HIV-positive patients were treated with clarithromycin 500 mg daily, to which rifabutin 300 mg daily was added on day 15. By day 42 the clarithromycin AUC had fallen by 44%, and levels of the metabolite, 14-hydroxyclarithromycin, had risen by 57%. A related study² in 14 patients given clarithromycin 500 mg every 12 hours and rifabutin 300 mg daily found that after 28 days the AUC of the rifabutin had increased by 99%, and the AUC of the active metabolite, 25-*O*-desacetyl-rifabutin, had increased by 375%. Another group of patients with lung disease due to MAC were treated with clarithromycin 500 mg twice daily. When rifabutin 600 mg was added the clarithromycin levels fell by 63% (from 5.4 to 2 micrograms/mL).³ Limited information from a randomised study in healthy subjects found similar results.^{1,4} Fluconazole appears to further increase the effects of clarithromycin on rifabutin.⁴ One study suggests that there is no pharmacokinetic interaction between azithromycin and rifabutin.¹

3. *Uveitis or arthralgias*. Uveitis, and in some cases pseudojaundice, aphthous stomatitis and an arthralgia syndrome have been described in patients treated with both clarithromycin 1 to 2 g daily and rifabutin 300 to 600 mg daily.^{5–8} The presence of fluconazole does not appear to affect the development of uveitis in patients taking clarithromycin with rifabutin,^{6,7,9} but it has been suggested that this was because only small doses (50 mg) were used.⁷

Reports suggest that uveitis develops between 27 to 370 days after taking the combination.^{6,7} The reaction appears to be dose-dependent. In patients taking rifabutin 600 mg with clarithromycin the incidence of uveitis was 14% in patients weighing more than 65 kg, 45% in those weighing between 55 and 65 kg and 64% in those weighing less than 55 kg. The risk of developing uveitis was reduced from a mean of 43% to 13% when the dose of rifabutin was reduced to 300 mg daily.⁹

Uveitis did not develop in 8 patients taking rifabutin and azithromycin 500 mg daily,⁷ although cases of uveitis have been reported in patients taking rifabutin, fluconazole, and azithromycin 1.2 g weekly but they have been attributed to an interaction between rifabutin and fluconazole.¹⁰ See ‘Azoles + Rifabutin’, p.219.

(b) Rifampicin (Rifampin)

Patients with lung disease due to MAC were treated with clarithromycin 500 mg twice daily. When rifampicin 600 mg daily was added, the mean serum levels of clarithromycin fell by almost 90% (from 5.4 to 0.7 micrograms/mL).³ Similar results are reported in another study.¹¹

The manufacturer notes that rifampicin reduces the AUC and maximum serum levels of telithromycin by 86% and 79%, respectively.¹²

Two cases of cholestatic jaundice have been reported in patients taking rifampicin with troleandomycin.^{13,14}

Mechanism

Both rifabutin and rifampicin are known enzyme inducers, which can increase the metabolism of other drugs by the liver, thereby reducing their serum levels. Rifampicin is recognised as being the more potent inducer. Rifabutin is also a substrate for cytochrome P450 isoenzyme CYP3A4. Both clarithromycin and fluconazole are inhibitors of CYP3A4 and it is probable that clarithromycin and fluconazole exert additive effects resulting in greater inhibition of rifabutin metabolism than occurs with either drug alone.⁴

The reason for the uveitis is not known, but based on *animal* studies it has been suggested that it is associated with effective treatment of MAC and is due to release of a mycobacterial protein, rather than a toxic effect of the drugs.¹⁵ It has been suggested that lower body weight and concurrent clarithromycin may result in toxic rifabutin serum levels, although concurrent fluconazole which increases levels does not appear to be a fac-

tor.⁹ The hepatotoxicity seen with rifampicin and troleandomycin is probably due to additive effects as both drugs are known to be hepatotoxic.

Importance and management

(a) Rifabutin and Rifampicin: Pharmacokinetics

Direct information appears to be limited to the reports cited but the interactions would appear to be established. What is not entirely clear is whether these interactions result in treatment failures because of the potentially subtherapeutic clarithromycin serum levels. Because of the lack of information, be alert for evidence of reduced efficacy if clarithromycin and rifampicin are used.

Although rifabutin can lower clarithromycin levels, the efficacy of this combination for MAC infection is established, although not without risk, see *Uveitis*, below. Clarithromycin raises rifabutin levels and therefore increases the risks of adverse effects. Concurrent use may therefore be desirable, but monitoring for adverse effects is necessary.

Due to a pharmacokinetic interaction the UK manufacturers recommend that telithromycin should not be given during and for 2 weeks after the use of rifampicin.¹²

(b) Rifabutin: Neutropenia

Information regarding neutropenia with macrolides and rifamycins is very limited but what is known suggests that white cell counts should be monitored closely if rifabutin is given with azithromycin or clarithromycin. Rifabutin is known to cause polyarthritides on rare occasions, but in conjunction with clarithromycin it appears to happen at much lower doses.⁸ Careful monitoring is necessary.

(c) Rifabutin: Uveitis

The CSM in the UK has warned about the need to be aware of the increased risk of uveitis with clarithromycin and rifabutin¹⁶ and of the raised rifabutin levels. If uveitis occurs the CSM recommends that rifabutin should be stopped and the patient should be referred to an ophthalmologist.¹⁶ Because of the increased risk of uveitis they also say that consideration should be given to reducing the dosage of rifabutin to 300 mg daily in the presence of macrolides.¹⁶ Later review and a case-control study suggest that this dose is associated with a reduced risk of uveitis and maintains efficacy.^{9,17}

Macrolides; Azithromycin + Ceftriaxone

A study in healthy subjects found that there did not appear to be a pharmacokinetic interaction between steady-state intravenous azithromycin and ceftriaxone and the combination was well-tolerated.¹

1. Chiu LM, Menhinick AM, Johnson PW, Amsden GW. Pharmacokinetics of intravenous azithromycin and ceftriaxone when administered alone and concurrently to healthy volunteers. *J Antimicrob Chemother* (2002) 50, 1075–9.

Macrolides; Azithromycin + Chloroquine

A study in which healthy subjects were given azithromycin 1 g daily for 3 days either alone or with chloroquine base 600 mg daily on days 1 and 2, and 300 mg on day 3, found no pharmacokinetic interaction.¹

1. Cook JA, Randinitis EJ, Bramson CR, Wesche DL. Lack of a pharmacokinetic interaction between azithromycin and chloroquine. *Am J Trop Med Hyg* (2006) 74, 407–12.

Macrolides; Azithromycin + Food

Food appears to halve azithromycin absorption from the capsule formulation, but does not alter the AUC of tablets or suspension.

Clinical evidence, mechanism, importance and management

A review by the manufacturers briefly mentions that food reduced the absorption of azithromycin by about half.¹ It is suggested therefore that azithromycin capsules should not be given at the same time as food, but should be taken at least 1 hour before or 2 hours after a meal.^{1,2} However, the US prescribing information states that a high-fat meal increased the maximum levels of azithromycin tablets by 23%, and had no effect on the AUC.³ Similarly, food increased the maximum levels of azithromycin suspension by 56%, without altering the AUC.³ Azithromycin suspension^{2,3} and tablets³ may therefore be taken without regard to food.

Macrolides; Clarithromycin + Disulfiram

Fatal toxic epidermal necrolysis and fulminant hepatitis occurred in a patient taking disulfiram and clarithromycin.

Clinical evidence, mechanism, importance and management

A 47-year-old man who had taken disulfiram 250 mg daily for about a month, with clarithromycin 500 mg twice daily and paracetamol 500 mg three times daily for one week, developed fatal toxic epidermal necrolysis and fulminant hepatitis. He had not drunk alcohol for several weeks and although he was taking paracetamol, the dose was below the toxic range and therefore an interaction between disulfiram and clarithromycin was considered probable.¹

Disulfiram alone may cause hepatic toxicity, possibly as the result of hypersensitivity or toxic metabolites. It was suggested that inhibition of cytochrome P450 isoenzyme CYP3A4 by clarithromycin could have resulted in the accumulation of toxic metabolites of disulfiram. Hepatocellular damage is uncommon in patients receiving clarithromycin alone, but may occur in patients with underlying disease. Both clarithromycin and disulfiram alone may cause adverse skin reactions, but neither has been reported to cause toxic epidermal necrolysis. The reason why this should occur with concurrent use is not understood.¹ Information seems to be limited to this single report, so no general conclusions can be drawn.

1. Masiá M, Gullérrez F, Jimeno A, Navarro A, Borrás J, Matarredona J, Martín-Hidalgo A. Fulminant hepatitis and fatal toxic epidermal necrolysis (Lyell disease) coincident with clarithromycin administration in an alcoholic patient receiving disulfiram therapy. *Arch Intern Med* (2002) 162, 474–6.

Macrolides; Erythromycin + Carbimazole

An isolated case describes torsade de pointes in an elderly patient taking carbimazole and oral erythromycin.

Clinical evidence

A 75-year-old woman with known mild mitral stenosis taking digoxin, furosemide, warfarin and carbimazole was given oral erythromycin 250 mg four times daily for a urinary tract infection. Three days later she experienced presyncopal episodes, and 4 days later she was admitted to hospital with syncope and self-terminating episodes of torsade de pointes. She completed the 7-day course of erythromycin on the day before admission. Five days after admission, when the QT interval was back to normal, she was inadvertently rechallenged with erythromycin, given as prophylaxis before permanent pacemaker insertion. After two doses of erythromycin 500 mg given at an interval of 6 hours, she developed torsade de pointes associated with a prolonged QT interval (QTc 612 milliseconds). The QT interval returned to normal 4 days after erythromycin was discontinued.¹

Mechanism

Intravenous erythromycin may cause QT prolongation and torsade de pointes. It is rare with oral erythromycin. Carbimazole is rapidly metabolised to thiamazole which is the active form of the drug. Thiamazole inhibits cytochrome P450 isoenzymes including CYP3A4 and it may therefore have inhibited the metabolism of erythromycin resulting in higher than normal levels. In addition, hypothyroidism can cause torsade de pointes, and therefore mild hypothyroidism induced by carbimazole could have contributed.¹ Furthermore, bradycardia (heart rate less than 60 bpm) may also have contributed.

Importance and management

It was suggested that the combination of oral erythromycin and carbimazole could lead to torsade de pointes in susceptible individuals. In this case, female sex, presence of valvular heart disease, bradycardia, hypokalaemia, and hypothyroidism may all have been contributory factors.¹ See also, 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

1. Koh TW. Risk of torsades de pointes from oral erythromycin with concomitant carbimazole (methimazole) administration. *PACE* (2001) 24, 1575–6.

Macrolides; Erythromycin + Sucralfate

Sucralfate does not appear to affect the pharmacokinetics of erythromycin.

Clinical evidence, mechanism, importance and management

The pharmacokinetics (elimination rate constant, half-life, AUC) of a single 400-mg dose of erythromycin ethylsuccinate were not significantly altered by a single 1-g dose of sucralfate in 6 healthy subjects. It was concluded that the therapeutic effects of erythromycin are unlikely to be affected by concurrent use.¹

1. Miller LG, Prichard JG, White CA, Vytla B, Feldman S, Bowman RC. Effect of concurrent sucralfate administration on the absorption of erythromycin. *J Clin Pharmacol* (1990) 30, 39–44.

Macrolides; Erythromycin + Urinary acidifiers or alkalinisers

In the treatment of urinary tract infections, the antibacterial activity of erythromycin is maximal in alkaline urine and minimal in acidic urine.

Clinical evidence

Urine taken from 7 subjects receiving erythromycin 1 g every 8 hours, was tested against 5 genera of Gram-negative bacilli (*Escherichia coli*, *Kleb-*

siella pneumoniae, *P. mirabilis*, *Ps. aeruginosa* and *Serratia* sp.) both before and after treatment with **acetazolamide** or **sodium bicarbonate**, given to alkalinise the urine. A direct correlation was found between the activity of the antibacterial and the pH of the urine. In general, acidic urine had little or no antibacterial activity, whereas alkalinised urine had activity.¹

Clinical studies have confirmed the increased antibacterial effectiveness of erythromycin in the treatment of bacteriuria when the urine is made alkaline.^{2,3}

Mechanism

The pH of the urine does not apparently affect the way the kidney handles the antibacterial (most of it is excreted actively rather than passively) but it does have a direct influence on the way the antibacterial affects the micro-organisms. Mechanisms suggested include effects on bacterial cell receptors, the induction of active transport mechanisms on bacterial cell walls, and changes in ionisation of the antibacterial, which enables it to enter the bacterial cell more effectively.

Importance and management

An established interaction, which can be exploited. Should erythromycin be used to treat urinary tract infections its efficacy can be maximised by making the urine alkaline (for example with acetazolamide or sodium bicarbonate). Treatment with urinary acidifiers will minimise the activity of the erythromycin for urinary tract infections and should be avoided. There is no evidence that the efficacy of erythromycin in other infections is affected by urinary acidifiers or alkalinisers.

Methenamine + Urinary acidifiers or alkalinisers

Urinary alkalinisers (e.g. potassium or sodium citrate) and those antacids that can raise the urinary pH above 5.5 should not be used during treatment with methenamine because they inhibit its activation.

Clinical evidence, mechanism, importance and management

Methenamine and methenamine mandelate are only effective as urinary antiseptics if the pH is about 5.5 or lower, when formaldehyde is released. This is normally achieved by giving urinary acidifiers such as ammonium chloride, ascorbic acid,^{1,2} or sodium acid phosphate. In the case of methenamine hippurate, the acidification of the urine is achieved by the presence of hippuric acid. The concurrent use of substances that raise the urinary pH such as **acetazolamide**, **sodium bicarbonate**, **potassium** or **sodium citrate** is clearly contraindicated. **Potassium citrate mixture BPC** has been shown to raise the pH by more than 1 at normal therapeutic doses, thereby making the urine sufficiently alkaline to interfere with the activation of methenamine to formaldehyde.³ Some **antacids** (containing magnesium, aluminium or calcium as well as sodium bicarbonate mentioned above) can also cause a significant rise in the pH of the urine.⁴

Metronidazole + Antacids, Colestyramine or Kaolin-pectin

The absorption of metronidazole is unaffected by kaolin-pectin, but it is slightly reduced by an aluminium hydroxide antacid and colestyramine, although not to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

The bioavailability of a single 500-mg dose of metronidazole in 5 healthy subjects was not significantly changed by 30 mL of a kaolin-pectin anti-diarrhoeal mixture. However, a 14.5% reduction in metronidazole bioavailability occurred with 30 mL of an **aluminium hydroxide/simeticone** suspension, and a 21.3% reduction occurred with a single 4-g dose of colestyramine.¹ The clinical importance of these reductions is probably small, and no special precautions seem necessary.

1. Molokhia AM, Al-Rahman S. Effect of concomitant oral administration of some adsorbing drugs on the bioavailability of metronidazole. *Drug Dev Ind Pharm* (1987) 13, 1229–37.

Metronidazole + Barbiturates

Phenobarbital markedly increases the metabolism of metronidazole and treatment failure has been reported in both adults and children.

Clinical evidence

A woman with vaginal trichomoniasis was given metronidazole on several occasions over the course of a year, but the infection flared up again as soon as it was stopped. When it was realised that she was also taking **phenobarbital** 100 mg daily, the metronidazole dosage was doubled to 500 mg three times daily, and she was cured after a 7-day course.¹ A pharmacokinetic study found that the clearance of metronidazole was increased (half-life 3.5 hours compared with the normal half-life of 8 to 9 hours).¹

A retrospective study in children who had not responded to metronidazole for giardiasis or amoebiasis found that 80% of them had been taking long-term **phenobarbital**. In a prospective study in 36 children the normal recommended metronidazole dosage had to be increased approximately threefold to 60 mg/kg to achieve a cure. The half-life of metronidazole in 15 other children taking **phenobarbital** was found to be 3.5 hours compared with the normal half-life of 8 to 9 hours.²

Other studies in patients with Crohn's disease and healthy subjects have shown that **phenobarbital** reduces the AUC of metronidazole by about one-third,³ and increases the clearance of metronidazole 1.5-fold.⁴

Mechanism

Phenobarbital is a known, potent liver enzyme inducer, which increases the metabolism and clearance of metronidazole from the body.

Importance and management

An established and clinically important interaction. Monitor the effects of concurrent use and anticipate the need to increase the metronidazole dosage two to threefold if phenobarbital is given. All of the barbiturates are potent liver enzyme inducers and would therefore be expected to interact similarly.

4. Loft S, Sonne J, Poulsen HE, Petersen KT, Jørgensen BG, Døssing M. Inhibition and induction of metronidazole and antipyrine metabolism. *Eur J Clin Pharmacol* (1987) 32, 35–41.

Metronidazole + Chloroquine

An isolated report describes acute dystonia in one patient, which was attributed to an interaction between metronidazole and chloroquine.

Clinical evidence, mechanism, importance and management

A patient was given a 7-day course of metronidazole and ampicillin, following a laparoscopic investigation. She developed acute dystonic reactions (facial grimacing, coarse tremors, and an inability to maintain posture) on day 6, within 10 minutes of being given chloroquine phosphate (equivalent to 200 mg of base) and intramuscular promethazine

25 mg. The dystonic symptoms started to subside within 15 minutes of being given diazepam 5 mg intravenously, and had completely resolved within 2 hours.¹

The authors of the report attribute the dystonia to an interaction between metronidazole and chloroquine as she had taken both drugs alone without adverse effect. However, they do not fully assess the possible contribution of **promethazine**, which is known to cause dystonias. It is therefore possible that the reaction seen was an adverse effect of the **promethazine**, or perhaps even an interaction between **promethazine** and chloroquine. No general recommendations can therefore be made from this single report.

1. Achumba JJ, Ette EI, Thomas WOA, Essien EE. Chloroquine-induced acute dystonic reactions in the presence of metronidazole. *Drug Intell Clin Pharm* (1988) 22, 308–10.

Metronidazole or Tinidazole + Cimetidine

Cimetidine reduces the metabolism of tinidazole, and possibly also metronidazole, but this is probably not clinically important.

Clinical evidence

(a) Metronidazole

The half-life of a 400-mg intravenous dose of metronidazole was increased from 6.2 to 7.9 hours in 6 healthy subjects after they took cimetidine 400 mg twice daily for 6 days. The total plasma clearance was reduced by almost 30%.¹ However, in another study in 6 patients with Crohn's disease, cimetidine 600 mg twice daily for 7 days was found not to affect either the AUC or the half-life of metronidazole,² and no evidence of an interaction was found in a further study in 6 healthy subjects.³

(b) Tinidazole

In a study in 6 healthy subjects cimetidine 400 mg twice daily for 7 days raised the peak serum levels of a single 600-mg dose of tinidazole by 21%, increased the 24-hour AUC by 40% and increased the half-life by 47%, from 7.66 to 11.23 hours.⁴

Mechanism

Cimetidine is a well known enzyme inhibitor, which probably inhibits the metabolism of the metronidazole and tinidazole by the liver.

Importance and management

The modest changes in the pharmacokinetics of tinidazole with cimetidine seem unlikely to be clinically significant, but bear them in mind in the case of an unexpected response to treatment. The interaction between metronidazole and cimetidine is not established, but any changes in metronidazole pharmacokinetics seem to be modest and unlikely to be important.

2. Eradiri O, Jamali F, Thomson ABR. Interaction of metronidazole with phenobarbital, cimetidine, prednisone, and sulfasalazine in Crohn's disease. *Biopharm Drug Dispos* (1988) 9, 219–27.
3. Loft S, Døssing M, Sonne J, Dalhof K, Bjerrum K, Poulsen HE. Lack of effect of cimetidine on the pharmacokinetics and metabolism of a single oral dose of metronidazole. *Eur J Clin Pharmacol* (1988) 35, 65–8.
4. Patel RB, Shah GF, Raval JD, Gandhi TP, Gilbert RN. The effect of cimetidine and rifampicin on tinidazole kinetics in healthy human volunteers. *Indian Drugs* (1986) 23, 338–41.

Metronidazole + Diosmin

Diosmin reduces the metabolism of metronidazole to some extent, but the clinical importance of this is probably small.

Clinical evidence, mechanism, importance and management

A single 800-mg dose of metronidazole was given to 12 healthy subjects following 9 days of treatment with diosmin 500 mg daily. The metronidazole AUC and maximum plasma concentrations were raised by 27% and 25%, respectively.¹ This interaction is thought to occur because of an inhibitory effect of diosmin on metronidazole metabolism by hepatic enzymes, and inhibition of P-glycoprotein. The increase in metronidazole levels is similar to that seen with other drugs (e.g. 'cimetidine' (above)) that are not considered to be clinically significant. Therefore no clinically

significant interaction is likely to occur if metronidazole is given with disulfiram.

1. Rajnarayana K, Reddy MS, Krishna DR. Diosmin pretreatment affects bioavailability of metronidazole. *Eur J Clin Pharmacol* (2003) 58, 803–807.

Metronidazole + Disulfiram

Acute psychoses and confusion can be caused by the concurrent use of metronidazole and disulfiram.

Clinical evidence, mechanism, importance and management

In a double-blind study in 58 hospitalised chronic alcoholics taking disulfiram, 29 patients were also given metronidazole 750 mg daily for a month, then 250 mg daily thereafter. Six of the 29 subjects in the group receiving metronidazole developed acute psychoses or confusion. Five of the 6 had paranoid delusions and in 3 visual and auditory hallucinations were also seen. The symptoms persisted for 2 to 3 days after the drugs were withdrawn, but disappeared at the end of a fortnight and did not reappear when disulfiram alone was restarted.¹ Similar reactions have been described in two other reports.^{2,3}

The reason for this interaction is not understood, but it appears to be established. Concurrent use should be avoided or very well monitored.

2. Goodhue WW. Disulfiram-metronidazole (well-identified) toxicity. *N Engl J Med* (1969) 280, 1482–3.
3. Scher JM. Psychotic reaction to disulfiram. *JAMA* (1967) 201,1051.

Metronidazole + Mebendazole

A case-control study identified the concurrent use of metronidazole and mebendazole as a risk factor in an outbreak of Stevens-Johnson syndrome/toxic epidermal necrolysis.

Clinical evidence, mechanism, importance and management

A case control study was conducted in an attempt to identify risk factors associated with an outbreak of Stevens-Johnson syndrome/toxic epidermal necrolysis that occurred amongst Filipino workers in Taiwan. The risk of developing this serious condition was significantly higher in workers who had taken both metronidazole and mebendazole sometime in the preceding 6 weeks (odds ratio of 9.5). In addition, there was an increase in risk with higher doses of metronidazole.¹

The information is limited to this report, which does not establish an interaction. However, Stevens-Johnson syndrome/toxic epidermal necrolysis is a serious condition, and therefore, the manufacturer of mebendazole states that the concurrent use of mebendazole and metronidazole should be avoided.² Caution would certainly seem appropriate if both drugs are considered essential.

1. Chen K-T, Twu S-J, Chang H-J, Lin R-S. Outbreak of Stevens-Johnson syndrome/toxic epidermal necrolysis associated with mebendazole and metronidazole use among Filipino laborers in Taiwan. *Am J Public Health* (2003) 93, 489–92.
2. Vermox (Mebendazole). Janssen-Cilag Ltd. UK Summary of product characteristics, June 2005.

Metronidazole + Prednisone

Prednisone modestly decreases the AUC of metronidazole.

Clinical evidence, mechanism, importance and management

In 6 patients with Crohn's disease the AUC of metronidazole 250 mg twice daily was reduced by 31% by prednisone 10 mg twice daily for 6 days, probably because prednisone induces the metabolism of metronidazole by liver enzymes.¹

Information appears to be limited to this report and the interaction is probably of only limited clinical importance. Information about other corticosteroids is lacking.

1. Eradiri O, Jamali F, Thomson ABR. Interaction of metronidazole with phenobarbital, cimetidine, prednisone, and sulfasalazine in Crohn's disease. *Biopharm Drug Dispos* (1988) 9, 219–27.

Metronidazole or Tinidazole + Rifampicin (Rifampin)

Rifampicin modestly increases the clearance of metronidazole and tinidazole but the clinical importance of this is uncertain.

Clinical evidence

(a) Metronidazole

Intravenous metronidazole 500 mg or 1 g was given to 10 healthy subjects before and after taking rifampicin 450 mg daily for 7 days. Rifampicin reduced the AUC of metronidazole by 33% and increased its clearance by 44%. Results were the same with both metronidazole doses.¹

(b) Tinidazole

After 6 healthy subjects took rifampicin 600 mg daily for 7 days the peak serum levels of a single 600-mg dose of tinidazole were reduced by 22%, the AUC₀₋₂₄ was reduced by 30% and the half-life was reduced by 27% (from 7.66 to 5.6 hours).²

Mechanism

This interaction almost certainly occurs because rifampicin (a well-recognised and potent enzyme inducer) increases the metabolism of metronidazole and tinidazole by the liver.

Importance and management

The clinical significance of these interactions appear not to have been studied. A 30% reduction in metronidazole levels would not be expected to be of much clinical significance and there do not appear to be any reports of an interaction in practice. Rifampicin is known to act synergistically with metronidazole,³ so it may be that any reduction in levels is offset by enhanced antimicrobial activity. Tinidazole acts very much like metronidazole, and therefore a clinically significant interaction between rifampicin and either of these drugs seems unlikely.

1. Djojoputro M, Mustofa SS, Donatus IA, Santoso B. The effects of doses and pre-treatment with rifampicin on the elimination kinetics of metronidazole. *Eur J Pharmacol* (1990) 183, 1870–1.
2. Patel RB, Shah GF, Raval JD, Gandhi TP, Gilbert RN. The effect of cimetidine and rifampicin on tinidazole kinetics in healthy human volunteers. *Indian Drugs* (1986) 23, 338–41.
3. Metronidazole Tablets. Dumex-Alpha A/S. UK Summary of product characteristics, October 2005.

Metronidazole + Silymarin

Silymarin (the active constituent of milk thistle) modestly reduces metronidazole levels, but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management

Silymarin 140 mg daily was given to 12 healthy subjects for 9 days, with metronidazole 400 mg three times daily on days 7 to 10. Silymarin reduced the AUC of metronidazole and hydroxymetronidazole (a major active metabolite) by 28% and the maximum serum levels by 29% and 20%, respectively. The authors suggest that silymarin causes these pharmacokinetic changes by inducing P-glycoprotein and the cytochrome P450 isoenzyme CYP3A4, which are involved in the transport and metabolism of metronidazole.¹ The clinical significance of this interaction is unclear, but a 28% reduction in the AUC of metronidazole would not be expected to be of much clinical significance.

1. Rajnarayana K, Reddy MS, Vidyasagar J, Krishna DR. Study on the influence of silymarin pretreatment on metabolism and disposition of metronidazole. *Arzneimittelforschung* (2004) 54, 109–113.

Metronidazole + Sucralfate

Sucralfate does not alter the pharmacokinetics of metronidazole.

Clinical evidence, mechanism, importance and management

Because oral triple therapy to eradicate *H. pylori* using sucralfate instead of bismuth has yielded inconsistent results, a 5-day study was undertaken in 14 healthy subjects to investigate whether sucralfate interacts with metronidazole. It was found that sucralfate 2 g twice daily had no effect on the pharmacokinetics of a single 400-mg dose of metronidazole.¹ Sucralfate would therefore not be expected to alter the effects of metronidazole.

1. Amaral Moraes ME, De Almeida Pierossi M, Moraes MO, Bezerra FF, Ferreira De Silva CM, Dias HB, Muscará MN, De Nucci G, Pedrazzoli J. Short-term sucralfate administration does not alter the absorption of metronidazole in healthy male volunteers. *Int J Clin Pharmacol Ther* (1996) 34, 433–7.

Nitrofurantoin + Antacids

Magnesium trisilicate reduces the absorption of nitrofurantoin, but the clinical significance of this is unknown. Aluminium hydroxide is reported not to interact with nitrofurantoin. Whether other antacids interact adversely is uncertain.

Clinical evidence

Magnesium trisilicate 5 g in 150 mL of water reduced the absorption of a single 100-g oral dose of nitrofurantoin in 6 healthy subjects by more than 50%. The time during which the concentration of nitrofurantoin in the urine was at, or above 32 micrograms/mL (a level stated to be the minimum inhibitory concentration) was also reduced.¹ The amounts of nitrofurantoin adsorbed by other antacids in *in vitro* tests were as follows: **magnesium trisilicate** and **charcoal** 99%, **bismuth subcarbonate** and **talc** 50 to 53%, **kaolin** 31%, **magnesium oxide** 27%, **aluminium hydroxide** 2.5% and **calcium carbonate** 0%.¹

A crossover study in 6 healthy subjects confirmed that **aluminium hydroxide gel** does not affect the absorption of nitrofurantoin from the gut (as measured by its excretion into the urine).² Another study in 10 healthy subjects found that an antacid containing **aluminium hydroxide, magnesium carbonate** and **magnesium hydroxide** reduced the absorption of nitrofurantoin by 22%.³

Mechanism

Antacids can, to a greater or lesser extent, adsorb nitrofurantoin onto their surfaces, as a result less is available for absorption by the gut and for excretion into the urine.

Importance and management

Information appears to be limited to these reports. There seems to be nothing in the literature confirming that a clinically important interaction occurs between nitrofurantoin and antacids. One reviewer offers the opinion that common antacid preparations are unlikely to interact with nitrofurantoin.⁴

It is not yet known whether magnesium trisilicate significantly reduces the antibacterial effectiveness of nitrofurantoin but the response should be monitored. While it is known that the antibacterial action of nitrofurantoin is increased by drugs that acidify the urine (so that reduced actions would be expected if the urine were made more alkaline by antacids) this again does not seem to have been confirmed. The results of the *in vitro* studies suggest that the possible effects of the other antacids are quite small, and aluminium hydroxide is reported not to interact.

Nitrofurantoin + Antigout drugs

On theoretical grounds the efficacy and toxicity of nitrofurantoin may possibly be increased by probenecid and sulfapyrazone.

Clinical evidence, mechanism, importance and management

A study of the way the kidneys handle nitrofurantoin found that intravenous **sulfapyrazone** 2.5 mg/kg reduced the secretion of nitrofurantoin by the kidney tubules by about 50%.¹ This reduction would be expected to reduce its urinary antibacterial efficacy, and the higher serum levels might lead to increased systemic toxicity, but there do not seem to be any reports suggesting that this represents a real problem in practice. The same situation would also seem likely with **probenecid**, but there do not appear to be any reports confirming this interaction.

The clinical importance of both of these interactions is therefore uncertain, but it would seem prudent to be alert for any evidence of reduced antibacterial efficacy and increased systemic toxicity if either sulfapyrazone or probenecid is used with nitrofurantoin.

1. Schirmeister J, Stefani F, Willmann H, Hallauer W. Renal handling of nitrofurantoin in man. *Antimicrob Agents Chemother* (1965) 5, 223–6.

Nitrofurantoin + Antimuscarinics or Diphenoxylate

Diphenoxylate and anticholinergic drugs such as propantheline can double the absorption of nitrofurantoin in some patients, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects **propantheline** 30 mg given 45 minutes before nitrofurantoin approximately doubled the absorption of nitrofurantoin 100 mg (as measured by the urinary excretion).¹ In another study, **diphenoxylate** 200 mg daily for 3 days nearly doubled nitrofurantoin absorption in 2 out of 6 men.² **Atropine** 500 micrograms given subcutaneously 30 minutes before a single 100-mg dose of nitrofurantoin had little effect on the bioavailability of nitrofurantoin, but the absorption and excretion into the urine was delayed.³

It was suggested that the reduced gut motility caused by these drugs allows the nitrofurantoin to dissolve more completely so that it is absorbed by the gut more easily. Whether this is of any clinical importance is uncertain but it could possibly increase the incidence of dose-related adverse reactions. So far there appear to be no reports of any problems arising from concurrent use.

Nitrofurantoin + Azoles

In an isolated case hepatic and pulmonary toxicity occurred when nitrofurantoin was given with fluconazole, but not with itraconazole.

Clinical evidence, mechanism, importance and management

A 73-year-old man who had taken nitrofurantoin 50 mg daily for 5 years was given **fluconazole** 150 mg weekly for onychomycosis. At the start of treatment with **fluconazole** his hepatic enzyme levels were slightly raised, and 3 weeks later they were increased more than twofold. Two months after starting **fluconazole** the patient's hepatic enzyme levels had increased fivefold and he had fatigue, dyspnoea on exertion, pleuritic pain, burning tracheal pain, and a cough. Bilateral pulmonary disease was confirmed by chest X-rays, and pulmonary function tests suggested nitrofurantoin toxicity. Both **fluconazole** and nitrofurantoin were discontinued, and hepatic and lung function gradually improved.¹

Either **fluconazole** or nitrofurantoin could have caused the liver toxicity. However, it was considered that both the lung and liver toxicity may have been due to an interaction between nitrofurantoin and **fluconazole**, possibly due to increased nitrofurantoin concentrations resulting from competition with **fluconazole** for renal tubular secretion.

Some 2 years earlier the patient had received pulse **itraconazole** (less

than 1% excreted in the urine as active drug) with nitrofurantoin without raised liver enzymes or any other adverse effects.¹

Information appears to be limited to this report, but bear it in mind in the event of increased nitrofurantoin adverse effects. More study is needed.

1. Linnebur SA, Parnes BL. Pulmonary and hepatic toxicity due to nitrofurantoin and fluconazole treatment. *Ann Pharmacother* (2004) 38, 612–16.

Nitrofurantoin + Metoclopramide

Metoclopramide reduces the absorption of nitrofurantoin.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects the urinary excretion of a 100-mg dose of nitrofurantoin was approximately halved by pretreatment with a 10-mg intramuscular dose of metoclopramide and a 10 mg oral dose of metoclopramide given 30 minutes before the nitrofurantoin.¹

It is thought that metoclopramide increases the gastric emptying rate, thus decreasing nitrofurantoin absorption. The practical importance of this is uncertain because there seem to be no reports of an interaction in practice.

1. Männistö P. The effect of crystal size, gastric content and emptying rate on the absorption of nitrofurantoin in healthy human volunteers. *Int J Clin Pharmacol Biopharm* (1978) 16, 223–8.

Nitroxoline + Antacids

The antibacterial effects of nitroxoline have been found to be reduced *in vitro* by magnesium and calcium ions because they form chelates with the nitroxoline.¹ In the absence of any direct clinical information it would seem prudent to monitor concurrent use for any evidence that its antibacterial effects are reduced.

1. Pelletier C, Prognon P, Bourlioux P. Roles of divalent cations and pH in mechanism of action of nitroxoline against *Escherichia coli* strains. *Antimicrob Agents Chemother* (1995) 707–13.

Novobiocin + Rifampicin (Rifampin)

Rifampicin reduces the half-life of novobiocin but this is unlikely to be clinically significant.

Clinical evidence, mechanism, importance and management

When 10 healthy subjects were given novobiocin 1 g daily for 13 days with rifampicin 600 mg daily, the novobiocin half-life was reduced from 5.85 to 2.66 hours and the AUC was reduced by almost 50%. There were no significant changes to the half-life or AUC of rifampicin. The serum novobiocin and rifampicin levels were not significantly altered and the trough serum levels of both antibacterials when given alone or concurrently remained in excess of the MIC for 90% of the strains of MRSA tested.¹ No special precautions would therefore seem to be necessary during concurrent use.

1. Drusano GL, Townsend RJ, Walsh TJ, Forrest A, Antal EJ, Standiford HC. Steady-state serum pharmacokinetics of novobiocin and rifampin alone and in combination. *Antimicrob Agents Chemother* (1986) 30, 42–5.

Penicillins + Acacia or Guar gum

The absorption of amoxicillin may be significantly reduced when given with or 2 hours after acacia. Guar gum causes a small reduction in the absorption of phenoxymethylpenicillin (penicillin V).

Clinical evidence, mechanism, importance and management

(a) *Acacia*

In healthy subjects the maximum serum levels and AUC of a single 500-mg dose of **amoxicillin** were reduced by 73% and 79%, respectively, when given with acacia (gum arabic: amount not stated) and by 56% and 49%,

respectively, when given 2 hours after ingestion of acacia. The pharmacokinetics of **amoxicillin** were not significantly affected when it was given 4 hours after acacia. Acacia is used in pharmaceutical preparations as a suspending, demulcent and emulsifying agent. Concurrent administration with **amoxicillin** could result in subtherapeutic levels of the antibacterial, but whether or not this would occur with the amount of acacia in a dose of a preparation containing it as an excipient is not known. In some countries acacia is given to patients with chronic renal failure. The authors suggest that if **amoxicillin** is used to treat urinary-tract infections in patients also treated with acacia, it should be given 4 hours before or after the acacia.¹

(b) *Guar gum*

Guar gum 5 g (*Guarem*, 95% guar gum) reduced the absorption of a single 1980-mg dose of **phenoxymethylpenicillin** (penicillin V) in 10 healthy subjects. Peak serum penicillin levels were reduced by 25% and the AUC_{0–6} was reduced by 28%.² The reasons are not understood.

The clinical significance of this interaction is uncertain, but the reduction in serum levels is only small. It would clearly only be important if the reduced amount of penicillin absorbed was inadequate to control infection. The effect of guar gum on other penicillins seems not to have been studied.

2. Huupponen R, Seppälä P, Iisalo E. Effect of guar gum, a fibre preparation, on digoxin and penicillin absorption in man. *Eur J Clin Pharmacol* (1984) 26, 279–81.

Penicillins + Allopurinol

The incidence of skin rashes in patients taking either ampicillin or amoxicillin is increased by allopurinol.

Clinical evidence

A retrospective search through the records of 1324 patients, 67 of whom were taking allopurinol and **ampicillin**, found that 15 of them (22%) developed a skin rash compared with 94 (7.5%) of the patients not taking allopurinol.¹ The types of rash were not defined. Another study found that 35 out of 252 patients (13.9%) taking allopurinol and **ampicillin** developed a rash, compared with 251 out of 4434 (5.9%) taking **ampicillin** alone.² A parallel study revealed that 8 out of 36 patients (22%) taking **amoxicillin** and allopurinol developed a rash, whereas only 52 out of 887 (5.9%) did so when taking **amoxicillin** alone.²

A case report describes a patient who developed erythema multiforme shortly after starting **amoxicillin** and allopurinol and who was found to have both allopurinol hypersensitivity and type IV amoxicillin hypersensitivity.³

In contrast, one study did not find that the incidence of penicillin-related rashes was increased by allopurinol, and the authors suggested that this contrasting finding may be because exposure to penicillins was shorter in their study.⁴

Mechanism

Not understood. One suggestion is that the hyperuricaemia was responsible.¹ Another is that hyperuricaemic individuals may possibly have an altered immunological reactivity.⁵

Importance and management

An established interaction of limited importance. There would seem to be no strong reason for avoiding concurrent use, but prescribers should recognise that the development of a rash is by no means unusual. Whether this also occurs with penicillins other than ampicillin or amoxicillin is uncertain, and does not seem to have been reported.

Penicillins + Antacids

Aluminium/magnesium hydroxide and aluminium hydroxide do not significantly affect the bioavailability of amoxicillin or amoxicillin with clavulanic acid (co-amoxiclav). Antacids may reduce the absorption of the hydrochloride salt of pivampicillin.

Clinical evidence, mechanism, importance and management

(a) Amoxicillin or Co-amoxiclav

The pharmacokinetics of amoxicillin 1 g, and both amoxicillin and clavulanic acid (given as co-amoxiclav 625 mg), were not significantly altered by 10 doses of **aluminium/magnesium hydroxide (Maalox)** 10 mL, with the last dose given 30 minutes before amoxicillin.¹ Another study found that four 40-mg doses of **aluminium hydroxide (Aludrox)** given at 20 minute intervals had no effect on the pharmacokinetics of either amoxicillin or clavulanic acid (given as co-amoxiclav 750 mg with the second dose of antacid).²

There would seem to be no reason for avoiding the concurrent use of antacids and amoxicillin or co-amoxiclav.

(b) Pivampicillin

The UK manufacturers³ used to recommend that, because antacids may decrease pivampicillin absorption, concurrent use should be avoided. This warning relates to a hydrochloride salt formulation, which needs acidic conditions for optimal absorption, whereas the basic salt formulation should not be affected by any pH change.⁴

Penicillins + Catha (Khat)

Chewing khat reduces the absorption of ampicillin and, to a lesser extent, amoxicillin, but the effects are minimal 2 hours after khat chewing stops.

Clinical evidence, mechanism, importance and management

A study in 8 healthy Yemeni male subjects found that chewing khat reduced the absorption of oral **ampicillin** from the gut.¹ When **ampicillin** 500 mg was taken with 250 mL water 2 hours before or just before khat chewing started, or midway through a 4 hour chewing session, the amounts of unchanged **ampicillin** in the urine fell by 46%, 41% and 49%, respectively. Even when **ampicillin** was taken 2 hours after a chewing session had stopped, the amount of drug excreted unchanged in the urine fell by 12%. A parallel series of studies with **amoxicillin** 500 mg found much smaller reductions. The equivalent reductions were 14%, 9%, 22% and 13%. A similar study found that chewing khat resulted in variable reduction in the bioavailability of **amoxicillin** 500 mg, which was maximal (22%) when it was given midway during the 4-hour chewing period.²

The reasons for this interaction are not known, but the authors of the reports suggest that tannins from the khat might form insoluble and non-absorbable complexes with these penicillins, and possibly also directly reduce the way the gut absorbs them.¹

Khat (the leaves and stem tips of *Catha edulis*) is chewed in some African and Arabian countries for its stimulatory properties. The authors of one of the studies concluded that both **ampicillin** and **amoxicillin** should be taken 2 hours after khat chewing to ensure that maximum absorption occurs.¹

Penicillins + Chloroquine

Chloroquine reduces the absorption of ampicillin, but bacampicillin is unaffected.

Clinical evidence

Chloroquine 1 g reduced the absorption (as measured by excretion in the urine) of a single 1-g dose of oral **ampicillin** by about one-third (from 29 to 19%) in 7 healthy subjects.¹ Another study by the same author demonstrated that the absorption of **ampicillin** from **bacampicillin** tablets was unaffected by chloroquine.²

Mechanism

A possible reason for the reduction in absorption is that the chloroquine irritates the gut so that the ampicillin is moved through more quickly, thereby reducing the time for absorption.

Importance and management

Information appears to be limited to the studies cited, which used large doses of chloroquine (1 g) when compared with those usually used for malarial prophylaxis (300 mg base weekly) or for rheumatic diseases (150 mg daily). The reduction in the ampicillin absorption is also only moderate. The general clinical importance of this interaction is therefore uncertain. However, one report suggests separating the dosing by not less than 2 hours.¹ An alternative would be to use bacampicillin (an ampicillin pro-drug), which does not appear to interact with chloroquine.² More study is needed to confirm and evaluate the importance of this interaction.

2. Ali HM. The effect of Sudanese food and chloroquine on the bioavailability of ampicillin from bacampicillin tablets. *Int J Pharmaceutics* (1981) 9, 185–90.

Penicillins + Food

The absorption of many penicillins is not significantly affected by food. The exceptions are ampicillin (food may reduce its levels by up to 50%), cloxacillin, and possibly pivampicillin and phenoxymethylpenicillin.

Clinical evidence, mechanism, importance and management

(a) Dietary fibre

The AUC of a single 500-mg oral dose of **amoxicillin** was found to be 12.17 micrograms/mL per hour in 10 healthy subjects on a low fibre diet (7.8 g of insoluble fibre daily) but only 9.65 micrograms/mL per hour when they ate a high fibre diet (36.2 g of insoluble fibre daily); a difference of about 20%. Peak serum levels were the same and occurred at 3 hours.¹ The clinical relevance of these changes is likely to be minimal.

(b) Enteral and parenteral feeds

A single 250-mg intravenous dose of **ampicillin** was given to 7 healthy subjects 2 hours into a 12-hour infusion of parenteral nutrition or 4 hours after an enteral meal. The parenteral nutrition was of two types, one with and one without amino acids, calcium and phosphorus, both without lipids, and of similar calorific content and volume to the enteral feed. None of the three regimens altered the pharmacokinetics of intravenous **ampicillin**.² Note that the **ampicillin** was given in a separate limb to the parenteral nutrition.

(c) Food

1. *Amoxicillin and co-amoxiclav*. Food eaten immediately before amoxicillin reduced its serum levels by about 50% and reduced urinary excretion, when compared with the fasted state.³ However, in another study, a standard breakfast had no effect on the AUC of a single 500-mg dose of amoxicillin in 16 healthy subjects.⁴ Similarly, a crossover study in 18 healthy subjects given co-amoxiclav (amoxicillin 500 mg with **clavulanic acid** 250 mg), either 2 hours before or with a fried breakfast, found that the breakfast had no significant effect on the pharmacokinetics of amoxicillin or **clavulanic acid**. Moreover, a further study in 43 healthy subjects found that taking co-amoxiclav with food tended to minimise the incidence (but

not the severity) of gastrointestinal adverse effects (watery stools, nausea and vomiting).³ It would therefore be beneficial to take co-amoxiclav with a meal.

2. **Ampicillin.** Food eaten immediately before a single 500-mg dose of ampicillin reduced its serum levels by about 50% and reduced urinary excretion.³ A standard breakfast reduced the AUC of a single 500-mg dose of ampicillin by 31% in 16 healthy subjects.⁴ Another study found ampicillin absorption was delayed and the total absorption reduced when it was taken with food. Urinary excretion of ampicillin was about 30% of a dose when given on an empty stomach and about 20% when given with food.⁶ It is recommended that ampicillin is taken one hour before food or on an empty stomach to optimise absorption.

3. **Bacampicillin.** The AUC of ampicillin was assessed when 6 healthy subjects took a 1.6-g dose of bacampicillin either 35 minutes after breakfast or 2 hours before breakfast. The AUC was 26% lower with the post-breakfast dose, but this difference was not statistically significant.⁷ On the basis of other work that also suggests that no important interaction occurs with food,^{8,9} the manufacturers say that bacampicillin can be given without regard to time of food intake.

4. **Flucloxacillin.** A study in children given flucloxacillin 12.5 mg/kg as either tablets or mixture found that while the absorption depended on both the formulation and age of the child, there was no difference in levels achieved when given to a subject when fasting or with a breakfast.¹⁰ However, it is recommended that flucloxacillin is taken one hour before food or on an empty stomach to optimise absorption. The presence of food is reported to reduce the rate and extent of absorption of the related drug **cloxacillin**,¹¹ and therefore it may be prudent to follow the advice given for flucloxacillin.

5. **Pivampicillin.** A study in healthy subjects found the absorption of pivampicillin was delayed when it was given with food, but the amount absorbed was not affected. The urinary excretion of ampicillin following pivampicillin was about 60% of the dose when taken with or without food.⁶ However, another study in which pivampicillin 350 mg was given in the fasting state or with a standardised cooked breakfast found that food both delayed and reduced the absorption of pivampicillin by almost 50%.¹²

6. **Pivmecillinam.** The manufacturers of pivmecillinam note that its absorption is practically unaffected when the tablets are taken with food.¹³

(d) Milk

The peak levels and the AUCs of oral **phenoxymethylpenicillin** and **oral benzylpenicillin** were reduced by 40 to 60% in infants and children when they were given with milk.¹⁴ It is recommended that **phenoxymethylpenicillin** is taken one hour before food or on an empty stomach to optimise absorption.

Co-amoxiclav (amoxicillin 500 mg with clavulanic acid 250 mg) was given to 16 healthy subjects at the same time as the second of four 200-mL glasses of milk (taken at 20 minute intervals). Although the bioavailability of the **amoxicillin** and **clavulanic acid** tended to be decreased, and the time to peak levels delayed, the changes did not reach statistical significance.¹⁵ No special precautions would seem to be necessary.

Penicillins + H₂-receptor antagonists

Cimetidine does not adversely affect the bioavailability of ampicillin or co-amoxiclav, but the bioavailability of oral benzylpenicillin may be increased in some subjects. Ranitidine does not affect the pharmacokinetics of amoxicillin, but may possibly reduce the bioavailability of bacampicillin.

Clinical evidence, mechanism, importance and management

(a) Amoxicillin and Co-amoxiclav

Cimetidine 200 mg, given three times daily the day before and with a single 200-mg dose of co-amoxiclav (amoxicillin with clavulanic acid), had no significant effect on the bioavailability of amoxicillin or clavulanic acid.¹ Another study found that **ranitidine** (300 mg given the day before and 150 mg given with the antibacterial) had no effect on the pharmacokinetics of a single 1-g dose of amoxicillin.²

(b) Ampicillin

The pharmacokinetics of ampicillin were unchanged in a placebo controlled study in which 6 healthy subjects were given **cimetidine** 400 mg every 6 hours for 6 days, with a single 500-mg dose of ampicillin on day 6.³

(c) Bacampicillin

One small study suggested that when bacampicillin was given with **ranitidine** 300 mg and **sodium bicarbonate** 4 g, the AUC was reduced by 78% when the drugs were given with breakfast and by 55% when the drugs were given without food.⁴ However, these results have been criticised because the study only included 6 subjects and because of differences in methodology between compared groups.⁵ The findings remain unconfirmed, and their clinical significance is uncertain.

(d) Benzylpenicillin

A study using a 600-mg *oral* dose of benzylpenicillin found that **cimetidine** raised the benzylpenicillin serum levels by about 3-fold in one subject, but did not significantly affect benzylpenicillin levels in another 4 subjects.⁵ The clinical significance of these findings is unclear, especially as benzylpenicillin is more usually given parenterally.

Penicillins + Miscellaneous

Aspirin, indometacin, phenylbutazone, sulfaphenazole and sulfapyrazone prolong the half-life of benzylpenicillin whereas chlorothiazide, sulfamethizole and sulfamethoxypridazine do not. Some sulfonamides reduce oxacillin blood levels. Pirenzepine does not affect the pharmacokinetics of amoxicillin.

Clinical evidence, mechanism, importance and management

Studies in patients given different drugs for 5 to 7 days showed the following increases in the half-life of **benzylpenicillin**: **aspirin** 63%, **indometacin** 22%, **phenylbutazone** 139%, **sulfaphenazole** 44% and **sulfapyrazone** 65%. It seems likely that competition between these drugs and **benzylpenicillin** for excretion by the kidney tubules caused these increases. Changes in the half-life with **chlorothiazide**, **sulfamethizole** and **sulfamethoxypridazine** were not significant.¹

In healthy subjects, **sulfamethoxypyridazine** 3 g given 8 hours before a 1-g dose of oral **oxacillin** reduced the 6-hour urinary recovery by 55%. **Sulfaethidole** 3.9 g given 3 hours before the **oxacillin** reduced the 6-hour urinary recovery by 42%.²

Pirenzepine 50 mg given three times daily on the day before and with a single 1-g dose of **amoxicillin** had no significant effect on the pharmacokinetics of the antibacterial.³

None of the interactions listed appears to be adverse, and no particular precautions would seem necessary during concurrent use of these drugs and the penicillins. The importance of the interaction between **oxacillin** and the sulfonamides is uncertain, but it can easily be avoided by choosing alternative drugs.

Penicillins + Nifedipine

Nifedipine increases the absorption of amoxicillin from the gut but this is unlikely to be clinically important. Nafcillin increases the clearance of nifedipine, but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management

(a) Amoxicillin

In 8 healthy subjects when amoxicillin 1 g was given 30 minutes after a 20-mg nifedipine capsule, the peak serum amoxicillin levels were raised by 33%, the bioavailability was raised by 21% and the absorption rate was raised by 70%.¹ The authors speculate that the uptake of amoxicillin through the gut wall is increased by nifedipine in some way.¹ There would seem to be no good reason for avoiding concurrent use as overall the bioavailability was not significantly altered.

(b) Nafcillin

In a randomised, placebo-controlled study, 9 healthy subjects were given a single 10-mg nifedipine capsule after a 5-day course of nafcillin 500 mg four times daily. The nifedipine AUC was decreased by 63% and the clearance was increased by 145%, but the effect of these changes on nifedipine pharmacodynamics was not assessed. It was suggested that nafcillin is an inducer of cytochrome P450 isoenzymes, and increased the metabolism of nifedipine.² The clinical significance of these changes is unclear.

Penicillins + Probenecid

Probenecid reduces the excretion of the penicillins.

Clinical evidence

(a) Amoxicillin

In 10 healthy subjects a single 3-g dose of amoxicillin was given with or without probenecid 1 g. Two hours after administration, the serum levels of amoxicillin taken with probenecid were 55% higher than those with amoxicillin alone, and they remained higher for up to 18 hours.¹ Similar results were found in another study.² Amoxicillin 3 g twice daily plus placebo, amoxicillin 1 g twice daily plus probenecid 1 g twice daily, and amoxicillin 1 g twice daily plus probenecid 500 mg four times daily were given to 6 patients to treat bronchiectasis. The maximum serum concentration and half-life of both high- and low-dose amoxicillin were similar, but in the regimens containing probenecid the clearance of amoxicillin was reduced by two-thirds, when compared with amoxicillin given alone.³

(b) Benzylpenicillin

Four healthy subjects were given infusions of benzylpenicillin at three different rates, either alone or with probenecid given as a separate infusion,

at rates to provide low and high plasma levels. An infusion rate of probenecid 83 mg/hour, corresponding to a daily dose of 2 g was found to produce about 90% inhibition of the tubular excretion of benzylpenicillin (at plasma levels of 25 mg/L). Doses of probenecid above 2 g daily did not have a significantly greater effect.⁴

(c) Mezlocillin

A study in healthy subjects found that probenecid 1 g, given one hour before an intramuscular injection of mezlocillin, increased the peak serum levels and AUC of mezlocillin by 65% and decreased the total clearance, renal clearance and apparent volume of distribution by 38%, 52%, and 35%, respectively.⁵

(d) Nafcillin

A study in 5 healthy subjects given 500 mg of intravenous nafcillin sodium with probenecid, 1 g given orally the previous night and 1 g given 2 hours prior to the antibacterial, showed that the urinary recovery of nafcillin was reduced from 30% to 17%, and its AUC was approximately doubled.⁶

(e) Piperacillin/Tazobactam

In 10 healthy subjects probenecid 1 g given 1 hour before a single infusion of piperacillin 3 g/tazobactam 375 mg caused a decrease of about 25% in the clearance of both components. The half-life of tazobactam was increased by 72%.⁷ A study in 8 healthy subjects found that oral probenecid 1 g, given one hour before an intramuscular injection of piperacillin 1 g, increased both the peak plasma level and terminal half-life of piperacillin by 30% and the AUC by 60%. The apparent volume of distribution of piperacillin was reduced by 20% and renal clearance was reduced by 40%.⁸

(f) Pivampicillin

In a crossover study healthy subjects were given either pivampicillin 350 mg every 8 hours or a tablet of MK-356 (approximately, pivampicillin 350 mg with probenecid 200 mg). Peak ampicillin levels of 4 to 5 micrograms/mL were found about 1 hour after administration of the first and last dose of both treatments suggesting that probenecid did not affect the ampicillin elimination. Administration of MK-356 (pivampicillin 700 mg with probenecid 400 mg) twice daily indicated that peak serum levels of ampicillin were increased and elimination rate slowed following successive doses.⁹

(g) Procaine benzylpenicillin

A study in patients given intramuscular procaine benzylpenicillin 2.4 or 4.8 million units with or without probenecid 2 g found the peak serum levels were higher in patients given probenecid, but because of wide interpatient variation, possibly associated with differences in the release of penicillin from the injection sites, the exact potentiating effect of probenecid could not be determined.¹⁰ However, another study in men and women given procaine benzylpenicillin 2.4 million units and 4.8 million units, respectively (for uncomplicated gonorrhoea), found treatment failure after 1 week in 15.4% of men and 10.4% of women. Failure rates were reduced to 1.8% and 3.7%, respectively, when oral probenecid 1 g was given with the penicillin.¹¹

(h) Ticarcillin

Probenecid, either 500 mg twice daily, 1 g daily, or 2 g daily was added to ticarcillin 3 g every 4 hours, which was being given to treat infections in adult cystic fibrosis patients. In all cases the clearance of ticarcillin was reduced: by about 27% with the 500-mg dose regimen, by about 32% with the 1-g dose regimen and by about 43% with the 2-g dose regimen.¹²

Mechanism

In each case the penicillin competes with the probenecid for excretion by the kidney tubules, although with nafcillin, non-renal clearance may also play a part.

Importance and management

In the case of amoxicillin, benzylpenicillin, nafcillin and ticarcillin the effects are of clinical significance. In the case of the ticarcillin study the authors suggest that a 12-hourly dosing regimen could be used if probenecid is given concurrently, which has implications for home treatment. With piperacillin/tazobactam the changes were not thought to provide any benefit in terms of dose reduction or alteration of the dosage interval. Note that this is generally considered to be a beneficial interaction, but bear in

mind that, in some cases, such as in renal impairment, the increase in penicillin levels may be undesirably large.

Penicillins + Tetracyclines

Data from the 1950s suggested that the tetracyclines can reduce the effectiveness of penicillins in the treatment of pneumococcal meningitis and probably scarlet fever. It is uncertain whether a similar interaction occurs with other infections. This interaction may possibly be important only with those infections where a rapid kill is essential.

Clinical evidence

When chlortetracycline originally became available it was tested as a potential treatment for meningitis. In patients with pneumococcal meningitis it was shown that benzylpenicillin one million units, intramuscularly every 2 hours was more effective than the same regimen of penicillin with chlortetracycline 500 mg intravenously every 6 hours. Out of 43 patients given penicillin alone, 70% recovered, compared with only 20% in another group of 14 essentially similar patients who had received both antibacterials.¹

Another report about the treatment of pneumococcal meningitis with intramuscular or intravenous penicillin and intravenous tetracyclines (chlortetracycline, oxytetracycline, tetracycline) confirmed that the mortality was much lower in those given only penicillin, rather than the combination of penicillin and a tetracycline.² In the treatment of scarlet fever (Group A beta-haemolytic streptococci), no difference was seen in the initial response to treatment with penicillin (oral procaine benzylpenicillin) and chlortetracycline or the penicillin alone, but spontaneous re-infection occurred more frequently in those who had received both antibacterials.³

Mechanism

The generally accepted explanation is that bactericides such as the penicillins, which inhibit bacterial cell wall synthesis, require cells to be actively growing and dividing to be maximally effective, a situation that will not occur in the presence of bacteriostatic antibacterials, such as the tetracyclines.

Importance and management

Documentation is limited, but this is an apparently important interaction when treating pneumococcal meningitis and probably scarlet fever as well. However, the use of these antibacterials for such severe infections has largely been superseded. It has not been shown to occur when treating pneumococcal pneumonia.⁴ It has been suggested that antagonism, if it occurs, may only be significant when it is essential to kill bacteria rapidly,⁴

i.e. in serious infections such as meningitis. Any penicillin and any tetracycline would be expected to behave in this way.

Note that, the macrolides, which are also bacteriostatic would be expected to attenuate the action of penicillins, but this does not seem to occur in practice. See 'Macrolides + Penicillins', p.316.

Penicillins; Amoxicillin + Amiloride

Amiloride can cause a small but probably clinically unimportant reduction in the absorption of amoxicillin.

Clinical evidence, mechanism, importance and management

When 8 healthy subjects were given amiloride 10 mg followed 2 hours later by a single 1-g oral dose of amoxicillin, the bioavailability and maximum serum levels of amoxicillin were reduced by 27% and 25%, respectively, and the time to reach maximum levels was delayed from 1 hour to 1.56 hours. When amoxicillin was given intravenously its bioavailability was unchanged by amiloride.¹ It is thought that the absorption of beta lactams like amoxicillin depends on a dipeptide carrier system in the cells lining the intestine (brush border membrane). This system depends on the existence of a pH gradient between the outside and inside of the cells, which is maintained by a Na-H exchanger. As this exchanger is inhibited by amiloride the reduced absorption would seem to be explained.

This reported reduction in the absorption of the amoxicillin is only small and unlikely to have very much clinical relevance. There seems to be no information about other penicillins.

- Westphal JF, Jehl F, Brogard JM, Carbon C. Amoxicillin intestinal absorption reduction by amiloride: possible role of the Na(+)-H(+) exchanger. *Clin Pharmacol Ther* (1995) 57, 257–64.

Penicillins; Cloxacillin + Proguanil

Proguanil may reduce the bioavailability of cloxacillin.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in healthy subjects given cloxacillin 500 mg with or without proguanil 200 mg found the total amount of cloxacillin excreted in the urine in 12 hours was reduced by up to 48% by proguanil. The time to maximum excretion and the half-life were increased by 23% and 34%, respectively. The reasons why cloxacillin absorption is reduced by proguanil are not known, but it has been suggested that it may be due to adsorption of cloxacillin on to proguanil in the gut, formation of a drug-complex, increased gastric motility or increased beta-lactam ring hydrolysis leading to reduced cloxacillin bioavailability.¹ The clinical implications of the interaction are unknown.

- Babalola CP, Iwheye GB, Olaniyi AA. Effect of proguanil interaction on bioavailability of cloxacillin. *J Clin Pharm Ther* (2002) 27, 461–4.

Penicillins; Dicloxacillin + Rifampicin

Rifampicin increases the oral clearance of dicloxacillin and reduces its plasma levels.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects found that rifampicin 600 mg daily for 10 days decreased the maximum plasma level of a single 1-g dose of dicloxacillin by 27% and increased the mean oral clearance by 26%. The mean absorption time increased from 0.71 to 1.34 hours. Rifampicin increased the formation clearance, maximum level and AUC of the 5-hydroxymetabolite of dicloxacillin by 135%, 119%, and 59%, respectively. Dicloxacillin is a substrate of P-glycoprotein and it was suggested that the

effects of rifampicin on dicloxacillin were due to induction of both intestinal P-glycoprotein and dicloxacillin metabolism.¹

1. Putnam WS, Woo JM, Huang Y, Benet LZ. Effect of the *MDR1* C3435T variant and P-glycoprotein induction on dicloxacillin pharmacokinetics. *J Clin Pharmacol* (2005) 45, 411–21.

Penicillins; Piperacillin/tazobactam + Vancomycin

Vancomycin does not interact to a clinically relevant extent with piperacillin/tazobactam.

Clinical evidence, mechanism, importance and management

A randomised, crossover study in 9 healthy subjects found that infusions of vancomycin 500 mg and piperacillin 3 g with tazobactam 375 mg had little or no effect on the pharmacokinetics of any of the antibacterials, except that the piperacillin AUC was slightly raised, by about 7%. It was concluded that no dosage adjustments are needed if these drugs are given together.¹

1. Vechlekar D, Sia L, Lanc R, Kuye O, Yacobi A, Faulkner R. Pharmacokinetics of piperacillin/tazobactam (Pip/Taz) IV with and without vancomycin IV in healthy adult male volunteers. *Pharm Res* (1992) 9 (10 Suppl), S-322.

Penicillins; Pivampicillin or Pivmecillinam + Valproate

An isolated report describes hyperammonaemic encephalopathy in an elderly patient during treatment with valproate and pivmecillinam. The manufacturers of both pivmecillinam and pivampicillin advise the avoidance of concurrent valproate because of the increased risk of carnitine deficiency.

Clinical evidence, mechanism, importance and management

There is a report of hyperammonaemic encephalopathy which developed in a 72-year-old woman taking valproate monotherapy for partial epilepsy after she started treatment with pivmecillinam 600 mg daily. She recovered after discontinuation of valproate and use of cefuroxime instead of pivmecillinam.¹ Valproate may reduce serum carnitine,¹ for reasons that are not well understood.² Valproate-induced hyperammonaemic encephalopathy may be due to reduced carnitine levels.¹

Pivmecillinam and pivampicillin are hydrolysed to release mecillinam or ampicillin respectively, pivalic acid and formaldehyde. One of the potential problems of these drugs is that the pivalic acid can react with carnitine to form pivaloyl-carnitine, which is excreted in the urine, and so the body can become depleted of carnitine. Carnitine deficiency also manifests as muscle weakness and cardiomyopathy.

The risks of carnitine deficiency due to pivmecillinam or pivampicillin seem to be small in healthy adults, but the manufacturers of pivmecillinam and pivampicillin issue a warning about long-term or frequently repeated treatment.^{3,4}

The authors of the report advise caution if pivmecillinam is added to treatment with valproate.¹ Although this appears to be the only report of an adverse effect due to the combined effects of pivmecillinam and valproate on carnitine levels, the manufacturers advise the avoidance of both pivampicillin or pivmecillinam with valproic acid or valproate or other medication liberating pivalic acid.^{3,4}

Protonamide + Other antimycobacterials

Protonamide appears to be very hepatotoxic and this is possibly increased by the concurrent use of rifampicin or rifandin. Pro-

tionamide does not affect the pharmacokinetics of either dapsone or rifampicin.

Clinical evidence

In a study of 39 patients with leprosy, 39% became jaundiced after treatment for 24 to 120 days with **dapsone** 100 mg daily, protonamide 300 mg daily and **rifandin** [isopiperazinylrifamycin SV] 300 to 600 mg monthly. Laboratory evidence of liver damage occurred in a total of 56% of patients and despite the withdrawal of the drugs from all the patients, 2 of them died.¹ All the patients except two had taken **dapsone** before, alone, for 3 to 227 months without reported problems.¹ In another group of leprosy patients, 22% (11 of 50) had liver damage after treatment with **dapsone** 100 mg and protonamide 300 mg given daily, and **rifampicin** 900 mg, protonamide 500 mg and **clofazimine** 300 mg given monthly over a period of 30 to 50 days. One patient died.¹ Most of the patients recovered within 30 to 60 days after withdrawing the treatment.

Jaundice, liver damage and deaths have occurred in other leprosy patients given **rifampicin** and protonamide or **ethionamide**.^{2–4} Protonamide does not affect the pharmacokinetics of either **dapsone** or **rifampicin**.⁵

Mechanism

Although not certain, it seems probable that the liver damage was primarily caused by the protonamide, and possibly exacerbated by the rifampicin or the rifandin.

Importance and management

This serious and potentially life-threatening hepatotoxic reaction to protonamide is established, but the part played by the other drugs, particularly the rifampicin, is uncertain. Strictly speaking this may not be an interaction. If protonamide is given the liver function should be very closely monitored in order to detect toxicity as soon as possible.

Pyrazinamide + Antacids

In 14 healthy subjects 30 mL of Mylanta (aluminium/magnesium hydroxide) given 9 hours before, with, and after a single 30-mg/kg dose of pyrazinamide decreased the time to peak absorption by 17%, but had no effect on other pharmacokinetic parameters.¹ This change is not clinically important.

1. Peloquin CA, Bulpitt AE, Jaresko GS, Jelliffe RW, James GT, Nix DE. Pharmacokinetics of pyrazinamide under fasting conditions, with food, and with antacids. *Pharmacotherapy* (1998) 18, 1205–11.

Pyrazinamide + Antigout drugs

Pyrazinamide commonly causes hyperuricaemia and may therefore reduce the uricosuric effect of benzbromarone and probenecid. Allopurinol is unlikely to be effective against pyrazinamide-induced hyperuricaemia, and may exacerbate the situation, whereas benzbromarone may have modest efficacy in reducing hyperuricaemia caused by pyrazinamide.

Clinical evidence, mechanism, importance and management

The manufacturers of pyrazinamide warn that hyperuricaemia is a contraindication for its use, and that if hyperuricaemia accompanied by acute gouty arthritis occurs during treatment, the pyrazinamide should be

stopped and not restarted. They also say that pyrazinamide should not be given unless regular uric acid determinations can be made.¹

(a) *Allopurinol*

It is thought that pyrazinamide is hydrolysed in the body to pyrazinoic acid, which appears to be responsible for the hyperuricaemic effect of pyrazinamide. Pyrazinoic acid is oxidised by the enzyme xanthine oxidase to 5-hydroxypyrazoic acid.² Since allopurinol is an inhibitor of xanthine oxidase, its presence increases pyrazinoic acid concentrations³ thereby probably worsening the pyrazinamide-induced hyperuricaemia.⁴ Allopurinol would therefore appear to be unsuitable for treating pyrazinamide-induced hyperuricaemia.

(b) *Benzbromarone*

A single dose of pyrazinamide completely abolished the uricosuric effect of a single 160-mg dose of benzbromarone in 5 subjects with hyperuricaemia and gout.⁵ Other authors also briefly mention the same finding.⁶ However in another study, when benzbromarone 50 mg daily for 8 to 10 days was given to 10 patients taking pyrazinamide 35 mg/kg daily for tuberculosis, uric acid levels were reduced by an average of 24.3%, and returned to normal in four of them.⁷ It is unclear from these studies whether or not pyrazinamide abolishes the uricosuric effects of benzbromarone. However, pyrazinamide commonly causes hyperuricaemia, and would be expected to antagonise the effects of uricosuric drugs such as benzbromarone. Benzbromarone may have modest efficacy in reducing hyperuricaemia caused by pyrazinamide, but further study is necessary. However, see above, for advice relating to hyperuricaemia caused by pyrazinamide.

(c) *Probenecid*

The interactions of probenecid and pyrazinamide and their effects on the excretion of uric acid are complex and intertwined. Probenecid increases the secretion of uric acid into the urine, apparently by inhibiting its reabsorption from the kidney tubules.⁸ Pyrazinamide on the other hand decreases the secretion of uric acid into the urine by one-third to one-half,⁹ resulting in a rise in the serum levels of urate in the blood, thereby causing hyperuricaemia.^{9,10} The result of using probenecid and pyrazinamide together is not however merely the simple sum of these two effects. This is because pyrazinamide additionally decreases the metabolism of the probenecid and prolongs its uricosuric effects, and the effect of pyrazinamide is reduced. Also, probenecid inhibits the secretion of pyrazinamide, increasing its effects.¹¹

The likely overall effect is that if probenecid were to be used to treat the hyperuricaemia caused by pyrazinamide, the normal uricosuric effects of probenecid would be diminished, and larger doses would be required. However, see above, for advice relating to hyperuricaemia caused by pyrazinamide.

Pyrazinamide + Food

A single 30-mg/kg dose of pyrazinamide taken with a high-fat breakfast approximately doubled the time to peak absorption in 14 subjects but had no effect on other pharmacokinetic parameters.¹

It would therefore seem that pyrazinamide may be taken without regard to meals.

Quinolones + Antacids or Calcium compounds

The serum levels of many of the quinolone antibacterials can be reduced by aluminium and magnesium antacids. Calcium compounds interact to a lesser extent, and bismuth compounds only minimally. Separating administration by 2 to 6 hours where significant interactions occur reduces admixture in the gut and can minimise the effects.

Clinical evidence

There is a wealth of information about the interaction between quinolones and antacids and for simplicity this is summarised in 'Table 10.3', (p.329). This table shows what happens to the maximum serum levels (C_{max}) and the relative bioavailabilities (%) when the quinolones listed have been given at the same time as antacids, and when separated by time intervals (e.g. –2 h; two hours before the antacid).

Mechanism

It is believed that certain of the quinolone functional groups (3-carboxyl and 4-oxo) form insoluble chelates with aluminium and magnesium ions within the gut, which reduces their absorption.^{1–3} The stability of the chelate formed seems to be an important factor in determining the degree of interaction.³ It has been suggested from *animal* studies that adsorption of quinolones by aluminium hydroxide re-precipitated in the small intestine may be a factor in the reduced bioavailability of quinolones.⁴ See also 'Quinolones + Iron or Zinc compounds', p.336.

Importance and management

The interaction between quinolones and antacids are generally well documented, well established and, depending on the particular quinolone and antacid concerned, of clinical importance. The risk is that the serum levels of the antibacterial may fall below minimally inhibitory concentrations (i.e. become subtherapeutic, particularly against organisms such as staphylococci and *Ps. aeruginosa*⁵), resulting in treatment failures.⁶ The overall picture is that the aluminium/magnesium antacids interact to a greater extent than the calcium compounds, and bismuth compounds hardly at all.

(a) Aluminium/magnesium antacids

'Table 10.3', (p.329) shows that the aluminium/magnesium antacids can greatly reduce the bioavailabilities of the quinolones. Separating their administration to reduce the admixture of the two drugs in the gut minimises the interaction, a very broad rule-of-thumb being that the quinolones should be taken at least 2 hours before and not less than 4 to 6 hours after the antacid.^{1,7–12} The only obvious exception is **fleroxacin**, which appears to interact minimally.

(b) Bismuth compounds

As can be seen from 'Table 10.3', (p.329), bismuth compounds have little or no effect on the bioavailability of **ciprofloxacin**. Information about other quinolones appears to be lacking. However, using **ciprofloxacin** as a guide it would seem that any interaction is likely only to be of minimal clinical importance, and no action appears to be necessary.

(c) Calcium compounds

Information about the interactions with calcium carbonate is more limited than with the aluminium/magnesium antacids, but 'Table 10.3', (p.329) shows that the bioavailabilities of **ciprofloxacin** and **norfloxacin**, and to a lesser extent **gemifloxacin**, can be reduced. These reductions are less than those seen with the aluminium/magnesium antacids, but using **ciprofloxacin** as a guide a very broad rule-of-thumb would be to separate the drug administration by about 2 hours to minimise this interaction.^{13,14} This is clearly not necessary with **levofloxacin**,¹⁵ **lomefloxacin**,¹⁶ **moxifloxacin**¹⁷ or **ofloxacin**,¹⁸ nor probably with some of the other qui-

nolones that have yet to be studied, but in the absence of direct information a 2-hour separation errs on the side of caution.

(d) *Sodium antacids*

Sodium bicarbonate does not interact significantly with **norfloxacin**¹⁹ but information about other quinolones appears to be lacking. However, bear in mind that in the case of **ciprofloxacin** an excessive rise in urinary pH (which can be caused by antacids like sodium bicarbonate) may possibly result in urinary crystalluria and kidney damage.²⁰

Possible alternatives to the antacids, which do not appear to interact with the quinolones, include the 'H₂-receptor antagonists', (p.335) and 'omeprazole', (p.338).

Quinolones + Antineoplastics

The absorption of ciprofloxacin and ofloxacin can be reduced by some cytotoxic antineoplastics but this seems unlikely to be clinically significant.

Clinical evidence

(a) *Ciprofloxacin*

Six patients with newly diagnosed haematological malignancies (5 with acute myeloid leukaemia and one with non-Hodgkin's lymphoma) were given ciprofloxacin 500 mg twice daily to control possible neutropenic infections. It was found that, after 13 days of chemotherapy, their mean maximum serum ciprofloxacin levels had fallen by 46%, from 3.7 to 2 mg/L and the AUC_{0–4} was reduced by 47%. There were large individual differences between the patients. The antineoplastics used were **cyclophosphamide, cytarabine, daunorubicin, doxorubicin, mitoxantrone** and **vincristine**.¹ Methotrexate toxicity has occurred in 2 patients during treatment with ciprofloxacin, see 'Methotrexate + Antibacterials; Ciprofloxacin', p.643.

(b) *Ofloxacin*

Ten patients with non-Hodgkin's lymphoma, hairy cell leukaemia or acute myeloid leukaemia were given ofloxacin 400 mg at breakfast time for antibacterial prophylaxis during neutropenia. Blood samples were taken

3 days before chemotherapy began and then at 2 to 3, 5 to 7, and 8 to 10 days. The maximum serum ofloxacin levels were reduced by 18% two to three days after the chemotherapy but none of the other pharmacokinetic measurements were changed by the antineoplastic treatment. The serum levels had returned to normal by days 5 to 7. At all times serum levels exceeded the expected MICs of the gram-negative potential pathogens. The antineoplastics used were **cyclophosphamide, cytarabine, doxorubicin, etoposide, ifosfamide** (with mesna), **vincristine**.²

Mechanism

Uncertain. The interaction seems to result from a reduction in the absorption of the quinolones by the small intestine, possibly related to the damaging effect cytotoxic antineoplastics have on the rapidly dividing cells of the intestinal mucosa.

Importance and management

Direct information is limited, but these reports are consistent with the way cytotoxic antineoplastics can reduce the absorption of some other drugs. The authors of both reports suggest that these changes are probably clinically unimportant, because the serum levels of achieved are likely to be sufficient to treat most infections. If the suggested mechanism of interaction is correct, no interaction should occur if quinolones are given parenterally. Nothing appears to be documented about any of the other quinolones.

Quinolones + Chinese herbal medicines

Sho-saiko-to, Rikkunshi-to and Sairei-to do not interact with ofloxacin, and Hotyu-ekki-to, Rikkunshi-to and Juzen-taiho-to do not interact with levofloxacin.

Clinical evidence, mechanism, importance and management

The bioavailability and urinary recovery of a single 200-mg oral dose of **ofloxacin** were not significantly altered in 7 healthy subjects by three Chinese herbal medicines (**Sho-saiko-to, Rikkunshi-to** or **Sairei-to**).¹ The bioavailability and renal excretion of a single 200-mg oral dose of **levofloxacin** was not affected in 8 healthy subjects given single 2.5-g doses of **Hotyu-ekki-to, Rikkunshi-to** or **Juzen-taiho-to**.² There would therefore seem to be no reason for avoiding concurrent use. Information about other quinolones is lacking. The ingredients of these herbal medicines are detailed in 'Table 10.4', (p.333).

Quinolones + Dairy products

Dairy products reduce the bioavailability of ciprofloxacin and norfloxacin, and to a minor extent, gatifloxacin, but not enoxacin, lomefloxacin, moxifloxacin, ofloxacin and probably not fleroxacin.

Clinical evidence

(a) *Ciprofloxacin*

A study in 7 healthy subjects given a single 500-mg dose of ciprofloxacin found that 300 mL of **milk** or **yoghurt** reduced the peak plasma levels by 36% and 47%, respectively, and the AUC by 33% and 36%, respectively.¹ In another study 300 mL of **milk** reduced the AUC of ciprofloxacin 500 mg by about 30%.²

Table 10.4 Herbs contained in some Chinese herbal remedies^{1,2}

Herb (plant part)	Amounts of herbs in the medicines (mg/2.5 g)				
	Hotyu-ekki-to	Rikkunshi-to	Juzen-taiho-to	Sho-saiko-to	Sairei-to

(b) Enoxacin

A study found that **milk** and a standard breakfast had no effect on enoxacin absorption.³

(c) Fleroxacin

In a study, a **fat and liquid calcium meal** had no clinically significant effect on the pharmacokinetics of fleroxacin.⁴ In another study, **milk** had no effect on fleroxacin pharmacokinetics.²

(d) Gatifloxacin

In one study 200 mL of **milk** reduced the AUC of gatifloxacin 200 mg by about 15%.⁵

(e) Lomefloxacin

Milk had no effect on the pharmacokinetics of lomefloxacin.⁶

(f) Moxifloxacin

A study found that the rate of absorption of a single 400-mg dose of moxifloxacin was slightly delayed by 250 g of **yoghurt**. The maximum plasma level of moxifloxacin was reduced by about 15%, but the bioavailability was unaffected.⁷

(g) Norfloxacin

A study found that 300 mL of **milk** or **yoghurt** reduced the absorption and the peak plasma levels of a single 200-mg dose of norfloxacin by roughly 50%.⁸

(h) Ofloxacin

A study in 21 healthy subjects found that 8 oz (about 250 mL) of **milk** had no clinically significant effects on the absorption of 300 mg of ofloxacin.⁹ Another study confirmed the lack of a significant interaction between ofloxacin and both **milk** and **yoghurt**.¹⁰

Mechanism

The proposed reason for these changes is that the calcium in milk and yoghurt or other dairy products combines with the ciprofloxacin and norfloxacin to produce insoluble chelates. Compare also 'Quinolones + Antacids or Calcium compounds', p.328.

Importance and management

The effect of these changes to ciprofloxacin and norfloxacin pharmacokinetics on the control of infection is uncertain but until the situation is clear patients should be advised not to take these dairy products within 1 to 2 hours of either ciprofloxacin or norfloxacin to prevent admixture in the gut. The slight reduction in gatifloxacin levels is probably not clinically relevant.

The quinolones that do not interact significantly would appear to be enoxacin, lomefloxacin, moxifloxacin, ofloxacin and probably fleroxacin. They may provide a useful alternative to the interacting quinolones.

Quinolones + Didanosine

An extremely marked reduction in the serum levels of ciprofloxacin occurs if it is given at the same time as didanosine tablets, because of an interaction with the antacid buffers in the didanosine formulation. Taking the ciprofloxacin 2 hours before or 6 hours after didanosine tablets minimises this interaction. Other quinolones are expected to interact similarly. Didanosine enteric-coated capsules do not interact with ciprofloxacin.

Clinical evidence

When 12 healthy subjects were given **ciprofloxacin** 750 mg with two didanosine placebo tablets (i.e. all of the antacid additives but no didanosine), the **ciprofloxacin** AUC and maximum serum levels were reduced by 98% and 93%, respectively.¹ The antacids in this formulation were dihydroxyaluminium sodium carbonate and magnesium hydroxide.

Other studies have looked at whether separating the administration times affects this interaction. When 16 HIV-positive patients were given **ciprofloxacin** 1.5 g daily 2 hours before didanosine tablets, the **ciprofloxacin** AUC was reduced by only 26%.² Another study in just one subject found that when **ciprofloxacin** 500 mg was given 2 hours after taking two didanosine placebo tablets the **ciprofloxacin** serum levels were reduced below minimal inhibitory concentrations, but giving the **ciprofloxacin** 2 hours before the didanosine placebo tablets resulted in normal blood levels.³

The enteric-coated capsule formulation of didanosine (which does not contain antacids) does not interact with **ciprofloxacin**.⁴

Mechanism

Didanosine is extremely acid labile at pH values below 3, so one of the formulations contains buffering agents (dihydroxyaluminium sodium carbonate and magnesium hydroxide) to keep the pH as high as possible to minimise the acid-induced hydrolysis. Ciprofloxacin forms insoluble non-absorbable chelates with these metallic ions in the buffer so that its bioavailability is markedly reduced. See also 'Quinolones + Antacids or Calcium compounds', p.328.

Importance and management

Direct information is limited to these reports but the interaction between buffered didanosine and ciprofloxacin appears to be clinically important. Such drastic reductions in serum ciprofloxacin levels mean that minimal inhibitory concentrations are unlikely to be achieved. Ciprofloxacin should be given at least 2 hours before or 6 hours after didanosine tablets (see 'Quinolones + Antacids or Calcium compounds', p.328). Other quinolone antibacterials that interact with antacids are also expected to interact with didanosine tablets, but so far reports are lacking. Didanosine enteric-coated capsules do not interact.

Quinolones + Enteral feeds or Food

The absorption of ciprofloxacin can be reduced by enteral feeds such as *Ensure*, *Jevity*, *Osmolite*, *Pulmocare* and *Sustacal*. An *in vitro* study found a significant reduction in the concentration of ciprofloxacin, levofloxacin and ofloxacin with *Ensure* but other studies suggest the interaction with moxifloxacin or ofloxacin is much smaller than that with ciprofloxacin and probably of little clinical importance.

Apart from 'dairy products' (p.332), most foods delay but do not reduce the absorption of ciprofloxacin, enoxacin, gemifloxacin, lomefloxacin, ofloxacin or sparfloxacin. A high-fat/high-calcium breakfast did not reduce ciprofloxacin levels. Calcium-fortified orange juice significantly reduces the absorption of ciprofloxacin, but not gatifloxacin or levofloxacin.

Clinical evidence

A. Enteral feeds

(a) Ciprofloxacin

The oral bioavailability of ciprofloxacin 750 mg was reduced by 28% and the mean maximum serum ciprofloxacin levels were reduced by 48% when it was given to 13 fasted subjects with *Ensure*. In this study the subjects were given 120 mL of the study liquid (*Ensure* or water) and this was repeated at 30-minute intervals for 5 doses. The ciprofloxacin was crushed and mixed with the second dose of the study liquid and the cup rinsed with another 60 mL of the study liquid.¹

Other enteral feeds given orally (*Osmolite*, *Pulmocare*, and *Resource*) similarly reduced the bioavailability and maximum serum levels of ciprofloxacin by about one-quarter to one-third in two other studies.^{2,3} One comparative study found that *Ensure* reduced the AUC of ciprofloxacin by 40.2% in men but by only 14.5% in women.⁴

Ciprofloxacin bioavailability was reduced by 53% and 67% by *Jevity* or *Sustacal*, respectively, when given via gastrostomy or jejunostomy tubes in a study of 26 hospitalised patients. Despite this, the serum levels achieved with gastrostomy tubes were roughly equivalent to those seen in subjects taking tablets orally.⁵ In another study in patients given *Jevity* or *Osmolite*, the 4 patients with a nasoduodenal tube achieved a ciprofloxacin AUC that was about double that seen in the 3 patients with a nasogastric tube or a gastrostomy.⁶ In contrast, in another study in healthy subjects, there was no difference in the bioavailability of ciprofloxacin when it was given alone or when it was given with *Osmolite* via a nasogastric tube.⁷

The bioavailability of ciprofloxacin 750 mg every 12 hours in 5 patients with severe gram-negative intra-abdominal infections was reduced by 47% when it was added to enteral feeding with *Nutrison* or *Nutrison E+* and given via nasogastric or nasoduodenal tubes. The serum levels were similar to those found in another 7 patients given ciprofloxacin with these enteral feeds and also to those found when the 5 original patients were given intravenous ciprofloxacin 400 mg every 12 hours.⁸ In another study in 12 intensive care patients the AUC of ciprofloxacin 400 mg given by intravenous infusion was similar to that found after a dose of 750 mg given via nasogastric tube during enteral feeding with *Normo-Réal fibres*.⁹

An *in vitro* study found an 83% decrease in the concentration of ciprofloxacin when a 500-mg ciprofloxacin tablet was crushed and mixed with *Ensure*. Mixing with solutions of calcium chloride and/or magnesium chloride did not significantly reduce ciprofloxacin concentrations.¹⁰

(b) Levofloxacin

An *in vitro* study found a 61% decrease in the concentration of levofloxacin when a 500-mg levofloxacin tablet was crushed and mixed with *Ensure*. Mixing with solutions of calcium chloride and/or magnesium chloride did not significantly reduce levofloxacin concentrations.¹⁰

(c) Moxifloxacin

Compared to oral administration of an uncrushed tablet with water, the oral bioavailability of a single 400-mg dose of moxifloxacin was slightly decreased (by 9%) when given to 12 healthy subjects as a suspension of a crushed tablet via a nasogastric tube with either water or *Isosource Energy*. Maximum plasma levels were decreased by 5% and 12% after nasogastric administration with water and *Isosource Energy*, respectively.¹¹

(d) Ofloxacin

The oral bioavailability of ofloxacin 400 mg was reduced by 10% when given to 13 healthy subjects with *Ensure*. The mean maximum serum ofloxacin levels were reduced by 36%. The same procedure as described in (a) was followed.¹ Only small reductions in the AUCs of ofloxacin were seen in another study (10.5% in men, 13.2% in women) with *Ensure*.⁴

However, an *in vitro* study found a 46% decrease in the concentration of ofloxacin when a 300-mg tablet of ofloxacin was crushed and mixed with *Ensure*. Mixing with solutions of calcium chloride and/or magnesium chloride did not significantly reduce ofloxacin concentrations.¹⁰

B. Food

Food delayed the absorption of **ciprofloxacin** and **ofloxacin** in 10 subjects, but their bioavailabilities remained unchanged.¹² A study in 12 healthy subjects found that standard or high-fat breakfasts did not affect the absorption of **ciprofloxacin**.¹³ Another study in healthy subjects found that a standard breakfast reduced the bioavailability of a single 300-mg dose of **ofloxacin** by about 18%, but this was not considered clinically significant.¹⁴ Other studies suggest that food delays the absorption of **ofloxacin**¹⁵ and **lomefloxacin**¹⁶ but the bioavailability is unchanged. Food also has no effect on the absorption of **enoxacin**, but high carbohydrate meals delayed the peak serum levels by almost an hour.¹⁷ The pharmacokinetics of **gemifloxacin** 320 mg or 640 mg¹⁸ or **sparfloxacin** 200 mg¹⁹ were not significantly affected when they were given to healthy subjects with high fat or standard meals, although the absorption of **sparfloxacin** was slightly delayed.

C. Calcium-fortified foods

Calcium-fortified orange juice decreased the AUC of **ciprofloxacin** by 38% and the maximum plasma level by 41%, when compared to water.²⁰ However, in another study, a high-fat/high-calcium breakfast did not affect the absorption of **ciprofloxacin**.¹³

The AUC of **gatifloxacin** was reduced by only 12% by calcium-fortified orange juice.²¹ Similarly, in two studies, orange juice, calcium-fortified orange juice,²² or a breakfast of calcium-fortified orange juice and cereal with or without milk²³ were found to decrease the bioavailability of **levofloxacin**. However, the **levofloxacin** AUC was decreased by less than 16%, an amount that rarely proves to be clinically significant.

Mechanism

Not fully understood. The quinolone antibacterials can form insoluble chelates with divalent ions, which reduces their absorption from the gut. Enteral feeds such as those used above contain at least two divalent ions, calcium and magnesium. However, an *in vitro* study found no evidence of chelate formation with fluoroquinolones and calcium or magnesium, and therefore suggested that either other divalent cations may be involved, or that the quinolones may be adsorbed onto other metal ions, proteins or fat in the enteral feed.¹⁰

It has also been suggested that alteration in pH as well as the presence of cations are required to form chelates with ciprofloxacin and while this helps explain the lack of effect of high calcium in a high fat breakfast,¹³ it does not explain the significant effect with enteral feeds or calcium-fortified orange juice. The differences seen in men and women are possibly due to a slower gastric emptying rate in men, which increases the exposure of the quinolone to the enteral feed.⁴

Importance and management

The interaction between ciprofloxacin and enteral feeds is established. No treatment failures have been reported but it may be clinically important. For example, if patients receiving enteral feeds were to be switched from parenteral to oral ciprofloxacin, there could be a significant reduction in serum ciprofloxacin levels. The authors of one study recommend that in patients with severe infections, such a switch from parenteral to nasogastric administration of ciprofloxacin should be restricted to those whose plasma ciprofloxacin levels can be routinely monitored. However, some have found the reduced levels with enteral feeding still provide adequate antibacterial levels,^{8,24} but be alert for any evidence that ciprofloxacin is less effective and raise the dosage as necessary. Use of enteral feeds with lower concentrations of divalent ions or even stopping tube feeding for a short period of time have been suggested as methods to try to improve ciprofloxacin absorption.²⁴ The authors of one study suggest that *Ensure* should be given at least 2 hours before or after fluoroquinolones.¹⁰

The interaction between ofloxacin or moxifloxacin and enteral feeds is much smaller and probably not clinically important but this needs confirmation. There are no specific reports about other quinolones but be alert for this interaction with any of them.

Apart from 'dairy products' (p.332), quinolones can be given with food without any decrease in levels. However, calcium-fortified foods may cause significant interactions with ciprofloxacin.

Quinolones + H₂-receptor antagonists

Cimetidine can increase the serum levels of some quinolones (intravenous enoxacin or fleroxacin and oral clinafloxacin or pefloxacin). Famotidine can reduce the serum levels of norfloxacin, and ranitidine can reduce the absorption of enoxacin. None of these interactions appear to be clinically important.

Clinical evidence and mechanism

(a) Ciprofloxacin

Neither **cimetidine**^{1,2} nor **ranitidine**^{3,4} appear to have a clinically important effect on the pharmacokinetics of ciprofloxacin.

(b) Clinafloxacin

Cimetidine 300 mg four times daily for 4 days increased the maximum serum levels of clinafloxacin by 15% and increased its AUC by 44%.⁵

(c) Enoxacin

The plasma levels of a 400-mg intravenous dose of enoxacin were higher when **cimetidine** 300 mg four times daily was given concurrently. Renal clearance and systemic clearance were reduced by 26% and 20%, respectively, and the elimination half-life was increased by 30%.⁶

In one study **ranitidine** 150 mg twice daily did not affect the pharmacokinetics of a single 400-mg intravenous dose of enoxacin.⁶ However, in another, **ranitidine** 50 mg given intravenously 2 hours before a single 400-mg oral dose of enoxacin reduced the absorption by 26 to 40%,^{7,8} which seemed to be related to changes in gastric pH caused by the **ranitidine**.⁸

(d) *Fleroxacin*

Cimetidine decreased the total clearance of fleroxacin by about 25%, without much effect on renal clearance, and increased its elimination half-life by 32%.⁹

(e) *Gatifloxacin*

Cimetidine does not alter the pharmacokinetics of gatifloxacin.¹⁰

(f) *Grepafloxacin*

Cimetidine does not alter the pharmacokinetics of grepafloxacin.¹¹ Similarly, intravenous **famotidine** in a dose of up to 40 mg had no effect on the pharmacokinetics of a 400-mg dose of grepafloxacin.¹²

(g) *Levofloxacin*

Cimetidine reduced the clearance of levofloxacin by about 25% and increased its AUC by almost 30%,¹³ whereas **ranitidine** did not affect the pharmacokinetics of levofloxacin.¹⁴

(h) *Lomefloxacin*

Ranitidine does not affect the pharmacokinetics of lomefloxacin.^{15,16}

(i) *Moxifloxacin*

Ranitidine does not affect the pharmacokinetics of moxifloxacin.¹⁷

(j) *Norfloxacin*

Famotidine given 8 hours before norfloxacin significantly reduced its maximum serum concentrations in 6 healthy subjects, but the AUC and urinary recovery rate were unchanged.¹⁸

(k) *Ofloxacin*

Cimetidine does not alter the pharmacokinetics of ofloxacin.¹⁹

(l) *Pefloxacin*

Cimetidine increased the AUC of intravenous pefloxacin by about 40%. It increased the half-life from 10.3 to 15.3 hours and the clearance was reduced by almost by 30%.²⁰

(m) *Sparfloxacin*

Cimetidine does not alter the pharmacokinetics of sparfloxacin.²¹

(n) *Trovafloxacin*

Cimetidine does not alter the pharmacokinetics of trovafloxacin.²²

Importance and management

Although the pharmacokinetic changes seen in some of these studies are moderate, none has been shown to affect the outcome of treatment and they are probably only of minor clinical relevance.

Quinolones + Iron or Zinc compounds

Ferrous fumarate, gluconate, sulfate and other iron compounds can reduce the absorption of ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, norfloxacin, ofloxacin and sparfloxacin from the gut. Serum levels of the antibacterial may become subtherapeutic as a result. Limited evidence suggests that fleroxacin is not affected and lomefloxacin is only minimally affected. Gemifloxacin does not appear to interact when given 2 hours before or 3 hours after ferrous sulfate. No interaction appears to occur with iron-ovotransferrin. Zinc appears to interact like iron.

Clinical evidence(a) *Ciprofloxacin*

The absorption of ciprofloxacin is markedly reduced by iron and zinc compounds. Several studies have clearly demonstrated reductions in the AUC and maximum serum levels of 30 to 90% with **ferrous fumarate**,¹ **ferrous gluconate**,² **ferrous sulfate**,^{2,5} **iron-glycine sulfate**,⁶ **Centrum Forte**² (a multi-mineral preparation containing iron, magnesium, zinc, calcium, copper and manganese) and with **Stresstabs 600-with-zinc**⁴ (a multivitamin-with-zinc preparation). However **iron-ovotransferrin** has been found to have no significant effect on the absorption of ciprofloxacin.⁷

(b) *Fleroxacin*

A study in 12 subjects found that **ferrous sulfate** (equivalent to 100 mg of elemental iron) had no significant effect on the pharmacokinetics of fleroxacin.⁸

(c) *Gatifloxacin*

A study in 6 healthy subjects found that **ferrous sulfate** 160 mg given with gatifloxacin 200 mg decreased the maximum serum levels and AUC of gatifloxacin by 49% and 29%, respectively.⁹

(d) *Gemifloxacin*

Gemifloxacin 320 mg was given either 3 hours before or 2 hours after **ferrous sulfate** 325 mg in a study in 27 healthy subjects. The pharmacokinetics of gemifloxacin were not significantly altered in either case.¹⁰

(e) *Levofloxacin*

Ferrous sulfate has been found to reduce the bioavailability of levofloxacin by 79%.¹¹

(f) *Lomefloxacin*

When lomefloxacin 400 mg was given with **ferrous sulfate** (equivalent to 100 mg of elemental iron), the lomefloxacin maximum serum levels were reduced by about 28% and the AUC by about 14%.¹²

(g) *Moxifloxacin*

In 12 healthy subjects **ferrous sulfate** (equivalent to 100 mg of elemental iron) reduced the AUC and maximum plasma levels of a single 400-mg dose of moxifloxacin by 39% and 59%, respectively. The rate of absorption was reduced (time to maximum plasma level increased from a mean of 1 hour to 2.79 hours).¹³

(h) *Norfloxacin*

In 8 healthy subjects **ferrous sulfate** reduced the AUC and maximum serum levels of a single 400-mg dose of norfloxacin by 73% and 75%, respectively.⁵ **Ferrous sulfate** caused a 51% reduction in the norfloxacin AUC in another study,^{14,15} and a 97% reduction in bioavailability in a further single dose study.¹⁶ The same authors also found that both **ferrous**

sulfate and zinc sulfate reduced the urinary recovery of norfloxacin by 55% and 56%, respectively.¹⁷

(i) *Ofloxacin*

In 8 healthy subjects **ferrous sulfate** (equivalent to 100 mg of elemental iron) reduced the AUC and maximum serum levels of a single 400-mg dose of ofloxacin by 25% and 36%, respectively.⁵ In 9 healthy subjects **ferrous sulfate** 1050 mg decreased the absorption of ofloxacin 200 mg by 11%.¹⁸ In 12 healthy subjects elemental iron 200 mg (in the form of an **iron-glycine-sulfate** complex) reduced the bioavailability of ofloxacin 400 mg by 36%.⁶

(j) *Sparfloxacin*

In a single dose study in 6 subjects, 525 mg of **ferrous sulfate** (equivalent to 170 mg of elemental iron) reduced the AUC of sparfloxacin 200 mg by 27%.^{14,15}

Mechanism

It is believed that the quinolones form a complex with iron and zinc (by chelation between the metal ion and the 4-oxo and adjacent carboxyl groups), which is less easily absorbed by the gut. However, a study in *rats* using oral iron and intravenous ciprofloxacin suggested that the interaction may not be entirely confined to the gut.¹⁹ This needs further study. Iron-ovotransferrin differs from other iron preparations in being able to combine directly with the transferrin receptors of intestinal cells, and appears to release little iron into the gut to interact with the quinolones.

Importance and management

The interactions between the quinolones and iron compounds are established and would appear to be of clinical importance because the serum antibacterial levels can become subtherapeutic. In descending order the extent of the interaction appears to be: norfloxacin, levofloxacin, ciprofloxacin, moxifloxacin, gatifloxacin, ofloxacin/sparfloxacin, then least affected, lomefloxacin.

None of these quinolones should be taken at the same time as any iron preparation that contains substantial amounts of iron (e.g. ferrous sulfate, ferrous gluconate, ferrous fumarate, iron-glycine sulfate). Since the quinolones are rapidly absorbed, taking them 2 hours before the iron should minimise the risk of admixture in the gut and largely avoid this interaction. Information about other quinolones seems to be lacking but the same precautions should be taken with all of them except fleroxacin, which appears not to interact, and lomefloxacin, which seems to interact only minimally.

Iron-ovotransferrin does not interact with ciprofloxacin and is not expected to interact with any of the quinolones (see 'Mechanism') but this awaits confirmation.

There seems to be very little data about the interactions between zinc compounds and quinolones, but zinc appears to interact like iron and therefore the same precautions suggested for iron should be followed.

Quinolones + NSAIDs

A number of cases of convulsions have been seen in Japanese patients given fenbufen with enoxacin, and there is also one possible case involving ofloxacin. Use of these particular drugs together should be avoided. Normally no interaction seems to occur with most quinolones and NSAIDs, except where there is a predisposition to convulsive episodes. Isolated cases of convulsions, other neurological toxicity or skin eruptions have been seen when ciprofloxacin was given with indometacin, mefenamic acid or naproxen. These appear to be very rare events.

Clinical evidence

(a) *Ciprofloxacin*

As of 1995 the manufacturer of ciprofloxacin had, on record, two confirmed spontaneous reports of convulsions in patients taking ciprofloxacin and an NSAID; one with **mefenamic acid** and the other with **naproxen**.¹ These appear to be the only medically validated reports of ciprofloxacin/NSAID reactions by 1995.¹

A woman taking **chloroquine** 250 mg and **naproxen** 1 g daily developed dizziness, anxiety and tremors within a week of starting ciprofloxacin 1 g daily. The symptoms largely resolved when the **chloroquine** was stopped; it was not known if she also stopped the naproxen. Two months after **chloroquine** was discontinued, and while she was still taking ciprofloxacin, **indometacin** was started. This time she developed pain in her feet and became extremely tired. The pain partially subsided and the fatigue vanished when the ciprofloxacin was stopped. Later she was found to have some axonal demyelination, compatible with drug-induced polyneuropathy.²

A study in 8 healthy subjects found that the pharmacokinetics of ciprofloxacin were unaffected by treatment with **fenbufen** for 3 days.³ Another study found that combined single doses of ciprofloxacin and **fenbufen** in 12 healthy subjects produced no evidence, using EEG recordings, of increased CNS excitatory effects.⁴

(b) *Enoxacin*

A total of 17 Japanese patients have been identified, with apparently no previous history of seizures, who in the 1986 to 1987 period developed convulsions when given **fenbufen** 400 mg to 1.2 g daily with enoxacin 200 to 800 mg.⁵ Two case reports of this interaction have been published.^{6,7} An 87-year-old Japanese woman taking enoxacin 200 mg also had convulsions after receiving a single 50-mg intravenous dose of **flurbiprofen**.⁸

(c) *Levofloxacin*

A study in 24 healthy subjects found plasma levels of single 125-mg and 500-mg doses of levofloxacin were increased by about 13%, 6.5 hours after they were given **fenbufen** 600 mg. No changes in CNS activity were found.⁹

(d) *Ofloxacin*

One patient taking **fenbufen** 800 mg had involuntary movements of the neck and upper extremities after taking ofloxacin 600 mg.⁵ The pharmacokinetics of ofloxacin 200 mg twice daily were unchanged by **ketoprofen** 100 mg daily for 3 days in 10 healthy subjects.¹⁰ The incidence of psychotic adverse effects (euphoria, hysteria, psychosis) in 151 patients on ofloxacin were not increased by the concurrent use of NSAIDs (**aspirin, diclofenac, indometacin, dipyrrone**).¹¹

(e) *Pefloxacin*

The pharmacokinetics of pefloxacin 400 mg twice daily were not affected by **ketoprofen** 100 mg daily for 3 days in 10 healthy subjects.¹⁰

(f) Sparfloxacin

A 62-year-old woman developed drug eruptions (erythematous papules), which were attributed to sparfloxacin hypersensitivity induced by **mefenamic acid**.¹²

Mechanism

Not fully understood. Convulsions have occurred in a few patients taking quinolones alone, some of whom were epileptics and some of whom were not (see 'Antiepileptics + Quinolones', p.522). Experiments in *mice* have shown that quinolones competitively inhibit the binding of gamma-aminobutyric acid (GABA) to its receptors.¹³ GABA is an inhibitory transmitter in the CNS, which is believed to be involved in the control of convulsive activity. Enoxacin and fenbufen are known to affect the GABA receptor site in the hippocampus and frontal cortex of *mice*, which is associated with convulsive activity.¹⁴ It could be that, if and when an interaction occurs, the NSAID simply lowers the amount of quinolone needed to precipitate convulsions in already susceptible individuals.

Importance and management

The interaction between enoxacin and fenbufen is established, but it seems to be uncommon. Nevertheless, it would seem prudent to avoid fenbufen with enoxacin. There are very many alternatives.

Reports of adverse interactions between other quinolones and NSAIDs are extremely rare. The general warning about convulsions with quinolones and NSAIDs issued by the CSM in the UK¹⁵ seems to be an extrapolation from the interaction between enoxacin and fenbufen, and from some *animal* experiments. In addition to the data cited above, an epidemiological study of 856 users of quinolones (ciprofloxacin, enoxacin, nalidixic acid) and a range of NSAIDs found no cases of convulsions.¹⁶ The overall picture would therefore seem to be that although a potential for interaction exists, the risk is very small indeed and normally there would seem to be little reason for most patients taking quinolones to avoid NSAIDs. Epileptic patients are a possible exception (see 'Antiepileptics + Quinolones', p.522) and it would seem prudent to avoid quinolones and NSAIDs wherever possible in these patients.

Quinolones + Omeprazole

Omeprazole has no clinically important effect on the pharmacokinetics of ciprofloxacin, gemifloxacin, lomefloxacin, ofloxacin or trovafloxacin.

Clinical evidence, mechanism, importance and management

A single-dose study found that omeprazole 20 or 80 mg had no significant effect on the pharmacokinetics of single doses of **ofloxacin** 400 mg, **ciprofloxacin** 500 mg or **lomefloxacin** 250 or 400 mg.¹ Another study in 27 subjects found that omeprazole 40 mg daily for 3 days did not affect the pharmacokinetics of a single 1-g dose of an extended-release formulation of **ciprofloxacin** (*Depomed*).² Omeprazole 40 mg caused an 18% reduction in the AUC of a single 300-mg dose of **trovafloxacin** and a 32% reduction in the maximum serum levels, but this was considered not to be of clinical significance.³ A double-blind, randomised, crossover study in 12 healthy subjects found that the maximum serum levels and the AUC of a single 320-mg dose of **gemifloxacin** were increased by 11% and 10%, respectively, after taking omeprazole 40 mg daily for 4 days. The confidence intervals indicated that the respective increases were unlikely to exceed 36% and 43%, and it was concluded that these two drugs could be given together without any need for dosage adjustments.⁴

Quinolones + Opioids

Morphine modestly reduces the AUC of trovafloxacin, but this is not considered to be clinically significant. Trovafloxacin did not alter the effects or pharmacokinetics of morphine. Oxycodone does not appear to significantly affect the pharmacokinetics of either levofloxacin or gatifloxacin. It has been suggested that opiates decrease oral ciprofloxacin levels, but good evidence for this appears to be lacking.

Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

In one non-randomised study¹ the levels of oral ciprofloxacin were only 1.3 mg/L in the presence of intramuscular **papaveretum**, compared to 3.22 mg/L in a control group not receiving **papaveretum**. The authors say that this means the peak ciprofloxacin levels in the **papaveretum** group would not reach the MIC of a number of gut pathogens. They name *Bacteroides fragilis* (but it should be noted that the levels of the control group also did not reach the MIC of this organism), and *Enterococcus faecalis*, many strains of which are only moderately susceptible to ciprofloxacin anyway. Further, the **papaveretum** group in this study had only 4 patients, and, as the authors note, the control group was not matched.¹ Based on this rather slim evidence, the manufacturers of ciprofloxacin state that the use of ciprofloxacin tablets is not recommended with opiate premedicants due to the risks of inadequate ciprofloxacin levels.^{2,3} This advice is also given by the manufacturers of **morphine** sulfate,⁴ and was added at the request of the UK Medicines and Healthcare Regulatory Agency.⁵

(b) Gatifloxacin

In 12 healthy subjects, the pharmacokinetics of gatifloxacin 400 mg were not significantly altered by **oxycodone** 5 mg every 4 hours.⁶

(c) Levofloxacin

In 8 healthy subjects, the pharmacokinetics of oral levofloxacin 500 mg were not significantly altered by **oxycodone** 5 mg every 4 hours.⁷

(d) Trovafloxacin

An intravenous infusion of **morphine** 150 micrograms/kg given with oral trovafloxacin 200 mg to 18 healthy subjects caused a 36% reduction in the trovafloxacin AUC and a 46% reduction in the maximum serum levels. These levels were considered sufficient for prophylaxis of infection, and remained above the MICs of the most likely organisms to cause post-surgical infections. The bioavailability and effects of **morphine** were not significantly changed by trovafloxacin.⁸

Quinolones + Other antibacterials

There appear to be few documented cases of clinically relevant interactions between the quinolones and other antibacterials. However, note that clindamycin may antagonise the effects of ciprofloxacin on *S. aureus*. Further, *in vitro* studies have demonstrated antagonistic antibacterial effects when nitrofurantoin and nalidixic acid are used together, and other quinolones are also said to antagonise the effects of nitrofurantoin.

Clinical evidence, mechanism, importance and management

(a) Aminoglycosides

A study found that a single 100-mg intravenous dose of tobramycin had no effect on the pharmacokinetics of pefloxacin, and pefloxacin did not affect the pharmacokinetics of tobramycin.¹ Similarly no pharmacokinetic interaction was found between pefloxacin and amikacin.²

(b) Cephalosporins

A study found that a single 2-g intravenous dose of ceftazidime had no effect on the pharmacokinetics of pefloxacin, and pefloxacin did not affect the pharmacokinetics of ceftazidime.¹

In a study of 11 healthy subjects, the pharmacokinetics of cefotaxime and ofloxacin were similar, whether given alone or in combination, and the antimicrobial effect of the combination was additive for *S. aureus*, *S. pneumoniae*, *E. cloacae* and *K. pneumoniae*, but not for *Ps. aeruginosa*.³

(c) Clindamycin

One study found that the pharmacokinetics of intravenous ciprofloxacin 200 mg were not affected by intravenous clindamycin 600 mg and there is evidence that combined use may possibly enhance the antibacterial activity, particularly against *S. aureus* and *S. pneumoniae*.⁴ However, another study found that the serum bactericidal activity of ciprofloxacin against *S. aureus* was completely antagonised by clindamycin, if the strains were susceptible to the latter.⁵

(d) Macrolides

A study designed to assess the potential interaction between trovafloxacin and azithromycin found no significant alteration in the pharmacokinetics of either drug.⁶

(e) Metronidazole

A study found that a single 400-mg oral dose of metronidazole had no effect on the pharmacokinetics of pefloxacin, and similarly pefloxacin did not affect the pharmacokinetics of metronidazole.¹ In another study no interaction was found between ciprofloxacin or ofloxacin (both 200 mg intravenously) and metronidazole 500 mg intravenously,⁷ and metronidazole with ciprofloxacin orally.⁸

A further study, investigating the use of metronidazole 500 mg intravenously and ciprofloxacin 200 mg intravenously, also did not find any significant pharmacokinetic changes, although metronidazole reduced the ciprofloxacin volume of distribution by 20%.⁴ This is not expected to be clinically significant.

(f) Nitrofurantoin

The antibacterial activity of nalidixic acid can be attenuated by sub-inhibitory concentrations of nitrofurantoin. In 44 out of 53 strains of *Escherichia coli*, *Salmonella* and *Proteus*, antagonism was shown.⁹ Another study confirmed these findings.¹⁰ Whether this similarly occurs if both antibacterials are given to patients is uncertain, but the advice that concurrent use should be avoided when treating urinary tract infections seems sound.⁹ Active division of bacteria is required for the bactericidal activity of quinolones such as nalidixic acid, and the presence of a bacteriostatic drug such as nitrofurantoin may inhibit its action.¹¹ Other quinolone antibacterials (not named) and nitrofurantoin have been found to be antagonistic *in vitro* and although the clinical significance of this is unknown.^{12,13}

(g) Penicillins

A single-dose study in 6 healthy subjects found that intravenous azlocillin 60 mg/kg reduced the clearance of intravenous ciprofloxacin 4 mg/kg by 35%. The pharmacokinetics of azlocillin were not affected.¹⁴

Another study found that when a single 4-g intravenous dose of piperacillin was given with pefloxacin 400 mg the pharmacokinetics of both drugs were unchanged.¹

The absorption of ofloxacin 400 mg was not altered by amoxicillin 3 g in 6 healthy subjects.¹⁵

In another study in 12 healthy subjects, the serum bacterial activity of ciprofloxacin plus piperacillin against a variety of organisms was found to be additive, rather than antagonistic or synergistic despite the fact that the clearance of ciprofloxacin was reduced by 24%.¹⁶

(h) Rifampicin (Rifampin)

A single-dose study in 5 healthy subjects found that ciprofloxacin 500 mg decreased the peak serum levels of rifampicin 600 mg by 12%, and prolonged its half-life from 3.5 to 3.8 hours.¹⁷ In a further study, ciprofloxacin did not affect the percentage of rifampicin recovered in the urine, but it did increase its initial rate of excretion.¹⁸ Ciprofloxacin 750 mg and rifampicin 300 mg, both given every 12 hours for 2 weeks, did not significantly affect the pharmacokinetics of either drug in 12 elderly patients (aged 67 to 95).¹⁹ This is confirmed by other pharmacokinetic studies, one of which also reported that combined use provided excellent serum bactericidal activity against *S. aureus* strains, although activity was modestly lower than rifampicin alone.^{5,20,21}

A study in 8 healthy subjects found that rifampicin 900 mg daily for 10 days decreased the half-life and AUC₀₋₁₂ of pefloxacin 400 mg twice daily by about 30%, due to a 35% increase in total plasma clearance.²² Despite these changes the serum pefloxacin levels still remained well above the minimal inhibitory concentrations (0.5 mg/L) for 90% of strains of methicillin-sensitive *S. aureus* and *S. epidermidis*.²² A single-dose study in 5 healthy subjects found that pefloxacin 500 mg increased the AUC of a single 600-mg dose of rifampicin by about twofold.²³ In a further study the urinary recovery of rifampicin was increased from 15.6% of the dose to 20.1% by pefloxacin.²⁴

Another study in 13 healthy subjects found that rifampicin 600 mg daily for a week increased the clearance of fleroxacin 400 mg daily by 15%. However, the fleroxacin levels remained above the MIC₉₀ of methicillin-sensitive strains of *S. aureus* and *S. epidermidis* for at least 24 hours.²⁵ No special precautions would seem necessary if rifampicin is given with any of these quinolones.

Quinolones + Pirenzepine

Four doses of pirenzepine 50 mg delayed the absorption of ciprofloxacin and ofloxacin in 10 healthy subjects, but their bioavailabilities remained unchanged.¹ The delayed absorption is unlikely to be of clinical significance.

1. Höffken G, Lode H, Wiley R, Glatzel TD, Sievers D, Olschewski T, Borner K, Koeppel T. Pharmacokinetics and bioavailability of ciprofloxacin and ofloxacin: effect of food and antacid intake. *Rev Infect Dis* (1988) 10 (Suppl 1), S138–S139.

Quinolones + Probenecid

Probenecid increases the serum levels and/or decreases the urinary excretion of cinoxacin, ciprofloxacin, clinafloxacin, enoxacin, fleroxacin, levofloxacin, nalidixic acid and norfloxacin. The clinical importance of these changes is uncertain, but it seems likely they will only be important in the presence of other drugs that also affect renal excretion. Grepafloxacin, moxifloxacin, sparfloxacin, and probably ofloxacin, appear not to interact with probenecid.

Clinical evidence

(a) Cinoxacin

A study in 6 healthy subjects found that probenecid 500 mg three times daily roughly doubled the serum levels of a 3-hour intravenous infusion of cinoxacin. The renal clearance of cinoxacin was also reduced from 68 to 46% during and for the 4 hours after the infusion.¹

(b) Ciprofloxacin

In one study, probenecid 1 g, given 30 minutes before ciprofloxacin 500 mg, was found to reduce the renal clearance of ciprofloxacin by up to 50%. Other pharmacokinetic parameters (maximum serum levels, AUC) were unchanged and no accumulation of ciprofloxacin appeared to occur, probably due to an increase in extra-renal elimination.²

Another study found that the renal clearance of ciprofloxacin was reduced by 64% by probenecid. However, in contrast to the other study cited, the AUC of ciprofloxacin was increased by 74% and the AUC of its 2-aminoethylamino metabolite was increased by 234%. As a consequence, levels of ciprofloxacin in tears, sweat and saliva were also increased, but probenecid had no direct effect on ciprofloxacin distribution into these fluids.³

(c) Clinafloxacin

Probenecid 1 g, given 1 hour before a single 400-mg dose of clinafloxacin, reduced the total and renal clearance of clinafloxacin by 24% and 36%, respectively, raised the AUC by 32% and increased the elimination half-life from 6.3 to 7 hours.⁴

(d) Enoxacin

In one subject, the renal clearance of enoxacin 600 mg was approximately halved, and the half-life increased from 3.5 to 4.5 hours by a single 2.5-g dose of probenecid.⁵

(e) Fleroxacin

A study in 6 healthy subjects given a single 200-mg dose of fleroxacin, followed by 500 mg of probenecid 0.5, 12, 24 and 36 hours later, found that the fleroxacin AUC was increased by 37%, and the fleroxacin urinary excretion was decreased by 22%.⁶ Another study found that probenecid increased the AUC of fleroxacin 400 mg by 26% (not statistically significant), and had no effect on fleroxacin urinary excretion.⁷

(f) Grepafloxacin

A study in 32 healthy subjects found that probenecid had no effect on the pharmacokinetics of a single 200-mg dose of grepafloxacin.⁸ In another 6 healthy subjects probenecid similarly had no significant effect on grepafloxacin pharmacokinetics.⁹

(g) Levofloxacin

A study in 12 healthy subjects found that although probenecid reduced the renal clearance of a single 500-mg oral dose of levofloxacin by about one-third and increased its AUC and half-life by similar amounts, the 72-hour urinary levofloxacin excretion was unaltered.¹⁰

(h) Moxifloxacin

A study in 12 healthy subjects found that probenecid had no clinically significant effects on the pharmacokinetics of a single 400-mg dose of moxifloxacin.¹¹

(i) Nalidixic acid

Two volunteers, acting as their own controls, took nalidixic acid 500 mg with and without probenecid 500 mg. The peak serum levels of nalidixic acid were unaffected at 2 hours, but at 8 hours the levels were increased threefold by the probenecid.¹²

Another study in 5 women with urinary tract infections treated with nalidixic acid showed that probenecid increased the maximum serum nalidixic acid levels and AUC by 43% and 74%, respectively.¹³

(j) Norfloxacin

The mean 12-hour urinary recovery of norfloxacin 200 mg was reduced by about half in 5 subjects when they were given probenecid 1 g. Norfloxacin serum concentrations were unaffected.¹⁴

(k) Ofloxacin

A study in 8 healthy subjects found that probenecid 500 mg increased the AUC of a single 200-mg dose of ofloxacin by 16% and decreased the total body clearance by 14%. Other pharmacokinetic parameters were not significantly affected.¹⁵

(l) Sparfloxacin

Probenecid 1.5 g did not significantly affect the clearance, the AUC or the half-life of sparfloxacin 200 mg in 6 healthy subjects.¹⁶

Mechanism

The likely explanation for this interaction is that probenecid successfully competes with some quinolones for tubular excretion, so that their renal elimination is reduced. Some quinolones are more dependent on glomerular filtration (e.g. grepafloxacin)⁹ than tubular excretion for elimination, and thus are unaffected by competition for tubular excretion.⁷

Importance and management

Established interactions, but their clinical importance seems not to have been assessed. There appears to be no reason for avoiding concurrent use.

The increased levels and decreased renal excretion of clinafloxacin caused by probenecid are not considered large enough to warrant dosage adjustment,⁴ and most of the changes seen with the other quinolones were of a similar magnitude. However, caution has been advised in the presence of other drugs that may also compete for renal excretion (such as some penicillins or cephalosporins).^{3,4} Grepafloxacin, moxifloxacin, sparfloxacin, and probably ofloxacin, appear not to interact.

Quinolones + Sucralfate

Sucralfate causes a marked reduction in the absorption of ciprofloxacin, enoxacin, gemifloxacin, lomefloxacin, moxifloxacin, ofloxacin, norfloxacin and sparfloxacin, but only a modest reduction in fleroxacin levels.

Clinical evidence

(a) Ciprofloxacin

In a study in 8 healthy subjects sucralfate 1 g four times daily reduced the AUC and maximum serum concentration of ciprofloxacin 500 mg by 88% and 90%, respectively.¹

A patient given sucralfate 1 g four times daily had serum ciprofloxacin levels which were 85 to 90% lower than 5 other patients who were not taking sucralfate.² A single dose study found a 96% reduction in the AUC of ciprofloxacin following a 2-g dose of sucralfate.³ A study in 12 healthy subjects found that a 1-g dose of sucralfate given 6 and 2 hours before a single 750-mg dose of ciprofloxacin, reduced the ciprofloxacin AUC by about 30%. Three of the subjects showed little or no changes in AUC but a decrease of more than 50% was seen in 4 others.⁴ A related study in 12 healthy subjects found that the bioavailability of ciprofloxacin 750 mg was reduced by 7%, 20%, and 95%, respectively, when sucralfate was given 6 hours before, 2 hours before, or at the same time as, the ciprofloxacin.⁵ Oral sucralfate does not alter the effects of ciprofloxacin on aerobic bacteria in the gut.⁶

(b) Enoxacin

In 8 healthy subjects the bioavailability of enoxacin 400 mg was reduced by 54% and 88%, respectively, when sucralfate 1 g was given 2 hours before or with the enoxacin. When sucralfate was given 2 hours after the enoxacin the bioavailability was not affected.⁷

(c) Fleroxacin

The bioavailability of fleroxacin 400 mg was reduced by 24% in 20 healthy subjects taking sucralfate 1 g every 6 hours.⁸

(d) Gemifloxacin

In a study in 27 healthy subjects gemifloxacin 320 mg was given either 3 hours before or 2 hours after sucralfate 2 g. The pharmacokinetics of gemifloxacin were not significantly altered when sucralfate was given after the gemifloxacin, probably due to its rapid absorption. However, when sucralfate was given 3 hours before gemifloxacin, the AUC and maximum plasma levels were decreased by 53% and 69%, respectively.⁹

(e) Levofloxacin

The pharmacokinetics of levofloxacin are unaffected by sucralfate taken 2 hours after the quinolone.¹⁰

(f) Lomefloxacin

A study in 12 subjects found that when lomefloxacin 400 mg was given 2 hours after sucralfate 1 g the lomefloxacin AUC and maximum serum concentration was reduced by about 25% and 30%, respectively.¹¹ Another study in 8 healthy subjects found that when lomefloxacin 400 mg was given with sucralfate 1 g, the lomefloxacin AUC was reduced by 51%.¹²

(g) Moxifloxacin

In 12 healthy subjects a total of five doses of sucralfate 1 g, given at the same time as a single 400-mg dose of moxifloxacin and then 5, 10, 15, and 24 hours after the dose, reduced the AUC and maximum serum concentration of moxifloxacin by 40% and 29%, respectively.¹³

(h) Norfloxacin

A study in 8 healthy subjects found that sucralfate 1 g four times daily reduced the AUC of a single 400-mg dose of norfloxacin by 98%, when taken with the sucralfate, and by 42% when taken 2 hours after the sucralfate.¹⁴ Another study found a reduction of 91% in the AUC of norfloxacin 400 mg when it was taken with sucralfate 1 g, but no reduction when it was taken 2 hours before sucralfate.¹⁵

(i) Ofloxacin

A single dose study found that sucralfate (dose not stated) reduced the maximum serum levels and AUC of a single 200-mg dose of ofloxacin by about two-thirds.¹⁶ Another study found a reduction of 61% when ofloxacin 400 mg was taken with sucralfate 1 g, but no reduction when the ofloxacin was taken 2 hours before sucralfate.¹⁵ Food reduced the extent of the interaction but it was still marked.¹⁷

(j) Sparfloxacin

In a study in 15 healthy subjects sucralfate 1 g four times daily reduced the maximum serum levels, the AUC and the relative bioavailability of sparfloxacin 400 mg daily by 39%, 47%, and 44%, respectively.¹⁸ In a study assessing staggered dosing of sucralfate 1.5 g on the pharmacokinetics of sparfloxacin 300 mg, the AUC was unaffected when sucralfate was given 4 hours after the quinolone, but was decreased by 34% when given 2 hours before, and 51% when given at the same time as sucralfate.¹⁹

Mechanism

The aluminium hydroxide component of sucralfate (about 200 mg in each gram) forms an insoluble chelate between the cation and the 4-keto and 3-carboxyl groups of the quinolone, which reduces its absorption. See 'Quinolones + Antacids or Calcium compounds', p.328 for more on this mechanism.

Importance and management

Established and clinically important interactions. Because it seems probable that serum ciprofloxacin, enoxacin, gemifloxacin, levofloxacin, lomefloxacin, moxifloxacin, ofloxacin, norfloxacin and sparfloxacin levels will be reduced to subtherapeutic concentrations if given with the sucralfate, separate the dosages as much as possible (by 2 hours or more), giving the quinolone first. The study with moxifloxacin suggested that sucralfate should not be given for 2 hours before or 4 hours after the quinolone, but more study is needed to confirm both these findings and the effectiveness of separating the dosages. The interaction with fleroxacin is only modest (bioavailability reduced by 24%) and probably not clinically important, but some separation of the dosages may reduce the interaction further. This needs confirmation. **Pefloxacin** interacts with antacids containing aluminium hydroxide (see 'Quinolones + Antacids or Calcium compounds', p.328) and is therefore likely to interact with sucralfate. The 'H₂-receptor antagonists', (p.335) and 'omeprazole', (p.338) do not interact with the quinolones and may therefore be alternatives to sucralfate in many situations.

Quinolones; Ciprofloxacin + Pancreatic enzymes

The pharmacokinetics of ciprofloxacin are not affected by pancreatic enzyme supplements.

Clinical evidence, mechanism, importance and management

Six patients with cystic fibrosis, chronically infected with *Ps. aeruginosa* and treated with a range of drugs including ceftazidime, tobramycin, ticarcillin and salbutamol, demonstrated no significant changes in the pharmacokinetics of a single 250-mg dose of ciprofloxacin when it was given with standard doses of pancreatic enzymes (seven *Pancrease* capsules).¹ Another study in 12 patients with cystic fibrosis found that administration of pancreatic enzyme supplements 30 minutes before a single 750-mg dose of ciprofloxacin did not alter the pharmacokinetics of ciprofloxacin.² No special precautions would seem to be necessary during concurrent use.

- Reed MD, Stern RC, Myers CM, Yamashita TS, Blumer JL. Lack of unique pharmacokinetic characteristics in patients with cystic fibrosis. *J Clin Pharmacol* (1988) 28, 691–9.

Quinolones; Ciprofloxacin + Phenazopyridine

Phenazopyridine appears to increase the bioavailability of ciprofloxacin.

Clinical evidence, mechanism, importance and management

A study in 23 healthy subjects given a single 500-mg dose of ciprofloxacin either alone or with phenazopyridine 200 mg found that phenazopyridine increased the AUC and mean residence time of ciprofloxacin by about 30%. The time to achieve maximum plasma levels was increased from 1 to 1.5 hours.¹ If anything, this seems likely to be a beneficial, rather than adverse, interaction.

- Marcelín-Jiménez G, Ángeles AP, Martínez-Rossier L, Fernández A. Ciprofloxacin bioavailability is enhanced by oral co-administration with phenazopyridine: a pharmacokinetic study in a Mexican population. *Clin Drug Invest* (2006) 26, 323–8.

Quinolones; Ciprofloxacin + Sevelamer

Sevelamer reduced the bioavailability of ciprofloxacin by 48% in one study.

Clinical evidence, mechanism, importance and management

In a crossover study in 15 healthy subjects the AUC of ciprofloxacin was reduced by 39% and the relative oral bioavailability was reduced by 48% when a single 750-mg dose of ciprofloxacin was taken with sevelamer 2.8 g. The reduction was variable.¹ The mechanism of the interaction is unknown. Based on the results of this study, sevelamer should not be given at the same time as ciprofloxacin because the efficacy of ciprofloxacin might be reduced in some patients. Further study is needed to establish whether or not the interaction could be avoided by separation of the doses.

- Kays MB, Overholser BR, Mueller BA, Moe SM, Sowinski KM. Effects of sevelamer hydrochloride and calcium acetate on the oral bioavailability of ciprofloxacin. *Am J Kidney Dis* (2003) 42, 1253–9.

Quinolones; Ciprofloxacin + Ursodeoxycholic acid (Ursodiol)

An isolated report describes a reduction in serum ciprofloxacin levels in a patient taking ursodeoxycholic acid.

Clinical evidence, mechanism, importance and management

A man with metastatic colon cancer had unusually low serum levels of ciprofloxacin following oral dosing; his only other medication was ursodeoxycholic acid 300 mg twice daily for gallstones. Despite the low antibacterial serum levels the bacteraemia cleared. Several months later when he was readmitted to hospital, both drugs were again given, initially staggered, and then later together. When taken together the AUC of the ciprofloxacin was reduced by 50% by ursodeoxycholic acid.¹ The reason for this interaction is not understood.

This seems to be the first and only report of an interaction between a quinolone and ursodeoxycholic acid and its importance is uncertain. More study is needed to establish this interaction, its importance, and its mechanism.

- Belliveau PP, Nightingale CH, Quintiliani R, Maderazo EG. Reduction in serum concentrations of ciprofloxacin after administration of ursodiol to a patient with hepatobiliary disease. *Clin Infect Dis* (1994) 19, 354–5.

Quinolones; Levofloxacin + Antiretrovirals

There appears to be no clinically important pharmacokinetic interaction between levofloxacin and efavirenz or nelfinavir.

Clinical evidence, mechanism, importance and management

A study in HIV-positive patients who were taking antiretroviral therapy consisting of zidovudine and lamivudine with either efavirenz or nelfinavir, found that levofloxacin 500 mg daily for 4 days did not affect the steady-state pharmacokinetics of either efavirenz 600 mg daily or nelfinavir 750 mg three times daily. The pharmacokinetics of levofloxacin during concurrent treatment with efavirenz or nelfinavir were unaffected, except for the time to maximum levels, which was increased from 0.9 to 1.7 hours in control subjects, to 3.3 hours with efavirenz. This may have occurred as a result of delayed gastric emptying caused by the efavirenz. A clinically important interaction between levofloxacin and either efavirenz or nelfinavir is unlikely.¹

- Villani P, Viale P, Signorini L, Cadeo B, Marchetti F, Villani A, Flocchi C, Regazzi MB, Carosi G. Pharmacokinetic evaluation of oral levofloxacin in human immunodeficiency virus-infected subjects receiving concomitant antiretroviral therapy. *Antimicrob Agents Chemother* (2001) 45, 2160–2.

Quinolones; Lomefloxacin + Furosemide

Furosemide causes a small, almost certainly unimportant, rise in the serum levels of lomefloxacin. The pharmacokinetics and diuretic effects of the furosemide are not changed.

Clinical evidence, mechanism, importance and management

A study in 8 healthy subjects found that when a single 200-mg dose of lomefloxacin was taken with furosemide 40 mg, the AUC of lomefloxacin was increased by 12%. The maximum serum levels and the half-life were

also increased, but not to a statistically significant extent.¹ The suggested reason for the interaction is that there is some competition between the two drugs for excretion by the kidney tubules. No significant changes were seen in the pharmacokinetics of the furosemide nor in its diuretic effects.¹ The small rise in the serum levels of lomefloxacin is almost certainly too small to be important and there would seem to be no reason for avoiding concurrent use. Information about other quinolone antibacterials appears to be lacking.

1. Sudoh T, Fujimura A, Shiga T, Sasaki M, Harada K, Tateishi T, Ohashi K, Ebihara A. Renal clearance of lomefloxacin is decreased by furosemide. *Eur J Clin Pharmacol* (1994) 46, 267–9.

Quinolones; Moxifloxacin + Itraconazole

A study in healthy subjects found that itraconazole 200 mg daily for 9 days did not affect the pharmacokinetics of a single 200-mg dose of moxifloxacin given on day 7. No clinically relevant changes were found in the pharmacokinetics of itraconazole.¹ No special precautions would seem to be necessary during concurrent use.

1. Stass H, Nagelschmitz J, Moeller J-G, Delesen . Pharmacokinetics of moxifloxacin are not influenced by a 7-day pre-treatment with 200 mg oral itraconazole given once a day in healthy subjects. *Int J Clin Pharmacol Ther* (2004) 42, 23–9.

Quinolones; Ofloxacin + Cetraxate

A single-dose study found that cetraxate (dose not stated) did not affect the pharmacokinetics of a single 200-mg dose of ofloxacin.¹ No special precautions would seem to be necessary on concurrent use.

1. Shiba K, Yoshida M, Kachi M, Shimada J, Saito A, Sakai N. Effects of peptic ulcer-healing drugs on the pharmacokinetics of new quinolone (OFLX). 17th Int Congr Chemother, June 1991, Berlin, Abstract 415.

Quinupristin/Dalfopristin + Miscellaneous

In vitro studies have found that quinupristin/dalfopristin inhibits the CYP3A4-mediated metabolism of docetaxel, tamoxifen and terfenadine and is predicted to inhibit the metabolism of other drugs by this enzyme system.

Clinical evidence, mechanism, importance and management

In vitro studies found quinupristin/dalfopristin inhibited the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of **docetaxel**, **tamoxifen**, and **terfenadine**.¹ Quinupristin/dalfopristin is predicted to raise the levels of other drugs including antiarrhythmics (**disopyramide**, **lidocaine**, **quinidine**), antiretrovirals (such as **delavirdine**, **indinavir**, **nevirapine**, **ritonavir**), **astemizole**, **carbamazepine**, **cisapride**, **methylprednisolone**, **paclitaxel**, **statins** (but see 'Lipid regulating drugs', (p.1086)), and **vinca alkaloids**.¹ More study is needed.

Rifampicin (Rifampin) + Aminosalicic acid

The serum levels of rifampicin are approximately halved if aminosalicic acid granules containing bentonite are given.

Clinical evidence

In 30 patients with tuberculosis the serum levels of rifampicin 10 mg/kg were reduced by more than 50%, from 6.06 to 2.91 micrograms/mL, at 2 hours by aminosalicylate.^{1,2} Later studies in 6 healthy subjects showed that this interaction was not due to the aminosalicic acid itself but to the **bentonite**, which was the main excipient of the granules.³ The rifampicin AUC was statistically unchanged in the presence of sodium aminosali-

cylic acid granules (no **bentonite**), whereas it was reduced by more than 37% in the presence of **bentonite** from aminosalicic acid granules.³

Other studies confirm this marked reduction in serum rifampicin levels in the presence of **bentonite** in aminosalicic acid granules.⁴

Mechanism

The bentonite excipient in the aminosalicic acid granules adsorbs the rifampicin onto its surface so that much less is available for absorption, which results in reduced serum levels.³ Bentonite is a naturally occurring mineral (montmorillonite) consisting largely of hydrate aluminium silicate, and is similar to kaolin.

Importance and management

A well documented and clinically important interaction. Separating the administration of the two drugs by 8 to 12 hours to prevent their mixing in the gut has been suggested as an effective way to prevent this interaction.¹ An alternative is to give aminosalicic acid preparations that do not contain bentonite.

Rifampicin (Rifampin) + Antacids

The absorption of rifampicin can be reduced up to about one-third by antacids, but the clinical importance of this is uncertain.

Clinical evidence

When 5 healthy subjects took a single 600-mg dose of rifampicin with various antacids the absorption of rifampicin was reduced. The antacids caused a fall in the urinary excretion of rifampicin as follows: 15 or 30 mL of **aluminium hydroxide gel** 29 to 31%; 2 or 4 g of **magnesium trisilicate** 31 to 36%; and 2 g of **sodium bicarbonate** 21%.¹

Three groups of 15 patients with tuberculosis were given a single oral dose of rifampicin 10 to 12 mg/kg, isoniazid 300 mg and ethambutol 20 mg/kg either alone or with about 20 mL of antacid. A 'significant number' of patients had peak rifampicin concentrations below 6.5 micrograms/mL (serum level quoted as necessary to achieve adequate lung concentrations) in the group receiving **Aludrox (aluminium hydroxide)**, but no significant effect was noted in the group receiving **Gelusil (aluminium hydroxide plus magnesium trisilicate)**.² However, in a further study in 14 healthy subjects, 30 mL of **Mylanta (aluminium/magnesium hydroxide)** given 9 hours before, with and after rifampicin had no effect on rifampicin pharmacokinetics.³

Mechanism

It has been suggested that the rise in stomach pH caused by these antacids reduces the dissolution of the rifampicin and thereby inhibits its absorption. In addition, aluminium ions may form less soluble chelates with rifampicin, and magnesium trisilicate can adsorb rifampicin, both of which would also be expected to reduce bioavailability.¹

Importance and management

Direct information seems to be limited to these reports. The effects of 20 to 35% reductions in rifampicin absorption do not appear to have been assessed, but if antacids are given it would be prudent to be alert for any evidence that treatment is less effective than expected. The US manufacturers of rifampicin advise giving rifampicin 1 hour before antacids.⁴

Rifampicin (Rifampin) + Clofazimine

There is no pharmacokinetic interaction between rifampicin and clofazimine.

Clinical evidence, mechanism, importance and management

Clofazimine 100 mg daily, given to 15 patients with leprosy taking rifampicin 600 mg daily and dapsone 100 mg daily, had no effect on the pharmacokinetics of rifampicin.¹ A single-dose study similarly found that the bioavailability of clofazimine remained unaltered when rifampicin was given, although a reduction in the rate of absorption was seen.² No special precautions would seem to be necessary on concurrent use.

1. Venkatesan K, Mathur A, Girdhar BK, Bharadwaj VP. The effect of clofazimine on the pharmacokinetics of rifampicin and dapsone in leprosy. *J Antimicrob Chemother* (1986) 18, 715–18.

Rifampicin (Rifampin) + Food

Food delays and reduces the absorption of rifampicin from the gut.

Clinical evidence

The absorption of a single 10-mg/kg dose of rifampicin was reduced when it was given to 6 healthy subjects with a **standard Indian breakfast** (125 g wheat, 10 g visible fat, 350 g vegetables). The AUC after 8 hours was reduced by 26% and the peak plasma levels were prolonged (from 11.84 micrograms/mL at 2 hours to 8.35 micrograms/mL at 4 hours) and reduced by about 30%.¹ In another study, a **high-fat breakfast** reduced the maximum serum level of rifampicin 600 mg by 36% and delayed the absorption, but the AUC was not significantly altered.²

Mechanism

Not understood.

Importance and management

An established interaction. Rifampicin should be taken on an empty stomach (at least 30 minutes before a meal, or 2 hours after a meal) to ensure rapid and complete absorption.

1. Polasa K, Krishnaswamy K. Effect of food on bioavailability of rifampicin. *J Clin Pharmacol* (1983) 23, 433–7.

Rifampicin (Rifampin) + H₂-receptor antagonists

No clinically significant interaction appears to occur between rifampicin and cimetidine or ranitidine.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

In a study, 12 patients given daily doses of rifampicin 8 mg/kg, isoniazid 8 mg/kg and ethambutol 25 mg/kg, and 13 untreated control subjects were given intravenous cimetidine 300 mg. In the patients receiving antimycobacterials, the non-renal clearance of cimetidine was increased by 52% but the total clearance and volume of distribution were unchanged. The reduction in renal clearance in the patients may have been associated with age-related impairment of renal function, but it was suggested that the increased non-renal clearance may have been due to enzyme induction of cimetidine metabolism.¹ As total clearance was unchanged this interaction seems unlikely to be clinically significant.

(b) Ranitidine

In a controlled study, 112 patients with pulmonary tuberculosis were treated in 2 groups, one with a daily regimen of rifampicin 10 mg/kg, isoniazid 300 mg and ethambutol 20 mg/kg and ranitidine 150 mg twice daily, and

the other with the same antimycobacterials but without ranitidine. The pharmacokinetics of rifampicin (as measured by the total and unchanged urinary excretion) were not affected by ranitidine. No changes occurred in the incidence of adverse hepatic reactions, while gastrointestinal reactions were reduced.² There would seem to be no reason for avoiding the use of ranitidine, or any other H₂-receptor antagonists, in patients taking rifampicin.

1. Keller E, Schollmeyer P, Brandenstein U, Hoppe-Seyler G. Increased nonrenal clearance of cimetidine during antituberculous therapy. *Int J Clin Pharmacol Ther Toxicol* (1984) 22, 307–11.

Rifampicin (Rifampin) + Phenobarbital

Phenobarbital possibly modestly increases the clearance of rifampicin. The effect of rifampicin on phenobarbital levels is unknown, but note that rifampicin markedly increased the clearance of another barbiturate hexobarbital, used as a marker of drug metabolism.

Clinical evidence

In one study, the serum levels of rifampicin were reduced by 20 to 40% in 12 of 15 patients taking phenobarbital 100 mg daily.¹ In another study, although phenobarbital 100 mg daily for 7 days reduced the mean half-life of a single 600-mg dose of rifampicin by 15%, this was not statistically significant. However, in a further 5 patients with cirrhosis of the liver, phenobarbital did reduce the half-life of rifampicin by a mean of 2.2 hours.²

The effect of rifampicin on phenobarbital levels does not appear to have been studied, but rifampicin markedly increased the clearance of another barbiturate **hexobarbital**, used as a marker of drug metabolism.^{3–6}

Mechanism

Both rifampicin and phenobarbital are potent liver enzyme inducers. The outcome of their effects when combined is not clear.

Importance and management

The documentation for this interaction is very limited, and the outcome of concurrent use is unclear. Concurrent use need not be avoided, but be alert for a reduced response to both drugs.

Rifampicin (Rifampin) + Probenecid

Probenecid increased rifampicin levels in one study, but not in another.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects given probenecid 2 g before and after a single 300-mg dose of rifampicin found that probenecid increased the mean peak serum rifampicin levels by 86%. At 4, 6, and 9 hours after the dose the increases were 118%, 90%, and 102%, respectively.¹ However, subsequent studies in patients taking either rifampicin 600 mg daily, or rifampicin 300 mg daily 30 minutes after a 2-g dose of probenecid found that the probenecid group achieved serum rifampicin levels that were only about half those achieved by those taking rifampicin 600 mg alone, suggesting that no interaction occurred.² The reasons for these discordant results are not understood, although it has been suggested that erratic

rifampicin absorption may have played a part.² The interaction is not proven, but it seems possible that some patients will experience a rise in rifampicin levels. Consider this interaction as a possible cause if rifampicin adverse effects are troublesome.

Sodium fusidate + Colestyramine

***In vitro* studies have shown that colestyramine can bind with sodium fusidate in the gut, thereby reducing its activity,¹ and *in vivo* animal studies have shown peak fusidate levels are decreased by 33 to 77% by colestyramine,² but whether this also occurs clinically has not been confirmed. It is generally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine.**

Sulfonamides + Local anaesthetics

Para-aminobenzoic acid (PABA), derived from certain local anaesthetics, can reduce the effects of the sulfonamides and allow the development of local and even generalised infections. However, it should be noted that the limited evidence for this interaction is from the 1940s.

Clinical evidence

Four patients taking sulfonamides developed local infections in areas where **procaine** had been injected before diagnostic taps for meningitis, or draining procedures in empyema. Extensive cellulitis of the lumbar region occurred in one case, and abscesses appeared at the puncture sites in another. However, it should be noted that lumbar punctures were being done at least daily and up to four times a day in the 3 patients with meningitis.¹

An *in vitro* study demonstrated that the amount of **procaine** in the pleural fluid after anaesthesia for thoracentesis was sufficient to inhibit the antibacterial activity of 0.005% **sulfapyridine** against type III pneumococci.² Another *in vitro* study found that some local anaesthetics derived from PABA inhibited the bacteriostatic activity of **sulfapyridine** and **sulfathiazole** but some other local anaesthetics not derived from PABA did not affect the antibacterial activity of these sulfonamides.³ Other studies in *animals* confirm that both *in vitro*^{4–6} and *in vivo*⁷ antagonism can occur between sulfonamides and local anaesthetics that are hydrolysed to **PABA**.

Mechanism

The ester type of local anaesthetic is hydrolysed within the body to produce PABA. Sulfonamides work by inhibiting bacterial DNA synthesis by competitively inhibiting folate production. The PABA competes with the sulfonamides, so higher PABA concentrations effectively dilute the effects of the sulfonamides.

Importance and management

Clinical examples of this interaction seem to be few and of poor quality (note that the patients were given repeated lumbar punctures, up to four times daily in some instances). It should also be noted that the supporting evidence (human, *animal* and *in vitro* studies) dates back to the mid-1940s with nothing more recent apparently on record. Local anaesthetics of the ester type that are hydrolysed to PABA (e.g. tetracaine, procaine, benzocaine) present the greatest risk of a reaction, whereas those of the amide type (bupivacaine, cinchocaine, lidocaine, mepivacaine and prilocaine) would not be expected to interact adversely. The evidence seems to be too

slim to preclude concurrent use of these drugs, but it is perhaps worth considering this interaction if high or repeated doses of the local anaesthetic are used. However, note that high doses or prolonged use of these ester-type anaesthetics are best avoided given their toxicity when used in this manner.

Sulfonamides; Sulfafurazole (Sulfisoxazole) + Laxatives

Sodium sulfate and castor oil used as laxatives can cause a modest but probably clinically unimportant reduction in sulfafurazole absorption.

Clinical evidence, mechanism, importance and management

In an experimental study of the possible effects of laxatives on the absorption of sulfafurazole, healthy subjects were given 10 to 20 g of oral **sodium sulfate** or 20 g of **castor oil** (doses sufficient to provoke diarrhoea). Absorption, measured by the amount of sulfafurazole excreted in the urine, was decreased by 50% with **castor oil**, and by 33% with **sodium sulfate** at 4 hours. However, serum levels of the drugs were relatively unchanged. The overall picture was that while these laxatives can alter the pattern of absorption, they do not seriously impair the total amount of drug absorbed.¹

1. Mattila MJ, Takki S, Jussila J. Effect of sodium sulphate and castor oil on drug absorption from the human intestine. *Ann Clin Res* (1974) 6, 19–24.

Tetracyclines + Antacids

The serum levels and therefore the therapeutic effectiveness of the tetracyclines can be markedly reduced or even abolished by antacids containing aluminium, bismuth, calcium or magnesium. Other antacids, such as sodium bicarbonate, may also reduce the bioavailability of some tetracyclines. Even intravenous doxycycline levels can be reduced by antacids.

Clinical evidence

(a) Aluminium-containing antacids

A study in 5 patients and 6 healthy subjects found that within 48 hours of starting to take about 10 mL of aluminium hydroxide gel (*Amphogel*) every 6 hours with **chlortetracycline** 500 mg the serum levels of the antibacterial were reduced by 80 to 90%. One patient had a recurrence of her urinary tract infection, which only subsided when the antacid was withdrawn, and one patient maintained **chlortetracycline** levels despite antacid treatment.¹ Similar results were obtained in other studies.^{2,3}

Further studies have shown similar interactions with other tetracyclines:

- 30 mL of aluminium hydroxide reduced **oxytetracycline** serum levels by more than 50%.³
- 20 mL of aluminium hydroxide caused a 75% reduction in **demeclocycline** serum levels.⁴
- 15 mL of aluminium hydroxide caused a 100% reduction in serum **doxycycline** levels.^{5,6}
- 30 mL of aluminium/magnesium hydroxide (*Maalox*) caused a 90% reduction in **tetracycline** serum levels.⁷

Intravenous doxycycline also appears to be affected. The mean serum levels of an intravenous dose of **doxycycline** were found to be reduced by

36% when 30 mL of aluminium hydroxide was taken four times daily, for 2 days before and after the antibacterial.⁸

(b) *Bismuth-containing antacids*

Bismuth subsalicylate reduces the absorption of **tetracycline** by 34%⁹ and reduces the maximum serum levels of **doxycycline** by 50%.¹⁰ It has been suggested the excipient **Veegum** (magnesium aluminium silicate) in some bismuth subsalicylate formulations enhances this effect.¹¹ Bismuth carbonate similarly interacts with the tetracyclines *in vitro*.¹²

(c) *Calcium-containing antacids*

There seem to be no direct clinical studies with calcium-containing antacids, but a clinically important interaction seems almost a certainty, based on *in vitro* studies with calcium carbonate,¹² calcium in milk, (see 'Tetracyclines + Food or Drinks', p.347), dicalcium phosphate,¹³ and calcium as an excipient in tetracycline capsules.¹⁴

(d) *Magnesium-containing antacids*

Magnesium sulfate certainly interacts with **tetracycline**, but in the only clinical study available¹⁵ the amount of magnesium was much higher than would normally be found in the usual dose of antacid.

(e) *Sodium-containing antacids*

Sodium bicarbonate 2 g reduced the absorption of a 250-mg capsule of **tetracycline** by 50% in 8 subjects. If however **tetracycline** was dissolved before administration, the absorption was unaffected by the sodium bicarbonate.¹⁶ Another study stated that sodium bicarbonate 2 g had an insignificant effect on **tetracycline** absorption.⁷

Mechanism

The tetracyclines bind with aluminium, bismuth, calcium, magnesium and other metallic ions to form compounds (chelates), which are much less soluble and therefore much less readily absorbed by the gut.¹⁷ Because doxycycline undergoes enterohepatic recirculation, even intravenous doxycycline is affected, although less so than oral. It has also been suggested that the antacids reduce gastric acidity and thereby decrease the absorption of tetracyclines,¹⁶ but studies demonstrating the lack of a significant interaction with 'H₂-receptor antagonists', (p.348) suggest that this is not the case. The reduced absorption with bismuth compounds may be because they adsorb tetracyclines.⁹ The interaction of some tetracycline preparations with sodium bicarbonate is unexplained.

Importance and management

Extremely well-documented, and well-established interactions. Their clinical importance depends on how much the serum tetracycline levels are lowered, but with normal antacid dosages the reductions cited above (50 to 100%) are large enough to mean that many organisms will not be exposed to minimum inhibitory concentrations (MIC) of antibacterial. As a general rule none of the aluminium, bismuth, calcium or magnesium-containing antacids should be given at the same time as the tetracycline antibacterials. If they must be used, separate the dosages by 2 to 3 hours or more to prevent their admixture in the gut. This also applies to **quinapril** formulations containing substantial quantities of magnesium (such as **Accupro**), although the interaction is less pronounced (see 'Tetracyclines + Quinapril', p.349), and is also predicted to occur with **didanosine** tablets formulated with antacids,¹⁸ but not with the enteric-coated capsule formulation (which contains no antacids).¹⁹

Patients should be warned about taking any antacids and indigestion preparations. Instead of using antacids to minimise the gastric irritant effects of the tetracyclines it is usually recommended that tetracyclines are taken after food, however it is not entirely clear how much this affects their absorption (see 'Tetracyclines + Food or Drinks', p.347). H₂-receptor antagonists may be suitable non-interacting alternatives to antacids in some situations, see 'Tetracyclines + H₂-receptor antagonists', p.348.

Tetracyclines + Antiepileptics

The serum levels of doxycycline are reduced and may fall below the accepted minimum inhibitory concentration in patients receiving long-term treatment with barbiturates, phenytoin or carbamazepine. Other tetracyclines do not appear to be affected.

Clinical evidence

A study in 14 patients taking **phenytoin** 200 to 500 mg daily, **carbamazepine** 300 mg to 1 g daily, or both, found that the half-life of **doxycycline** was approximately halved from 15.1 hours in patients not taking antiepileptics, to 7.2 hours in patients taking **phenytoin**, 8.4 hours in patients taking **carbamazepine**, and 7.4 hours in patients taking both drugs.¹

Similar results were found in 16 other patients taking various combinations of **phenytoin**, **carbamazepine**, **primidone** or **phenobarbital**. The serum **doxycycline** levels of almost all of them fell below 0.5 micrograms/mL during the 12 to 24 hour period following their last dose of **doxycycline** 100 mg. **Tetracycline**, **methacycline**, **oxytetracycline**, **demeclocycline** and **chlortetracycline** levels were not significantly affected by these antiepileptics.² Other studies confirm this interaction between some **barbiturates** (**amobarbital**, **pentobarbital**, **phenobarbital**) and **doxycycline**.^{3,4}

Mechanism

Uncertain. These antiepileptics and barbiturates are known enzyme inducers and it seems probable that they increase the metabolism of the doxycycline by the liver, thereby increasing its clearance from the body.

Importance and management

The interactions between doxycycline and the enzyme-inducing antiepileptics are established, but the clinical significance of the reduction in levels does not seem to have been studied. Serum doxycycline levels below 0.5 micrograms/mL are less than the minimum inhibitory concentration (MIC) quoted by the authors, so that it seems likely that the antibacterial will be less effective. To accommodate this potential problem it has been suggested that the doxycycline dosage could be doubled.² Alternatively any of the tetracyclines that are reported not to be affected by these antiepileptics (tetracycline, methacycline, oxytetracycline, demeclocycline and chlortetracycline) may provide a suitable alternative.²

Tetracyclines + Colestipol

Colestipol can reduce the absorption of tetracycline by about a half. Information about other tetracyclines is lacking but it seems likely that they will interact similarly.

Clinical evidence

Colestipol 30 g taken either in 180 mL of water or orange juice reduced the absorption of a single 500-mg dose of oral **tetracycline** in 9 healthy subjects by 54 to 56%, as measured by recovery in the urine.¹

Mechanism

Colestipol binds to bile acids in the gut and can also bind with some drugs, thereby reducing their availability for absorption. An *in vitro* study found a 30% binding with tetracycline.² The presence of citrate ions in the orange juice, which can also bind to colestipol, appears not to have a marked effect on the binding of the tetracycline.

Importance and management

An established interaction. Direct information seems to be limited to the report cited, but it is consistent with the way colestipol interacts with other drugs. In practice up to 30 g of colestipol is given daily in single or two divided doses, and tetracycline 250 to 500-mg is given every 6 hours. As other drugs need to be given 1 hour before or 4 hours after colestipol it may be difficult to avoid some mixing in the gut. It seems very probable that a clinically important interaction will occur, but by how much the efficacy of tetracycline is affected seems not to have been determined. Tell patients to separate the dosages as much as possible. Monitor the outcome well. Information about other tetracyclines is lacking but it also seems likely that they will interact similarly, but those that can be given less often may prove easier to administer, although note that doxycycline undergoes enterohepatic recirculation and therefore separating dosages may not be completely effective..

Tetracyclines + Diuretics

It has been recommended by some that the concurrent use of tetracyclines and diuretics should be avoided because of their association with rises in blood urea nitrogen levels.

Clinical evidence, mechanism, importance and management

A retrospective study of patient records as part of the Boston Collaborative Drug Surveillance Program showed that an association existed between tetracycline use with diuretics (not named) and rises in blood urea nitrogen (BUN) levels.¹ Both diuretics and tetracyclines are known to cause rises in BUN levels.² It was suggested that tetracyclines should be avoided in patients taking diuretics when alternative antibacterials could be substituted.¹ However, the results of this study have been much criticised as the authors could not exclude physician bias,^{1,2} they did not define what was meant by 'clinically significant rise in BUN',² they did not state whether or not this rise affected patient outcomes,² they did not measure creatinine levels³ and they did not specify which diuretics were involved.² The patients most affected also had the highest levels of BUN before starting tetracyclines. Tetracyclines alone are known to cause rises in BUN, especially where a degree of renal impairment exists, although it has been suggested that **doxycycline** is less prone to this effect.⁴ It would seem that tetracyclines and diuretics may be used together safely, although it would be wise to give thought to the patient's renal function.

4. Alexander MR. Tetracyclines and rises in urea nitrogen. *JAMA* (1972) 221, 713–14.

Tetracyclines + Food or Drinks

The calcium in food can complex with tetracycline to reduce its absorption. This is particularly notable with dairy products, which can reduce the absorption of the tetracyclines by up to 80%, thereby reducing or even abolishing their therapeutic effects. Doxycycline and minocycline are less affected by dairy products (25 to 30% reduction). Orange juice and coffee do not interact with tetracycline.

Clinical evidence, mechanism, importance and management

(a) Dairy products

1. *Demeclocycline*. The serum levels of a 300-mg dose of demeclocycline were 70 to 80% lower in 4 subjects given dairy products, when compared with those who took it with a meal containing no dairy products. The dairy products used were either 8 oz (about 250 mL) of **fresh pasteurized milk**, 8 oz of **buttermilk** or 4 oz of **cottage cheese**.¹

2. *Doxycycline*. The plasma doxycycline levels were reduced by 20%, from 1.79 to 1.45 micrograms/mL, 2 hours after a single 100-mg oral dose was taken with 240 mL of **milk**.² Another study in 9 healthy subjects found a 30% reduction in the absorption, and a 24% reduction in the peak serum levels of doxycycline 200 mg when it was taken with 300 mL of **fresh milk**.³ However, two other studies suggest that the absorption of 200 mg of doxycycline is unaffected by milk,^{4,5} although in one the half-life was almost halved and the clearance increased.⁵

3. *Methacycline*. In one study 300 mL of **milk** reduced the absorption of methacycline 300 mg by about 63%.⁴

4. *Minocycline*. About 180 mL (6 oz) of **homogenised milk** reduced the absorption of minocycline 100 mg by 27% in one study.⁶

5. *Oxytetracycline*. In one study 300 mL of **milk** reduced the absorption of oxytetracycline 500 mg by about 64%.⁴

6. *Tetracycline*. About 180 mL (6 oz) of **homogenised milk** reduced the absorption of tetracycline hydrochloride 250 mg by 65% in one study.⁶ In another study the absorption of tetracycline 500 mg was reduced by about 50% by 300 mL of **milk**.⁴

(b) Other calcium-containing foods or drinks

A study in 9 healthy subjects found that 200 mL of **orange juice** or **coffee** (milk content, if any, unstated) did not significantly affect the bioavailability of a single 250-mg dose of **tetracycline**. This is despite the fact that **orange juice** contains 35 to 70 mg calcium per 100 mL.⁷

Tetracycline 250 mg was given to 9 healthy subjects with 200 mL of water on an empty stomach. The **tetracycline** bioavailability was compared with its administration after a **standard meal** (two slices of bread, ham, tomato, and water, containing 145 mg calcium) and a **Mexican meal** (two tortillas, beans, two eggs, tomato and water, containing 235 mg calcium). The cumulative amounts of **tetracycline** excreted in the urine at 72 hours were about 151 mg (fasting), 90 mg (**standard meal**) and 68 mg (**Mexican meal**).⁸ The absorption of a 300-mg dose of **demeclocycline** was not affected when it was given with a meal not containing dairy products,¹ and **doxycycline** seems to be minimally affected by food not containing dairy products.²

Mechanism

The tetracyclines have a strong affinity for the calcium ions that are found in abundance in dairy products and some foodstuffs. The tetracycline/calcium chelates formed are much less readily absorbed from the gastrointestinal tract and as a result the serum tetracycline levels achieved are much lower. Some tetracyclines have a lesser tendency to form chelates, which explains why their serum levels are reduced to a smaller extent.⁹

Orange juice appears not to interact, despite its calcium content, because at the relevant pH values in the gut, the calcium is bound to components within the orange juice (citric, tartaric and ascorbic acids) and is not free to combine with the tetracycline.⁷

Importance and management

Well documented and very well established interactions of clinical importance. Reductions in serum tetracycline levels of 50 to 80% caused by calcium-rich foods are sufficiently large to reduce or even abolish their

antibacterial effects. For this reason tetracyclines should not be taken with milk or dairy products such as yoghurt or cheese. Separate the ingestion of these foods and tetracycline as much as possible. In the case of iron, which interacts by the same mechanism, 2 to 3 hours is enough. Doxycycline^{3,10} and minocycline⁶ are not affected as much by dairy products (reductions of about 25 to 30%) and in this respect have some advantages over other tetracyclines.

It is usual to recommend that tetracyclines are taken 1 hour before or 2 hours after food (which would be expected to contain at least some calcium), to minimise admixture in the gut and thereby reduce the effects of the interaction. The separation is something of a compromise, because food can help to minimise the gastric irritant effects of the tetracyclines.

Tetracyclines + H₂-receptor antagonists

Cimetidine reduces the absorption of tetracycline but does not appear to affect its serum levels. Ranitidine seems not to affect the bioavailability of doxycycline. Information about other tetracyclines and H₂-receptor antagonists is lacking, but there would seem to be no reason to suspect that they will interact.

Clinical evidence, mechanism, importance and management

A study in 5 subjects found that **cimetidine** 200 mg three times daily and 400 mg at bedtime for 3 days reduced the absorption of a single 500-mg dose of a **tetracycline** capsule by about 30%, but had no effect when the **tetracycline** was given as a solution.¹ However, when **tetracycline** as either a tablet or a suspension was given to 6 subjects with **cimetidine** 1.6 g daily for 6 days, no changes in the plasma levels of **tetracycline** were seen.² Similar results were found in another study.³

In 10 healthy subjects, the bioavailability of **doxycycline** 200 mg was not altered by three 150-mg doses of **ranitidine**.⁴

No special precautions would seem necessary with either combination. Information about other tetracyclines seems to be lacking, but there would seem to be no reason to suspect that they will interact.

Tetracyclines + Iron compounds

The absorption of both the tetracyclines and iron compounds is markedly reduced by concurrent use, leading to reduced serum levels of the tetracyclines. Their therapeutic effectiveness may be reduced or even abolished.

Clinical evidence

(a) Effect on tetracyclines

An investigation in 10 healthy subjects given single oral doses of tetracyclines showed that **ferrous sulfate** 200 mg decreased the serum antibacterial levels as follows: **doxycycline** 200 mg, 80 to 90%; **methacycline** 300 mg, 80 to 85%; **oxytetracycline** 500 mg, 50 to 60% and **tetracycline** 500 mg, 40 to 50%.¹ Another study in 2 groups of 8 healthy subjects found that **ferrous sulfate** 300 mg reduced the absorption of **tetracycline** and **minocycline** by 81% and 77%, respectively.²

Other studies found that in some instances iron caused the tetracycline serum levels to fall below minimum bacterial inhibitory concentrations.^{3,4} If the iron was given 3 hours before or 2 hours after most tetracyclines the serum levels were not significantly reduced.^{3,5} However, even when the iron was given up to 11 hours after **doxycycline**, serum concentrations were still lowered by 20 to 45%.⁵ In contrast to this, another study found that four doses of **ferrous sulfate** (each equivalent to 80 mg of elemental iron) starting 11.5 hours after doxycycline did not affect the absorption of a 200-mg dose of **doxycycline**, and only reduced the AUC of a 100-mg dose of **doxycycline** by 17%.⁶

(b) Effect on iron

When **ferrous sulfate** 250 mg (equivalent to 50 mg of elemental iron) was given with **tetracycline** 500 mg, the absorption of iron was reduced by up to 78% in healthy subjects, and up to 65% in those with depleted iron stores.^{7,8}

Mechanism

The tetracyclines have a strong affinity for iron and form poorly soluble tetracycline-iron chelates, which are much less readily absorbed by the gut, and as a result the serum tetracycline levels achieved are much lower.^{9,10} There is also less free iron available for absorption. Separating the administration of the two prevents their admixture.^{3,4} However, doxycycline undergoes enterohepatic recycling, which could affect any attempt to keep the iron and antibacterial apart, although the significance of the enterohepatic recycling has been said to be minimal.⁶ Even when given intravenously the half-life of doxycycline is reduced.⁵ The different extent to which iron compounds interact with the tetracyclines appears to be a reflection of their ability to liberate ferrous and ferric ions, which are free to combine with the tetracycline.¹¹

Importance and management

The interactions between the tetracyclines and iron compounds are well-documented, well-established, and of clinical importance. The 30 to 90% reductions in serum tetracycline levels that are caused by iron are so large that tetracycline levels may fall below the MIC.⁴ However, the extent of the reductions depends on a number of factors.

- *the particular tetracycline used:* tetracycline and oxytetracycline in the study cited above were the least affected.¹
- *the time-interval between the administration of the two drugs:* giving the iron 3 hours before or 2 to 3 hours after the antibacterial is satisfactory with tetracycline itself,³ but one study found that even 11 hours was inadequate for doxycycline.
- *the particular iron preparation used:* with tetracycline the reduction in serum levels with ferrous sulfate was 80 to 90%, with **ferrous fumarate, succinate and gluconate**, 70 to 80%; with **ferrous tartrate**, 50%; and with **ferrous sodium edetate**, 30%. This was with doses containing equivalent amounts of elemental iron.¹¹

The interaction can therefore be accommodated by separating the dosages as much as possible. It would also seem logical to choose one of the iron preparations causing minimal interference, but it seems unlikely that there will be a clinically significant difference between those that are commonly available (i.e. sulfate, fumarate and gluconate).

Only tetracycline, oxytetracycline, methacycline, minocycline and doxycycline have been shown to interact with iron, but it seems reasonable to expect that the other tetracyclines will behave in a similar way.

Tetracyclines + Kaolin-pectin

Kaolin-pectin reduces the absorption of tetracycline by about 50%.

Clinical evidence, mechanism, importance and management

Healthy subjects were given **tetracycline** 250 mg as a solution or as a capsule, with and without 30 mL of kaolin-pectin (*Kaopectate*). The absorption of both formulations was reduced by about 50% by the kaolin-pectin. Even when the kaolin-pectin was given 2 hours before or after the **tetracycline**, the drug absorption was still reduced by about 20%.¹ The likely reason for this interaction is that **tetracycline** becomes adsorbed onto the kaolin-pectin so that less is available for absorption.

If these two drugs are given together, consider separating the dosages by at least 2 hours to minimise admixture in the gut. It may even then be necessary to increase the **tetracycline** dosage. Information about other tetracyclines is lacking, but be aware that they may interact similarly.

- Gouda MW. Effect of an anti-diarrhoeal mixture on the bioavailability of tetracycline. *Int J Pharmaceutics* (1993) 89, 75–7.

Tetracyclines + Metoclopramide

Metoclopramide 20 mg was found to double the rate of absorption and slightly reduce the maximum serum levels of a single 500-mg dose of tetracycline in 4 patients.¹ This appears to be of little clinical importance.

- Nimmo J. The influence of metoclopramide on drug absorption. *Postgrad Med J* (1973) 49 (July Suppl), 25–8.

Tetracyclines + Quinapril

The absorption of oral tetracycline is reduced by the magnesium carbonate excipient in some quinapril formulations.

Clinical evidence

Quinapril, formulated as *Accupro* also contains **magnesium carbonate** (250 mg in a 40 mg quinapril capsule, 47 mg in a 5 mg capsule). A pharmacokinetic study in 12 healthy subjects investigating the potential interaction between the **magnesium carbonate** in these capsules and **tetracycline** found that single doses of both of these formulations of quinapril markedly reduced the **tetracycline** absorption. The 5 mg and 40 mg quinapril capsules reduced the **tetracycline** AUC by 28% and 37%, respectively, and the maximum serum levels were reduced by 25% and 34%, respectively.¹

Mechanism

The reason for these reductions in tetracycline levels is that the magnesium carbonate and the tetracycline form a less soluble chelate in the gut which is less well absorbed (see 'Tetracyclines + Antacids', p.345).

Importance and management

An established interaction but the extent of the reduction is only moderate and its clinical importance is uncertain. However, the authors of the study recommend that the concurrent use of this formulation of quinapril and tetracycline should be avoided.¹ This is repeated by the manufacturers.² Other

tetracyclines would be expected to behave similarly. One possible way to accommodate this interaction (as with the antacid interaction) is to separate the dosages as much as possible (by about 2 to 3 hours) to minimise admixture in the gut.

- Accupro (Quinapril hydrochloride). Pfizer Ltd. UK Summary of product characteristics, March 2007.

Tetracyclines + Sucralfate

On theoretical grounds the absorption of tetracycline may possibly be reduced by sucralfate, but clinical confirmation of this appears to be lacking.

Clinical evidence, mechanism, importance and management

The manufacturers of sucralfate, point out that it may reduce the bioavailability of **tetracycline**, probably because the two become bound together in the gut, thereby reducing absorption. It is suggested that they should be given 2 hours apart to minimise their admixture in the gut.¹ There do not appear to be any clinical reports in the literature confirming this potential interaction so it has yet to be shown to be clinically relevant.

However, the *in vitro* formation of a **tetracycline**-sucralfate acid complex has been investigated in *animal* studies and indicates that the interaction may be clinically useful for *Helicobacter pylori* eradication because of direct delivery of **tetracycline** to the gastric mucosa for extended periods of time.^{2–4}

Tetracyclines + Thiomersal

Patients being treated with tetracyclines who use contact lens solutions containing thiomersal may experience an inflammatory ocular reaction.

Clinical evidence, mechanism, importance and management

The observation that 2 patients had ocular reactions (red eye, irritation, blepharitis) when they used a 0.004% thiomersal-containing contact lens solution while taking a tetracycline, prompted further study of this interaction. A questionnaire revealed another 9 similar cases that suddenly began shortly after patients who had used thiomersal containing solutions for 6 months without problem started to take a tetracycline. In each case the reaction cleared when the thiomersal or the tetracycline was stopped. The same reaction was also clearly demonstrated in *rabbits*.¹ The reasons are not understood. It would seem prudent to avoid the concurrent use of these compounds.

- Crook TG, Freeman JJ. Reactions induced by the concurrent use of thiomersal and tetracycline. *Am J Optom Physiol Opt* (1983) 60, 759–61.

Tetracyclines + Zinc compounds

The absorption of tetracycline can be reduced by as much as 50% by zinc sulphate. Separating their administration as much as possible minimises the effects of this interaction. Doxycycline interacts minimally with zinc.

Clinical evidence

When **tetracycline** 500 mg was given to 7 subjects either alone or with zinc sulfate 200 mg (equivalent to 45 mg of elemental zinc) the **tetracycline** serum concentrations and AUC were reduced by about 30 to 40%.¹

This study was repeated with **doxycycline** 200 mg and zinc, but **doxycycline** absorption was not affected.¹ A reduction in **tetracycline** absorption of more than 50% has been seen in other studies when zinc was given concurrently.^{2,3}

Tetracycline appears to cause minimal reductions in zinc concentrations.²

Mechanism

Zinc (like iron, calcium, magnesium and aluminium) forms a relatively stable and poorly absorbed chelate with tetracycline in the gut, which results in a reduction in the amount of antibacterial available for absorption.^{4,5}

Importance and management

An established and moderately well documented interaction of clinical importance. Separate the administration of tetracycline and zinc compounds as much as possible to minimise admixture in the gut. In the case of 'iron', (p.348), which interacts by the same mechanism, 2 to 3 hours is usually enough. Alternatively it would seem that doxycycline is less affected, so it may be a useful alternative.¹ Other tetracyclines would be expected to interact like tetracycline itself, but this needs confirmation. The small reduction in serum zinc concentrations is likely to be of little practical importance.²

Tetracyclines; Doxycycline + Dimeticone

A study in 8 healthy subjects found that dimeticone 2.25 g did not alter the bioavailability of a single 200-mg dose of doxycycline.¹

1. Bistue C, Perez P, Becquart D, Vinçon G, Albin H. Effet du diméticone sur la biodisponibilité de la doxycycline. *Thérapie* (1987) 42, 13–16.

Tetracyclines; Doxycycline + Rifampicin (Rifampin)

Rifampicin may cause a marked reduction in doxycycline levels, which has led to treatment failures in some cases.

Clinical evidence

Rifampicin 10 mg/kg daily caused a considerable reduction in the serum levels of doxycycline 200 mg daily in 7 patients. The reduction was very marked in 4 patients but not significant in the other 3 patients. The AUC of doxycycline was reduced by 54%, its clearance was approximately doubled, and its half-life was reduced from about 14 hours to 9 hours.^{1,2}

Five patients with brucellosis taking doxycycline 200 mg daily had a reduction in the doxycycline half-life from 14.52 to 7.99 hours when they took rifampicin 200 mg daily.³ Another study of 20 patients treated for brucellosis found that the mean AUC of doxycycline was nearly 60% lower in the presence of rifampicin as opposed to streptomycin. There were no treatment failures in the patients taking doxycycline and streptomycin, but 2 treatment failures occurred in the 10 patients taking doxycycline and rifampicin.⁴

A meta-analysis of 6 studies involving 544 patients with brucellosis found a significantly higher numbers of relapses and lower numbers of initial cures if doxycycline was given with rifampicin rather than streptomycin.⁵

Mechanism

Not established, but it seems almost certain that the rifampicin (a known potent enzyme inducer) increases the metabolism of the doxycycline thereby reducing its levels.

Importance and management

The interaction between doxycycline and rifampicin is established and of clinical importance. Monitor the effects of concurrent use and increase the doxycycline dosage as necessary. No clinically important adverse interaction appears to occur between doxycycline and streptomycin.

Tetracyclines; Minocycline + Ethinylestradiol

There is some evidence that ethinylestradiol may accentuate the facial pigmentation that can be caused by minocycline.

Clinical evidence

Two teenage sisters with severe acne vulgaris, taking minocycline 50 mg four times daily for 14 days then 50 mg twice daily thereafter, developed dark-brown pigmentation in their acne scars when they took *Dianette* (cyproterone acetate and ethinylestradiol) for about 15 months.¹ The type of pigmentation was not identified because they both declined to have a biopsy, but in other cases it has been found to consist of haemosiderin, iron, melanin and a metabolic degradation product of minocycline.¹ Two other reports describe facial pigmentation in patients taking minocycline, two of whom were taking oral contraceptives containing ethinylestradiol.^{2,3} Other young women who have developed minocycline pigmentation may also have been taking **oral contraceptives** because they fall into the right age-group, but this is not specifically stated in any of the reports.

Mechanism

Not understood. It seems possible that the facial pigmentation (melasma, chloasma) that can occur with oral contraceptives may have been additive with the effects of the minocycline.¹

Importance and management

Evidence is very limited but it has been suggested that all patients given long-term minocycline treatment should be well screened for the development of pigmentation, particularly if they are taking other drugs such as the oral contraceptives that are known to induce hyperpigmentation.¹ Remember also that very rarely contraceptive failure has been associated with the use of minocycline and other tetracyclines, see 'Hormonal contraceptives + Antibacterials; Tetracyclines', p.983.

Tetracyclines; Minocycline + Phenothiazines

An isolated report describes black galactorrhoea, which was attributed to an interaction between minocycline and perphenazine.

Clinical evidence, mechanism, importance and management

A woman taking minocycline 100 mg twice daily for 4 years to control pustulocystic acne, and also taking **perphenazine**, amitriptyline and diphenhydramine, developed irregular darkly pigmented macules in the areas of acne scarring and later began to produce droplets of darkly coloured milk. The milk was found to contain macrophages filled with positive iron-staining particles, assumed to be haemosiderin. The situation resolved when the drugs were withdrawn: the galactorrhoea within a week

and the skin staining over 6 months.¹ Galactorrhoea is a known adverse effect of the phenothiazines and is due to an elevation of serum prolactin levels caused by the blockade of dopamine receptors in the hypothalamus. The dark colour appeared to be an adverse effect of the **minocycline**, which can cause haemosiderin to be deposited in cells, and in this instance to be scavenged by the macrophages that were then secreted in the milk. The general significance of this isolated case is unknown, but it seems likely to be small.

1. Basler RSW, Lynch PJ. Black galactorrhea as a consequence of minocycline and phenothiazine therapy. *Arch Dermatol* (1985) 121, 417–18.

Trimethoprim + Food or Guar gum

Guar gum and food can modestly reduce the absorption of trimethoprim suspension.

Clinical evidence, mechanism, importance and management

In a study over a 24-hour period, 12 healthy subjects were given a single 3-mg/kg oral dose of a trimethoprim suspension with food, with or without guar gum. The mean peak serum levels were reduced by food and by food given with 5 g of guar gum by 21% and 15%, respectively. Food, both with guar gum and alone, reduced the AUC of trimethoprim by about 22%.¹ The greatest individual reductions in peak serum levels and AUC were 44% and 36%, respectively with food, and 48% and 38%, respectively, with food and guar gum.¹ The reasons are not understood but it may be due to adsorption of the trimethoprim onto the food and guar gum.

The clinical importance of this interaction is uncertain but a marked reduction in absorption can occur in some individuals. However, trimethoprim is generally taken without regard to food, so this interaction would not appear to be significant in most patients.

1. Hoppu K, Tuomisto J, Koskimies O and Simell O. Food and guar decrease absorption of trimethoprim. *Eur J Clin Pharmacol* (1987) 32, 427–9.

Vancomycin + Colestyramine

Colestyramine may bind with vancomycin in the gut.

Clinical evidence, mechanism, importance and management

Colestyramine binds with vancomycin within the gut, thereby reducing its biological activity (about tenfold according to *in vitro* studies). The combination of vancomycin and colestyramine used to be used in antibiotic-associated colitis (now no longer recommended) and to overcome this interaction it was suggested that a vancomycin dosage of 2 g daily should be used, and that administration of the vancomycin and colestyramine should be separated as much as possible to minimise their admixture in the gut.¹ It is usually recommended that other drugs should be taken 1 hour before or 4 to 6 hours after colestyramine.

1. Taylor NS, Bartlett JG. Binding of *Clostridium difficile* cytotoxin and vancomycin by anion-exchange resins. *J Infect Dis* (1980) 141, 92–7.

Vancomycin + Dobutamine, Dopamine and Furosemide

There is some evidence to suggest that dobutamine, dopamine and furosemide can markedly reduce vancomycin serum levels following cardiac surgery.

Clinical evidence, mechanism, importance and management

A retrospective evaluation of the records of 18 critically ill patients in intensive care units following cardiac surgery, suggested that drugs with important haemodynamic effects (dopamine, dobutamine, furosemide) may lower the serum levels of vancomycin. It was noted that withdrawal of the interacting drugs was followed by an increase of in the minimum steady-state serum levels of vancomycin, from 8.79 mg/L to 13.3 mg/L, despite no major changes in body weight or estimated renal clearance. This resulted in a mean dose reduction of 4.26 mg/kg per day.

It is suggested that this interaction occurs because these drugs increase cardiac output, which increases the renal clearance of vancomycin, and

therefore reduces its serum levels.¹ The clinical implication is that in this particular situation creatinine clearance is a less good predictor of vancomycin clearance and consequently dose. Good therapeutic drug monitoring is needed to ensure that serum vancomycin levels are optimal. More confirmatory study is needed.

1. Pea F, Porreca L, Baraldo M, Furlanut M. High vancomycin dosage regimens required by intensive care unit patients cotreated with drugs to improve haemodynamics following cardiac surgical procedures. *J Antimicrob Chemother* (2000) 45, 329–35.

Vancomycin + Indometacin

Indometacin reduces the renal clearance of vancomycin in premature neonates. This interaction does not appear to have been studied in adults.

Clinical evidence, mechanism, importance and management

In 6 premature neonates with patent ductus arteriosus given indometacin, the half-life of vancomycin 15 to 20 mg/kg given intravenously over 1 hour was found to be 24.6 hours, compared with only 7 hours in 5 other premature neonates without patent ductus arteriosus who were not given indometacin.¹ The reason for this effect is uncertain but it seems possible that the indometacin reduces the renal clearance of vancomycin. The authors of this report suggest that the usual vancomycin maintenance dosage should be halved if indometacin is also being used. If vancomycin therapeutic drug monitoring is possible it would be advisable to take levels and adjust the vancomycin dose accordingly. It is not known whether indometacin has the same effect on vancomycin in adults.

1. Spivey JM, Gal P. Vancomycin pharmacokinetics in neonates. *Am J Dis Child* (1986) 140, 859.

Vancomycin + Nephrotoxic or Ototoxic drugs

The risk of nephrotoxicity and ototoxicity with vancomycin may possibly be increased if it is given with other drugs with similar toxic effects.

Clinical evidence, mechanism, importance and management

Vancomycin is both potentially nephrotoxic and ototoxic, and its manufacturers therefore suggest that it should be used with particular care, or avoided in patients with renal impairment or deafness.¹ They also advise the avoidance of other drugs that have nephrotoxic potential, because the effects could be additive. They list **amphotericin B**, **aminoglycosides**, **bacitracin**, **colistin**, **polymyxin B**, **viomycin** and **cisplatin**. They also list **etacrynic acid** and **furosemide** as potentially aggravating ototoxicity.

The monograph 'Aminoglycosides + Vancomycin', p.291 outlines some of the evidence that additive nephrotoxicity can occur with the **aminoglycosides**, but there seems to be no direct evidence about the other drugs. Even so, the general warning issued by the manufacturers to monitor carefully is a reasonable precaution.

1. Vancomycin hydrochloride. Mayne Pharma plc. UK Summary of product characteristics, December 2003.

Vancomycin + Theophylline

Theophylline appears not to interact with vancomycin in premature infants.

Clinical evidence, mechanism, importance and management

Five premature infants (mean gestational age of 25 weeks and weighing 1.1 kg) were given theophylline (serum levels of 6.6 mg/L) for apnoea of prematurity. It was found that the pharmacokinetics of vancomycin 20 mg/kg given every 12 to 18 hours for suspected sepsis were unchanged by the presence of the theophylline, when compared with previously published data on the pharmacokinetics of vancomycin in neonates.¹ There seems to be no other clinical reports about vancomycin with theophylline, and nothing to suggest that vancomycin has any effect on the serum levels of theophylline.

1. Ilagan NB, MacDonald JL, Liang K-C, Womack SJ. Vancomycin pharmacokinetics in low birth weight preterm neonates on therapeutic doses of theophylline. *Pediatr Res* (1996) 39, 74A.

Anticholinesterases

The anticholinesterase drugs (or cholinesterase inhibitors) can be classified as **centrally-acting, reversible** inhibitors such as donepezil (used in the treatment of Alzheimer's disease), **reversible** inhibitors with **poor CNS penetration**, such as neostigmine (used in the treatment of myasthenia gravis), or **irreversible** inhibitors, such as ecothiopate and metrifonate. The centrally-acting anticholinesterases and the reversible anticholinesterases form the basis of this section, and these are listed in 'Table 11.1', (see below). Interactions where the anticholinesterases are affecting other drugs are covered elsewhere in the publication.

Due to their differing pharmacokinetic characteristics, the centrally-acting anticholinesterases have slightly different interaction profiles, although they share a number of common pharmacodynamic interactions. Tacrine¹ is metabolised by the cytochrome P450 isoenzyme CYP1A2, and so interacts with 'fluvoxamine', (p.356), a potent inhibitor of this isoenzyme, whereas there is no evidence to suggest the other centrally acting anticholinesterases do. On the other hand, donepezil¹ and galantamine¹ are metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP2D6, and so they may interact with 'ketoconazole', (p.353) and 'quinidine', (p.356), respectively, whereas tacrine would not be expected to do so. Rivastigmine,¹ which is metabolised by conjugation, seems relatively free of *pharmacokinetic* interactions. Consideration of concurrent drug use would

therefore seem to be an important factor in the choice of centrally-acting anticholinesterase.

Note that, organophosphorus compounds such as insecticides are also anticholinesterases.

1. Jann MW, Shirley KL, Small GW. Clinical pharmacokinetics and pharmacodynamics of cholinesterase inhibitors. *Clin Pharmacokinet* (2002) 719-39.

Table 11.1 Anticholinesterase drugs; reversible

<i>Centrally-acting inhibitors used principally for Alzheimer's disease</i>	<i>Inhibitors with poor CNS penetration used principally for myasthenia gravis</i>
Donepezil	Ambenonium
Galantamine	Distigmine
Rivastigmine	Edrophonium (mainly used diagnostically)
Tacrine	Neostigmine
	Physostigmine
	Pyridostigmine (also used for glaucoma)

Anticholinesterases; Centrally acting + Antipsychotics

No pharmacokinetic interaction appears to occur between risperidone and donepezil or galantamine, but extrapyramidal symptoms occurred in one patient given donepezil with risperidone. The pharmacokinetics of thioridazine are not affected by donepezil. Two isolated reports describe severe parkinsonism when haloperidol was given with tacrine.

Clinical evidence, mechanism, importance and management

(a) Donepezil

1. *Risperidone*. In a randomised, crossover study 24 healthy subjects were given risperidone 500 micrograms twice daily with donepezil 5 mg daily. Although donepezil caused slight changes in the levels of risperidone and 9-hydroxyrisperidone they did not exceed the limits for bioequivalence. Concurrent use did not increase adverse effects.¹ In one study 16 schizophrenic patients taking risperidone were given donepezil 5 mg daily for 7 days without any alteration in their risperidone and 9-hydroxyrisperidone levels. The pharmacokinetics of donepezil were similar in the risperidone-treated patients and healthy controls taking donepezil alone.² However, a case report describes the emergence of parkinsonian symptoms in an 80-year-old woman after she was given donepezil 5 mg daily, with risperidone 1 mg daily added 12 days later. Risperidone was discontinued and she recovered without treatment.³ This appears to be an isolated report and its general significance is therefore unknown.

2. *Thioridazine*. In a crossover study 11 healthy subjects were given donepezil 5 mg daily for 16 days, with a single 50-mg dose of thioridazine on the final day. Although donepezil did not affect the pharmacokinetics of thioridazine or its effects on the QT interval, thioridazine, either alone or in combination with donepezil, was poorly tolerated and resulted in postural hypotension and increases in heart rate.⁴ It would therefore seem prudent to use an alternative antipsychotic wherever possible.

(b) Galantamine

In a randomised, crossover study 16 patients over 60-years-old were given a 14-day dose escalation of galantamine, after which they were given galantamine 12 mg twice daily with risperidone 500 micrograms twice daily, both for 13 doses. Although galantamine caused slight changes in the levels of risperidone and 9-hydroxyrisperidone, their combined level (the active moiety) was unchanged. The combination was well-tolerated so no additional precautions would seem to be necessary on concurrent use.⁵

(c) Tacrine

An isolated report describes an 87-year-old man with dementia, who started taking haloperidol 5 mg daily for symptoms of agitation and paranoia. Doses of greater than 5 mg were noted to cause extrapyramidal symptoms. After 10 days, tacrine 10 mg four times daily was added. Within 72 hours he developed severe parkinsonian symptoms, which resolved within 8 hours of stopping both drugs.⁶ Another isolated report describes a woman taking haloperidol 10 mg daily who similarly developed a disabling parkinsonian syndrome within one week of starting tacrine 10 mg four times daily.⁷ One possible reason is that the haloperidol blocked the dopamine receptors in striatum, thereby increasing striatal acetylcholine activity, which was further increased by the tacrine.¹ It is not clear whether patients given other dopamine receptor blocking drugs and tacrine would similarly show this reaction.

Anticholinesterases; Centrally acting + CYP3A4 inducers and inhibitors

Ketoconazole modestly increases the levels of donepezil. Even though this was not considered to be clinically significant, the manufacturers suggest that potent inhibitors of CYP3A4 will raise donepezil levels and inducers of CYP3A4 will lower donepezil levels. Galantamine levels are also increased by ketoconazole.

Clinical evidence, mechanism, importance and management

(a) Donepezil

Donepezil 5 mg daily was given to 18 healthy subjects with ketoconazole 200 mg daily, which is a specific and potent inhibitor of the cytochrome P450 isoenzyme CYP3A4. After one week of concurrent use, the maximum serum levels and AUC of donepezil were increased by less than 30%. Donepezil had no effect on the pharmacokinetics of ketoconazole.¹ None of the increases in donepezil levels were considered to be clinically relevant, and the authors suggest that no dose modifications will be required with ketoconazole or other CYP3A4 inhibitors.¹ Despite this, the UK manufacturer recommends that donepezil should be used with CYP3A4 inhibitors with care, and they specifically name itraconazole and erythromycin. Furthermore, both the US and UK manufacturers suggest that CYP3A4 inducers (they name carbamazepine, dexamethasone, phenobarbital, phenytoin and rifampicin) may lower donepezil levels.^{2,3} Be aware that a reduction in donepezil levels is possible with these drugs, but that a clinically significant interaction seems unlikely.

(b) Galantamine

The manufacturers note that ketoconazole increased the bioavailability of galantamine by 30%, probably as a result of CYP3A4 inhibition. They therefore predict that ketoconazole (and other potent CYP3A4 inhibitors such as ritonavir) may increase the incidence of nausea and vomiting with galantamine, and suggest that, based on tolerability, a decrease in the maintenance dose be considered.^{4,5} Whether this is in fact necessary in practice remains to be established. Erythromycin, a moderate CYP3A4 inhibitor, only increased galantamine bioavailability by about 10%,^{4,5} and so a clinically significant interaction would not be expected.

Anticholinesterases; Centrally acting + Diazepam

Diazepam does not appear to affect the pharmacokinetics of tacrine or rivastigmine.

Clinical evidence, mechanism, importance and management

In a small study a single 2-mg dose of diazepam did not affect the pharmacokinetics of tacrine 20 mg every 6 hours, when compared with subjects not taking diazepam.¹ Similarly the manufacturers of rivastigmine say that no pharmacokinetic interaction has been seen with diazepam in healthy subjects.^{2,3} No special precautions would seem necessary if diazepam is given with tacrine or rivastigmine.

Anticholinesterases; Centrally acting + H₂-receptor antagonists

Cimetidine possibly increases the effects of tacrine. Cimetidine does not appear to significantly affect the pharmacokinetics of donepezil or galantamine, and ranitidine does not affect the bioavailability of galantamine.

Clinical evidence, mechanism, importance and management

(a) Donepezil

In one study, donepezil 5 mg daily was given to 18 healthy subjects with cimetidine 800 mg daily. It was found that after one week of concurrent use the maximum serum levels and AUC of donepezil were increased by 13% and 10%, respectively. Donepezil had no effect on the pharmacokinetics of cimetidine.¹ None of the increases in donepezil levels were considered to be clinically relevant.¹

(b) Galantamine

The US manufacturer notes that when a single 40-mg dose of galantamine was given on day 2 of a 3-day course of cimetidine 800 mg daily the bioavailability of galantamine was increased by 16%, which would not be expected to be clinically significant. Ranitidine 300 mg daily had no effect on galantamine bioavailability.² No interaction would therefore be expected with any H₂-receptor antagonist.

(c) Tacrine

Cimetidine 300 mg four times daily for 2 days decreased the clearance of a single 40-mg dose of tacrine by 30%, and increased the AUC and maximum level by about 35% in 11 healthy subjects.³ The manufacturers of tacrine also say that cimetidine increases the AUC and the maximum plasma level of tacrine by 64% and 54%, respectively.⁴ The reason is not known, but it seems probable that cimetidine (a well-recognised liver enzyme inhibitor) reduces the metabolism of tacrine by the cytochrome P450 isoenzyme CYP1A2 (see also 'fluvoxamine', (p.356)).³ An increase in the effects and possibly adverse effects of tacrine (nausea, vomiting, diarrhoea) seems possible. One patient in the study mentioned³ had to be withdrawn due to nausea and vomiting, but none of the other 11 subjects particularly suffered from adverse effects. More study is needed to find out whether this interaction is generally clinically important. If the suggested mechanism of interaction is correct, the other H₂-receptor antagonists would not be expected to interact. Tacrine also increases the secretion of gastric acid but it is not clear whether this would oppose the actions of the H₂-receptor antagonists.

Anticholinesterases; Centrally acting + HRT

A small study suggests that HRT treatment can almost double the serum levels of tacrine. Limited evidence suggests that oestrogens do not affect rivastigmine pharmacokinetics.

Clinical evidence, mechanism, importance and management

Following the observation that HRT appeared to increase the response of postmenopausal Alzheimer's patients to tacrine, a randomised, crossover, placebo-controlled study was undertaken in 10 healthy women who were given HRT (estradiol 2 mg with levonorgestrel 250 micrograms daily) with a single 40-mg dose of tacrine on day 10. The HRT increased the mean tacrine AUC by 60%, increased the mean peak serum level of tacrine by 46% and reduced the tacrine clearance by 31%. The AUC of one individual was increased threefold. These pharmacokinetic changes are

thought to occur because HRT reduces the metabolism of the tacrine to its main metabolite (1-hydroxytacrine) by the cytochrome P450 isoenzyme CYP1A2.¹ The importance of this interaction is still uncertain, but increased tacrine levels would be expected to increase its adverse effects. Be alert therefore for the need to use a smaller tacrine dose in patients given HRT. More study of this interaction is needed.

In contrast, analysis of population data from 70 subjects found that oestrogens did not affect rivastigmine pharmacokinetics.²

2. Exelon (Rivastigmine tartrate). Novartis Pharmaceuticals Corp. US Prescribing information, June 2006.

Anticholinesterases; Centrally acting + Memantine

Memantine does not appear to attenuate the anticholinesterase effects of donepezil, galantamine, or tacrine, nor affect the pharmacokinetics of galantamine or donepezil.

Clinical evidence, mechanism, importance and management

(a) Donepezil

An *in vitro* study in rats suggested that memantine does not attenuate the anticholinesterase effects of donepezil at therapeutic concentrations.¹ In a later study 19 healthy subjects were given memantine 10 mg before and on the last day of taking donepezil (5 mg daily for 7 days then 10 mg daily for 22 days). The pharmacokinetics of both drugs were not significantly affected by concurrent use, and the effects of donepezil on anticholinesterase were also unaffected.² Furthermore, an efficacy and safety study of one year's duration has reported that the combination is well tolerated and beneficial.³

(b) Galantamine

An *in vitro* study in rats suggested that memantine does not attenuate the anticholinesterase effects of galantamine at therapeutic concentrations.¹ A study in 15 healthy subjects found that the concurrent use of extended-release galantamine 16 mg daily with memantine 10 mg twice daily for 12 days did not affect the pharmacokinetics of galantamine and generally did not increase the incidence of adverse effects, although dizziness may have been more common.⁴

Furthermore, a review of efficacy studies suggested that the effects of galantamine on anticholinesterase are unaffected, that the combination is safe and generally well tolerated.⁵

(c) Tacrine

An *in vitro* study in rats suggested that memantine does not attenuate the anticholinesterase effects of tacrine at therapeutic concentrations.¹

Anticholinesterases + Miscellaneous

A number of drugs can affect myasthenia gravis, often by increasing muscular weakness. This is, strictly speaking, a drug-disease interaction, but such effects may be expected to oppose the actions of the drugs used to treat myasthenia gravis. A number of drugs (e.g. chlorpromazine, methocarbamol, and propafenone) are clearly contraindicated in patients with myasthenia, and, as this is not strictly a drug interaction, they

Table 11.2 Case reports of drugs aggravating or unmasking myasthenia gravis

Drug	Effect seen	Refs
Acetazolamide 500 mg intravenously	Aggravation of muscular weakness in patients with myasthenia gravis taking unnamed anticholinesterases.	1
Ampicillin up to 1.5 g daily	Aggravation of myasthenic symptoms in 2 patients taking pyridostigmine.	2
Aspirin	Mild aggravation of myasthenic symptoms in a patient taking neostigmine.	3
Beta blockers	See Beta blockers + Anticholinesterases, p. 834.	
Chloroquine	Persisting myasthenic symptoms, including muscular weakness, attributed to prior chloroquine use. Development of myasthenic symptoms in 3 patients, one who took chloroquine in overdose.	4-7
Ciprofloxacin	Aggravation of myasthenic symptoms in a patient taking pyridostigmine, and unmasking of myasthenia in one patient.	8, 9
Dipyridamole* 75 mg three times daily	Aggravation of myasthenic symptoms in a patient taking distigmine.	10
Erythromycin 500 mg intravenously	Precipitation of a myasthenic crisis in an undiagnosed 15-year-old girl.	11
Imipenem/cilastatin 500 mg four times daily	Aggravation of myasthenic symptoms in a patient taking pyridostigmine.	12
Ketoprofen 50 mg daily	Aggravation of myasthenic symptoms in a patient taking neostigmine.	3
Lithium carbonate 600 mg daily	Unmasking of myasthenia in one patient.	13
Norfloxacin*	Aggravation of myasthenic symptoms in a patient taking pyridostigmine.	14
Penicillamine	Aggravation of myasthenic symptoms in numerous patients taking anticholinesterases. Amitriptyline and imipramine also implicated in 2 cases.	15-18
Phenytoin 100 mg three times daily	Aggravation of myasthenic symptoms in an untreated patient.	19
Procainamide* 250 mg	Serious aggravation of myasthenic symptoms in a patient taking pyridostigmine. Two other less severe cases also reported.	20, 21
Quinidine* up to 970 mg daily	Mild aggravation of myasthenic symptoms in one patient taking pyridostigmine and another taking neostigmine. Development of myasthenic symptoms in 2 undiagnosed patients.	21-23

are not dealt with here. A number of case reports (see 'Table 11.2', (above)) describe the worsening or unmasking of myasthenia gravis with a range of different drugs. The evidence for many of these interactions is very sparse indeed, and in some instances they are simply rare and isolated cases. It would therefore be wrong to exaggerate their importance, but it would nevertheless be prudent to be alert for any evidence of worsening myasthenia if any of the drugs listed are added to established treatment.

Anticholinesterases + Other drugs that affect acetylcholine

The effects of centrally-acting anticholinesterases (e.g. donepezil) are expected to be additive with those of other anticholinesterases (e.g. neostigmine) and cholinergics (e.g. pilocarpine). The effects of centrally-acting anticholinesterases and drugs with antimuscarinic effects are expected to be antagonistic.

Clinical evidence, mechanism, importance and management

Anticholinesterases raise acetylcholine levels: some are more selective for raising acetylcholine levels in the brain (e.g. **donepezil**), whereas others (e.g. **neostigmine**) have a more generalised effect. Therefore if both drugs are given together their effects may be expected to be additive. Similarly, additive effects may be expected if anticholinesterases are given with cholinergic drugs, such as **bethanechol**, **carbachol**, and **pilocarpine**, which mimic the effects of acetylcholine,¹⁻⁶ and depolarising neuromuscular blockers, which act like acetylcholine to cause depolarisation (see 'Neuromuscular blockers + Anticholinesterases', p. 114, for reports of this interaction).

In contrast, drugs with **antimuscarinic** (anticholinergic) effects (see 'Table 18.2', (p.674)), which block the actions of acetylcholine, would be expected to oppose the actions of the anticholinesterases.

A number of case reports describe an interaction between centrally-acting anticholinesterases and other antimuscarinics. Two patients taking **donepezil** and one taking **rivastigmine** were given **tolterodine** (an antimuscarinic). One patient (taking **donepezil**) developed confusion, while the other two developed delusional states. This is the opposite effect to the predicted interaction (where the anticholinesterase inhibitor may be expected to oppose the antimuscarinic effects of **tolterodine**). The authors suggest that the combination causes 'cholinergic neurogenic hypersensitivity' similar to that seen as a withdrawal reaction to anticholinesterases.⁷ In contrast, a case report describes the successful use of **tolterodine** 6 mg daily in a patient taking **donepezil** 10 mg daily. The authors of this report suggest that, despite the predictions of an interaction, a trial of an **antimuscarinic** for urinary incontinence may be worthwhile in patients taking centrally-acting anticholinesterases.⁸

All of these interactions, additive or antagonistic, are in theory possible, but whether most of them are of real practical importance awaits confirmation. It would certainly be prudent to monitor the concurrent use of any of these potentially interacting groups of drugs.

Anticholinesterases; Centrally acting + Quinidine

Quinidine does not affect the metabolism of tacrine, but is predicted to inhibit the metabolism of donepezil and galantamine.

Clinical evidence, mechanism, importance and management

(a) Donepezil

In vitro study has shown that quinidine inhibits donepezil metabolism, and, as no clinical information is available, the manufacturer suggests care with the combination,¹ as an increase in donepezil levels and adverse effects is theoretically possible.

(b) Galantamine

Quinidine, like paroxetine, is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, an enzyme involved in the metabolism of galantamine. 'Paroxetine', (below) has been shown to increase galantamine levels and therefore quinidine is predicted to do the same. Consequently the manufacturers of galantamine suggest that concurrent treatment with quinidine may result in increased adverse effects (mainly nausea and vomiting), and, if this occurs, a reduction in the maintenance dose of galantamine should be considered.²

(c) Tacrine

Quinidine 83 mg every 8 hours did not affect the clearance of a single 40-mg dose of tacrine in 11 healthy subjects.³ Since quinidine inhibits the cytochrome P450 isoenzyme CYP2D6 in the liver, it may be concluded that

CYP2D6 does not have an important role to play in the metabolism of tacrine and therefore that other drugs that inhibit this enzyme are unlikely to interact with tacrine by this means.

1. Aricept (Donepezil hydrochloride). Eisai Ltd. UK Summary of product characteristics, January 2007.
2. Reminyl (Galantamine hydrobromide). Shire Pharmaceuticals Ltd. UK Summary of product characteristics, July 2005.
3. deVries TM, O'Connor-Semmes RL, Guttendorf RJ, Reece PA, Posvar EL, Sedman AJ, Koup JR, Forgue ST. Effect of cimetidine and low-dose quinidine on tacrine pharmacokinetics in humans. *Pharm Res* (1993) 10 (10 Suppl), S-337.

Anticholinesterases; Centrally acting + SSRIs

Fluvoxamine markedly increases the levels of tacrine, and increases its cholinergic adverse effects, whereas fluoxetine, paroxetine, and sertraline are not expected to interact. Paroxetine and fluoxetine may increase donepezil and galantamine levels. Sertraline does not appear to have a pharmacokinetic interaction with donepezil, and concurrent use seems generally well tolerated; however, one report describes hepatotoxicity, possibly as a result of their concurrent use. Rivastigmine and fluoxetine appear not to interact.

Clinical evidence, mechanism, importance and management

(a) Donepezil

Two case reports suggest that donepezil and **paroxetine** may interact, in one case with an increase in gastrointestinal adverse effects, and the other with increased CNS effects. These adverse effects were thought to occur because **paroxetine** may inhibit donepezil metabolism by the cytochrome P450 isoenzyme CYP2D6.¹ The manufacturer logically predicts that **fluoxetine** could also inhibit the metabolism of donepezil, and until more information is available, they suggest caution with concurrent use of donepezil and CYP2D6 inhibitors.²

In a crossover study 16 healthy subjects were given **sertraline** (50 mg daily increasing after 5 days to 100 mg daily) with donepezil 5 mg daily for 15 days. The pharmacokinetics of both drugs were not significantly altered by concurrent use, and, although there was some indication that digestive adverse effects may have been increased, overall adverse effects were not changed.³ Another study has similarly found that the concurrent use of donepezil and **sertraline** is well tolerated.⁴ A case report describes an 83-year-old woman taking **sertraline** 200 mg daily, who developed drug-induced cholestatic jaundice within 10 days of starting donepezil 5 mg daily. The authors suggest that although this reaction could have been in response to either drug, it may also have been precipitated by their concurrent use. The general significance of this report is unclear.⁵

(b) Galantamine

The manufacturers^{6,7} note that interaction studies have shown that **paroxetine** 20 mg daily for 16 days increased the bioavailability of galantamine by about 40%, by inhibiting galantamine metabolism by the cytochrome P450 isoenzyme CYP2D6. They therefore warn about the increased risk of galantamine adverse effects (in particular nausea and vomiting) if **paroxetine** is added. If such adverse effects develop or worsen, the manufacturers suggest a reduction in the galantamine dosage.⁶ They also predict that other SSRIs that are potent inhibitors of CYP2D6 may interact similarly, and they list **fluoxetine** and **fluvoxamine**,⁶ although it should be noted that **fluvoxamine** is only a weak inhibitor of CYP2D6. Thus far there appear to be no reports of adverse reactions with any of these drugs.

(c) Rivastigmine

The manufacturers of rivastigmine report that in studies in healthy subjects no pharmacokinetic interactions were seen between rivastigmine and **fluoxetine**.^{8,9} No special precautions appear necessary.

(d) Tacrine

Fluvoxamine is an inhibitor of cytochrome P450 isoenzyme CYP1A2, the main isoenzyme involved in the metabolism of tacrine. *In vitro* study showed that **fluvoxamine** is a potent inhibitor of tacrine metabolism, and it was therefore predicted that **fluvoxamine** may dramatically increase tacrine plasma levels in patients.¹⁰ This prediction was confirmed in a placebo-controlled study in 13 healthy subjects who had an eightfold increase in the mean AUC of a single 40-mg dose of tacrine after taking **fluvoxamine** 100 mg for 6 days. A very large increase in the AUC of the hydroxylated metabolites of tacrine, and an eightfold fall in the clearance of tacrine

was also seen. No subjects had any adverse effects when they took tacrine after placebo, but 5 had adverse effects (nausea, vomiting, sweating, and diarrhoea) when they took tacrine after **fluvoxamine**.¹¹ Another pilot study in one individual found that the total clearance of tacrine was reduced about tenfold and its half-life increased tenfold by **fluvoxamine** 100 mg daily.¹² A further study by the same authors found that the clearance of tacrine was reduced by about 85% in 18 healthy subjects taking **fluvoxamine** 50 or 100 mg.¹³ It is likely that standard tacrine doses will be poorly tolerated in the presence of **fluvoxamine** because of cholinergic adverse effects, and a decrease in tacrine dose is probably necessary.¹³ Alternatively, other SSRIs such as **fluoxetine**, **paroxetine**, or **sertraline** may be suitable alternatives, since these are unlikely to inhibit tacrine metabolism (they are only weak inhibitors of CYP1A2).

Anticholinesterases; Centrally acting + Tobacco

Smoking tobacco reduces the serum levels of tacrine and increases the clearance of rivastigmine.

Clinical evidence, mechanism, importance and management

A comparative study in 7 tobacco smokers and 4 non-smokers found that the AUC of a single 40-mg dose of **tacrine** in the smokers was about 10% of that in the non-smokers. The elimination half-life in the smokers was also reduced, to about two-thirds of that in non-smokers. The increase in **tacrine** metabolism in smokers is thought to occur because some of the components of tobacco smoke increase the activity of the cytochrome P450 isoenzyme CYP1A2 in the liver, by which **tacrine** is metabolised.¹ In practical terms this means that smokers are likely to need larger doses of **tacrine** than non-smokers, although this needs confirmation in multiple dose studies. Other centrally acting anticholinesterases (**donepezil**, **galantamine**, **rivastigmine**) would not be expected to interact in this way, as they are not metabolised by CYP1A2. However, the US manufacturers² note that nicotine use increases **rivastigmine** clearance by 23%, and so other mechanisms may have a part to play. One observational study has suggested that patients with Alzheimer's disease who are smokers are more likely to improve if they are given centrally-acting anticholinesterases than non-smokers.³ Whether this counteracts the effects of any pharmacokinetic interaction is unclear.

Donepezil + Ginkgo biloba

Ginkgo biloba does not appear to affect the pharmacokinetics or pharmacodynamics of donepezil.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study 14 elderly patients with Alzheimer's disease were given donepezil 5 mg daily for at least 20 weeks, after which *Ginkgo biloba* extract 90 mg daily was also given for a further 30 days. Concurrent use did not affect the pharmacokinetics or cholinesterase activity of donepezil, and cognitive function appeared to be unchanged.¹ Therefore, over the course of 30 days, concurrent use appears neither beneficial nor detrimental.

Tacrine + Ibuprofen

An isolated report describes a woman taking tacrine who became delirious when she also started to take ibuprofen.

Clinical evidence, mechanism, importance and management

A 71-year-old diabetic woman with probable Alzheimer's disease developed delirium while taking tacrine 40 mg four times daily. The symptoms included delusions, hallucinations, and fluctuating awareness. She was also bradycardic, diaphoretic and dizzy.¹ She was eventually stabilised with tacrine 20 mg four times daily, and continued this for 8 months without problems, but became delirious again 2 weeks after starting to take ibuprofen 600 mg daily. The delirium resolved when both drugs were withdrawn. The reasons for this reaction are unknown. This is the first and only report of this apparent interaction and its general importance is probably small, especially as the patient had previously experienced delirium with tacrine alone.

1. Hooten WM, Pearson G. Delirium caused by tacrine and ibuprofen interaction. *Am J Psychiatry* (1996) 153, 842.

Tacrine + Quinolones

Enoxacin possibly increases the effects of tacrine.

Clinical evidence, mechanism, importance and management

In vitro studies with human and *rat* liver microsomes found that enoxacin, a specific inhibitor of the cytochrome P450 isoenzyme CYP1A2, significantly inhibited all known routes by which tacrine is metabolised.¹ A reasonable conclusion to be drawn from this is that the effects of tacrine (both beneficial and adverse) would be increased by enoxacin, but this interaction does not appear to have been studied in patients or healthy subjects. The same study also suggested that enoxacin possibly inhibits the production of the hepatotoxic metabolites of tacrine.¹

Other quinolones vary in the extent to which they inhibit CYP1A2 (see 'Theophylline + Quinolones', p.1192), so that any interaction with other quinolones would be expected to reflect this variation.

Anticoagulants

The blood clotting process

When blood is lost or clotting is initiated in some other way, a complex cascade of biochemical reactions is set in motion, which ends in the formation of a network or clot of insoluble protein threads enmeshing the blood cells. These threads are produced by the polymerisation of the molecules of fibrinogen (a soluble protein present in the plasma) into threads of insoluble fibrin. The penultimate step in the chain of reactions requires the presence of an enzyme, thrombin, which is produced from its precursor prothrombin, already present in the plasma. This is initiated by factor III (tissue thromboplastin), and subsequently involves various factors including activated factor VII, IX, X, XI and XII, and is inhibited by anti-thrombin III. Platelets are also involved in the coagulation process. Fibrinolysis is the mechanism of dissolution of fibrin clots, which can be promoted with thrombolytics. For further information on platelet aggregation and clot dissolution, see 'Antiplatelet drugs and thrombolytics', (p.697).

Mode of action of the anticoagulants

Anticoagulants may be divided into direct anticoagulants, which have an immediate effect, and the indirect anticoagulants, which inhibit the formation of coagulation factors, so have a delayed effect as they do not inactivate coagulation factors already formed. See 'Table 12.1', (p.359), for a list.

(a) Direct anticoagulants

The direct anticoagulants include **heparin**, which principally enhances the effect of antithrombin III, thereby inhibiting the effect of thrombin (factor IIa) and activated factor X (factor Xa). **Low-molecular-weight heparins** are salts of fragments of heparin and act similarly, except that they have a greater effect on factor Xa than factor IIa. They have a longer duration of action than heparin and usually require less monitoring. The **heparinoids** (such as **danaparoid**) are similar. A more recent introduction is the synthetic polysaccharide **fondaparinux**, which is an inhibitor of factor Xa. The other group of direct anticoagulants are the **thrombin inhibitors**, which bind to the active thrombin site. These include recombinant forms or synthetic analogues of **hirudin** such as bivalirudin and lepirudin. Megaltran and its oral prodrug **ximelagatran** act similarly, but have been withdrawn because of liver toxicity.

(b) Indirect anticoagulants

The indirect anticoagulants inhibit the vitamin K-dependent synthesis of factors VII, IX, X and II (prothrombin) in the liver, and may also be referred to as **vitamin K antagonists**. The most commonly used are the **coumarins**, principally warfarin, but also acenocoumarol and phenprocoumon. The **indanediones** such as phenindione are now less frequently used. The indirect anticoagulants have the advantage over currently available direct anticoagulants in that they are orally active. They are often therefore referred to as **oral anticoagulants**, but this term may become misleading with the development of direct-acting oral anticoagulants, such as ximelagatran, which have different monitoring requirements and interactions.

Coagulation tests

During anticoagulant therapy the aim is to give protection against intravascular clotting, without running the risk of bleeding. To achieve this, doses of heparin and oral anticoagulants should be individually titrated until the desired response is attained. With the coumarin and indanedione oral anticoagulants, this procedure normally takes several days because

they do not act directly on the blood clotting factors already in circulation, but on the rate of synthesis of new factors by the liver. The successful titration is determined by one of a number of different but closely related laboratory tests, see 'Table 12.2', (p.360) and below. Note that routine monitoring of anticoagulant effect is not required for low-molecular weight heparins or heparinoids, except in patients at increased risk of bleeding, such as those with renal impairment or who are overweight. Also, note that these tests cannot be used to monitor the anticoagulant effect of fondaparinux or the direct thrombin inhibitors, and these require no routine monitoring.

(a) Prothrombin time

The prothrombin time test (PT, Pro-Time, tissue factor induced coagulation time) is the most common method employed in clinical situations. It measures the time taken for a fibrin clot to form in a citrated plasma sample containing calcium ions and tissue thromboplastin. The PT is usually reported as the International Normalised Ratio (INR).

1. *International normalised ratio (INR)*. The INR was adopted by the WHO in 1982 to standardise (using the International Sensitivity Index) oral anticoagulant therapy to take into account the sensitivities of the different thromboplastins used in laboratories across the world. The formula for calculating the INR is as follows:

$$\text{INR} = (\text{patient's prothrombin time in seconds} / \text{mean normal prothrombin time in seconds})^{\text{ISI}}$$

The PT values obtained from the patient's sample are compared to a control, and this gives the INR. The higher the INR, the higher the PT value so if the patient's ratio is 2, this means the PT (and therefore clotting) is twice as long as the normal plasma. The British Corrected Ratio is essentially the same, but was calculated to a standard British thromboplastin.

2. *Quick Value*. The Quick Value is expressed as a percentage; the lower the value, the longer the blood takes to coagulate. Therefore as the Quick Value increases, the corresponding INR value gets smaller and vice versa.

(b) Activated partial thromboplastin time

The activated partial thromboplastin time (aPTT) is the second most common method for monitoring anticoagulant therapy, measuring all the clotting factors in the intrinsic pathway as opposed to the PT test, which measures the extrinsic pathway.

(c) Other methods of assessing clotting

Other tests used, which in some instances offer more sensitivity to specific aspects of therapy, include the prothrombin-proconvertin ratio (PP), the thrombotest, the thrombin clotting time test (TCT, activated clotting time, activated coagulation time), the platelet count and the bleeding time test. The use of the most appropriate test will depend on the situation and the desired result.

Anticoagulant interactions

Stable oral anticoagulant therapy is difficult to achieve even during close monitoring. For example, in one controlled study in patients with atrial fibrillation, only 61% of INR values were within the target range of 2 to 3, despite monitoring the INR monthly and adjusting the warfarin dose appropriately.¹ A large number of factors can influence levels of coagulation, including diet, disease (fever, diarrhoea, heart failure, thyroid dysfunction), and the use of other drugs. It must therefore be remembered that it is particularly difficult to ascribe a change in INR specifically to a drug interaction in a single case report, and single case reports or a few isolated reports for widely used drugs do not prove that an interaction occurs. Nevertheless, either the addition or the withdrawal of drugs may upset the

Table 12.1 Anticoagulants

balance in a patient already well stabilised on an anticoagulant. Some drugs are well known to increase the activity of the anticoagulants and can cause bleeding if the dosage of the anticoagulant is not reduced appropriately. Others reduce the activity and return the prothrombin time to normal. Both situations are serious and may be fatal, although excessive hypoprothrombinaemia manifests itself more obviously and immediately as bleeding and is usually regarded as the more serious. The interaction mechanism may be pharmacodynamic or pharmacokinetic: pharmacokinetic mechanisms are particularly well established and important for coumarin anticoagulants.

(a) *Metabolism of the coumarins*

The coumarins, warfarin, phenprocoumon and acenocoumarol, are racemic mixtures of *S*- and *R*-enantiomers. The *S*-enantiomers of these

coumarins have several times more anticoagulant activity than the *R*-enantiomers. Reports suggest for example, that *S*-warfarin is three to five times more potent a vitamin K antagonist than *R*-warfarin. The *S*-enantiomer of warfarin is metabolised primarily by the cytochrome P450 isoenzyme CYP2C9, and to a much lesser extent, by CYP3A4. The metabolism of *R*-warfarin is more complex, but this enantiomer is primarily metabolised by CYP1A2, CYP3A4, and CYP2C19. *S*-warfarin is eliminated in the bile and *R*-warfarin is excreted in the urine as inactive metabolites. There is much more known about the metabolism of warfarin compared with other anticoagulants, but it is established that *S*-phenprocoumon and *S*-acenocoumarol are also substrates for CYP2C9 and that they differ from warfarin in their hepatic metabolism, and stereospecific potency.²

It makes sense to assume therefore, that an inhibitor of CYP2C9 (e.g. 'fluconazole', (p.387)) is likely to increase the concentration of the coumarin and enhance the anticoagulant effect. Drugs that induce CYP2C9 (e.g. 'rifampicin', (p.375)) reduce plasma levels of the coumarins by increasing the clearance.

'Genetic differences', (p.4), in the genes for these cytochrome P450 isoenzymes may have an important influence on drug metabolism of the coumarins. For example, different versions of the gene encoding CYP2C9 exist and the enzymatic activity of the most clinically important CYP2C9 variants, CYP2C9*2 and CYP2C9*3, is significantly reduced. Studies have suggested an association between patients possessing one or more of these variants and a low-dose requirement of warfarin. Similar observations have been seen with the CYP2C9*3 variant and acenocoumarol.

While the metabolism of the coumarins, especially warfarin, are well known, the numerous interaction pathways and the variability in patient responses, makes the clinical consequences difficult to predict.

(b) *Other mechanisms for anticoagulant interactions*

Some drugs, such as 'colestyramine', (p.393), may also prevent the absorption of the coumarins and reduce their bioavailability. See also 'Drug absorption interactions', (p.3). Additive anticoagulant effects can occur if anticoagulants are given with other drugs that also impair coagulation by other mechanisms such as 'antiplatelets', (p.700). Coumarins and indanediones act as vitamin K antagonists, and so dietary intake of 'vitamin K', (p.409) can also 'reduce or abolish', (p.9) their effects. 'Protein-binding displacement', (p.3) is another possible drug interaction mechanism but this usually plays a minor role compared with other mechanisms.³

Bleeding and its treatment

When prothrombin times become excessive, bleeding can occur. In order of decreasing frequency the bleeding shows itself as ecchymoses, blood in the urine, uterine bleeding, black faeces, bruising, nose-bleeding, haematoma, gum bleeding, coughing and vomiting blood.

Vitamin K is an antagonist of the coumarin and indanedione oral anticoagulants. The British Society for Haematology has given advice on the appropriate course of action if bleeding occurs in patients taking warfarin, and this is readily available in summarised form in the British National Formulary.

If the effects of heparin are excessive it is usually sufficient just to stop the heparin, but protamine sulfate is a specific antidote if a rapid effect is required. Protamine sulfate only partially reverses the effect of low molecular weight heparins.

There is currently no known specific antidote for fondaparinux, or for the direct thrombin inhibitors.

Table 12.2 Coagulation tests

<i>Test</i>	<i>Normal range</i>	<i>Therapeutic/diagnostic range</i>
Activated partial thromboplastin time	20 to 39 seconds after reagents added	1.5 to 2.5 x control
Bleeding time	1 to 9 minutes depending on method used	Critical value greater than 15 minutes
International normalised ratio	0.9 to 1.2	2 to 4 depending on indication for anticoagulation
Plasma thrombin time test	10 to 15 seconds	Greater than 15 seconds
Prothrombin-proconvertin ratio	70 to 130%	10 to 30%
Prothrombin time	10 to 15 seconds	1 to 2 x control
Quick value	70 to 130%	10 to 20%
Thrombin clotting time	70 to 120 seconds	150 to 600 seconds depending on indication for anticoagulation
Thrombotest	100%	10 to 20%

Coumarins + ACE inhibitors

There is a single, isolated and unexplained case of melaena attributed to an interaction between acenocoumarol and fosinopril. No other ACE inhibitor studied has so far been shown to interact to a clinically relevant extent with the coumarins.

Clinical evidence

(a) Benazepril

Benazepril 20 mg daily for 7 days did not affect the steady-state plasma levels of either **warfarin** or **acenocoumarol** in healthy subjects. The anticoagulant activity of **acenocoumarol** was not altered. The effects of **warfarin** were slightly reduced, as demonstrated by a mean reduction in PT of about 4%, but this is not enough to be clinically important.¹

(b) Cilazapril

Cilazapril 2.5 mg daily for 3 weeks had no effect on the thrombotest times or coagulation factors II, VII and X in 26 patients taking long-term **acenocoumarol** or **phenprocoumon**.²

(c) Enalapril

Enalapril 20 mg for 5 days did not affect the anticoagulant effects of **warfarin** 2.5 to 7.5 mg daily, according to a brief summary of unpublished data cited in a review.³

(d) Fosinopril

A 74-year-old patient stabilised on **acenocoumarol**, **enalapril**, pirtanide, and digoxin had the pirtanide and **enalapril** switched to furosemide and fosinopril. Eleven days later, he presented with dark faeces (melaena) and had a low haemoglobin. Fosinopril and acenocoumarol were stopped, and then **enalapril** and acenocoumarol were restarted. On gastrointestinal endoscopy, no explanation for the melaena was found, and his haemoglobin level had returned to normal 15 days later. This case was attributed to possible potentiation of the effect of acenocoumarol by fosinopril,⁴ but as the drugs were not taken alone, the interaction is not proven.

(e) Moexipril

In 10 healthy subjects, the pharmacokinetics and pharmacodynamics of a single 50-mg dose of **warfarin** were not altered when it was given with the first dose of moexipril 15 mg daily for 6 days.⁵

(f) Ramipril

In 8 healthy subjects, ramipril 5 mg daily for 7 days had no effect on the steady-state pharmacokinetics or anticoagulant effects of **phenprocoumon**.⁶ Similarly, ramipril 5 mg daily for 3 weeks did not alter the anticoagulant effects of **acenocoumarol** or **phenprocoumon** in patients stabilised on these anticoagulants, when compared with placebo.⁷

(g) Temocapril

In 24 healthy subjects, temocapril 20 mg daily for 2 weeks had no effect on the steady-state pharmacokinetics or pharmacodynamics of **warfarin**.⁸ The absence of an interaction between **warfarin** and temocapril was also shown in another study.⁹

(h) Trandolapril

In a study in 19 healthy subjects,¹⁰ **trandolapril** 2 mg daily for 13 days did not affect the pharmacodynamics of a single 25-mg dose of **warfarin** given on day 8.

Mechanism, importance and management

No important pharmacokinetic or pharmacodynamic interaction has been demonstrated for any ACE inhibitor and coumarin anticoagulant. Contrasting with all this evidence, there is a single, unexplained and isolated case of melaena attributed to an interaction between acenocoumarol and fosinopril. There seems to be no other evidence that fosinopril normally interacts with the oral anticoagulants and so this interaction is unlikely to be of general significance.

No special precautions would therefore seem necessary if any of these coumarin anticoagulants and ACE inhibitors are used concurrently.

Coumarins + Alcohol

A number of early studies showed that the effects of the coumarin oral anticoagulants are unlikely to be changed in those with normal liver function who drink small or moderate amounts of alcoholic beverages such as wine or spirits. An increase in bleeding time may occur in patients with liver disease who drink to excess.

Clinical evidence

(a) Patients and subjects free from liver disease

The daily consumption of 1 pint (about 560 mL) of Californian white table wine for a 3-week period at meal times by 8 healthy subjects anticoagulated with **warfarin**, was found to have no significant effects on either the serum **warfarin** levels or the anticoagulant response.¹

Other studies in both patients^{2,3} and healthy subjects^{4,5} taking either **warfarin**^{2,3,5} or **phenprocoumon**⁴ have very clearly confirmed the absence of an interaction with wine^{3,5} gin,⁴ or 40% alcohol.² In one of these studies the subjects were given almost 600 mL of a table wine (12% alcohol) or 300 mL of a fortified wine (20% alcohol) without adverse effects on coagulation.⁵

In contrast to the above studies, a 58-year-old man stabilised on **warfarin** experienced a sharp rise in his INR to 8 when he started to drink half a can of light beer (5.35 g alcohol) every other day. In the previous 5 months he had an INR in the range of 1.9 to 2.5 with a stable warfarin dose, and no other explanation for the change in INR was found. He stopped taking the alcohol, and was eventually restabilised on the original dose of warfarin.⁶

(b) Chronic alcoholics or those with liver disease

In one study, 15 alcoholics who had been drinking heavily (250 g ethanol or more daily) for at least 3 months and 11 control subjects (minimal social drinkers or non-drinkers) were given a single 40-mg dose of **warfarin**. The half-life of **warfarin** was lower in the alcoholics (26.5 versus 41.1 hours), but a comparison of the prothrombin times with those of healthy subjects found no differences.⁷

One patient with liver cirrhosis had marked fluctuations in prothrombin times and **warfarin** levels associated with weekend binge drinking of vodka.² Another patient with abnormal liver function had a fall in plasma **warfarin** levels and effect when he stopped drinking 50 mL of whiskey daily. When rechallenged with alcohol, warfarin levels and effect rose, and he had a nosebleed.⁸ In contrast, a large retrospective cohort study did not find a significantly increased risk of serious bleeding in 140 patients with a history of alcoholic binge drinking who were taking **warfarin**. The relative risk was 1.3 (0.8 to 1.9) compared with patients who had no record of alcohol abuse.⁹

Mechanism

It seems probable that, as in *rats*,¹⁰ continuous heavy drinking stimulates the hepatic enzymes concerned with the metabolism of warfarin, leading to its more rapid elimination.^{7,11} As a result the half-life shortens. The fluctuations in prothrombin times in those with liver impairment^{2,8} may possibly occur because sudden large amounts of alcohol exacerbate the general dysfunction of the liver and this affects the way it metabolises warfarin. Alcohol may also change the ability of the liver to synthesise clotting factors.¹² Constituents of beer other than alcohol may affect warfarin metabolism.⁶

Importance and management

The absence of an interaction between warfarin or phenprocoumon and alcohol in those free from liver disease is well documented and well established. It appears to be quite safe for patients taking oral anticoagulants to drink small or moderate amounts of wine or spirits. Even much less conservative amounts (up to 8 oz/250 mL of spirits⁴ or a pint of wine¹) do not create problems with the anticoagulant control, so that there appears to be a good margin of safety even for the less than abstemious. Only warfarin and phenprocoumon have been investigated but other coumarin anticoagulants would be expected to behave similarly. The single case of increased INR in a patient who started to drink beer is unexplained. Further study specifically with beer is needed to throw light on this possible interaction.

On the other hand, those who drink heavily may possibly need above-average doses of the anticoagulant, while limited evidence suggests that those with liver damage who binge drink may experience marked fluctuations in their prothrombin times. It might be prudent to avoid anticoagulation in this type of patient unless they can abstain from drinking. Nevertheless, although one cohort study in patients taking warfarin found a slight trend towards serious bleeding events in patients with a history of binge drinking, this was not significant, and other risk factors were more important (highly variable prothrombin time ratio, or prothrombin time ratio greater than 2).⁹

Coumarins + Aliskiren

Aliskiren did not alter the pharmacodynamics or pharmacokinetics of a single dose of warfarin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study in 15 healthy subjects, aliskiren 150 mg daily for 11 days did not alter the pharmacodynamics of a single dose of warfarin given on day 8. In addition, there was no change in the AUC or half-life of R- and S-warfarin.¹

This study suggests that no warfarin dose adjustments would be expected to be needed if aliskiren is used in patients taking warfarin.

- Dieterle W, Corynen S, Mann J. Effect of the oral renin inhibitor aliskiren on the pharmacokinetics and pharmacodynamics of a single dose of warfarin in healthy subjects. *Br J Clin Pharmacol* (2004) 58, 433–6.

Coumarins + Allopurinol

A number of studies and case reports suggest that allopurinol does not alter the pharmacokinetics or pharmacodynamics of warfarin. Nevertheless, a few case reports suggest that allopurinol might have increased the effect of warfarin. Two cases have also been reported with phenprocoumon. Allopurinol increased the half-life of dicoumarol in some healthy subjects, but there do not appear to be any reports of a clinically significant interaction.

Clinical evidence

(a) Dicoumarol

In 6 healthy subjects, allopurinol 2.5 mg/kg twice daily for 14 days increased the mean half-life of a single 4-mg/kg dose of dicoumarol from 51 to 153 hours, with large inter-individual variation.¹ In another similar study, only 1 of 3 healthy subjects showed an increase in dicoumarol half-life (from 13 to 17 hours) when they were also given allopurinol.²

(b) Phenprocoumon

Two patients stabilised for a few weeks taking phenprocoumon developed prolonged bleeding times, with haematuria in one of them, within 4 to 5 weeks of starting to take allopurinol 300 mg daily.³

(c) Warfarin

In a study in 8 healthy subjects, the half-life of a single 25-mg dose of warfarin was not altered by pretreatment with allopurinol 100 mg twice daily for 10 days.² Similarly, in 6 subjects, the elimination of a single 50-mg dose of warfarin was not altered by 2 or 4 weeks treatment with allopurinol 100 mg three times daily, although one subject had a 30% reduction in the elimination of warfarin after 4 weeks.⁴ No change was seen in the prothrombin ratios of 2 patients taking warfarin who took allopurinol 100 mg three times daily for 3 weeks.⁴ In contrast, one patient stabilised on warfarin had a 42% increase in his prothrombin ratio after taking allopurinol 100 mg daily for 2 days.⁵

In a retrospective study⁶ of the adverse effects of allopurinol in 1835 patients, 3 patients were identified who had developed excessive anticoagulation while taking warfarin and allopurinol. One of them developed extensive intrapulmonary haemorrhage and had a prothrombin time of 71 seconds. An increase in prothrombin time was seen in an 82-year-old woman stabilised on warfarin when given both allopurinol 300 mg daily and 'indometacin', (p.432), but the precise role of allopurinol in this case is unclear.⁷

Mechanism

It has been suggested that, as in rats, allopurinol inhibits the metabolism of the anticoagulants by the liver, thereby prolonging their effects and half-lives.^{1,2,5} There is a wide individual variability in the effects of allopurinol on drug metabolism,⁴ so that only a few individuals are affected.

Importance and management

Documentation is poor, and a pharmacokinetic interaction is not established. There appear to be few case reports of any important interaction. Nevertheless, consider increased monitoring of the anticoagulant effect in any patient taking a coumarin with allopurinol.

Coumarins + Alpha blockers

Studies suggest that tamsulosin does not alter the pharmacokinetics or anticoagulant effect of acenocoumarol, and alfuzosin does not interact with warfarin. Doxazosin is said not to interact with anticoagulants.

Clinical evidence, mechanism, importance and management

In a double-blind, placebo-controlled, crossover study in 12 healthy subjects, tamsulosin 400 micrograms daily for 9 days had no effect on the pharmacokinetics or anticoagulant effects of a single 10-mg dose of acenocoumarol given on day five.¹

The UK manufacturers of alfuzosin report that no pharmacodynamic or pharmacokinetic interaction was observed in healthy subjects given alfuzosin with warfarin,² and the US manufacturers report that in 6 healthy

subjects **alfuzosin** 5 mg twice daily for 6 days did not affect the pharmacological response to a single 25-mg dose of **warfarin**.³

One UK manufacturer of **doxazosin** says that no adverse drug interaction has been observed with **anticoagulants** (unspecified).⁴

No coumarin dose adjustment would therefore be expected to be needed with concurrent use of these alpha blockers.

Coumarins and related drugs + Amiodarone

The anticoagulant effects of warfarin, phenprocoumon and acenocoumarol are increased by amiodarone and bleeding may occur. The interaction may be maximal in 2 to 7 weeks, and may persist long after the amiodarone has been withdrawn.

Clinical evidence

A. Inhibition of coumarin metabolism

(a) Warfarin

In the one of the first reports of an interaction between amiodarone and warfarin, 5 out of 9 patients who were stabilised on warfarin showed signs of bleeding (4 had microscopic haematuria and one had diffuse ecchymoses) within 3 to 4 weeks of starting to take amiodarone (dosage not stated). All 9 had increases in their prothrombin times averaging 21 seconds. It was necessary to decrease the warfarin dosage by an average of a third (range 16 to 45%) to return their prothrombin times to the therapeutic range. The effects of amiodarone persisted for 6 to 16 weeks in 4 of the patients from whom it was withdrawn.¹

Since then numerous other case reports have described a prolongation in prothrombin times and/or bleeding in patients taking **warfarin** and also given amiodarone (maintenance doses of 100 to 800 mg daily, sometimes with initial higher loading doses).^{2–11} One patient died of haemorrhage.⁶ Warfarin dose reductions varied between about 25 to 60%,^{4,6,8,11} with only a few patients not needing a reduction.⁴ In one retrospective study, the required dose of warfarin was related to the amiodarone maintenance dose, leading to the recommendation that the warfarin dose should be reduced by 40% for a daily maintenance dose of amiodarone of 400 mg, by 35% for 300 mg, by 30% for 200 mg and by 25% for 100 mg.¹¹

A few pharmacokinetic studies have shown that amiodarone decreased the clearance of warfarin by 44 to 55% in patients receiving the drugs clinically^{7,12} and by 20 to 37% in healthy subjects given a single dose of warfarin after taking amiodarone for 3 to 4 days.^{13,14} In the two studies in healthy subjects, amiodarone caused a similar decrease in the clearance of both *R*- and *S*-warfarin.^{13,14} However, a recent study in patients concluded that amiodarone had a much greater effect on *S*-warfarin than on *R*-warfarin.¹⁵

(b) Other coumarins

A number of retrospective studies^{16–19} have shown that patients stabilised on **acenocoumarol** require a dose reduction when they are given amiodarone, the combined range in these studies being 4 to 69%. In a prospective study, 10 patients stabilised on **acenocoumarol** were given amiodarone 600 mg daily for a week, then 400 mg daily. Eight of the 10 had a decrease in prothrombin time after a mean of 4 days of amiodarone. Six patients required a decrease in **acenocoumarol** dose of 60% while taking amiodarone 600 mg daily, but by the third week of taking amiodarone 400 mg daily the effects had diminished, and only a 33% reduction in dose was necessary.²⁰ A couple of case reports of the interaction have also been published.^{21,22} Amiodarone similarly interacts with **phenprocoumon**, with one case series in 7 patients reporting that a 9 to 59% phenprocoumon dose reduction was required within 1 to 3 weeks of starting amiodarone.²³ Conversely, an early study in 12 patients stabilised on **phenprocoumon** and given amiodarone 400 mg to 1 g daily failed to identify an interaction.²⁴

B. Thyrotoxicosis (Hyperthyroidism)

The INR of a patient stabilised on **warfarin** and amiodarone was noted to increase from about 2 to 5.5 after he developed amiodarone-induced thyrotoxicosis.²⁵ Another 3 well-described cases of this potential interaction have been reported.²⁶

Mechanism

Amiodarone inhibits the metabolism of warfarin, probably because it, and/or its metabolite desethylamiodarone,²⁷ inhibit the cytochrome P450 isoenzyme CYP2C9, CYP3A4 and CYP1A2 (see 'metabolism of the coumarins', (p.358)).

Thyrotoxicosis, which can be caused by amiodarone, potentiates the effect of warfarin, see 'Coumarins and related drugs + Thyroid and Antithyroid compounds', p.455. As a result less warfarin would be required to prolong the prothrombin time.^{25,26}

Importance and management

The potentiating effect of amiodarone on coumarin anticoagulants is a well documented, established and clinically important interaction. It appears to occur in most patients.^{1,4,8} It would seem prudent to adjust the doses of the coumarin anticoagulants based on INR measurements. Some recommend the dosage of warfarin should initially be reduced by 25%⁸ or 50%⁴ when amiodarone is added to established anticoagulant treatment, with increased INR monitoring until a new steady-state is achieved. The potentiation of coumarins starts within a few days and is usually maximal by 2 to 7 weeks.^{8,11,15} The final reduction in warfarin dose required may depend on the amiodarone maintenance dose: average warfarin dose reductions of 25% have been required for amiodarone 100 mg daily, 30 to 35% for amiodarone 200 mg daily, 35% for amiodarone 300 mg daily, 40 to 50% for amiodarone 400 mg daily, and 65% for amiodarone 600 mg daily.^{7,11} These suggested reductions are broad generalisations and individual patients may need more or less.^{19,28} If established amiodarone therapy is withdrawn in a patient taking warfarin, it is likely that the dose of warfarin will need increasing gradually over the first few months after amiodarone is stopped. This is because amiodarone has such a long half-life. If warfarin is required in a patient on established amiodarone therapy, a lower initial dose of warfarin should be used.

Similar advice applies to acenocoumarol and phenprocoumon, and probably also other coumarins. Some recommend an initial reduction in acenocoumarol dose of 50% when amiodarone is added,¹⁶ whereas others recommend that the INR should be closely monitored, and the dose of acenocoumarol only reduced in response to an increase in INR.²⁸

In patients stabilised on warfarin and amiodarone, the possibility of amiodarone-induced thyrotoxicosis should be considered if an abrupt increase in INR occurs.^{25,26}

Some sources appear to suggest that the **indanediones** may interact similarly, but this appears to be an extrapolation from the known interaction with warfarin. There seems no clinical evidence available to support this prediction.

Coumarins and related drugs + Anabolic steroids and Androgens

Increased anticoagulant effects and bleeding has been seen in patients taking a coumarin anticoagulant or the indanedione, phenindione and an anabolic steroid or testosterone.

Clinical evidence

(a) Anabolic steroids

Six patients stabilised on **warfarin** or **phenindione** were given **oxymetholone** 15 mg daily. One patient developed extensive subcutaneous bleeding and another had haematuria. After 15 to 30 days all 6 patients had thrombotests of less than 5%, which returned to the therapeutic range within a few days of **oxymetholone** being withdrawn.¹ Other similar cases have been reported with **oxymetholone** and **warfarin**,^{2–4} or **acenocoumarol**.⁵ In 3 of the reports^{1,3,4} the interaction was severe enough to discontinue the **oxymetholone**. In one patient² the **warfarin** dose was reduced by 59%, and in another⁵ the **acenocoumarol** dose was reduced by 66 to 75%.

Similarly increased anticoagulant effects and bleeding have been described in studies and case reports involving:

- **dicoumarol** with **norethandrolone**,⁶
- **dicoumarol** with **stanozolol**,⁷
- **phenindione** with **methandienone**,⁸
- **phenindione** with **ethylestrenol**,⁹
- **warfarin** with **methandienone**^{2,8,10,11} (62% to 73% decrease in dose required in 3 cases² and 38% in 7 others⁸)
- **warfarin** with **stanozolol**^{12–15} (40% and 64% decrease in dose required in 2 patients and about a 70% increase required after stopping stanozolol¹²).

In a pharmacokinetic study in 15 healthy subjects, the manufacturer noted that the concurrent use of **warfarin** and **oxandrolone** 5 or 10 mg twice daily increased the *S*-warfarin AUC by 2.65-fold and doubled its half-life, and had similar effects on *R*-warfarin.¹⁶ Microscopic haematuria occurred in 9 subjects and gingival bleeding in one. A 5.5-fold decrease in warfarin dose (about 80 to 85%) was necessary to maintain a target INR of 1.5.

(b) Androgens

A 58-year-old man receiving **methyltestosterone** replacement therapy 37.5 mg daily required a maintenance dose of **phenprocoumon** of just 0.94 mg daily: control subjects required 2.62 mg daily.¹⁷

One report notes that 3 patients receiving **warfarin** and **Sustanon** (containing four combined esters of **testosterone**) had no changes in their anticoagulant requirements,⁴ whereas another report describes a woman who showed a 78% and a 65% increase in prothrombin times on two occasions when using a 2% **testosterone propionate** vaginal ointment twice daily. She needed a 25% reduction in **warfarin** dosage.¹⁸

Mechanism

Not understood. One study showed that **norethandrolone** did not alter the metabolism of **dicoumarol**, and did not alter the plasma levels of vitamin-K dependent clotting factors.⁶ However, a more recent study of **oxandrolone** and **warfarin** shows a pharmacokinetic basis for this interaction.¹⁶

Importance and management

Well documented, well established and clinically important interactions that develop rapidly, possibly within 2 to 3 days. Most, if not all, patients are affected.^{1,6} If concurrent use cannot be avoided, the dosage of the anticoagulant should be appropriately reduced. In a few cases, where patients have been able to be stabilised on the combination, up to 75% reductions in anticoagulant dose have been required, and the study¹⁶ with **oxandrolone** suggests an 85% reduction in dose of **warfarin** might be necessary. After withdrawal of the interacting drug the anticoagulant dosage will need to be increased.

It seems probable that all the coumarin and indanedione anticoagulants will interact with any 17-alkyl substituted anabolic steroid. The situation with **testosterone** and other non 17-alkylated steroids is not clear as there are only case reports, which are conflicting. Until more is known it would seem prudent to increase the frequency of INR monitoring if these drugs are given with coumarins or indanediones.

Coumarins + Angiotensin II receptor antagonists

None of the angiotensin II receptor antagonists appear to interact to a clinically relevant extent with warfarin..

Clinical evidence

(a) Candesartan

In healthy subjects stabilised on individualised doses of **warfarin**, **candesartan** cilexetil 16 mg daily for 10 days reduced the trough serum levels of **warfarin** by 7%, but this had no effect on prothrombin times.¹

(b) Eprosartan

No clinically relevant changes in anticoagulation occurred in 18 healthy subjects stabilised on **warfarin** with INRs between 1.3 and 1.6 when they were given **eprosartan** 300 mg twice daily for 7 days.²

(c) Irbesartan

Warfarin 2.5 to 10 mg daily was given to 16 healthy subjects for 2 weeks, with **irbesartan** 300 mg or a placebo daily for a further week. There was no evidence that **irbesartan** affected the pharmacokinetics or pharmacodynamics of **warfarin**.³

(d) *Losartan*

In a placebo-controlled, randomised, crossover study, 10 healthy subjects were given losartan 100 mg daily for 13 days with a single 30-mg dose of **warfarin** on day 7. The pharmacokinetics of **warfarin** (both *R*- and *S*-enantiomers) and its anticoagulant effects were not altered. Losartan, given alone for a week, also had no effect on prothrombin times.⁴

(e) *Telmisartan*

Telmisartan 120 mg daily for 10 days was given to 12 healthy subjects stabilised on **warfarin**, with INRs of between 1.2 and 1.8. A small 11% decrease in the mean trough plasma **warfarin** concentration occurred, but the anticoagulation effect remained unchanged.⁵

(f) *Valsartan*

In 12 healthy subjects, **warfarin** (10 mg daily for 3 days) and valsartan (160 mg daily for 3 days) were each given alone then valsartan 160 mg daily was given for 7 days with warfarin 10 mg daily for the first 3 of these. Warfarin had no effect on the pharmacokinetics of valsartan. Valsartan caused a small increase in prothrombin time of about 12%, which was not considered clinically important. Warfarin pharmacokinetics were not assessed.^{6,7}

Mechanism

The angiotensin II antagonists, and warfarin, are substrates for the cytochrome P450 isoenzyme CYP2C9. It was therefore possible that they might affect warfarin metabolism. However, this does not appear to happen.

Importance and management

The available pharmacokinetic and pharmacodynamic studies showing that the angiotensin II receptor antagonists (candesartan, eprosartan, irbesartan, losartan, telmisartan, valsartan) do not interact with warfarin, and the lack of any published evidence to the contrary, suggest that no warfarin dose adjustments should be needed if these drugs are used.

Coumarins + Antacids

There is some evidence that the absorption of dicoumarol may be increased by magnesium hydroxide, but there is no direct evidence that this is clinically important. Aluminium hydroxide does not interact with either warfarin or dicoumarol, and magnesium hydroxide does not interact with warfarin.

Clinical evidence(a) *Dicoumarol*

Magnesium hydroxide (*Milk of Magnesia*) 15 mL taken with and 3 hours after a single dose of dicoumarol was found to raise the peak plasma levels and AUC of dicoumarol by 75% and 50%, respectively, in 6 healthy subjects. Conversely, **aluminium hydroxide** (*Amphogel*) 30 mL did not alter dicoumarol levels.¹

(b) *Warfarin*

Aluminium/magnesium hydroxide (*Maalox*) 30 mL given with and for four 2-hourly doses after warfarin had no effect on the plasma warfarin levels or on the anticoagulant response in 6 subjects.² Similarly, neither **aluminium hydroxide** (*Amphogel*) 30 mL nor **magnesium hydroxide** (*Milk of Magnesia*) 15 mL taken with and 3 hours after a single 75-mg dose of warfarin had any effect on warfarin peak levels or AUC.¹

Mechanism

It is suggested that dicoumarol forms a more readily absorbed chelate with magnesium so that its effects are increased.^{1,3} An *in vitro* study suggested that the absorption of warfarin may be decreased by **magnesium trisilicate**,⁴ where as another *in vitro* study found no effect.⁵

Importance and management

No special precautions need be taken if aluminium or magnesium hydroxide antacids are given to patients taking warfarin, or if aluminium hydroxide is given to those taking dicoumarol. Choosing these antacids avoids the possibility of an adverse interaction. Despite the evidence of increased absorption of dicoumarol with magnesium hydroxide, there seems to be no direct clinical evidence of any important adverse interaction for this combination, or indeed between any coumarin and an antacid.

Coumarins + Antibacterials

Altered (usually enhanced) coumarin response has been reported with virtually every class of antibacterial. While some such as sulfamethoxazole, clearly have a pharmacokinetic interaction, for others there is no clear explanation for why an interaction might be expected. Theoretical mechanisms include reduced intestinal bacterial production of vitamin K₂ substances, or reduced enterohepatic recycling. Possible confounding mechanisms include a reduction in dietary vitamin K₁ intake because of illness, or the effect of fever or infection on coagulation or drug metabolism.

Clinical evidence and mechanism

Various studies have implicated antibacterials in general as being a risk factor for overanticoagulation. For example, in a large prospective cohort study, INR levels of greater than 7 were recorded in 31 patients. When compared with 100 patients with stable INRs, these 31 patients were more likely to have been treated with an antibacterial (not specified) in the previous 4 weeks (odds ratio 6.2), and more likely to have an intercurrent illness (odds ratio 4.48).¹ Various mechanisms may be responsible for these findings, and these are discussed below.

(a) *Confounding effects relating to the infection*

1. *Dietary factors.* Patients taking coumarins and related drugs are advised to maintain a constant dietary intake of 'vitamin K₁', (p.409), since sustained changes in intake of vitamin K₁-rich foods, such as green leafy vegetables, causes clinically relevant changes in anticoagulation. It is therefore possible that patients who stop eating for a more than a day or so could develop over-anticoagulation. The same could happen with a reduced appetite leading to a sustained reduction in intake of vitamin K₁-rich foods.

2. *Fever.* Fever might possibly be a confounding factor in reports of antibacterial warfarin interactions, because it might increase the catabolism of vitamin K-dependent coagulation factors by producing a hypermetabolic state. However, in one cohort study, there was no difference in the frequency of fever between patients who developed over-anticoagulation (INR greater than 6) while taking antibacterials and those who did not develop over-anticoagulation while taking antibacterials.²

3. *Reduced metabolism.* There is some evidence from *animal* studies that infection can down regulate cytochrome P450 isoenzymes, which might result in reduced drug metabolism.³ Whether the metabolism of warfarin is different during an acute infection does not appear to have been studied.

(b) *Effects relating to the antibacterial*

1. *Direct anticoagulant effects.* Cephalosporins and related beta lactams with an *N*-methylthiotetrazole or similar side-chain can occasionally cause enough hypoprothrombinaemia for bleeding to occur when they are used

alone, and this effect might therefore be additive with coumarins, although there is not that much evidence to support this, see 'Coumarins + Antibacterials; Cephalosporins and related beta lactams', p.367.

2. *Intestinal production of vitamin K₂ substances by bacteria.* The activity of intestinal microflora produces menaquinones (vitamin K₂ substances). Suppression of the microflora might therefore result in reduced vitamin K₂, and hence reduced synthesis of vitamin-K dependent clotting factors. There is some evidence from studies in healthy subjects receiving vitamin-K₁ restricted diets and taking warfarin that giving menaquinones (an extract of bacterially synthesised material) decreases the response to warfarin.⁴ In addition, 'Natto', (p.408), which is a rich source of bacterially-derived menaquinones markedly inhibits the effect of warfarin. It is therefore possible that antibacterials that decimate gut microflora might increase the effect of warfarin by reducing vitamin K₂ levels. However, this effect might be important only if vitamin-K₁ intake from dietary sources is also reduced.

3. *Protein-binding displacement.* Many drugs can displace warfarin from protein-binding sites leading to an increase in unbound (active) concentrations. However, any effect is transient, as the unbound warfarin is quickly metabolised. The exception to this is if the metabolism of warfarin is markedly inhibited at the same time. The only drug that is known to interact via both these mechanisms is 'phenylbutazone', (p.434). Consider also 'Protein-binding interactions', (p.3). Altered protein binding has not clearly been shown to be an important mechanism in any interaction between warfarin and an antibacterial, but it is often suggested as one.

4. *Reduced or increased metabolism.* Sulfamethoxazole clearly inhibits the metabolism of warfarin by the cytochrome P450 isoenzyme CYP2C9, so enhancing its effect. Some macrolides such as erythromycin inhibit CYP3A4, and therefore have a minor inhibitory effect on warfarin, which would, on its own, be unlikely to be of any clinical relevance. Conversely, 'rifamycins', (p.375) are well established inducers of drug metabolism, and clearly reduce the effect of warfarin. Most other antibacterial classes have no effect on warfarin pharmacokinetics.

Importance and management

All these factors in their own right might affect the intensity of anticoagulation. Therefore, a few case reports of an enhanced response to warfarin on starting a specific antibacterial does not necessarily imply that the antibacterial has a direct interaction with warfarin. Conversely, demonstration of a lack of a specific interaction between an antibacterial and warfarin does not mean that a patient prescribed that drug for an infection will not have a change in coagulation status. Therefore, if a patient is unwell enough to require an antibacterial, it may be prudent to increase monitoring of coagulation status even if no interaction is expected. Monitor within 3 days of starting the antibacterial. The expectation of an interaction should not exclude the use of an antibacterial if it is considered clinically appropriate.

Coumarins and related drugs + Antibacterials; Aminoglycosides

Limited data suggest that no clinically significant interaction occurs between dicoumarol or warfarin and oral neomycin or paromomycin in most patients. However, individual patients have shown some alteration in anticoagulant effect (usually increases) when given oral neomycin and parenteral streptomycin.

Clinical evidence

Six out of 10 patients taking warfarin who were given oral neomycin (2 g daily¹ or 4 g daily²) over a 3-week period had a gradual increase in their prothrombin times averaging 5.6 seconds.^{1,2}

In patients taking an unnamed anticoagulant, 2 of 5 given oral neomycin with bacitracin had a fall in their prothrombin-proconvertin concentration from a range of 10 to 30% to less than 6%. Similarly, one of 3 patients given parenteral streptomycin 500 mg twice daily, and 2 patients given parenteral streptomycin 500 mg twice daily with 1 million units of penicillin daily had a fall in their prothrombin-proconvertin concentration from a range of 10 to 30% down to 6 to 9%.³ This suggests an increase in anticoagulant effect. Five of 7 patients taking unnamed anticoagulants had no change in their mean daily dose of anticoagulant when given oral neomycin 1 to 2 g daily for 18 weeks. Of the remaining two, one required an increase of about 100%, and one required a small 27% decrease.⁴ The concurrent use of oral paromomycin 2 g daily with dicoumarol or warfarin did not alter anticoagulant requirements in 2 subjects.⁵

Mechanism

Not understood. One idea is that these antibacterials increase the anticoagulant effects by diminishing the bacterial population in the gut, thereby reducing their production of vitamin K₂ substances, see 'Coumarins + Antibacterials', p.365. Another suggestion is that these antibacterials decrease the vitamin K₁ absorption as part of a general antibacterial-induced malabsorption syndrome.⁶

Importance and management

A sparsely documented interaction but common experience seems to confirm that normally no interaction of any significance occurs. Concurrent use need not be avoided. Occasionally vitamin K deficiency and/or spontaneous bleeding is seen after the prolonged use of broad-spectrum antibacterials combined with a totally inadequate diet, starvation or some other condition in which the intake of vitamin K is very limited.^{7,8} Under these circumstances the effects of the oral anticoagulants (coumarins and indanediones) would be expected to be significantly increased and appropriate precautions should be taken. There is nothing to suggest that an adverse interaction occurs between the oral anticoagulants and other parenteral aminoglycosides.

Coumarins + Antibacterials; Aminosalicic acid and/or Isoniazid

A report attributes bleeding in a patient taking warfarin to the concurrent use of isoniazid. Another report describes a markedly increased anticoagulant response in a patient taking warfarin when the dose was doubled and aminosalicic acid and isoniazid were started. In one study, isoniazid inhibited warfarin metabolism *in vitro*.

Clinical evidence

A man who had recently started to take warfarin 10 mg daily and isoniazid 300 mg daily began to bleed (haematuria, bleeding gums) within 10 days of accidentally doubling his dosage of isoniazid. His prothrombin time had increased from about 26 to 53 seconds.¹

Another patient taking digoxin, potassium chloride, docusate, diazepam and warfarin 2.5 mg daily, was also given aminosalicic acid 12 g, isoniazid 300 mg and pyridoxine 100 mg daily, and at the same time the warfarin dose was doubled to 5 mg daily. His prothrombin time increased from 18 to 130 seconds over 20 days but no signs of haemorrhage were seen.²

Mechanism

Not understood. It seems possible that isoniazid may inhibit the metabolism of the coumarin anticoagulants, since *in vitro* study in human liver microsomes has shown it inhibits *S*-warfarin 7-hydroxylation by the cytochrome P450 isoenzyme CYP2C9,³ but this needs confirmation *in vivo*. Isoniazid increased the anticoagulant effects of dicoumarol in *dogs*⁴ but not of warfarin in *rabbits*.⁵ Two patients taking isoniazid, aminosalicic acid and streptomycin (but not taking anticoagulants) developed haemorrhage attributed to the anticoagulant effects of isoniazid.⁶

Importance and management

These two isolated cases of possible interactions are far from conclusive, and the interactions of warfarin with isoniazid and aminosalicic acid are not established. Nevertheless, given that the *in vitro* data suggest that isoniazid might inhibit warfarin metabolism, some caution might be appropriate. Further study is needed.

Coumarins + Antibacterials; Cephalosporins and related beta lactams

Cephalosporins and related beta lactams with an *N*-methylthiotetrazole or similar side-chain can occasionally cause enough hypoprothrombinaemia for bleeding to occur when they are used alone. These effects could therefore be additive with those of the coumarins, and this appears to have been shown in a study with cefamandole or cefazolin and warfarin. Similarly, a few cases of over-anticoagulation have been reported with cefonicid and cefotiam in patients taking acenocoumarol or warfarin. Although not having an *N*-methylthiotetrazole side-chain, the manufacturers of cefixime and cefaclor have on record a few cases of over-anticoagulation. Cephalosporins and related beta lactams that have caused increases in prothrombin times when used alone, and might therefore be predicted to interact, include aztreonam, cefalotin, cefoperazone, ceftriaxone, and latamoxef. Other cephalosporins with a related side-chain include cefmenoxime, cefmetazole, cefminox, ceforanide, cefotetan and cefpiramide.

Clinical evidence

(a) Cephalosporins with *N*-methylthiotetrazole or similar side-chains

1. *Cefamandole* or *cefazolin*. Two patients who had received prophylactic cefamandole before cardiac valve replacement developed unusually high prothrombin times, with bleeding in one case, within 48 hours of an initial dose of **warfarin** 10 mg. Because of this, the records of a total of 60 other patients who had undergone heart valve replacement surgery were reviewed. They had been given antibacterials prophylactically before the chest incision was made, and every 6 hours thereafter for about 72 hours. The 44 patients given cefamandole 2 g showed a much greater anticoagulant response than the 16 patients given vancomycin 500 mg. Fourteen of the cefamandole group had a prothrombin time greater than 32 seconds after the initial warfarin dose, compared with only one of the vancomycin group.¹ In a later randomised study by the same workers, the prothrombin times as a percentage of activity after 3 days of concurrent use with **warfarin** were as follows: cefamandole 29%, cefazolin 38%, and vancomycin 51%, suggesting that cefamandole had a much greater effect on anticoagulation response than vancomycin.²

2. *Cefonicid*. In a study in 9 patients stabilised on **warfarin**, there was no change in prothrombin times when they were given intravenous cefonicid 2 g daily for 7 days.³ In contrast, a later study identified 9 patients taking **acenocoumarol** who had increased INRs within 3 to 8 days of being given cefonicid. They needed a reduction in the anticoagulant dosage of about

one-third to one-half.⁴ Another patient stabilised on **acenocoumarol**, with a prothrombin index of 28% bled 2 days after starting cefonicid 1 g daily and had a prothrombin index of less than 5%.⁵

3. *Cefotiam*. Severe haemorrhage has been reported in 3 patients taking **acenocoumarol** with cefotiam. One developed an abdominal haematoma and an INR of 10.4 within 2 days. Another had gastrointestinal bleeding and melaena after one day of concurrent use. The third died from intracranial haemorrhage on the day she started cefotiam.⁶

(b) Cephalosporins without *N*-methylthiotetrazole or similar side-chains

1. *Cefaclor*. Over the period 1979 to 1997, there had been 3 cases of raised INRs with or without clinical bleeding in patients taking **acenocoumarol**, **warfarin** or an unknown anticoagulant and cefaclor reported to the CSM in the UK.⁷ No cases seem to have been published.

2. *Cefixime*. Cefixime has also been implicated in a handful of cases of bleeding and/or increased INRs in patients taking **warfarin** or **phenindione**, but the evidence is inconclusive.⁸ No cases seem to have been published.

(c) Unnamed cephalosporins

None of 36 patients taking warfarin and prescribed an oral cephalosporin (not named) experienced a change in their INR in a prospective study of the effect of antibacterials on anticoagulation.⁹

Mechanism

Cephalosporins with an *N*-methylthiotetrazole side-chain can, like the oral anticoagulants, act as vitamin K antagonists to reduce the production of some blood clotting factors. They can therefore cause bleeding on their own. For example, serious bleeding following the use of **cefamandole** (in the absence of an anticoagulant) has been described in 3 out of 37 patients in one report,¹⁰ and a further report highlights a further 16 cases.¹¹ Other similar cephalosporins and related beta lactams that have been reported to cause hypoprothrombinaemia when used alone include cefoperazone,^{12–16} cefotetan,¹⁷ ceftriaxone,¹⁸ cefalotin,¹⁹ cefazolin,^{20–22} and latamoxef.^{23,24} The incidence is very variable: in some instances only isolated cases have been reported whereas a 15% bleeding rate was found in one study²⁴ with latamoxef alone, 22% in another²³, but only 8% with cefoxitin alone.²³ These cephalosporins might therefore worsen the risk of bleeding by simple addition if given with coumarin or **indanedione** anticoagulants. In addition, some of them may also inhibit platelet function.²⁵ Ceftriaxone seems to act similarly although it has an *N*-methylthio*triazine* ring instead, as does cefazolin, which has an *N*-methylthio*adiazolethiol* side-chain. **Aztreonam** can also increase the prothrombin time.^{26–29} See also 'antibacterials', (p.365).

Importance and management

Most cephalosporins and related beta lactams do not normally cause bleeding so would not be expected to have an additive interaction with the oral anticoagulants. In contrast, cephalosporins with the *N*-methylthiotetrazole side-chain appear to increase the risk of bleeding, and might therefore interact. Both **cefamandole** and to a lesser extent **cefazolin** have been shown to increase the response to warfarin, and cases of over-anticoagulation have been reported for **cefonicid** and **cefotiam**. All other cephalosporins and related beta-lactams with the *N*-methylthiotetrazole or similar side-chain might be expected to behave similarly, but have not so far been reported to do so. These include **cefalotin**, **cefmenoxime**, **cefmetazole**, **cefminox**, **cefoperazone**, **ceforanide**, **cefotetan**, **cefpiramide**, **ceftriaxone**, and **latamoxef**. **Aztreonam** has also been predicted to interact similarly, although, again there are no reports. Although not having an *N*-methylthiotetrazole side-chain, the manufacturers of **cefixime** and **cefaclor** have on record a few cases of over-anticoagulation.

Patients most at risk seem to be those whose intake of vitamin K is restricted (poor diet, malabsorption syndromes, etc.) and those with renal failure. The use of an anticoagulant represents just another factor that may precipitate bleeding.

A possible solution to the problem is to use a non-interacting cephalosporin. Alternatively you should monitor the outcome closely, particularly in the early stages of treatment, adjusting the anticoagulant dosage if necessary. Excessive hypoprothrombinaemia can be controlled with vitamin K.

Coumarins + Antibacterials; Chloramphenicol

There is some limited evidence to suggest that the anticoagulant effects of acenocoumarol and dicoumarol can be increased by oral chloramphenicol. An isolated report attributes a marked INR rise in a patient taking warfarin to the use of chloramphenicol eye drops.

Clinical evidence

A study in 4 patients showed that the half-life of **dicoumarol** was increased on average from 8 to 25 hours when they were given oral chloramphenicol 2 g daily for 5 to 8 days.¹

Three out of 9 patients taking an unnamed anticoagulant had a fall in their prothrombin-proconvertin values from a range of 10 to 30% down to less than 6% (suggesting an increased anticoagulant effect) when given oral chloramphenicol 1 to 2 g daily for 4 to 6 days. One patient had a smaller reduction.² In early clinical experience with **acenocoumarol**, one of 3 patients taking chloramphenicol had greater sensitivity to the anticoagulant.³

An isolated report describes an 83-year-old woman stabilised on **warfarin** who showed a rise in her INR to about 8.9 from her normal range of 1.9 to 2.8 within 2 weeks of starting to use eye drops containing chloramphenicol 5 mg/mL, dexamethasone sodium phosphate 1 mg/mL and tetrahydrozoline hydrochloride 0.25 mg/mL. She used one drop in each eye

four times daily.⁴ Hypoprothrombinaemia and bleeding have also been described in patients given intramuscular,⁵ intravenous,⁵ or oral⁶ chloramphenicol in the absence of an anticoagulant.

Mechanism

Uncertain. One suggestion is that the chloramphenicol inhibits the liver enzymes concerned with the metabolism of the anticoagulants so that their effects are prolonged and increased.⁴ *In vitro* work with human liver microsomes showed that chloramphenicol did not inhibit the hydroxylation of *S*-warfarin, but it did inhibit *R*-warfarin metabolism, probably via CYP3A4.⁷ Another suggestion is that the antibacterial diminishes the gut bacteria thereby decreasing a source of vitamin K, but it is doubtful if these bacteria are normally an important source of the vitamin except in exceptional cases where dietary levels are very inadequate.⁸ A third suggestion is that chloramphenicol blocks production of prothrombin by the liver.⁵ See also 'antibacterials', (p.365)

Importance and management

The documentation for the interaction between anticoagulants and oral chloramphenicol is very sparse and poor (the best being the pharmacokinetic report about dicoumarol) so that this interaction is by no means adequately established. There would therefore appear to be little reason for avoiding concurrent use, but it would seem prudent to monitor prothrombin times if oral chloramphenicol is started in patients taking a coumarin, being alert for the need to reduce the anticoagulant dosage.

The report about an apparent interaction between warfarin and topical chloramphenicol is very surprising because the amount of chloramphenicol absorbed from eye drops is relatively small and because, despite the very widespread use of warfarin and chloramphenicol for very many years, this report appears to be the only one. This suggests that any such interaction is very unlikely indeed, however the ultra-cautious may wish to monitor the outcome if topical chloramphenicol is used.

Coumarins + Antibacterials; Clindamycin

An isolated report describes bleeding and a markedly increased INR in a woman stabilised on warfarin, which was tentatively attributed to an interaction with clindamycin. Another report found no cases of a serious increase in INR in patients taking acenocoumarol or phenprocoumon with clindamycin.

Clinical evidence, mechanism, importance and management

A 47-year-old woman with multiple medical problems stabilised on **warfarin** (and also taking azathioprine, captopril, furosemide, insulin, captopril, prednisone, levothyroxine, valproic acid and zolpidem) had all her teeth removed under general anaesthetic. Sixteen days later she needed a dental abscess drained and was given oral clindamycin 300 mg four times daily with ibuprofen 600 mg for any discomfort. On day 17 she needed a suture to stop some bleeding and her INR was found to be 3.5. By day 20 she had developed more severe oral bleeding, which needed emergency room treatment. Her INR was found to have risen to 13 and her haematocrit decreased to 18%. She was treated successfully with a blood transfusion and vitamin K.¹

This appears to be an isolated case, from which no general conclusions should be drawn (see also 'antibacterials', (p.365)) because the whole picture is so uncertain. Note that in a cohort study, none of 37 patients stabilised on **acenocoumarol** or **phenprocoumon** developed over-

anticoagulation (an INR greater than 6) when they were given clindamycin.²

Coumarins + Antibacterials; Linezolid

Linezolid had only minor effects on the pharmacokinetics and anticoagulant activity of single-dose warfarin, which were not considered to be clinically significant.

Clinical evidence, mechanism, importance and management

Linezolid 600 mg twice daily was given to 13 healthy subjects for 5 days followed by a single 25-mg dose of warfarin. The pharmacokinetics of warfarin with linezolid were within 20% of those seen with warfarin alone, and the INR was minimally affected (about a 10% increase in maximal INR).¹ These effects were not considered to be clinically relevant. See also 'antibacterials', (p.365).

1. Azie NE, Stalker DJ, Jungbluth GL, Sisson T, Adams G. Effect of linezolid on CYP2C9 using racemic warfarin (W) as a probe. *Clin Pharmacol Ther* (2001) 69, 21.

Coumarins + Antibacterials; Macrolides

Most studies suggest that macrolides do not significantly alter the pharmacokinetics or anticoagulant effects of warfarin. There is less information about other anticoagulants but studies similarly suggest that acenocoumarol and phenprocoumon do not usually interact with the macrolides; however one study has suggested that clarithromycin increases the risk of bleeding in patients taking these coumarins. Furthermore, a number of case reports describe bleeding in patients taking coumarins and macrolides.

Clinical evidence

(a) Azithromycin

There are no studies of the effect of azithromycin on the pharmacokinetics of coumarins. One pharmacodynamic study and two case series suggest no interaction occurs with warfarin. However, at least 7 published case reports suggest an interaction might occur. These are discussed below.

The manufacturer notes that a 5-day course of azithromycin (500 mg on day one then 250 mg daily for 4 days) did not affect the prothrombin time response to a single 15-mg dose of warfarin in healthy subjects.^{1,2} A retrospective study of 26 patients stabilised on warfarin found no evidence that treatment with azithromycin had any effect on their INRs. The patients had stable INRs for at least 2 consecutive records before receiving azithromycin, and an INR taken within 14 days (9 patients) or 30 days (17 patients) of starting the azithromycin.³ The same finding was reported in another similar smaller study in 17 patients.⁴ A major disadvantage of these 2 retrospective studies is the small numbers of patients who had an INR value within 7 days of starting azithromycin.

In contrast, there are now a number of published case reports suggesting that azithromycin might potentiate the activity of warfarin.^{5–11} In one of these cases, a 57-year-old woman stabilised on warfarin with an INR ranging from 1.75 to 3.03 in the previous 3 months was prescribed a 5-day course of azithromycin (500 mg on day one, then 250 mg daily for 4 days) for a possible upper respiratory tract infection. Two days after completing the azithromycin, a routine INR was found to be 8.32. She had no signs or symptoms of bleeding. During the infection she had a fever on the second day, and she reduced her 'smoking', (p.456) from 1 pack of cigarettes daily to 1 pack over 3 days.⁹ In other cases, a rise in INR of 1.4-fold to sixfold occurred within 1 to 7 days of starting azithromycin.^{5–8,10,11} Three patients had bleeding complications,^{6,7,10} and 4 required vitamin K administration.^{6–8,10} Most of these patients had possible confounding factors such as recent increases in warfarin dose,^{7,8} other concurrent antibacterials,^{8,11} fever and decreased appetite,^{5,10} or complex disease states and heart failure.^{6–8,10}

The manufacturers¹² say that as of December 1998, they had received 47 reports (40 in the US, 7 elsewhere in the world, including 2 in the UK) of

possible interactions between azithromycin and warfarin. A 2004 report from the Australian Adverse Drug Reactions Advisory Committee said they had received 3 reports of interactions between warfarin and azithromycin,¹³ which presumably includes the 2 published cases.⁸

(b) Clarithromycin

There are no studies of the effect of clarithromycin on the pharmacokinetics or anticoagulant activity of coumarins. However, there are at least 13 cases of increased INRs in published reports, and one cohort study suggesting that the use of clarithromycin is associated with an increased risk of bleeding in patients taking coumarins. These are discussed below.

1. *Acenocoumarol*. The INR of a 75-year-old woman stabilised on acenocoumarol rose from 2.1 to 9 within a week of starting to take clarithromycin 250 mg twice daily.¹⁴ Five patients stabilised on acenocoumarol had a mean increase in their INRs from about 2.5 to 5.5 when they took clarithromycin.¹⁵ The largest increase was from 1.95 to 7.01. In one cohort study in patients taking acenocoumarol or phenprocoumon, clarithromycin significantly increased the risk of overanticoagulation (INR greater than 6: relative risk of 11.7 range 3.6 to 37.8). The risk was highest during the first 3 days of combined use.¹⁶

2. *Phenprocoumon*. A 70-year-old woman stabilised on phenprocoumon developed a marked increase in prothrombin time from a range of 140 to 180 seconds up to 304 seconds, but no bleeding, within 4 days of starting to take clarithromycin 500 mg daily. The phenprocoumon was stopped and phytomenadione given. When the antibacterial was withdrawn she was restabilised on the original dosage of phenprocoumon.¹⁷ For discussion of a cohort study in patients stabilised on phenprocoumon or acenocoumarol, which showed an increased risk of over-anticoagulation with clarithromycin, see *Acenocoumarol*, above.

3. *Warfarin*. In 1992 the CSM in the UK notified prescribers in the UK of a case of a woman taking warfarin for mitral valve disease who suffered a fatal cerebrovascular bleed 3 days after starting to take clarithromycin.¹⁸ Her INR was above 10. A further patient stabilised on warfarin had a suprachoroidal haemorrhage 7 days after starting clarithromycin 250 mg twice daily, with permanent vision loss. Her INR was 8.2. She had a normal INR (2.3) three days prior to starting clarithromycin, and also 3 days after starting the course (2.9).¹⁹

Other patients taking warfarin have been found to have INRs of 5.6 five days after starting clarithromycin,²⁰ of 90.3 five days after completing a 10-day course of clarithromycin,²⁰ of 17 five days after finishing a 14-day course of clarithromycin,²¹ and of 7.3 within 12 days of starting clarithromycin.²² None of these patients had bleeding complications. In a brief report in 2004, the Adverse Drug Reactions Advisory Committee of Australia state that they had received 6 reports of interactions between clarithromycin and warfarin (median INR of 7.6), two of which were symptomatic.¹³

(c) Dirithromycin

In a study in 15 healthy subjects the pharmacokinetics and pharmacodynamics of a single 0.5-mg/kg dose of warfarin were not altered when it was given on day 10 of a 14-day course of dirithromycin 500 mg daily.²³

(d) Erythromycin

Erythromycin caused a minor inhibition of warfarin metabolism in three pharmacokinetic studies, and there are at least 11 published cases of interactions with coumarins, and 19 cases mentioned in a report from the Adverse Drug Reactions Advisory Committee of Australia. These are discussed below.

1. *Acenocoumarol*. Haematuria occurred in a patient stabilised on acenocoumarol on the last day of a 14-day course of erythromycin.²⁴ Another patient stabilised on acenocoumarol with an INR in the range of 3 to 4.5 was found to have an INR of 15 a week after starting to take erythromycin ethylsuccinate 1.5 g daily but no bleeding was seen.²⁵ Conversely, in one cohort study in patients taking acenocoumarol or phenprocoumon, no cases of over-anticoagulation (INR greater than 6) occurred in patients treated with erythromycin (78 patients received this antibacterial).¹⁶ Note that this study did show an increase for *clarithromycin*, see above.

2. *Warfarin*. A study in 12 healthy subjects found that the clearance of a single 1-mg/kg dose of warfarin was reduced by an average of 14% (range 0 to about 30%) when taken on day 5 of an 8-day course of erythromycin 250 mg every 6 hours. This change was greatest in those subjects with relatively slow warfarin clearance rates.²⁶ In another similar study, warfarin 0.5 mg/kg, given on day 10 of a 14-day course of erythromycin 250 mg four times daily increased the AUC of *S*-warfarin by 11.2% and of *R*-war-

farin by 11.9%. The INR increased by 10.2%.²³ Similar effects were seen in another study in 8 patients stabilised on warfarin and who did not have infections. In these patients, erythromycin 333 mg three times daily for 7 days caused a mean 9.9% increase in the prothrombin time ratio, which was maximal by day 2 to 5. There was also a mean 9.4% increase in total plasma warfarin level, which was similar for the *S*- and *R*-enantiomers, and was maximal by day 7. No patient had a prothrombin time ratio above the therapeutic range and none required a reduction in warfarin dose.²⁷ In contrast to the modest effects in the above studies, various case reports have demonstrated a marked increase in INR. For example, an elderly woman taking warfarin developed haematuria and bruising within a week of starting to take erythromycin stearate 500 mg four times daily for a chest infection. Her prothrombin time had risen to 64 seconds (prothrombin time ratio about 5.5). Within the previous month she had started taking digoxin and quinidine, and had her warfarin dose increased because of a decrease in prothrombin time.²⁸ At least 8 other cases of bleeding and/or an increase in prothrombin time or INR have been described in patients taking warfarin with erythromycin (as the base, ethylsuccinate, stearate, or lactobionate).²⁹⁻³⁵ In addition, in a brief report in 2004, the Adverse Drug Reactions Advisory Committee of Australia stated that they had received 19 reports of interactions between erythromycin and warfarin (median INR of 9.7), only 4 of which were symptomatic.¹³ There is also a case report of sulfonamide-induced bullous haemorrhagic eruption in a patient taking warfarin, 'co-trimoxazole', (p.376) and erythromycin, in which the authors considered an interaction between warfarin and erythromycin may have contributed to the haemorrhagic component.³⁶

(e) *Midecamycin diacetate*

The pharmacokinetics of a single 8-mg oral dose of acenocoumarol were not significantly changed when it was taken on day 4 of a 9-day course of midecamycin diacetate 800 mg twice daily.³⁷

(f) *Roxithromycin*

Roxithromycin did not alter the pharmacokinetics or effect of warfarin in one study. However, there are at least 2 published cases of interactions with coumarins, and one report reviewing 16 cases. These are discussed below.

1. *Acenocoumarol*. A 79-year-old man stabilised on acenocoumarol developed an abdominal wall haematoma 2 days after starting to take roxithromycin 150 mg twice daily for a lung infection.³⁸ Six days later, on admission to hospital, his INR was found to be 5.9. Conversely, in one cohort study in patients taking acenocoumarol or phenprocoumon, no cases of over-anticoagulation (INR greater than 6) occurred in patients treated with roxithromycin (only 14 patients received this antibacterial).¹⁶ Note that this study did show an increase for *clarithromycin*, see above.

2. *Phenprocoumon*. A 75-year-old man taking phenprocoumon developed a marked increase in prothrombin time but no bleeding when he was given roxithromycin 300 mg daily for 5 days. The phenprocoumon was stopped and phytomenadione given. When the antibacterial was withdrawn he was restabilised on the original dosage of phenprocoumon.¹⁷ For mention of a cohort study in patients stabilised on phenprocoumon or acenocoumarol showing no increased risk of overanticoagulation with roxithromycin, see *Acenocoumarol*, above.

3. *Warfarin*. In a study in which warfarin was given at a daily dose sufficient to maintain the thrombotest percentages at 10 to 20%, there was no difference in warfarin dose or AUC between 10 subjects given roxithromycin 150 mg twice daily for 2 weeks and 11 subjects given placebo. The dose of warfarin and the AUC of warfarin increased by about 10% in both the roxithromycin group and the placebo group, which was taken as indicating that steady state had not been achieved. Serum roxithromycin levels were unchanged by warfarin.³⁹ In contrast, during the 1992 to 1995 period The Centre for Adverse Reactions Monitoring of New Zealand received 7 reports of a possible interaction with roxithromycin resulting in increased warfarin effects, and, during the same period, the Adverse Drug Reactions Advisory Committee of Australia received 9 similar reports. Review of the 16 cases showed that 7 patients had clinical symptoms of over-anticoagulation, and the other 9 were asymptomatic and detected by routine testing.⁴⁰ In a 2004 update from ADRAC, it was noted that they now had on record 56 cases of an interaction between roxithromycin and warfarin, with 27 cases being symptomatic. The median INR was 8.8, and the median time to onset was 6 days. One fatality occurred in a 79-year-old

woman who started taking warfarin and roxithromycin at the same time. By day 8, she had an INR of 11.6, and subsequently died from widespread bleeding.¹³

(g) *Telithromycin*

In a placebo-controlled, crossover study in healthy subjects, telithromycin 800 mg once daily for 7 days did not alter the pharmacodynamics of a single-dose of warfarin 25 mg given on day 4. There was a small 20% increase in the AUC of *R*-warfarin, and a 5% increase in the AUC of *S*-warfarin,⁴¹ effects which the manufacturer does not consider to be clinically relevant.^{42,43} Conversely, a 73-year-old man taking warfarin for a metallic valve replacement started taking telithromycin 800 mg daily for 5 days for a cough. On the last day of treatment he developed haemoptysis and was found to have an INR of 11. His INR 10 days before telithromycin was started was 3.1. The telithromycin was stopped and he was subsequently restabilised on warfarin.⁴⁴ Moreover, Health Canada reported that from May 2003 to September 2004 they had received 7 reports of suspected coagulation disorder interactions with telithromycin, 6 with warfarin and one with an unspecified oral anticoagulant. The INR was increased in 6 of the reports and decreased in the seventh.⁴⁵

(h) *Unspecified macrolides*

The INR increased by an estimated 0.319 in 35 patients taking warfarin when prescribed an oral macrolide (not named) in a prospective study of the effect of antibacterials on anticoagulation.⁴⁶

Mechanism

Erythromycin is a known inhibitor of the cytochrome P450 isoenzyme CYP3A4. However, this isoenzyme has only a minor role in the 'metabolism of warfarin', (p.358), specifically the less active *R*-isomer of warfarin. Consequently, only minor increases in the levels of warfarin have been seen in pharmacokinetic studies, which would generally not be expected to be clinically relevant. However, it is possible that even these small changes might be important in a very few patients, particularly those with a low prothrombin complex activity.²⁶ Other macrolides (azithromycin, clarithromycin, dirithromycin, roxithromycin) have less effect on CYP3A4 than erythromycin, and consequently would be expected to have even less effect on the pharmacokinetics of warfarin or acenocoumarol, which is borne out in the few studies available. Nevertheless, cases of interactions have been reported for nearly all these macrolides. Moreover, one cohort study found that clarithromycin increased the risk of an interaction and erythromycin did not. It is possible that there is some other, as yet unidentified, mechanism involved. Alternatively, it is equally possible that the relatively few cases just represent idiosyncratic effects attributable to other factors, and not to any interaction (see also 'Coumarins + Antibacterials', p.365).

Importance and management

The minor pharmacokinetic interaction with erythromycin and warfarin is established, but would not generally be expected to be clinically relevant. This is borne out by the relatively few published reports of an interaction (11 published case reports worldwide and 19 cases reported to the Adverse Drug Reactions Advisory Committee of Australia). Other macrolides would be even less likely to inhibit the metabolism of warfarin or acenocoumarol than erythromycin, and this is borne out by studies with dirithromycin, midecamycin and roxithromycin. Nevertheless, cases of important interactions have been reported for most of the other macrolides (azithromycin, clarithromycin, roxithromycin, and telithromycin). Moreover, one cohort study found an increased risk of over-anticoagulation with clarithromycin but not with erythromycin. Taken together, the available evidence suggests that because very occasionally and unpredictably the effects of warfarin and acenocoumarol or phenprocoumon appear to markedly increased by macrolides, it would be prudent to increase monitoring in all patients when they are first given any macrolide antibacterial. There is some evidence that this may be particularly important in those who clear warfarin and other anticoagulants slowly and who therefore only need low doses. The elderly in particular would seem to fall into this higher risk category. With azithromycin, bear in mind that, because of azithromycin's long half-life, the interaction may possibly not become apparent until a couple of days after a short course (i.e. 5 days) of azithromycin has been stopped.

Coumarins + Antibacterials; Metronidazole or Nimorazole

One early study found that metronidazole increased the half-life of a single dose of warfarin by one-third and increased its effects,

and another cohort study showed that the combination caused a marked increase in INR, without bleeding. Case reports support these findings. There is a single case of a markedly increased INR and bleeding in a man taking phenprocoumon who was given nimorazole.

Clinical evidence

(a) Metronidazole

Metronidazole 250 mg three times daily for a week increased the half-life of a single 1.5-mg/kg dose of warfarin by about one-third (from 35 to 46 hours) in 8 healthy subjects, and increased the prothrombin time from a mean of 100 to 142 seconds. When the warfarin enantiomers were given separately, the anticoagulant effects of *S*-warfarin were virtually doubled and the half-life increased by 60%, but the response to *R*-warfarin was only affected in one subject.¹ In a retrospective cohort study, 32 patients taking warfarin had an INR reading before and during concurrent metronidazole use. In these patients, the mean INR increased from 2.2 to a maximum of 4.3 by day 8 of concurrent use. Fourteen of the 32 had an INR above 4, but no bleeding events were recorded.²

Bleeding has been seen in 2 patients taking warfarin and metronidazole.^{3,4} One of them had severe pain in one leg, ecchymoses, and haemorrhage of both legs, and an increase in her prothrombin time from 17 to 19 seconds to 147 seconds within 17 days of starting the metronidazole.³ A further report describes 3 elderly patients taking warfarin, who developed raised INRs after being given intravenous metronidazole.⁵ In the first patient the INR on admission was 4.6, and so warfarin was stopped. The next day metronidazole was given for about 24 hours, and on day 4 the INR had reached 10.3. In the second patient the INR on admission was 4.9 and so the warfarin was stopped. Later that day metronidazole was started, and the INR was reduced to 1.7 with fresh frozen plasma. Nevertheless by day 5 the INR had reached 6 (metronidazole had been stopped on day 2). In the third patient the INR on admission was 4 and so the warfarin was stopped. Later that day metronidazole was given, and the INR was reduced to 2.1 with fresh frozen plasma. Nevertheless by day 5 (while still receiving metronidazole) the INR had reached 10.

(b) Nimorazole

A 66-year-old man who had been taking phenprocoumon for 15 years with an INR around 2.5 was diagnosed with carcinoma of the glottis.⁶ He received radiotherapy 6 times a week with nimorazole 2.5 g given 1.5 hours prior to the radiotherapy as a radiosensitiser. At the 16th dose, he had haemoptysis, on the 17th dose continuous haematuria, and then on the 22nd dose his INR was found to be 7.5. Fluconazole had been started 4 days previously. When the patient had recovered and restarted phenprocoumon, he was rechallenged with nimorazole prior to his last 5 days of radiotherapy, with an INR increase from 3.7 to 5.3.

Mechanism

In the early study, it was suggested that metronidazole probably inhibits the activity of the enzymes responsible for the metabolism (ring oxidation) of the more potent isomer *S*-warfarin, but not *R*-warfarin.¹ Reduction of protein binding coupled with reduced metabolism was suggested by other authors.⁵ Nimorazole may act similarly, although there are other likely contributing factors in the case with this drug including concomitant 'fluconazole', (p.387), and reduced 'vitamin-K intake', (p.409). See also, 'antibacterials', (p.365).

Importance and management

The interaction between metronidazole and warfarin appears to be established and clinically important, although the documentation is limited. Monitor the INR when both drugs are used and adjust the warfarin dose accordingly. Nothing seems to be documented about other anticoagulants but it would be prudent to expect other coumarins to behave similarly. The single case with nimorazole suggests that caution may also be warranted with this drug.

Coumarins + Antibacterials; Penicillins

Isolated cases of increased prothrombin times and/or bleeding have been seen in patients given amoxicillin (with or without clavulanic acid) intravenous benzylpenicillin, pheneticillin or talampicillin. An increased risk of over-anticoagulation was seen with amoxicillin with or without clavulanic acid in cohort studies, but not flucloxacillin. There is also some evidence that phenoxymethylpenicillin (penicillin V) does not interact.

In contrast, several cases of markedly reduced warfarin effects (warfarin resistance) have been seen with intravenous nafcillin, with a 75% reduction in warfarin half-life documented in one case. Similarly, other studies and cases suggest that dicloxacillin may cause a modest reduction in warfarin effects in many patients, and that some may experience greater reductions, with thrombosis being reported in one case.

Clinical evidence

(a) Amoxicillin ± clavulanic acid

An 81-year-old woman taking **acenocoumarol** 3 mg daily (INR 2.5 to 4) developed bruising and an increased INR of 7.1 within a week of starting amoxicillin 500 mg every 8 hours.¹ Another patient stabilised on **warfarin** (INR 2 to 3) had a normal INR (2.55) 4 days after completion of a 7-day course of co-amoxiclav (amoxicillin with clavulanic acid), but about 2.5 weeks after the course a routine INR was 6.2. A further 3 days later it was 8.7 and microscopic haematuria was detected.² In one case control study, use of co-amoxiclav was found to be associated with an increased risk of an INR of greater than 6 (odds ratio 4.1; range 0.9 to 19.2) in patients stabilised on either **acenocoumarol** or **phenprocoumon**. Amoxicillin alone was associated with a smaller increased risk (odds ratio 1.7; range 0.6 to 4.7).³ Conversely, in a population-based cohort study in similar patients conducted by the same research group, the risk of over-anticoagulation (INR greater than or equal to 6) was greater for amoxicillin alone than amoxicillin plus an enzyme inhibitor. The relative risk for amoxicillin alone was 10.5 (range 5.1 to 21.7) and for amoxicillin plus an enzyme inhibitor was 5.1 (range 1.9 to 13.9).⁴ The increased risk was observed in the early stages of concurrent use but was greater after 4 or more days of treatment.⁴

In contrast to these reports of increased anticoagulation, a very brief report states that in an audit of an anticoagulant clinic, 5 patients who had taken amoxicillin had an unspecified decrease in prothrombin time.⁵

(b) Ampicillin

A bulletin briefly mentions a case of an increased prothrombin time in a patient taking **warfarin** with ampicillin and **flucloxacillin**.⁶

(c) Benzylpenicillin

One patient stabilised on **warfarin** (prothrombin time 20 seconds) was found to have an increased prothrombin time of 32 seconds 8 days after starting intravenous benzylpenicillin 24 million units daily for subacute bacterial endocarditis. The benzylpenicillin was continued, and the warfarin dose reduced for 18 days. However, the prothrombin time dropped below the therapeutic range, and the warfarin dose was increased back to the original dose, still with continuation of the benzylpenicillin for a further 3 weeks.⁷

(d) Dicloxacillin

In a controlled study in 7 patients stabilised on **warfarin** and without infections, dicloxacillin 500 mg four times daily for 7 days reduced the mean prothrombin time by 1.9 seconds. One patient had a 5.6 second reduction.⁸ This study was conducted because the authors had noted a case of a patient receiving **warfarin** who had a decrease in prothrombin time when dicloxacillin was started.⁸ Another patient stabilised on **warfarin** had a 17% fall in prothrombin times within 4 to 5 days of starting dicloxacillin 500 mg four times daily, with a documented 20 to 25% reduction in both *S*- and *R*-warfarin levels.⁹ In a retrospective review, 7 other patients similarly treated were also identified as having a 17% reduction in pro-

thrombin times.⁹ In yet another case, a patient who had previously required **warfarin** 10 mg daily subsequently needed an increased dosage of 15 mg daily while taking dicloxacillin 4 g daily long-term.¹⁰ However, another case report suggested a greater effect of dicloxacillin—a patient taking 500 mg every 6 hours required an increase in **warfarin** dose from a range of 35 to 40 mg weekly up to 50 to 60 mg weekly, with INRs still being subtherapeutic (about 1.5).¹¹ Moreover, when a woman taking **warfarin** was given dicloxacillin 500 mg four times daily she developed a heart valve thrombosis, suggesting inadequate anticoagulation. Her INR was 1.4, and an increased **warfarin** dose was required for 3 weeks after she stopped dicloxacillin.¹²

(e) Flucloxacillin

In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, no cases of over-anticoagulation (INR greater than 6) occurred in patients taking flucloxacillin (25 patients received this antibacterial).⁴ Note that this study did show an increase for *amoxicillin*, see above. A bulletin briefly mentions a case of an increased prothrombin time in a patient taking **warfarin** with **ampicillin** and flucloxacillin.⁶

(f) Nafcillin

The prothrombin time of a 29-year-old patient stabilised on **warfarin** fell from a range of 20 to 25 seconds down to 16 seconds five days after intravenous nafcillin 2 g every 4 hours was started for endocarditis.¹³ Over the next 2 weeks the prothrombin time ranged between 14 and 17 seconds despite an eventual doubling of the warfarin dose, and heparin was substituted. In this patient the half-life of a single 30-mg dose of warfarin was 11 hours when nafcillin was taken, 17 hours 4 days after stopping nafcillin, and 44 hours eight months after the nafcillin was discontinued. At least 10 other cases of this warfarin resistance have been reported with high-dose nafcillin.^{10,14-18}

(g) Pheneticillin

In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, one case of over-anticoagulation (INR greater than 6) occurred in a group of 219 patients treated with pheneticillin, giving a calculated relative risk of 0.9.⁴

(h) Phenoxymethylpenicillin (Penicillin V)

When 10 patients taking an unnamed anticoagulant were given intravenous phenoxymethylpenicillin calcium 300 000 units four times daily for 4 days, none had a change in their prothrombin-proconvertin value.¹⁹ For mention that, in another study no patients taking penicillins including phenoxymethylpenicillin had an increase in INR see (j) below.

(i) Talampicillin

A bulletin briefly mentions a case of bleeding (haematuria, epistaxis) and an increase in the prothrombin ratio in a patient taking **warfarin** and talampicillin.²⁰

(j) Unspecified penicillins

In one analysis of patients taking **warfarin** with antibacterials, there was no association between use of penicillins (**phenoxymethylpenicillin (penicillin V)** and **broad-spectrum penicillins**) and an increase in INR. The estimated change in INR was 0.117 in 109 patients given the combination.²¹

Mechanism

Not understood. The interaction between nafcillin and warfarin is possibly due to increases in the metabolism of warfarin by the liver. Dicloxacillin also possibly reduces serum warfarin levels.⁹ Other penicillins (ampicillin,²² benzylpenicillin,^{22,23} carbenicillin,²⁴⁻²⁹ methicillin,²² ticarcillin³⁰) have caused increased bleeding times when given alone, principally due to platelet inhibition,²²⁻²⁴ which might be additive with the effects of oral anticoagulants. Broad-spectrum antibacterials may decrease the gut flora and thereby possibly decrease production of vitamin K. Other factors relating to the disease may be important, see 'Coumarins + Antibacterials' p.365.

Importance and management

The reduced effect of warfarin with **dicloxacillin** and **nafcillin** appears to be established. If these penicillins are used, increase monitoring of the INR and anticipate the need to increase the warfarin dose. Some patients taking nafcillin have been warfarin resistant, and needed heparin treatment.

Documented reports of interactions between oral anticoagulants and other penicillins are relatively rare, bearing in mind how frequently these drugs are used, so that the broad picture is that no clinically relevant interaction normally occurs with most other penicillins. This lack of interaction was supported by one clinical study.²¹ However, in one case-control study, amoxicillin/clavulanic acid (co-amoxiclav) increased the risk of bleeding, and the authors recommended avoiding this combination,³ although a later cohort study by the same authors just recommended increased monitoring with amoxicillin or co-amoxiclav.⁴ Even though the general picture is of no interaction, there are a number of reports of adverse interactions between coumarins and penicillins. Although there appear to be no reports of an interaction, if the mechanism of the interaction is correct, the **indanediones** are also likely to be affected. However, these interactions may be due to a number of different factors, and these are discussed in detail in the monograph 'Coumarins + Antibacterials', p.365. Therefore concurrent use should be monitored so that the very occasional and unpredictable cases (increases or decreases in the anticoagulant effects) can be identified and handled accordingly.

Coumarins + Antibacterials; Quinolones

Most studies show that the quinolones have, at most, a small, clinically insignificant effect on the pharmacokinetics and pharmacodynamics of warfarin. Despite this, increased effects and even bleeding have been seen quite unpredictably in isolated cases in patients taking warfarin with ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, nalidixic acid, norfloxacin or ofloxacin; or while taking acenocoumarol when given nalidixic acid, norfloxacin or pefloxacin, or phenprocoumon with norfloxacin. Fur-

thermore, two studies suggest that there may be an increased risk of over-anticoagulation in patients taking acenocoumarol or phenprocoumon with norfloxacin, and warfarin with gatifloxacin.

Clinical evidence

(a) Ciprofloxacin

In a randomised, placebo-controlled study in 32 patients stabilised on warfarin and without infections, ciprofloxacin 750 mg twice daily for 12 days had no clinically relevant effect on measures of anticoagulation. There was a mean increase in prothrombin time ratio of just 3% (range 0 to 6%), with a 10 to 13% decrease in the levels of clotting factors II and VII. In this study, ciprofloxacin had no effect on *S*-warfarin levels, but did slightly increase *R*-warfarin levels by 14.7%.¹ Similarly, no clinically relevant effects on warfarin anticoagulation were seen in two other studies in a total of 16 patients without infections given ciprofloxacin 500 mg twice daily for 7 or 10 days.^{2,3} In a population-based cohort study,⁴ there were no cases of over-anticoagulation (INR greater than 6) in patients taking acenocoumarol or phenprocoumon with ciprofloxacin (just 19 received ciprofloxacin). Note that this study did find an increased risk for norfloxacin, see below.

In contrast, there are reports where ciprofloxacin has apparently been responsible for moderate to markedly increased prothrombin times and/or bleeding in patients taking warfarin. The FDA in the US has a total of 64 such cases over the 10 year period 1987 to 1997 on its Spontaneous Reporting System database. Those cases where details were available, plus an additional 2 cases, showed that the median prothrombin time was 38 seconds, the INR 10, and the median time to detection after starting ciprofloxacin was 5.5 days. Hospitalisation was reported in 15 cases, bleeding in 25 cases and death in one case.⁵ There are a number of other individual published case reports from the USA describing moderate to marked increases in prothrombin times and/or bleeding in a total of 8 patients stabilised on warfarin, which was associated with taking ciprofloxacin.⁶⁻¹² For the period December 1989 to January 2004, Health Canada had received 10 reports of suspected coagulation disorders associated with ciprofloxacin and warfarin, 7 of which were considered serious, and in one case, fatal.¹³ Similarly, in February 2006, the Australia Adverse Drug Reaction Advisory Committee stated they had received 9 reports of a suspected interaction between warfarin and ciprofloxacin.¹⁴

(b) Clinafloxacin

Clinafloxacin 200 mg twice daily for 14 days had no effect on the steady-state levels of *S*-warfarin in healthy subjects, but the levels of the less active enantiomer *R*-warfarin were increased by 32% and the mean INR was increased by 13%.¹⁵

(c) Enoxacin

When a single 25-mg dose of warfarin was given to 6 healthy subjects on day 8 of a 14-day course of enoxacin 400 mg twice daily, the pharmacokinetics of *S*-warfarin were not altered, but the clearance of *R*-warfarin was decreased by 32% and its elimination half-life was prolonged from 36.8 to 52.2 hours. The overall anticoagulant response to the warfarin was unaltered.¹⁶ Another report about one patient taking warfarin also suggested that the use of enoxacin does not alter the prothrombin time ratio.¹⁷

(d) Fleroxacin

The pharmacokinetics of *R*- and *S*-warfarin, the prothrombin time and factor VII clotting time were unaffected when 12 healthy subjects were given a single 25-mg dose of warfarin on day 4 of a 9-day course of fleroxacin 400 mg daily.¹⁸

(e) Gatifloxacin

The manufacturer notes that gatifloxacin 400 mg daily for 11 days had no effect on the pharmacokinetics of a single 25-mg dose of warfarin, nor was the prothrombin time altered.¹⁹ In contrast, in a review of 94 patients taking warfarin and given antibacterials for community-acquired pneumonia, 22 of the 40 patients treated with gatifloxacin (55%) had INRs greater than 3 during or within 48 hours after stopping gatifloxacin therapy, compared with 20 of 54 patients treated with ceftriaxone and/or azithromycin (37%). In the gatifloxacin group, 38% needed a warfarin dose adjustment, compared with 18% of patients taking other antibacterials. There was no difference in infection severity between the two groups.²⁰ For the period February 2001 to January 2004, Health Canada had received 13 reports of suspected coagulation disorders associated with gati-

floxacin and **warfarin**, all of which were considered serious, and 2 of which were fatal.¹³

(f) *Gemifloxacin*

A double-blind, randomised, placebo-controlled study found that healthy subjects taking fixed doses of **warfarin** and with INRs in the range of 1.3 to 1.8 had no INR changes when they were given gemifloxacin 320 mg daily for 7 days.²¹

(g) *Levofloxacin*

Levofloxacin 500 mg twice daily for 9 days had no effect on the pharmacokinetics or pharmacodynamics of *R*- and *S*-warfarin in 15 healthy subjects given a single 30-mg dose of **warfarin** on day 4.²² In a prospective study 18 patients stabilised on **warfarin** were given a course of levofloxacin. There was no difference in the mean INR obtained before levofloxacin and the first INR taken a median of 5 days after levofloxacin was started (2.61 versus 2.74). However, 4 patients had an increase in INR (to a range of 3.89 to 4.2) and 3 had a decrease in INR (to a range of 1.39 to 1.84) outside of the therapeutic range (2 to 3), and required **warfarin** dosage adjustments. Only 7 patients had INRs that were therapeutic (range 2 to 3) throughout the study (before, during, and after levofloxacin) and did not require adjustment in **warfarin** dose.²³ Similar findings were reported in a retrospective analysis of 22 patients taking **warfarin** with levofloxacin.²⁴

However, two elderly patients taking **warfarin** were found to have increased INRs (of 5.7 and 7.9) on routine testing shortly after stopping levofloxacin 500 mg daily.²⁵ Six other cases of modest to markedly increased INRs have been reported in patients stabilised on **warfarin** who were given courses of levofloxacin 500 mg daily for 5 to 10 days;^{26,27} epistaxis occurred in one patient.²⁷ Moreover, for the period November 1997 to January 2004, Health Canada had received 16 reports of suspected coagulation disorders associated with levofloxacin and **warfarin**, 14 of which were considered serious, and one of which was fatal.¹³

(h) *Moxifloxacin*

The pharmacokinetics of *R*- and *S*-warfarin were not altered when a single 25-mg dose of **warfarin** was given on day 5 of an 8-day course of moxifloxacin 400 mg once daily in healthy subjects. The prothrombin time increased by 3% (0 to 6%), which is not clinically relevant.²⁸

In contrast, one report describes 2 patients stabilised on **warfarin** who had marked rises in their INRs (to 6.2 and 7.3), and another patient recently started on **warfarin** who had a more modest rise (to 4.2) within 1 to 5 days of starting moxifloxacin.²⁹ All these patients had recently been receiving other antibacterials, which complicates interpretation. For the period October 2000 to January 2004, Health Canada had received 12 reports of suspected coagulation disorders associated with moxifloxacin and **warfarin**, 11 of which were considered serious.¹³ Similarly, in February 2006, the Australia Adverse Drug Reactions Advisory Committee stated they had received one report of a suspected interaction between **warfarin** and moxifloxacin. In this patient the INR rose from around 2 to greater than 10, four days after starting moxifloxacin.¹⁴

(i) *Nalidixic acid*

A patient stabilised on **warfarin** (prothrombin ratio 2), developed a purpuric rash and bruising within 6 days of starting nalidixic acid 500 mg four times daily. Her prothrombin ratio had risen to 3.46.³⁰ Another patient, previously well controlled on **warfarin**, developed a prothrombin time of 60 seconds 10 days after starting nalidixic acid 1 g three times daily.³¹ The INR of an 84-year-old woman taking **warfarin** rose from 1.9 to 9.6 when nalidixic acid was added.³² Similarly, a patient taking **acenocoumarol** developed hypoprothrombinaemia after receiving nalidixic acid 1 g daily.³³

(j) *Norfloxacin*

In 10 healthy subjects norfloxacin 400 mg twice daily for 9 days was found not to alter either the pharmacokinetics or anticoagulant effects of a single 30-mg dose of **warfarin** given on day 4.³⁴

In contrast, a 91-year-old woman taking **warfarin** and digoxin developed a brain haemorrhage within 11 days of starting to take norfloxacin (precise dose not stated). Her prothrombin times had risen from 21.6 to 36.5 seconds. At this time, the manufacturers of norfloxacin were said to have 6 other reports of an interaction between warfarin and norfloxacin on file.³⁵ In a population-based cohort study, patients taking **acenocoumarol** or **phenprocoumon** were found to have an increased risk of overanticoagulation (INR greater than or equal to 6) during norfloxacin treatment (relative risk 9.8). The risk was greatest during the first 3 days of treatment.⁴ Furthermore, for the period December 1986 to January 2004,

Health Canada had received 6 reports of suspected coagulation disorders associated with norfloxacin and **warfarin**, 4 of which were considered serious.¹³ Similarly, in February 2006, the Australia Adverse Drug Reactions Advisory Committee stated they had received 11 reports of a suspected interaction between **warfarin** and norfloxacin.¹⁴

(k) *Ofloxacin*

Ofloxacin 200 mg daily for 7 days did not significantly affect the prothrombin times of 7 healthy subjects stabilised on **phenprocoumon**.³⁶ In a population-based cohort study,⁴ there were no cases of over-anticoagulation (INR greater than 6) in patients taking **acenocoumarol** or **phenprocoumon** with ofloxacin (33 received ofloxacin). Note that this study did find an increased risk for *norfloxacin*, see (j) above. Furthermore, for the period December 1990 to January 2004, Health Canada had not received any reports of suspected coagulation disorders associated with ofloxacin and **warfarin**.¹³

In contrast, a woman who had recently started to take **warfarin** 5 mg daily, had a marked increase in her INR (from 2.5 to 4.4) within 2 days of starting to take ofloxacin 200 mg three times daily.³⁷ Two days later her INR had risen to 5.8. Another patient stabilised on **warfarin** developed gross haematuria and a prothrombin time of 78 seconds 5 days after starting to take ofloxacin 400 mg twice daily.³⁸

(l) *Pefloxacin*

A patient had a marked increase in the effects of **acenocoumarol** (Quick time reduced from 26% to less than 5%) within 5 days of starting to take pefloxacin 800 mg daily and rifampicin 1.2 g daily.³⁹ Rifampicin is an enzyme inducer, which normally causes a reduction in the effects of the 'anticoagulants', (p.375), so the findings in this case are surprising.

(m) *Trovafloxacin*

Healthy subjects stabilised on **warfarin** with INRs in the range of 1.3 to 1.7 were additionally given trovafloxacin 200 mg daily for 7 days. No changes in the pharmacokinetics of either *S*- or *R*-warfarin occurred and no significant changes in mean INRs were seen.⁴⁰

Mechanism

Uncertain. It is not clear what other factors might have been responsible in those cases where the effects of the anticoagulants were increased. Factors relating to acute infection rather than the antibacterial used to treat it may be responsible for increased INRs, see also 'Coumarins + Antibacterials', p.365. However, one study that controlled for severity of infection indicated this is not the case and that an interaction between the quinolone and anticoagulant probably occurs.²⁰ *In vitro* experiments^{41,42} have shown that nalidixic acid can displace warfarin from its binding sites on human plasma albumin, but this mechanism on its own is almost certainly not the full explanation. In a single-dose study enoxacin was shown to inhibit the metabolism of the less potent *R*-warfarin isomer, without affecting the anticoagulant response.¹⁶ This effect may become important if accumulation of the *R*-warfarin isomer (which is cleared slowly) occurred during prolonged dosing.³ Other quinolones may have a similar effect. It has also been suggested that fluoroquinolones may suppress vitamin K-producing gut bacteria with resultant potentiation of anticoagulant effects,³⁷ see also 'Coumarins + Antibacterials', p.365.

Importance and management

The minor pharmacokinetic interaction between ciprofloxacin and warfarin in patients taking warfarin would appear to be established, but unlikely to be clinically relevant. Similarly no other quinolone has been shown to have a clinically significant interaction with warfarin. Despite this, there are isolated published case reports of marked over-anticoagulation with many of the quinolones, and other known unpublished cases reported to regulatory authorities. Given the widespread use of warfarin and quinolones, these interactions would appear to be rare.

The overall picture is that no adverse interaction normally occurs between these quinolones and coumarin anticoagulants, but rarely and unpredictably increased anticoagulant effects and even bleeding can occur with some of them. There is no need to avoid using any of the quinolones with oral anticoagulants but it would be prudent to monitor the effects when any quinolone antibacterial is first added to treatment with any coumarin so that any problems can be quickly identified.

Coumarins + Antibacterials; Rifamycins

The anticoagulant effects of warfarin are markedly reduced by rifampicin (rifampin), with two to fivefold increases in dose needed to maintain efficacy in a number of case reports. Acenocoumarol and phenprocoumon are similarly affected.

Clinical evidence

(a) Acenocoumarol

The dosage of acenocoumarol needed to be markedly increased to maintain the Quick value within the therapeutic range in 18 patients stabilised on acenocoumarol who were given rifampicin 450 mg twice daily for 7 days. The effect was apparent 5 to 8 days after starting the rifampicin, and had not reached a maximum at 14 days, at which point a mean 76% increase in the acenocoumarol dosage was needed.¹ In another study the Quick time of a single dose of acenocoumarol, measured 35 hours after the dose, was reduced by 44% when rifampicin 10 mg/kg daily was given for 2 weeks.²

(b) Phenprocoumon

In a study in healthy subjects, rifampicin 600 mg daily for 14 days increased the clearance of a single dose of phenprocoumon by 2.2-fold.³ Similarly, two patients stabilised on phenprocoumon required the dose to be doubled while taking rifampicin 600 mg daily (plus isoniazid with or without ethambutol). In one case, the patient developed severe gross haematuria 3 months after rifampicin had been discontinued because the phenprocoumon dose had not been reduced.⁴

(c) Warfarin

In one controlled study in 8 healthy subjects, rifampicin 600 mg daily for 21 days reduced the steady-state plasma warfarin levels by 85% (range 64% to 100%). In addition, rifampicin abolished the anticoagulant effect of warfarin (the prothrombin time averaged 27% of normal during warfarin alone, and 85% of normal when rifampicin was taken).⁵ Similar findings were seen in 2 other single-dose warfarin studies.^{6,7} One of these measured the isomers of warfarin separately and found that rifampicin increased the clearance of *R*-warfarin threefold and *S*-warfarin twofold.⁷ This interaction has also been described in a number of case reports.^{8–14} In these reports the dosage of warfarin was doubled^{8,10} or even tripled¹⁰ to accommodate this interaction, and reduced by an equivalent amount over two⁹ to three weeks¹² following withdrawal of the rifampicin. In one more-recent well-described case, a threefold increase in warfarin dose from 5 to 15 mg daily over 4 months failed to achieve a therapeutic INR during long-term rifampicin therapy, and eventually a fivefold increase in dose (25 mg daily) attained an INR of 1.7 and 1.9. A gradual 70% dose reduction over 4 to 5 weeks was required when the rifampicin was discontinued.¹⁴

Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism and clearance of the anticoagulants from the body, thereby reducing their effects.⁷ Other mechanisms may also be involved.¹² See also 'antibacterials', (p.365).

Importance and management

The interaction between rifampicin and the coumarins is very well documented, clinically important, and occurs in most patients. A marked reduction in the anticoagulant effects may be expected within a week of starting the rifampicin, and persisting for about 2 to 5 weeks after the rifampicin has been withdrawn. With warfarin there is evidence that the dosage may need to be markedly increased (two to fivefold) over a number of weeks to accommodate this interaction, and reduced slowly by an equivalent amount following withdrawal of the rifampicin. Warfarin dose titrations should be carried out with close monitoring. There does not seem to be any information regarding the other rifamycins, **rifabutin** (a weak enzyme inducer) and **rifapentine** (a moderate enzyme inducer). However, the manufacturers and the CSM in the UK warn that rifabutin may possibly reduce the effects of a number of drugs, including oral anticoagulants.^{15,16}

Coumarins and related drugs + Antibacterials; Sulfonamides and/or Trimethoprim

Co-trimoxazole modestly inhibits the metabolism of *S*-warfarin, and a number of case reports show that the anticoagulant effects of the coumarins warfarin, acenocoumarol, and phenprocoumon are increased by co-trimoxazole. Case reports suggest that sulfafurazole, sulfadoxine, and sulfamethizole may have similar effects. Two cohort studies have suggested that trimethoprim alone is associated with an increased risk of overanticoagulation, but this was less than that for co-trimoxazole in one of these studies. Anecdotal evidence suggests that the indanedione phenindione might not interact with co-trimoxazole, but in one study sulfaphenazole increased the effect of phenindione.

Clinical evidence

(a) Co-trimoxazole (Sulfamethoxazole with trimethoprim)

1. *Coumarins*. Six out of 20 patients taking warfarin had an increase in their prothrombin ratios (to about 4 to 6) within 2 to 6 days of starting to take co-trimoxazole 960 mg twice daily.¹ One patient had a gastrointestinal haemorrhage and needed to be given vitamin K. The warfarin was temporarily withdrawn from 5 patients and the dosage was reduced in one patient to control excessive hypoprothrombinaemia.¹ Similarly, an increase in the effects of warfarin, with or without bleeding complications, in patients given co-trimoxazole has been described in a number of other case reports.^{2–14} In one study in healthy subjects, co-trimoxazole 480 mg four times daily for 8 days increased the prothrombin time after a single dose of warfarin by 1.5-fold, but no change in the half-life of warfarin was seen.¹⁵ However, a later similar study by the same research group, in which warfarin was given as its separate isomers, co-trimoxazole increased the AUC of *S*-warfarin by 22% and caused a 5% decrease in AUC of *R*-warfarin.¹⁶

In a population based cohort study¹⁷ in patients taking acenocoumarol or phenprocoumon, co-trimoxazole was associated with an increased risk of over-anticoagulation (INR greater than or equal to 6); the adjusted relative risk of over-anticoagulation was noted to be 20.1 (range 10.7 to 37.9). The risk was increased in the first 3 days of use (RR 16.6), but was greatest after 4 days of concurrent use (RR 23.2).

2. *Indanediones*. In one anecdotal report, the author noted that in several years experience of the use of phenindione in an anticoagulant clinic serving 1000 patients, he had not come across a clinically important case of anticoagulant potentiation with co-trimoxazole.¹⁸ Nothing else seems to have been published on the combination, but note that another sulphonamide, sulfaphenazole, potentiated the effect of phenindione, see (d) below.

(b) Sulfadoxine

A 19-year-old with a valve replacement and taking warfarin presented with melaena and coughing up blood about a week after self-medicating with Fansidar (sulfadoxine/pyrimethamine). He had not had his anticoagulant control monitored.¹⁹

(c) Sulfafurazole (Sulfisoxazole)

A man taking digitalis, diuretics, antacids and warfarin was later given sulfafurazole 500 mg every 6 hours. After 9 days, his prothrombin time had risen from 20 to 28 seconds, and after 14 days he bled (haematuria, haemoptysis, gum bleeding). His prothrombin time had risen to 60 seconds.²⁰

Another patient who had recently started taking warfarin developed haematuria and had a prolonged prothrombin time 7 days after also starting sulfafurazole.²¹

(d) Sulfamethizole

The half-life of warfarin was increased by over 40% (from 65 to 93 hours) in 2 patients taking sulfamethizole 1 g four times daily for a week.²²

(e) Sulfaphenazole

Sixteen patients given single oral doses of phenindione and sulfaphenazole 500 mg had prothrombin time increases after 24 hours of 16.8 seconds, compared with 10.3 seconds in 12 other patients who took phenindione alone.²³

(f) Trimethoprim

Trimethoprim combined with sulfamethoxazole (co-trimoxazole) is known to interact with coumarins, see (a) above. However, there appear to be no controlled studies of the effect of trimethoprim alone on these drugs, and no case reports of any interaction. In one cohort study, 12 patients taking warfarin had a small INR increase of about 0.36 when given trimethoprim, but this was not statistically significant.²⁴ In another cohort study in patients taking acenocoumarol or phenprocoumon, the use of trimethoprim was associated with an increased risk of over-anticoagulation (INR greater than or equal to 6). The adjusted relative risk of over-anticoagulation was noted to be 5.6 (range 1.3 to 23.1), and the greatest risk was in the first 3 days of concurrent use. The risk from trimethoprim alone in this study was less than that for co-trimoxazole.¹⁷

Mechanism

Not fully understood. Sulfamethoxazole is a known inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which *S*-warfarin is predominantly metabolised. The finding that co-trimoxazole caused a modest 22% increase in *S*-warfarin levels supports this mechanism.^{16,25} Acenocoumarol and phenprocoumon are also metabolised by CYP2C9 and might be expected to be similarly affected. Plasma protein binding displacement has been suggested as a mechanism,^{26,27} but on its own it does not provide an adequate explanation because the interaction is sustained.^{17,25} Sulfonamides can drastically reduce the intestinal bacterial synthesis of vitamin K, but this is not normally an essential source of the vitamin unless dietary sources are exceptionally low,^{25,28} see also 'Coumarins + Antibacterials', p.365.

Importance and management

The interaction between co-trimoxazole and coumarin anticoagulants is well documented and well established. The incidence appears to be high. If bleeding is to be avoided the INR should be well monitored and the warfarin, acenocoumarol, or phenprocoumon dosage should be reduced. Anecdotal evidence suggests that co-trimoxazole may not interact with the indanedione phenindione, but note that sulfaphenazole did, so some caution is still appropriate.

The other interactions are poorly documented. However, it would seem prudent to follow the precautions suggested for co-trimoxazole if any sulfonamide is given with a coumarin or indanedione.

The relative silence in the literature for trimethoprim alone would suggest that, in practice, any interaction, if it occurs, is of only minor importance, and the anticoagulant dosage probably needs little or no adjustment, but note that 2 cohort studies have shown some increased risk when trimethoprim was given with warfarin, acenocoumarol or phenprocoumon so an interaction cannot entirely be dismissed.

Coumarins + Antibacterials; Teicoplanin or Vancomycin

An isolated case report describes a marked reduction in the effects of warfarin, which was attributed to teicoplanin, but which could be equally be explained by rifampicin treatment. One study found that vancomycin possibly causes a small increase in the effects of warfarin, and a cohort study suggested that vancomycin increased risk of over-anticoagulation with acenocoumarol or phenprocoumon.

Clinical evidence, mechanism, importance and management

(a) Teicoplanin

A 60-year-old woman taking digoxin, furosemide and warfarin (INR 3.5 to 5) developed a fever after mitral valve replacement surgery and was given rifampicin 450 mg twice daily and teicoplanin 400 mg twice daily. Within 3 days her INR began to fall and by day 6 the anticoagulant effect was completely lost. Despite progressive warfarin increases to 10, 15, and then 20 mg daily, her INR stayed between 1.2 and 1.6, even when the rifampicin was stopped, and remained low for a further 20 days, at which point the teicoplanin was also stopped.¹

Some of this resistance to warfarin was undoubtedly due to the rifampicin (a known and potent inducer of warfarin metabolism) but as the INRs remained depressed for a further 20 days after rifampicin was withdrawn the authors suggested that the teicoplanin had its own part to play. However, rifampicin has been shown in several cases to decrease the effects of warfarin for 3 or more weeks after its withdrawal (see 'Coumarins + Antibacterials; Rifamycins' p.375), so an interaction with teicoplanin would seem doubtful.

(b) Vancomycin

In a retrospective review of 60 patients undergoing heart valve replacement surgery and receiving prophylactic antibacterials, 44 patients given cefamandole had a much greater anticoagulant response to their first dose of warfarin than 16 patients given vancomycin.² In a later prospective study by the same workers, in patients taking warfarin with an antibacterial, after 3 days the prothrombin times as a percentage of activity were as follows: cefamandole 29%, cefazolin 38%, and vancomycin 51%, suggesting that 'cefamandole', (p.367) had a much greater effect on anticoagulant response than vancomycin.³

In a cohort study, the use of vancomycin was associated with an increased risk of over-anticoagulation (an INR greater than 6) in patients

stabilised on acenocoumarol or phenprocoumon. The relative risk was 13.6; however, the confidence interval was very large (1.7 to 107), so it is not possible to draw any firm conclusions from this.⁴ Consider also 'Coumarins + Antibacterials', p.365.

Coumarins and related drugs + Antibacterials; Tetracyclines

Isolated cases suggest that doxycycline and tetracycline can increase the effects of coumarins. Similarly, some small studies (none controlled) suggest that chlortetracycline (alone or with oxytetracycline), doxycycline, or the tetracyclines as a class may increase the risks of over-anticoagulation, but there appear to be no studies of the effect of tetracyclines on the pharmacokinetics of coumarins. However, the related antibacterial, tigecycline, increased the AUC of warfarin, and has been shown to increase the prothrombin time when given alone.

Clinical evidence

There are no controlled studies of the effect of any tetracycline on the pharmacokinetics or pharmacodynamics of warfarin or other coumarins, although there are data for tigecycline, a new glycolcylcine antibacterial structurally related to tetracyclines.

(a) Chlortetracycline

Six out of 9 patients taking an unnamed anticoagulant had a fall in their prothrombin-proconvertin concentration from a range of 10 to 30% to less than 6% when given chlortetracycline 250 mg four times a day for 4 days. Although the anticoagulant effects were increased, there was no evidence of bleeding.¹ In one early study of dicoumarol and ethyl biscoumacetate, the authors briefly comment that 4 cases of combined use with chlortetracycline plus oxytetracycline increased the prothrombin response.²

(b) Doxycycline

A woman stabilised on warfarin developed menorrhagia after taking doxycycline 100 mg twice daily for 10 days, and her prothrombin time ratio had increased from about 2 to 4.4.³ Two other patients stabilised on acenocoumarol or warfarin developed markedly increased prothrombin ratios (3.82 and 4.09, respectively) with bruising, haematomas and bleeding when they took doxycycline.⁴ Another patient with multiple medical problems, taking warfarin and a range of drugs (alendronate, atorvastatin, salbutamol, diltiazem, fluticasone) developed peritoneal bleeding and an INR of 7.2 (previously 2.6) 6 days after starting doxycycline 100 mg twice daily.⁵

In a population-based cohort study in patients taking acenocoumarol or phenprocoumon, doxycycline was found to increase the risk of over-anticoagulation (INR greater than or equal to 6) with an adjusted relative risk of 4.3 (range 1.8 to 10.4). The risks were greatest after 4 or more days of concurrent use.⁶

(c) Oxytetracycline

In one early study of dicoumarol and ethyl biscoumacetate, the authors briefly comment that 4 cases of combined use with chlortetracycline plus oxytetracycline increased the prothrombin response.²

(d) Tetracycline

In one analysis of haemorrhagic events in patients taking dicoumarol and antibacterials, 1 patient out of 20 who received tetracycline had a bleeding event.⁷ A patient stabilised on warfarin had a marked increase in INR (from about 2 to 7.7) 6 weeks after starting to take tetracycline 250 mg four times daily. Warfarin was withheld for a few days, then restarted at a 40% lower dose. The INR decreased over the following months, broadly in parallel with decreases in the tetracycline dosage.⁸ A patient taking warfarin bled (right temporal lobe haematoma) and had an extended pro-

thrombin time a week after starting to take tetracycline and nystatin.⁹ Another patient taking **warfarin** also bled (epistaxis, haematemesis, melaena) 3 weeks after starting to take tetracycline and nystatin.⁹

(e) *Tigecycline*

The manufacturer notes that, in healthy subjects, intravenous tigecycline 100 mg then 50 mg every 12 hours decreased the clearance of *R*-warfarin by 40% and *S*-warfarin by 23% after a single 25-mg dose of **warfarin**. The AUC was increased by 68% and 29%, respectively. However, the INR was not affected.^{10,11}

(f) *Unnamed tetracyclines*

In a prospective study of the effect of antibacterials on anticoagulation, there was an estimated 0.53 increase in the INR in 9 patients taking warfarin and a tetracycline (unnamed). The effect with tetracyclines was greater than the effect of other antibacterials studied (penicillins, cephalosporins, macrolides).¹²

Mechanism

Not understood. Tetracyclines in the absence of anticoagulants can reduce prothrombin activity,¹³ and both hypoprothrombinaemia and bleeding have been described.^{14,15} It seems possible that very occasionally the anticoagulant and the tetracycline have additive hypoprothrombinaemic effects. Tigecycline alone has commonly caused prolonged prothrombin time (incidence 1 to 10%) or uncommonly caused an increased INR (incidence 0.1 to 1%) in clinical studies.¹⁰ It is also possible that antibacterials can diminish the intestinal flora of the gut thereby depleting the body of vitamin K₂, although this might be clinically important only where normal dietary intake of vitamin K₁ is extremely low, see 'Coumarins + Antibacterials', p.365. There appear to be no data on the effect of tetracyclines on the pharmacokinetics of coumarins. Although tigecycline decreased the clearance of warfarin, the mechanism for this is unclear.^{10,11}

Importance and management

A relatively sparsely documented interaction, bearing in mind that the tetracyclines have been in very widespread use for many years. It can therefore reasonably be concluded that normally any changes are of little clinical relevance. As a few patients have unpredictably shown increased anticoagulant effects and even bleeding, bear this interaction in mind when a tetracycline is first added to established anticoagulant treatment with a coumarin. Because tigecycline decreased the clearance of warfarin, and because it could cause an increase in INR, it is recommended that the INR be closely monitored in patients taking warfarin when given tigecycline.^{10,11} There appears to be no information about the indanediones, but if the mechanism suggested is correct they may also interact like the coumarins.

Coumarins + Anticholinesterases; Centrally acting

Donepezil, galantamine, rivastigmine and tacrine do not appear to alter the pharmacokinetics or effects of warfarin.

Clinical evidence, mechanism, importance and management

(a) *Donepezil*

In an open-label, crossover study, 12 healthy men were given donepezil 10 mg daily for 19 days with a single 25-mg dose of **warfarin** on day 14. The pharmacokinetics of *R*- and *S*-warfarin and the prothrombin times were unchanged by the presence of the donepezil, and vital signs, ECG and laboratory tests were unaltered.¹

(b) *Galantamine*

The manufacturers of galantamine^{2,3} say that galantamine 12 mg twice had no effect on the pharmacokinetics of *R*- and *S*-warfarin after a single 25-mg dose of **warfarin**. In addition, galantamine did not alter the prothrombin time.³

(c) *Rivastigmine*

The manufacturers of rivastigmine^{4,5} say that no pharmacokinetic interaction has been noted between rivastigmine and **warfarin** in healthy subjects. In addition, rivastigmine did not affect the increase in prothrombin time seen with warfarin.

(d) *Tacrine*

A study in 10 patients stabilised on **warfarin** found that the addition of tacrine 20 mg four times daily for 5 days had no significant effect on prothrombin times.⁶

Coumarins + Antidiabetics; Alpha-glucosidase inhibitors

Acarbose, miglitol and voglibose did not appear to alter the pharmacokinetics or effects of warfarin. However, there are a few cases of reduced or increased INRs in patients given warfarin and acarbose.

Clinical evidence, mechanism, importance and management

(a) *Acarbose*

There are 3 isolated case reports of apparent interactions between **warfarin** and acarbose. A 66-year-old man taking fosinopril, hydrochlorothiazide, diphenhydramine, insulin, glipizide and **warfarin** started taking acarbose to improve the control of his diabetes. Four days before starting acarbose his INR was 3.09, but after 2 weeks (25 mg acarbose daily for week 1 and then 50 mg daily for week 2) his INR had risen to 4.85. The **warfarin** was temporarily stopped, then it was reintroduced at a lower dosage, and finally the acarbose was withdrawn, resulting in an INR of 2.84. No bleeding was seen.¹ In contrast, the manufacturer has on record 2 other cases of patients taking **warfarin** whose INRs were reduced when acarbose was added. One of them stopped taking the acarbose, whereupon her INR returned to its previous value. The other patient needed an increased **warfarin** dosage.²

The picture presented by these cases is that usually no interaction occurs, but in isolated cases some changes in **warfarin** requirements occur. Bear this potential interaction in mind if anticoagulant control alters in a patient taking acarbose.

(b) Miglitol

In a double-blind, randomised, placebo-controlled study, 24 healthy subjects were given miglitol 100 mg three times daily for 7 days, with a single 25-mg oral dose of **warfarin** on day 4. Neither the pharmacokinetics nor the pharmacodynamics of *R*- or *S*-warfarin was affected by the miglitol.³ No special precautions would therefore appear to be needed if these two drugs are used concurrently.

(c) Voglibose

Twelve healthy male subjects were given individually adjusted doses of **warfarin** to give Quick values of 30 to 40%, and then from day 11 to 15 they were also given voglibose 5 mg three times daily. It was found that the voglibose had no effect on the pharmacokinetics of the **warfarin** nor on its anticoagulant effects.⁴ No special precautions would therefore appear to be needed if these two drugs are used concurrently.

Coumarins + Antidiabetics; Biguanides

One patient had a marked increase in the effects of phenprocoumon when she stopped taking metformin for a short period, and there is some evidence that metformin increases the metabolism of phenprocoumon.

One patient taking warfarin developed haematuria with a therapeutic prothrombin time three months after starting phenformin. Another patient developed metformin-induced lactic acidosis after warfarin-induced bleeding caused renal obstruction. However, these interactions are isolated and seem unlikely to be of general importance.

Clinical evidence

(a) Phenprocoumon

The Quick value of a 58-year old woman stabilised on **metformin** 1.7 g twice daily and phenprocoumon 3 to 4.5 mg daily fell from a range of 20 to 30% down to 0% when she stopped taking the **metformin** while on holiday. Despite the increased anticoagulant effect no signs of bleeding were observed, and she was eventually restabilised on the original doses of both drugs.¹ This case prompted a further observational study in 13 patients with type 2 diabetes. It was found that the 7 patients taking **metformin** 1.1 to 3 g daily were less well anticoagulated than those taking only 400 mg to 1 g of **metformin**, even though the mean phenprocoumon dosage was slightly higher in those taking the higher **metformin** dose (2.57 mg daily versus 2.27 mg daily).¹ In another study, the half-life of phenprocoumon was reduced by about one-third (from 123 to 85 hours) by **metformin** 1.7 g daily.¹

(b) Warfarin

An elderly woman taking warfarin 5 mg daily and **metformin** 1 g twice daily developed fatigue, epistaxis, haematuria and gingival bleeding, with an INR of 16.9, which was treated with vitamin K. The following morning, she was given **metformin**, then she was found to have a retroperitoneal haematoma and bilateral perinephric blood with obstruction of both renal collecting systems. Over the next 8 hours, she developed progressive metabolic acidosis and suffered a cardiopulmonary arrest. Her **metformin** level was 7.3 micrograms/mL (therapeutic range 1 to 2 micrograms/mL). It was suggested that **metformin** accumulation occurred because of renal insufficiency caused by the site of renal bleeding secondary to the excessive effects of warfarin. This then resulted in metabolic acidosis.²

Haematuria occurred in a patient taking warfarin 3 months after **phenformin** was started. Her prothrombin values were normal.³ **Phenformin** may have increased fibrinolysis to the point where it was additive with the effects of the warfarin.

Mechanism

Metformin possibly reduces the effects of phenprocoumon by altering blood flow to the liver and interfering with enterohepatic circulation.

Importance and management

The information about a biguanide interaction with warfarin appears to be limited to these isolated reports, neither of which definitively suggest that the biguanide altered anticoagulant effects. In general no interaction would be expected between metformin or phenformin and warfarin.

There is some evidence that a small increase in the dosage of phenprocoumon may be necessary if metformin is given but it seems likely that this can be managed with routine anticoagulant monitoring.

Coumarins + Antidiabetics; Nateglinide or Repaglinide

Nateglinide and repaglinide do not appear to interact with warfarin, and nateglinide does not interact with acenocoumarol

Clinical evidence, mechanism, importance and management

(a) Nateglinide

In a randomised, double-blind study, 11 healthy subjects were given nateglinide 120 mg three times daily for 5 days, with a single 10-mg dose of **acenocoumarol** on day 3. Nateglinide had no effect on the tolerability, pharmacokinetics or anticoagulant activity of **acenocoumarol**.¹

In another study, 12 healthy subjects were given nateglinide 120 mg three times daily for 4 days with a single 30-mg dose of **warfarin** on day 2. No pharmacokinetic or pharmacodynamic interaction was noted.² No dosage adjustments would therefore be expected to be necessary if nateglinide is taken with either acenocoumarol or warfarin.

(b) Repaglinide

In a double-blind, placebo-controlled study in 28 healthy subjects who were stabilised on **warfarin**, repaglinide did not alter the anticoagulant effects of **warfarin** or the steady-state warfarin pharmacokinetics.³ Therefore, no **warfarin** dosage adjustment would be anticipated on concurrent use.

3. Rosenberg M, Strange P, Cohen A. Assessment of pharmacokinetic (PK) and pharmacodynamic (PD) interaction between warfarin and repaglinide. *Diabetes* (1999) 48 (Suppl 1), A356.

Coumarins + Antidiabetics; Pioglitazone or Rosiglitazone

Pioglitazone does not appear to alter the pharmacokinetics or anticoagulant effect of warfarin or phenprocoumon. Rosiglitazone did not affect the pharmacokinetics of warfarin.

Clinical evidence

(a) Pioglitazone

Pioglitazone 45 mg daily for 7 days did not alter the steady-state pharmacokinetics of *R*- or *S*-warfarin and there was no significant change in prothrombin time.^{1,2} Similar results were noted with **phenprocoumon**.² Pioglitazone had no effect on prothrombin time when it was given to patients stabilised on **warfarin**.¹

(b) Rosiglitazone

Rosiglitazone has been found to have no clinically relevant effect on the steady-state pharmacokinetics of **warfarin**.³

Mechanism

In vitro, troglitazone (the first thiazolidinedione, which has now been withdrawn) significantly inhibited the cytochrome P450 isoenzyme CYP2C9-dependent 7-hydroxylation of *S*-warfarin; however, pioglitazone and rosiglitazone only slightly inhibited this activity.⁴

Importance and management

Controlled studies have shown no interaction between pioglitazone and warfarin or phenprocoumon, or between rosiglitazone and warfarin. This suggests that coumarin dose adjustments are unlikely to be needed when these antidiabetics are used.

Coumarins and related drugs + Antidiabetics; Sulfonylureas

Dicoumarol inhibits the metabolism of tolbutamide and increases its effects; cases of hypoglycaemic coma have been reported. Chlorpropamide may be affected similarly. Although isolated cases of interactions (raised prothrombin times, bleeding or hypoglycaemia) have been seen in patients taking sulfonylureas and coumarins, in general, no important interaction appears to occur. There also appears to be no interaction between phenindione and tolbutamide.

Clinical evidence

A. Coumarins

(a) Chlorpropamide

1. *Acenocoumarol*. A woman with normal renal function had an increase in the half-life of chlorpropamide to 88 hours (normally about 36 hours) when she took acenocoumarol.¹

2. *Dicoumarol*. A 67-year-old non-diabetic man taking chlorpropamide for Parkinson's disease developed severe hypoglycaemia about 3 months after starting dicoumarol. He had high chlorpropamide levels with a half-life of 80 to 90 hours. Dicoumarol was withdrawn, and 3 weeks later his chlorpropamide half-life was 30 hours.² This observation prompted further study in 3 other patients and 2 non-diabetics. Dicoumarol doubled the serum chlorpropamide levels within 3 to 4 days and also more than doubled the half-life.²

(b) Glibenclamide (Glyburide)

1. *Phenprocoumon*. The pharmacokinetics of glibenclamide remained unchanged by phenprocoumon.³ Similarly, the plasma levels and half-life of single doses of phenprocoumon did not differ between patients with type 2 diabetes managed by diet alone (12 patients) and those taking glibenclamide (9 patients).⁴

2. *Warfarin*. There do not appear to be any controlled studies on the effect of glibenclamide on the pharmacokinetics of coumarins, although recent *in vitro* data suggest that an effect is possible because glibenclamide inhibited *S*-warfarin hydroxylation (a 7 to 37% *in vivo* inhibition was predicted).⁵ Moreover, isolated reports describe increased warfarin effects (INR increased from 2.3 to 6.6 with haematomas in one instance⁶) in 2 patients given glibenclamide.^{6,7}

(c) Glibornuride

Phenprocoumon, given to 3 subjects for 4 days, slightly increased the half-life of a single 25-mg dose of glibornuride by 29%.⁸ The plasma levels and half-life of a single dose of **phenprocoumon** did not differ between patients with type 2 diabetes managed by diet alone (12 patients) and those taking glibornuride (12 patients).⁴

(d) Glimepiride

In healthy subjects, glimepiride 4 mg daily caused only minor, clinically unimportant changes in the prothrombin times (about 10% decrease in mean maximum prothrombin time) in response to single 25-mg doses of

warfarin. In addition, glimepiride had no effect on the pharmacokinetics of *R*- and *S*-warfarin.⁹

(e) Tolbutamide

1. *Dicoumarol*. Dicoumarol has been shown to increase the serum levels of tolbutamide, prolong its half-life (more than threefold), and reduce blood-glucose levels in both diabetics¹⁰ and healthy subjects.^{10–12} This may become excessive in a few patients and hypoglycaemic coma has been described in 3 diabetics,^{10,13,14} and one non-diabetic.¹⁵

Two patients taking dicoumarol had marked increases in prothrombin times (a rise from 33 to 60 seconds) within 2 days of starting to take tolbutamide, but no bleeding occurred. However, no increases were seen in 3 other patients taking dicoumarol when they started tolbutamide.¹⁶ Conversely, the half-life of dicoumarol was approximately halved in 2 out of 4 healthy subjects given tolbutamide, but the hypoprothrombinaemic effects were unchanged.¹² However, in a retrospective study there was no difference in the initial or average dose of dicoumarol between 15 patients taking tolbutamide and 24 control subjects taking insulin.¹⁷

2. *Phenprocoumon*. Phenprocoumon did not alter the half-life of tolbutamide in 3 patients.¹⁸

The plasma levels and half-life of single doses of phenprocoumon did not differ between patients with type 2 diabetes managed by diet alone (12 patients) and those taking tolbutamide (10 patients).⁴

3. *Warfarin*. In a retrospective study, there was no difference in the initial or average dose of warfarin between 42 patients taking tolbutamide and 54 control subjects taking insulin.¹⁷ However, a bulletin mentions an isolated report of an increased INR in a patient taking warfarin and tolbutamide.¹⁹

B. Indanediones

In one early study, phenindione given 6 days did not affect the half-life of **tolbutamide** in 2 healthy subjects. Similarly, the average plasma levels of **tolbutamide** in 3 patients taking phenindione were not different from 4 patients not taking phenindione.¹⁰

Mechanism

Dicoumarol appears to increase the effects of tolbutamide by inhibiting its metabolism by the liver.^{10,11} This may also be true for chlorpropamide.² The increase in the anticoagulant effects of dicoumarol by tolbutamide may, in part, be due to a plasma protein binding interaction. In the case of phenprocoumon there seem to be several different mutually opposing processes going on, which cancel each other out.¹² There is no clear explanation for most of these interactions.

Importance and management

Information is patchy and very incomplete. The effect of dicoumarol on tolbutamide has been most thoroughly investigated, and the interaction is clinically important. Increased blood-glucose lowering effects may be expected if dicoumarol is given to patients taking tolbutamide, and there is a risk of hypoglycaemic coma. Whether tolbutamide alters the anticoagulant response to dicoumarol is unclear. Avoid concurrent use unless the outcome can be well monitored and dosage adjustments made. The same precautions should be taken with dicoumarol and chlorpropamide, but information is limited to one study.

Information on other interactions is limited to isolated cases, and these are therefore of doubtful general significance.

Coumarins + Antihistamines

Findings from a retrospective review suggest that the anticoagulant effects of acenocoumarol may be reduced by loratadine, ebastine, or cetirizine. Conversely, an isolated report describes bleeding and a markedly raised INR in an elderly man taking acenocoumarol and cetirizine.

Clinical evidence, mechanism, importance and management

A retrospective review of patients taking **acenocoumarol** with **loratadine**, **ebastine**, or **cetirizine** found that INRs were decreased during concurrent use, but no thromboembolic event was noted. The authors consider that temporary increases in the anticoagulant dosage might be required.¹

In contrast, there is a case report of an 88-year-old man taking **acenocoumarol** for a deep vein thrombosis who developed acute and severe epistaxis after a fall, and within 3 days of starting to take **cetirizine** 10 mg daily for allergic rhinitis.² His INR was found to have risen from 1.5 to 14. The **cetirizine** concentration may have been particularly high because of some renal impairment and because cetirizine may have displaced **acenocoumarol** from its plasma protein binding sites, although this mechanism on its own is now largely discredited as an explanation for interactions between anticoagulants and highly bound drugs.

Information is limited, and given the widespread use of these drugs any consistent clinically significant interaction might have been expected to have come to light by now. No specific precautions seem necessary if these drugs are given in combination, but bear the interaction in mind in the case of an unexpected response to treatment.

Coumarins + Antineoplastics; Fluorouracil and related prodrugs

Capecitabine markedly increases warfarin levels and increases its anticoagulant effects. A number of case reports describe over-anticoagulation in patients taking warfarin with capecitabine. Similarly, case reports describe overanticoagulation in patients taking warfarin and fluorouracil, ftorafur or tegafur.

Clinical evidence

(a) Capecitabine

In an open study, 4 patients with breast or colorectal cancer received a single 20-mg dose of **warfarin** 8 days before starting oral capecitabine (3 cycles of capecitabine 1250 mg/m² twice daily for 14 days, then 7 days rest), then again on day 12 of the third cycle of capecitabine. Capecitabine increased the AUC of *S*-warfarin was increased by 57%, and its elimination half-life by 51%, without any significant changes to *R*-warfarin. The maximum INR was increased by 1.9-fold and the AUC of the INR increased 2.8-fold. Three of the patients required vitamin K administration. Because of the clear, statistically significant findings in these 4 patients, the study was terminated early.¹

Various cases of this interaction have been reported.^{2–6} In one of these reports, 2 patients starting **warfarin** developed gastrointestinal bleeding

with an INR of greater than 10, after 2 cycles of capecitabine.² In another case, a patient who had been taking long-term **warfarin** required a gradual 85% reduction in warfarin dose to 0.78 mg daily over 3 cycles of capecitabine and **irinotecan**, and required an increase to 4 mg daily over the 3 weeks after stopping chemotherapy.⁴ Another patient required a 50% reduction in **warfarin** dose while taking capecitabine.

The manufacturers of **capecitabine** also report that this interaction has occurred with the coumarins including **phenprocoumon**.^{7,8}

(a) Fluorouracil and fluorouracil-based regimens

In an early clinical study, 25 patients with colon cancer were given bolus fluorouracil 15 to 20 mg/kg weekly plus **warfarin** daily, titrated to maintain the prothrombin time in the 20 to 30% range, and modified weekly as necessary. Three patients developed blood loss from the gut, which was controlled by giving a transfusion and stopping the **warfarin**. This study did not report the required dose of warfarin, or how often it needed adjusting in these patients.⁹

Various case reports have described clinically important over-anticoagulation with concurrent use of dose adjusted **warfarin** (for treatment of deep vein thrombosis, or in patients with prosthetic heart valves) and fluorouracil, either alone,^{10,11} with folic acid (leucovorin),^{12–15} or levamisole.^{13,16,17} In one well-described case, an elderly man taking **warfarin** long-term was found to have an INR of almost 40 (usual INR 3) four weeks after he started taking fluorouracil (450 mg/m² daily for 5 days then once weekly) and **levamisole** (50 mg every 8 hours for 3 days every other week). He required a two-thirds reduction in **warfarin** dose. Later, when the chemotherapy was withheld for 5 weeks his INR became subtherapeutic, and then increased again when the chemotherapy was re-started.¹⁶ In another retrospective case series, 4 patients taking **warfarin** long-term (target INR 2 to 3) required an 18 to 74% reduction in **warfarin** dose during treatment with fluorouracil and **folic acid** or **levamisole**. The maximum INR in 3 of these patients was 3.66 to 8.15, and the other patient had a maximum INR of 23.7 and a retroperitoneal bleed.¹³

Other cases of overanticoagulation have been reported with **warfarin** and fluorouracil-based regimens including **CMF** (cyclophosphamide, **methotrexate** and fluorouracil),^{13,18,19} **CMF** plus **vincristine** and prednisone,²⁰ fluorouracil, **cisplatin** and **etoposide**,²¹ and fluorouracil, **cisplatin** and **mitomycin**.¹¹

A case has also been reported with the use of fixed dose **warfarin** (1 mg daily) for prophylaxis of venous catheter-associated thrombosis in a patient receiving fluorouracil with **vinblastine**.²² Similarly, in a large retrospective analysis of fixed dose **warfarin**, 31 of 95 patients given regimens based on continuous infusions of **fluorouracil** had INR elevations above 1.5, and, of these, 18 had an INR of 3 to 4.9 and seven had an INR of more than 5. Epistaxis and haematuria occurred in 8 of the patients. The regimens used were fluorouracil plus **folic acid**; folic acid, fluorouracil plus **oxaliplatin** (FOLFOX), and folic acid, fluorouracil plus **irinotecan** (FOLFIRI).²³ In a further analysis of the use of fixed dose **warfarin** with the FOLFOX regimen, 25 of 50 patients had an INR greater than 1.5 (range 1.55 to 9.4). Two of these developed haematuria, and one had a nosebleed.²⁴

(c) Ftorafur

Increased INRs and bleeding (haemoptysis) were seen in a patient taking **warfarin** when *Orzel* (**uracil/ftorafur** in a 4:1 molar ratio) was given, and a 63% reduction in the warfarin dose was needed.²⁵

(d) Tegafur

The manufacturers of *Uftoral* (**tegafur/uracil**) say that marked elevations in prothrombin times and INRs have been reported in patients taking **warfarin** when *Uftoral* was added.²⁶

Mechanism

Uncertain. However, in a pharmacokinetic study in *rats*, fluorouracil significantly reduced the total clearance of *S*-warfarin by inhibiting its metabolism.²⁷ Data from the clinical study with the fluorouracil prodrug, capecitabine, suggests this interacts similarly.¹

Importance and management

Fairly well-documented and established interactions of clinical importance. Prothrombin times should be regularly monitored in patients taking warfarin and other **coumarins** and requiring fluorouracil, capecitabine or other fluorouracil pro-drugs, anticipating the need to reduce the warfarin dose. Note that, from a disease perspective, when treating venous throm-

boembolic disease in patients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.²⁸

Coumarins + Antineoplastics; Miscellaneous

A number of case reports describe an increase in the effects of warfarin, accompanied by bleeding in some cases, caused by antineoplastic regimens containing carboplatin, chlormethine, cyclophosphamide, doxorubicin, etoposide, gefitinib, gemcitabine, ifosfamide with mesna, methotrexate, procarbazine, trastuzumab, vincristine or vindesine. A decrease in the effects of warfarin has been seen with azathioprine, cyclophosphamide, mercaptopurine and mitotane, a decrease in the effects of acenocoumarol has been seen with mercaptopurine, and a decrease in the effects of phenprocoumon have been seen with azathioprine.

Clinical evidence

(a) Azathioprine

A survey of 103 patients with antiphospholipid syndrome found that azathioprine appeared to increase warfarin requirements.¹ A woman who

was resistant to warfarin, needing 14 to 17 mg daily while taking azathioprine, began to bleed (epistaxes, haematemesis) when the azathioprine was stopped. She was restabilised on warfarin 5 mg daily.² Reduced warfarin effects were seen in 2 other patients taking azathioprine,^{3,4} one of whom had a marked fall in serum warfarin levels during azathioprine treatment.⁴ Two women with systemic lupus erythematosus taking phenprocoumon⁵ and a third taking warfarin⁶ had marked falls in their INRs during treatment with azathioprine, and another woman needed an almost fourfold increase in the dose of warfarin when she was given azathioprine.⁷

(b) Carboplatin

The INR of a man taking warfarin increased from a baseline range of 1.15 to 2.11 up to 12.6 within 16 days of a first course of chemotherapy with carboplatin and etoposide.⁸

(c) Cyclophosphamide

A woman taking warfarin had a marked rise in her prothrombin time when her treatment with cyclophosphamide was withdrawn.⁹

(d) Etoposide

The INR of a man taking warfarin increased from a baseline range of 1.15 to 2.11 up to 12.6 within 16 days of a first course of chemotherapy with carboplatin and etoposide.⁸ Another elderly man taking warfarin had a marked increase in prothrombin times (prolongation of 8 to 15 seconds) on two occasions when he took etoposide 500 mg and vindesine 5 mg.¹⁰

(e) Gefitinib

A woman stabilised on warfarin required a gradual decrease in the dose from 4 mg to 2.5 mg daily after starting gefitinib 250 mg/m² daily for lung cancer. In contrast, a second patient did not have an increase in warfarin effect while taking gefitinib.¹¹

(f) Gemcitabine

A 63-year-old man needed a reduction in his weekly warfarin dosage from 59.23 mg to 50.75 mg in order to keep his INR at about 2.5 during 2 cycles of gemcitabine. When the gemcitabine was stopped his warfarin dosage had to be increased again.¹² The manufacturers have information on 4 cases of suspected interactions between gemcitabine and warfarin, and one with phenprocoumon (reported by December 2000).¹³ Based on 724 reports of the concurrent use of gemcitabine and anticoagulants,¹³ they suggest that the incidence of the suspected interaction is 0.8%.

(g) Ifosfamide

Three patients taking warfarin had a marked and very rapid increase in their INRs when they took ifosfamide with mesna.¹⁴

(h) Mercaptopurine

A man well stabilised on warfarin had a marked reduction in his anticoagulant response on two occasions while taking mercaptopurine, but no changes occurred when he took busulfan, cyclophosphamide, cytarabine, hydroxycarbamide, mitobronitol, demecolcine or melphalan.¹⁵ A woman needed a marked increase in her dosage of acenocoumarol, from 21 to 70 mg weekly, when she was given mercaptopurine 100 mg daily.¹⁶ Another patient required about a 25% increase in warfarin dose while taking mercaptopurine 100 mg daily.¹⁷

(i) Mitotane

The anticoagulant effects of warfarin were progressively reduced in a woman taking mitotane.¹⁸ Later this effect began to reverse.

(j) ProMace-Mopp

The prothrombin times of an elderly man given warfarin increased by 50 to 100% in the middle of three cycles of treatment with ProMace-Mopp (cyclophosphamide, doxorubicin, etoposide, chlormethine, vincristine, procarbazine, methotrexate and prednisone), and he developed a subconjunctival haemorrhage during the first cycle.¹⁹

(k) Trastuzumab

Two women stabilised on warfarin developed nosebleeds after 10 and 8 weekly doses of trastuzumab, respectively, and were found to have INRs of 6 and 5.8, respectively.²⁰ However, the manufacturer notes that in an analysis of clinical study data the rate of bleeding events was similar for patients receiving or not receiving trastuzumab, with or without anticoagulants.²¹

Mechanism

Not well understood. Mercaptopurine possibly increases the synthesis or activation of prothrombin.²² Azathioprine is metabolised to mercaptopurine, and would therefore be expected to interact similarly.

Importance and management

The absence of problems in early small studies using warfarin as an adjunct to chemotherapy,^{23,24} and the small number of reports describing difficulties, suggest that many of these interactions may be uncommon events. The concurrent use of these drugs need not be avoided but there is clearly a need to be aware that any antineoplastic regimen might increase the response to anticoagulants. It would also be prudent to note that mercaptopurine and azathioprine may decrease the anticoagulant response. The anticoagulant dosages may need adjustment. Note that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.²⁵

Coumarins and related drugs + Antiplatelet drugs; Cilostazol

Cilostazol does not appear to have a clinically relevant effect on the pharmacokinetics or pharmacodynamics of warfarin. Nevertheless, as with other antiplatelet drugs, concurrent use might increase the bleeding risk.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, two-way crossover study in 15 healthy subjects, cilostazol 100 mg twice daily for 13 days did not alter the pharmacokinetics of a single 25-mg dose of warfarin given on day 7. Also, prothrombin times, aPTT time and Ivy bleeding time were unaffected.¹

This suggests that no interaction is likely during concurrent use. Nevertheless, because cilostazol is an antiplatelet drug, the manufacturer advises caution with the concurrent use of anticoagulants, with more frequent monitoring to reduce the possibility of bleeding.²

2. Pletal (Cilostazol). Otsuka Pharmaceuticals (UK) Ltd. UK Summary of product characteristics, May 2006.

Coumarins and related drugs + Antiplatelet drugs; Clopidogrel

Clopidogrel does not appear to have a clinically relevant effect on the pharmacokinetics or pharmacodynamics of warfarin. Nevertheless, concurrent use might increase the bleeding risk.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, placebo-controlled study involving 43 patients who had been taking warfarin for at least 2 months, the addition of clopidogrel 75 mg daily for 8 days had no effect on plasma warfarin levels or INRs. No bleeding occurred with clopidogrel and no serious adverse events were reported.¹

Nevertheless, as with other antiplatelet drugs, combined use might increase the risk or intensity of bleeding. Therefore, in the UK, the manufacturers of clopidogrel state that the concurrent use of warfarin is not recommended,² whereas the US manufacturers recommend caution.³ This caution would be prudent with clopidogrel and any coumarin or indandione.

Coumarins and related drugs + Antiplatelet drugs; Dipyridamole

The combination of dipyridamole and coumarin anticoagulants does not alter the prothrombin time, but might cause an increased risk of serious bleeding when compared with anticoagulants alone. There is some evidence that the risk of bleeding may be lower, without a reduction in efficacy, if the INR is maintained within a lower range.

Clinical evidence

(a) Prosthetic heart valves

In a short-term study in 6 patients stabilised on warfarin, the addition of dipyridamole 75 mg three times daily did not alter prothrombin time ratios measured 8 times over 17 days.¹

A meta-analysis of 6 randomised, controlled studies of the combined use of an oral anticoagulant and dipyridamole compared with an oral anticoagulant alone, found no increased risk of any bleeding events when dipyridamole was given (odds ratio 1.001).² In contrast, in a later meta-analysis of the same studies, the risk of major bleeding with the addition of dipyridamole was increased (odds ratio 2.22). In addition to the difference in classification of bleeding events, the authors of the second analysis stated that they had used published data from two studies, which showed a slightly higher bleeding risk, whereas the earlier meta-analysis had used unpublished data from these studies, showing a lower bleeding risk.³

In one randomised study, the risk of excessive bleeding was 4% in patients taking warfarin and dipyridamole 400 mg daily, compared with 14% in patients taking warfarin and aspirin 500 mg daily. When compared with a non-randomised control group taking warfarin alone, the risk

of excessive bleeding was not increased by dipyridamole (4% combined therapy versus 5% warfarin alone).⁴

In another randomised study, the risk of bleeding was lower (1% versus 3.7%) in patients receiving dipyridamole 225 mg daily with phenindione at a target INR range of 2 to 2.5 than in patients receiving phenindione alone with a target INR of 2.5 to 3.5, and the combination was more effective.⁵ Similarly, the risk of bleeding was lower with a lower target INR of 2 to 3 than with a target INR of 3 to 4.5 (3.9% versus 20.8%) in patients taking acenocoumarol, aspirin 330 mg twice daily and dipyridamole 75 mg twice daily.⁶

(b) Other conditions

Thirty patients with glomerulonephritis stabilised on either warfarin (28 patients) or phenindione (2 patients) with a prothrombin activity of between 20 to 30% of control had no significant changes in prothrombin times when they were given dipyridamole in doses increased from 100 mg daily up to a maximum of 400 mg daily over about a month. Twelve to 19 days after starting dipyridamole, 3 patients with normal renal function developed mild bleeding (epistaxis, bruising, haematuria), which resolved when either drug was withdrawn or the dosage reduced.⁷

Mechanism

Dipyridamole reduces platelet adhesiveness or aggregation, which prolongs bleeding time. This may increase the risk or severity of bleeding if overanticoagulation occurs.

Importance and management

The combination of dipyridamole with coumarin anticoagulants is in established clinical use for the prophylaxis of thromboembolism associated with prosthetic heart valves. There is clearly some uncertainty regarding the increased risk of bleeding with the combination, with one analysis showing no increased risk,² and a second showing about a doubling of risk of serious bleeding.³ The authors of the second analysis consider that their results represent a more conservative estimate of bleeding risk.³ There is some evidence that maintaining anticoagulant control at the lower end of the therapeutic range minimises possible bleeding complications and it would therefore seem prudent to consider this wherever possible.

Coumarins and related drugs + Antiplatelet drugs; Ditazole

Ditazole does not alter the anticoagulant effects of acenocoumarol. Nevertheless, as with other antiplatelet drugs, concurrent use might increase bleeding risk.

Clinical evidence, mechanism, importance and management

Fifty patients with artificial heart valves taking acenocoumarol had no changes in their prothrombin times while taking ditazole 800 mg daily.¹ Nevertheless, as with other antiplatelet drugs, combined use with oral anticoagulants might increase the risk or intensity of bleeding. Some caution is therefore appropriate on concurrent use.

1. Jacovella G, Milazzotto F. Ricerca di interazioni fra ditazolo e anticoagulanti in portatori di protesi valvolari intracardiache. *Clin Ter* (1977) 80, 425–31.

Coumarins + Antiplatelet drugs; Picotamide

Picotamide did not alter the anticoagulant effects of warfarin. Nevertheless, as with other antiplatelet drugs, concurrent use might increase bleeding risk.

Clinical evidence, mechanism, importance and management

Picotamide 300 mg three times daily for 10 days did not alter the anticoagulant effects of established warfarin therapy in 10 patients with aortic or mitral valve prostheses.¹ No warfarin dose adjustments would therefore be expected to be needed on concurrent use. Nevertheless, as with other antiplatelet drugs, combined use with oral anticoagulants might increase the risk or intensity of bleeding. Some caution is therefore appropriate on concurrent use.

Coumarins + Antiplatelet drugs; Ticlopidine

In a retrospective analysis, the anticoagulant effects of acenocoumarol were modestly reduced by ticlopidine in 80% of patients, whereas, in a small prospective study, the anticoagulant effects of warfarin were unchanged by ticlopidine. As with other antiplatelet drugs, combined use might possibly increase bleeding risk. Cholestatic hepatitis has been reported in some patients given warfarin and ticlopidine.

Clinical evidence

(a) Acenocoumarol

A retrospective study of 36 patients with heart valve prostheses found that when they took ticlopidine 250 mg daily, 29 of them needed a mean 13% increase in acenocoumarol dosage from 15.5 to 17.5 mg weekly, accompanied by a small INR rise from 3.05 to 3.13. One patient needed a dosage increase from 14 to 22 mg weekly. INR changes were detectable with a week of starting the ticlopidine.¹

(b) Warfarin

Ticlopidine 250 mg twice daily for 2 weeks given to 9 men taking warfarin long-term increased the mean *R*-warfarin levels by 25.7% but did not change *S*-warfarin levels or their INRs.² *R*-warfarin is the much less active of the two enantiomers.

In a Japanese study, 4 out of 132 patients (3%) given both warfarin and ticlopidine after cardiovascular surgery developed cholestatic hepatitis.³

Mechanism

It seems possible that ticlopidine inhibits the metabolism of *R*-warfarin, but the interaction with acenocoumarol is not understood. Ticlopidine alone can cause raised liver enzymes and cholestatic hepatitis,⁴ and whether these cases represent an interaction is unclear.

Importance and management

Information seems to be limited to the reports cited. A small to moderate increase in the acenocoumarol dosage may be needed if ticlopidine is added, but none seems to be necessary with warfarin. However, as with other antiplatelet drugs, an increased risk of bleeding (a combination of anticoagulant and platelet anti-aggregant activity) might be anticipated on concurrent use. The manufacturer states that the long-term safety of concurrent use of ticlopidine with oral anticoagulants has not been established, and they recommend that if a patient is switched from an anticoagulant to ticlopidine, the anticoagulant should be discontinued prior to ticlopidine administration.⁴ Whether the incidence of cholestatic hepatitis is higher with the combination of warfarin and ticlopidine than with ticlopidine alone is unclear.

- Ticlid (Ticlopidine hydrochloride). Roche Pharmaceuticals. US Prescribing information, March 2001.

Coumarins + Aprepitant

Aprepitant modestly reduces warfarin levels and slightly decreases the INR in healthy subjects. It is expected to interact similarly with acenocoumarol.

Clinical evidence, mechanism, importance and management

In a double-blind study, healthy subjects were stabilised on **warfarin** and then given either aprepitant (125 mg on day one, then 80 mg daily on days 2 and 3) or placebo. On day 3, there was no change in **warfarin** levels. However, by day 8 (5 days after stopping aprepitant) there was a 34% decrease in trough *S*-warfarin levels, and a 14% decrease in INR in the aprepitant group.¹

Aprepitant is an inducer of the cytochrome P450 isoenzyme CYP2C9, by which *S*-warfarin is metabolised. The manufacturer recommends that, in patients taking **warfarin**, the INR should be monitored closely for 2 weeks, particularly at 7 to 10 days,² after each 3-day course of aprepitant,^{2,3} and this seems a prudent precaution. They similarly recommend caution with **acenocoumarol**, which is also metabolised by CYP2C9.³

Coumarins + Aromatase inhibitors

The anticoagulant effects of warfarin and acenocoumarol can be markedly reduced by aminoglutethimide. The extent of the reduction appears to be related to the aminoglutethimide dosage. However, in controlled studies, anastrozole and letrozole did not interact with warfarin.

Clinical evidence

(a) Aminoglutethimide

In a study in 9 patients being treated for breast cancer, a low-dose aminoglutethimide regimen (125 mg twice daily) increased the clearance of a single-dose of *R*- or *S*-warfarin by 41.2% with marked variability between individuals (range 15 to 103%). A high-dose regimen (250 mg four times daily) increased the clearance by 90.8%. The effects of the interaction had developed fully by 14 days. Both enantiomers of **warfarin** were equally affected.¹

One 79-year-old woman taking aminoglutethimide 250 mg four times daily showed resistance to **warfarin** requiring a dose of 17.5 to 20 mg daily. Two weeks after the aminoglutethimide was stopped, the required dose of warfarin gradually declined, eventually reaching a level of 3.75 and 5 mg on alternate days (about a fourfold reduction).² Another patient stabilised on warfarin gradually needed about a threefold increase in the **warfarin** dosage after starting aminoglutethimide 250 mg four times a day.² The increased requirement persisted for 2 weeks after the aminoglutethimide was stopped, and then declined. A study briefly mentions a patient who required greatly increased doses of **warfarin** after starting aminoglutethimide.³ Three patients taking **acenocoumarol** needed a doubled dosage to maintain adequate anticoagulation when they took aminoglutethimide 250 mg four times daily for 3 to 4 weeks.⁴

(b) Anastrozole

A randomised, double-blind, placebo-controlled, crossover study⁵ in 16 healthy men found that anastrozole (7 mg loading dose followed by 1 mg daily for a further 10 days) had no effect on the pharmacokinetics or pharmacodynamics of a single dose of **warfarin** given on day 3.

(c) Letrozole

The manufacturers report that letrozole had no clinically relevant effect on the pharmacokinetics of **warfarin**.^{6,7}

Mechanism

Uncertain. The most likely explanation is that aminoglutethimide, like glutethimide, stimulates the activity of the liver enzymes concerned with the metabolism of the anticoagulants, thereby reducing their levels and efficacy. Alternatively, it has been suggested that aminoglutethimide may affect blood steroid levels, which in turn might affect coagulation.²

Importance and management

An established and clinically important interaction. Monitor the effects of adding aminoglutethimide to patients already taking warfarin or acenocoumarol and increase the anticoagulant dosage as necessary. Up to four times the dosage may be needed. The extent of the effects would appear to be related to the dosage of aminoglutethimide used. Monitor the INR and reduce the anticoagulant dosage accordingly if aminoglutethimide is withdrawn. Information about other coumarins is lacking but it would be prudent to apply the same precautions with any of them.

Conversely, controlled studies have shown no interaction between anastrozole or letrozole and warfarin. This suggests that coumarin dose adjustments are unlikely to be needed when these aromatase inhibitors are used.

Coumarins and related drugs + Aspirin

Low-dose aspirin (75 to 325 mg daily) increases the risk of bleeding when given with warfarin by about 1.5 to 2.5-fold, although, in most studies the absolute risks have been small. The overall benefits of concurrent use outweigh the risks in certain patient groups; however, for some warfarin indications, there is not enough data to assess this. In addition to increased bleeding, high doses of aspirin (4 g daily or more) can increase prothrombin times. Therefore, aspirin is not considered a suitable analgesic or anti-inflammatory drug for those taking oral anticoagulants.

Clinical evidence

A. Analgesic-dose aspirin

In a pharmacological study in patients stabilised on **acenocoumarol**, aspirin 2.4 g daily for one week increased faecal blood loss from an average of 1.1 mL to 4.7 mL. While taking aspirin, 11 of 17 patients required a 29% reduction in their **acenocoumarol** dose from a mean of 3.1 mg to 2.2 mg. One patient required a slight increase of 0.5 mg, and the remaining 5 required a dose reduction of less than 0.5 mg.¹

In another study in healthy subjects, aspirin 1.95 g daily for 11 days had no effect on the prothrombin time response to a single dose of **warfarin** given on day 4. When 11 healthy subjects were stabilised on **dicoumarol** or **warfarin** and given aspirin 1.95 g daily, 7 had no significant change in prothrombin time activity, and 4 had a slight reduction (of 5 to 10% points). Of the 2 subjects showing signs of bleeding, neither had a reduction in prothrombin time activity. A further 4 subjects stabilised on **warfarin** received a higher dose of aspirin (3.9 g daily), and all 4 had a reduction in prothrombin time activity of 6 to 12% points and signs of bleeding occurred. Bleeding time was significantly prolonged by the combination of aspirin 1.95 g daily and **warfarin** than by **warfarin** alone (10.3 minutes versus 4 minutes).² In 2 further studies in healthy subjects, aspirin 6 g daily moderately prolonged prothrombin times,^{3,4} and in one study this effect tended to be reversed by vitamin K.³

In contrast, in another study in 10 patients, adding aspirin 3 g daily to **warfarin** for 2 weeks had no effect on prothrombin times (20.9 versus 21.2 seconds).⁵

B. Antiplatelet-dose aspirin

In a study in healthy subjects, low-dose aspirin 75 mg daily doubled the normal blood loss from the gastric mucosa. However, concurrent **warfarin** (dose individualised to achieve an INR of 1.4 to 1.6) did not increase the gastric mucosal bleeding any further.⁶

(a) Atrial fibrillation

In a large study in patients with atrial fibrillation, the cumulative incidence of bleeding events after 3 years was no different in those receiving fixed low-dose **warfarin** 1.25 mg daily plus aspirin 300 mg daily (24.4%) than with fixed low-dose **warfarin** alone (24.7%) or aspirin 300 mg daily alone (30%).⁷ This study also contained an adjusted-dose **warfarin**-only group, which proved more effective than the other group, so the study was terminated early. Other studies have found similar results.⁸

In another study, the combination of adjusted dose **fluidione** (INR 2 to 2.6) plus aspirin 100 mg daily was associated with a much higher incidence of haemorrhagic complications than **fluidione** alone (13.1% versus 1.2%). The overall balance of benefit to risk could not be assessed because of the low incidence of the primary endpoint (ischaemic events).⁹

(b) Coronary stents

In a retrospective analysis, a 20% incidence of severe upper gastrointestinal bleeding was seen in 138 coronary stent patients given heparin post-procedure, then **warfarin** with aspirin 325 mg daily. Ten of the patients needed a blood transfusion.¹⁰ In another analysis of patients who had been taking **warfarin** long-term and who underwent stent implantation and were then discharged taking aspirin, clopidogrel and **warfarin**, the incidence of major bleeding was 6.6% and of minor bleeding was 14.9%. This compared with 0% and 3.8% for major and minor bleeding, respectively, in patients not given aspirin with clopidogrel post-procedure (no **warfarin**).¹¹ Another study reported an incidence of 9.2% of bleeding in patients who had undergone stent placement and received **warfarin**, aspirin and clopidogrel.¹²

(c) Myocardial infarction

1. *Primary prevention.* In a large primary prevention study in men at high risk of ischaemic heart disease, the incidence of haematuria was twofold higher in those receiving both low-dose aspirin 75 mg daily and low-intensity **warfarin** (INR 1.5) than in those receiving low-dose aspirin alone, or low-intensity **warfarin** alone. Similarly, the incidence of minor episodes of bleeding (nose bleeds, bruising, rectal bleeding, pink/red urine) was 1.27-fold higher in those receiving the combination than in those receiving low-dose aspirin alone, or low-intensity **warfarin** alone (49% versus 38% and 39%, respectively), although the difference was not statistically significant. There was no difference in incidence of major and intermediate episodes of bleeding.¹³

2. *Secondary prevention.* In a meta-analysis of randomised, controlled studies¹⁴ in patients following myocardial infarction or acute coronary syndrome, intensive **warfarin** (INR greater than 2) plus aspirin 80 to 325 mg daily was associated with 2.5-fold increased risk of major bleeding, when compared with aspirin alone, although the actual incidence was low (1.5% versus 0.6%). This analysis excluded studies of coronary stenting, see (b) above. In another similar meta-analysis, combined use of aspirin and **warfarin** (INR 2 to 3) was associated with a 2.3 odds ratio of a major bleed, when compared with aspirin alone.¹⁵ The number needed to treat to cause one major bleed was 100. This compared with a number needed to treat to avoid one major adverse event (death, myocardial infarction or stroke) of 33.

Similarly, in an observational cohort study of elderly survivors of acute myocardial infarction, the rate of bleeding was higher in patients receiving **warfarin** with aspirin (0.08 per patient year), or the triple drug combination of **warfarin** and aspirin with either clopidogrel or ticlopidine (0.09 per patient-year), than in patients receiving aspirin alone (0.03 per patient-year).¹⁶

Using lower intensity **warfarin** with the low-dose aspirin was still associated with more major bleeding than aspirin alone (1.77 in one study, although this is less than higher intensity warfarin; 2.3 as mentioned above). Nevertheless, low-intensity **warfarin** with low-dose aspirin does not appear to be any more effective than aspirin alone.^{15,17}

(d) Peripheral arterial disease

In a meta-analysis of studies of patients with peripheral arterial disease, combined use of **oral anticoagulants** together with aspirin increased the risk of major bleeding about twofold when compared with aspirin alone, and appeared to be associated with increased mortality.¹⁸

(e) Prosthetic heart valves

In one randomised study in patients with artificial heart valves, the risk of bleeding episodes requiring blood transfusion or hospitalisation was much higher among those taking aspirin 500 mg daily and **warfarin** (14%), compared with those taking **warfarin** and dipyridamole 400 mg daily (4%), and compared with a non-randomised control group taking **warfarin** alone (5%). Bleeding was mainly gastrointestinal or cerebral. All of those with intracerebral bleeding died.¹⁹

A further study found that aspirin 1 g daily combined with **unnamed anticoagulants** was associated with a threefold higher incidence of bleeding episodes than those taking anticoagulants alone (13.9 versus 4.7 per 100 patients per year).^{20,21} However, in another study there was no difference in haemorrhagic risk between patients receiving aspirin 500 mg daily and **acenocoumarol** or **acenocoumarol** alone.²²

More recent studies have used lower doses of aspirin. In one study in patients stabilised on **warfarin** with a target INR range of 3.0 to 4.5, the addition of aspirin 100 mg daily increased the risk of any bleeding by 55%, when compared with placebo (35% versus 22% per year), mainly due to an increase in minor haematuria, nosebleeds and bruising. However, the risk was more than offset by the overall reduction in mortality.²³

The preliminary report of a meta-analysis of these four studies, concluded that the combined use of oral anticoagulants and aspirin (100 mg to 1 g daily) significantly reduced mortality and embolic complications in patients with prosthetic heart valves, with an estimated increased odds ratio of major bleeds of 1.7 and of total bleeds of 1.98. Nevertheless the overall picture was that the benefits possibly outweighed the problems.²⁴ In a more recent meta-analysis,²⁵ which excluded one non-randomised study,¹⁹ but included 2 other randomised controlled studies, the risk of major bleeding for the combination of **warfarin** and aspirin was 1.53. For the two low-dose aspirin (100 mg daily) trials, there did not appear to be an excess risk of major bleeding.²⁵ Another analysis of these studies provided essentially the same risk of increased major bleeding with the combination.²⁶

Mechanism

Aspirin has a direct irritant effect on the stomach lining and can cause gastrointestinal bleeding, even in doses as low as 75 mg daily.²⁷ It also decreases platelet aggregation and prolongs bleeding times. In addition, large doses of aspirin (4 g daily or more) alone are known to have a direct hypoprothrombinaemic effect, which is reversible by vitamin K.^{3,4} The effects of the aspirin can be additive with the effects of the anticoagulant.

Importance and management

The interaction of aspirin and warfarin at high doses is not well documented, but is clinically important. It is usual to avoid normal analgesic and anti-inflammatory doses of aspirin while taking any coumarin anticoagulant, although only dicoumarol, acenocoumarol and warfarin appear to have been investigated. Patients should be told that many non-prescription analgesic, antipyretic, cold and influenza preparations may contain substantial amounts of aspirin. Warn them that it may be listed as acetylsalicylic acid. Paracetamol is a safer analgesic substitute (but not entirely without problems, see 'Coumarins + Paracetamol (Acetaminophen)', p.438).

The effect of low-dose aspirin (used for its antiplatelet effects) combined with warfarin has been far more extensively studied. Overall, the evidence shows that the combination is still associated with an increased risk of bleeding over either drug alone, and this is in the region of 1.5 to 2.5-fold. Nevertheless, the absolute risk is small. A twofold increased risk of haematuria and a slight increased risk of minor bleeding of 1.27 was still seen in the study using the lowest dose of warfarin (INR 1.5) combined with just 75 mg of aspirin a day.¹³ In certain patient groups the benefits of combined use have been clearly shown to outweigh this increased risk of bleeding, such as patients with prosthetic heart valves at high risk of thromboembolism. However, in many of the common indications for war-

farin such as atrial fibrillation, there is insufficient evidence to answer the question of whether the combination should be used.²⁶

Coumarins + Azoles; Fluconazole

Fluconazole causes a dose-related inhibition of the metabolism of warfarin, and increases its anticoagulant effect. Cases of minor to major bleeding have been reported. There is one case report with acenocoumarol and fluconazole.

Clinical evidence

(a) Acenocoumarol

A patient stabilised on acenocoumarol suffered an intracranial haemorrhage (prothrombin time 170 seconds) 5 days after starting to take fluco-

nazole 200 mg daily for the management of relapsed prosthetic valve candidal endocarditis.¹

(b) Warfarin

1. *Multiple-dose fluconazole.* In a well-designed study in healthy subjects, fluconazole was given at three dose levels (100 mg, 200 mg and 400 mg daily) for 14 days with a single dose of warfarin given both before fluconazole and on day 7, at each fluconazole dose level. In this study, fluconazole markedly potentiated the anticoagulant effect of warfarin in a dose-related manner. The duration of anticoagulant effect was 4 to 7 days for the single dose of warfarin alone, 5 to 9 days with fluconazole 100 mg daily, 6 to 11 days with fluconazole 200 mg daily, and 8 to 15 days with fluconazole 400 mg daily. Fluconazole increased the levels of both *R*- and *S*-warfarin. The AUC of *R*-warfarin was increased 1.28-, 1.63-, and 1.7-fold with the 3 doses of fluconazole, respectively, and that of *S*-warfarin by 1.35-, 1.86-, and 2-fold, respectively.² Two other studies in healthy subjects have shown broadly similar results.^{3–5}

The clinical importance of this interaction was shown in an earlier study, which found that when fluconazole 100 mg daily was given to 7 patients stabilised on warfarin, the prothrombin time increased from 15.8 seconds on day one, to 18.9 seconds on day 5, and 21.9 seconds on day 8. The fluconazole was stopped early in 3 of the patients due to high prothrombin times, but none exceeded an increase of 9.7 seconds, and no bleeding occurred.⁶

At least 7 reports have described increased prothrombin times or INRs in patients stabilised on warfarin who took fluconazole in doses of 50 to 400 mg daily.^{7–14} Several patients had haemorrhagic effects (gastrointestinal bleeding, melaena, ocular haemorrhage, spinal epidural haematoma).^{7,10,12–14}

2. *Single-dose fluconazole.* Six women on stable doses of warfarin with an INR between 2 and 3 were given a single 150-mg dose of fluconazole, and their prothrombin time measured on day 2, 5 and 8. The prothrombin time increased by 11% at day 2, and 34% on day 5, with a 2% increase on day 8, although none of these differences was statistically significant. However, three of the women had an increase in the INR to above 4 or had bleeding.¹⁵

Mechanism

In vitro studies using human liver microsomes clearly demonstrate that fluconazole inhibits the cytochrome P450 isoenzyme CYP2C9-mediated 7-hydroxylation of *S*-warfarin and the CYP3A4-mediated metabolism of *R*-warfarin, and possibly other isoenzymes involved in the metabolism of warfarin.¹⁶ *In vivo*, this results in the accumulation of warfarin and in an increase in its effects, possibly leading to bleeding.⁵

Importance and management

An established and clinically important interaction. If fluconazole is added to treatment with warfarin or acenocoumarol the prothrombin times should be very well monitored and the anticoagulant dosage reduced as necessary. On the basis of pharmacokinetic studies it has been predicted that the warfarin dosage may need to be reduced by about 20% when using fluconazole 50 mg daily, ranging to a reduction of about 70% when using fluconazole 600 mg daily. These larger reductions should be gradual over 5 days or so.¹⁷ However, remember that individual variations between patients can be considerable. Most of the available data relate to multiple-dose fluconazole, with just one small study with a single-dose of fluconazole 150 mg. Although the effect in this study was not as great as that for multiple-dose fluconazole, it suggests that careful monitoring of prothrombin times is still required.¹⁵

Of the other azole antifungals, 'ketoconazole', (p.388) and 'itraconazole', (p.388), appear less likely to interact.

Coumarins + Azoles; Itraconazole

An isolated report describes a very marked increase in the anticoagulant effects of warfarin, accompanied by bruising and bleeding, in a patient given itraconazole. Limited evidence suggests that itraconazole may increase the risk of over-anticoagulation with acenocoumarol or phenprocoumon.

Clinical evidence

A woman stabilised on **warfarin** 5 mg daily and also taking ipratropium bromide, salbutamol, budesonide, quinine sulfate and omeprazole, was given itraconazole 200 mg twice daily for oral candidiasis caused by the inhaled steroid. Within 4 days she developed generalised bleeding and recurrent nosebleeds. Her INR had risen to more than 8. The **warfarin** and itraconazole were stopped, but next day she had to be admitted to hospital for intractable bleeding and increased bruising, for which she was treated with fresh frozen plasma. Two days later when the bleeding had stopped, and her INR had returned to 2.4, she was restarted on **warfarin** and later restabilised on her original dosage.¹

In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, itraconazole significantly increased the risk of over-anticoagulation (INR greater than 6: relative risk of 13.9, range 1.7 to 115). However, the authors say this figure should be interpreted cautiously since it was based on just one case.²

Mechanism

Itraconazole is a known potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, but this isoenzyme is involved only in the metabolism of the less potent *R*-warfarin, and therefore inhibition would not be expected to have a marked effect on 'warfarin metabolism', (p.358). However, there appear to be no pharmacological studies to confirm this. 'Omeprazole' (p.444) may also have had some minor part to play in the case described.¹

Importance and management

A minor to modest pharmacokinetic interaction would be predicted, but as yet there appear to be no studies to confirm this. The case report and cohort study suggest that this interaction might be clinically important in some individuals. Therefore, it would be prudent to increase monitoring of anticoagulant control when any patient on a coumarin anticoagulant is given itraconazole. Further study is needed.

Coumarins + Azoles; Ketoconazole

In two healthy subjects the anticoagulant effect of warfarin was unchanged when they were given ketoconazole. However, there are three isolated cases of an increase in the anticoagulant effects of warfarin in patients also taking ketoconazole. Some evidence

suggests that topical ketoconazole does not interact with acenocoumarol or phenprocoumon.

Clinical evidence

Two healthy subjects had no changes in their anticoagulant response to **warfarin** when they were given ketoconazole 200 mg daily over a 3-week period.^{1,2}

However, an elderly woman, stabilised on **warfarin** for 3 years, complained of spontaneous bruising 3 weeks after starting a course of ketoconazole 200 mg twice daily. Her British Comparative Ratio was found to have risen from 1.9 to 5.4. Her liver function was normal. She was restabilised on her previous **warfarin** dosage 3 weeks after the ketoconazole was withdrawn.³ In 1984, the CSM in the UK had one report of an 84-year-old man taking **warfarin** whose British Comparative Ratio rose to 4.8 when he was given ketoconazole, and fell to 1.4 when it was withdrawn.³ In 1986, the manufacturers of ketoconazole had one other report of an elderly man taking **warfarin** whose prothrombin time rose from a range of 34 to 39 seconds to over 60 seconds when he was given ketoconazole 400 mg daily.⁴ In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, topical ketoconazole did not significantly increase the relative risk of over-anticoagulation (INR greater than 6; relative risk 1.1, range 0.3 to 4.3). However, this figure should be interpreted cautiously since it was based on just two patients.⁵

Mechanism

In *rats*,⁶ ketoconazole potentiated the anticoagulant effect of acenocoumarol, but at much higher doses than 'miconazole', (p.388). It is now known that ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, but this isoenzyme has only a minor role in the 'metabolism of warfarin' (p.358), specifically the less active *R*-isomer.

Importance and management

Information about this interaction seems to be limited to the reports cited. Its general importance and incidence is therefore uncertain, but it is probably quite small. However, it would seem prudent to monitor the anticoagulant response of any patient given both drugs, particularly the elderly, to ensure that excessive anticoagulation does not occur.

Coumarins and related drugs + Azoles; Miconazole

The anticoagulant effects of acenocoumarol, and warfarin can be markedly increased if miconazole is given orally as an oral (buccal) gel, and bleeding can occur. Oral miconazole has also been reported to interact with ethyl biscoumacetate, flutidione, phenindione and tiocloamarol in a few reports. The interaction has also rarely been seen in some women using intravaginal miconazole, and in those using a miconazole cream on skin. In one cohort study, use of oral miconazole markedly increased the risk of over-anticoagulation with acenocoumarol and phenprocoumon, whereas intravaginal miconazole caused a non-statistically significant minor increase, and cutaneous miconazole barely increased the risk.

Clinical evidence

(a) Oral gel

In one early report, a patient with a prosthetic heart valve and stabilised on **warfarin** developed blood blisters and bruised easily 12 days after starting miconazole gel 250 g four times a day for a presumed fungal mouth

infection. Her prothrombin time ratio had risen from less than 3 to about 16. She was subsequently restabilised in the absence of miconazole on her former dose of **warfarin**.¹

Numerous other cases of this interaction with **warfarin** have been reported, and, where stated, often involved the use of 5 mL (125 mg) of the gel four times daily for oral candidiasis.²⁻¹⁰ One case of an increase in INR to 11.4 with frank haematuria and spontaneous bruising was reported in a woman who had used 30 g of non-prescription miconazole (*Daktarin*) over 8 days (estimated daily dose of 75 mg).⁷ In 1996, the New Zealand Centre for Adverse Reactions Monitoring reported 5 patients taking **warfarin** whose INRs rose from normal values to between 7.5 and 18 within 7 to 15 days of starting to use miconazole oral gel.⁵ In 2002, the Australian Adverse Drug Reactions Advisory Committee (ADRAC) stated that they had received 18 reports of this interaction. In the 17 cases for which it was documented, the INR was above 7.5. Eight of the cases had bleeding complications, 9 required vitamin K, and 5 fresh frozen plasma.¹¹

A few similar cases have also been reported for **acenocoumarol**¹²⁻¹⁴ or **fluidione**¹⁵ with miconazole oral gel. In addition, in one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, use of oral miconazole (form and doses not stated) markedly increased the risk of over-anticoagulation (INR greater than 6: adjusted relative risk 36.6; range 12.4 to 108). When analysed separately, the adjusted relative risk was higher for **acenocoumarol** than **phenprocoumon** (35.1 versus 16.5).¹⁶

(b) Tablets

In a study in 6 healthy subjects, miconazole 125 mg daily for 18 days (in the form of *tablets*) caused a very marked fivefold increase in prothrombin time response to a single dose of **warfarin** given on day 3. In addition, there was a threefold increase in the AUC of warfarin, with *S*-warfarin most affected (fourfold), and *R*-warfarin increased 1.7-fold.¹⁷ In one early case report with warfarin, one patient with a prosthetic heart valve and stabilised on **warfarin** was found to have a prothrombin time ratio of 23.4 within 10 days of starting miconazole tablets 250 mg four times a day for a suspected fungal diarrhoea. He developed two haematomas soon after both drugs were withdrawn, and was subsequently restabilised, in the absence of miconazole, on his former dose of **warfarin**.¹

The Centres de Pharmacovigilance Hospitalière in Bordeaux have on record 5 cases where miconazole (oral doses of 500 mg daily, where stated; form not mentioned) was responsible for a marked increase in prothrombin times and/or bleeding (haematomas, haematuria, gastrointestinal bleeding) in patients taking **acenocoumarol** (2 cases), **ethyl biscoumacetate** (1 case), **tiocloमारol** (1 case) and **phenindione** (1 case).¹⁸ Other cases and reports of this interaction involving **acenocoumarol** have been described elsewhere.¹⁹⁻²¹

(c) Skin creams

An 80-year-old man stabilised on **warfarin** with an INR of 2.2 to 3.1 was found to have an INR of 21.4 at a routine check 2 weeks after starting to use miconazole cream for a fungal infection in his groin. He showed no evidence of bruising or bleeding.²² In 2001, Health Canada reported that they had on record a case of an 80-year-old man taking **warfarin** and using topical miconazole who had a cerebral vascular accident, although this case was complicated by multiple medical conditions and medications.²³ In 2002, the Australian Adverse Drug Reactions Advisory Committee stated that they had received one report of an interaction involving topical miconazole cream.¹¹

In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, use of topical miconazole was associated with a small increased risk of over-anticoagulation (INR greater than 6: adjusted relative risk 1.4) but this was not statistically significant. Note that this was markedly less than the increased risk seen with oral miconazole (relative risk 36.6).¹⁶

(d) Vaginal dose forms

In 1999, the Netherlands Pharmacovigilance Foundation LAREB reported 2 elderly women patients taking **acenocoumarol** whose INRs rose sharply and rapidly when they were given a 3-day course of 400-mg miconazole pessaries.²⁴ Another report describes the development of bruising and an INR of about 9.78 in a 55-year-old woman taking **warfarin** on the third day of using 200-mg miconazole pessaries. For a subsequent course of intravaginal miconazole 100 mg daily for 7 days, the dose of warfarin was decreased by 28%, and her INR was 3.27.²⁵ Yet another report describes haemorrhage of the kidney in a 52-year old woman taking **warfarin** after she used vaginal miconazole for 12 days.²³ In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, use of vaginal miconazole

was associated with a small increased risk of over-anticoagulation (INR greater than 6: adjusted relative risk 4.3) but this was not statistically significant. Note that this was markedly less than the increased risk seen with oral miconazole (relative risk 36.6).¹⁶

Mechanism

There is evidence that miconazole is a very potent inhibitor of the metabolism of *S*-warfarin by the cytochrome P450 isoenzyme CYP2C9, and that it also inhibits the metabolism of *R*-warfarin to a lesser extent.¹⁷ Even low oral doses of miconazole (125 mg daily) markedly inhibit warfarin metabolism, so it is not surprising that prescription doses of miconazole oral gel (480 to 960 mg daily) interact, since this is swallowed after retaining in the mouth. Very unusually, absorption of miconazole from the vagina (see also comments below) and even exceptionally through the skin, can result in increased anticoagulant effects.

Importance and management

The interaction of miconazole oral gel and miconazole tablets with and coumarin anticoagulants is a very well established and potentially serious interaction. Most of the reports are about warfarin or acenocoumarol, but many other oral anticoagulants have been implicated. In some cases the bleeding has taken 7 to 15 days to develop,^{1,3,18} whereas others have bled within only 3 days.^{20,25} Raised INRs have been seen even sooner. Usual prescription doses of miconazole oral gel [5 to 10 mL (120 to 240 mg) four times daily] should therefore not be given to patients taking any oral anticoagulant unless the prothrombin times can be closely monitored and suitable dosage reductions made. Given the very large increased relative risk of over-anticoagulation seen in one cohort study, the authors suggest that the concurrent use of oral miconazole and coumarins should be discouraged.¹⁶ The interaction has been seen with a lower oral dose of about 75 mg daily (one 30 g tube given over 8 days), which is not surprising in the context of the pharmacokinetic study, and suggests that patients taking oral anticoagulants should also avoid using non-prescription miconazole. Nevertheless, the UK patient information leaflet for non-prescription *Daktarin* oral gel contains no specific cautions regarding anticoagulants.²⁶ Nystatin and amphotericin are possible alternative antifungals to miconazole for mouth infections.

An interaction with **intravaginal miconazole** would not normally be expected because its systemic absorption is usually very low (less than 2%) in healthy women of child-bearing age.²⁷ However, the reports cited above show that significant absorption could apparently occur in a few patients with particular conditions (possibly in postmenopausal women with inflamed vaginal tissue), which allows an interaction to occur. Appropriate monitoring is therefore needed even with this route of administration in potentially at-risk women.

Topical (cutaneous) miconazole would also not be expected to interact, but the few reports cited shows that some caution might be warranted.

Coumarins + Azoles; Voriconazole

In one pharmacodynamic study, voriconazole approximately doubled the prothrombin time in response to warfarin.

Clinical evidence, mechanism, importance and management

When a single 30-mg dose of **warfarin** was given to 16 healthy subjects on day 7 of a 12-day course of voriconazole 300 mg twice daily, the maximal increase in prothrombin time was about doubled.¹ These increases in prothrombin time were still present 6 days after the **warfarin** dose, at which point the prothrombin time had returned to baseline with **warfarin** alone. Two subjects were withdrawn from the study because of an increased prothrombin time.¹

Voriconazole is a known inhibitor of the cytochrome P450 isoenzymes CYP2C9 and CYP3A4, by which the coumarins (**phenprocoumon**, **acenocoumarol** and **warfarin**) are metabolised.^{2,3} The manufacturers advise close monitoring of the prothrombin time in any patient on a coumarin anticoagulant who is given voriconazole. Dose adjustments of the coumarin should be made accordingly.^{2,3}

Coumarins + Barbiturates

The effects of the coumarins are substantially reduced by the barbiturates. Primidone is metabolised to phenobarbital and is expected to interact similarly.

Clinical evidence

(a) Phenobarbital

A study in 16 patients stabilised on **warfarin** found that when they were also given phenobarbital 2 mg/kg their average daily **warfarin** requirements rose over a 4-week period by 25% (from 5.7 to 7.1 mg daily).¹ In another study, phenobarbital 100 mg at night for 4 weeks reduced the mean prothrombin time by 13% in patients stabilised on **warfarin**.² Other studies have shown that phenobarbital causes a 29% or 46% reduction in the half-life of **warfarin**,^{3,4} and that the reduction was similar for both *R*- and *S*-warfarin.⁵ A retrospective analysis in patients taking **warfarin** revealed that use of phenobarbital was associated with more erratic anticoagulation control, and that discontinuation of phenobarbital in a patient taking **warfarin** resulted in severe hypoprothrombinaemia and haematuria 2 weeks later.⁶ In contrast, there is one isolated report of a woman stabilised on **warfarin** who developed haematuria three days after starting to take phenobarbital 60 mg four times daily.⁷

A reduced anticoagulant response has also been described in studies with **dicoumarol**,^{8–10} and 2 cases have been reported with **ethyl biscoumacetate**.¹¹

(b) Other barbiturates

An investigation in 12 patients taking either **warfarin** or **phenprocoumon** found that **secbutobarbital sodium**, 15 mg four times daily for the first week and 30 mg four times daily for the next two weeks, increased their anticoagulant requirements by 35 to 60%, reaching a maximum after 4 to 5 weeks.¹²

This interaction has also been described in pharmacological studies between:

- **acenocoumarol** and **pentobarbital**,¹³ or **heptabarb**;¹⁴
- **dicoumarol** and **aprobarbitone**,¹⁵ **heptabarb**,^{14,16} or **vinbarbital**;¹⁵
- **ethyl biscoumacetate** and **heptabarb**;¹⁴
- **warfarin** and **amobarbital**,^{17–19} **heptabarb**,²⁰ **secobarbital**,^{2,17–19,21–23} or **secbutobarbital**.¹²

Cases have been described in patients taking **ethyl biscoumacetate** who were treated with **amobarbital**, **heptabarb**, or **secobarbital**.¹¹ Cases have also been described of apparent resistance to coumarins in patients taking barbiturates,^{15,24} and of bleeding in patients who were stabilised on a coumarin and a barbiturate when they stopped taking the barbiturate.^{15,24,25}

Mechanism

Pharmacokinetic studies in man and animals^{3,4,18–20,22} clearly show that the barbiturates are potent liver enzyme inducers, which increase the metabolism and clearance of the coumarin anticoagulants from the body. The effect is similar for both *R*- and *S*-warfarin.^{5,23} Barbiturates may also reduce the absorption of dicoumarol from the gut.¹⁶

Importance and management

The interactions between the anticoagulants and barbiturates are clinically important and very well documented. The reduced anticoagulant effects expose the patient to the risk of thrombus formation if the dosage is not increased appropriately. A very large number of anticoagulant/barbiturate pairs have been found to interact and the others may be expected to behave similarly. The reduction in the anticoagulant effects begins within a week, sometimes within 2 to 4 days, reaching a maximum after about 3 weeks, and it may still be evident up to 6 weeks after stopping the barbiturate.¹² Patients' responses can vary considerably. Stable anticoagulant control can be re-established²⁶ in the presence of the barbiturate by increasing the anticoagulant dosage by about 30 to 60%.^{1,6,10,12} Care must be taken not to withdraw the barbiturate without also reducing the anticoagulant dosage, otherwise over-anticoagulation will occur. Alternative non-interacting drugs that are now considered more appropriate sedatives than the barbiturates include the 'benzodiazepines', (p.391).

Primidone is metabolised in the body to phenobarbital and is therefore expected to interact like phenobarbital, although there seem to be no reports of interactions with anticoagulants. Notwithstanding it would be prudent to be alert for reduced anticoagulant effects if primidone is given concurrently.

Coumarins + Benfluorex

Benfluorex does not alter the anticoagulant effects of phenprocoumon.

Clinical evidence, mechanism, importance and management

No significant changes occurred in the prothrombin times of 22 patients stabilised on **phenprocoumon** when they were given benfluorex 150 mg three times daily for 9 weeks, when compared with equivalent periods before and after taking benfluorex.¹

1. De Witte P, Brems HM. Co-administration of benfluorex with oral anticoagulant therapy. *Curr Med Res Opin* (1980) 6, 478–80.

Coumarins and related drugs + Benzbromarone or Benziodarone

The anticoagulant effects of warfarin are increased by benzbromarone and bleeding has been seen. Similarly, the anticoagulant effects of acenocoumarol, ethyl biscoumacetate, diphenadione and warfarin are increased by benziodarone. Clorindione, dicoumarol and phenindione were not affected by benziodarone in one study. Phenprocoumon was not affected in one study, but was in another.

Clinical evidence

(a) Benzbromarone

The observation that 2 patients bled (haematuria, gastrointestinal bleeding) when given **warfarin** and benzbromarone, prompted a more detailed study in 7 other patients who were stabilised on both drugs. The thrombotest values of these 7 averaged 24.7% while taking both **warfarin** and benzbromarone (average dosage 57.1 mg daily), but when the benzbromarone was stopped for a week they rose to 47.3%. On restarting the benzbromarone the thrombotest values decreased to 30.3% (indicating an enhanced anticoagulant effect). The Factor II activity paralleled the thrombotest values. The total plasma **warfarin** levels were reduced during the period that benzbromarone was stopped.¹ Another later study found that the **warfarin** requirements of 13 patients given benzbromarone 50 mg daily were 36% lower than in 18 other patients given **warfarin** alone (3.9 versus 2.5 mg daily). The oral clearance of *S*-warfarin was 54% lower in the benzbromarone recipients, but the clearance of *R*-warfarin did not differ between the groups.² These two studies confirm observations in other patients with prosthetic valve replacements who showed haemorrhagic tendencies when given both drugs.¹

Early information about benzbromarone noted that no increase in the anticoagulant effects of the coumarins **acenocoumarol** and **ethyl biscoumacetate** or the indanedione **phenindione** had been seen in a few patients also given benzbromarone.³

(b) Benziodarone

Benziodarone 200 mg three times daily for 2 days then 100 mg three times daily thereafter was given to 90 patients taking various anticoagulants. To maintain constant prothrombin-proconvertin percentages the coumarin anticoagulant dosages were reduced as follows: **ethyl biscoumacetate** 17% (9 patients), **acenocoumarol** 25% (7) and **warfarin** 46% (15). No changes in dose were needed in patients taking **dicoumarol** (9) or **phenprocoumon** (8). For the indanedione anticoagulants, a dose reduction of 42% was required in 8 patients taking **diphenadione**, but no changes were needed in those taking **clorindione** (5 patients) or **phenindione** (10 patients).⁴ A parallel study in healthy subjects also found that benziodarone 300 mg or 600 mg daily increased the effects of a single dose of **warfarin**.⁴

In another study, benziodarone 300 to 600 mg daily increased the anticoagulant effects of **phenprocoumon** in just 9 out of 29 patients.⁵ Plasma levels of **ethyl biscoumacetate** after a single intravenous dose were increased by pre-treatment with benziodarone 600 mg daily for 6 days.⁵

Mechanism

Benzbromarone selectively inhibits the metabolism of *S*-warfarin by the cytochrome P450 isoenzyme CYP2C9 so that its effects are increased. The metabolism of the *R*-warfarin remains unchanged.² Acenocoumarol and phenprocoumon are also known to be metabolised by CYP2C9, and would therefore be expected to interact similarly. Benziodarone is another benzofuran derivative with a similar structure to benzbromarone, and therefore probably interacts via a similar mechanism.

Importance and management

The interaction between warfarin and benzbromarone or benziodarone is established and clinically important. If benzbromarone is added to warfarin monitor prothrombin times and be alert for the need to reduce the dosage by about one-third to prevent over-anticoagulation. Information about other coumarins is limited, but what is known about the mechanism of action suggests that acenocoumarol and phenprocoumon would also be predicted to interact, and this has been shown for benziodarone and acenocoumarol or phenprocoumon, in a few patients. The limited evidence suggesting an interaction with some indanediones also suggests that some caution is appropriate with these drugs as well.

Coumarins + Benzodiazepines and related drugs

The anticoagulant effects of warfarin are not affected by chlordiazepoxide, diazepam, flurazepam, or nitrazepam, or the related hypnotics, eszopiclone, zaleplon, or zolpidem. The effects of phenprocoumon are not affected by nitrazepam or oxazepam, and those of ethyl biscoumacetate are not affected by chlordiazepoxide. An interaction between any oral anticoagulant and a benzodiazepine is unlikely, but there are three unexplained and unconfirmed cases of increased or decreased anticoagulant responses, which were attributed to an interaction.

Clinical evidence

A. Benzodiazepines

(a) Chlordiazepoxide

In a placebo-controlled study in 7 patients stabilised on **warfarin**, chlordiazepoxide 10 mg three times daily for 2 weeks had no effect on anticoagulant control.¹ Other studies in healthy subjects^{2,3} and patients⁴ have similarly shown that chlordiazepoxide does not alter the anticoagulant ef-

fect or the half-life of **warfarin**. Similarly, chlorthalidopoxide 10 mg three times daily for 10 days had no effect on the half-life of a single intravenous dose of **ethyl biscoumacetate** in healthy subjects.⁵ However, one patient stabilised on warfarin had a small 18% fall in mean plasma **warfarin** levels with a corresponding change in the anticoagulant response when given chlorthalidopoxide 15 mg daily.⁶

(b) *Diazepam*

In 4 patients stabilised on **warfarin**, diazepam 5 mg three times daily for 30 days had no effect on anticoagulant control (thrombotest). In one of the patients, the half-life of **warfarin** was measured, and this was not changed by diazepam.⁴ Similarly, diazepam 5 mg daily did not alter the anticoagulant response or the half-life of a single dose of **warfarin** in healthy subjects.³

However, there are two discordant reports. A patient stabilised on **dicoumarol** developed multiple ecchymoses and a prothrombin time of 53 seconds within 2 weeks of starting to take **diazepam** 5 mg four times daily.⁷ The New Zealand Committee on Adverse Drug Reactions has received one report of an increased anticoagulant effect in a patient taking **warfarin** with **diazepam**.⁸ It is by no means certain that these responses were due to an interaction.

(c) *Flurazepam*

In healthy subjects, flurazepam 30 mg at bedtime for 28 days had no effect on the half-life of a single dose of **warfarin** given on day 14 and 28, but there was a slight statistically significant reduction in prothrombin time. In a further placebo-controlled study in 12 patients stabilised on **warfarin**, flurazepam 30 mg at night for 28 days had no effect on prothrombin time or plasma warfarin concentrations.⁹

(d) *Nitrazepam*

In 2 reports by the same researchers, nitrazepam 10 mg at night for 30 days had no effect on steady-state warfarin levels or anticoagulant control in a few patients stabilised on **warfarin**.^{4,6} In a placebo-controlled study in 22 patients stabilised on **phenprocoumon**, nitrazepam 5 mg at night for 2 weeks had no effect on thrombotest times.¹⁰

(e) *Oxazepam*

Oxazepam 10 mg in the morning and 10 to 20 mg in the evening for 3 weeks had no effect on anticoagulant response in 21 patients stabilised on **phenprocoumon**.¹¹

B. Non-benzodiazepine hypnotics

(a) *Eszopiclone*

In a study in healthy subjects, eszopiclone 3 mg daily for 5 days had no effect on the AUC of *S*- or *R*-warfarin after a single 25-mg dose of **warfarin** and there was no change in the INR.¹²

(b) *Zaleplon*

In a study in healthy subjects, zaleplon 20 mg daily for 12 days had no effect on the AUC of *S*- or *R*-warfarin after a single 25-mg dose of **warfarin**. There was a minor 17% increase in the maximum serum levels of *S*-warfarin. However, zaleplon did not alter the prothrombin time response to **warfarin**.^{13,14}

(c) *Zolpidem*

The prothrombin times of 8 healthy subjects given **warfarin** were unaffected by zolpidem 20 mg daily for 4 days.¹⁵

Mechanism

The three discordant reports are not understood. Enzyme induction is a possible explanation in one case with chlorthalidopoxide,⁶ because increases in the urinary excretion of 6-beta-hydroxycortisol (a marker of enzyme induction) have been described during chlorthalidopoxide use.^{4,6}

Importance and management

The weight of evidence and common experience shows that the benzodiazepines do not interact with the anticoagulants. Not all of the anticoagulant and benzodiazepines have been examined, but none of the possible pairs would be expected to interact. Similarly, based on pharmacodynamic studies, no interaction would be anticipated with the newer non-benzodiazepine hypnotics eszopiclone, zaleplon or zolpidem.

Coumarins and related drugs + Beta blockers

The effects of the coumarins are not normally altered by any beta blocker. However, propranolol has caused small increases in warfarin levels in a couple of studies, and one or two isolated cases of increased warfarin and phenindione effects have been reported.

Clinical evidence

(a) *Acenocoumarol*

In a study in 4 patients stabilised on acenocoumarol there was no difference in anticoagulation tests when **atenolol** 100 mg daily, **metoprolol** 100 mg twice daily, or placebo, was given for 3 weeks.¹

(b) *Phenindione*

In one early clinical study, haemorrhagic tendencies without any changes in Quick value or any other impairment of coagulation were described in three patients stabilised on phenindione within 6 weeks of starting **propranolol**.²

(c) *Phenprocoumon*

In healthy subjects, a single dose of **atenolol** 100 mg or **metoprolol** 100 mg did not affect the AUC of a single dose of **phenprocoumon**, although **phenprocoumon** levels were slightly higher at 4 and 6 hours after the **metoprolol** dose. Nevertheless, neither beta blocker altered the prothrombin time response.³

In healthy subjects, **carvedilol** 25 mg daily for 7 days had no effect on the pharmacokinetics of a single 15-mg dose of phenprocoumon given on day 5 phenprocoumon.⁴

In 12 patients stabilised on phenprocoumon, there was no difference in Quick time between those randomised to receive **pindolol** 5 mg three times daily for 6 weeks and those who received placebo.⁵

(d) *Warfarin*

In 6 patients stabilised on warfarin, **acebutolol** 300 mg three times daily for 3 days had no effect on prothrombin time response.⁶ Similarly, in one patient taking warfarin, neither **atenolol** 100 mg daily nor metoprolol 100 mg twice daily for 3 weeks had any effect on prothrombin time.¹ Similarly, in studies in healthy subjects the following beta blockers had no clinically relevant effects on the pharmacokinetics and/or anticoagulant response to warfarin; **atenolol** 100 mg daily,⁷ **betaxolol** 20 mg daily,⁸ **bisoprolol** 10 mg daily,⁹ **esmolol**,¹⁰ or **metoprolol** 100 mg twice daily.⁷

In contrast, the minimum steady state plasma **warfarin** levels of 6 healthy subjects rose by 15% when they took **propranolol** 80 mg twice daily in one study.¹¹ Similarly, in another study in 6 healthy subjects given **propranolol** 80 mg twice daily for 7 days with a single dose of warfarin on day 4, the AUC of warfarin was increased by 16.3% and the in maximum serum level was increased by 23%, but there was no change in the prothrombin time.⁷ A patient stabilised on **warfarin** had a rise in his Brit-

ish Corrected Ratio from a low of 1.3 up to 2.5 while taking **propranolol** 80 mg twice daily.¹²

Mechanism

None known.

Importance and management

Overall, the findings of these pharmacological studies in patients and healthy subjects confirm the general clinical experience that the effects of the coumarin anticoagulants are not normally altered by the beta blockers. No special precautions are needed on concurrent use. The only uncertainty is with propranolol, which has shown a small rise in warfarin levels in two studies, and for which there are a couple of reports of possible increased anticoagulant responses of warfarin and phenindione. Even so, a clinically significant interaction would seem to be extremely rare.

Coumarins + Bicalutamide, Flutamide or Nilutamide

The manufacturer has on record a few cases of flutamide possibly increasing the anticoagulant effects of warfarin. *In vitro*, bicalutamide displaced warfarin from its protein binding sites. The clinical relevance of this, if any, has not been assessed. *In vitro*, nilutamide inhibited P450 isoenzymes, and might therefore interact with coumarins, although there does not appear to be any further information on this.

Clinical evidence, mechanism, importance and management

(a) Bicalutamide

The manufacturers say^{1,2} that *in vitro* studies show that bicalutamide can displace **warfarin** from its protein binding sites. They therefore recommended close monitoring of the prothrombin time. It used to be thought that the displacement of **warfarin** from its protein binding sites by other drugs normally resulted in clinically important interactions, but that is now known to rarely be true (see 'Protein-binding interactions', (p.3)). In 1995, the manufacturers said that they did not know of any reports of an interaction between **warfarin** and bicalutamide, apart from an isolated case of a raised INR in one patient taking **warfarin** with bicalutamide 150 mg, but no causal link with bicalutamide was established.³ In a clinical study of bicalutamide and finasteride, it was briefly stated that one patient developed a prolonged prothrombin time while also taking warfarin.⁴ To date, there appear to be no published cases of an interaction. There would therefore seem little reason to believe that bicalutamide interacts with **warfarin**, but until more is known it would seem prudent to remain aware of the possibility if it is started in any patient taking **warfarin**.

(b) Flutamide

In 1990, the manufacturer had on record, 5 cases of patients with prostatic cancer receiving **warfarin** whose prothrombin times had increased when

they were given flutamide. For example, one patient needed reductions in his **warfarin** dosage from 35 to 22.5 mg weekly over a 2-month period. Another had a prothrombin time rise from 15 to 37 seconds within 4 days of starting flutamide 750 mg daily.⁵ There appears to be no published information about this interaction, but the manufacturer recommends that prothrombin times are monitored if flutamide is given to patients taking **warfarin**, reducing the dosage when necessary.⁶

(c) Nilutamide

The manufacturer notes that, *in vitro*, nilutamide has been shown to inhibit cytochrome P450 isoenzymes (specific isoenzymes not stated). Because of this, they suggest that nilutamide might increase the toxicity of drugs with a low therapeutic margin such as the vitamin K antagonists (i.e. **coumarins** and **indanediones**). They therefore recommend that the prothrombin time be carefully monitored when nilutamide is given with these drugs, and their dosages reduced if necessary.⁷ There does not appear to be any further information about this potential interaction.

Coumarins + Bile-acid binding resins

The anticoagulant effects of phenprocoumon and warfarin can be reduced by colestyramine, especially if the coumarin is given at the same time. An isolated report describes unexpected sensitivity to warfarin in a patient taking colestyramine, which was attributed to a possible reduction in vitamin K absorption with colestyramine. Colestipol did not alter the absorption or effect of phenprocoumon or warfarin and colesevelam did not alter the pharmacokinetics of warfarin.

Clinical evidence

(a) Colesevelam

Colesevelam 4.5 g had no effect on the pharmacokinetics of **warfarin** 10 mg in a single-dose study in 24 healthy subjects.¹

(b) Colestipol

In a placebo-controlled, single-dose study in 4 healthy subjects, **phenprocoumon** plasma levels and the prothrombin response were unaffected by colestipol 8 g given at the same time as **phenprocoumon** 12 mg.² Similarly, in an study quoted in a review,³ the concurrent use of colestipol 10 g did not cause any changes in the absorption of a single 10-mg dose of **warfarin** in healthy subjects.

(c) Colestyramine

1. *Phenprocoumon*. It was noted that establishing effective anticoagulation was difficult in patients taking phenprocoumon with colestyramine, in spite of doubling the dose of phenprocoumon. This prompted a study in healthy subjects in which it was found that concurrent single doses of phenprocoumon and colestyramine markedly reduced phenprocoumon plasma levels and effect.⁴ In another study using *intravenous* phenprocoumon, colestyramine reduced the effect of the anticoagulant by this route, presumably by reducing enterohepatic recycling.⁵ This fact has been used clinically to enhance the elimination of phenprocoumon after phenprocoumon overdose. In one case, the half-life of phenprocoumon was measured as 6.8 days without colestyramine, and 3.5 days with colestyramine 4 g three times daily.⁶

A patient stabilised on phenprocoumon developed a fatal valve thrombosis after starting colestyramine, despite separation of doses in accordance with the manufacturer's instructions.⁷

2. *Warfarin*. Ten subjects were treated for one-week periods with warfarin alone then warfarin with colestyramine 8 g given three times daily, with the warfarin taken 30 minutes after colestyramine for one week, then 6 hours after colestyramine for one week. When warfarin was taken 30 minutes after colestyramine, peak warfarin levels were reduced by 52% and the prolongation in prothrombin times was reduced by 27%,

compared with warfarin alone. However, when warfarin was taken 6 hours after colestyramine, peak warfarin levels were reduced by only 16%, and the prolongation in prothrombin times was the same as with warfarin alone.⁸

Comparable results were found in another similar study; simultaneous administration of warfarin and colestyramine reduced the prothrombin time response by 21%, and separation by 3 hours still caused an 11% reduction in the prothrombin time response.⁹ Another study using *intravenous* warfarin has shown that colestyramine also reduces the effect of warfarin by this route, presumably by reducing enterohepatic recycling.¹⁰

Another report describes a patient taking colestyramine 4 g three times daily who was successfully stabilised on warfarin with alternating doses of 5 mg and 7.5 mg daily. The warfarin was given at 8 am, then the colestyramine at 12 noon with lunch, with dinner, and with an evening snack.¹¹ In contrast, an isolated report describes a 77-year-old patient taking multiple medications including colestyramine who was found to have a very high prothrombin time of 78.9 seconds and microscopic haematuria 6 weeks after starting warfarin 5 mg daily. Four days after starting the warfarin her prothrombin time was 17.1 seconds, and it had not been checked again.¹² However, as it is not certain that this patient was properly stabilised on warfarin this may simply have been an effect of the warfarin alone.

Mechanism

Colestyramine binds to coumarin anticoagulants in the gut, thereby preventing their absorption.^{4,9,13,14} Data with intravenous warfarin and phenprocoumon show that they undergo enterohepatic recycling, and that colestyramine can reduce this as well.^{5,10} Long-term use of colestyramine also reduces the absorption of fat-soluble vitamins such as vitamin K so that it can have some direct hypoprothrombinaemic effects of its own.^{15,16} This may to some extent offset the full effects of its interaction with anticoagulants. Colestipol on the other hand appears not to bind to any great extent at the pH values in the gut.² The paradoxical increase in the effects of warfarin in the isolated case cited above was attributed to the effect of colestyramine on vitamin K.¹²

Importance and management

The interaction of colestyramine with phenprocoumon and warfarin is established, and can be clinically important. If concurrent use is thought necessary, prothrombin times should be monitored and the dosage of the anticoagulant increased appropriately. Giving the colestyramine 4 to 6 hours after the anticoagulant has been shown to minimise the effects of this interaction,^{8,11} and it is a standard recommendation that other drugs should be given 1 hour before or 4 to 6 hours after colestyramine. However, despite adequate separation of doses, one patient taking phenprocoumon developed fatal valve thrombosis when given colestyramine, leading the authors to suggest that colestyramine should not be used in patients taking oral anticoagulants.⁷ Information about other anticoagulants is lacking but as colestyramine interacts with dicoumarol and ethyl biscoumacetate in *animals*¹⁴ it would be prudent to expect all coumarins to interact similarly. Bear in mind that long-term colestyramine can reduce vitamin K absorption and can cause hypoprothrombinaemia. This might result in an increased effect of warfarin, as has been suggested in one unconfirmed case report but there seems to be no other evidence to suggest that this is clinically relevant.

No special precautions appear necessary if warfarin or phenprocoumon and colestipol or colesevelam are given concurrently.

Coumarins + Bosentan

Bosentan modestly enhanced the metabolism of warfarin and reduced its anticoagulant effects in one study and in one case a patient needed a 64% increase in her warfarin dose after taking bosentan.

Clinical evidence

In a double-blind, randomised, placebo-controlled, crossover study, 12 healthy subjects were given bosentan 500 mg twice daily or placebo for 10 days, with a single 26-mg dose of **warfarin** on day 6. Bosentan reduced the AUC of *R*-warfarin by 38% and of *S*-warfarin by 29%. A significant decrease in the anticoagulant effects of **warfarin** was also noted, with a 23% reduction in prothrombin time occurring with bosentan.¹

One case highlights the clinical significance of this interaction. A 35-year-old woman taking **warfarin** with a stable INR of 2 to 3 over three months started taking bosentan 62.5 mg twice daily. After 10 days her INR was 1.7, and remained at this level over the next 4 weeks, despite an increase in her weekly **warfarin** dose from 27.5 to 40 mg. The bosentan dose was then increased to the maintenance dose of 125 mg twice daily, and two further weekly increases in **warfarin** dose were made. The INR was then high (3.2 to 4.1) for 3 weeks, before she was finally stabilised on **warfarin** 45 mg each week.²

However, the manufacturer of bosentan notes that, in clinical experience, the use of bosentan with **warfarin** did not result in clinically relevant changes in the INR or **warfarin** dose. There was no difference in the frequency of **warfarin** dose changes (due to INR changes or adverse effects) between bosentan or placebo recipients.³

Mechanism

It has been suggested that bosentan induces both cytochrome P450 isoenzymes CYP3A4 and CYP2C9, which are involved in the metabolism of *R*-warfarin and *S*-warfarin, respectively.¹

Importance and management

Both the reports suggest that a clinically significant interaction between warfarin and bosentan is possible, although exactly how frequently this may occur is unclear, since it was not detected in clinical studies. However, the INR should be closely monitored in any patient taking warfarin during the period that bosentan is started or stopped, or if the dose is altered.³

Coumarins + Broxuridine

A case report describes an increase in the effects of warfarin in a patient taking broxuridine.

Clinical evidence, mechanism, importance and management

A man taking **warfarin** and with grade III anaplastic astrocytoma was given intravenous broxuridine as a radiosensitiser. His prothrombin times were unaffected by the first course of broxuridine 1.4 g daily for 4 days, but became more prolonged with successive courses, and after the fourth course his prothrombin time reached about 45 seconds. This which was

managed with 10 mg of vitamin K. Warfarin was stopped after a significant increase also took place with a fifth cycle of broxuridine 990 mg daily.¹ The clinical relevance of this single case is uncertain.

Coumarins + Bucolome

Bucolome increases the anticoagulant effects of warfarin by inhibiting its metabolism.

Clinical evidence

A study in Japanese patients stabilised on **warfarin** found that the addition of bucolome 300 mg daily increased the INR of 21 patients 1.5-fold despite a 58% reduction in the **warfarin** dose, when compared with another group of 34 patients taking **warfarin** and not receiving bucolome.¹ In another 7-day study, 25 Japanese patients with heart disease on **warfarin** and bucolome 300 mg daily were compared with another control group of 30 patients taking **warfarin** alone. It was found that bucolome had no effect on the serum levels of *R*-warfarin but both the serum levels of *S*-warfarin and the prothrombin times rose. These changes were complete within 7 days.² In one analysis, the daily dose of **warfarin** was found to be about 40% lower in 78 patients taking bucolome, when compared with 99 patients not taking bucolome, although the thrombotest values were lower in those also taking bucolome (suggesting greater anticoagulation). Bucolome appeared to reduce the between patient variation in intrinsic hepatic clearance of warfarin.³

A patient who had been taking **warfarin** with bucolome for 18 days developed gross haematuria. He was found to have an intraluminal ureteral haematoma and an excessively prolonged prothrombin time, and was treated with intravenous vitamin K.⁴

Mechanism

In vitro studies show that the bucolome can inhibit the metabolism of the more potent enantiomer *S*-warfarin by the cytochrome P450 isoenzyme CYP2C9, thereby reducing its clearance and increasing its effects.¹

Importance and management

Information appears to be limited to the reports cited here but the interaction would seem to be established and clinically important. Monitor the INR closely. A reduced warfarin dosage (the study cited above suggests a 30 to 60% reduction)² is likely to be needed if both drugs are used concurrently to avoid excessive anticoagulation and possible bleeding. Note that bucolome is sometimes used with warfarin to enhance its therapeutic effect.³ Based on the mechanism of action, **acenocoumarol** and **phenprocoumon** would be anticipated to be similarly affected.

Coumarins + Calcium-channel blockers

In pharmacological studies neither amlodipine nor felodipine affected the anticoagulant effects of warfarin. Similarly, although diltiazem may cause a minor decrease in warfarin metabolism, this did not alter the anticoagulant effect in two studies.

Clinical evidence

(a) Dihydropyridine calcium-channel blockers

The manufacturers say that **amlodipine** did not significantly alter the effect of **warfarin** on prothrombin times in healthy subjects.^{1,2}

In healthy subjects given **warfarin** until at steady state, **felodipine** 10 mg daily for 14 days did not alter the dose of warfarin required to maintain a stable INR, or the pharmacokinetics of *S*- or *R*-warfarin.³ Because **felodipine** does not interact with **warfarin** it has been used as a control drug in retrospective cohort studies assessing **warfarin** drug interactions.^{4,5}

(b) Diltiazem

In a study, 11 healthy men were given racemic **warfarin**, and 8 were given *R*-warfarin, both as a single 1.5-mg/kg intravenous dose. Another 10 subjects were given *S*-warfarin as a single 0.75-mg/kg intravenous dose. After taking diltiazem 120 mg three times a day (for 4 days before and 9 days after the dose of **warfarin**) the clearance of *R*-warfarin was decreased by about 20% but the more potent *S*-warfarin remained unaffected. The total anticoagulant response remained unchanged.⁶ Similarly, in another study in 20 healthy subjects, diltiazem 30 mg three times daily for one week caused no clinically relevant changes in the anticoagulant effects of a single dose of **warfarin**. There was a small 13% decrease in **warfarin** clearance and an 8% increase in AUC when given with diltiazem, which were not statistically significant.⁷

Mechanism

Diltiazem is a known inhibitor of the cytochrome P450 isoenzyme CYP3A4. However, this isoenzyme has only a minor role in the 'metabolism of warfarin', (p.358), specifically in the metabolism of the less active *R*-isomer of warfarin. Consequently, only minor increases in the levels of warfarin have been seen in pharmacokinetic studies, which would generally not be expected to be clinically relevant. **Verapamil** is also an inhibitor of CYP3A4, but the dihydropyridine calcium-channel blockers are not.

Importance and management

No special precautions would seem to be necessary during the concurrent use of warfarin and dihydropyridine calcium-channel blockers. Although the minor pharmacokinetic interaction between diltiazem and warfarin would appear to be established, in the studies cited this did not change anticoagulant control, and is therefore unlikely to be of clinical importance. **Verapamil** would be expected to cause a similar pharmacokinetic interaction, although no data appear to be available on this.

The absence of adverse reports about these very widely used drugs suggests that concurrent use is normally uneventful.

Coumarins + Carbamazepine or Oxcarbazepine

The anticoagulant effects of warfarin can be markedly reduced by carbamazepine, and two case reports suggest phenprocoumon is similarly affected. Oxcarbazepine appears not to interact significantly with warfarin.

Clinical evidence

(a) Carbamazepine

1. *Phenprocoumon*. A man in his mid-twenties developed multiple thrombotic episodes due to hereditary resistance to activated protein C. Because of cerebral embolic strokes he developed epileptic seizures and was given carbamazepine 400 mg daily, followed 6 days later by phenprocoumon. It was found that relatively large doses of phenprocoumon (8 mg daily) had to be given without achieving adequate anticoagulation (Quick value 50 to 60%; target 10 to 20%) until the carbamazepine was withdrawn, whereupon the phenprocoumon dosage could be reduced to 1.5 mg daily with a Quick value of 30 to 40%.¹ Similarly, another patient stabilised on phenprocoumon was found to have a markedly reduced anticoagulant effect (a

dramatic increase in his Quick value) 21 days after he started taking carbamazepine 400 mg daily. The values returned to normal when the carbamazepine was stopped.²

2. **Warfarin.** In one study, 2 patients taking warfarin with carbamazepine (200 mg daily for the first week, 400 mg daily for the second and 600 mg for the third) had a fall of about 50% in serum warfarin levels, and sharp rises in their prothrombin-proconvertin percentages.³ The half-life of a single intravenous dose of warfarin in three other patients fell by about 11%, 53%, and 60%, respectively, when they were similarly treated.³ In another analysis, warfarin dose requirements were 2.3-fold higher in 5 patients stabilised on warfarin and carbamazepine than in 54 patients not taking any interacting drugs (median 9 mg daily versus 3.86 mg daily). These 5 patients had higher clearances of both *R*- and *S*-warfarin, and had about 11-fold higher plasma levels of the 10-hydroxymetabolite of warfarin.⁴ This interaction has been described in 5 case reports.⁵⁻⁹ One of them describes a patient stabilised on warfarin and carbamazepine who developed widespread dermal ecchymoses and a prothrombin time of 70 seconds, one week after stopping the carbamazepine. She was restabilised on approximately half the dose of warfarin in the absence of the carbamazepine.⁹

(b) *Oxcarbazepine*

In a study in 7 healthy subjects given warfarin until steady-state, oxcarbazepine 450 mg twice daily for one week slightly increased the mean Quick values from 36.6% to only 38.1%, which was not statistically significant.¹⁰

Mechanism

Carbamazepine is a known enzyme inducer, and increases the metabolism of warfarin. Phenprocoumon would be similarly affected. Oxcarbazepine on the other hand has relatively little enzyme-inducing activity.

Importance and management

The interaction between warfarin and carbamazepine is moderately well documented, established and clinically important. The incidence is uncertain, but monitor the anticoagulant response if carbamazepine is added to established treatment with warfarin and anticipate the need to double the dosage. Oxcarbazepine appears to be a relatively non-interacting alternative.

Information about an interaction between phenprocoumon and carbamazepine seems to be limited to the two reports cited. Nevertheless it would be prudent to monitor concurrent use in any patient, being alert for the need to increase the phenprocoumon dosage. The same precautions would seem sensible with any other coumarin but information appears to be lacking.

Coumarins + Carbon tetrachloride

A single case report describes an increase in the anticoagulant effects of dicoumarol in a patient who accidentally drank some cleaning liquid containing carbon tetrachloride.

Clinical evidence, mechanism, importance and management

A patient, well stabilised on **dicoumarol**, accidentally drank a small amount of cleaning liquid later estimated to contain just 0.1 mL of carbon tetrachloride. The next day his prothrombin time had risen to 41 seconds.

This value was about the same after another day even though the **dicoumarol** had been withdrawn, and marked hypoprothrombinaemia persisted for another 5 days.¹

The probable reason for this reaction is that carbon tetrachloride is very toxic to the liver, the changed anticoagulant response being a manifestation of this. Carbon tetrachloride, once used as an anthelmintic in man, is no longer used in human medicine, but is still employed as an industrial solvent and degreasing agent. On theoretical grounds it would seem possible for anticoagulated patients exposed to substantial amounts of the vapour to experience this interaction, but this has not been reported.

1. Luton EF. Carbon tetrachloride exposure during anticoagulant therapy. Dangerous enhancement of hypoprothrombinemic effect. *JAMA* (1965) 194, 1386-7.

Coumarins + Chlorpromazine

Chlorpromazine does not interact significantly with acenocoumarol.

Clinical evidence, mechanism, importance and management

Although in one early report, chlorpromazine 40 to 100 mg daily was said to have "slightly sensitised" 2 out of 8 patients to the effects of **acenocoumarol**¹ and in another was reported to increase its anticoagulant effects in *animals*,² there appears to be nothing else published to suggest that an interaction occurs. *In vitro* study in human liver microsomes³ found that chlorpromazine did not inhibit CYP2C9, the cytochrome P450 isoenzyme predominantly involved in the 'metabolism of **warfarin**', (p.358) and other coumarins. No coumarin dose adjustments would therefore be anticipated to be needed on concurrent use.

Coumarins + Cloral and derivatives

The anticoagulant effects of warfarin are increased in the first few days of cloral hydrate use, but this is normally of little or no clinical importance. Cloral betaine and triclofos may be expected to behave similarly.

Clinical evidence

In a retrospective study in patients just starting **warfarin**, the same loading doses of **warfarin** were given to 32 patients taking **cloral hydrate** daily and 67 patient who did not receive cloral hydrate. The **warfarin** requirements of the **cloral** group during the first 4 days fell by about one-third, but rose again to control requirements by the fifth day.¹

In a study in 8 subjects, the concurrent use of **warfarin** (loading dose 25 mg then 5 mg daily for 5 days) and **cloral hydrate** 1 g each night resulted in potentiation of the effect of **warfarin**, when compared with placebo (increase in prothrombin time of about 3 to 4 seconds). However, in a longer term study, the addition of **cloral hydrate** 500 mg at night for 4 weeks to subjects stabilised on **warfarin** did not alter the average prothrombin time before, during, and after the **cloral** treatment (18.9, 19.3, and 19.2 seconds, respectively).^{2,3}

Similar results have been described in other studies in patients taking **warfarin** and **cloral hydrate**⁴⁻⁸ or **triclofos**.⁹ **Cloral betaine** appears to behave similarly.¹⁰ An isolated and by no means fully explained case of fatal hypoprothrombinaemia occurred in a patient taking **dicoumarol** who was given **cloral hydrate** for 10 days, later replaced by secobarbital.¹¹ Another patient taking **dicoumarol** had a reduction in prothrombin times when given **cloral hydrate**.¹¹

Mechanism

Cloral hydrate is mainly metabolised to trichloroacetic acid, which then successfully competes with warfarin for its binding sites on plasma proteins.⁶ As a result, free and active molecules of warfarin are displaced into the plasma water and the effects of the warfarin are increased. But this is

only short-lived because the warfarin molecules become exposed to metabolism by the liver, so the warfarin level is reduced.

Importance and management

The interaction between warfarin and chloral hydrate is well documented and well understood, but normally of little or no clinical importance. There is very good evidence that concurrent use need not be avoided.¹⁻⁸ However, it may be prudent to keep an eye on the anticoagulant response during the first 4 to 5 days, just to make sure it does not become excessive. It is not certain whether other anticoagulants behave in the same way because the evidence is sparse, indirect and inconclusive,^{11,12} but what is known suggests that the coumarins probably do. Triclofos and cloral betaine appear to behave like chloral hydrate. Dichloralphenazone on the other hand interacts quite differently (see 'Coumarins + Dichloralphenazone', p.399).

Coumarins and related drugs + Colchicine

One report describes five cases of a possible marked increase in the effect of fludione when colchicine was given for acute gout.

Clinical evidence, mechanism, importance and management

The national pharmacovigilance system in France have reported 5 cases where colchicine appeared to increase the anticoagulant effect of **fludione**. All 5 patients were stabilised on **fludione** and were given short-term colchicine 1 to 6 mg daily for an acute attack of gout. All 5 patients had markedly raised INRs (6.5 to in excess of 18), but only one had clinical bleeding (haemorrhoidal bleeding).¹ The authors consider that colchicine may have been a factor in a case of raised INR with **warfarin**, which was attributed to the 'SSRI', (p.448), fluvoxamine.

The mechanism of this interaction is unknown, although the authors rule out protein binding or P-glycoprotein alterations. They suggest that it may occur because colchicine decreases expression of various cytochrome P450 isoenzymes, so decreasing the metabolism of **fludione**.¹

This appears to be the only report of an interaction of anticoagulants with colchicine. Bear it in mind in the event of an unexpected response to treatment. Further study is needed.

Coumarins + COMT inhibitors

Entacapone caused a slight increase in INR in subjects given warfarin, and slightly increased R-warfarin levels. These effects are unlikely to be generally clinically relevant, but some caution may be prudent. Tolcapone is not expected to interact with S-warfarin.

Clinical evidence

In a double-blind, crossover study in 12 healthy subjects given individualised **warfarin** doses to achieve an INR of between 1.4 and 1.8, **entaca-**

pone 200 mg four times daily slightly increased the INR by 13%. The AUC of R-warfarin was increased by 18%, with no change in the AUC of S-warfarin.¹

Mechanism

Not known. Based on *in vitro* data, both entacapone and **tolcapone** were thought to potentially interfere with the metabolism of drugs by the cytochrome P450 isoenzyme CYP2C9, such as S-warfarin.²⁻⁴ However, the above study shows that entacapone does not alter S-warfarin pharmacokinetics, and tolcapone is also thought not expected to interact by this mechanism because it does not interact with 'tolbutamide', (p.516), another CYP2C9 substrate.

Importance and management

The minor pharmacokinetic interaction between entacapone and warfarin would appear to be established, but its clinical relevance is uncertain. Changes of this magnitude would not generally be expected to be clinically relevant, and there do not appear to be any published case reports of problems. Nevertheless, it is possible that some patients might show a greater effect, and the manufacturer in the UK recommends that the INR be monitored when entacapone is started in patients taking warfarin.²

Similarly, although the manufacturers do not predict a pharmacokinetic interaction between **tolcapone** and warfarin, they still recommend monitoring because of the limited clinical information on the combination.^{3,4}

Coumarins and related drugs + Corticosteroids or Corticotropin

In two early studies, small increases or decreases in anticoagulation were reported when dicoumarol or phenindione were used with low-to-moderate doses of corticotropin or prednisone. In the most recent analysis, use of unspecified corticosteroids appeared to be associated with a slightly higher incidence of INRs over the target range in children taking warfarin. In one study, very marked prothrombin time increases were seen in patients taking fludione or acenocoumarol when given high-dose intravenous methylprednisolone, and two cases of this interaction have been reported with warfarin.

Clinical evidence

(a) Corticotropin

Ten out of 14 patients receiving long-term treatment with either **dicoumarol** or **phenindione** had a small but definite increase in their anticoagulant responses when they were given intramuscular or intravenous corticotropin for 4 to 9 days.¹ A patient stable on **ethyl biscouacetate** developed frank melaena and microscopic haematuria within 3 days of starting treatment with intravenous corticotropin 10 mg twice daily.²

In contrast, a decrease in the anticoagulant effects of **ethyl biscouacetate** was described in one patient given corticotropin and one patient given **cortisone**.³

(b) Methylprednisolone

A sharp increase in the INR of a patient with APS (antiphospholipid syndrome) occurred after **methylprednisolone** was added to treatment with an unnamed oral anticoagulant.^{4,5} This prompted a controlled study in 10 patients stabilised on anticoagulants (8 taking **fludione** and 2 taking **acenocoumarol**) and 5 patients not taking an anticoagulant. It was found that pulse high-dose intravenous **methylprednisolone** (500 mg or 1 g) increased the mean INR of those taking an anticoagulant from a baseline of 2.75 to 8.04, but had no effect on the prothrombin time in those taking **methylprednisolone** alone.^{4,5} Two patients stabilised on **warfarin** are also reported to have shown significant prolongations in their prothrombin times when given high-dose **methylprednisolone** (960 mg or 1 g, fol-

lowed by **dexamethasone** 60 mg three times daily for 3 days in one case) for the treatment of multiple sclerosis.⁶

(c) *Prednisone*

A study in 24 patients anticoagulated for several days with **dicoumarol** found that 2 hours after receiving prednisone 10 mg their silicone coagulation time had decreased from 28 to 24 minutes, and 2 hours later was down to 22 minutes.⁷

(d) *Unspecified corticosteroids*

In an analysis of a cohort of children receiving **warfarin**, there was no difference in dose of **warfarin** required to achieve and maintain the target INR between **warfarin** courses if corticosteroids were given (38 courses) and courses where corticosteroids were not given (314). However, courses with corticosteroids were associated with a higher percentage of INR measurements greater than the target (21% versus 14%).⁸

Mechanism

Not understood. Corticotropin, cortisone and prednisone can increase the coagulability of the blood in the absence of anticoagulants.^{9,10} It has been suggested that methylprednisolone may inhibit the metabolism of anticoagulants.⁵

Importance and management

The interaction of low to moderate doses of corticosteroids with coumarins is by no means established, and is very poorly documented. Most of the few reports are from the 1950s and 60s, with very little appearing to have been published since then, suggesting that any effects are generally not clinically relevant. In an analysis from the 1990s, the use of corticosteroids appeared to be associated with a slightly higher incidence of INRs over the target range in children. The most constructive thing that can be said is that if either corticotropin (corticotrophin, ACTH) or any corticosteroid is given to patients taking anticoagulants, be aware that an interaction might very rarely occur. Also note that corticosteroids are associated with a weak increase in peptic ulceration and gastrointestinal bleeding, and the risk of this could theoretically be increased if over-anticoagulation occurs.

The situation with high dose methylprednisolone is clearly different. Although the evidence is limited, marked INR increases have been reported and INRs should be closely monitored (daily has been recommended⁵) if this or other high-dose corticosteroids are added to established treatment with any coumarin or indanedione oral anticoagulant. More study is needed.

Coumarins + Cranberry juice

A number of case reports suggest that cranberry juice can increase the INR of patients taking warfarin, and one patient has died as a result of this interaction. Limited evidence suggests that the use of cranberry juice in patients taking warfarin can result in unstable INRs, or, in one isolated case, a *reduced* INR.

Clinical evidence

In September 2003, the CSM in the UK noted that they had received 5 reports suggesting an interaction between **warfarin** and cranberry juice (*Vaccinium macrocarpon*) since 1999.¹ The most serious case involved a man taking **warfarin** whose INR markedly increased (INR greater than 50) 6 weeks after starting to drink cranberry juice. He died from gastrointestinal and pericardial haemorrhages.¹ Further details of this case included that he had recently been treated with cefalexin (not known to interact, although consider ‘antibacterials’, (p.365)) for a chest infection, and had been eating virtually nothing,² a fact that would have contributed to increased anticoagulation. Less marked INR increases (not specified) were seen in two other patients, one of whom was restabilised on a lower **warfarin** dosage, while the other regained normal INR values after cranberry juice was stopped.¹ A further patient had unstable INRs, while the final patient had a decrease in INR.¹

In a further case,³ a patient stabilised on **warfarin** was found to have INRs of 10 to 12 in the days prior to a surgical procedure, although he had no previous record of an INR greater than 4. Vitamin K was given, and heparin was substituted for warfarin. When **warfarin** was restarted post-operatively, the INR quickly rose to 8 and then to 11 with haematuria, and postoperative bleeding. The patient was drinking almost 2 litres of cranberry juice daily, because of recurrent urinary tract infections, and was advised to stop drinking this. After three days the INR had stabilised at 3.

In October 2004, the MHRA/CSM in the UK noted that they had now received 12 reports of a suspected interaction.⁴ These included 5 additional cases of bleeding episodes and two additional cases of unstable INRs in patients drinking cranberry juice while taking warfarin.

In the US major bleeding and a high INR have been reported, which occurred shortly after cranberry juice was started.⁵

Mechanism

Not known. It was suggested that one or more of the constituents of cranberry juice might have inhibited the metabolism of warfarin by the cytochrome isoenzyme CYP2C9, thereby reducing its clearance from the body and increasing its effects.¹ However, doubt has been cast on this mechanism, since cranberry juice had no effect on flurbiprofen pharmacokinetics, a drug used as a surrogate index of CYP2C9 activity, and had only weak CYP2C9-inhibitory activity *in vitro*.⁶ Alternatively, the salicylate constituent of cranberry juice might cause hypoprothrombinaemia,⁷ similarly to high-dose ‘aspirin’, (p.385).

Importance and management

The incidence and general clinical importance of this interaction is unknown, but the current recommendation of the CSM/MHRA in the UK is that patients taking warfarin should avoid drinking cranberry juice unless the health benefits are considered to outweigh any risks. They recommend increased INR monitoring for any patient taking warfarin and a regular intake of cranberry juice.⁴ They also advise similar precautions with other cranberry products (such as capsules or concentrates).⁴ Further study is needed.

Coumarins + Danazol or Gestrinone

Increased anticoagulant effects and bleeding have been seen in a few patients taking warfarin with danazol. A case describes similar effects in a patient taking warfarin and gestrinone.

Clinical evidence

(a) Danazol

A 40-year-old woman stabilised on **warfarin** 6 mg daily with a prothrombin ratio of 2.3 presented after vomiting blood. She was found to have a prothrombin ratio of 14, and required fresh frozen plasma and 2 litres of blood. Three weeks previously she had been prescribed danazol 200 mg twice daily.¹ Four other similar cases of this interaction with danazol have been reported.²⁻⁴ In two of the cases the patients were subsequently stabilised on **warfarin** and danazol, but with 50 to 70% lower **warfarin** doses.^{3,4}

(b) Gestrinone

A bulletin includes a brief mention of an increased INR with vaginal bleeding and multiple bruising in a woman taking **warfarin** and gestrinone.⁵

Mechanism

The reason for this interaction is unknown, but both danazol and gestrinone have androgenic properties, and 'anabolic steroids,' (p.364), are known to increase the effects of warfarin.

Importance and management

Although data are limited, the interaction with danazol would appear to be established, and close monitoring of the INR is advisable if danazol is added to established coumarin anticoagulant therapy. Some suggest that the initial dosage of anticoagulant should be halved when danazol is started.² However, others note that this may not be appropriate in patients at high thrombotic risk, such as those with mechanical valves. In these patients, they recommend a cautious reduction in dose with weekly monitoring of the INR until it becomes stable (several weeks).⁴ Gestrinone might be expected to interact similarly, and some caution is therefore appropriate.

Coumarins + Darifenacin or Solifenacin

Solifenacin did not alter the pharmacokinetics or effect of warfarin. Similarly, darifenacin did not alter the prothrombin time in response to warfarin.

Clinical evidence, mechanism, importance and management

(a) Darifenacin

The manufacturer notes that steady state darifenacin 30 mg daily did not alter the prothrombin time after a single 30-mg dose of **warfarin**.¹ No **warfarin** dose adjustment would be expected to be needed on concurrent use.

(b) Solifenacin

In a placebo-controlled, crossover study in healthy subjects, solifenacin 10 mg daily for 10 days had no effect on the pharmacokinetics of *S*- or *R*-warfarin after a single 25-mg dose of **warfarin** was given on day 10. In addition, solifenacin did not alter the prothrombin time.²

This study suggests that no pharmacokinetic or pharmacodynamic interaction occurs, and that no **warfarin** dose adjustment would be expected to be needed on concurrent use.

Coumarins + Dichloralphenazone

The anticoagulant effects of warfarin are reduced by dichloralphenazone.

Clinical evidence

Five patients stabilised taking **warfarin** long-term and given dichloralphenazone 1.3 g each night for 30 days had a reduction of about 50% (range 20.2 to 68.5%) in plasma **warfarin** levels and a fall in the anticoagulant response during the last 14 days of concurrent use. Another patient given dichloralphenazone 1.3 g nightly for one month had a 70% fall in plasma **warfarin** levels and a thrombotest percentage rise from 9 to 55% (indicating a reduced anticoagulant effect). These values returned to normal when the hypnotic was withdrawn.^{1,2}

Mechanism

The 'phenazone', (p.434) component of dichloralphenazone is a potent liver enzyme inducer, which increases the metabolism and clearance of the warfarin, thereby reducing its effects.^{1,2} The effects of the 'cloral hydrate', (p.396) component appear to be minimal.

Importance and management

Information is limited, but the interaction between warfarin and dichloralphenazone appears to be an established and clinically important interaction, probably affecting most patients. The dosage of warfarin will need to be increased to accommodate this interaction. If the effect of warfarin has been reduced by using dichloralphenazone, it may take up to a month for it to restabilise. There does not appear to be any information about other anticoagulants, but other coumarins would be expected to be similarly affected. The 'benzodiazepines', (p.391) would now be preferred hypnotics, and do not interact.

Anticoagulants + Dietary supplements; Ascorbic acid (Vitamin C)

Although two isolated cases have been reported in which the effects of warfarin were reduced by ascorbic acid, four subsequent prospective studies have not found any interaction.

Clinical evidence

In a woman recently stabilised on **warfarin** 7.5 mg daily, who began to simultaneously take ascorbic acid (dose not stated) with her warfarin, the prothrombin time fell steadily from 23 seconds, to 19, 17, and then 14 seconds, with no response to an increase in the dosage of **warfarin** to 10, 15, and finally 20 mg daily. The prothrombin time returned to 28 seconds within 2 days of stopping the ascorbic acid.¹ Another woman recently stabilised on warfarin 5 mg daily had a recurrence of acute thrombophlebitis with a prothrombin time of 12 seconds. She was unusually resistant to the actions of **warfarin** and required 25 mg daily before a significant increase in prothrombin times was achieved. On questioning, she had been taking massive amounts of ascorbic acid (about 16 g daily) for several weeks. She was eventually stabilised on warfarin 10 mg daily.²

In contrast, in prospective studies no changes in the effects of **warfarin** were seen:

- in 5 patients given ascorbic acid 1 g daily for a fortnight,³
- in 11 patients (some taking **dicoumarol**) given ascorbic acid 4 g daily for 2 weeks,⁴
- in 14 patients given ascorbic acid 3 g then 5 g daily for one week or 5 patients given 10 g daily for one week:⁵ a mean fall of 17.5% in total plasma **warfarin** concentrations was seen at all doses.
- in a 10-week study, where the proportion of patients requiring a change in **warfarin** dose did not differ between 84 patients given ascorbic acid (dose unstated) and 96 control patients (31 versus 18 patients required a dose reduction, and 7 versus 13 required a dose increase, respectively).⁶

Mechanism

Not understood. One *animal* study has demonstrated this interaction⁷ and others have not,^{8,9} but none of them has provided any definite clues about why it ever occurs. One suggestion is that high doses of ascorbic acid can cause diarrhoea, which might prevent adequate absorption of the anticoagulant.

Importance and management

Four clinical studies in patients stabilised on warfarin have failed to confirm that ascorbic acid alters the anticoagulant effect of warfarin, even using very large doses of ascorbic acid (up to 10 g daily), even though there are two isolated reports of reduced warfarin efficacy. All these data are from the 1970s, and nothing further seems to have been published. Coumarin dose adjustments are therefore unlikely to be needed when ascorbic acid is also used.

Coumarins + Dietary supplements; Fish oils

The use of warfarin with fish oils did not alter the INR in two studies, nor the incidence of bleeding episodes in another. However, in one study, fish oil significantly prolonged bleeding time, and there is one report of an increased INR in a patient taking warfarin who doubled her fish oil dose.

Clinical evidence

In one early study, 40 patients took 4 g of a fish oil preparation daily for 4 weeks: 18 of these patients were taking **warfarin**. In the group as a whole (40 patients), the bleeding time was significantly prolonged from 240 to 270 seconds. In the subset of patients taking **warfarin** who had stable anticoagulant control in the preceding 3 months (15 patients), the thrombotest was shortened from 114 to 90 seconds, although no changes in warfarin dosage were made. One patient taking warfarin had a minor nose-bleed.¹ In a large randomised study of the effect of fish oils or placebo, taken with either aspirin or **warfarin** over 9 months, there was no difference in the frequency of bleeding episodes between 132 patients taking **warfarin** and fish oil and 154 taking **warfarin** alone (17 versus 14, respectively).²

One case of a possible interaction with a rise in INR has been reported. A woman had INRs in the range of 2 to 3 for five months while taking **warfarin** 1.5 mg and 1 mg on alternate days. During this time, she starting taking 1 g of a fish oil preparation daily with no change in her INR. Her **warfarin** was then increased to 1.5 mg daily, with stable INRs for about 5 months. A routine INR was then found to be 4.3 (raised from 2.8 one month earlier). One week previously, she had started to take double the dose of fish oil (to 2 g daily). The dose of **warfarin** was reduced to 1.5 mg and 1 mg on alternate days, and she was asked to reduce the fish oil back to 1 g daily. Eight days later her INR was 1.6, and the **warfarin** was increased back to 1.5 mg daily.³

Mechanism

Fish oils contain omega-3 fatty acids particularly **eicosapentaenoic acid** and **docosahexaenoic acid**. These are considered to have some antithrombotic activity, and may prolong the bleeding time.

Importance and management

This interaction is not established. One large study found no increase in bleeding episodes in over 150 patients taking warfarin and fish oils, suggesting that most patients do not show any interaction. However, based on

the possible moderate increase in bleeding times with high-dose fish oils, the manufacturers of one product, **Omacor** (omega-3-acid ethyl esters), say that patients receiving anticoagulants should be monitored, and the dose of anticoagulant adjusted as necessary.⁴

Coumarins + Dietary supplements; Glucosamine ± Chondroitin

A few reports suggest that glucosamine with or without chondroitin may increase the INR in patients taking warfarin. In contrast, one case of a decreased INR has been reported when glucosamine was given with acenocoumarol.

Clinical evidence, mechanism, importance and management

A 69-year-old man stabilised on **warfarin** 47.5 mg weekly had an increase in his INR from 2.58 to 4.52 four weeks after starting to take 6 capsules of **Cosamin DS** (glucosamine hydrochloride 500 mg, sodium chondroitin sulfate 400 mg, manganese ascorbate per capsule) daily. His **warfarin** dose was reduced to 40 mg weekly, and his INR returned to the target range of 2 to 3 (INR 2.15) with continued **Cosamin DS** therapy.¹ A comment on this report noted that this is twice the usual dose of glucosamine.² The Canadian Adverse Drug Reaction Monitoring Program briefly reported that an increase in INR had been noted when glucosamine was given to patients on **warfarin**, and that INR values decreased when glucosamine was stopped.³ Moreover, in 2006 the CHM in the UK reported that they had received 7 reports of an increase in INR in patients taking **warfarin** after they started taking glucosamine supplements.⁴

In contrast, a 71-year-old man stabilised on **acenocoumarol** 15 mg weekly had a *decrease* in his INR to 1.6 after taking glucosamine sulfate (**Xicil**) 1.5 g daily for 10 days. The glucosamine was stopped and the INR reached 2.1. When the glucosamine was restarted, with an increase in **acenocoumarol** dose to 17 mg weekly, the INR only reached 1.9. The glucosamine was eventually stopped.⁵

There do not appear to have been any controlled studies of the effects of glucosamine supplements on the pharmacodynamics or pharmacokinetics of oral anticoagulants. The cases described suggest it would be prudent to monitor the INR more closely if glucosamine is started. If a patient shows an unexpected change in INR, bear in mind the possibility of self-medication with supplements such as glucosamine. Note that the CHM in the UK recommend that patients taking **warfarin** do not take glucosamine.⁴

Coumarins + Dietary supplements; Levocarnitine

Two isolated reports describe a marked increase in the anticoagulant effects of acenocoumarol in patients taking levocarnitine (L-carnitine), one of which was associated with melaena.

Clinical evidence, mechanism, importance and management

A woman who had taken **acenocoumarol** for 17 years because of aortic and mitral prosthetic valves, was admitted to hospital with melaena within 5 days of starting to take levocarnitine (L-carnitine) 1 g daily, which she was prescribed for congestive heart failure. Her INR had risen from 2.1 to 7.

Endoscopy and colonoscopy revealed diffuse bleeding from superficial erosions in the gut. She was discharged 10 days later with the same dose of **acenocoumarol** and an INR of 2.1 without the carnitine.¹ A similar case has been described in a man stabilised on **acenocoumarol** (INR 1.99 to 2.94) who had a rise in INR to 4.65 despite a dose correction. The increases in INR occurred when he was using levocarnitine 1 g daily for 10 weeks in the form of a drink (*Maximize*) promoted for bodybuilding and fitness training. When this product was discontinued, the INR returned to the therapeutic range.²

The reason for this apparent interaction is not known. These seem to be the only recorded cases of an interaction between an oral anticoagulant and levocarnitine, but it may be prudent to bear this interaction in mind if levocarnitine is taken with acenocoumarol, or possibly any coumarin, being alert for an increased response.

Coumarins + Dietary supplements; Ubidecarenone (Coenzyme Q10)

Ubidecarenone did not alter the INR or required warfarin dose in a controlled study in patients stabilised on warfarin. However, two reports describe reduced anticoagulant effects of warfarin in four patients taking ubidecarenone. A transient increase in INR has been reported in one patient taking ubidecarenone and warfarin.

Clinical evidence

In a randomised, double-blind, crossover study in 21 patients stabilised on **warfarin**, ubidecarenone 100 mg daily (*Bio-Quinone*) for 4 weeks did not alter the INR or the required dose of **warfarin**, when compared with placebo.¹ Similarly, 2 patients taking ubidecarenone to treat alopecia caused by **warfarin** treatment did not have any notable changes in INR, except that one had a transient INR *increase* when ubidecarenone was started.²

In contrast, another report describes 3 patients taking **warfarin** who had a drop in INR while taking ubidecarenone. In two of these INR reductions from about 2.5 to 1.4 occurred when they took ubidecarenone 30 mg daily for 2 weeks. The INRs rapidly returned to normal when the ubidecarenone was stopped.³ In another case, a patient appeared to have a reduced response to **warfarin** while taking ubidecarenone, and responded normally when it was stopped.⁴

Mechanism

The reasons for these INR changes are not known but it may be that ubidecarenone has some vitamin K-like activity. In a study in *rats*, ubidecarenone reduced the anticoagulant effect of warfarin and increased the clearance of both enantiomers of warfarin.⁵

Importance and management

The well-controlled study suggests that ubidecarenone does not interact with warfarin, and that no warfarin dose adjustment would be expected to be necessary in patients who take this substance. However, the finding in 2 reports of a decrease in warfarin effect introduces a note of caution. The authors of the controlled study do recommend close monitoring of the INR if a patient decides to use ubidecarenone, because the underlying health problem resulting in them choosing to take this substance may alter their response to warfarin.¹

Coumarins + Dietary supplements; Vitamin E substances

In two studies in patients the anticoagulant effects of warfarin were unchanged by small to large doses of vitamin E, although there is an isolated case of bleeding attributed to concurrent use. In three healthy subjects, the effects of dicoumarol were slightly increased by vitamin E.

Clinical evidence

(a) Dicoumarol

A study in 3 healthy subjects found that 42 units of vitamin E daily for a month increased the response to a single dose of dicoumarol after 36 hours (decrease in prothrombin activity from 52 to 33%).¹

(b) Warfarin

In a double-blind, placebo-controlled study in 25 patients stabilised on warfarin, moderate to large daily doses of vitamin E (800 or 1200 units) for a month caused no clinically relevant changes in prothrombin times and INRs.² Similarly, in another study in 12 patients taking warfarin, the anticoagulant effects of warfarin were unchanged by smaller daily doses of 100 or 400 units of vitamin E given for 4 weeks.³

However, in one case, a patient taking warfarin (and multiple other drugs) developed ecchymoses and haematuria, which was attributed to him taking 1200 units of vitamin E daily over a 2-month period. His prothrombin time was found to be 36 seconds. A later study in this patient showed that 800 units of vitamin E daily for 6 weeks reduced his blood clotting factor levels, increased the prothrombin time from about 21 to 29 seconds, and caused ecchymoses.⁴

Mechanism

Not understood. The suggested explanation is that vitamin E interferes with the activity of vitamin K in producing the blood clotting factors,^{4,5} and increases in the dietary requirements of vitamin K.^{6,7}

Importance and management

Information is limited but the evidence suggests that most patients taking warfarin are unlikely to have problems if given even quite large daily doses (up to 1200 units) of vitamin E. Nevertheless the isolated case cited here shows that occasionally and unpredictably the warfarin effects can be changed. It has been recommended that prothrombin times should be monitored when vitamin E is first given (within 1 to 2 weeks has been recommended).² The same precautions could be applied to dicoumarol as well. However, as only one case of bleeding has been reported this does seem somewhat over-cautious. Information about other oral anticoagulants is lacking.

Coumarins + Dietary supplements; Vitamin K₁-containing

In patients with normal vitamin K status, multivitamin supplements containing 10 to 50 micrograms of vitamin K₁ (phytonadione) will generally have no clinically important effect on the INR or anticoagulant requirements. Vitamin K doses of 150 micrograms daily are likely to require a dose adjustment in a proportion of patients. However, in patients with poor vitamin K status, even low vitamin K doses of 25 micrograms daily may have an important effect.

Clinical evidence

In a controlled study in healthy subjects stabilised on individual doses of **acenocoumarol**, the dose of vitamin K₁ tablets required to cause a statistically significant reduction in INR was 150 micrograms daily (INR 1.59 versus 2.04). Each dose of vitamin K₁ was taken daily for a week, and in successive weeks the dose was increased in increments of 50 micrograms from 50 to 300 micrograms daily, then 500 micrograms daily for the final week. The authors noted that their usual clinical criteria requiring an adjustment in **acenocoumarol** dose would have been met in 3 of the 12 subjects at a dose of vitamin K₁ of 150 micrograms daily.¹ However, in another study in 9 patients stabilised on **warfarin** with low vitamin K levels the median INR dropped by 0.51 requiring a **warfarin** dose increase of 5.3% after they took just one multivitamin tablet containing vitamin K₁ 25 micrograms daily for 4 weeks. Conversely, in a control group with normal plasma vitamin K levels, the same multivitamin did not change the INR or warfarin requirement.² In another study in patients taking **phenprocoumon**, supplementation with vitamin K₁ 50 micrograms daily for 3 weeks had little effect on the INR, and required just a 3% increase in **phenprocoumon** dose. A higher dose of vitamin K₁ of 100 micrograms daily resulted in a mean dose increase of 9%. On stopping the supplements, a mean 7% decrease in dose was needed. However, there was wide variation between patients.³

A patient who required **warfarin** 15 to 17.5 mg daily to maintain an INR of about 3 was found to be taking vitamin K (dose not stated) as part of a vitamin supplement. When he stopped taking the vitamin K, his **warfarin** dose requirement decreased to 10.5 to 12.5 mg daily.⁴ In another report, a woman required an increase in her **warfarin** dose from 45 mg to 60 mg weekly when she started taking a daily multivitamin containing vitamin K₁ 25 micrograms (*Centrum Plus*). Two weeks after stopping the multivitamin, she had haematuria and flank pain and was found to have a haematoma of the kidney and an INR of 13.2. A second patient had an acute occlusion of an aorto-bifemoral graft, requiring emergency surgery, 4 weeks after starting *Centrum Plus*. His INR had fallen from a mean of 2.48 to 1.1. A third patient had a fall in INR from a mean of 2.54 to 1.65 after taking *Centrum Plus* for 2 weeks. It was postulated that all three patients had low levels of vitamin K.⁵

Mechanism

Vitamin K₁ reduces the effect of vitamin K-antagonists (coumarins and **indanediones**). The dose of vitamin K₁ at which this becomes clinically important appears to depend on the vitamin K status of the individual.

Importance and management

The data from the controlled studies suggest that taking multivitamin supplements containing 10 to 50 micrograms of vitamin K₁ is probably acceptable in most patients taking anticoagulants, and is likely to require no change or only small changes to the anticoagulant dose. However, in patients with poor vitamin K status, even these low levels of vitamin K may be sufficient to antagonise the effect of their therapy. Note that a review of selected US supplements found that they contained 10 to 80 micrograms of vitamin K₁. Therefore, patients should be advised to *not* take a multivitamin preparation containing vitamin K₁ (phytonadione) without increased monitoring when starting or stopping treatment. Because of this, and because of the increasing recognition of the importance of vitamin K in bone health, some consider that patients taking anticoagulants should be advised to consume sufficient vitamin K to meet the recommended adequate intakes,⁶ see also 'Coumarins and related drugs + Foods; Vitamin K₁-rich', p.409. Others have even suggested that a low and steady vitamin K supplement may reduce the risk of excessive anticoagulation without altering efficacy.⁷

Coumarins + Disopyramide

In two small uncontrolled studies, the anticoagulant effects of warfarin were slightly reduced by disopyramide. In contrast, there is an isolated report of a patient who needed his warfarin dose to be doubled after stopping disopyramide.

Clinical evidence

In a preliminary report of a study in 10 patients with recent atrial fibrillation taking **warfarin** and with a British Corrected Ratio of 2 to 3, disopyramide (dose not stated) increased the clearance of **warfarin** by 21%.¹ Similarly, another study found that 2 out of 3 patients needed a slight **warfarin** dosage increase of about 10% after cardioversion and after starting disopyramide 200 mg three times daily for atrial fibrillation.²

In contrast, another report describes a patient who, following a myocardial infarction, was given **warfarin** 3 mg daily and disopyramide 100 mg every 6 hours with digoxin, furosemide and potassium supplements. When the disopyramide was withdrawn his **warfarin** requirements doubled over a 9-day period.^{3,4}

Mechanism

Unknown. One idea is that when the disopyramide controls fibrillation, changes occur in cardiac output and in the flow of blood through the liver, which might have an effect on the synthesis of the blood clotting factors.^{2,5} But the discordant response in the isolated case remains unexplained.

Importance and management

Very poorly documented and not established. Limited data suggest only a minor interaction occurs (a slight reduction in anticoagulant effect), but an isolated case suggests a greater and opposite effect. Bear the possibility of an interaction in mind in the case of an unexpected response to warfarin in a patient starting or stopping disopyramide.

Coumarins + Disulfiram

The anticoagulant effects of warfarin were increased by disulfiram in two studies, and two cases showing this effect have also been reported.

Clinical evidence

In one study in 7 healthy subjects, **warfarin** (adjusted to maintain a prothrombin activity of 40%) was given alone for 21 days, then given with disulfiram 500 mg daily for 21 days. The plasma **warfarin** levels of 5 of the 7 subjects rose by an average of 20% and their prothrombin activity fell from about 34% to 24% of normal (suggesting an increased anticoagulant effect); one of the subjects had little change, and the other had the opposite effect.¹ Other experiments with single doses of **warfarin** confirm these results.¹ However, a further study found that, although disulfiram potentiated the effect of *S*-warfarin, it did not change the plasma levels of either *R*- or *S*-warfarin.²

An alcoholic patient stabilised on **warfarin** had an increase in his prothrombin time associated with gross haematuria when disulfiram 250 mg daily was given. Two subsequent attempts to introduce disulfiram 250 mg on alternate days also had a similar effect. He was eventually stabilised on a 43% lower daily dose of warfarin and disulfiram 250 mg daily.³ Another case of increased prothrombin time and the need for a reduced warfarin dose has been reported.⁴

Mechanism

Not fully understood. The suggestion¹ that disulfiram inhibits the liver enzymes concerned with the metabolism of warfarin has not been confirmed by later studies.² It has instead been suggested² that disulfiram may

chelate with the metal ions necessary for the production of active thrombin from prothrombin, thereby augmenting the actions of warfarin.

Importance and management

An interaction appears to be established, although direct information about patients is very limited. What is known suggests that most individuals will demonstrate this interaction. If concurrent use is thought appropriate, the effects of warfarin should be monitored and suitable dosage adjustments made when adding or withdrawing disulfiram. Care should be taken when starting warfarin in patients already taking disulfiram, and consideration should be given to using a smaller loading dose.

Coumarins + Diuretics

The loop diuretics, bumetanide, furosemide and torasemide, the potassium-sparing diuretic spironolactone, and the thiazides chlortalidone and chlorothiazide, have all been shown either not to interact or to cause only a small reduction in the effects of the coumarin anticoagulants of minimal or no clinical importance. The lack of reports of clinically relevant interactions suggests that, in general, diuretics do not interact with anticoagulants. The possible exception is etacrynic acid, which on rare occasions has caused a marked increase in the effects of warfarin.

Clinical evidence

A. Loop diuretics

(a) Bumetanide

In 10 healthy subjects, bumetanide 1 mg daily for 14 days did not alter the anticoagulant effect of a single-dose of **warfarin** given on day 8, and did not alter serum **warfarin** levels.¹ This confirms findings of a previous study in 5 healthy subjects given single-dose **warfarin** after bumetanide 2 mg daily for 5 days.²

(b) Etacrynic acid

A case report describes a marked increase in the anticoagulant effects of **warfarin** in a woman with hypoalbuminaemia on two occasions when she was given etacrynic acid 150 mg to 300 mg daily.³ In a preliminary report of a cohort study, it was stated that a therapeutically significant interaction between **warfarin** and etacrynic acid was documented, but no details are given.⁴

(c) Furosemide

In 6 healthy subjects, plasma levels, half-lives and prothrombin times were not altered when a single 50-mg dose of **warfarin** was given after furosemide 80 mg daily for 5 days.² However, a 28% decrease in the INR of one patient taking **warfarin** was seen when furosemide was taken on a regular basis. This was attributed to volume depletion caused by the diuretic, although interpretation of this case is complicated by the patient's admission of previous non-compliance and abuse of alcohol and cocaine.⁵ In a pharmacokinetic study in 17 healthy subjects, furosemide 40 mg twice daily had no effect on the pharmacokinetics of a single 0.22-mg/kg dose of **phenprocoumon**.⁶ In another study in 22 patients with congestive heart failure stabilised on **phenprocoumon**, furosemide 40 mg daily for 8 days did not alter the anticoagulant effects or required dose of **phenprocoumon**.⁷

(d) Tienilic acid (Ticrynafen)

In 6 healthy subjects, tienilic acid 250 mg daily for about 14 days caused a mean 265% increase in the anticoagulant effect of a single dose of **warfarin** given on day 4. Analysis showed the interaction was stereoselective, with the AUC of *S*-warfarin increased by 192%, with the AUC for *R*-warfarin increased by only 8%.⁸ Two patients taking **ethyl biscoumacetate** began to bleed spontaneously (haematuria, ecchymoses of the legs and gastrointestinal bleeding) when they started to take tienilic acid 250 mg daily. The thrombotest percentage of one of them was found to have fallen by 10%.⁹ Increased anticoagulant effects and/or bleeding, which began

within a few days, have been described in a number of other case reports in patients given tienilic acid while taking **ethyl biscoumacetate**,^{10,11} **acenocoumarol**¹² or **warfarin**.^{10,13}

(e) Torasemide

In a study in 24 patients with congestive heart failure stabilised on **phenprocoumon**, torasemide 20 mg daily for 8 days did not alter the anticoagulant effects or required dose of **phenprocoumon**.⁷

B. Potassium-sparing diuretics

(a) Spironolactone

In a study in 9 healthy subjects, spironolactone 50 mg four times daily for about 16 days reduced the prothrombin time response to a single dose of warfarin given on day 8 by 24%, when compared with **warfarin** alone. Plasma **warfarin** levels remained unchanged.¹⁴

C. Thiazides

(a) Chlortalidone

Six healthy subjects given a single 1.5-mg/kg dose of **warfarin** showed reduced hypoprothrombinaemia (prothrombin activity reduced from 77 to 58 units) when they were also given chlortalidone 100 mg daily for 7 days with the **warfarin** given on the first day, although the plasma **warfarin** levels remained unaltered.¹⁵ Similarly, reduced anticoagulant effects have been described when chlortalidone was given with **phenprocoumon**, but no significant effects were seen when chlortalidone was given with **acenocoumarol**.¹⁶

(b) Chlorothiazide

A study in 8 healthy subjects given single 40 to 60-mg doses of **warfarin** before and after chlorothiazide 1 g daily for 21 days found that the mean half-life of the anticoagulant was increased from 39 to 44 hours, but the prothrombin time was only decreased by 0.3 seconds.¹⁷

Mechanism

It has been suggested that the diuresis induced by chlortalidone, furosemide and spironolactone reduces plasma water, which leads to a concentration of the blood clotting factors.^{5,14,15} Etacrynic acid can displace warfarin from its plasma protein binding sites,¹⁸ and it was originally thought that other diuretics also interacted by drug displacement.^{9,19,20} Only 3% of total plasma warfarin is in the free active form, thus a small displacement could result in marked enhancement of activity,³ but it is almost certain that this, on its own, does not explain the interaction described.⁴ Tienilic acid (ticrynafen), which is structurally related to etacrynic acid, reduces the metabolism of *S*-warfarin (but not *R*-warfarin) thereby prolonging its stay in the body and increasing its effects.⁸ It is possible that etacrynic acid interacts via a similar mechanism.

Importance and management

The documentation relating to diuretics in general (other than tienilic acid) is limited and seems to be confined to the reports cited here, most of which are single-dose pharmacological studies. The evidence suggests that these diuretics either do not interact at all with the coumarin anticoagulants, or only to an extent which is of little clinical relevance. This seems to be supported by the lack of case reports of problems with these combinations, and is in general agreement with common experience. No special precautions normally seem to be necessary, except possibly with etacrynic acid where it might be prudent to monitor the outcome particularly in those with hypoalbuminaemia or renal impairment.

The interaction between the coumarins and tienilic acid is established and of clinical importance, but the incidence is uncertain. Concurrent use should be avoided. If that is not possible, prothrombin times should be closely monitored and the anticoagulant dosage reduced as necessary. Tienilic acid has been withdrawn in many countries because of its hepatotoxicity.

Coumarins + Dofetilide

Dofetilide did not alter the anticoagulant effect of warfarin in one study.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 14 healthy subjects dofetilide 750 micrograms twice daily for 8 days had no effect on the prothrombin time in response to a single 40-mg dose of **warfarin** given on day 5.¹ No dose adjustment of **warfarin** would be anticipated to be needed on concurrent use.

- Nichols DJ, Dalrymple I, Newgreen MW, Kleinermans D. The effect of dofetilide on pharmacodynamics of warfarin and pharmacokinetics of digoxin. *Eur Heart J* (1999) 20 (Abstr Suppl), 586.

Coumarins + Etanercept

Etanercept did not alter the pharmacodynamics or pharmacokinetics of a single dose of warfarin.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, subcutaneous etanercept 25 mg twice weekly for 7 doses did not alter the pharmacodynamics (INR) of a single dose of **warfarin** given with the last dose of etanercept. In addition, there was no change in the AUC of *R*- and *S*-warfarin.¹

This study suggests that no **warfarin** dose adjustments would be expected to be needed if etanercept is used in patients taking **warfarin**.

Coumarins + Ethchlorvynol

The anticoagulant effects of dicoumarol and warfarin are reduced by ethchlorvynol.

Clinical evidence

Six patients who had recently started taking **dicoumarol** had a rise in their Quick index from 38 to 55% (suggesting a reduction in anticoagulant effect) while taking ethchlorvynol 1 g daily over an 18-day period. Another patient stabilised on **dicoumarol** became over-anticoagulated and devel-

oped haematuria on two occasions when ethchlorvynol was withdrawn for periods of 6 days and 4 days.¹ A marked reduction in the anticoagulant effects of **warfarin** occurred in another patient given ethchlorvynol.²

Mechanism

Uncertain. The idea that ethchlorvynol increases the metabolism of the anticoagulants by the liver has not been confirmed by studies in *dogs* and *rats*.³

Importance and management

Information is very sparse and limited to dicoumarol and warfarin, but the interaction seems to be established. Be alert for other coumarins to behave similarly. Anticipate the need to alter the anticoagulant dosage if ethchlorvynol is started or stopped. The benzodiazepines may be a useful non-interacting alternative to ethchlorvynol, see 'Coumarins + Benzodiazepines and related drugs', p.391.

Coumarins and related drugs + Ezetimibe

No clinically significant interaction occurred between ezetimibe and warfarin in one study. However, raised INRs have been seen in patients taking warfarin after they were also given ezetimibe.

Clinical evidence, mechanism, importance and management

In a two-way, crossover study, 12 healthy subjects were given ezetimibe 10 mg or placebo daily for 11 days, with a single 25-mg dose of **warfarin** on day 7. The pharmacokinetics and pharmacodynamics (prothrombin time) of **warfarin** were not significantly altered by ezetimibe. In addition, the pharmacokinetics of ezetimibe were similar to those previously seen with the drug alone.¹ However, the manufacturers of ezetimibe state that raised INRs have been seen in patients taking **warfarin** after they were also given ezetimibe. They therefore advise that the INR should be monitored if ezetimibe is given with any coumarin or **fluidione**,² (this is probably a prudent precaution for any **indanedione**).

Coumarins + Felbamate

An isolated case report describes a marked increase in the effects of warfarin, which were attributed to felbamate.

Clinical evidence, mechanism, importance and management

A 62-year-old man with a seizure disorder who was receiving **warfarin** had his antiepileptic treatment with carbamazepine, phenobarbital and sodium valproate discontinued and replaced by felbamate 2.4 g daily and later 3.2 g daily. Within 14 days his INR had risen from a normal range of 2.5 to 3.5 up to 7.8. After stopping and later restarting the **warfarin** his INR rose within about another 14 days to 18.2. He was eventually stabilised on about half his former **warfarin** dosage. The authors of the report suggest that the withdrawal of the carbamazepine and phenobarbital was an unlikely reason for this reaction because no increases in **warfarin** dosage had been needed when they were started.¹ Suspicion therefore falls on the enzyme-inducing antiepileptics did not have some part to play. A letter commenting on this report favours the idea that what occurred was in fact due to the withdrawal of the 'carbamazepine', (p.395) and 'phenobarbital', (p.390).²

The general importance of this interaction (if such it is) is uncertain, and this appears to be the only case. Bear it in mind in the event of an unexpected response to **warfarin**.

Coumarins and related drugs + Fibrates

Clofibrate increases the effects of coumarin and indanedione anticoagulants. This has been fatal in some cases. Other fibrates appear to interact similarly, although data in many cases is limited to case reports.

Clinical evidence

(a) Bezafibrate

In a study in patients with hyperlipidaemia and stabilised on **phenprocoumon**, it was necessary to reduce the anticoagulant dosage by about 20% when bezafibrate 450 mg daily was given for 4 weeks to 10 patients, and by 33% when bezafibrate 600 mg daily was given to 5 patients.¹ In another study in 22 patients taking bezafibrate 400 mg daily the dosage of **acenocoumarol** had to be reduced by 20% to maintain a constant INR.²

A patient (with hypoalbuminaemia due to nephrotic syndrome and chronic renal failure) stabilised on **acenocoumarol** developed severe haematemesis with an INR of 25.9, two weeks after starting to take bezafibrate 800 mg daily.³ A woman stabilised on **warfarin** and bezafibrate 400 mg daily had an increase in her INR to 5.29 after being given an incorrect double dose of bezafibrate for a few days, and a man had a reduced response to **warfarin** (INR 1.5) when he stopped taking bezafibrate for a week.⁴

(b) Ciprofibrate

In a randomised, placebo-controlled, crossover study, 12 young healthy men were given a single 25-mg dose of **warfarin** on day 21 of a 26-day course of ciprofibrate 100 mg daily. The ciprofibrate increased the anticoagulant response to warfarin by 50% and caused a 28% decrease in the apparent intrinsic clearance of *S*-warfarin, which is the more active enantiomer.⁵

(c) Clofibrate

1. **Coumarins.** In a study including 11 patients stabilised on **warfarin**, clofibrate/androsterone (*Atromid*), given for 5 to 7 months, reduced the weekly **warfarin** dose requirement in all patients by a mean of 32%, with variability between patients.^{6,7} This interaction has been confirmed in a number of other similar studies in patients stabilised on **warfarin** and given clofibrate,^{8,9} or clofibrate with androsterone,¹⁰ with only 2 of 10 patients affected in one study⁸ but all 13 patients affected in another study.¹⁰ One fatal case of haemorrhage has been reported in a man stabilised on **warfarin** who was given clofibrate 500 mg four times daily for a week.¹¹ The interaction has been studied in 4 healthy subjects given the enantiomers of **warfarin** separately. In this study, clofibrate increased the effect of *S*-warfarin without altering its clearance, whereas there was no alteration of the effect of *R*-warfarin and an increase in clearance.¹² In another study in 10 healthy subjects, clofibrate 500 mg four times daily for 18 days increased the anticoagulant effect of a single dose of **dicoumarol** given on day 14 without altering the half-life or plasma **dicoumarol** levels.¹³

2. **Indanediones.** Ten out of 15 patients stabilised on **phenindione** needed a 33% reduction in **phenindione** dose and 5 of them bled (haematuria or haematoma) when they were given clofibrate, or clofibrate with androsterone (*Atromid*).⁷ In another series, of 13 patients stabilised on **phenindione** and given clofibrate/androsterone (*Atromid*) there were 5 cases of haemorrhagic episodes, two of which were not associated with a prolonged prothrombin time, and one of which was fatal.^{14,15} In yet another study, clofibrate/androsterone appeared to be less effective in reducing serum cholesterol in the patients taking **phenindione** than in 12 other patients taking clofibrate alone.¹⁶

(d) Fenofibrate

In an early clinical study of fenofibrate, 2 patients stabilised on **acenocoumarol** needed a 30% reduction in their dosage to maintain the same prothrombin time when they were given long-term fenofibrate 200 mg in the morning and 100 mg in the evening.¹⁷ In other similar studies, reductions

in the dose of unnamed **coumarins** of 12% (range 0 to 21%)¹⁸ or about one-third¹⁹ were needed when fenofibrate was given. One patient developed haematuria.²⁰

A number of case reports of this interaction have subsequently been published, as follows:

- A patient taking **warfarin** had a rise in his INR to 8.5 (from a previous range of 2 to 2.5) within a week of starting to take fenofibrate 200 mg daily. His INR later restabilised when the **warfarin** dosage was reduced by 27%.
- A patient taking **warfarin** had a marked INR rise from a range of 2.8 to 3.5 up to 5.6 within 10 days of starting to take fenofibrate (dosage not stated).²¹
- A patient taking **warfarin** bled, and was found to have an INR of 18 when his gemfibrozil was replaced by fenofibrate.²²
- In 2 cases 30 to 40% reductions in the **warfarin** dose were required when fenofibrate was given.²³

(e) Gemfibrozil

In a randomised, placebo-controlled, crossover study, gemfibrozil 600 mg twice daily for 8 days did not alter the anticoagulant effect of a single dose of **warfarin** given on day 3. In addition, gemfibrozil unexpectedly slightly decreased the AUC of both *R*- and *S*-warfarin (by 6% and 11%, respectively).²⁴ In contrast, a brief report describes bleeding ('menstrual cycle prolonged and lots of blood clots') and much higher prothrombin times (values not given) two weeks after a woman stabilised on **warfarin** started to take gemfibrozil 1.2 g daily in divided doses. Halving the **warfarin** dosage resolved the problem.²⁵ Another patient stabilised on **warfarin** developed severe hypoprothrombinaemia (INR 43) and bleeding (melaena, bruising) 4 weeks after starting to take gemfibrozil 1.2 g daily.²⁶

Mechanism

Uncertain. Clofibrate can displace warfarin from its plasma protein binding sites,^{5,27-29} but this does not adequately explain the interaction. Another suggestion is that the fibrates have an additive pharmacodynamic effect.^{1,12} Altered metabolism may also account for the interaction with ciprofibrate, since this decreased the clearance of *S*-warfarin.⁵ However, this did not occur with clofibrate^{12,13} or gemfibrozil.²⁴

Importance and management

The interactions of clofibrate with dicoumarol, warfarin and phenindione are established, clinically important and potentially serious. Severe bleeding (fatal in some instances) has been seen. The incidence of the interaction is reported to be between 20 and 100%, but it would be prudent to assume that all patients will be affected. Dosage reductions of one-third to one-half may be needed to avoid the risk of bleeding. Monitor the INR and adjust the dose accordingly. Information about other coumarins and indanediones is lacking but it would be prudent to assume that they will interact with clofibrate in a similar way.

Information about other fibrates is much less conclusive, and limited to case reports in many instances. Nevertheless, overall the evidence suggests that it would be prudent to monitor the INR in any patient taking a coumarin or indanedione with a fibrate.

Coumarins + Flupirtine

In one study, flupirtine did not interact with phenprocoumon.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects had no significant changes in their plasma levels of phenprocoumon 1.5 mg daily when they were given flupirtine 100 mg three times daily for 14 days. The prothrombin times were also not significantly changed.¹ There would therefore seem to be no reason for taking special precautions if these drugs are given concurrently.

Coumarins + Fondaparinux

Warfarin did not alter the pharmacokinetics of fondaparinux, and fondaparinux did not alter the effect of warfarin on prothrombin time.

Clinical evidence, mechanism, importance and management

Subcutaneous fondaparinux 4 mg was given daily for 5 days to 12 healthy subjects, with warfarin 15 mg given on day 4 and 10 mg on day 5 in a placebo controlled study. Warfarin had no effect on fondaparinux pharmacokinetics. In addition, the effect of warfarin on prothrombin time was not altered by fondaparinux. The authors concluded that the prothrombin time (INR) can still be used to monitor the effect of oral anticoagulants during the switch from fondaparinux to oral anticoagulants.¹

Coumarins + Food

The rate of absorption of dicoumarol can be increased by food. Two reports describe antagonism of the effects of warfarin by ice cream, and another report attributes an increase in prothrombin time to the use of aspartame. However, the most common food-warfarin interaction is that due to foods containing vitamin K.

Clinical evidence

(a) Dicoumarol

A study in 10 healthy subjects showed that the peak serum concentrations of a single 250-mg dose of dicoumarol, were increased on average by 85%

by food. Two subjects showed increases of 242% and 206%, respectively.¹

(b) Warfarin

A very brief report states that a patient taking warfarin had a raised prothrombin time, possibly due to the use of aspartame.²

A woman taking warfarin 22.5 mg daily did not have the expected prolongation of her prothrombin times. It was then discovered that she took the warfarin in the evening and she always ate ice cream before going to bed. When the warfarin was taken in the mornings, the prothrombin times increased.³ Another patient's warfarin requirements almost doubled when she started to eat very large quantities of ice cream (1 litre each evening). The effect was not seen when she ate normal amounts of ice cream. She took the warfarin at 6 pm and the ice cream at about 10 pm.⁴

Mechanism

Not understood. One suggestion for the interaction between food and dicoumarol¹ is that food may cause prolonged retention of dicoumarol in the upper part of the gut, leading to increased tablet dissolution and increased absorption.

Importance and management

None of these interactions is very well documented, and their clinical relevance is unclear. Note that vitamin K in food commonly interacts with warfarin, and these interactions are discussed in 'Coumarins and related drugs + Foods; Vitamin K₁-rich', p.409. See also 'cranberry juice', (p.398), 'enteral and parenteral nutrition', (below), 'grapefruit juice', (p.411), 'mango', (p.408) and 'soya bean products', (p.408).

Coumarins and related drugs + Foods; Enteral and parenteral nutrition

A number of early case reports described warfarin resistance in patients taking enteral feeds that contained high levels of added vitamin K₁. These products were then reformulated to contain lower amounts of vitamin K₁, commonly now about 4 to 10 micrograms per 100 mL; however, some cases of interactions have still been reported, and one study in children reported that those receiving enteral nutrition (mostly vitamin K enriched formula) required 2.4-fold higher maintenance warfarin doses. Lipid emulsions containing soya oil might contain sufficient natural vitamin K₁ to alter warfarin requirements. Parenteral multivitamin preparations may also contain vitamin K₁.

Clinical evidence

A. Enteral feeds

Case reports from the early 1980s described patients stabilised on warfarin who had reversal of the anticoagulant effect when they started taking the liquid dietary supplements *Ensure*,^{1,2} or *Osmolite*.³ Other patients who were resistant to warfarin were found to be taking *Ensure*⁴ or *Ensure Plus*.^{5,6} At this time, these products contained high levels of vitamin K₁ (240 to 380 micrograms per 240 or 250 mL, an amount equivalent to approximately 1 mg of vitamin K₁ for every 1000 calories). Two of the patients were successfully anticoagulated with warfarin when their enteral nutrition was switched to *Compleat B* (vitamin K₁ 16.6 micrograms/250 mL)⁶ or *Meritene* (trace of vitamin K₁).⁴

In response to these reports, *Ensure*, *Ensure-Plus*, and *Osmolite* were reformulated to reduce the vitamin K₁ content to 50 micrograms in 240 mL (140 micrograms per 1000 calories).⁴ However, further case reports for *Ensure Plus*⁷ and *Osmolite*⁸ suggested that this lower level of vitamin K may still be sufficient to cause an interaction. The vitamin K₁ content of these products was reduced further to 36 to 37 micrograms per 1000 calories,⁹ but even then one further case of increased warfarin requirement was reported with *Ensure*.¹⁰ In another case, a patient taking

Osmolite and intermittent **Ensure Plus** (total mean vitamin K₁ dose 81 micrograms daily) only achieved satisfactory anticoagulation with **warfarin** when the **Osmolite** was stopped, which reduced the vitamin K₁ intake to 36 micrograms daily.¹¹ Another patient given **Osmolite** (vitamin K₁ 68.4 micrograms daily), only achieved satisfactory anticoagulation with **warfarin** when the dose was given separately from the **Osmolite**.¹²

In another case, **Isocal** 3550 mL daily (equivalent to 460 micrograms of vitamin K₁) caused an increase in **warfarin** requirement from 8 mg daily to 13 mg daily.¹³ A further patient had a decrease in anticoagulant response requiring an increase in **warfarin** dose when she started a weight-reducing diet consisting solely of **Nutrilite 330** (vitamin K content unknown).¹⁴

Another patient required twice the dose of **acenocoumarol** during a period of enteral feeding (vitamin K₁ 200 micrograms daily).¹⁵

In a prospective cohort study in 319 children, the use of enteral nutrition (mostly **vitamin K supplemented formula**, and some **vitamin K supplemented tube feeds**) was associated with a higher dose of **warfarin** to achieve a target INR (0.28 versus 0.16 mg/kg) and similarly a higher dose of **warfarin** was needed to maintain the INR (0.26 versus 0.11 mg/kg).¹⁶

B. Parenteral nutrition

(a) Intravenous lipids

Warfarin resistance was seen in a patient who was given a constant intravenous infusion of **soya oil emulsion (Intralipid)**. In this case intravenous **warfarin** up to 15 mg daily only slightly prolonged the prothrombin time.¹⁷ In another patient, an emulsified infusion of **propofol** containing 10% **soya oil** antagonised the effect of **warfarin**; anticoagulation was not achieved until the **propofol** was discontinued despite an increase in the **warfarin** dose to 30 mg daily. The dose of propofol given was estimated to provide about 154 to 231 micrograms of vitamin K₁ daily. The same effect was later seen when the patient was given parenteral nutrition supplemented with 20% **Liposyn II**, which also contains **soya oil**, and was estimated to provide 53 micrograms vitamin K₁ daily.¹⁸

(b) Multivitamins

The FDA in the US now require that multivitamin products for inclusion in total parenteral nutrition contain 150 micrograms of vitamin K₁. The aim of this is to provide a daily physiological amount of the vitamin, rather than the previous practice of giving a large single weekly dose. Previously, patients taking anticoagulants were not given this single large weekly dose, therefore it is anticipated that with the new multivitamin preparation, **warfarin** doses for anticoagulation may be higher than previously needed. What effect this level of vitamin K₁ will have on the fixed dose **warfarin** used for prophylaxis of catheter-associated thrombosis is not known.¹⁹

In the UK, **Vitlipid N** contains vitamin K₁ (phytonadione) 15 micrograms/mL for adults and 20 micrograms/mL for children under 11 years.

Mechanism

The coumarin and **indanedione** anticoagulants are vitamin K antagonists, and consequently giving 'vitamin K₁', (p.458) reduces their effects. The dose at which this might become clinically important is not firmly established, but in one controlled study 150 micrograms of vitamin K₁ daily produced a clinically relevant effect in 25% of subjects (see 'Dietary supplements; Vitamin K₁-containing, (p.401)'). There is also some evidence that a physicochemical interaction (possibly binding to protein) may occur between warfarin and enteral foods in the gut.^{12,20}

Lipid emulsions given as part of parenteral nutrition often contain soya oil, which has a moderate level of vitamin K (see 'Table 12.3', (below)). These preparations may also have direct coagulation effects.¹⁸ Parenteral nutrition may also be supplemented with vitamin K.

Importance and management

Established interactions of clinical importance. Be aware that enteral feeds might contain sufficient vitamin K to alter coagulation status, so starting or stopping these feeds might affect dose requirements of vitamin K antagonists such as warfarin. It is also possible that there is a local interaction in the gut, as in one case separating the administration of the warfarin and an enteral feed by 3 hours or more was effective.¹² Patients should be advised not to add or substitute dietary supplements such as **Ensure** without increased monitoring of their coagulation status.

Table 12.3 Foods with a moderate to high content of Vitamin K₁ (phytonadione)

Foods	Vitamin K ₁ content (micrograms/100 g)
Vegetables	
Asparagus	51 to 80
Beet greens	484
Broccoli	101 to 156
Brussels sprouts	122 to 289
Cabbage	50 to 98
Collards (non-heading cabbage)	440 to 623
Endive	231
Kale	817 to 882
Lettuce (iceberg to green leaf)	24 to 174
Parsley (fresh or dried)	360 to 1640
Spinach	270 to 575
Spring onions	207
Turnip greens	367 to 519
Fats and oils	
Soya oil	25 to 145
Rapeseed oil	112 to 150
Olive oil	30 to 60
Margarines	40 to 110
Fruit and nuts	
Avocado	14 to 20
Cashew nuts	19 to 64
Kiwi fruit	25 to 40
Pine nuts	33 to 74
Prunes, dried	1.4 to 68

Fat emulsions used for parenteral use containing soya oil may themselves contain sufficient vitamin K₁ for daily needs. Parenteral multivitamin preparations may also contain important levels of vitamin K₁. It would be advisable to keep the vitamin K₁ intake constant in any patient requiring long-term supplemental or total parenteral nutrition and warfarin. If the amount of lipid and/or multivitamins is altered, anticipate a

change in warfarin requirement.

Although there is only a single case, bear in mind that propofol may interact because it is formulated with soya oil, which contains vitamin K₁.

Coumarins + Foods; Mango fruit (*Mangifera indica*)

A daily intake of 1 to 6 mangoes was considered the reason for a moderate increase in the anticoagulant effects of warfarin in one report. None of the patients in whom this interaction was seen showed any evidence of bleeding.

Clinical evidence, mechanism, importance and management

In 13 patients taking **warfarin**, eating mango fruit (*Mangifera indica*) appeared to increase their INRs by an average of 38% (from 2.79 to 3.85), but no bleeding occurred. No other explanation for the increased INRs could be identified. The patients were reported to have eaten 1 to 6 mangoes daily for 2 days to 1 month before attending the anticoagulant clinic. When mango was identified as a possible cause for their increased INRs, the patients were told to stop eating mango, whereupon their mean INR fell within 2 weeks, by almost 18%. When 2 of the patients whose mean INRs had originally risen by 13% were later rechallenged with mango (rather less than before), their mean INR rose by 9%.¹

The reason for this apparent interaction is not known but the authors of the report speculate about the possible role of vitamin A (reported to be 8061 units in an average sized mango of 130 g, without seed). In practical terms this increase in INR would not seem to represent a serious problem, although note that one patient's INR rose to 5.1 (a 54% increase).

There appear to be no other reports in the literature of an interaction between mango and **warfarin**, nor of interactions between mango and any other oral anticoagulant. More study of this interaction is needed, but at the present time there is insufficient reason to suggest that patients taking **warfarin** should avoid mango fruit.

- Monterrey-Rodríguez J, Feliú JF, Rivera-Miranda GC. Interaction between warfarin and mango fruit. *Ann Pharmacother* (2002) 36, 940–1.

Coumarins + Foods; Soya bean products

Natto, a Japanese food made from fermented soya bean, can markedly reduce the effects of warfarin and acenocoumarol, because of the high levels of vitamin K₂ substance produced in the fermentation process. In one study, soya bean protein also modestly reduced the effects of warfarin, and a similar case has been reported with soy milk.

Clinical evidence

(a) Fermented soya bean products (natto)

In a controlled study in 12 healthy subjects stabilised on **acenocoumarol**, a single meal containing 100 g of natto decreased the mean INR from 2.1 to 1.5 after 24 hours, and the INR had still not returned to the original level after 7 days (INR 1.75 one week later). The effect was considered clinically important in 6 of the 12 subjects.¹ Similarly, in an earlier retrospective study of 10 patients taking **warfarin**, eating natto caused the thrombotest values to rise from a range of 12 to 29% up to a range of 33 to 100%. The extent of the rise appeared to be related to the amount of natto eaten. The thrombotest values fell again when the natto was stopped. A healthy subject taking **warfarin**, with a thrombotest value of 40%, ate 100 g of natto. Five hours later the thrombotest value was unchanged, but 24 hours later it was 86%, and after 48 hours it was 90% (suggesting that the anticoagulant effect was decreased).²

(b) Soya milk

In a 70-year-old man stabilised on **warfarin** 3 mg daily, consumption of soya milk 480 mL daily (240 mL of both *Sun Soy* and 8th *Continent* mixed together) decreased the INR from 2.5 to 1.6 after about 4 weeks.³ One week after stopping the soya milk, his INR was 1.9, and 4 weeks after it was 2.5.

(c) Soya oil

Soya oil is an important source of dietary vitamin K, see 'Table 12.3', (p.407). For two cases of 'warfarin resistance' with intravenous soya oil emulsions, see 'Coumarins and related drugs + Foods; Enteral and parenteral nutrition', p.406.

(d) Soya protein

In a study in 10 patients with hypercholesterolaemia who were stabilised on **warfarin**, substitution of all animal protein for textured **soya protein** for 4 weeks caused a marked reduction (Quick value approximately doubled) in the anticoagulant effects of warfarin by the second week.⁴

Mechanism

Soya beans are a moderate source of vitamin K₁ (19 micrograms per 100 g),⁵ and soya oil and products derived from it are an important dietary source of vitamin K (see 'Table 12.3', (p.407)). However, the soy milk brand taken in the case report did not contain vitamin K,³ and another reference source lists soya milk as containing just 7.5 micrograms vitamin K per 250 mL,⁵ which would not be expected to cause an interaction. Why this product decreased the effect of warfarin is therefore open to speculation. The vitamin K content of textured soya protein is unknown. Note that **soy sauce** made from soy and wheat is reported to contain no vitamin K, and soft **tofu** made from the curds by coagulating soy milk contains only low levels (2 micrograms per 100 g).⁵

In contrast, *fermented* soya bean products such as natto contain very high levels of a particular vitamin K₂ substance (MK-7)⁶, because of the fermentation process with *Bacillus natto*. In addition, the bacteria might continue to act in the gut to increase the synthesis and subsequent absorption of vitamin K₂.² Although the role of vitamin K₂ in anticoagulation is less well established than vitamin K₁, it appears that this also opposes the actions of coumarins and indanediones, which are vitamin K antagonists.

Importance and management

The interaction with fermented soya bean products is established, marked, and is likely to be clinically relevant in all patients. Patients taking coumarin and probably **indanedione** anticoagulants should probably be advised to avoid natto, unless they want to consume a regular constant amount.

Although information is limited, it appears that soya protein might also modestly reduce the effect of warfarin. In particular, complete substitution

of animal protein for soya protein appears to reduce the effect of warfarin. A single report suggests that soy milk may also interact. 'Soya oil', (p.406) has been reported to interact in a couple of cases. On the basis of known vitamin K-content, **whole soya beans** could potentially reduce the effect of warfarin, whereas **soy sauce** should not.⁵

Coumarins and related drugs + Foods; Vitamin K₁-rich

Unintentional and unwanted antagonism of warfarin has occurred in patients who ate exceptionally large amounts of some green vegetables, which can contain significant amounts of vitamin K₁. Isolated cases have also been reported with avocado, green tea, liver, and seaweed sushi. Patients should be advised to maintain a constant dietary intake of vitamin K₁. Foods containing significant amounts of vitamin K₂ substances such as fermented soya beans might also interact.

Clinical evidence and mechanism

The coumarin and indanedione oral anticoagulants are vitamin K antagonists, which inhibit the enzyme vitamin K epoxide reductase so reducing the synthesis of vitamin K-dependent blood clotting factors by the liver. If the intake of dietary vitamin K₁ increases, the synthesis of the blood clotting factors begins to return to normal. As a result the prothrombin time also begins to fall to its normal value. Naturally occurring vitamin K₁ (phytomenadione) is found only in plants.

A. Individual foods

(a) Avocado

Two women taking **warfarin** had a reduction in their INRs (from 2.5 to 1.7 and from 2.7 to 1.6, respectively) when they started to eat avocado 100 g daily, or 200 g of avocado on two consecutive days. Their INRs climbed again when the avocado was stopped.¹ Avocado contains a small to moderate amount of vitamin K₁, see 'Table 12.3', (p.407), so might occasionally reduce the efficacy of **warfarin** if eaten in these quantities.

(b) Green tea

A patient taking **warfarin** had a reduction in his INR from a range of 3.2 to 3.79 down to 1.37, which was attributed to the ingestion of very large quantities of green tea (about 2 to 4 litres each day for a week). This interaction was attributed to the vitamin-K content of the tea.² However, although dried tea, including green tea, is very high in vitamin-K₁, the brewed liquid made from the tea contains negligible amounts of vitamin K₁,^{1,3} and is therefore not considered to contribute any vitamin K₁ to the diet.³ The reason for this interaction is therefore unclear, unless the patient was eating some of the brewed tea leaves. A pharmacokinetic interaction also appears unlikely, because, although black tea inhibited CYP2C9 *in vitro*, brewed tea had no effect on the CYP2C9 substrate flurbiprofen in healthy subjects.⁴ For discussion of a case where a patient had an increase in INR after stopping taking a herbal preparation of which green tea leaves were one of 25 ingredients, see 'Coumarins + Herbal medicines; Vitamin K₁-rich', p.418.

(c) Green vegetables

In a formal study in patients stabilised on **warfarin**, one day of a high intake of vitamin K₁-rich vegetables (**brussels sprouts** 400 g, **broccoli** 400 g, **lettuce** 750 g, or **spinach** 300 g, estimated to contain 1 mg of vitamin K₁ daily) decreased anticoagulant effects: the thrombotest values rose above the normal range of 10 to 25% in 2 of 5 patients in 2 to 3 days. Two days of a high intake of the same vegetable caused values above the therapeutic range in 3 of 7 patients, and 7 days intake did the same in 9 of

13 patients.⁵ In another similar study, intake of **spinach** 250 g or **broccoli** 250 g daily for 7 days increased the mean thrombotest values to above the therapeutic limit of 15%, and the effect was similar to that of a supplement containing phytomenadione 250 micrograms daily. A reduction in the anticoagulant effect of **warfarin** was also seen in one healthy subject given about 450 g **spinach** daily.^{6,7} In a pharmacokinetic study in healthy subjects, a daily intake of 400 g of **brussels sprouts** for 2 weeks slightly decreased the AUC of **warfarin** by 16% and increased its metabolic clearance by 27%.⁸ This is probably because **brussels sprouts** induce the cytochrome P450 isoenzyme CYP1A2, which has a role in the 'metabolism of warfarin', (p.358).

A few cases of this interaction (often described as warfarin resistance) have been reported in patients taking **dicoumarol**,⁹ or **warfarin**^{10–13} when consuming diets containing large amounts of green vegetables (about 300 to 700 g daily),^{11,12} such as **spinach**,^{9,14} **broccoli**,^{11,12} or a weight-loss diet consisting of **lettuce**, **turnip greens**, and **broccoli**.¹³ The dietary vitamin K was estimated to be 1277 micrograms daily in one case,¹⁰ and 6000 micrograms daily in another.¹³ In two cases, patients suffered a serious thromboembolic event.^{12,13} For discussion of a case where a patient had an increase in INR after stopping a herbal preparation, of which **spinach**, **broccoli** and **cabbage** were 3 of 25 ingredients, see 'Coumarins + Herbal medicines; Vitamin K₁-rich', p.418.

Conversely, a single intake of **spinach** 250 g or **broccoli** 250 g had no effect on thrombotest values over 7 days.¹⁴ Similarly, in another study in healthy subjects stabilised on **acenocoumarol**, a single meal containing either **spinach** 400 g or **broccoli** 400 g with corn oil caused just 0.27 and 0.41 reductions in mean INR, an effect that was not considered clinically relevant. These reductions were equivalent to that seen with about 200 micrograms of vitamin K₁.¹⁵

(d) Liver

A patient taking **acenocoumarol** had a soft tissue bleed, and was found to have a very low thrombotest value of about 3%. She had always consumed about 142 g daily of green vegetables, but about 4 months previously had been advised to stop eating liver (750 g weekly) as part of a low-fat diet.¹⁶ In another case, a man taking **warfarin** 5 mg daily had diffuse bruising and an INR of 5.6 two weeks after he was advised to stop eating pork liver¹² (1 kg per week). He was eventually restabilised on just 1.5 mg of warfarin daily. Early studies showed that liver contained high levels of vitamin K, but more recent studies using more specific detection techniques have shown that liver generally contains very low levels of vitamin K₁ (4 and 7 micrograms in 100 g).¹⁷ However, liver may contain vitamin K₂ substances in sufficient levels to be of possible nutritional relevance.^{17,18} The precise role of vitamin K₂ substances in anticoagulation control is less clear, but 'Natto', (p.408), which is a rich source of these, clearly reduces the effects of coumarins.

(e) Seaweed and Japanese food

A patient taking **warfarin** had, on two occasions, reduced INRs of 1.6 and 1.8 (usual range 2 to 3) within 24 hours of eating sushi with **seaweed** (*asakusa-nori*). It was estimated that she had consumed only about 45 micrograms of **phytomenadione**, but because her vitamin K stores may have been low, this amount could have accounted for a large percentage of her vitamin K intake or stores.¹⁹ In an early report, a Japanese man recently stabilised on **warfarin** developed bleeding episodes on two occasions shortly after resuming his usual diet of Japanese food (specific foods not mentioned). However, ingestion of 3 similar Japanese meals in a 24-hour period had no effect on the prothrombin time in 6 Caucasian patients taking **warfarin**.²⁰

B. Overall dietary vitamin K intake

(a) Relationship between dietary vitamin K and INR with anticoagulants

There is evidence that the average dietary vitamin K₁ intake is correlated with the efficacy of **warfarin**. In one study, patients consuming a diet containing more than 250 micrograms daily of vitamin K₁ had a lower INR five days after starting **warfarin** than patients consuming less dietary vitamin K₁ (median INR 1.9 versus 3). Also, the high-vitamin K₁ group needed a higher maintenance **warfarin** dose (5.7 mg/day versus 3.5 mg/day).²¹ In another study, multiple regression analysis indicated that, in patients taking warfarin, the INR was altered by 1, by a weekly change in the intake of vitamin K of 714 micrograms.²² Similarly, for each increase in daily dietary vitamin K₁ intake of 100 micrograms, the INR decreased by just 0.2 in another study.²³

In a randomised, crossover study in patients taking **warfarin** or **phenprocoumon**, increasing the dietary intake of vitamin K₁ by 500% relative to the baseline value (from 118 to 591 micrograms daily) for 4 days only modestly decreased the INR from 3.1 to 2.8 on day 4. Decreasing the dietary intake of vitamin K₁ by 80% (from 118 to 26 micrograms daily) for 4 days increased the INR from just 2.6 to 3.3 on day 7.²⁴

(b) *Stability of anticoagulant control and dietary vitamin K*

There is some evidence that patients with a very low dietary vitamin K₁ intake are more sensitive to alterations in vitamin K₁ intake, and have less stable anticoagulant control. For example, in one study, patients with unstable control of anticoagulation were found to have a much lower dietary intake of vitamin K₁, when compared with another group of patients with stable anticoagulant control (29 micrograms daily versus 76 micrograms daily).²⁵ In another study in 10 patients with poorly controlled anticoagulation taking **acenocoumarol**, and receiving a diet with a low, controlled vitamin K₁ content of 20 to 40 micrograms daily increased the percentage of INR values within the therapeutic range, when compared with a control group of 10 patients not subjected to any dietary restrictions.²⁶

Importance and management

A very well established, well documented and clinically important drug-food interaction, expected to occur with every coumarin or indanedione anticoagulant because they have a common mode of action. The evidence suggests that, in patients with normal vitamin K₁ status, in general, clinically relevant changes in coagulation status require large continued changes in intake of vitamin K₁ from foods. However, there is some evidence to suggest that patients with low dietary vitamin K₁ intake may be sensitive to smaller changes in dietary vitamin K₁. This suggests that patients taking anticoagulants should be advised to eat a normal balanced diet, maintaining a relatively consistent amount of vitamin-K₁ rich foods. They should be told to avoid making major changes to their diet, including starting a weight-loss diet, without increased monitoring of their INR. It is estimated that a normal Western diet contains 300 to 500 micrograms of vitamin K₁ daily. The minimum daily requirement is about 1 micrograms/kg and, in the US, an adequate intake has been determined to be 120 micrograms for adult men and 90 micrograms daily for adult women. 'Table 12.3', (p.407), gives the vitamin K₁ content of some vitamin-K₁ rich foods; however, it is important to note that these are not the bioavailable contents, which may be much lower for green vegetables, particularly if they are eaten in the absence of fat.^{18,27} Nevertheless, green leafy vegetables usually contribute 40 to 50% of the total intake, followed by certain vegetable oils and margarines made from these oils.²⁸ Also, processed foods can have moderate to high vitamin K₁ levels if they contain fats with high vitamin K₁ levels. Note that some foods that have a low vitamin K₁ content can contribute significantly to total intake because of how often they are eaten. Cooking and freezing do not alter the vitamin K₁ content, but vitamin K₁ in oils is degraded by exposure to light.²⁹ In the US, a chart has been devised to help patients and researchers determine the daily intake of vitamin K₁.³⁰

For the effect of multivitamins containing vitamin K₁, see 'Coumarins + Dietary supplements; Vitamin K₁-containing', p.401, and for the effect of supplements in enteral and parenteral feeds, see 'Coumarins and related drugs + Foods; Enteral and parenteral nutrition', p.406.

There is growing evidence that vitamin K₂ substances (menaquinones) may also be important, and in one analysis rich dietary sources of these included goose liver paste, hard and soft cheeses, egg yolk,¹⁸ and 'natto', (p.408), the effect of which is already established.

Coumarins + Glucagon

In one early analysis, the anticoagulant effects of warfarin were markedly increased by very large doses of glucagon (total dose exceeding 50 mg over 2 days), but not by doses of less than 30 mg over 1 to 2 days. Doses of glucagon this high are unlikely to be encountered in clinical use.

Clinical evidence

In an analysis of 24 patients taking **warfarin** who were given glucagon for inadequate cardiac contractility, no potentiation of the action of **warfarin** was noted in 11 patients given a total of less than 30 mg of glucagon over 1 to 2 days. However, 8 out of 9 patients had a marked increase in anticoagulant effects (prothrombin times of 30 to 50 seconds or more) when they were given higher doses of glucagon (62 to 362 mg over 3 to 8 days). Three of them bled. The interaction was not able to be assessed in 4 patients.¹

Mechanism

Unknown. Changes in the production of blood clotting factors and an increase in the affinity of warfarin for its site of action have been proposed.¹ A study in *guinea pigs* using acenocoumarol suggested that changes in warfarin metabolism or its absorption from the gut are *not* responsible.²

Importance and management

Direct information is limited to the report cited,¹ which relates to doses far in excess of those used clinically for hypoglycaemia (1 mg) or in the management of beta blocker overdose (2 to 10 mg then 50 micrograms/kg per hour). As such, its findings are probably of no general relevance. Its authors recommend that if glucagon 25 mg per day or more is given for two or more days, the dosage of warfarin should be reduced in anticipation of the interaction, and prothrombin times closely monitored.¹

Coumarins + Glutethimide

The anticoagulant effects of warfarin and ethyl biscoumacetate can be decreased by glutethimide.

Clinical evidence

Ten subjects stabilised on **warfarin**, with average prothrombin times of 18.8 seconds, had a mean reduction of 2.7 seconds in their prothrombin times after they took glutethimide 500 mg at bedtime for 4 weeks.^{1,2} Other studies have shown that up to 1 g of glutethimide daily for 1 to 3 weeks reduced the half-life of single-dose **warfarin** by between one-third to one-half.^{3,4} Conversely, an unexplained report describes a paradoxical increase in prothrombin times and severe bruising in a patient stabilised on **warfarin** who took 3.5 g of glutethimide over a 5-day period.⁵

Glutethimide 500 or 750 mg daily for 10 days has been shown to reduce the half-life of single-dose **ethyl biscoumacetate** by about one-third,^{6,7} whereas in contrast, an early study in 25 patients taking **ethyl biscoumacetate** found no evidence of an interaction.⁸

Mechanism

Glutethimide is a liver enzyme inducer, which increases the metabolism and clearance of the anticoagulants from the body, thereby reducing their effects.^{1-4,6,7} There is no obvious explanation for the reports finding no interaction or increased effects.

Importance and management

The interaction of glutethimide with warfarin is established, while the interaction with ethyl biscoumacetate is uncertain. Information about both interactions is limited and there seems to be nothing documented about any other anticoagulant. However, it would be prudent to monitor the effect of adding glutethimide to patients taking any coumarin anticoagulant, being alert for the need to increase the anticoagulant dosage. Other interactions due to enzyme induction can take several weeks to develop fully and persist after withdrawal, so good monitoring and dosage adjustment should continue until anticoagulant stability has been achieved. The benzodiazepines may be a useful non-interacting alternative, see 'Coumarins + Benzodiazepines and related drugs', p.391.

Coumarins + Grapefruit juice

Preliminary evidence from one study suggests that grapefruit juice might cause a modest rise in the INR of a few patients taking warfarin, and one case report describes a marked rise in INR, which was attributed to grapefruit juice. However, other studies have suggested that grapefruit juice does not interact with warfarin or acenocoumarol.

Clinical evidence

(a) Acenocoumarol

In the preliminary report of a single-dose, placebo-controlled study in 12 healthy subjects, 150 mL of grapefruit juice did not alter the maximum

INR of a 10-mg dose of acenocoumarol, and the AUCs of *S*- and *R*-acenocoumarol were not altered.^{1,2}

(b) Warfarin

In a study in 9 patients stabilised on warfarin, consumption of grapefruit juice 240 mL three times daily for one week had no effect on the INR or prothrombin times.³ Similarly, in the preliminary report of a two-way crossover study in 24 patients stabilised on warfarin, the frequency of the **warfarin** dosage adjustments needed by the group as a whole, when taking 250 mL grapefruit juice daily for 4 weeks was the same as when taking a placebo (orange juice). However, 4 individuals had a clinically significant, progressive and sustained 12 to 25% decrease in the warfarin dose to INR ratio when taking grapefruit juice, but not orange juice.⁴ A 64-year-old man stabilised on warfarin was found to have an INR of 6.29 on routine testing 10 days after starting to drink about 1.5 litres of grapefruit juice daily. However, when the author took warfarin to achieve an INR of 2 to 3 and then drank 1.5 litres of grapefruit juice daily there was no clinically relevant change in his INR.⁵

Mechanism

The patients who showed some evidence of an interaction between grapefruit juice and warfarin may possibly have had an increased susceptibility to the inhibitory effects of grapefruit juice on the activity of the cytochrome P450 isoenzyme CYP3A4 in the gut.⁴

Importance and management

Information is limited. One study with warfarin suggests that some patients might require a slight reduction in dose if they regularly consume grapefruit juice, but further study is needed. Current evidence suggests that routine testing should be sufficient to detect any interaction.

Coumarins + Griseofulvin

The anticoagulant effects of warfarin might be reduced by griseofulvin in some patients.

Clinical evidence

The anticoagulant effects of **warfarin** were modestly and markedly reduced, respectively, in 2 patients stabilised on **warfarin** when they were given griseofulvin 1 g daily in divided doses. Griseofulvin 1 g daily had no effect on the prothrombin time in one healthy subject given warfarin, whereas 2 g daily caused a marked reduction in the prothrombin time. Another healthy subject showed no interaction, even when the griseofulvin dosage was raised to 4 g daily for 2 weeks.¹

In another study there was no change in the mean prothrombin time in 10 patients stabilised on **warfarin** when they were given griseofulvin 1 g daily in divided doses for 2 weeks. Four of the patients had an equivocal average reduction in prothrombin time of 4.2 seconds.² One case report describes decreased anticoagulant effects in a man stabilised on **warfarin** when he took griseofulvin 250 mg twice daily, which took 12 weeks to develop fully.³ He eventually needed a 41% increase in his daily dose of **warfarin**. Another report very briefly mentions a case of a coagulation defect in a patient taking **warfarin** and griseofulvin.⁴

Mechanism

Not understood. It has been suggested that the griseofulvin acts as a liver enzyme inducer, which increases the metabolism of the warfarin, thereby reducing its effects.^{1,3}

Importance and management

This interaction is poorly documented and not well established. It possibly affects some patients. Because of the uncertainty, the prothrombin times

of all patients taking warfarin who are given griseofulvin should be monitored, and suitable warfarin dosage increases made as necessary.

Coumarins and related drugs + H₂-receptor antagonists

The anticoagulant effects of warfarin can be increased by cimetidine. The effect is generally minor to modest, although severe bleeding has been reported in a few cases. Acenocoumarol seems to interact similarly, but phenprocoumon appears not to be affected. In one patient the effects of phenindione were modestly increased by cimetidine. Famotidine, nizatidine, ranitidine and roxatidine normally do not appear to interact, although isolated cases of bleeding have been reported.

Clinical evidence

(a) Cimetidine

A brief report in 1978, published as a letter by the manufacturers of cimetidine, stated that preliminary details of a study in healthy subjects indicated that cimetidine 1 g daily could cause a prothrombin time rise of about 20% in patients stabilised on warfarin. At that time, they were aware of 17 cases worldwide, most of moderate rises in prothrombin times.¹

A number of studies^{2,3} and case reports^{4–8} have confirmed this interaction with warfarin. In the studies, plasma warfarin levels were reported to rise by 25% and 80%, and prothrombin times were increased by 18% and 20% by cimetidine 1.2 g daily. In the case reports, severe bleeding (haematuria, internal haemorrhages) and very prolonged prothrombin times have been seen in few patients given cimetidine 900 mg or 1.2 g daily.^{4,6–8} In one study, 7 out of 14 patients stabilised on warfarin had a greater than 30 second increase in their prothrombin time, whereas the other 7 had no prolongation or only a minor prolongation in their prothrombin time when they were given cimetidine 1.2 g daily for 10 days.⁹ In another study in 27 patients, although the AUC of warfarin was increased by 21 to 39% and its clearance fell by 22 to 28%, prothrombin times only increased by 2 to 2.6 seconds by cimetidine 800 mg or 1.2 g daily.¹⁰ A pharmacokinetic study in 6 healthy subjects found that cimetidine did not affect *S*-warfarin but increased the trough plasma levels of *R*-warfarin by 28%, with minimal effect on prothrombin times.¹¹ Other pharmacokinetic studies have confirmed that the interaction affects only *R*-warfarin.^{12–15} In one analysis of combined use of warfarin and H₂-receptor antagonists in inpatients, there was no difference in the intensity of prothrombin time monitoring, and no difference in bleeding rates between 35 patients receiving cimetidine, 38 patients receiving ranitidine, or 36 patients receiving famotidine. Two patients in the cimetidine group had a bleed after they had taken both drugs for one or two days but neither had abnormally high prothrombin times.¹⁶

In 3 studies, the AUC of single-dose acenocoumarol was increased by cimetidine, and the prothrombin time prolonged,^{17–19} with the effect greatest for *R*-acenocoumarol.¹⁹ However, another study found no interaction.²⁰ Data from one patient taking acenocoumarol and one taking phenindione showed that cimetidine increased their anticoagulant effects.² In one study in patients stabilised on phenprocoumon, cimetidine 400 mg twice daily did not alter the pharmacokinetics of phenprocoumon nor its anticoagulant effect.²¹

(b) Famotidine

In a study in 8 healthy subjects taking doses of warfarin titrated to prolong the prothrombin time by 2 to 5 seconds (mean dose 4 mg daily), treatment with famotidine 40 mg daily for 7 days did not affect prothrombin times, thrombotest coagulation times or steady-state plasma warfarin levels.²² No changes in prothrombin times were seen in 3 patients stabilised on acenocoumarol or fluidione when they were given famotidine.²³

However, in another report 2 patients taking warfarin are said to have had prolonged prothrombin times and bled when they took famotidine.²⁴

(c) Nizatidine

Nizatidine 300 mg daily for 2 weeks had no significant effect on the prothrombin times, kaolin-cephalin clotting times, the activity of factors II, VII, XI and X, or on steady-state serum warfarin levels in 7 healthy subjects taking warfarin.²⁵ A lack of a pharmacokinetic interaction was also reported in the preliminary results of another study.²⁶ An isolated case of gastrointestinal bleeding, associated with markedly prolonged prothrombin times, occurred after a 78-year-old took six doses of nizatidine 300 mg.²⁴

(d) Ranitidine

Ranitidine 200 mg twice daily for 2 weeks had no effect on warfarin concentrations or prothrombin times in 5 healthy subjects.²⁷ In another study in 11 healthy subjects, ranitidine 150 mg twice daily for 3 days had no effect on the pharmacodynamics or pharmacokinetics of a single dose of warfarin.³ The same finding was reported in another similar study.¹⁵ In contrast, in a fourth study in 5 subjects, ranitidine 150 mg twice daily for a week reduced the clearance of a single dose of warfarin by almost 30%, but the half-life was not significantly changed and prothrombin times were not measured.²⁸ Ranitidine 750 mg daily given to 2 subjects reduced the warfarin clearance by more than 50%.²⁸ In an isolated case, a patient stabilised on ranitidine 150 mg twice daily and warfarin vomited blood one week after her ranitidine dose was doubled to 300 mg twice daily. Her prothrombin time had risen from 17.6 to 36.7 seconds. She was subsequently restabilised on ranitidine 150 mg twice daily and the original dose of warfarin with a prothrombin time between 19 and 20 seconds.²⁹

In one study in 10 patients stabilised on phenprocoumon, ranitidine 150 mg twice daily for 14 days had no effect on anticoagulation or on phenprocoumon plasma levels.³⁰

(e) Roxatidine

Roxatidine 150 mg daily for 4 days had no effect on the steady-state pharmacokinetics of warfarin or the prothrombin ratio in 12 healthy subjects.³¹

Mechanism

Cimetidine binds with the cytochrome P450 isoenzymes and inhibits oxidative metabolism in the liver. Although cimetidine is considered to be a general inhibitor, it exhibits a degree of specificity for certain isoenzymes such as CYP1A2 and CYP2C19. These isoenzymes are principally involved in the metabolism of *R*-warfarin and not *S*-warfarin (see 'metabolism of the coumarins', (p.358), for more detail). Thus, the interaction between warfarin and cimetidine has been found to be stereoselective (i.e. cimetidine interacts with the *R*-isomer but not with the *S*-isomer).^{11–14} Because *R*-warfarin is the less active isomer, and the pharmacokinetic interaction is not marked, the interaction is generally modest.

Cimetidine also appears to interact with acenocoumarol, but not phenprocoumon. The other H₂-receptor antagonists normally do not act as enzyme inhibitors.

Importance and management

The interaction between warfarin and cimetidine is well documented, well established and potentially clinically important. Its effects are generally modest, but rarely, patients have shown a marked interaction. Because of this unpredictability, and to avoid bleeding, the response should be monitored well in every patient when cimetidine is first added, being alert for the need to reduce the warfarin dosage. The onset of the interaction appears rapid; effects have been seen within days,^{4,7} and even as early as 24 hours.⁹ The effect of low non-prescription doses of cimetidine on warfarin do not appear to have been studied. Acenocoumarol is reported to interact similarly, and there is one case of phenindione being affected. Expect other coumarins and indanediones to behave in the same way, with the possible exception of phenprocoumon, which was not affected in one study.

Famotidine, nizatidine, ranitidine and roxatidine normally appear not to interact with oral anticoagulants although note that, in rare cases, increases in prothrombin times and bleeding have been seen.

Coumarins + Heparin

Heparin may prolong the prothrombin time, therefore a sufficient time interval should be allowed after the last heparin dose in a patient taking a coumarin to obtain a valid prothrombin time.

Clinical evidence, mechanism, importance and management

Heparin may prolong the one-stage prothrombin time.¹ The US manufacturer notes that, if a valid prothrombin time is to be obtained in a patient starting warfarin or other coumarins, a period of at least 5 hours after the last intravenous heparin dose or 24 hours after the last subcutaneous dose should be left before measuring the prothrombin time.² Note that it is usual clinical practice to start heparin and a coumarin anticoagulant at the same time. Further, it is clear that the concurrent use of warfarin and heparin will have an at least additive anticoagulant effect.

- Lutowski DM, Djuric PE, Draeger RW. Warfarin therapy: the effect of heparin on prothrombin times. *Arch Intern Med* (1987) 147, 432–3.
- Heparin Sodium Injection. Pharmacia & Upjohn. US Prescribing information, December 2000.

Coumarins and related drugs + Heparinoids

Some of the normal tests of anticoagulation (prothrombin time, thrombotest) are unreliable for a few hours after giving intravenous danaparoid to patients taking coumarins.

Oral pentosan polysulfate sodium did not alter the pharmacokinetics or pharmacodynamics of warfarin in healthy subjects, but note that this heparinoid is associated with rectal bleeding.

An isolated case report describes bleeding in a patient taking acenocoumarol after a heparinoid-impregnated bandage was applied.

In general, the use of heparinoids with coumarins or indanediones would be expected to increase the risk of bleeding.

Clinical evidence, mechanism, importance and management

(a) Intravenous danaparoid

A study in 6 healthy subjects given acenocoumarol (steady-state thrombotest values of 10 to 15%), found that a single intravenous bolus injection of 3250 anti-Xa units of danaparoid prolonged the prothrombin time and thrombotest for up to 1 hour and 5 hours, respectively, which was more than would have been expected by the simple addition of the effects of both drugs. However, no significant differences were seen in bleeding time, and danaparoid did not alter acenocoumarol pharmacokinetics.¹ The authors concluded that when monitoring the anticoagulant effects of acenocoumarol, the prothrombin time and the thrombotest may therefore be unreliable for at least one hour and five hours, respectively, after intravenous danaparoid has been given. This advice would apply equally to other coumarins and other drugs monitored using these tests, such as the indanediones.

(b) Oral pentosan polysulfate sodium

In a placebo-controlled, crossover study in 24 healthy subjects stabilised on warfarin, pentosan polysulfate sodium 100 mg every 8 hours for 7 days did not alter the anticoagulant effect of warfarin or the pharmacokinetics of R- or S-warfarin.² The authors consider it appears that, unlike intravenous administration, oral pentosan polysulfate sodium has no anticoagulant activity. However, the manufacturer notes that rectal haemorrhage was reported as an adverse effect in 6.3% of patients receiving pentosan polysulfate sodium at a dose of 300 mg daily.³

On the basis of the pharmacological study, the authors considered that it seems unnecessary to make changes in the warfarin dose or the oral pentosan polysulfate sodium dose when the two drugs are used together. However, they do recommend careful monitoring on starting concurrent therapy.² Logic would suggest that, if bleeding occurs, this could be more severe in anticoagulated patients. The patient information provided by the manufacturer states that concurrent use of pentosan polysulfate and warfarin should be avoided until they have spoken with their doctor.³

(c) Topical heparinoid

A man who was well stabilised on acenocoumarol and also taking metoprolol, dipyridamole and isosorbide dinitrate began to bleed within about 3 days of starting to use a medicated bandage on an inflamed lesion on his hand, probably caused by a mosquito bite. His prothrombin percentage was found to have fallen to less than 10%. The bandage was impregnated with a semi-synthetic heparinoid compound based on xylane acid polysulfate [possibly pentosan polysulfate].⁴ It would appear that enough of the heparinoid had been absorbed through his skin to increase his anticoagulation to the point where he began to bleed. This case is unusual but it illustrates the need to keep a close watch on patients who are given several drugs that can potentially cause bleeding.

Coumarins + Herbal medicines

Many of the interactions of herbal medicines (health foods, dietary supplements) with warfarin in the published literature are solely hypothetical based on the postulated pharmacological effects of known chemical constituents of the plants. These mechanisms are discussed further below. Where specific clinical data on a herbal medicine interaction with warfarin are available, this is covered in a separate monograph.

All patients should be encouraged to report their use of herbal medicines and food supplements and cases of uneventful concurrent use should be published as well as cases of possible interactions to increase the clinical information available.

Clinical evidence and mechanism

(a) Antiplatelet effects

Antiplatelet doses of 'aspirin', (p.385), do not alter the anticoagulant efficacy of warfarin (INR); however, these doses of aspirin by themselves increase the risk of gastrointestinal bleeding, and the risk of this is higher in patients taking warfarin. On this basis, many herbs with antiplatelet activity *in vitro* are postulated to interact with warfarin, including 'ginger', (p.416) and 'garlic', (p.415). To establish the increased risk with antiplatelet doses of aspirin with warfarin, very large studies were needed because the absolute risks are small (about 1 in 100 in one study). Studies of this size are very unlikely to be conducted with herbals. One way might be to compare the *in vivo* antiplatelet activity of the herbal product with that of aspirin 75 mg, and then to extrapolate to the likely increased risk of bleeding.

(b) Coumarin constituents

There is a misconception that if a plant contains natural coumarins it will have anticoagulant properties. More than 3400 coumarins occur naturally throughout at least 160 plant families. Of these, just 13 have been tested for antithrombotic or anticoagulant activity, and only about half (7) were found to be active.¹ There are no established interactions between warfarin and herbal medicines that have been attributed to the coumarin content of the herb. Even in the classic case of hemorrhagic death of livestock that led to the discovery of dicoumarol, it was the action of the mould on the coumarin in the sweet clover ('melilot', (p.417)) that led to the production of the anticoagulant, so consumption of a spoiled product would seem to be necessary for this interaction to occur. This suggests that the occurrence of coumarins in dietary supplements or herbal medicines should not trigger immediate concern.¹

(c) Hepatic cytochrome P450 metabolism

St John's wort is the most well established example of a herb that can induce the metabolism of drugs, principally by the cytochrome P450 isoenzyme CYP3A4. This herb appears to have a modest effect on 'warfarin', (p.418), which might be clinically important. 'Danshen', (p.415) might interact by increasing the bioavailability of warfarin. No other herbs appear to have an established effect on the metabolism of warfarin.

(d) Vitamin K content

Vitamin K is found in highest levels in 'green leafy vegetables', (p.409), which, if ingested in sufficient quantities, can markedly reduce the effects of warfarin and related drugs. It would therefore not be surprising if many herbal medicines derived from dark green leaves contain vitamin K. However, whether enough of these herbs could be taken to cause an interaction seems less likely than with foods. Nevertheless, two case reports of altered coagulation status attributed to the vitamin K content of herbal preparations have been reported, see 'vitamin K', (p.418).

Importance and management

There are many reviews of the effect of various herbal medicines on warfarin. Most of these include interactions based on theoretical data, based on the knowledge that a plant has been shown to contain antiplatelet substances or coumarins. The problem with these lists is that a suggested interaction might never be clinically relevant if, for example, the coumarins present are found not to be anticoagulants, or the substances are found in such small quantities and the herb cannot be ingested in sufficient amounts to cause an interaction. With natural substances, there is also the problem of chemical variations between batches of product if they are not standard-

ised. Moreover, even isolated reports of an interaction between a herbal medicine and warfarin cannot definitively establish that such an interaction exists (see also 'anticoagulant interactions', (p.358)).

Because of the potential for interactions, some consider that patients taking warfarin would be well advised to avoid all herbal medications. However, this approach may not be practical: there are many papers showing that patients taking warfarin do use a number of herbal medicines and dietary supplements (19.2% in a UK survey;² 26% in a Hong Kong survey³). If patients have been told to avoid all herbal products, they may be less likely to admit to their use, and become less cautious in the future if they discover that the use of one product is uneventful. It may be better to advise patients to discuss the use of any products they wish to try, and to increase monitoring if this is thought advisable. Cases of uneventful use should be reported, as they are as useful as possible cases of adverse use.

Coumarins + Herbal medicines; Boldo or Fenugreek

A report describes a woman taking warfarin whose INR rose modestly when she began to take boldo and fenugreek.

Clinical evidence, mechanism, importance and management

A woman taking warfarin for atrial fibrillation whose INR was normally within the range 2 to 3 had a modest rise in her INR to 3.4, apparently due to the use of 10 drops of boldo after meals and one capsule of fenugreek before meals. A week after stopping these two herbal medicines her INR had fallen to 2.6. When she restarted them, her INR rose to 3.1 after a week, and to 3.4 after 2 weeks. Her INR was later stabilised in her normal range in the presence of these two medicines by reducing the warfarin dosage by 15%.¹ The mechanism of this apparent interaction remains unknown, and it is not known whether both herbs or just one was responsible for what happened. Boldo comes from *Peumus boldus*, and might have antiplatelet activity, and fenugreek comes from *Trigonella foenum-graecum*, which might contain coumarins (but see 'Coumarins + Herbal medicines', above).

This patient had no undesirable reactions (e.g. bruising or bleeding), but this case serves to draw attention to the possibility of an interaction in other patients taking anticoagulants if these herbal medicines are also taken.

- Lambert JP, Cormier A. Potential interaction between warfarin and boldo-fenugreek. *Pharmacotherapy* (2001) 21, 509–12.

Coumarins + Herbal medicines; Chamomile

A single case report describes a woman stabilised on warfarin who developed a marked increase in her INR with bleeding complications five days after she started using two chamomile products.

Clinical evidence

A 70-year-old woman stabilised on warfarin with an INR of 3.6 started drinking 4 to 5 cups of chamomile tea daily for chest congestion, and using a chamomile-based skin lotion 4 to 5 times daily for foot oedema. About 5 days later she developed ecchymoses and was found to have an INR of 7.9, a retroperitoneal haematoma and other internal haemorrhages.¹

Mechanism

Both species of chamomile used medicinally (*Matricaria recutita* also known as *Matricaria chamomilla* or *Chamomilla recutita* and *Anthemis nobilis* also known as *Chamaemelum nobile*) are known to contain coumarins, but natural coumarins are not always anticoagulants, see 'Coumarins + Herbal medicines', above. There appear to be no reports of chamomile alone causing bleeding.

Importance and management

This appears to be the first report of an interaction between warfarin and chamomile, and it may be that it was due to excessive use of two chamomile-based products. It serves to draw attention to the possibility of an interaction in other patients taking anticoagulants if chamomile is used concurrently. Further study is needed. However, note that there appear to be no reports of chamomile alone causing anticoagulation, which might suggest that the risk of an additive effect is small.

1. Segal R, Pilote L. Warfarin interaction with *Matricaria chamomilla*. *Can Med Assoc J* (2006) 174, 1281–2.

Coumarins + Herbal medicines; Curbicin

The INR of one patient taking warfarin modestly increased after he took Curbicin (saw palmetto, cucurbita, and vitamin E). This product has also been associated with an increased INR in a patient not taking anticoagulants.

Clinical evidence, mechanism, importance and management

A 61-year-old man taking **warfarin** and simvastatin, with a stable INR of around 2.4, had an increase in his INR to 3.4 within 6 days of starting to take 5 tablets of **Curbicin** daily. Within a week of stopping the **Curbicin**, his INR had fallen to its previous value. Another elderly man who was not taking any anticoagulants and was taking 3 tablets of **Curbicin** daily was found to have an INR of 2.1 (normal 0.9 to 1.2). His INR improved (1.3 to 1.4) when he was given vitamin K, but did not normalise until a week after stopping the **Curbicin**. **Curbicin** is a herbal remedy used for micturition problems, and contains extracts from the fruit of *Serenoa repens* (saw palmetto) and the seed of *Cucurbita pepo*.¹

The authors of this report suggest that what happened was possibly due to the presence of vitamin E in the **Curbicin** preparation (each tablet contains 10 mg), but 'vitamin E', (p.401) does not normally affect INRs. The clinical significance of this interaction is unknown, but bear it in mind in the case of an unexpected response to treatment.

1. Yue, Q-Y, Jansson K. Herbal drug Curbicin and anticoagulant effect with and without warfarin: possibly related to the vitamin E component. *J Am Geriatr Soc* (2001) 49, 838.

Coumarins and related drugs + Herbal medicines; Danshen (*Salvia miltiorrhiza*)

Two case reports and some animal data indicate that Danshen, a Chinese herbal remedy, can increase the effects of warfarin, resulting in bleeding.

Clinical evidence

A woman who had undergone venous mitral valve valvuloplasty and who was taking furosemide, digoxin and **warfarin**, began to take **Danshen** (the root of *Salvia miltiorrhiza*) every other day for intermittent influenza-like symptoms. After about a month she was hospitalised with malaise, breathlessness and fever and was found to be both very anaemic and over-anticoagulated (prothrombin time greater than 60 seconds, INR greater than 5.62). The anaemia was attributed to occult gastrointestinal bleeding and the over-anticoagulation to an interaction with the **Danshen**. She was later restabilised on the **warfarin** in the absence of the **Danshen** with an INR of 2.5, and within 4 months her haemoglobin levels were normal.¹

Another report describes a man taking **warfarin**, digoxin, captopril and furosemide with an INR of about 3, who developed chest pain and breathlessness about 2 weeks after starting to take **Danshen**. He was found to have a massive pleural effusion, which was later drained of blood, and an INR of more than 8.4. He was later discharged on his usual dose of **warfarin** with an INR stable at 3, in the absence of the **Danshen**.²

Mechanism

Not fully understood. Studies in *rats* show that **Danshen** can increase the bioavailability of both *R*- and *S*-warfarin thereby increasing its effects.³

It may affect haemostasis by inhibiting platelet aggregation and by interfering with extrinsic coagulation, and it also has antithrombin III-like ac-

tivity and can promote fibrinolytic activity. The additive effects of these activities might be expected to result in bleeding complications.

Importance and management

Clinical information appears to be limited to these two case reports and one other, which also involved 'methyl salicylate', (p.457), which is also known to increase the effects of warfarin. This interaction is therefore not very well established but there is enough evidence to suggest that normally patients on warfarin should avoid **Danshen** (although with very careful monitoring and warfarin dosage adjustments safe concurrent use might be possible). More study is needed. Information about other oral anticoagulants is lacking but, given the proposed mechanism of interaction, it would seem sensible to take the same precautions if using any indanedione or coumarin.

3. Lo ACT, Chan K, Yeung JHK, Woo KS. The effects of Danshen (*Salvia miltiorrhiza*) on pharmacokinetics and dynamics of warfarin in rats. *Eur J Drug Metab Pharmacokinet* (1992) 17, 257–62.

Coumarins + Herbal medicines; Dong quai (*Angelica sinensis*)

Two case reports describe a very marked increase in the anticoagulant effects of warfarin when dong quai was given.

Clinical evidence, mechanism, importance and management

A 46-year-old African-American woman with atrial fibrillation taking **warfarin** had a greater than twofold increase in her prothrombin time and INR after taking dong quai for 4 weeks. The prothrombin time and INR were back to normal 4 weeks after stopping the dong quai.¹ Another woman who had been taking **warfarin** for 10 years developed widespread bruising and an INR of 10, a month after starting to take dong quai.²

The reasons are not understood but dong quai is known to consist of natural coumarin derivatives, which may possibly have anticoagulant properties and inhibit platelet aggregation, but note that not all natural coumarins are anticoagulants, see 'Coumarins + Herbal medicines', p.414.

These seem to be only reports of this apparent interaction, but patients taking **warfarin** should be warned of the potential risks of also taking dong quai. For safety dong quai should be avoided unless the effects on anticoagulation can be monitored. More study is needed.

2. Ellis GR, Stephens MR. Untitled report. *BMJ* (1999) 319, 650.

Coumarins + Herbal medicines; Garlic

An isolated report described increases in the anticoagulant effects of warfarin in two patients taking garlic supplements. Garlic supplements alone have also rarely been associated with bleeding. However, in one study, aged garlic extract did not increase the INR or risk of bleeding in patients taking warfarin.

Clinical evidence

The INR of a patient stabilised on **warfarin** more than doubled and haematuria occurred 8 weeks after the patient started to take three *Höfels garlic pearls* daily. The situation resolved when the garlic was stopped. The INR rose on a later occasion while the patient was taking two *Kwai* garlic tablets daily. The INR of another patient was also more than doubled by six *Kwai* garlic tablets daily.^{1,2}

In contrast, in a placebo-controlled study in 48 patients stabilised on **warfarin**, there was no change in INR or evidence of increased bleeding in those receiving 5 mL of aged garlic extract twice daily.³ Similarly, in a preliminary report of the use of alternative and complementary medicines in 156 patients taking **warfarin**, there was no apparent increased risk or bleeding or raised INRs in 57 patients taking potentially interacting complementary medicines (garlic in 10%), compared with 84 who did not.⁴

Mechanism

Garlic has been associated with decreased platelet aggregation, which has on at least two documented occasions led to spontaneous bleeding in the absence of an anticoagulant.^{5,6} These effects might therefore increase the risk of bleeding with anticoagulants, see also 'Coumarins + Herbal medicines', p.414.

Importance and management

Information about an adverse interaction between warfarin and garlic seems to be limited to these two cases from one author. Bearing in mind the wide-spread use of garlic and garlic products, and the limited information from the review,⁴ and study with aged garlic extract,³ it seems most unlikely that garlic usually has any generally important interaction with anticoagulants. Nevertheless, bear the possibility in mind in the event of an unexpected response to treatment.

Coumarins + Herbal medicines; Ginger

Evidence from pharmacological studies suggests that ginger does not increase the anticoagulant effect of warfarin, neither does it alter coagulation or platelet aggregation on its own. However, two case reports describe markedly raised INRs with phenprocoumon and warfarin, which were associated with eating dried ginger and drinking ginger tea.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study in 12 healthy subjects, 3 ginger capsules three times daily for 2 weeks did not affect either the pharmacokinetics or pharmacodynamics (INR) of a single 25-mg dose of **warfarin** taken on day 7. The brand of ginger used was *Blackmores Travel Calm Ginger*, each capsule containing an extract equivalent to 400 mg of ginger rhizome powder. Moreover, ginger alone did not affect the INR or platelet aggregation.¹

However, a case report describes a rise in INR to greater than 10, with epistaxis, in a woman stabilised on **phenprocoumon** several weeks after she started to eat ginger regularly in the form of pieces of dried ginger and tea from ginger powder. She was eventually restabilised on the original dose of **phenprocoumon**, and was advised to stop taking ginger.² Another very similar case has been described in a woman taking **warfarin**.³

These appear to be the only reports of ginger as a probable cause of over-anticoagulation, despite the fact that prior to these *Ginger (Zingiber officinale)* has been sometimes listed as a herb that interacts with **warfarin**.^{4,5} on the basis that *in vitro* it inhibits platelet aggregation. However, this antiplatelet effect has not been demonstrated in clinical studies (which have been the subject of a review⁶), see also 'Coumarins + Herbal medicines', p.414.

Evidence from pharmacological studies suggests that ginger does not increase the anticoagulant effect of **warfarin**, neither does it alter coagulation or platelet aggregation on its own. However, two case reports describe markedly raised INRs with **phenprocoumon** and **warfarin**, which were associated with ginger root and ginger tea. Bear the possibility in mind in the event of an unexpected response to treatment.

Coumarins + Herbal medicines; Ginkgo biloba

Evidence from pharmacological studies in patients and healthy subjects suggests that Ginkgo biloba extracts do not interact with warfarin. However, an isolated report describes intracerebral haemorrhage associated with the use of Ginkgo biloba and warfarin, and there are a few reports of bleeding associated with the use of ginkgo alone.

Clinical evidence

In a randomised, crossover study in 21 patients stabilised on **warfarin**, *Ginkgo biloba* extract 100 mg daily (*Bio-Biloba*) for 4 weeks did not alter the INR or the required dose of **warfarin**, when compared with placebo.¹ Similarly, in another study in healthy subjects,² *Tavonin* (containing standardised dry extract EGb 761 of *Ginkgo biloba* equivalent to 2 g of leaf) 2 tablets three times daily for 2 weeks did not affect either the pharmacokinetics or pharmacodynamics (INR) of a single dose of **warfarin** given on day 7. Moreover, a retrospective review of 21 clinical cases involving the concurrent use of ginkgo and **warfarin** also found no evidence of altered INRs.³

Conversely, a report describes an intracerebral haemorrhage in an elderly woman within 2 months of starting *Ginkgo biloba*. Her prothrombin time was found to be 16.9 and her partial thromboplastin time was 35.5 seconds. She had been taking **warfarin** uneventfully for 5 years.⁴ The author of the report speculated that *Ginkgo biloba* may have contributed towards the haemorrhage.

Mechanism

Uncertain. Isolated cases of bleeding have been reported with ginkgo alone (which have been the subject of a review⁵). In pharmacological studies, *Ginkgo biloba* extract alone did not alter coagulation parameters or platelet aggregation.^{2,3} However, in *animal* studies it was found that the AUC of warfarin was decreased by 23.4% during EGb 761 administration, and the prothrombin time was also reduced by EGb 761, which would suggest that ginkgo should *reduce* the effects of warfarin.³ In healthy subjects, *Ginkgo biloba* extract had no effect on diclofenac or tolbutamide, which were used as marker substrates for the cytochrome P50 isoenzyme CYP2C9, suggesting that it will not alter the metabolism of *S*-warfarin.⁶

Importance and management

There is good evidence from pharmacological studies in patients and healthy subjects that *Ginkgo biloba* extract would not be expected to interact with warfarin. However, there is one case report of over-anticoagulation, and a few reports of bleeding with ginkgo alone. This is insufficient evidence to justify telling patients taking warfarin to avoid *Ginkgo biloba*, but they should be told to monitor for early signs of bruising or bleeding and seek informed professional advice if any bleeding problems arise.

Coumarins + Herbal medicines; Ginseng

One pharmacological study found that American ginseng (*Panax quinquefolius*) modestly decreased the effect of warfarin, whereas another study found that *Panax ginseng* did not alter the effect of warfarin. Two case reports describe decreased warfarin effects, one with thrombosis, attributed to the use of ginseng (probably *Panax ginseng*).

Clinical evidence

In a placebo-controlled study, 20 healthy subjects were given **warfarin** 5 mg daily for 3 days alone then again on days 15 to 17 of a 3-week course of American ginseng 1 g twice daily. In the 12 subjects given ginseng, the peak INR was modestly reduced by 0.16, compared with a non-significant reduction of 0.02 in the 8 subjects given placebo. There was also a modest reduction in the AUC of **warfarin**. In this study, American ginseng (*Panax quinquefolius*) root was ground and capsulated.¹

Evidence from two earlier case reports supports a reduction in warfarin effect. A man taking **warfarin** long-term, and also diltiazem, glyceryl trinitrate and salsalate, had a fall in his INR from 3.1 to 1.5 within 2 weeks of starting to take ginseng capsules (*Ginsana*) three times daily. This preparation contains 100 mg of standardised concentrated ginseng [probably *Panax ginseng*] in each capsule. Within 2 weeks of stopping the ginseng his INR had risen again to 3.3.² Another patient taking **warfarin** was found to have thrombosis of a prosthetic aortic valve, with a subtherapeutic INR of 1.4. Three months prior to this episode his INR had become persistently subtherapeutic, requiring a progressive increment in his **warfarin** dose. It was suggested that this might have been because he had begun using a ginseng product (not identified).³ In contrast, in a randomised, crossover study in 12 healthy subjects, ginseng capsules 1 g three times daily for 2 weeks did not affect either the pharmacokinetics or pharmacodynamics (INR) of a single 25-mg dose of **warfarin** taken on day 7. The brand of ginseng used was *Golden Glow*, each capsule containing an extract equivalent to 0.5 g of *Panax ginseng* root.⁴

Mechanism

Ginseng can come from the root of *Panax ginseng* (known in the US as Asian ginseng) or *Panax quinquefolius* (American ginseng), which differ in the concentrations and specific ginsenosides.⁵ The study showing a reduction in effect of warfarin used American ginseng, and the study showing no effect used *Panax ginseng*. A study in *rats* also failed to find any evidence of an interaction between warfarin and an extract from *Panax ginseng*.⁶ Nevertheless, the two case reports of reduced warfarin effect are probably *Panax ginseng*.

In contrast there have been handful of reports of spontaneous bleeding in patients using ginseng preparations (unspecified) in the absence of an anticoagulant,^{7,8} and, *in vitro*, *Panax ginseng* has been found to contain antiplatelet components.⁹ See also 'Coumarins + Herbal medicines', p.414.

Importance and management

The available evidence suggests that ginseng might *decrease* the effect of warfarin. It is possible that the effect is greater with, or specific to, American ginseng (*Panax quinquefolius*), since this interacted in one study whereas *Panax ginseng* did not. Although the ginseng dose was higher in the *Panax ginseng* study, the treatment duration was not as long, which may have obscured an effect. Moreover, the two case reports of decreased warfarin effects attributed to the use of ginseng were probably *Panax ginseng*.

Until further information becomes available it would seem prudent to be alert for decreased effects of coumarins in patients using ginseng, particularly American ginseng. However, the possibility of an increased risk of bleeding due to the antiplatelet component of *Panax ginseng* cannot entirely be ruled out, but see also 'Coumarins + Herbal medicines', p.414.

Coumarins + Herbal medicines; *Lycium barbarum*

There is an isolated report of a modest increase in the anticoagulant effects of warfarin in a patient taking a herbal tea made from *Lycium barbarum* L.

Clinical evidence, mechanism, importance and management

A 61-year-old Chinese woman stabilised on **warfarin** (INRs normally 2 to 3) had an unexpected rise in her INR to 4.1, which was identified during a routine monthly check. No bleeding was seen. She was also taking atenolol, benazepril, digoxin and fluvastatin. It was found that 4 days before visiting the clinic she had started to take one glass (about 170 mL) 3 or 4 times daily of a Chinese herbal tea made from the fruits of *Lycium barbarum* L (also known as Chinese wolfberry, gou qi zi, Fructus Lycii Chinensis, or *Lycium chinense*) to treat blurred vision caused by a sore eye. When the herbal treatment was stopped, her INRs rapidly returned to normal. Later *in vitro* studies showed that an infusion of *Lycium barbarum* L caused some inhibition of the cytochrome P450 isoenzyme CYP2C9, which is involved in the metabolism of warfarin, but this was apparently too weak to explain why this interaction occurred.¹ So far this is an isolated case but it draws attention to the possibility of problems with this herbal remedy in other patients.

1. Lam AY, Elmer GW, Mohutsky M. Possible interaction between warfarin and *Lycium barbarum*. *Ann Pharmacother* (2001) 35, 1199–1201.

Coumarins + Herbal medicines; Melilot

Increased anticoagulation was seen in a patient taking acenocoumarol after using a melilot-containing topical cream.

Clinical evidence

A 66-year-old taking **acenocoumarol**, levothyroxine and prazepam had an increase in her INR after massaging a proprietary topical cream (*Cyclo 3*) containing melilot (*Melilotus officinalis*; **sweet clover**) and butcher's broom (*Ruscus aculeatus*) on her legs three times daily. On the first occasion her INR rose from about 2 to 5.8 after 7 days of use, and on a later occasion it rose to 4.6 after 10 days of use.¹

Mechanism

Melilot (sweet clover) is known to contain natural coumarins, which can be turned into dicoumarol by moulds, see 'Coumarins + Herbal medicines', p.414. In another report, a woman with unexplained abnormal menstrual bleeding was found to have a prothrombin time of 53 seconds, and laboratory tests showed that her blood clotting factors were abnormally low. When given parenteral vitamin K her prothrombin time rapidly returned to normal (suggesting that she was taking a vitamin K antagonist of some kind). She strongly denied taking any anticoagulant drugs, but it was eventually discovered that she had been drinking large quantities of a herbal tea containing among other ingredients **tonka beans**, **melilot** and **sweet woodruff**, all of which might contain natural coumarins, but see 'Coumarins + Herbal medicines', p.414.²

Importance and management

This case is isolated, but it shows that herbal preparations of this kind might affect anticoagulation. Absorption through the skin appears to be enough to upset the anticoagulant control.

2. Hogan RP. Hemorrhagic diathesis caused by drinking an herbal tea. *JAMA* (1983) 249, 2679–80.

Coumarins + Herbal medicines; Quilinggao

A single case report describes a man who had a marked increase in his INR with bleeding complications, nine days after he switched the brand of quilinggao he was using.

Clinical evidence

A 61-year-old man stabilised on **warfarin** with an INR in the range of 1.6 to 2.8 was found to have an INR greater than 6 and skin bruising, and complained of gum bleeding and epistaxis in the previous 3 days. For the past 3 years he had taken quilinggao, apparently without problems. However, 9 days previously he had started taking a different brand of quilinggao. He was eventually stabilised on the previous dose of **warfarin** with an INR of 2.5, but after discharge started taking a third brand of quilinggao, and 3 days later had an INR of 5.2.¹

Mechanism

Quilinggao is a Chinese herbal product made from a mixture of herbs. The first brand did not contain any herbs suspected to have anticoagulant effects except one with possible antiplatelet activity, but the second brand contained Chinese peony (*Paeoniae rubra*), *Poncirus trifoliata* and a couple of other herbs known to contain substances with anticoagulant or antiplatelet effects *in vitro*, but see also 'Coumarins + Herbal medicines', p.414.

Importance and management

This appears to be the only case of a possible interaction, and as such the interaction is not established. Quilinggao did not affect anticoagulant control in this patient for a number of years, and then did after switching brands. Bear the possibility of an interaction in mind.

1. Wong ALN, Chan TYK. Interaction between warfarin and the herbal product *quilinggao*. *Ann Pharmacother* (2003) 37, 836–8.

Coumarins + Herbal medicines; St John's wort (*Hypericum perforatum*)

St John's wort can cause a moderate reduction in the anticoagulant effects of phenprocoumon and warfarin.

Clinical evidence

(a) Phenprocoumon

In a randomised, placebo-controlled crossover study in 10 healthy men,¹ St John's wort extract (*LI 160*, *Lichtwer Pharma*) 900 mg daily for 11 days reduced the AUC of a single 12-mg dose of phenprocoumon by a modest 17.4%. There is also a case report of a 75-year-old woman taking phenprocoumon who had a reduced anticoagulant response (a rise in the Quick value) 2 months after starting to take St John's wort.²

(b) Warfarin

In a randomised, crossover study in 12 healthy subjects, one tablet of St John's wort three times daily for 3 weeks modestly decreased the AUC of both *R*- and *S*-warfarin by about 25% after a single 25-mg dose of warfarin taken on day 14. In this study, the brand of St John's wort used was *Bioglan* tablets, each tablet containing an extract equivalent to 1 g of *Hypericum perforatum* flowering herb top containing 825 micrograms of hypericin and 12.5 mg of hyperforin.³

The Swedish Medical Products Agency received 7 case reports over the 1998 to 1999 period of patients stabilised on warfarin who showed decreased INRs when St John's wort was added. Their INRs fell from the normal therapeutic range of about 2 to 4 to about 1.5. Two patients needed warfarin dosage increases of 6.6% and 15% when St John's wort was added. The INRs of 4 of the patients returned to their former values when the St John's wort was stopped.⁴

Mechanism

Uncertain, but it is suggested that the St John's wort increases the metabolism and clearance of the anticoagulants^{1,3,4} possibly by induction of cytochrome P450 isoenzymes. It affected both *R*- and *S*-warfarin.³ Oral bioavailability was not altered.³

Importance and management

Information seems to be limited to these reports, but a modest pharmacokinetic interaction is established, which might be clinically important. It would be prudent to monitor the INRs of patients taking phenprocoumon, warfarin or any other coumarin if they start taking St John's wort, being alert for the need to slightly raise the anticoagulant dosage. However, note that the advice of the CSM in the UK is that St John's wort should not be used with warfarin. They note that the degree of induction of warfarin metabolism is likely to vary because levels of active ingredients may vary between St John's wort preparations. If a patient is already taking the combination, they advise checking the INR, stopping the St John's wort and then monitoring the INR closely and adjusting the anticoagulant dosage as necessary.⁵

Coumarins + Herbal medicines; Vitamin K₁-rich

A man had a rise in his INR after stopping taking a herbal nutritional supplement (*Nature's Life Greens*), which contained a number of plants known to be high in vitamin K₁. Another patient had a decrease in INR after starting to drink a plant extract juice (called *Noni Juice*).

Clinical evidence, mechanism, importance and management

(a) *Nature's Life Greens*

A 72-year-old man stabilised on **warfarin** was found to have an INR of 4.43 at a routine clinic visit, which was increased from 3.07 six weeks previously. The patient had stopped taking a herbal product *Nature's Life Greens* that month because he did not have enough money to buy it. He had been taking it for the past 7 years as a vitamin supplement because he had previously been instructed to limit his intake of green leafy vegetables. He was eventually restabilised on **warfarin** and the same nutritional product.

The product label listed 25 vegetables without stating the amounts or concentrations,¹ but at least 5 of the listed ingredients are known to contain high levels of vitamin K₁ including **parsley, green tea leaves, spinach, broccoli, and cabbage** (see also 'foods; vitamin K-rich', (p.409)). It is therefore likely it contained sufficient vitamin to antagonise the effect of the **warfarin** so that when it was stopped the warfarin requirements fell, and without an appropriate adjustment in dose, this resulted in an increased INR.

This case reinforces the view that all patients taking **warfarin** should seek advice when they want to stop or start any herbal medicine or nutritional supplement.

(b) *Plant extracts juices*

A 41-year-old woman stabilised on **warfarin** was found to have an INR of 1.6 at a routine clinic visit. The only possible cause identified was that the patient had begun to drink one to two small glasses daily of *Noni Juice 4 Everything*. This was identified as a brown liquid that contains extracts and derivatives from more than 115 components. The authors noted that many of the listed plants contained vitamin K and that vitamin K was listed as a separate component, indicating that the juice might be fortified with vitamin K. The patient was given heparin and then discharged on her previous dose of **warfarin**, and advised to stop taking this brand of juice.²

This case reinforces the view that all patients taking **warfarin** should seek advice when they want to stop or start any herbal medicine or nutritional supplement.

Coumarins + Herbicides

An isolated report describes a marked increase in the anticoagulant effects of acenocoumarol, with bleeding, caused by use of a herbicide containing thiocarbamates.

Clinical evidence, mechanism, importance and management

A 55-year-old patient with mitral and aortic prostheses, stabilised on acenocoumarol 2 mg daily and with an INR of 3.6 to 4.2 was hospitalised because of severe and uncontrollable gum bleeding. He responded when given a transfusion of fresh plasma. The cause of the marked increase in the anticoagulant effects of the acenocoumarol was eventually identified as almost certainly being due to the use of a herbicide (*SATURN-S*) containing thiobencarb and molinate (two thiocarbamates), which the patient was using to spray his rice crop. The thiobencarb can be absorbed through the skin and the molinate by inhalation. Just how these two compounds interact with acenocoumarol is not known but the authors of the report suggest that these herbicides may possibly have inhibited the metabolism of the anticoagulant, thereby increasing its effects. The patient was later restabilised on his former dose of acenocoumarol.¹

This seems to be the first and only report of this interaction but it highlights one of the possible risks of using chemical sprays that have never been formally tested for their potential to interact with drugs. See also 'Coumarins + Insecticides', p.421.

1. Fernández MA, Aznar J. Potenciación del efecto anticoagulante del acenocoumarol por un herbicida. *Rev Iberoamer Tromb Hemostasia* (1988) 1, 40–1.

Coumarins + Hormonal contraceptives

One small study found that the acenocoumarol dose requirements were about 20% lower during the use of a combined hormonal contraceptive. An isolated report describes a marked INR increase in the INR of a woman taking warfarin when she was given emergency contraception with levonorgestrel. In contrast, in small single-dose studies in healthy subjects, the anticoagulant effects of dicoumarol and phenprocoumon were slightly decreased by oral contraceptives.

Note that, in general, the indications for the use of oral anticoagulants are contraindications to the use of combined oral contraceptives.

Clinical evidence

(a) Acenocoumarol

The anticoagulant requirements of 12 patients taking acenocoumarol were about 20% lower while they were taking a combined hormonal contraceptive (average 19 months) than when they were not taking the contraceptive (average 12 months). Even then, they were anticoagulated to a higher degree while taking the contraceptive (prothrombin ratio of 1.67 compared with 1.5) than with the anticoagulant alone. The contraceptives used were *Neogynona*, *Microgynon*, *Eugynon* (ethinylestradiol with levonorgestrel) or *Topasel* (intramuscular estradiol enantate with algestone).¹

(b) Dicoumarol

A study in 4 healthy subjects given single 150- or 200-mg doses of dicoumarol on day 17 of a 20-day course of *Enovid* (noretynodrel and mestranol) found that the anticoagulant effects were decreased in 3 of the 4 subjects, although the dicoumarol half-life remained unaltered.²

(c) Phenprocoumon

In a controlled study in 14 healthy women, the clearance of a single 0.22-mg/kg dose of phenprocoumon was increased by 20% in the 7 subjects taking combined oral contraceptives, compared with that in the 7 not taking oral contraceptives.³

(d) Warfarin

A 39-year-old woman with familial type 1 antithrombin deficiency and a history of extensive deep vein thrombosis and pulmonary embolism, taking warfarin, was given levonorgestrel for emergency contraception.

Within 3 days her INR had risen from 2.1 to 8.1. No bleeding occurred. Her INR returned to normal after stopping the warfarin for 2 days.⁴

Mechanism

Not understood. The oral contraceptives are well known to be associated with a small increased risk of venous thromboembolism in otherwise healthy women, and are therefore contraindicated in women who have had thrombosis. They can apparently increase the metabolism (glucuronidation) of phenprocoumon.³ The authors of the report about levonorgestrel suggest that it might have displaced the warfarin from its binding sites thereby increasing its activity,⁴ although this mechanism is now generally discounted.

Importance and management

Direct information seems to be limited to these reports. Oral contraceptives are normally contraindicated in those with thromboembolic disorders but if they must be used, be alert for any changes in the anticoagulant response if an oral contraceptive is started or stopped. The report about the apparent interaction between warfarin and postcoital levonorgestrel seems to be isolated and therefore its general importance is unknown.

4. Ellison J, Thomson AJ, Greer IA, Walker ID. Apparent interaction between warfarin and levonorgestrel used for emergency contraception. *BMJ* (2000) 321, 1382.

Coumarins and related drugs + HRT or Tibolone

A retrospective analysis of women starting HRT found that only three needed warfarin dose increases, of about 10 to 30%. A case report describes a woman who needed 75% more acenocoumarol when her HRT treatment with oral conjugated oestrogens was changed to transdermal estradiol.

Four women taking warfarin and one taking phenindione who started taking tibolone had modest to marked increases in INR and required 12% to 56% reductions in anticoagulant dose.

Note that, because of the increased risk of developing venous thromboembolism with HRT, the use of HRT in women already on anticoagulant therapy requires careful consideration of the risks and benefits. Whether tibolone is associated with the same risk is unknown, therefore similar caution would seem prudent.

Clinical evidence

(a) Oestrogens for menopausal HRT

In a retrospective analysis, 18 women were identified who had started HRT while taking warfarin (n=16) or phenindione (n=2). A wide variety of HRT preparations were being used, including topical and oral preparations, oestrogens with or without progestogens, and progestogens alone. Half of the women taking warfarin had no change in their warfarin dose requirement after starting HRT. Five required a less than 10% increase or decrease in average warfarin dose, and 3 required a 12.8%, 22%, and 28% increase in average warfarin dose, the latter two of these being the only 2 women taking oestrogen-only oral HRT. Of the 2 women taking phenindione, one needed no change in dose, and the other a 4.6% increase in dose.¹

In one case, a postmenopausal 53-year-old woman needed an increase in her daily dose of acenocoumarol from 2 to 3.5 mg when her HRT was changed from oral conjugated oestrogens 0.625 mg daily to transdermal estradiol 50 micrograms daily. When the oral HRT was restarted, her acenocoumarol requirements returned to their former levels.²

(b) Tibolone

In a retrospective analysis, five women were identified who had started tibolone while taking warfarin or phenindione, and one who discontinued tibolone while taking warfarin. All of the 5 patients had an increase in INR to a range of 4.6 to 9.5 after starting tibolone, and required reductions

Table 12.4 Summary of the evidence for and against an interaction between influenza vaccine and coumarins

Study type (year)	Group	Coumarin	Influenza vaccine	Route	Notes	Refs
Studies showing no interaction						
Prospective (1983)	33 patients and 15 controls	Warfarin	Not stated	Not stated	No evidence of an interaction (one vaccinated patient had haematuria 27 days later, and one control patient had epistaxis)	1
Prospective series (1984)	21 patients	Stable warfarin	Trivalent type A and B, Wyeth	Not stated	No change in average prothrombin time at 0, 3, 7, 10 and 14 days after vaccination	2
Randomised, placebo-controlled (1984)	25 patients vaccinated and 25 placebo	Stable warfarin	Trivalent type A and B (<i>Fluvirin</i>)	Deep subcutaneous	No change in mean ratio of prothrombin times at 0, 2, 7 and 21 days after vaccination	3
Prospective (1984)	4 healthy subjects	Low-dose warfarin	<i>Influvac</i>	Intramuscular	No change in average prothrombin time at 7, 11, 14, 16, 21 and 28 days after vaccination, and no change in warfarin levels	4
Prospective series (1985)	7 patients	Stable warfarin	Trivalent type A and B, Wyeth	Not stated	No change in prothrombin time at 4, 6, 10, 14 and 21 days after vaccination	5
Prospective series (1986)	26 patients	Stable warfarin	Trivalent (subvirion) type A and B (<i>Fluogen</i>)	Intramuscular	No change in mean INR at day 14 after vaccination	6
Prospective series (1986)	7 patients and 9 controls	Stable warfarin	Trivalent type A and B, Wyeth	Not stated	No change in prothrombin time at 1, 3 and 5 weeks after vaccination, or compared with controls	7
Prospective series (1990)	9 patients	Stable warfarin	Trivalent, split virion, A and B (<i>MFV-Ject</i>)	Not stated	No significant change in INR at 3, 6, 8, 10, 13, 22 and 30 days after vaccination (mean decrease of 4.8%)	8
Prospective series (1993)	43 patients	Stable acenocoumarol	Trivalent type A and B	Subcutaneous	No change in mean INR at 7, 15 and 30 days after vaccination. INR values increased in 3 patients and decreased in 6 patients requiring modification in acenocoumarol dose	9
Prospective series (1995)	41 patients	Stable warfarin	Not stated	Intramuscular	No significant change in prothrombin time at 3, 7 and 14 days after vaccination, and no local complications	10
Studies showing an increase in effect						
Prospective series (1984)	8 patients	Stable warfarin	Trivalent type A and B	Not stated	All patients had an increase in prothrombin time to at least the upper limit of their range for the previous year (40% from baseline)*	11
Prospective series (1986)	10 patients	Stable warfarin	Trivalent (subvirion) type A and B (<i>Fluogen</i>)	Intramuscular	Slight maximal 7.6% increase in mean INR at day 14 after vaccination	6
Case-control (2003)	90 patients and 45 controls	Stable warfarin (98%) Acenocoumarol (2%)	<i>Inflexel V</i> , <i>Isiflu V</i> , <i>Fluad</i> , or <i>Agrippal</i>	Intramuscular	49 out of 90 patients had a clear increase in INR from a mean of 2.64 to 3.85, and 2 of these had bleeding episodes. In the remaining patients and controls there was no change in INR	12
Studies showing a decrease in effect						
Prospective series (1988)	24 patients	Stable warfarin	Trivalent type A and B	Not stated	A slight 8.3% decrease in prothrombin time occurred in the first 2 weeks after vaccination.	13
Prospective series (2002)	73 patients and 72 controls	Stable warfarin	Not stated	Subcutaneous	Overall, there was no change in anticoagulation, but the 34 vaccinated patients aged 70 or more had a slight reduction in INR in month after vaccination (mean 2.8 versus 2.99)	14

in their anticoagulant dose (range of 12% to 53% reductions in **warfarin** dose, and 56% for **phenindione**). The woman who discontinued tibolone required an increase in her **warfarin** dose from 6 to 7.5 mg daily.¹

Mechanism

Not understood. Menopausal HRT alone is now known to be associated with a small increased risk of venous thromboembolism. Tibolone alone increases fibrinolytic activity without altering prothrombin time,³ and might therefore be expected to increase the risk of bleeding with anticoagulants. However, this would not result in raised INRs, and it was suggested that the effect on the INR might be because of the androgenic effect of tibolone causing a reduction in factor VIIa.¹

Importance and management

Published information on concurrent use of warfarin and HRT or tibolone appears to be very limited. The retrospective study suggests that usually HRT causes no or only minor changes in warfarin requirements, whereas tibolone causes more marked increases in INR and reduced warfarin requirements of up to about 50%.¹ Because of this, increased monitoring of the INR on starting tibolone in patients stabilised on warfarin, other coumarins, or indanediones is required.

Note that, because of the increased risk of developing venous thromboembolism with HRT, the use of HRT in women already taking an anticoagulant requires careful consideration of the risks and benefits. Whether tibolone is associated with the same risk is unknown,⁴ therefore similar caution would seem prudent.

Coumarins and related drugs + Influenza vaccines

The concurrent use of warfarin and influenza vaccine is usually safe and uneventful, but there are reports of bleeding in a handful of patients (life threatening in one case) attributed to an interaction. Acenocoumarol also does not normally interact.

Clinical evidence

(a) Effect on anticoagulant control

About 15 studies of the effect of influenza vaccine on the anticoagulant effect of coumarins have been published, and these are summarised in 'Table 12.4', (p.420). Most of these are non-controlled studies in small to moderate numbers of patients, and the majority were unable to demonstrate a significant change in prothrombin time or INR in patients taking coumarins, including the only randomised placebo-controlled study. Some studies found a slight change in anticoagulant effect (both slight increases and slight reductions), but they are probably of limited clinical relevance. However, in one larger case-control study, a clear increase in INR from 2.64 to 3.85 was seen in about half of the 90 patients, and 2 of these

had bleeding episodes. The reasons for the clear difference between this study and the many others are not known.

There are also various brief case reports of a possible interaction. In one review paper, there is a very brief report of a patient receiving **warfarin** who had serious bleeding, which was almost fatal, after receiving a 'flu shot'. No further details are given.¹ An elderly man receiving **warfarin** developed bleeding (haematemesis and melaena) within 10 days of being given an influenza vaccination. His prothrombin time was found to be 36 seconds.² Another patient taking **warfarin** had raised INRs in two successive years when an influenza vaccination was given.³

(b) Route of injection of vaccine

In a randomised study in 26 patients stabilised on **warfarin**, there was no difference in injection site adverse events between intramuscular or subcutaneous injection of a standard trivalent influenza vaccine, and no patient had bruising or swelling. In addition, both routes of administration produced similar levels of antibody titres.⁴ In another study that specifically assessed the local reactions to intramuscular influenza vaccination, there were no detectable local complications after intramuscular injection, including no change in arm circumference.⁵

Mechanism

Not understood. In a placebo-controlled study in healthy subjects, influenza vaccine did not alter the half-life of either *R*- or *S*-warfarin.² It has therefore been suggested that when an interaction occurs the synthesis of the blood clotting factors is altered.²

Importance and management

A well-investigated interaction, but with some contradictory data. The weight of evidence shows that influenza vaccination in those taking warfarin is normally safe and uneventful, nevertheless it would be prudent to be on the alert because very occasionally and unpredictably bleeding may occur. Acenocoumarol appears not to be affected.

Limited evidence suggests that intramuscular administration is not associated with increased local complications, but also that subcutaneous administration is effective. Because of the theoretical risk of local muscle haematoma, it may be preferable to give influenza vaccines by deep subcutaneous injection in patients taking coumarins and related anticoagulants.

Coumarins + Insecticides

A patient showed a marked increase in his response to acenocoumarol when exposed to insecticides containing ivermectin and methidathion. Another patient was resistant to the effects of warfarin after very heavy exposure to a toxaphene and lindane-containing insecticide.

Clinical evidence

(a) Acenocoumarol

A farmer in Spain, normally well stabilised on acenocoumarol and amiodarone, had marked rises in his INR, from 3.5 up to 7.9, requiring a reduction in his anticoagulant dosage (from 12 to 8 mg weekly), which occurred during the summer months. No bleeding occurred. It was then discovered that he was using insecticides containing **ivermectin** and an organophosphate **methidathion** on his trees without any protective clothing.¹

(b) Warfarin

A rancher in the USA, who was taking warfarin, had a very marked reduction in his anticoagulant response after dusting his sheep with an insecticide containing 5% **toxaphene (campechlor)** and 1% **lindane (gamma-benzene hexachloride)**. Over a 2-year period he had periods of considerable warfarin resistance, which were linked to the use of this insecticide. Normally warfarin 7.5 mg daily maintained his prothrombin time in the therapeutic range, but after exposure to the insecticide even 15 mg daily failed to have any effect at all.² The dusting was done by putting the insecticide in a sack and hitting the sheep with it in an enclosed barn.²

Mechanism

The interaction between acenocoumarol and ivermectin with methidathion is not understood. When used on its own, ivermectin used for onchocerciasis normally has no effect on prothrombin times,^{3,4} but two unexplained cases of prolonged prothrombin times associated with the development of haematomas have been reported.⁵ Methidathion is an organophosphate. Lindane and other chlorinated hydrocarbon insecticides are known liver enzyme inducers,⁶ which increase the metabolism and clearance of the warfarin, thereby reducing or even abolishing its effects.

Importance and management

Information about these interactions appears to be limited to these isolated case reports. Neither interaction is well established and neither would appear to be of general clinical importance. The chlorinated hydrocarbon insecticides have been withdrawn from general use in most countries so that the possibility of an interaction with any anticoagulant is now very small. No other cases of an interaction between an anticoagulant and ivermectin, whether used as an insecticide or for the treatment of onchocerciasis, appear to have been reported.

As a general rule, farm workers and others should use proper protection (gloves, masks, protective clothing) if they are exposed to substantial amounts of any insecticide, because these can be both directly toxic and can also apparently interact with some prescribed drugs, including the anticoagulants, even if only very rarely.

Coumarins + Interferons

Isolated case reports indicate that the effects of acenocoumarol and warfarin may be increased by interferons.

Clinical evidence

A woman stabilised on long-term **warfarin** 2.5 to 3.5 mg daily had a prothrombin time rise from 16.7 to 20.4 seconds after receiving 6 million units of **interferon-alfa** daily for 10 days, then three times a week. Her serum **warfarin** levels rose from about 0.8 to 5.2 micrograms/mL. She responded to a reduction in the **warfarin** dosage to 2 mg daily. The authors of the report also say that they have seen 4 other

patients taking **warfarin** who needed a dosage reduction when given interferon, two of them while taking **interferon beta** and the other two while taking **interferon alfa-2b**.¹ A woman taking **acenocoumarol** 1 and 2 mg on alternate days had gingival bleeding and a thrombotest change from 35% to 19% (indicating an increased anticoagulant effect) within 6 weeks of starting treatment with 3 million units of **interferon-alpha 2b** three times weekly. Her thrombotest percentages stabilised between 25 and 40% when the **acenocoumarol** dosage was reduced to 1 mg daily. A later reduction in the interferon dosage caused a decrease in the anticoagulant effects of acenocoumarol.²

Mechanism

Not understood. The authors of both reports suggest that interferon reduces the metabolism of the anticoagulants by the liver, thereby reducing their clearance and increasing their effects.^{1,2}

Importance and management

These reports seem to be the only ones to describe this interaction so the interaction is not yet established. However it would seem prudent to monitor the effects if interferon is given to patients taking coumarins, reducing the dosage if necessary. For a case of decreased warfarin effects in a patient given interferon alfa-2b and ribavirin, see 'Coumarins + Ribavirin', p.447.

Coumarins + Ispaghula (Psyllium)

Ispaghula (psyllium) did not affect either the absorption or the anticoagulant effects of warfarin in one study. A cohort study also found no evidence of an interaction in patients taking acenocoumarol or phenprocoumon.

Clinical evidence, mechanism, importance and management

In a study in 6 healthy subjects, ispaghula (given as a 14-g dose of colloid (*Metamucil*) in a small amount of water with a single 40-mg dose of **warfarin**, and three further doses of ispaghula every 2 hours thereafter) did not affect either the absorption or the anticoagulant effects of the **warfarin**.¹ Similarly, in a population-based cohort study in patients taking **acenocoumarol** or **phenprocoumon**, there was no increased risk of over-anticoagulation (INR greater than 6) associated with the use of ispaghula (psyllium seeds), although the number of people treated was small.² No alteration of the anticoagulant response would therefore be expected on concurrent use.

Coumarins + Lanthanum

Lanthanum did not alter the pharmacokinetics of a single dose of warfarin.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study in healthy subjects, lanthanum (3 doses of 1 g the day before **warfarin**, then 1 g thirty minutes before **warfarin**) had no effect on the pharmacokinetics of a single dose of **warfarin**.¹

Lanthanum is a phosphate-binding drug, and does not appear to alter **warfarin** absorption. This suggests that no **warfarin** dose adjustments are expected to be needed on concurrent use. However, note that the pharmacodynamics of **warfarin** (e.g. the effects on INR) were not assessed in this study.

1. Fiddler G. Fosrenol (lanthanum carbonate) does not affect the pharmacokinetics of concomitant treatment with warfarin. *J Am Soc Nephrol* (2002) 13, 749A–750A.

Coumarins + Lasofoxifene

In a study, lasofoxifene caused a minor 16% decrease in prothrombin time without changing warfarin pharmacokinetics.

Clinical evidence, mechanism, importance and management

In 12 healthy postmenopausal women, lasofoxifene 4 mg on day one then 500 micrograms daily for 13 days had no effect on the pharmacokinetics of *R*- or *S*-warfarin when a single 20-mg dose of **warfarin** was given on day 8. Conversely, the maximum prothrombin time was decreased by 16%, with a similar decrease in maximum INR from 1.9 to 1.6.¹

Because this slight decrease in **warfarin** effects has been seen with 'raloxifene', (p.446), the authors suggested that it might be because oestrogenic compounds increase plasma concentrations of vitamin K-dependent clotting factors.¹

The authors suggest that the small decrease in **warfarin** effect with lasofoxifene may not be clinically relevant. Nevertheless, they say that until more data are available on longer-term concurrent use, it is recommended that prothrombin times should be monitored when starting or stopping lasofoxifene.¹ This seems a sensible precaution.

1. Quellet D, Bramson C, Carvajal-Gonzalez S, Roman D, Randinitis E, Remmers A, Gardner MJ. Effects of lasofoxifene on the pharmacokinetics and pharmacodynamics of single-dose warfarin. *Br J Clin Pharmacol* (2006) 61, 741–5.

Coumarins + Laxatives

In one cohort study, the long-term use of lactulose appeared to be associated with an increased risk of overanticoagulation. Limited evidence suggested no interaction occurred with liquid paraffin or colocyath.

Clinical evidence

In a population-based cohort study in patients taking **acenocoumarol** or **phenprocoumon**, lactulose significantly increased the risk of over-anticoagulation (INR greater than 6) (relative risk of 3.4, range 2.2 to 5.3). When analysed by duration of use, less than 27 days use of **lactulose** actually decreased the risk of over-anticoagulation, whereas longer use was associated with an increased risk. In this study, neither **liquid paraffin** nor **colocyath** preparations were associated with an increased risk of over-anticoagulation, but numbers of patients treated with these drugs was small.¹

Mechanism

In theory, drugs that shorten gastrointestinal transit time such as laxatives and liquid paraffin (mineral oil) might be expected to decrease the absorption of both vitamin K and the oral anticoagulants. Decreasing the absorption of vitamin K would be expected to increase the effect of oral anticoagulants, which could be offset by the decrease in absorption of oral anticoagulants. In the case of short-term lactulose use, it was suggested that decreasing the colonic pH might have increased the absorption of vitamin K, thereby reducing the effect of the anticoagulant. On longer term use, it was postulated that lactulose might reduce faecal flora that produce vitamin K, so increasing the risk of over-anticoagulation.¹ Liquid paraffin might also be expected to impair the absorption of vitamin K.

Importance and management

The cohort study cited appears to be the first and only evidence of a possible interaction with laxatives, and it suggests that long-term use of lactulose may increase the effect of coumarins. This finding requires confirmation in a controlled pharmacological study. Until further data are available, it may be prudent to consider the possibility of an interaction in anybody taking lactulose long-term. Limited evidence suggested no interaction occurred with liquid paraffin or colocyath. Clinical evidence for an interaction with other laxatives is lacking, despite the theoretical considerations.

1. Visser LE, Penning-van Beest FJA, Wilson JHP, Vulto AG, Kasbergen AAH, De Smet PAGM, Hofman A, Stricker BHC. Overanticoagulation associated with combined use of lactulose and acenocoumarol or phenprocoumon. *Br J Clin Pharmacol* (2003) 57, 522–4.

Coumarins + Leflunomide

There are a few reports of increased INRs, some with bleeding complications, in patients taking warfarin with leflunomide.

Clinical evidence, mechanism, importance and management

A short report describes a patient taking **warfarin** whose INR rose from 2.5 to over 6, resulting in a hospital admission, shortly after she started taking leflunomide (3 days of 100 mg daily).¹

Another report describes a patient taking **warfarin** who developed haematuria after taking leflunomide 100 mg daily for 2 days. His INR was found to have risen from 3.4 to over 11, and **warfarin** was discontinued. The haematuria spontaneously resolved, but as the INR remained elevated for the next 2 days he was given 1 mg of vitamin K, which brought his INR down to 1.9. He was later stabilised on **warfarin** 1 mg daily with a leflunomide maintenance dose of 20 mg daily.² The authors of this report stated that at that time (2002) the CSM in the UK had received over 300 reports of leflunomide raising the INRs of patients taking **warfarin**;² however, this was an error, and it should have read that of 300 reports of raised INRs with **warfarin** and another drug, *four* reports related to leflunomide.³ An additional case describes a patient who required a 22% decrease in her weekly **warfarin** dose after starting leflunomide.⁴

The manufacturers of leflunomide note that *in vitro*, the active metabolite of leflunomide inhibits the cytochrome P450 isoenzyme CYP2C9. They therefore advise caution if leflunomide is given with drugs metabolised by CYP2C9, of which they give **warfarin** and **phenprocoumon** as examples.⁵ On the basis of the cases seen, it would seem prudent to monitor the INR of any patient taking a coumarin anticoagulant who is started on leflunomide.

Coumarins + Leukotriene antagonists

Zafirlukast increases the anticoagulant effects of warfarin and bleeding has been seen. Pranlukast is predicted to interact similarly. In contrast, montelukast did not alter the pharmacokinetics or anticoagulant effects of single-dose warfarin.

Clinical evidence

(a) Montelukast

In a double-blind, placebo-controlled, randomised study, 12 healthy subjects were given oral montelukast 10 mg daily for 12 days and a single 30-mg dose of **warfarin** on day 7. It was found that the pharmacokinetics of the **warfarin** were virtually unchanged by the montelukast, and prothrombin times and INRs were not significantly altered.¹

(b) Zafirlukast

In a placebo-controlled study, 16 healthy subjects taking zafirlukast 80 mg twice daily for 10 days were given a single 25-mg dose of **warfarin** on day 5. The mean AUC of *S*-warfarin was increased by 63% and the half-life by 36%, but the pharmacokinetics of *R*-warfarin were not significantly changed. The mean prothrombin time increased by 35%.²

An 85-year-old woman taking **warfarin**, salbutamol (albuterol), diltiazem, digoxin, furosemide and potassium was admitted to hospital with various cardiac-related problems and bleeding (epistaxis, melaena, multiple bruising), which was attributed to the use of zafirlukast 20 mg twice daily. Her INR had risen from 1.1 (measured 6 months previously) to 4.5. The report does not say how long she had been taking the both drugs together.³

Mechanism

The reason for the interaction is thought to be that the zafirlukast inhibits the cytochrome P450 isoenzyme CYP2C9, which metabolises *S*-warfarin.^{2,4} *In vitro* studies suggest that **pranlukast** has a similar effect.⁵

Importance and management

Information appears to be limited to these reports but the interaction with zafirlukast would seem to be established. If zafirlukast is given to patients stabilised on warfarin, monitor prothrombin times well and be alert for the need to reduce the warfarin dosage to avoid over-anticoagulation. Other coumarins might be expected to be affected similarly. Pranlukast is also predicted to interact, as it is also an inhibitor of CYP2C9. In contrast, montelukast does not appear to interact with warfarin, and no warfarin dose adjustments are predicted to be needed on concurrent use.

Coumarins + Levetiracetam

In a controlled study, levetiracetam did not alter the pharmacokinetics or pharmacodynamics of warfarin.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, placebo-controlled study in 42 healthy subjects stabilised on **warfarin**, levetiracetam 1 g twice daily for 7 days had no significant effect on the pharmacokinetics of *R*- or *S*-warfarin and the INRs were not significantly altered.¹ No **warfarin** dose adjustments would therefore be expected to be needed on concurrent use.

Coumarins + MAOIs or RIMAs

Although some animal data show that the non-selective MAOIs increase the effects of some oral anticoagulants, there appears to be no clinical evidence of an interaction. Moclobemide did not interact with phenprocoumon in a pharmacological study.

Clinical evidence, mechanism, importance and management

A number of studies in *animals*^{1–4} have shown that some of the non-selective MAOIs can increase the effects of some oral anticoagulants. However, there appear to be no clinical studies or case reports of this interaction, and therefore no special precautions seem to be necessary. A study in healthy subjects found that **moclobemide** 200 mg three times daily for 7 days did not alter the anticoagulant effects of steady-state **phenprocoumon**.⁵

Coumarins + Medroxyprogesterone acetate or Megestrol

High-dose medroxyprogesterone acetate and megestrol prolonged the half-life of single-dose warfarin in one small study in patients with advanced breast cancer. There is also a case of increased bleeding times when megestrol was given with unnamed anticoagulants.

Clinical evidence, mechanism, importance and management

In a study in patients with advanced breast cancer, a single 0.3-mg/kg doses of **warfarin** were given to 2 patients before and after oral medroxyprogesterone acetate 500 mg twice daily for 5 weeks and to 2 patients before and after megestrol 160 mg daily for 5 weeks. The half-life of **warfarin** was increased by 71% and the clearance decreased by 35%.¹ A bulletin includes a brief mention of increased bleeding times in a patient taking unnamed anticoagulants and given **megestrol** (dose not stated).²

Although the evidence is limited, what is known suggests that it would be prudent to monitor prothrombin times in patients taking **warfarin** who are high-dose medroxyprogesterone acetate or megestrol, being alert for any increased warfarin effects.

2. Beeley L, Stewart P, Hickey FM. *Bulletin of the West Midlands Centre for Adverse Drug Reaction Reporting* (1988) 27, 24.

Coumarins + Mefloquine

The effects of warfarin and an unnamed coumarin were increased in two patients who took mefloquine.

Clinical evidence, mechanism, importance and management

A 66-year-old man taking **warfarin** and various other drugs presented to an emergency department unwell with a distended abdomen while travelling in Kenya. His prothrombin time was grossly prolonged and the distension was found to be due to bleeding. One week before travel he had started mefloquine 250 mg weekly without a check of his prothrombin time. He was given subcutaneous enoxaparin instead of **warfarin** while continuing the mefloquine. Another patient taking a coumarin and oral anti-diabetics presented with hypoglycaemia and a large haematoma of the right leg after taking 3 doses of mefloquine 250 mg weekly. His INR was 6.4.¹

The author considered that mefloquine may have caused the increased anticoagulation in these two cases, and suggested that mefloquine should be started several weeks before travel to allow for monitoring of any changes in anticoagulant effects.¹ The manufacturers of mefloquine also recommend that, before departure, travellers also taking anticoagulants should be checked for any alteration in their effect.^{2,3} This is probably prudent, although patients should be advised that many other factors to do with travel such as altered diet could contribute to a change in anticoagulant control.

Coumarins + Menthol lozenges

A man had a reduction in the effects of warfarin, which were attributed to the use of menthol cough lozenges during a flu-like illness.

Clinical evidence, mechanism, importance and management

A 57-year-old man taking **warfarin** 49 mg weekly with an INR in the range of 2.28 to 2.68 for the previous 3 weeks was found to have an INR of 1.45. He had been unwell with a flu-like illness over the past week, for which he had been taking about 6 *Halls* menthol cough lozenges (cough

drops) per day for 4 days. He said he had not changed his diet or missed any warfarin doses. The **warfarin** dose was increased to 53 mg weekly for a week with an INR rise to 2.2, then the **warfarin** dose was decreased to 52 mg weekly with an INR of 3.06, so the previous dose of 49 mg weekly was resumed with an INR of 2.92.¹

Whether this case represents an interaction with the menthol lozenges is uncertain. Further study is needed.

1. Kassebaum PJ, Shaw DL, Tomich DJ. Possible warfarin interaction with menthol cough drops. *Ann Pharmacother* (2005) 39, 365–7.

Coumarins + Meprobamate

The anticoagulant effects of warfarin are not altered to a clinically relevant extent by meprobamate.

Clinical evidence, mechanism, importance and management

Meprobamate 400 mg four times daily for 2 weeks was given to 9 patients stabilised on **warfarin**. Three of them showed a small increase in prothrombin times, five a small decrease and one remained unaffected: all the changes were considered to fall within the range of variations normally seen in clinical practice.¹ Moreover, in a later placebo-controlled study in 17 patients taking **warfarin**, the 8 patients who were also given meprobamate 2.4 g daily for 4 weeks showed only a small clinically unimportant reduction in prothrombin times.² Similar results were found in another study.³ No **warfarin** dose adjustments would therefore seem to be needed if meprobamate is added to established treatment with **warfarin**.

Coumarins + Mesalazine (Mesalamine) or Sulfasalazine

A single case report describes reduced warfarin effects in a patient given mesalazine. Another single case report describes a marked reduction in the response to warfarin when mesalazine was switched to sulfasalazine.

Clinical evidence

(a) Mesalazine

A woman stabilised on **warfarin** 5 mg daily, with INRs between 2 and 3, started taking mesalazine 800 mg three times daily for the treatment of a caecal ulcer. Four weeks later she presented to hospital with left leg pain, which was diagnosed as an acute popliteal vein thrombosis, and at the same time it was found that her prothrombin time and INR had fallen to 11.3 seconds and 0.9, respectively. The patient was treated with intravenous heparin. Over the next 10 days INRs of up to 1.7 were achieved by increasing the doses of **warfarin** up to 10 mg daily, but a satisfactory INR of 2.1 was only reached when the mesalazine was stopped. The report says that serum **warfarin** levels were not detectable during the use of mesalazine.¹ For discussion of a patient who had a reduction in the response to warfarin when switched from mesalazine to sulfasalazine, see below.

(b) Sulfasalazine

A 37-year-old woman taking **warfarin** 30 mg weekly with stable INRs between 2 and 3 in the previous 2 years (and also taking beclometasone, salbutamol, aspirin, azathioprine, ethinyloestradiol/norgestrel), had her treatment for arthritis and ulcerative colitis changed from **mesalazine** to sulfasalazine 1 g four times daily. The day after the change her INR was found to be subtherapeutic (1.5) and she needed numerous increases in the **warfarin** doses over the next 6 weeks, eventually needing **warfarin** 75 mg weekly before acceptable INRs were achieved. During this period she developed a new deep vein thrombosis. When the sulfasalazine was later stopped and the mesalazine restarted, her **warfarin** dosage requirements dropped to 45 mg weekly.²

Mechanism

Not understood. Sulfasalazine is broken down in the colon to a sulfonamide, sulfapyridine, and 5-aminosalicylic acid (mesalazine). Some 'sulfonamides', (p.376) are known inhibitors of warfarin metabolism, and increase the effects of warfarin. In contrast, in the case with sulfasalazine a marked decrease was noted.

Importance and management

Not established. The case of a reduction in effect of warfarin on starting mesalazine appears to be the first and only report of an interaction, which suggests that it is unlikely to be of general importance. Similarly, the case when mesalazine was switched to sulfasalazine is an unexplained and isolated case, and its validity has been debated.^{3,4} There are no other reports in the literature and this possible interaction also seems unlikely to be of general importance. Consider these cases in the event of an unexpected response to treatment.

Coumarins + Methaqualone

Methaqualone may cause a very small and clinically unimportant reduction in the anticoagulant effects of warfarin.

Clinical evidence, mechanism, importance and management

The average prothrombin time of 10 patients stabilised on **warfarin** was 20.9 seconds before, 20.4 seconds during, and 19.6 seconds after taking methaqualone 300 mg at bedtime for 4 weeks.¹ The plasma **warfarin** levels of another patient were unaffected by methaqualone, although there was some evidence that enzyme induction had occurred.² Methaqualone has some enzyme-inducing effects so that any small changes in prothrombin times reflect a limited increase in the metabolism and clearance of **warfarin**, but these appear to be too small to be of clinical significance.^{2,3} No special precautions seem to be necessary.

Coumarins + Methylphenidate

Methylphenidate appears not to interact with ethyl biscoumate.

Clinical evidence, mechanism, importance and management

In one study in 4 healthy subjects, the half-life of a single dose of **ethyl biscoumate** was approximately doubled after they took methylphenidate 20 mg daily for 3 to 5 days.¹ However, a later double-blind, placebo-controlled study failed to confirm this interaction: the half-life of **ethyl biscoumate** was not altered by methylphenidate 20 mg daily for 4 days in 4 healthy subjects, and was not different to that seen in 4 subjects given placebo.² The first authors suggested that methylphenidate inhibits the metabolism of the oral anticoagulant, but this seems unlikely given the findings of the second study.

Although the findings of these 2 studies are at odds with each other, the better-controlled study and the lack of reports of problems in the literature suggest that an interaction is unlikely. There does not seem to be any information about other anticoagulants. Nevertheless the manufacturers recommend caution and suggest that patients taking coumarins should have their INR monitored if methylphenidate is started or stopped.³

Coumarins + Metoclopramide

Metoclopramide caused a small decrease in the AUC of phenprocoumon, without altering its anticoagulant effects seemed to occur.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, metoclopramide 30 mg daily for 10 days slightly reduced the AUC of a single dose of **phenprocoumon** given on day 4 by 16%, but no significant changes were seen in the anticoagulant effects.¹ This suggests that no phenprocoumon dose adjustment would be expected to be necessary if these two drugs are given together. There seems to be no information about any other anticoagulant.

- Wesermeyer D, Mönig H, Gaska T, Masuch S, Seiler KU, Huss H, Bruhn HD. Der Einfluß von Cisaprid und Metoclopramid auf die Bioverfügbarkeit von Phenprocoumon. *Hamostaseologie* (1991) 11, 95–102.

Coumarins + Metrifonate

Metrifonate did not interact with single-dose warfarin in one study.

Clinical evidence, mechanism, importance and management

A double-blind, placebo-controlled, crossover study in 14 healthy subjects found that metrifonate 50 mg daily for 8 days did not change the pharmacokinetics and pharmacodynamics of a single 25-mg dose of **warfarin** given on day 4. Plasma **warfarin** levels and prothrombin times remained unchanged.¹ This suggests that no **warfarin** dose adjustments are needed if these two drugs are used concurrently. Information about other anticoagulants is lacking.

- Heinig R, Kitchin N, Rolan P. Disposition of a single dose of warfarin in healthy individuals after pretreatment with metrifonate. *Clin Drug Invest* (1999) 18, 151–9.

Coumarins + Misoprostol

A reduction in the anticoagulant effects of acenocoumarol has been attributed to the use of misoprostol in one patient.

Clinical evidence, mechanism, importance and management

A 39-year-old woman taking **acenocoumarol**, celiprolol, triamterene, cyclothiazide, pravastatin and diosmin had a rise in her prothrombin levels from 0.3 to 1 within 8 days of starting to take diclofenac and misoprostol 400 micrograms daily. A day after these two drugs had been withdrawn her prothrombin level had fallen to 0.67, and after another 3 days to 0.32.¹ The reasons for this reaction are not known, but suspicion falls on the misoprostol because diclofenac, if and when it interacts with anticoagulants, increases rather than reduces their effects (see 'Coumarins + NSAIDs; Diclofenac', p.429). But just why misoprostol should cause these changes is not clear.

This is an isolated case, complicated by the presence of a number of other drugs, which suggests that it is unlikely to be of general importance. More study is needed.

- Martin MP, Jonville-Bera AP, Bera F, Caillard X, Autret E. Interaction entre le misoprostol et l'acenocoumarol. *Presse Med* (1995) 24, 195.

Coumarins + Moracizine

Moracizine did not alter the pharmacodynamics of single-dose warfarin, and the only pharmacokinetic change was a slight decrease in half-life. An isolated report describes bleeding in a patient taking warfarin with moracizine.

Clinical evidence

In a study in 12 healthy subjects, moracizine 250 mg every 8 hours for 21 days caused little or no change in the pharmacokinetics of a single 25-mg dose of **warfarin** given on day 14. There was only a slight decrease in the **warfarin** elimination half-life, from 37.6 to 34.2 hours, and no change in prothrombin times.^{1,2} The manufacturer also noted that clinical experience in 34 patients showed that no significant changes in **warfarin** dosage requirements were needed after moracizine was started.¹

However, in one case report the prothrombin time of a woman taking **warfarin**, digoxin, captopril and prednisone rose from a range of 15 to 20 seconds up to 41 seconds within 4 days of starting moracizine 300 mg three times daily. She bled (haematemesis, haematuria), but responded rapidly to withdrawal of the **warfarin** and moracizine, and the administration of phytonadione.³

Mechanism

Not understood.

Importance and management

Information appears to be limited to these reports. The study and early clinical experience suggest that no interaction occurs. The case of an increased effect seems to be an isolated report, and therefore unlikely to be of general importance.

- Serpa MD, Cossolias J, McGreevy MJ. Moricizine-warfarin: a possible interaction. *Ann Pharmacother* (1992) 26, 127.

Coumarins + Nefazodone or Trazodone

In a one study, nefazodone decreased the level of S-warfarin by just 12% and did not alter the prothrombin ratio. A handful of case reports describe a moderate reduction in the anticoagulant effects of warfarin caused by trazodone.

Clinical evidence

(a) Nefazodone

In one study, 17 healthy subjects given **warfarin** to achieve a prothrombin ratio of 1.2 to 1.5 for 14 days were then given nefazodone 200 mg or placebo every 12 hours for a further 7 days. The only pharmacokinetic changes were a 12% decrease in the AUC and maximum serum levels of S-warfarin. No changes occurred in the prothrombin ratios.¹

(b) Trazodone

In an early case series, a patient stabilised on **warfarin** was given trazodone 75 mg daily for 8 days without any significant changes in the prothrombin time. Similarly, the same dosage of trazodone had no obvious effect on prothrombin time in a patient who had recently started taking **phenprocoumon** and another who had recently started taking **ethyl biscoumacetate**.² However, in another report, a woman needed a small increase in her **warfarin** dose, from 6.4 to 7.5 mg daily, when she was given trazodone 300 mg daily, in order to maintain her prothrombin time at 20 seconds. Her **warfarin** requirements fell when the trazodone was later withdrawn.³ A retrospective review from June 1998 to June 1999 identified 75 patient taking both trazodone and **warfarin**. Of the patients who had started trazodone during this period (number not stated), at least 3 had a probable interaction. One had a decrease in INR from 2.79 to 1.07 six days after starting trazodone, and needed a 25% increase in the dose of **warfarin**. Another patient had an increase in INR when he ran out of trazodone, and a decrease in INR on restarting the trazodone. A third required a 39% increase in **warfarin** dose after starting trazodone.⁴ The manufacturer in the US notes that there have been reports of both increased and decreased prothrombin times in patients taking warfarin with trazodone.⁵

Mechanism

Unknown.

Importance and management

The incidence of this interaction is unknown. All the evidence suggests that some patients require a moderate increase in warfarin dose when starting trazodone. Be aware of this interaction in all patients taking warfarin if trazodone is started or stopped, and adjust the dosage if necessary. The interaction can occur within a few days. The clinical relevance of the 12% decrease in *S*-warfarin levels seen with nefazodone is likely to be minor. The authors of the study concluded that no change in warfarin dose is likely to be required on concurrent use.¹

Coumarins + Nevirapine

One report of 3 cases suggests that warfarin requirements are markedly increased by nevirapine.

Clinical evidence, mechanism, importance and management

A man taking **warfarin** 2.5 mg daily (INR 2.1 to 2.4) needed a doubled **warfarin** dose when his treatment with zidovudine and didanosine was replaced by stavudine, lamivudine and nevirapine. A few days later when his treatment was again changed (to stavudine, lamivudine and saquinavir) his original **warfarin** dosage was found to be adequate. Another patient was resistant to doses of **warfarin** of up to 17 mg daily while taking zidovudine, lamivudine and nevirapine, but he responded to **warfarin** 5 mg daily when the nevirapine was withdrawn. The warfarin dosage had to be raised to 12 mg daily when nevirapine was restarted. Yet another patient showed resistance to **warfarin** while taking nevirapine.¹

Nevirapine is a known enzyme inducer, and therefore possibly induces the enzymes concerned with the metabolism of the **warfarin**.

Information seems to be limited to these three cases, but it would be prudent to monitor prothrombin times and INRs in any patient if **warfarin** and nevirapine are used concurrently, being alert for the need to increase the **warfarin** dosage (possibly twofold). Information about other oral anticoagulants seems to be lacking, but if the suggested mechanism is correct, all coumarins would be expected to interact to some extent.

- Dionisio D, Mininni S, Bartolozzi D, Esperti F, Vivarelli A, Leoncini F. Need for increased dose of warfarin in HIV patients taking nevirapine. *AIDS* (2001) 15, 277–8.

Coumarins and related drugs + NSAIDs

Combined use of NSAIDs and coumarin anticoagulants increases the risk of gastrointestinal haemorrhage. Care is needed with the combination. Some individual NSAIDs also alter the pharmacokinetics of warfarin, and these effects are covered in specific monographs that follow.

Clinical evidence

(a) Gastrointestinal bleeding

In a retrospective cohort study of patients hospitalised for peptic ulcer disease, combined current use of both oral anticoagulants and NSAIDs was associated with a marked increase in the risk of haemorrhagic peptic ulcer disease of 12.7 (95% confidence interval 6.3 to 25.7). This was much higher than the risk associated with NSAIDs alone or oral anticoagulants alone (both about a fourfold increased risk). In this study, about 10% of the hospitalisations for haemorrhagic peptic ulcer disease in patients taking anticoagulants were attributed to the concurrent use of NSAIDs. The

oral anticoagulants used were the coumarins **warfarin**, **phenprocoumon** and **acenocoumarol**, and the indanediones **phenindione** and **anisindione**. The NSAIDs used were nonacetylated salicylates, **ibuprofen**, **indometacin**, **sulindac**, **naproxen**, **fenoprofen**, **piroxicam**, **tolmetin**, and **meclofenamate**.¹

In a case-control study, patients taking **warfarin** who were admitted to hospital with upper gastrointestinal haemorrhage were significantly more likely to be taking non-selective NSAIDs (odds ratio 1.9). A similar increased risk was seen with the ‘coxibs’, (p.428), **celecoxib** and **rofecoxib**.² Similarly, in a questionnaire-based study, 12.2% of patients taking **acenocoumarol** or **phenprocoumon** who had a bleeding complication were found to have used an NSAID in the previous month compared with only 2.5% of coumarin users who did not have a bleed (an increased relative risk of bleeding of 5.8). The NSAIDs used in the patients with bleeding complications were **diclofenac** (more than 50% patients), **ibuprofen**, **indometacin**, **naproxen** (all 10 to 12%), **ketoprofen**, **piroxicam**, and **tiaprofenic acid** (all 1 to 6%). The specific NSAIDs and the frequency of their use was similar in the patients without bleeds.³

(b) Pharmacokinetic interactions

‘Phenylbutazone’ (p.434) and related drugs are well known to inhibit the metabolism of **warfarin** by the cytochrome P450 isoenzyme CYP2C9. Few other NSAIDs are known CYP2C9 inhibitors; however, many are CYP2C9 substrates. In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, use of NSAIDs that are known substrates of CYP2C9 (**celecoxib**, **diclofenac**, **flurbiprofen**, **ibuprofen**, **indometacin**, **ketoprofen**, **meloxicam**, **naproxen** and **piroxicam**) slightly increased the risk of over-anticoagulation (INR greater than 6) in patients with wild-type CYP2C9 (relative risk of 1.69). However, the risk was greater in patients with variant CYP2C9 (relative risk 2.28), and particularly high in those with *3 variant alleles (relative risk 10.8).⁴ In another smaller retrospective cohort study, starting the CYP2C9 substrates **diclofenac**, **naproxen**, or **ibuprofen** increased the INR above the therapeutic range in 52 of 112 patients taking **acenocoumarol**. However, in this study CYP2C9 genotype did not influence the interaction between **acenocoumarol** and **diclofenac**, **naproxen**, and **ibuprofen**.⁵ For more general information, see ‘Genetic factors in drug metabolism’, (p.4).

Mechanism

NSAIDs, to a greater or lesser extent irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Many also have antiplatelet activity, which can affect bleeding times.

Some NSAIDs are inhibitors of the cytochrome P450 isoenzyme CYP2C9, and inhibit the metabolism of warfarin via this isoenzyme. There is also possibly a pharmacokinetic interaction with NSAIDs that are substrates for CYP2C9. People with variant CYP2C9 (about 5 to 11% of Caucasians) have a lower metabolising capacity for warfarin, and require much lower maintenance doses. It is possible that use of an NSAID that is a CYP2C9 substrate may result in reduced warfarin metabolism, although this requires confirmation in controlled studies.

Importance and management

The available data indicate that the risk of bleeding is increased if NSAIDs are used in patients taking coumarin or **indanedione** anticoagulants. For this reason, it would be prudent to avoid the unnecessary concurrent use of NSAIDs when simple analgesics will do. When concurrent use is necessary, extra caution may be appropriate. Further study is required to ascertain whether people with CYP2C9 poor metabolising capacity are at increased risk of an interaction when given NSAIDs that are CYP2C9 substrates.

Coumarins + NSAIDs; Benzydamine

Oral benzydamine did not alter the anticoagulant effects of phenprocoumon. Topical formulations (mouthwash and spray) would not be expected to interact.

Clinical evidence, mechanism, importance and management

In 10 patients stabilised on **phenprocoumon**, the anticoagulant response was not significantly changed by benzydamine 50 mg three times daily for 2 weeks, although there was some evidence of an increase in blood levels of the anticoagulant.¹ This suggests that no **phenprocoumon** dosage adjustments are likely to be needed on concurrent use. Note that benzydamine tends to be used as a topical mouthwash or spray. Neither of these topical formulations would be expected to interact.

Coumarins + NSAIDs; Clonixin

Clonixin lysine did not alter the anticoagulant effects of phenprocoumon in a pharmacological study. However, note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study in 12 healthy men, the pharmacokinetics and the anticoagulant activity of a single 18-mg dose of **phenprocoumon** were unchanged by clonixin lysine 125 mg five times daily, given for 3 days before and for 13 days after the **phenprocoumon**.¹ On the basis of this study, no adjustment in coumarin dose would be expected to be needed when clonixin is used. However, care is still needed with every NSAID, because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. For more information, see 'NSAIDs', (p.427).

Coumarins and related drugs + NSAIDs; Coxibs

Etoricoxib, lumiracoxib and rofecoxib caused a slight 8% to 15% increase in the INR in response to warfarin, whereas celecoxib and parecoxib had no effect. However, raised INRs accompanied by bleeding, particularly in the elderly, have been attributed to the use of warfarin and celecoxib or rofecoxib in other reports. In addition, in a case-control study in patients taking warfarin, the use of celecoxib or rofecoxib was associated with an increased risk of hospitalisation for upper gastrointestinal haemorrhage, which was of a similar magnitude to that seen with non-selective NSAIDs.

Clinical evidence

(a) Celecoxib

In a placebo-controlled study, **warfarin** 2 to 5 mg daily was given to 24 healthy subjects to maintain a stable prothrombin time of 1.2 to 1.7 times their pretreatment values for at least 3 consecutive days. They were then given placebo or celecoxib 200 mg twice daily for a week. It was found that the steady-state pharmacokinetics of both *S*- and *R*-warfarin and the prothrombin times were unchanged by the presence of the celecoxib.¹

However, in 16 patients stabilised on **warfarin** and given celecoxib 200 mg daily for 3 weeks, the INR increased by 13%, 6% and 5% at week 1, 2 and 3, respectively, the change at week 1 being statistically significant.² In another analysis, of 28 patients taking **warfarin** who were prescribed either celecoxib or rofecoxib, 13 had increases in their INR, of which 7 (5 taking celecoxib) had no other explanation for the INR increase

other than the coxib. The average increase in INR in these 7 patients was 1.5, and one patient had bruising and epistaxis and required treatment with phytomenadione.³

Case reports of an interaction have also been published.^{4–9} In one report, an 88-year-old woman stabilised on **warfarin** had a rise in her INR from 3.1 to 5.8 when celecoxib 200 mg daily was substituted for diclofenac. After several **warfarin** dosage adjustments she was later restabilised on a 25% lower **warfarin** dose.⁴ There is a similar case report of a 77-year old patient who required a 10% decrease in **warfarin** dosage to maintain her target INR when celecoxib 100 mg twice daily was also given.⁷ In another case, the patient was shown to have a variant of CYP2C9, with lower metabolising capacity, which was thought to explain the interaction,⁹ see also 'Mechanism', below. The manufacturers also noted that bleeding events have been reported with this combination, predominantly in the elderly, which led to a change in the product labelling.¹⁰ A 2001 report from the Australian Adverse Drug Reactions Advisory Committee noted they had received 21 reports of increases in the INR in patients taking **warfarin** with celecoxib since the introduction of celecoxib in October 1999. Six of these cases reported bleeding complications. In addition, they had 11 cases of bleeding in patients taking the combination, with no reference to INR, or with an unchanged INR in one case.¹¹ A review of adverse effects of coxibs mentioned 2 patients taking **warfarin** who had increases in their INR while taking celecoxib.¹²

Moreover, in a case-control study, patients taking **warfarin** and admitted to hospital with upper gastrointestinal haemorrhage were significantly more likely to be also taking celecoxib (odds ratio 1.7). A similar increased risk was seen with rofecoxib and non-selective 'NSAIDs', (p.427).¹³ In a retrospective analysis, the relative risk of all bleeding complications was slightly increased (1.34) in 123 patients taking celecoxib with **warfarin** when compared with 1022 control patients taking **warfarin** alone.¹⁴

(b) Etoricoxib

The manufacturer notes that in healthy subjects stabilised on **warfarin**, etoricoxib 120 mg daily increased the INR by about 13%.¹⁵

(c) Lumiracoxib

The manufacturer notes that in healthy subjects stabilised on **warfarin**, lumiracoxib 400 mg daily increased the INR by about 15%.¹⁶

(d) Parecoxib

In a randomised study in healthy subjects given **warfarin**, the use of intravenous parecoxib 10 mg twice daily for 7 days had no significant effects on prothrombin times when compared with placebo. Parecoxib did not affect the pharmacokinetics of *S*- or *R*-warfarin.¹⁷

(e) Rofecoxib

In a study in 12 healthy subjects,¹⁸ rofecoxib 50 mg daily for 12 days increased the maximum INR after a single 30-mg dose of **warfarin** given on day 7 by about 14%. In a steady-state study, 15 healthy subjects were given **warfarin** 5 mg daily to produce a stable prothrombin time of 1.4 to 1.7 for at least 3 consecutive days. They were then additionally given rofecoxib 25 mg or placebo daily for 3 weeks. It was found that the 24-hour average INR was increased by 8.6% by rofecoxib. Rofecoxib had no effect on the pharmacokinetics of the more potent *S*-warfarin enantiomer, but the AUC of *R*-warfarin was increased by about 40% in both the single dose and steady-state studies.¹⁸ Moreover, in 16 patients stabilised on **warfarin** and given rofecoxib 25 mg daily for 3 weeks, the INR increased by 5%, 9%, and 5% at week 1, 2, and 3, respectively, the change at week 2 being statistically significant.² In one case report, an increase in INR was seen in two elderly patients taking **warfarin** and rofecoxib. The INRs were raised, in one case from less than 3 to 4.1 within a month of starting rofecoxib 12.5 mg daily, and in the other case from 3.2 to 4.6 within 2 days of starting rofecoxib. The INRs decreased when the **warfarin** dosage was reduced.³ In another case, this time in a patient taking **acenocoumarol**, the INR rose from the range of 2 to 3 up to over 8 two weeks after starting rofecoxib 50 mg daily.¹⁹ A 2002 report from the Australian Adverse Drug Reactions Advisory Committee noted that they had received 8 reports of increases in the INR of patients taking **warfarin** with rofecoxib since the introduction of rofecoxib in late 2000. Two of these cases reported bleeding complications. A further patient died of a cerebral haemorrhage, although the INR was stable.²⁰ A review of the adverse effects of coxibs included 5 patients taking **warfarin** who had increases in their INR while taking rofecoxib and **warfarin**.¹²

Moreover, in a case-control study, patients taking **warfarin** and admitted to hospital with an upper gastrointestinal haemorrhage were significantly more likely to be also taking rofecoxib (odds ratio 2.4).¹³ Note that rofecoxib has generally been withdrawn because of adverse cardiovascular effects.

Mechanism

Non-selective 'NSAIDs', (p.427), inhibit platelet aggregation and cause gastrointestinal toxicity, which can result in bleeding, the risk of which is increased in patients taking anticoagulants. Although coxibs are generally considered to be associated with a lower risk of gastrointestinal haemorrhage than non-selective NSAIDs, the only available comparative epidemiological study found a similar increased risk of bleeding when coxibs were given with warfarin.

There is also possibly a pharmacokinetic interaction. Both warfarin and celecoxib are substrates of the cytochrome P450 isoenzyme CYP2C9, and it is possible that people with variants of CYP2C9 with lower metabolising capacity may develop an interaction if given the combination. For more general information, see 'Genetic factors in drug metabolism', (p.4).

Rofecoxib possibly inhibits the metabolism of the less active *R*-warfarin via inhibition of CYP1A2,¹⁸ and the active *R*-acenocoumarol by the same isoenzyme and CYP2C19.¹⁹

Importance and management

The interaction of coumarin anticoagulants with these coxibs can be clinically significant, but is apparently rare. For example, of the 4 million prescriptions for celecoxib dispensed over the 18-month period from December 1998, about 1% were estimated to be for patients who would have been taking warfarin,¹⁰ and only a handful of cases of an interaction had been reported. However, the manufacturers recommend that anticoagulant activity should be monitored in patients taking warfarin, other coumarins, or indanediones, particularly in the first few days after initiating or changing the dose of a coxib. Others recommend increased monitoring for 3 weeks.² Some increased monitoring is certainly appropriate because all NSAIDs, including coxibs, can irritate the gastrointestinal tract and cause bleeding, the risk of which is increased with anticoagulants.

Coumarins + NSAIDs; Diclofenac

Studies suggest that diclofenac does not alter the anticoagulant effect of acenocoumarol, phenprocoumon or warfarin, suggesting dose adjustments are unlikely to be needed. Isolated cases of raised INRs have been described. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

In a crossover study in 29 patients stabilised on **acenocoumarol**, diclofenac 25 mg four times daily for one week did not alter the anticoagulant effect (prothrombin value) of **acenocoumarol**, when compared with placebo.¹ Other studies similarly confirm that diclofenac does not alter the anticoagulant effect of either **phenprocoumon**² or **warfarin**.³

However, a patient taking **acenocoumarol** developed a pulmonary haemorrhage associated with a very prolonged prothrombin time within 10 days of starting to take diclofenac.⁴ Another report mentions a Chinese patient taking **warfarin** who developed an INR of 4 within 4 days of using a 1% diclofenac topical gel for joint pain.⁵

For studies, including the one assessing the effect of CYP2C9 substrates, such as diclofenac, on the risk of bleeding when used with warfarin, see 'Coumarins and related drugs + NSAIDs', p.427.

Mechanism

See 'Coumarins and related drugs + NSAIDs', p.427.

Importance and management

On the basis of the pharmacological studies, no adjustment in coumarin dose would be anticipated to be needed when diclofenac is used. The isolated cases of raised INRs are unexplained. However, care is still needed with every NSAID because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. For more information about this and potential CYP2C9-mediated interactions, see 'Coumarins and related drugs + NSAIDs', p.427.

Coumarins + NSAIDs; Diflunisal

There is limited evidence to suggest that diflunisal might increase the anticoagulant effects of acenocoumarol and possibly warfarin, but probably not phenprocoumon. All NSAIDs increase the risk of gastrointestinal bleeding, and should be used with care in patients taking oral anticoagulants.

Clinical evidence

The total plasma **warfarin** levels of 5 healthy subjects fell by about one-third (from 741 to 533 nanograms/mL) when they were given diflunisal 500 mg twice daily for 2 weeks. Also, unbound **warfarin** increased from 1.02 to 1.34%, but the anticoagulant response was unaffected. When the diflunisal was withdrawn the anticoagulant response was reduced.¹ Another report very briefly describes an increased INR when a patient taking **warfarin** was given diflunisal.²

A brief report states that 3 out of 6 subjects taking **acenocoumarol** had significant increases in prothrombin times, but no interaction was seen in 2 subjects on **phenprocoumon**, when they were given diflunisal 750 mg daily.³

Mechanism

Uncertain. Diflunisal can displace warfarin from its plasma protein binding sites but this on its own is almost certainly not the full explanation.¹ The fall in anticoagulant response when diflunisal was stopped is possibly linked to a difference in the rates that total and unbound plasma warfarin returned to their original levels.¹

Importance and management

This interaction is neither well defined nor well documented. Its importance is uncertain. However, the reports cited and the manufacturers suggest that an increased anticoagulant effect should be looked for if diflunisal is added to established treatment with any anticoagulant. A decreased effect might be expected if diflunisal is withdrawn. Note that care is needed with every 'NSAID', (p.427), because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Coumarins + NSAIDs; Etodolac

In a pharmacological study, etodolac did not interact significantly with warfarin, suggesting dose adjustments are unlikely to be needed. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence, mechanism, importance and management

In a three-period, crossover study, each period lasting 2.5 days 18 healthy subjects were given **warfarin** 20 mg on day 1, 10 mg on days 2 and 3 and etodolac 200 mg every 12 hours. Although the median peak serum levels of the **warfarin** fell by 19% and the median total clearance rose by 13% in the presence of etodolac, the prothrombin time response remained unchanged.^{1,2} On the basis of this study, no adjustment in coumarin dose would be expected to be needed when etodolac is used. However, care is still needed with every 'NSAID', (p.427), because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Coumarins and related drugs + NSAIDs; Fenamates

In pharmacological studies, the anticoagulant effect of acenocoumarol was modestly increased by floclofenine, that of phenprocoumon was increased by floclofenine and glafenine, and that of warfarin was increased to some extent by meclofenamic acid and mefenamic acid. Tolfenamic acid might be expected to interact similarly. However, limited evidence from one small study found glafenine did not alter the response to acenocoumarol, or ethyl biscoumacetate. Note also that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

(a) Floclofenine

In a double-blind study in 20 patients stabilised on **acenocoumarol** or **phenprocoumon** and given either floclofenine 200 mg or placebo four times daily for 3 weeks, floclofenine prolonged their thrombotest times by an average of about one-third, even though the anticoagulant dosage of some of the patients was reduced.¹

(b) Glafenine

In a double-blind study in 20 patients stabilised on **phenprocoumon** and given either glafenine 200 mg or placebo three times daily it was noted that within a week of starting glafenine there was a significant increase in thrombotest times.² In another report, 5 out of 7 patients needed a **phenprocoumon** dose reduction while taking glafenine.³ Conversely, in another study, 10 patients taking **acenocoumarol**, **ethyl biscoumacetate** or '**indanedione**' had no changes in their anticoagulant response when given glafenine 800 mg daily over a 4-week period.⁴

(c) Meclofenamic acid

After taking sodium meclofenamate 200 to 300 mg daily for 7 days, the average dose of **warfarin** required by 7 patients fell from 6.5 to 4.25 mg daily, and by the end of 4 weeks it was 5.5 mg (a 16% reduction with a 0 to 25% range).⁵

(d) Mefenamic acid

After taking mefenamic acid 500 mg four times daily for a week the mean prothrombin concentrations of 12 healthy subjects stabilised on **warfarin** fell by about 3.5%. Microscopic haematuria was seen in 3 of them, but no overt haemorrhage. Their prothrombin concentrations were 15 to 25% of normal, well within the accepted anticoagulant range.⁶

Mechanism

Uncertain. Mefenamic acid can displace warfarin from its plasma protein binding sites,^{7,9} and *in vitro* studies have shown that therapeutic concentrations (equivalent to 4 g daily) can increase the unbound and active warfarin concentrations by 140 to 340%,^{7,8} but this interaction mechanism alone is only likely to have a transient effect. See also 'Coumarins and related drugs + NSAIDs', p.427.

Importance and management

The pharmacological studies cited suggest that all the fenamates can cause a small to modest increase in the effects of coumarin anticoagulants. If both drugs are given, increase monitoring and anticipate the need for a small reduction in coumarin dosage. Although there are no data on combined use with the fenamate **tolfenamic acid**, the manufacturer similarly recommends close monitoring of coagulation.¹⁰ Also note that, all 'NSAIDs', (p.427), to a greater or lesser extent irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Coumarins + NSAIDs; Ibuprofen and related drugs

In pharmacological studies, ibuprofen, indoprofen, ketoprofen, naproxen and oxaprozin did not alter the anticoagulant effect of coumarins, but isolated cases of raised INRs have been described with ibuprofen and ketoprofen. A slight increase in anticoagulant effect has been seen with fenbufen, flurbiprofen and tiaprofenic acid, although the clinical relevance is probably small. However, note also that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

(a) Fenbufen

In a study in 10 healthy subjects who were stabilised on **warfarin** then given either fenbufen 400 mg twice daily or placebo for a week, the prothrombin times were increased by 1.9 seconds within 2 days in the fenbufen recipients, and the serum **warfarin** levels fell by 14%.¹

(b) Flurbiprofen

A small but significant fall in Quick value (from 23.84 and 25.05% to 20.68 and 20.29%) occurred in 19 patients stabilised on **phenprocoumon** when they were given flurbiprofen 50 mg three times daily for 2 weeks. Two patients bled (haematuria, epistaxis, haemorrhoidal bleeding) and the prothrombin times of 3 patients fell below the therapeutic range.²

A case report describes two patients taking **acenocoumarol** who had a rise in thrombotest times and bled (haematuria, melaena, haematomas) within 2 to 3 days of starting to take flurbiprofen 150 to 300 mg daily.³

(c) Ibuprofen

Ibuprofen 600 mg to 2.4 g daily for 7 to 14 days did not alter the effects of coumarins in studies in: patients stabilised on **phenprocoumon**;⁴⁻⁶ healthy subjects^{7,8} or patients⁸ stabilised on **warfarin**; or patients stabilised on **dicoumarol**.⁹ However, in one study in 20 patients taking **warfarin**, ibuprofen 600 mg three times daily for 1 week had no effect on prothrombin time; however, it did prolong bleeding time (4 cases above the normal range) and microscopic haematuria and haematoma were seen.¹⁰ Note that, this finding is probably more of a function of the effect of ibuprofen than an interaction *per se*,¹¹ although it does explain why the combination of an anticoagulants and an 'NSAID', (p.427), has an increased risk of haemorrhage.

A raised INR occurred in one patient on **warfarin** who used topical ibuprofen,¹² and subclinical bleeding with a raised INR occurred in a 74-year-old woman with multiple medical problems taking **warfarin** when she was given ibuprofen.¹³ For studies, including one assessing the effect of CYP2C9 substrates, such as diclofenac, on the risk of bleeding, see 'Coumarins and related drugs + NSAIDs', p.427.

(d) Indoprofen

In a placebo-controlled study in 18 patients stabilised on **warfarin** and given indoprofen 600 mg daily for 7 days, no changes occurred in any of the blood coagulation measurements made.¹⁴

(e) Ketoprofen

In a study in 15 healthy subjects stabilised on **warfarin**, ketoprofen 100 mg twice daily for 7 days had no effect on prothrombin times or coagulation cascade parameters, and there was no evidence of bleeding.¹⁵ This contrasts with an isolated case of bleeding in a patient taking **warfarin** (prothrombin time increased from 18 to 41 seconds) a week after starting ketoprofen 25 mg three times daily.¹⁶

(f) Naproxen

In a study in 10 healthy subjects, naproxen 375 mg twice daily for 17 days did not alter the pharmacokinetics of a single dose of **warfarin** given on day 10, or its anticoagulant effects.¹⁷ Similar results were found in a study of **warfarin** at steady state.¹⁸ A further study in patients taking **phenprocoumon** showed that naproxen 250 mg twice daily transiently increased the anticoagulant effects and caused an unimportant change in primary bleeding time.¹⁹

For studies, including one assessing the effect of CYP2C9 substrates, such as diclofenac, on the risk of bleeding, see 'Coumarins and related drugs + NSAIDs', p.427.

(g) Oxaprozin

In a study in 10 healthy subjects stabilised on **warfarin** for an average of 15 days, oxaprozin 1.2 g daily for 7 days did not significantly alter prothrombin times.²⁰

(h) Tiaprofenic acid

In a study in 6 healthy subjects, the anticoagulant effects and the pharmacokinetic profile of **phenprocoumon** remained unchanged when they took tiaprofenic acid daily for 2 days.²¹ This study is also published elsewhere.²² No significant interaction occurred in 9 patients stabilised on **acenocoumarol** and given tiaprofenic acid 200 mg three times daily for

2 weeks, but in 4 patients a 'rebound' rise in prothrombin percentages occurred following withdrawal of the NSAID.²³ However, an elderly man taking **acenocoumarol** had severe epistaxis and bruising 4 to 6 weeks after starting to take tiaprofenic acid 300 mg twice daily. His prothrombin time had risen to 129 seconds.²⁴

Mechanism

When given alone, ibuprofen and related drugs can prolong bleeding times because of their antiplatelet effects.¹¹ They may also cause gastrointestinal toxicity. Because of these effects, in patients on anticoagulants, the risk of bleeding is increased by 'NSAIDs', (p.427). Most of the propionic acid derivatives can displace the anticoagulants from plasma protein binding sites to some extent, but this mechanism on its own is rarely, if ever, responsible for clinically important drug interactions.

Importance and management

It is well established that ibuprofen does not alter the anticoagulant effect of warfarin or other coumarins, (although isolated and unexplained cases of bleeding or raised INRs have occurred but only very rarely). On the basis of these studies, no adjustment in coumarin dose would be anticipated to be needed when ibuprofen is used. Pharmacological studies also show no interaction for related propionic acid derivatives including indoprofen, ketoprofen, naproxen and oxaprozin, although the documentation is more limited. A slight increase in anticoagulant effects has been seen with fenbufen, flurbiprofen, and possibly tiaprofenic acid, although this is probably of limited clinical relevance. However, note that some care is still needed with every NSAID, because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. For more information about this and potential CYP2C9-mediated interactions, see 'Coumarins and related drugs + NSAIDs', p.427.

Coumarins + NSAIDs; Indometacin and related drugs

In pharmacological studies, the anticoagulant effects of acenocoumarol, phenprocoumon and warfarin were not affected by indometacin, or phenprocoumon by acemetacin. However, isolated cases of a possible interaction with a raised INR and bleeding complications have been reported. Also, note that, like all NSAIDs, indometacin can irritate the gut thereby increasing the risk of gastrointestinal bleeding, the risk of which is further increased in patients taking anticoagulants.

Clinical evidence

(a) Acemetacin

In a placebo-controlled study in 20 patients stabilised on phenprocoumon, acemetacin 60 mg three times daily for 3 weeks did not alter the thromboplastin value.¹

(b) Indometacin

In a placebo-controlled, double-blind study, indometacin 100 mg daily for 5 days had no effect on the anticoagulant effects of steady-state warfarin in 8 healthy subjects.² Similarly, when 19 healthy subjects took either indometacin 25 mg four times daily or placebo for 11 days, neither the anticoagulant effects nor the half-life of single doses of warfarin were affected.²

Other studies in healthy subjects and patients anticoagulated with acenocoumarol³ or phenprocoumon⁴⁻⁶ similarly showed that the anticoagulant effects were not changed by indometacin.

However, isolated cases of possible interactions in patients taking warfarin have been reported.⁷⁻¹⁰ One patient had a rise in INR from 2 to 5.3,⁸ and another had a rise from 2.75 to 3.42, then to 3.6 despite a reduction in warfarin dose.¹⁰ However, there are other possible interpretations of this case.¹¹ In another report a patient taking indometacin appeared to have an enhanced response to warfarin, which subsequently improved when ibuprofen was substituted for indometacin.⁷ The preliminary report of an analysis of possible drug interactions with warfarin stated that indometacin was found to have a clinically relevant effect on the anticoagulant action of warfarin.¹² One patient taking warfarin and indometacin died from acute peptic ulceration.¹³ Another report includes the interaction in a list, with no details.⁹ In a recent report, a patient who was very sensitive to acenocoumarol was found to have melaena and an INR of greater than 10 a week after starting indometacin and tetrazepam. He was found to have poor metaboliser phenotype of isoenzyme CYP2C9 (variant *3).¹⁴ For studies, including the one assessing the effect of CYP2C9 substrates, such as diclofenac, on the risk of bleeding, see 'Coumarins and related drugs + NSAIDs', p.427.

Mechanism

None. Indometacin reduces platelet aggregation and thereby prolongs bleeding when it occurs. Acemetacin would act similarly since it is a glycolic acid ester of indometacin and indometacin is the major metabolite.

Importance and management

In pharmacological studies it is well established that indometacin does not normally alter the anticoagulant effects acenocoumarol, phenprocoumon or warfarin. No coumarin dose adjustments would therefore be expected to be needed during concurrent use. However, caution is still appropriate, because indometacin, like other NSAIDs, can cause gastrointestinal irritation, ulceration and bleeding, which will be more severe in anticoagulated patients. For more information about this and potential CYP2C9-mediated interactions, see 'Coumarins and related drugs + NSAIDs', p.427.

Coumarins and related drugs + NSAIDs; Ketorolac

Ketorolac did not alter the pharmacokinetics of, or prothrombin time response to, warfarin. However, ketorolac has been associated with serious gastrointestinal bleeding.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study¹ in 10 healthy subjects, ketorolac 10 mg four times daily for 12 days caused no major changes in the pharmacokinetics of *R*- or *S*-warfarin, nor in the prothrombin time after a single 25-mg dose of warfarin given on day 6. This suggests that ketorolac is normally unlikely to affect the anticoagulant response of patients taking warfarin chronically, and that no warfarin dose adjustments would be anticipated to be necessary on concurrent use. However, in 1993 the CSM in the UK reported on an analysis of adverse reactions associated with ketorolac: they had received 5 reports of postoperative haemorrhage and four reports of gastrointestinal haemorrhage (one fatal) in patients taking ketorolac.² As result of this analysis, the use of ketorolac with anticoagulants was contraindicated in the UK.^{2,3} In the US, the manufacturers state that patients taking anticoagulants have an increased risk of bleeding complications if they are also given ketorolac, and therefore they should be used together extremely cautiously. They note that, in particular, there is an increased risk of intramuscular haematoma from intramuscular ketorolac in patients taking anticoagulants.⁴ See also 'Coumarins and related drugs + NSAIDs', p.427.

Coumarins + NSAIDs; Metamizole sodium (Dipyrone)

One report claims that metamizole sodium does not interact with phenprocoumon or ethyl biscoumacetate, whereas another describes a rapid but transient increase in the effects of ethyl biscoumacetate. All NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence, mechanism, importance and management

A single 1-g dose of metamizole sodium did not alter the steady-state anticoagulant effects of either phenprocoumon (5 subjects) or ethyl biscoumacetate (6 subjects).¹ Conversely, another report describes a short-lived but rapid increase (within 4 hours) in the effects of ethyl biscoumacetate caused by single 1-g dose metamizole sodium.² The reasons are not understood. However, care is still needed with every 'NSAID', (p.427), because, to a greater or lesser extent, they irritate the stomach lining, which

can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

2. Mehvar SR, Jamali F. Dipyron-ethylbiscoumacetate interaction in man. *Indian J Pharm* (1981) 7, 293–9.

Coumarins + NSAIDs; Nabumetone

In pharmacological studies, nabumetone did not alter the anticoagulant effects of acenocoumarol or warfarin. An isolated report describes a raised INR and haemarthrosis in one patient taking warfarin attributed to an interaction with nabumetone. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence, mechanism, importance and management

Nabumetone 2 g daily for 2 weeks did not significantly alter the anticoagulant effects of steady-state warfarin in healthy subjects.¹ Similarly, nabumetone 1 to 2 g daily for 6 weeks had no effect on the INR in 58 patients stabilised on warfarin.^{1,2} Another clinical study in osteoarthritis patients also found that there was no difference in the proportion of patients with no INR change and no change in acenocoumarol dose in 27 patients given nabumetone 1 to 2 g daily for 4 weeks and 29 patients given placebo.³ Moreover, nabumetone also appears not to affect bleeding time, platelet aggregation or prothrombin times in the absence of an anticoagulant.⁴ However, an isolated and unexplained report describes an increase in INR from 2 to 3.7 and haemarthrosis in a patient taking warfarin a week after nabumetone 750 mg twice daily was added.⁵

On the basis of the above studies, no coumarin dose adjustment would be expected to be needed with nabumetone. However, care is still needed with every 'NSAID', (p.427), because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Coumarins + NSAIDs; Nimesulide

In pharmacological studies, nimesulide did not alter the effects of acenocoumarol or warfarin. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence, mechanism, importance and management

In a pilot study in 6 patients stabilised on acenocoumarol, a single 100-mg dose of nimesulide did not affect the clotting mechanisms, although the platelet aggregating response to adenosine diphosphate, adrenaline (epinephrine) and collagen was reduced for 2 to 4 hours.¹ Ten patients stabilised on warfarin 5 mg daily had no significant changes in their prothrombin times, partial thromboplastin time or bleeding times when they were given nimesulide 100 mg twice daily for a week.² However, a few patients showed some increase in anticoagulant activity.¹

The studies above suggest that no coumarin dose adjustments are expected to be needed when nimesulide is used. However, care is still needed with every 'NSAID', (p.427), because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Coumarins + NSAIDs; Oxicam derivatives

Piroxicam increased plasma levels of *R*-acenocoumarol, and a few cases of raised INRs and bleeding have been reported when it was given with acenocoumarol or warfarin. In pharmacological studies, lornoxicam modestly increased the anticoagulant effects of warfarin, and possibly decreased the effect of phenprocoumon, but it did not to interact with acenocoumarol. Studies have indicated that meloxicam does not interact with warfarin, and that tenoxicam does not interact with warfarin or phenprocoumon. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

(a) Lornoxicam

In an open, crossover study in 6 healthy subjects, lornoxicam 8 mg twice daily for 7 days had no effect on the pharmacokinetics or the anticoagulant activity of a single 10-mg dose of acenocoumarol given on day 4.¹

In an open, crossover study in 6 healthy subjects, lornoxicam 8 mg twice daily for 21 days increased the bioavailabilities of *S*- and *R*-phenprocoumon by 14% and 6%, respectively, and decreased their clearances by 15% and 6%, respectively, after a single 9-mg dose of phenprocoumon given on day 4. Despite the minor pharmacokinetic changes, statistically significant reductions in the activities of factors II and VII were seen.²

Lornoxicam 4 mg twice daily was given to 12 healthy subjects for 5 days, then warfarin was added until a stable prothrombin time, averaging about 23.6 seconds, was achieved. The period to achieve this varied from 9 to 24 days, depending on the subject. The warfarin was then continued and the lornoxicam withdrawn, whereupon the mean prothrombin time fell to 19.5 seconds, the INR fell from 1.48 to 1.23 and the serum warfarin levels fell by 25%.³

(b) Meloxicam

Meloxicam 15 mg daily for 7 days did not significantly affect the pharmacokinetics of warfarin or INR values⁴ in a group of 13 healthy subjects stabilised with INRs of 1.2 to 1.8.

(c) Piroxicam

1. *Acenocoumarol*. In a single-dose study in healthy subjects, when piroxicam 40 mg was given with acenocoumarol 4 mg the AUC of the more active *R*-isomer was increased by 47% and its maximum plasma level was increased by 28%.⁵

In patients stabilised on acenocoumarol, piroxicam 20 mg daily for 2 weeks increased the effects of acenocoumarol in 4 out of 11 patients: the effect was considered mild in 3 patients, and significant in the fourth, although no specific values were given.⁶ An increased prothrombin ratio has been seen in another patient.⁷ A further patient taking acenocoumarol developed gastrointestinal bleeding 3 days after starting to take piroxicam 20 mg daily. His INR rose from 2.2 to 6.5.⁸

2. *Warfarin*. A man stabilised on warfarin had a fall in his prothrombin time from a range of 1.7 to 1.9 times his control value to 1.3 when he stopped taking piroxicam 20 mg daily. The prothrombin times rose and fell when he re-started and then stopped the piroxicam.⁹ Another patient taking warfarin had an increase in her prothrombin time (from a range of 16.5 to 18.1 seconds to 24.9 seconds) when piroxicam 20 mg daily was started, and a decrease when it was then stopped.¹⁰ The INR of 2 Chinese patients rose to 4.5 and 4.2 after they were treated with piroxicam 20 mg daily and 0.5% topical piroxicam gel. One of them had bruises over the legs within 3 days.¹¹

A woman who spread warfarin rat poison with her bare hands developed intracerebral bleeding, possibly exacerbated by piroxicam, which she took occasionally.¹²

(d) Tenoxicam

In single-dose and steady-state studies in a total of 16 healthy subjects, tenoxicam 20 mg daily for 14 days had no significant effect on the anticoagulant effects of warfarin or on bleeding times.¹³ This report also mentions case studies in a small number of patients and healthy subjects, which similarly found that tenoxicam had no significant effect on the anticoagulant effects of phenprocoumon.¹³

Mechanism

Piroxicam inhibits the metabolism of the active *R*-acenocoumarol, but its effect on the metabolism of warfarin is unknown. Lornoxicam inhibited the metabolism of warfarin, but not acenocoumarol, *in vitro*.¹⁴ In addition NSAIDs have antiplatelet effects, which can prolong bleeding if it occurs. They may also cause gastrointestinal toxicity. Because of these effects, in patients taking anticoagulants, the risk of bleeding is increased by 'NSAIDs', (p.427).

Importance and management

The interaction of piroxicam with acenocoumarol would appear to be established, and case reports suggest that warfarin might be similarly affected. Concurrent use need not be avoided, but monitor the outcome well and anticipate the need to reduce the anticoagulant dosage. Lornoxicam appears to have a similar effect with warfarin, although no cases of an interaction have been reported. Meloxicam and tenoxicam appear not to interact. However, care is still needed with every 'NSAID', (p.427), because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Coumarins + NSAIDs; Phenazone (Antipyrine)

The anticoagulant effects of warfarin are reduced by phenazone.

Clinical evidence

The plasma **warfarin** concentrations were halved (from 2.93 to 1.41 micrograms/mL) and the anticoagulant effects accordingly reduced after 5 patients took phenazone 600 mg daily for 50 days.¹ The thrombotest percentage of one patient rose from 5 to 50%. In an associated study it was found that phenazone 600 mg daily for 30 days caused a reduction in the **warfarin** half-life from 47 to 27 hours and from 69 to 39 hours, respectively, in 2 patients.^{1,2}

Mechanism

Phenazone is an enzyme inducer, which increases the metabolism and clearance of warfarin, thereby reducing its effects.^{1,2}

Importance and management

An established interaction. The effects of concurrent use should be monitored and the dosage of warfarin increased appropriately. However, note that phenazone is little used clinically, and an alternative 'NSAID',

(p.427), that does not alter the metabolism of coumarins would be more appropriate. Other coumarins might be expected to behave similarly.

Coumarins and related drugs + NSAIDs; Phenylbutazone and related drugs

The anticoagulant effects of warfarin are markedly increased by azapropazone, oxyphenbutazone and phenylbutazone. Concurrent use should be avoided because serious bleeding can occur. Feprazone appears to interact similarly.

Bleeding has also been seen in patients taking phenindione or phenprocoumon when given phenylbutazone, but successful concurrent use has been achieved with both phenprocoumon and acenocoumarol, apparently because the anticoagulant dosage was carefully reduced. Note also that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

(a) Azapropazone

A woman taking digoxin, furosemide, spironolactone, allopurinol, and **warfarin** (prothrombin ratio 2.8) developed haematemesis within 4 days of starting to take azapropazone 300 mg four times a day. Her prothrombin ratio was found to have risen to 15.7. Subsequent gastroscopic examination revealed a benign ulcer, the presumed site of the bleeding.¹

At least 12 other patients are reported to have developed this interaction. Bruising or bleeding (melaena, epistaxis, haematuria) and prolonged prothrombin times were occurred within a few days of starting azapropazone.^{2–7} Three patients died.^{4,6} Another patient taking **warfarin** and azapropazone, diclofenac and co-proxamol had an increase in prothrombin time.⁸

(b) Feprazone

Five patients stabilised on **warfarin** had a mean prothrombin time rise from 29 to 38 seconds after taking feprazone 200 mg twice daily for 5 days, despite a 40% reduction in the **warfarin** dosage (from 5 to 3 mg daily). Four days after feprazone was stopped, their prothrombin times were almost back to usual. The interaction with feprazone was less marked than that with phenylbutazone.⁹

(c) Oxyphenbutazone

A man stabilised on **warfarin** developed gross haematuria within 9 days of starting to take oxyphenbutazone 400 mg daily. His prothrombin time had increased to 68 seconds.¹⁰ Two similar cases have been described elsewhere.^{11,12} A clinical study has also shown that oxyphenbutazone slows the clearance of **dicoumarol**.¹³

(d) Phenylbutazone

In a study in 3 subjects and one patient, phenylbutazone 200 mg three times daily and twice daily, respectively, given for 11 to 19 days before and 11 days after a single dose of **warfarin**, markedly increased the prothrombin time, but *decreased* the half-life of **warfarin**, and the **warfarin** AUC.¹⁴ In another study that gave the enantiomers of **warfarin** separately, it was found that phenylbutazone inhibited the clearance of *S*-warfarin, but increased the clearance of *R*-warfarin.¹⁵ This was confirmed in other studies, were the AUC of *R*-warfarin was decreased by 41% and the AUC of *S*-warfarin increased by 18%.¹⁶

A number of other studies have shown a markedly increased prothrombin times in patients^{9,17} or healthy subjects¹⁸ taking **warfarin** and given phenylbutazone. Moreover, there are a number of case reports demonstrating the clinical importance of this interaction.^{14,19–23} In one, a man stabilised on **warfarin** following mitral valve replacement was later given phenylbutazone for back pain by his general practitioner. On admission to hospital a week later he had epistaxis, and his face, legs and arms had begun to swell. He showed extensive bruising of the jaw, elbow and calves, some evidence of gastrointestinal bleeding, and a prothrombin time of 89 seconds. Two similar cases were also reported.²² A similar interaction occurs between phenylbutazone and **phenprocoumon**. In one study in

healthy subjects, phenylbutazone 300 mg daily for 14 days markedly increased the prothrombin time response to a single dose of phenprocoumon given on day 4 by twofold, while decreasing the phenprocoumon AUC by 31%.²⁴ Cases of a clinically important interaction have also been reported for **phenprocoumon**.²⁵ In one early report, the required dose of **acenocoumarol** was 25% lower in patients taking phenylbutazone.²⁶ A single unconfirmed report describes this interaction in two patients taking **phenindione**.²⁷

Mechanism

Phenylbutazone very effectively displaces the anticoagulants from their plasma protein binding sites, thereby increasing the concentrations of free and active anticoagulant (an effect easily demonstrated *in vitro*^{14,28-32}). By itself, the importance of this mechanism is usually small, since any displaced drug is then available to be cleared, so any effect is usually transient (see 'Protein-binding interactions', (p.3)). However, phenylbutazone also inhibits the metabolism of *S*-warfarin (the more potent of the two warfarin enantiomers) so its effects are increased and prolonged.^{15,16,33} In one study, the unbound clearance of *S*-warfarin was decreased fourfold.³³ In contrast, the unbound clearance of *R*-warfarin is not altered, so the total clearance of *R*-warfarin is increased due to displacement.³³ Thus, overall it appears that phenylbutazone decreases total plasma warfarin levels, while increasing its effect.

Azapropazone³⁴⁻³⁶ and oxyphenbutazone (the major metabolite of phenylbutazone) probably act similarly.

Importance and management

The pharmacokinetic interaction between warfarin and azapropazone or phenylbutazone is very well established and clinically important. Serious bleeding can result and concurrent use should be avoided. Feprozone and oxyphenbutazone appear to interact similarly. Much less is known about phenindione with phenylbutazone, but they probably interact similarly.²⁷ Direct evidence of a serious interaction with phenprocoumon seems to be limited to two reports, and there is some evidence (from one paper published in 1957) that successful and apparently uneventful concurrent use is possible, presumably because in the case cited the response and the anticoagulant dosages were carefully controlled.³⁷ However, the practicalities of such close monitoring outside of a study are unclear. One study found that 25% less acenocoumarol was needed in patients given phenylbutazone.²⁶ Remember too that phenylbutazone and related drugs affect platelet aggregation and can cause gastrointestinal bleeding, whether an anticoagulant is present or not. It would seem advisable to use an alternative NSAID that interacts to a lesser extent, such as ibuprofen or naproxen, although it should be noted that no 'NSAID', (p.427), is entirely free from interactions with anticoagulants.

Coumarins + NSAIDs; Sulindac

In pharmacological studies, sulindac did not significantly alter the anticoagulant effect of warfarin or phenprocoumon. Isolated cases of a modest to marked increase in the anticoagulant effects of warfarin have been reported with sulindac. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

In a study in healthy subjects stabilised on **warfarin**, sulindac 200 mg twice daily for 7 days did not significantly alter the prothrombin time, when compared with placebo, although prothrombin time was slightly higher in the sulindac group.¹ Similarly, in 20 patients stabilised on **phenprocoumon**, sulindac 200 to 400 mg daily for 4 weeks did not alter measures of coagulation or bleeding time.²

However, a patient stabilised on **warfarin**, ferrous sulfate, phenobarbital and sulfasalazine had a marked increase in his prothrombin time ratio from about 3.2 to 10 after taking sulindac 100 mg twice daily for 5 days.³⁻⁵ There are 4 similar cases of this interaction on record.^{1,5-7} One of the patients had a gastrointestinal bleed after taking only three 100-mg doses of sulindac, although this patient was also taking flurbiprofen.⁵ Another patient was stabilised on about a 40% lower dose of **warfarin** with continuation of the sulindac.⁶ Another patient had a potassium-losing renal tubular defect, which was thought to contribute to the interaction.¹

Mechanism

Not understood. In one patient, renal impairment may have caused sulindac accumulation, which in turn may have affected warfarin pharmacokinetics.¹ See also 'Coumarins and related drugs + NSAIDs', p.427.

Importance and management

The pharmacological studies cited suggest that usually no coumarin dose adjustment would be needed in patients given sulindac. However, the isolated cases of an interaction suggest that, rarely, some patients may be affected. Also note that all 'NSAIDs', (p.427) can irritate the gastric mucosa, affect platelet activity and cause gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Coumarins + NSAIDs; Tolmetin

In pharmacological studies, tolmetin did not alter the anticoagulant effect of phenprocoumon or warfarin. Isolated cases of raised INRs have been described. Note that all NSAIDs increase the risk of gastrointestinal bleeding, and an increased risk is seen when they are combined with anticoagulants.

Clinical evidence

In a placebo-controlled study, no changes in prothrombin times occurred in 15 healthy subjects stabilised on **warfarin** when they took tolmetin 400 mg three times daily for 14 days.¹ Similarly, no changes in prothrombin times occurred in 15 patients taking **phenprocoumon** when they were given tolmetin 200 mg four times daily for 10 days.² Bleeding times were reported to be slightly prolonged though not to a clinically relevant extent.² Bleeding times were not significantly altered in healthy subjects given **acenocoumarol** and tolmetin 400 mg twice daily, or patients taking **acenocoumarol** and tolmetin.³

However, there is a single published case report of a diabetic patient stabilised on **warfarin**, insulin, digoxin, theophylline, ferrous sulfate, furosemide and sodium polystyrene sulfonate who had a nosebleed after taking three 400-mg doses of tolmetin. His prothrombin time had risen from a range of 15 to 22 seconds up to 70 seconds.⁴ The manufacturers of tolmetin and the FDA in the US also have 10 other cases on record,^{4,5} received over a 10-year period.⁵

Mechanism

See 'Coumarins and related drugs + NSAIDs', p.427.

Importance and management

The pharmacological studies cited suggest that usually no coumarin dose adjustment would be needed in patients given tolmetin. The isolated cases of an interaction are unexplained.

However, care is needed with every 'NSAID', (p.427) because, to a greater or lesser extent, they irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients.

Coumarins + Olanzapine

A single dose of olanzapine did not alter the pharmacokinetics or anticoagulant effect of a single dose of warfarin.

Clinical evidence, mechanism, importance and management

In a three-way, randomised, crossover study, 15 healthy subjects were given olanzapine 10 mg, **warfarin** 20 mg or both drugs together as single doses. No significant changes were seen in the pharmacokinetics of either drug, and the adverse effects of the olanzapine and the anticoagulant effects of the **warfarin** were unchanged.¹ Similarly, a 71-year-old woman stabilised on **warfarin** 15 mg/week with an INR of 2.6 had no significant change in INR after taking olanzapine 20 mg daily for 6 weeks (INR 2.6 when taking 15 mg/week and 2 while taking 12.5 mg/week).² This evi-

dence suggests that no **warfarin** dose adjustments are anticipated to be needed on concurrent use with olanzapine.

Coumarins + Opioids; Dextropropoxyphene (Propoxyphene)

In one study, dextropropoxyphene did not alter the prothrombin time in patients taking unspecified coumarins. There are isolated cases of patients on warfarin who have shown a marked increase in prothrombin times and/or bleeding when given co-proxamol (dextropropoxyphene with paracetamol).

Clinical evidence

(a) Co-proxamol (Dextropropoxyphene with paracetamol)

A man taking **warfarin** developed marked haematuria within 6 days of starting to take two tablets of co-proxamol three times a day. Thirteen days previously his **warfarin** dose had been increased from 6 mg to 7 mg daily (thrombotest 16%), and then 9 days previously it had been reduced back to 6 mg daily (thrombotest 5%). His plasma **warfarin** levels had risen by one-third (from 1.8 to 2.4 micrograms/mL) despite the reduction in **warfarin** dose.¹ A woman stable for 6 weeks on **warfarin** developed gross haematuria 11 hours after starting co-proxamol. She had taken 6 tablets of co-proxamol over a 6-hour period. Her prothrombin time increased from about 30 to 40 seconds up to 130 seconds.¹

This interaction has been reported in 5 other patients taking **warfarin**.^{2–6} The prothrombin time of one of them rose from 28 to 44 seconds up to 80 seconds within 3 days of substituting paracetamol with two tablets of co-proxamol four times a day.³ Another developed a prothrombin time of more than 50 seconds after taking 30 tablets of *Darvocet-N 100* (dextropropoxyphene 100 mg, paracetamol 650 mg) and possibly an unknown amount of ibuprofen over a 3-day period.⁴ Increased **warfarin** effects leading to severe retroperitoneal haemorrhage have also been briefly reported in a patient taking co-proxamol.⁵

(b) Dextropropoxyphene

A double-blind study in 23 patients anticoagulated with un-named coumarol derivatives and given dextropropoxyphene 450 mg daily for 15 days or ibuprofen did not show any change in prothrombin times with either drug.⁷

Mechanism

Not understood. The effect dextropropoxyphene has on the metabolism of the warfarin enantiomers does not appear to have been studied. Dextropropoxyphene does not interact with other cytochrome P450 isoenzyme CYP2C9 substrates such as 'tolbutamide', (p.486), although it does interact with the CYP3A4 substrate 'carbamazepine', (p.527). There is also the possibility that the paracetamol component had some part to play (see also 'Coumarins + Paracetamol (Acetaminophen)', p.438). Alternatively, these cases may just represent idiosyncratic reactions.

Importance and management

Information about this interaction is very sparse and seems to be limited to the reports cited. The cases cited could just be idiosyncratic reactions. Bear them in mind in the event of an unexpected response to treatment.

Coumarins + Opioids; Hydrocodone

In an isolated report, the anticoagulant effects of warfarin were increased by hydrocodone in one patient and in one healthy subject.

Clinical evidence, mechanism, importance and management

A patient, well stabilised on **warfarin** (and also taking digoxin, propranolol, clofibrate and spironolactone) had a rise in his prothrombin time of about 2 to 3 times his control value when he began to take *Tussionex* (hydrocodone with phenyltoloxamine) for a chronic cough. When the cough syrup was discontinued, his prothrombin time fell again. In a subsequent study in one healthy subject the equivalent dosage of hydrocodone increased the elimination half-life of **warfarin** from 30 to 42 hours.¹ The reason for this interaction is not known, and this case appears to be the only information available. Any interaction is not therefore established. Be aware of the possibility of an interaction in the case of an unexpected increase in the response to **warfarin**.

1. Azarnoff DL. Drug interactions: the potential for adverse effects. *Drug Inf J* (1972) 6, 19–25.

Coumarins + Opioids; Meptazinol

The anticoagulant effects of warfarin were not altered by meptazinol in one study.

Clinical evidence, mechanism, importance and management

Meptazinol 200 mg four times daily for 7 days had no significant effect on the prothrombin indexes of 6 elderly patients stabilised on **warfarin**, nor on the required **warfarin** dose.¹ No **warfarin** dose adjustments would be expected to be needed on concurrent use.

1. Ryd-Kjellen E, Alm A. Effect of meptazinol on chronic anticoagulant therapy. *Hum Toxicol* (1986) 5, 101–2.

Coumarins + Opioids; Tramadol

In one study tramadol did not change the mean INR in response to phenprocoumon, although two patients had increases. Isolated cases of an increase in anticoagulant effects of warfarin and phenprocoumon have been reported. One retrospective cohort study also found an increased risk of bleeding when acenocoumarol or phenprocoumon was given with tramadol.

Clinical evidence

In a double-blind, placebo-controlled, crossover study the mean INRs of 19 patients anticoagulated with **phenprocoumon** were unchanged when they were given tramadol 50 mg three times daily for a week.^{1,2} Although the mean difference was not changed, one patient had an INR rise from 4 to 7.3, and another from a just under 5 to 6, while taking tramadol, but not while taking placebo.

A brief report describes 5 elderly patients (aged 71 to 84 years), anticoagulated with **warfarin** or **phenprocoumon** and taking a range of other drugs, who had clinically important rises in INRs (up to threefold) shortly after starting to take tramadol. One of the patients had gastrointestinal bleeding. Three of the patients were able to continue the tramadol with a reduced anticoagulant dosage.³

In another report, a 61-year old woman with a mitral valve replacement stabilised on **warfarin** developed ecchymoses about 2 weeks after starting tramadol 50 mg every 6 hours. Her prothrombin time was found to have risen to 39.6 seconds and her INR was 10.6. These values returned to normal when the tramadol was withdrawn and the **warfarin** temporarily stopped.⁴ Other cases have been reported with **warfarin**⁵ and **phenprocoumon**.⁶ In 2004, the Australian Adverse Drug Reactions Advisory Committee said they had received 11 reports of increases in INR or a haemorrhagic event in patients taking **warfarin** given tramadol. Two patients died of haemorrhagic stroke. They note that this number of cases suggests that the interaction is an uncommon event.⁷ Up until March 2003, the Swedish Adverse Drug Reactions Advisory Committee had received

reports of 17 cases of a suspected interaction between tramadol and **warfarin** resulting in increases in the INR (to 3.4 to 8.5) and bleeding complications in 35% of patients. One patient who continued tramadol needed the **warfarin** dose to be almost halved.⁸

In a retrospective cohort study of patients taking **acenocoumarol** or **phenprocoumon**, tramadol was found to be associated with a threefold increased risk of bleeding. The study was specifically looking at potentially interacting drugs taken by at least 50 patients and with at least 5 cases of bleeding.⁹

Mechanism

Unknown. It has been suggested that the interaction might be related to a variation in CYP genotype. Seven of 10 patients from the 17 suspected cases of interaction in Sweden had defective CYP2D6 alleles. The authors suggested that since this isoenzyme metabolises tramadol, these patients might have changes in tramadol metabolism that could increase the risk of an interaction with warfarin via CYP3A4. However, CYP3A4 only has a role in the 'metabolism', (p.358), of R-warfarin, and inhibition of CYP3A4 usually results in just minor to modest increases in INR. Moreover, defective CYP2D6 alleles have a population prevalence of 42.2%, so if this were the mechanism, many more cases would be expected. Because of the rarity of reports, it could just be that it is not really an interaction, and that there were unknown confounding factors in the suspected cases. Further study is needed.

Importance and management

Not established. One pharmacological study did not show a clear interaction for phenprocoumon and tramadol, although data from 2 patients suggested the possibility. Moreover, isolated cases of an interaction with warfarin and phenprocoumon have been published or reported to regulatory authorities, but the incidence seems to be rare. Because of the uncertainty, it would be prudent to consider monitoring prothrombin times in any patient taking coumarins when tramadol is first added, being aware that a small proportion of patients may need a reduction in the anticoagulant dosage. More study is needed.

Coumarins and related drugs + Orlistat

Orlistat had no effect on the pharmacodynamics or pharmacokinetics of single-dose warfarin in healthy subjects. However, orlistat reduces fat absorption, and might therefore reduce vitamin K absorption. There is a published report of a patient taking warfarin who developed a modest increase in INR after taking orlistat. Similar cases have been reported to regulatory authorities.

Clinical evidence

In a placebo-controlled, randomised, crossover study, 12 healthy subjects were given orlistat 120 mg three times daily for 16 days, with a single 30-mg dose of **warfarin** on day 11. The pharmacokinetics and pharmacodynamics of the **warfarin** were not altered by the orlistat, and markers of vitamin K nutritional status were not affected.¹ However, regarding this study, the manufacturers US prescribing information states that vitamin K levels did tend to decline in subjects taking orlistat.² It is also noted that reports of "decreased prothrombin, increased INR and unbalanced anticoagulant treatment resulting in change of haemostatic parameters" have been reported in patients taking orlistat and anticoagulants.² In addition, in 2001 the Canadian

regulatory authorities reported that unexpected increases in INR were noted after orlistat was given to patients taking either **warfarin** or **acenocoumarol**. These were managed by dosage adjustments of the coumarin or discontinuation of orlistat.³

In a published report, a 66-year-old man stabilised on **warfarin** for 2.5 years who started taking orlistat 120 mg three times daily for weight reduction had a modest increase in his INR, from less than 3, to 4.7 within 18 days. **Warfarin** was withheld and he was later restabilised on approximately two-thirds of the previous dose while continuing the orlistat.⁴

Mechanism

Orlistat may reduce the absorption of fat soluble vitamins including vitamin K,^{4,5} and a change to a lower fat diet associated with the use of orlistat may also contribute to changes in the balance between vitamin K and **warfarin**.⁴

Importance and management

The manufacturers say that patients stabilised on anticoagulants and given orlistat should be closely monitored for changes in coagulation parameters.^{2,5} Given the reports of changes in INRs, and the fact that changes in dietary 'vitamin K', (p.409) are known to affect warfarin efficacy, this seems prudent in patients taking a coumarin or an **indanedione**.

Coumarins + Oxolamine

Oxolamine markedly increases the effect of warfarin.

Clinical evidence, mechanism, importance and management

In a retrospective study, 11 patients were identified who had been receiving stable **warfarin** therapy and were then given oxolamine in doses of 100 to 600 mg daily for 3 to 10 days. Of six patients who did not have their **warfarin** dose adjusted, the INR increased by 70 to 190% from a range of 1.51 to 2.82 up to a range of 3.24 to 6.45. One patient had a **warfarin** dose reduction of just 14%, with an INR increase from 2.29 to 9.11. Four patients had their **warfarin** dose reduced by 30 to 36%, but one of these still had an INR increase from 2.14 to 4.01. Two of the 11 patients developed a hematoma.¹ In a further prospective study, six patients receiving stable **warfarin** therapy were given oxolamine 300 to 600 mg daily for 4 to 7 days, and the **warfarin** dose was reduced by 50% on starting oxolamine. Three patients had no change in INR, one had a 24% increase and two a 6% and 17% decrease.¹

The mechanism of this interaction is unknown. Although published information is limited to this study, an interaction seems to be established. If any patient taking **warfarin** requires oxolamine, anticipate the need to roughly halve the **warfarin** dose.

Coumarins + Paracetamol (Acetaminophen)

An equal number of randomised studies have found a modest increase in the anticoagulant effect (e.g. an increase in INR of 1) of coumarins as have reported no effect. One retrospective cohort study reported that concurrent use tends to increase the incidence of upper gastrointestinal bleeding, but other cohort studies found no evidence of a change in anticoagulant effect. There are isolated case reports of an increase in anticoagulant effects in patients taking warfarin or acenocoumarol and paracetamol.

Clinical evidence

Over 10 published studies have investigated whether or not paracetamol alters the effect of coumarin anticoagulants, with equal numbers finding no effect or an increased effect, see 'Table 12.5', (p.439). All the randomised, controlled studies showing an interaction have demonstrated a minor to modest effect (e.g. average increase in INR of 1.04 in one well-controlled study¹). The only study to show a much greater effect (an increased odds ratio of an INR above 6 ranging from 3.5 to 10 for different doses of paracetamol alone or combined with an opioid) was a retrospective case-control study,^{2,3} which has the limitations of being non-randomised with all the attendant problems of controlling for possible confounding variables.^{4–6} Excluding this study, there appears to be no obvious explanation for the disparate findings between the studies showing an interaction and those not, either by study group, coumarin used, or dose of paracetamol.

There are only 5 published case reports of a possible interaction between paracetamol without opioids and a coumarin (**warfarin** or **acenocoumarol**), which are summarised in 'Table 12.5', (p.439). In addition, there are two reports of a possible interaction with paracetamol combined with codeine or dihydrocodeine listed in 'Table 12.5', (p.439), and 7 others with paracetamol combined with 'dextropropoxyphene (propoxyphene)', (p.436). Note that this incidence is very rare, given the widespread use of paracetamol, and the fact that it is generally considered safe for use with warfarin.

Moreover, in response to one case-control study² other clinicians running outpatient anticoagulant clinics have contended that they have not observed an interaction with paracetamol in their experience.^{5,6}

Mechanism

Not understood. Paracetamol is mainly metabolised by glucuronidation and sulfation,^{7,8} but the cytochrome P450 isoenzymes CYP1A2, CYP3A4 and CYP2E1 metabolise up to 15% of paracetamol under normal conditions.⁷ *R*-warfarin is mainly metabolised by CYP3A4 and CYP1A2.^{7,8} It has been suggested that in conditions such as ageing, hypoxia or hypertension, the isoenzymes play a more important part in paracetamol metabolism. Consequently paracetamol may then compete with the metabolism of *R*-warfarin to a sufficient degree to provoke an interaction.⁸ However, as the *S*-warfarin enantiomer has significantly greater anticoagulant activity than the *R*-warfarin enantiomer, interactions with *R*-warfarin are considered by some to be of questionable significance.⁶ Moreover, this explanation might explain rare case reports, but not the slight increases in INR seen in some studies in otherwise healthy subjects and patients.

Another idea is that the toxic metabolite of paracetamol inhibits the enzymes in the vitamin K cycle, and so has additive effects with anticoagulants, but so far this mechanism has only been investigated *in vitro*.⁹ Yet another idea is that it is the indications for paracetamol use such as pain or fever that cause the interaction, rather than paracetamol *per se*,¹⁰ but this does not explain why an interaction has been found in otherwise healthy patients or subjects given paracetamol in controlled studies.

Importance and management

Despite the number of studies, an interaction between paracetamol and coumarin anticoagulants is not firmly established, and the importance of the findings remain controversial. Some consider that the dose of paracetamol and its duration of use should be minimised in patients taking coumarins.^{7,11} However, in randomised controlled studies, even maximum daily doses of paracetamol (4 g daily) for 2 weeks, had, at most, a modest effect, see 'Table 12.5', (p.439). A dose-related effect has been suggested in a case-controlled study,² but a more recent randomised controlled study did not find a dose-response (i.e. there was a slight change in INR of 0.5 with both 1.5 g daily and 3 g daily).¹⁰ Further evidence is therefore required on the possible dose-response effect, and whether there is any value in minimising the dose. Moreover, on the basis of the studies suggesting an interaction, many have advocated increased monitoring in patients starting regular paracetamol. However, others consider that an increase in monitoring is unnecessary, or that increased monitoring during paracetamol use is not necessary unless the underlying illness (e.g. fever) requires increased monitoring. On the basis of the available data, it is not possible to firmly recommend increased monitoring, or dismiss its advisability. Further study is clearly needed.

Table 12.5 Summary of the evidence for and against an interaction between paracetamol (acetaminophen) and coumarins

Study type (year)	Group	Coumarin	Paracetamol	Outcome	Refs
Studies showing no interaction					
Randomised, crossover (1999)	20 healthy subjects	Warfarin, single-dose	1 g four times daily for one day, and 22 days	No change in warfarin pharmacokinetics or anticoagulant effect with either 1 day or 22 days	1
Clinical (1970)	10 patients	Stable warfarin	3.25 g daily for 2 weeks	No change in average prothrombin time	2
Randomised, placebo-controlled (1969)	20 patients	Phenprocoumon (19 patients) Warfarin (1 patient)	Two doses of 650 mg four hours apart	No change in average prothrombin time over 3 days	3
Randomised, placebo-controlled (2003)	31 patients	Phenprocoumon	Placebo (10 patients), 500 mg three times daily (11 patients), or 1 g three times daily (10 patients) for 2 weeks	Mean rise in INR of 0.46 at day 8 for both doses, which was not considered clinically relevant	4
Cohort (2002)	54 patients taking paracetamol and 180 others not taking paracetamol	Phenprocoumon	2 to 2.5 g per day for 3 days preceding INR determination	No change in anticoagulant effect	5
Cohort (recently started) (2002)	54 patients and 20 controls not given paracetamol	Acenocoumarol or phenprocoumon	Mean of 2.1 g daily	No difference in changes in INR between groups	6
Studies showing an interaction					
Randomised, placebo-controlled, crossover (1968)	50 patients	Stable warfarin, dicoumarol, anisindione,* phenprocoumon	650 mg four times daily for 2 weeks	Average increase in prothrombin time of 3.6 seconds	7
Randomised, placebo-controlled (1982, 1983)	20 patients	Stable acenocoumarol (8 patients) or phenprocoumon (12 patients)	500 mg four times daily for 3 weeks (10 patients); placebo (10 patients)	Average increase in thrombotest value of about 20 seconds (14% increase), which necessitated a reduction in coumarin dose in 5 patients	8, 9
Randomised, placebo-controlled, crossover (1984)	15 healthy subjects	Stable warfarin	4 g daily for 2 weeks	7 of 15 subjects had a prothrombin ratio rise of more than 20% while taking paracetamol compared with 1 of 15 taking placebo	10
Randomised, placebo-controlled, crossover (2005)	11 patients	Stable warfarin	4 g daily for 2 weeks	INR increased by a mean of 1.04 to a mean maximum of 3.47 in patients taking paracetamol, but did not change with placebo	11
Case-control (1998)	93 cases with INR greater than 6 and 196 controls (INR 1.7 to 3.3)	Warfarin	325 mg each week to greater than 1.3 g daily	52 cases (56%) and 70 controls (36%) reported using paracetamol in the preceding week. [†] The increased risk (3.5 to 10-fold) was related to paracetamol dose	12
Cohort (2001)	4204 patients	Warfarin and/or Phenprocoumon		Standardised incidence ratio of hospitalisation for upper GI bleeding was higher with combined use of paracetamol (4.4) than oral anticoagulants alone (2.8)	13
Case reports of an interaction: paracetamol					
Case report (1999)	72-year-old	Acenocoumarol	1 to 2 g daily long-term	13 days after stopping paracetamol, the INR decreased from a range of 2.5 to 3 down to 1.62. INR gradually increased on restarting paracetamol	14
Case report (2004)	77-year-old	Acenocoumarol	2 to 2.5 g daily for a few weeks	INR 5.4 then 9.1 one week later. Patient restabilised on same acenocoumarol dose and asked not to take more paracetamol than 2 g daily for more than 3 days	15
Case report (2002)	62-year-old	Warfarin	4 to 5 g (duration not stated)	INR of 7.5, with retroperitoneal haematoma. One month previously the INR had been 2.5	16
Case report (2003)	74-year-old	Warfarin	a. 1 g twice daily for 3 days b. 1 g four times daily for 3 days	a. INR of 3.4 then 4 b. INR increased from 2.3 to 6.4	17

Continued

Table 12.5 Summary of the evidence for and against an interaction between paracetamol (acetaminophen) and coumarins (continued)

Study type (year)	Group	Coumarin	Paracetamol	Outcome	Refs
Case report (2004)	76-year-old	Warfarin	Patient recently taking more paracetamol for a flare of arthritis	INR increase from 2.1 to 7, with haematuria and gingival bleeding	18
Paracetamol in combination with opioids[‡]					
Case report (1991)	66-year-old	Warfarin	Paracetamol/codeine; about 1.6 g daily of paracetamol over 10 days	Increase in prothrombin time from range of 15 to 19 up to 96 seconds. Haematuria and gingival bleeding	19
Case report (1997)	63-year-old	Warfarin	a. Paracetamol/dihydrocodeine 500 mg/10 mg, four daily for 7 days b. Paracetamol/codeine 500 mg/30 mg, three daily for 8 days	a. Increase in INR to 9.6 then 12, with gingival bleeding b. Increase in INR to 8.5	20

*Note that this is an indanedione

[†]Including 11 cases and 6 controls who reported taking a preparation of paracetamol in combination with an opioid, mostly codeine and oxycodone

[‡]There are also cases reported with dextropropoxyphene/paracetamol.

Coumarins + Pentoxifylline

Some studies have suggested that pentoxifylline does not alter the anticoagulant effects of phenprocoumon or acenocoumarol; however, one study suggests that there is an increased risk of serious bleeding if pentoxifylline is given with acenocoumarol. Pentoxifylline alone has rarely been associated with bleeding.

Clinical evidence

The anticoagulant effects of **phenprocoumon** were not altered by pentoxifylline 400 mg four times daily for 27 days in 10 patients on stable **phenprocoumon** therapy. Two patients had a slight increase in platelet aggregation.¹

In a placebo-controlled study of either pentoxifylline 400 mg three times daily, **acenocoumarol** (adjusted to maintain an INR of 2 to 4.5), or both drugs together, 3 major haemorrhagic problems (2 fatal cerebral, 1 gastrointestinal) occurred in the 36 patients taking both drugs. In the 36 patients taking **acenocoumarol** alone, one case of cerebral haemorrhage (resulting in hemiplegia) and another of haematuria with epistaxis occurred. This difference was not statistically significant, but the authors

considered that the risk of bleeding was probably increased by the combination.² In this study, 69% of patients had an INR within desired range, and 7% had an INR above 4.5. In another randomised study in patients with recurrent venous thrombosis, there was no difference in dose of **acenocoumarol** necessary to reach an INR of 2.5 to 3.5 between 100 patients taking **acenocoumarol** with pentoxifylline 1.2 g daily and 100 patients taking **acenocoumarol** alone. No patients had severe bleeding, and 3 to 4% of patients in both groups had moderate bleeding (haematomas, haematuria).³

Mechanism

Pentoxifylline alone has rarely been associated with bleeding,⁴ indicating that bleeding may not necessarily be the result of an interaction. The manufacturers say that a causal relationship between pentoxifylline and bleeding has not been established.^{5,6}

Importance and management

Information is limited, and an interaction is not established. In the US, the manufacturer recommends that patients taking **warfarin** should have more frequent monitoring of coagulation parameters when given pentoxifylline,⁶ and this seems a prudent precaution with this and any other coumarin.

Coumarins + Phosphodiesterase type-5 inhibitors

In pharmacological studies, sildenafil did not interact with warfarin or acenocoumarol. However, in pulmonary hypertension, there is some evidence of an increased risk of bleeding with concurrent use, and nosebleeds were a common adverse effect of sildenafil alone. There is also a report of two possible cases of rises in INRs in patients taking acenocoumarol or warfarin and sildenafil. Studies suggest that tadalafil and vardenafil do not interact with warfarin.

Clinical evidence

(a) Sildenafil

The manufacturer notes that no significant interaction occurred when sildenafil 50 mg was given with **warfarin** 40 mg,¹⁻⁴ or when sildenafil 100 mg was given with **acenocoumarol**.³ However, in studies in pulmonary hypertension, nosebleeds were a common adverse effect (13%), and concurrent use of vitamin K antagonists and sildenafil resulted in a greater incidence of reports of bleeding (primarily nosebleeds) than placebo.⁴ A 68-year-old man taking **acenocoumarol** and enalapril had an increase in his INR from 3.05 to 7.7 without bleeding complications after taking sildenafil. The patient continued to take sildenafil once a week, and the daily dose of **acenocoumarol** was split into two, with a return to stable therapeutic INR values. Another patient taking **warfarin**, ranitidine and pravastatin had a rise in INR on three occasions after taking sildenafil once a week, omitting the dose of ranitidine when he took the sildenafil. On one of these occasions, he had bleeding gums. This rise in INR no longer occurred when he started taking the ranitidine with the sildenafil.⁵

(b) Tadalafil

A double-blind, randomised, crossover study in which a single-dose of **warfarin** was given on day 7 of 12 consecutive days of treatment with either tadalafil 10 mg or placebo found that tadalafil did not affect the AUCs

of either *S*-warfarin and *R*-warfarin, and prothrombin times were unchanged.⁶

(c) Vardenafil

No pharmacokinetic interaction was observed when vardenafil was given with **warfarin**,^{7,8} and the prothrombin time was unchanged.⁸

Mechanism

The two cases of interactions are unexplained. It is not obvious why dividing the acenocoumarol dose, or using ranitidine, would have reversed an interaction. No interaction via inhibition of coumarin metabolism is likely. Sildenafil alone appears to commonly cause nosebleeds in patients with pulmonary hypertension.⁴

Importance and management

There is no established pharmacokinetic or pharmacodynamic interaction between the phosphodiesterase type-5 inhibitors and warfarin, and no warfarin dose adjustment would therefore be expected to be needed on concurrent use. However, in pulmonary hypertension, sildenafil appears to increase the risk of nosebleeds, and this may be greater in patients taking coumarins. Similarly, the two possible cases with acenocoumarol and warfarin, although not conclusive, do introduce a note of caution.

Coumarins + Piracetam

In a large clinical study, piracetam did not alter the dose of acenocoumarol required to produce a given INR. A single case report describes a woman stabilised on warfarin who began to bleed within a month of starting to take piracetam. Piracetam has antiplatelet activity, so some caution seems prudent on combined use.

Clinical evidence, mechanism, importance and management

In a randomised study in patients with recurrent venous thrombosis, there was no difference in dose of **acenocoumarol** necessary to reach an INR of 2.5 to 3.5 between 100 patients taking **acenocoumarol** with high-dose piracetam 9.6 g daily and 100 patients taking **acenocoumarol** alone. No patients had severe bleeding, and 3 to 4% of patients in both groups had moderate bleeding (haematomas, haematuria). The addition of piracetam decreased platelet aggregation, levels of fibrinogen, and blood viscosity.¹

A woman taking **warfarin**, insulin, levothyroxine and digoxin complained of menorrhagia at a routine follow up. Investigations revealed that her British Corrected Ratio had risen to 4.1 (normal range 2.3 to 2.8), and that one month previously she had started to take low-dose piracetam 200 mg three times daily. Within 2 days of withdrawing both the **warfarin** and piracetam her BCR had fallen to 2.07, and the original dose of warfarin was restarted.²

Piracetam alone is known to decrease platelet aggregation,¹ and might therefore be expected to increase the risk of bleeding with anticoagulants, similar to other drugs with antiplatelet activity such as 'aspirin', (p.385). The early case appears to be the only report of a possible interaction, but some caution might be prudent on concurrent use.

- Pan HYM, Ng RP. The effect of Nootropil in a patient on warfarin. *Eur J Clin Pharmacol* (1983) 24, 711.

Coumarins + Pirmenol

The anticoagulant effects of warfarin are not altered by pirmenol.

Clinical evidence, mechanism, importance and management

The prothrombin time response to a single 25-mg dose of **warfarin** was slightly reduced in most of 12 healthy subjects (reductions ranged from 0.2 to 1.3 seconds) who had taken pirlmenol 150 mg twice daily for 14 days, with the warfarin taken on day 8.¹ This suggested that some changes in the dosage of **warfarin** might be required in practice, but a later placebo-controlled study found that the prothrombin times of 10 patients stabilised on **warfarin** were not significantly changed when they were given oral pirlmenol 150 mg twice daily for 14 days.² No **warfarin** dose adjustments would therefore be expected to be required on concurrent use.

Coumarins + Probenecid

In healthy subjects, probenecid increased the clearance of single-dose phenprocoumon without altering its anticoagulant effect. The anticoagulant effects of multiple-dose phenprocoumon might be expected to be decreased by probenecid, but this requires confirmation.

Clinical evidence, mechanism, importance and management

In 9 healthy subjects probenecid 500 mg four times daily for 7 days reduced the AUC of a single 0.22-mg/kg dose of **phenprocoumon** given on day one by 47% and reduced the elimination half-life by about one-third. Nevertheless, the reduction in prothrombin time by **phenprocoumon** was not altered by probenecid.¹

The reasons for this interaction are not understood, but one possibility is that, while probenecid inhibits the glucuronidation of **phenprocoumon** (its normal route of metabolism), it may also increase the formation of hydroxylated metabolites so that its overall loss is increased.¹

Although the anticoagulant effect of single-dose **phenprocoumon** was not altered in this study, its findings suggests that, in the presence of probenecid, the dosage of phenprocoumon might need to be increased, but this awaits formal clinical confirmation in a multiple-dose study. Nothing further seems to have been published on this potential interaction, so bear its possibility in mind if probenecid is used in a patient taking phenprocoumon. There seems to be nothing documented about other coumarins.

- Mönig H, Böhm M, Ohnhaus EE, Kirch W. The effects of frusemide and probenecid on the pharmacokinetics of phenprocoumon. *Eur J Clin Pharmacol* (1990) 39, 261–5.

Coumarins + Proguanil

An isolated report describes bleeding in a patient stabilised on warfarin after she took proguanil for about five weeks.

Clinical evidence, mechanism, importance and management

A woman stabilised on **warfarin** developed haematuria, bruising and abdominal and flank discomfort about 5 weeks after starting to take proguanil 200 mg daily. Her prothrombin ratio was found to be 8.6. Within 12 hours of being given fresh frozen plasma and vitamin K her prothrombin ratio had fallen to 2.3. During the 5 weeks she had travelled from Britain to Thailand, Bali, Australia and then New Zealand, and her prothrombin ratio had not been checked during this time. The mechanism of this potential interaction is unknown.¹ Its general importance is uncertain, as factors related to travel (such as a changing diet and changing dose times in different time zones) may have had a part to play in this interaction.

- Armstrong G, Beg MF, Scahill S. Warfarin potentiated by proguanil. *BMJ* (1991) 303, 789.

Coumarins + Prolintane

The anticoagulant effects of ethyl biscoumacetate are not affected by prolintane.

Clinical evidence, mechanism, importance and management

The response to a single 20-mg/kg dose of **ethyl biscoumacetate** was examined in 4 healthy subjects given prolintane 20 mg daily for 4 days. Assessments were made before prolintane, on day 1 of prolintane, and 8 days after prolintane was stopped. The mean half-life of the anticoagulant and prothrombin times remained unchanged.¹ No **ethyl biscoumacetate** dose adjustments would appear to be required on concurrent use.

- Hague DE, Smith ME, Ryan JR, McMahon FG. The effect of methylphenidate and prolintane on the metabolism of ethyl biscoumacetate. *Clin Pharmacol Ther* (1971) 12, 259–62.

Coumarins and related drugs + Propafenone

The anticoagulant effects of warfarin, and possibly fluidione and phenprocoumon, are increased by propafenone.

Clinical evidence

The mean steady-state plasma levels of 8 healthy subjects taking **warfarin** 5 mg daily rose by 38% after they took propafenone 225 mg three times daily for a week. Five of the 8 had a distinct prothrombin time increase. The average rise in prothrombin time of the whole group was about 7 seconds, which was considered to be clinically significant.¹ Two case reports describe marked increases in the anticoagulant effects of **fluidione** and **phenprocoumon** in 2 patients taking propafenone.^{2,3}

Mechanism

Propafenone may reduce the metabolism of these anticoagulants, thereby increasing their effects. From *in vitro* data, it was concluded that propafenone would affect only *R*-warfarin, whereas both *R*- and *S*-acenocoumarol were affected.⁴

Importance and management

Information seems to be limited to these reports but they suggest that anticoagulant control should be well monitored if propafenone is given to patients taking warfarin, and probably also phenprocoumon and the indanedione fluidione. The anticoagulant dosage should be reduced where necessary. It would be prudent to apply the same precautions with any other coumarin or indanedione anticoagulant.

Coumarins and related drugs + Prostaglandins

Limited evidence suggests that the combined use of intravenous high-dose epoprostenol and warfarin may increase the risk of pulmonary haemorrhage. Continuous subcutaneous treprostnil did not alter the pharmacokinetics or the INR in response to single-dose warfarin, and also did not appear to increase the risk of bleeding when used with warfarin in clinical studies. Because these prostaglandins inhibit platelet aggregation, some caution is appropriate on combined use with anticoagulants.

Clinical evidence*(a) Epoprostenol*

In a small retrospective review of 31 patients with primary pulmonary hypertension receiving **warfarin** and continuous intravenous epoprostenol, 9 patients were identified who experienced 11 bleeding episodes (9 cases of pulmonary haemorrhage, 2 of nasal bleeding). Of the 9 cases of pulmonary haemorrhage, 8 were identified clinically by persistent haemoptysis, and 2 cases were associated with severe respiratory distress. Of the 7 patients with an INR available at the time of the first bleeding episode, 6 had an INR under 2 and one had an INR of 3.1. The dose of epoprostenol in patients with bleeds ranged from 28.1 to 164 nanograms/kg per minute,

and no patient receiving less than 28 nanograms/kg per minute had a bleed. There was no significant difference in survival in patients with a bleeding episode and those without.¹ In contrast, the manufacturer states that there was no evidence of increased bleeding in patients taking anticoagulants and receiving infusions of epoprostenol in clinical studies.²

(b) Treprostinil

In a crossover study in 15 healthy subjects, continuous subcutaneous treprostinil 5 then 10 nanograms/kg every minute for 9 days did not alter the pharmacodynamics (INR) of a single 25-mg oral dose of **warfarin** given on day 3. In addition, there was no change in the pharmacokinetics of *R*- and *S*-warfarin.³ In the discussion of this study, the authors mention an unpublished retrospective review of data from placebo-controlled clinical studies in patients with pulmonary artery hypertension. From this there was no evidence to suggest that concurrent **warfarin** and treprostinil (155 patients) was associated with increased bleeding or coagulation-related events, when compared with warfarin and placebo (156 patients).³

Mechanism

Epoprostenol (prostacyclin) and its long-acting analogue treprostinil are vasodilators that also inhibit platelet aggregation. The related drug iloprost also has these actions. As such, it is anticipated that they might increase the potential for bleeding when given with other anticoagulants.

Importance and management

Anticoagulants such as warfarin are commonly used in patients with pulmonary artery hypertension, a condition for which epoprostenol and now treprostinil have been developed, so the combination is likely to be used frequently. Because these prostaglandins are potent inhibitors of platelet aggregation, they might increase the risk of bleeding with anticoagulants (including coumarins and **indanediones**), although the manufacturers say that there was no evidence of increased bleeding in clinical studies using epoprostenol² or treprostinil.³ Nevertheless, limited evidence from the small survey in Japanese patients given epoprostenol suggests that this may be the case with high-dose epoprostenol. In this study, the authors commented that they no longer use anticoagulant therapy in patients receiving high-dose epoprostenol.¹ However, the manufacturers information states that since almost all patients in clinical studies of epoprostenol were receiving oral anticoagulants, concurrent oral anticoagulation is recommended,⁴ although the manufacturers say that there was no evidence of increased bleeding in clinical studies using epoprostenol² or treprostinil.³ There appears to be no direct information about **iloprost** but it seems likely that it will interact similarly. Some caution would be appropriate if any of these prostaglandins is given with a coumarin or **indanedione**. Further study is needed.

Coumarins + Protease inhibitors

In pharmacokinetic studies, ritonavir slightly raised *S*-warfarin levels and modestly decreased *R*-warfarin levels, while lopinavir/ritonavir decreased *S*-warfarin levels. In case reports both increased and decreased warfarin effects have been reported with ritonavir. One of these reports also found that indinavir might cause a moderate reduction in anticoagulation. There is also a report of a marked reduction in anticoagulation in a patient taking acenocoumarol, which was associated with the concurrent use of ritonavir or nelfinavir. An isolated report describes a gradual INR rise in an elderly patient taking warfarin when he was given saquinavir.

Clinical evidence

(a) Acenocoumarol

A 46-year-old HIV-positive man with mitral valve replacements stabilised on acenocoumarol (INR 2.5 to 3.5) for 5 years and taking zidovudine and didanosine for 17 months was found to have a dramatic decrease in his INR when his drug regimen was changed to stavudine, lamivudine and **ritonavir** 600 mg twice daily. Increasing the acenocoumarol dosage over 5 days from an average of 24 mg to over 70 mg failed to increase the INR to target levels. The INR returned to previous levels within 4 days of stopping **ritonavir**, and the acenocoumarol dosage could be reduced to 3 mg daily. The patient was subsequently given **nelfinavir** and a similar, though less dramatic interaction occurred: while taking **nelfinavir** an INR of 2.5 was achieved with a 210% increase in the acenocoumarol dose.¹

(b) Warfarin

1. *Indinavir*. A 50-year-old HIV-positive man, stabilised on warfarin (prothrombin complex activity (PCA) range of 20 to 35%), started taking indinavir 800 mg every 8 hours, but it had to be withdrawn after 12 days because of a generalised skin rash. It was then found that the indinavir had caused a moderate reduction in his level of anticoagulation: 10 and 25 days after indinavir was stopped his PCA was 53% and 43%, respectively. The warfarin dosage was increased to 6.25 and 7.5 mg on alternate days for one week, during which time a PCA of 34% was achieved, and he was then subsequently given warfarin 6.25 mg daily.² This patient subsequently needed an increase in warfarin dose when given *ritonavir*, see below.

2. *Lopinavir/Ritonavir*. In a pharmacokinetic study in healthy subjects,³ lopinavir/ritonavir 400 mg/100 mg twice daily for 10 days modestly decreased the AUCs of *R*- and *S*-warfarin by 37% and 29%, respectively, after a single 10-mg dose of warfarin and vitamin K were given on day 7. Vitamin K was given to inhibit the pharmacological effect of warfarin without affecting its pharmacokinetics.

3. *Ritonavir*. The manufacturer reports that, in 12 healthy subjects given ritonavir 400 mg every 12 hours for 12 days, the AUC of *S*-warfarin was increased by 9% (90% confidence interval, 17 to 44%) while that of *R*-warfarin was decreased by 33% (-38% to -27%) after a single 5-mg dose of warfarin.⁴ The effect of these changes on prothrombin time was not mentioned, but potentially could result in an increased warfarin effect due to the more potent *S*-warfarin, or a decreased effect due to the *R*-warfarin. Both of these outcomes have been reported in individual cases. An increase in warfarin effect was seen in a man taking warfarin 10 mg daily (INRs 2.4 to 3) when his treatment for HIV was changed from efavirenz and abacavir to **ritonavir**, **nelfinavir** and *Combivir* (zidovudine/lamivudine). Within 5 days his INR had risen to 10.4 without any sign of bleeding. It proved difficult to achieve acceptable and steady INRs both while in hospital and after discharge, but eventually it was discovered that the patient could not tolerate liquid ritonavir because of nausea and vomiting, so that he had sometimes skipped or lowered the ritonavir dose or even refused to take it. On the occasions where no ritonavir or low-dose ritonavir was taken, the INRs had been low, whereas when he took the full dose of ritonavir the INRs were high.⁵

In contrast, the INR of a 27-year-old HIV-positive woman taking warfarin fell when she was given **ritonavir**, clarithromycin and zidovudine. It was necessary almost to double the warfarin dosage to maintain satisfactory INRs. Three months later when the **ritonavir** was withdrawn, her INR more than tripled within a week. Her final warfarin maintenance dose was half of that needed before the **ritonavir** was started, and a quarter of the dose needed just before she stopped the **ritonavir**. This case was complicated by the use or withdrawal of a number of other drugs (co-trimoxazole, rifabutin, an oral contraceptive, megestrol), which can also interact with warfarin.⁶ Similarly, in another patient taking warfarin 6.25 mg daily with a prothrombin activity complex (PCA) of about 34%, a decrease in warfarin effects (PCA increase to 62%) was noted 20 days after starting **ritonavir** (escalating doses up to 600 mg every 12 hours). The warfarin dosage was then increased to 8.75 mg daily and 24 days later a satisfactory PCA of 33% was achieved.² This patient had previously shown a decrease in warfarin effects while taking *indinavir*, see above.

4. *Saquinavir*. A 73-year-old man who was HIV-positive and who had been taking warfarin, co-trimoxazole, nizatidine, stavudine and lamivudine for 7 months started taking saquinavir 600 mg three times daily. His INR, which had been stable at around 2 for five months, rose to about 2.5 after 4 weeks, and to about 4.2 after 8 weeks, which the author of the report attributed to an interaction with the saquinavir. The situation was solved by reducing the warfarin dosage by 20%.⁷

Mechanism

Protease inhibitors are well known to alter the metabolism of many drugs via inhibition, but sometimes induction of, cytochrome P450 isoenzymes, see 'Table 21.2', (p.773), so it is not surprising that they have altered warfarin effects, although the precise mechanism is unclear. The findings of the two pharmacokinetic studies suggest that, with warfarin, induction predominates, and that the anticoagulant effects are likely to be decreased.

Importance and management

Pharmacokinetic studies have suggested that ritonavir and lopinavir/ritonavir can modestly reduce warfarin levels. Clinical information on an interaction between coumarins and protease inhibitors is limited to the case reports cited, which either show an increase in warfarin effects (ritonavir or saquinavir) or a decrease in warfarin or acenocoumarol effects (indinavir, nelfinavir, or ritonavir). These cases show it would be prudent to monitor the prothrombin times and INRs of any patient if any HIV protease inhibitor is added, being alert for the need to modify the coumarin dosage.

Coumarins + Proton pump inhibitors

In pharmacological studies, omeprazole caused a minor increase in R-warfarin levels, with no or a minor increase in anticoagulant effect. Conversely, lansoprazole, pantoprazole and rabeprazole did not alter warfarin pharmacokinetics or anticoagulant effect. Omeprazole does not appear to alter the effects of acenocoumarol and pantoprazole does not appear to later the effects of phenprocoumon. Nevertheless, a number of isolated reports describe increased anticoagulant effects when PPIs are given with coumarins.

Clinical evidence

(a) Esomeprazole

Esomeprazole is the *S*-isomer of omeprazole, and would be expected to behave similarly, see below. The manufacturers say that esomeprazole 40 mg daily did not cause any clinically relevant effects on anticoagulant times in patients stabilised on **warfarin**, but a few isolated cases of raised INRs have been reported post-marketing.^{1,2}

(b) Lansoprazole

A study in 24 healthy subjects stabilised on **warfarin** found that lansoprazole 60 mg daily for 9 days had no effect on the pharmacokinetics of either *S*- or *R*-warfarin, and did not alter the effect of **warfarin** on prothrombin times.³

However, in 1998 the manufacturers of lansoprazole had on record two reports of possible interactions. An elderly patient taking **warfarin** developed an INR of 7 when lansoprazole was added. Despite a **warfarin** dosage adjustment he had a gastrointestinal haemorrhage, a myocardial infarction and died after 3 weeks. Another man taking **warfarin** (as well as amiodarone, furosemide and lisinopril) became confused, had hallucinations and developed an increased INR (value not known) when given lansoprazole. The lansoprazole was stopped after 4 days, and he then recovered. However, it is uncertain whether this was an interaction or whether he had taken an incorrect **warfarin** dosage because of his confusion.⁴

(c) Omeprazole

1. **Acenocoumarol**. In a placebo-controlled study in 8 healthy subjects, omeprazole 40 mg daily for 3 days had no effect on the pharmacokinetics of *R*- or *S*-acenocoumarol when a single 10-mg dose of acenocoumarol was given on day 2. In addition, omeprazole did not alter the anticoagulant effects of acenocoumarol.⁵ Similarly, there was no evidence of an interaction in a retrospective study of 118 patients given acenocoumarol with omeprazole and 299 patients taking acenocoumarol without omeprazole (matched for age and sex).⁶

However, an isolated case report describes a 78-year-old woman who had been taking acenocoumarol for 60 days and who developed gross haematuria within 5 days of starting omeprazole 20 mg daily. Her INR had risen from a range of 2.5 to 3 up to 5.7, and when the omeprazole was stopped, her INR fell.⁷

2. **Warfarin**. In 21 healthy subjects who had been stabilised on warfarin, omeprazole 20 mg daily for 2 weeks caused a small but statistically significant decrease in the mean thrombotest percentage, from 21.1 to 18.7%. *S*-warfarin serum levels remained unchanged, but a small 12% rise in *R*-warfarin levels was seen.⁸ In a further study, no changes in coagulation times or thrombotest values occurred in 28 patients anticoagulated with warfarin and given omeprazole 20 mg daily for 3 weeks. *S*-warfarin levels were unchanged, while a 9.5% increase in *R*-warfarin levels occurred.⁹

However, a man stabilised on warfarin 5 mg daily developed widespread bruising and haematuria 2 weeks after starting to take omeprazole 20 mg daily. His prothrombin time was found to have risen to 48 seconds. He was later restabilised on omeprazole 20 mg daily with the warfarin dosage reduced to 2 mg daily.¹⁰

(d) Pantoprazole

In 26 healthy subjects, pantoprazole 40 mg daily for 8 days caused no change in the response to a single 25-mg dose of **warfarin** given on day 2. The pharmacokinetics of *R*- and *S*-warfarin were unaltered, and no changes in the pharmacodynamics of the **warfarin** (prothrombin time, factor VII) were seen.¹¹ However, the manufacturer notes that there have been reports of increased INR and prothrombin time in patients taking pantoprazole and **warfarin**.¹²

No change in the prothrombin time ratio, was seen in 16 healthy subjects taking individualised maintenance **phenprocoumon** doses when they were given pantoprazole 40 mg daily for 5 days, nor was there any change in the pharmacokinetics of *R*- and *S*-phenprocoumon.¹³ However, there is a report of 2 possible cases of an interaction.¹⁴ One patient who was given **phenprocoumon** (loading dose 12 mg on day 1, 9 mg on day 2, 3 mg on day 3, and further as required) and omeprazole 20 mg daily concurrently, had an INR of 3.28 by the fourth day. The **phenprocoumon** was withheld, but the INR remained high for 9 days, when the omeprazole was stopped. Four days later the INR was 1.5 and **phenprocoumon** was restarted at 16.5 mg/week, and stabilised at 9 to 10.5 mg/week. She subsequently had a similar loading dose without problems, in the absence of omeprazole, when **phenprocoumon** was stopped for 3 weeks prior to surgery.¹⁴ Another patient stabilised on **phenprocoumon** 18 mg/week required a slight reduction in dose to 16.5 mg/week after starting omeprazole 20 mg daily.¹⁴

(e) Rabeprazole

In a placebo-controlled study a single 0.75-mg/kg dose of **warfarin** was given to 21 patients before and after rabeprazole 20 mg daily for 7 days. No significant changes in prothrombin times or in the pharmacokinetics of *R*- or *S*-warfarin were seen.¹⁵ However, the manufacturer notes that there have been reports of increased INR and prothrombin time in patients receiving rabeprazole and **warfarin**.¹⁶

Mechanism

Studies have shown that omeprazole partially inhibits the metabolism of *R*-warfarin, but not *S*-warfarin,^{17,18} which confirms the findings in the pharmacokinetic studies above. It also partially inhibits the metabolism of acenocoumarol.¹⁷ However, these small changes would generally not be expected to be clinically relevant. It has been suggested that the interaction might occur only in patients who are poor metabolisers of the cytochrome P450 isoenzyme CYP2C19 (seen in about 5% of Caucasians), who have five to tenfold higher levels of omeprazole than extensive metabolisers.⁵ Other proton pump inhibitors are generally considered to have less potential for pharmacokinetic interactions than omeprazole, but even with these, isolated cases of anticoagulant interactions have been reported. It is

possible that the isolated cases of interactions with proton pump inhibitors just represent idiosyncratic effects attributable to other factors, and not to any interaction.

Importance and management

The very minor pharmacokinetic interaction between omeprazole and warfarin, resulting in a less than 15% rise in just the *R*-warfarin levels, is established, but probably of limited clinical relevance. This is borne out by the fact there is only one published case report of an interaction. No pharmacokinetic or pharmacodynamic interaction occurred between warfarin and lansoprazole, pantoprazole or rabeprazole in clinical studies. However, isolated cases of raised INRs have been reported for all the proton pump inhibitors (esomeprazole, lansoprazole, pantoprazole, omeprazole and rabeprazole) and acenocoumarol (one published), phenprocoumon (2 published), and warfarin. When prescribing proton pump inhibitors to patients taking coumarins it would seem prudent to bear in mind that rarely bleeding can occur. Note that the US prescribing information for every proton pump inhibitor states that patients taking a proton pump inhibitor and warfarin may need to be monitored for increases in INR and prothrombin time. The advice in UK varies from recommending monitoring with warfarin and omeprazole¹⁹ or esomeprazole,¹ recommending monitoring with pantoprazole and coumarins on the basis of it being good practice to increase monitoring with any change in concurrent therapy,²⁰ to no advice with lansoprazole²¹ or rabeprazole.²² Further study is needed to determine whether the risk of an interaction with omeprazole is increased in poor metaboliser phenotypes for CYP2C19, as has been suggested.⁵

Coumarins + Quetiapine

A case report describes a woman taking warfarin who developed a raised INR when quetiapine was started.

Clinical evidence, mechanism, importance and management

A 71-year old woman receiving long-term treatment with **warfarin**, phenytoin, olanzapine and benzotropine had her **warfarin** dosage slightly reduced (from 20 to 19.5 mg weekly) because her INR was raised (from 1.6 to 2.6). Eight days later her treatment with olanzapine was changed to quetiapine 200 mg daily, and after 5 days her INR was 2.7. Two weeks later she was found to have an INR of 9.2. The quetiapine was stopped and she was given two doses of vitamin K by injection. The only clinical symptoms seen were a small amount of bleeding from the injection site and a bruise on her hand. She was eventually later restabilised on phenytoin, olanzapine and **warfarin** 21 mg weekly with an INR of 1.6.

The reasons for this apparent interaction are not known but the authors suggest that the quetiapine may have inhibited the metabolism of the **warfarin** (possibly by competitive inhibition of the cytochrome P450 isoenzymes CYP3A4 and CYP2C9), thereby increasing its effects. They also suggest that the phenytoin may have had some part to play.¹ This is only an isolated case but bear it in mind in the case of an unexpected response to concurrent use.

Coumarins + Quinidine

Quinidine did not alter the anticoagulant effect of warfarin in a study in patients, nor in a retrospective analysis of patient data. However, isolated reports of increased warfarin effects and bleeding have been reported, although these stem from over 35 years ago, and nothing further seems to have been reported, suggesting that an interaction is unlikely. Quinidine did not alter the half-life of phenprocoumon in healthy subjects. A small decrease in the effects of dicoumarol and warfarin has also been reported with quinidine, which was attributed to changes in haemodynamic factors following cardioversion.

Clinical evidence

In a controlled study, 10 patients receiving long-term treatment with **warfarin** 2.5 to 12.5 mg daily had no significant alteration in their prothrombin times when they were given quinidine 200 mg four times daily for 2 weeks.^{1,2} Similarly, in a retrospective analysis of 8 patients stabilised on **warfarin**, there was no change in anticoagulant control associated with starting or stopping quinidine (600 mg to 1.2 g daily as sulfate or 660 mg daily as gluconate).³ In the preliminary report of another study in 5 healthy subjects, quinidine 100 mg daily, started 7 days after a single 12-mg dose of **phenprocoumon** did not change the elimination half-life of **phenprocoumon**.⁴

In contrast, another report described 3 patients stabilised on **warfarin**, with Quick values within the range of 15 to 25%, who began to bleed within 7 to 10 days of starting to take quinidine 800 mg to 1.2 g daily. Their Quick values were found to have fallen to 6 to 8%. Bleeding ceased when the warfarin was withdrawn.⁵ There is one other case report of haemorrhage associated with the concurrent use of **warfarin** and quinidine,⁶ and in an analysis of haemorrhage in patients taking anticoagulants, it was reported that quinidine seemed partly responsible for some cases.⁷

In a further report, 4 patients taking **warfarin** or **dicoumarol** needed dosage *increases* of 8 to 24% to maintain adequate anticoagulation after DC conversion for atrial fibrillation and starting quinidine 400 mg three times daily, an effect that was attributed to haemodynamic factors.⁸

Mechanism

Uncertain. The cases of increased warfarin effects were attributed to quinidine possibly having a direct hypoprothrombinaemic effect of its own.⁵ The cases of a slight decrease in anticoagulant effect were attributed to changes in haemodynamic factors as a result of cardioversion.⁸

Importance and management

In one study and one retrospective analysis, quinidine had no effect on the anticoagulant control with warfarin in patients. Therefore, no interaction would normally be anticipated. However, a few isolated cases of increased anticoagulant effect with bleeding have been reported. Nevertheless, the literature is limited, and based solely on evidence from more than 35 years

ago. The lack of reports of any further interactions in this time suggests that a clinically relevant interaction is unlikely. Limited evidence suggests that quinidine does not alter phenprocoumon pharmacokinetics.

Coumarins + Quinine

Isolated reports describe increased anticoagulant effects in two women taking warfarin and a man taking phenprocoumon, which were attributed to the quinine content of tonic water. Limited evidence suggests that quinine does not alter the half-life of phenprocoumon.

Clinical evidence

In the preliminary report of a study in 5 healthy subjects, quinine 100 mg daily started 7 days after a single 12-mg dose of **phenprocoumon** did not change the elimination half-life of **phenprocoumon** in the following 7 days.¹

However, a patient on long-term **phenprocoumon** treatment repeatedly developed extensive haematuria within 24 hours of drinking 1 litre of Indian tonic water containing 30 mg of quinine.¹

A woman stabilised on **warfarin** needed a dosage reduction from 6 mg to 4 mg daily when she started to drink 1 to 1.5 litres of tonic water containing quinine each day. Her **warfarin** requirements rose again when the tonic water was stopped. Another woman needed a **warfarin** dosage reduction from 4 mg to 2 mg daily when she started to drink over 2 litres of tonic water daily. They were probably taking about 80 to 180 mg of quinine daily.²

Mechanism

Not understood. Two studies^{3,4} using the Page method (Russell viper venom)⁵ to measure prothrombin times showed that marked increases of up to 12 seconds could occur when 330-mg doses of quinine were given in the absence of an anticoagulant, but other studies^{4,6} using the Quick method found that the prothrombin times were only prolonged by up to 2.1 seconds. The changes in prothrombin times could be completely reversed by vitamin K (menadiol sodium diphosphate),^{3,4} which suggests that quinine, like the oral anticoagulants, is a competitive inhibitor of vitamin K. However, because the only reports relate to tonic water, it cannot be excluded that some other ingredient is responsible for the effect seen in these patients. Also, they may just represent idiosyncratic reactions.

Importance and management

Not established. The lack of reports relating to the therapeutic use of quinine suggest that no interaction of clinical importance occurs. The isolated cases cited show that very exceptionally decreased anticoagulant requirements and even bleeding can occur when large quantities of tonic water are ingested. However, whether the effect seen was related to the quinine content of this beverage is not established.

Coumarins + Raloxifene

In one study, raloxifene caused a minor increase in warfarin levels, but a 10% decrease in prothrombin time. The manufacturer notes that a small and slow decrease in prothrombin times may occur when raloxifene is given with warfarin, and possibly other coumarins.

Clinical evidence, mechanism, importance and management

In 15 healthy postmenopausal women, raloxifene 120 mg daily for 15 days had minor effects on the pharmacokinetics and pharmacodynamics of a single 20-mg dose of **warfarin** given on day 11. The clearance of both *R*- and *S*-warfarin was slightly decreased (by 7% and 14%, respectively), with similar increases in AUC. Conversely, the maximum prothrombin time was decreased by 10%.¹ As has been suggested for 'lasofoxifene', (p.423), this might be because oestrogenic compounds increase plasma concentrations of vitamin K-dependent clotting factors, so antagonising the effect of **warfarin**.

The manufacturer recommends that because modest decreases in prothrombin times have been seen, which may develop over several weeks, prothrombin times should be checked. They extend this recommendation to cover the use of other coumarins.²

Coumarins + Retinoids

Case reports describe reduced warfarin effects in a patient given etretinate, and in a patient given isotretinoin. Acitretin did not significantly alter the anticoagulant effects of phenprocoumon in healthy subjects.

Clinical evidence

(a) Phenprocoumon

Acitretin 50 mg daily for 10 days slightly increased the Quick test of 10 healthy subjects stabilised on phenprocoumon, from 22 to 24%, and the corresponding INR value decreased from 2.91 to 2.71. However, these changes were not considered to be significant.¹

(b) Warfarin

1. *Etretinate*. A man with T-cell lymphoma who had recently been given chemotherapy (cyclophosphamide, doxorubicin, vincristine and prednisolone) was anticoagulated with warfarin after developing a pulmonary embolism. About three weeks later, he started etretinate 40 mg daily and it was found necessary to increase his warfarin dosage from 7 to 10 mg daily. His liver function tests were normal.² This patient had also recently started taking 'co-proxamol', (p.436), 'tolbutamide', (p.380) and 'cimetidine', (p.412)', but all of these have been reported to only rarely increase the effect of warfarin.

2. *Isotretinoin*. A 61-year-old man stabilised on warfarin 2.5 mg daily for 2 to 3 years had a decrease in his INR to below 2.5 after starting oral cefpodoxime proxetil 200 mg twice daily and oral isotretinoin 30 mg daily for inflammatory lesions of the face. He required an increase in warfarin dose to 3.75 mg daily. The cefpodoxime was stopped after 10 days without a further change in warfarin requirement. However, when the isotretinoin was discontinued after 40 days, the INR progressively increased and the warfarin dose was eventually reduced to the pretreatment dose of 2.5 mg daily.³

Mechanism

Not understood. It has been suggested that etretinate or isotretinoin may increase the rate of metabolism of warfarin.^{2,3}

Importance and management

Information appears to be limited to these reports. The clinical relevance of the two case reports of a modest increase in warfarin requirements on

starting etretinate or isotretinoin is uncertain, but, until more is known, consideration could be given to monitoring the INR if patients are given warfarin and these retinoids. The study with acitretin suggests that no phenprocoumon dose adjustments are expected to be needed on starting acitretin.

3. Fiallo P. Reduced therapeutic activity of warfarin during treatment with oral isotretinoin. *Br J Dermatol* (2004) 150, 164.

Coumarins + Ribavirin

In a single patient, ribavirin appeared to decrease the effect of warfarin requiring a 40% increase in warfarin dose.

Clinical evidence

A 61-year-old patient who had been taking **warfarin** for a number of years with an INR in the range of 1.8 to 2.7 required a progressive 40% increase in **warfarin** dose (from 45 to 62.5 mg weekly) over the month after starting oral ribavirin 600 mg twice daily and subcutaneous interferon alfa-2b for active hepatitis C infection. During the following 11 months, the **warfarin** dose was stabilised at 57.5 mg weekly. Three weeks after discontinuation of the ribavirin and interferon, his INR had increased from 2.2 to 3.4 requiring a reduction in **warfarin** dose to 47.5 mg weekly. One year later, the patient was rechallenged with ribavirin 1 g daily for 4 weeks alone. At a weekly **warfarin** dose of 52.5 mg, his INR decreased from 2.6 to 1.8.¹

Mechanism

Unknown. The few cases with 'interferon', (p.422) have suggested that this may *increase* the effect of warfarin. In this case, ribavirin seems to have decreased the effect of warfarin, and overridden any effect of interferon.

Importance and management

This is the only case of this interaction, so it is not established, although the evidence on rechallenge with ribavirin alone lends weight to it being an interaction. The authors recommend increased monitoring of anticoagulant effects in patients taking warfarin requiring ribavirin. Until more is known, this may be prudent.

1. Schulman S. Inhibition of warfarin activity by ribavirin. *Ann Pharmacother* (2002) 36, 72–4.

Coumarins + Ropinirole

A man stabilised on warfarin had an increase in INR necessitating a 25% decrease in his warfarin dose while taking ropinirole.

Clinical evidence, mechanism, importance and management

A frail 63-year-old man taking levodopa/carbidopa daily and **warfarin** 4 mg daily with a stable INR ranging from 1.8 to 2.6 over the past 14 months was evaluated for possible progression of Parkinson's disease. He was then given ropinirole 250 micrograms three times daily with a 25% reduction in his levodopa/carbidopa dose, and 9 days later his INR was noted to have increased to 4.6, but there were no apparent signs of bleeding. **Warfarin** was withheld for 4 days, and then restarted at 2 mg daily, and increased to 3 mg daily 19 days later when his INR was 1.2. After one month the ropinirole was discontinued because of adverse gastrointestinal effects, and 2 months later his INR was 1.4 necessitating an increase in the **warfarin** dose to the original dose of 4 mg daily.¹

The mechanism of this probable interaction is unknown, and it appears to be the first evidence of such an interaction. No definite conclusions can be drawn from this isolated case.

1. Bair JD, Oppelt TF. Warfarin and ropinirole interaction. *Ann Pharmacother* (2001) 35, 1202–4.

Coumarins + Sevelamer

Sevelamer does not alter the pharmacokinetics of warfarin.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, the pharmacokinetics of a single 30-mg oral dose of **warfarin** were not statistically changed by sevelamer 2.4 g (equivalent to 6 capsules). Five more doses of sevelamer were given with meals over 2 days to check whether it had any effect on the enterohepatic circulation. No effect was seen.^{1–3} Thus it appears that sevelamer does not bind to **warfarin** within the gut to reduce its absorption.

2. Renagel Capsules (Sevelamer hydrochloride). Genzyme. US Prescribing information, April 2007.
3. Burke SK, Amin NS, Incerti C, Plone MA, Watson N. Sevelamer hydrochloride (Renagel®), a nonabsorbed phosphate-binding polymer, does not interfere with digoxin or warfarin pharmacokinetics. *J Clin Pharmacol* (2001) 41, 193–8.

Coumarins + SNRIs

In at least six cases venlafaxine appears to have increased the INRs and caused bleeding in patients taking warfarin. A similar case has been seen with duloxetine and warfarin.

Clinical evidence

(a) Duloxetine

A woman taking **warfarin** with a stable INR (mean 2.2 over the previous year) developed petechiae and purpura 55 days after starting duloxetine 30 mg daily, and was found to have an INR of 5. **Warfarin** was stopped on day 58, but the INR continued to rise to greater than 19 on day 85, and she was given vitamin K. On day 94 the duloxetine was stopped. **Warfarin** was restarted on day 110 and by day 140 the INR was 2.2 with the **warfarin** dose stabilised at the original level.¹

(b) Venlafaxine

The possible interactions of **warfarin** or other anticoagulants with venlafaxine do not appear to have been studied, but, as of May 2000, the manufacturers had on record 6 case reports of increased prothrombin times, raised INRs and bleeding (haematuria, gastrointestinal bleeding, melaena, haemarthrosis) in patients taking **warfarin** with venlafaxine.²

Mechanism

Just why these adverse interactions should have occurred is not understood, especially as no pharmacokinetic interaction is thought likely. Venlafaxine alone may uncommonly cause ecchymosis and mucosal bleeding and, rarely, prolonged bleeding time and haemorrhage.³ However, given the many other factors that can influence anticoagulant control, the reports of possible interactions could just represent idiosyncratic cases.

Importance and management

No interaction is established, and the general relevance of these unpublished cases is uncertain. If one subscribes to the view that increased monitoring is necessary when any drug is started or stopped in a patient on warfarin or related drugs, then it would be prudent to monitor prothrombin times with venlafaxine. More study is needed.

2. Wyeth Laboratories. Personal communication, May 2000.
3. Efexor (Venlafaxine hydrochloride). Wyeth Pharmaceuticals. UK Summary of product characteristics, May 2006.

Coumarins + Sodium edetate

A man had a reduction in the effects of warfarin, which was attributed to intravenous chelation therapy that included sodium edetate.

Clinical evidence, mechanism, importance and management

A 64-year-old man who had been taking **warfarin** for 3 weeks, with a gradually increasing dose to 25 mg weekly, had an INR decrease from 2.6 to 1.6 the day after he received intravenous chelation therapy with sodium edetate. He was given a single 10-mg dose of **warfarin** that day, then continued on his 25 mg weekly dose, with an INR in the range of 2.3 to 2.8. The chelation therapy also contained high-dose vitamin C along with various other vitamins and electrolytes.¹

Whether this case represents an interaction with the chelation therapy is uncertain. Further study is needed.

1. Grebe HB, Gregory PJ. Inhibition of warfarin anticoagulation associated with chelation therapy. *Pharmacotherapy* (2002) 22, 1067–69.

Coumarins and related drugs + SSRIs

In a study, warfarin plasma levels were increased by 65% by fluvoxamine, and raised INRs have been seen in several cases. In another study with warfarin and paroxetine, the majority of patients experienced no interaction, but a few had minor bleeding events. Other studies suggest that citalopram and sertraline do not significantly alter the pharmacokinetics or effects of warfarin. However, isolated reports describe bleeding in patients taking SSRIs and coumarins or fluidione, and SSRIs alone have, rarely, been associated with bleeding.

Clinical evidence

(a) Citalopram

In a study in 12 healthy subjects given a single 25-mg oral dose of **warfarin** either alone or on day 15 of a 21-day course of citalopram 40 mg daily, the pharmacokinetics of both *R*- and *S*-**warfarin** remained unchanged in the presence of the citalopram, but the maximum prothrombin time was increased by 6.4% (1.6 seconds). This was considered to be clinically irrelevant.¹

Nevertheless, a 63-year-old patient who had just started **acenocoumarol** 18 mg per week developed spontaneous gingival haemorrhage 10 days after also starting citalopram 20 mg daily for depression. Her INR had increased from a value of 1.8 to greater than 15. She was treated with 2 units of blood and citalopram was withdrawn. Her INR decreased to 1.95 within 5 days and she was able to continue on **acenocoumarol** 18 mg per week.²

(b) Escitalopram

Escitalopram is the *S*-isomer of citalopram, and as such would not be expected to interact pharmacokinetically with **warfarin**, see above.

(c) Fluoxetine

In a study in 3 healthy subjects, the half-life of a single 20-mg dose of **warfarin** was not altered by either a single 30-mg dose of fluoxetine given 3 hours before the **warfarin**, or by fluoxetine 30 mg daily for a week with the **warfarin** dose given 3 hours after the last dose of fluoxetine. In addition, fluoxetine had no effect on the warfarin-induced prolongation of prothrombin time.³ In another study, 6 patients stabilised on **warfarin** had no significant changes in their prothrombin times or INRs while taking fluoxetine 20 mg daily for 21 days. The maximum change was a decrease in prothrombin time of 3.5% (15%) in one patient.⁴

However, there are few reports of increases in INR in patients taking **warfarin** with fluoxetine. In one report, the INR of a man stabilised on **warfarin**, amiodarone, furosemide, digoxin, ciprofloxacin and levothyroxine rose sharply from a range of 1.8 to 2.3 up to 14.9 within 5 days of starting fluoxetine 30 mg daily.⁵ The INR of another man with metastatic carcinoma taking **warfarin**, dexamethasone, bisacodyl and lactulose rose from a range of 2.5 to 3.5 up to 15.5 within 2 weeks of starting fluoxetine 20 mg daily. He showed microscopic haematuria but no bleeding.⁵ Other reports describe an abdominal haematoma,⁵ cerebral haemorrhage,⁶ severe bruising⁷ and increases in INRs⁸ in patients taking fluoxetine and **warfarin**. In 1993, the CSM in the UK was also said to have 4 other similar cases on record.⁸ In the preliminary report of one retrospective review of patients records, all of 8 evaluable cases of concurrent use of fluoxetine and **warfarin** had an abnormally prolonged prothrombin time.⁹

Bowel haemorrhage has been reported in a patient taking **warfarin**, fluoxetine and mefenamic acid,¹⁰ but it is likely that mefenamic acid was the contributing factor in this case.¹¹

Conversely, in a case-control study in patients stabilised on **warfarin**, the increase in risk of hospitalisation for an upper gastrointestinal bleed after starting either fluvoxamine or fluoxetine was higher than for other SSRIs (relative risk 1.2) but this did not reach statistical significance (95% confidence interval 0.9 to 1.6).¹² Note that these drugs were considered separately, and the number taking each individual SSRI was not stated.

(d) Fluvoxamine

In a study in healthy subjects, fluvoxamine 50 mg three times daily for 12 days increased steady-state plasma **warfarin** levels by about 65% and increased prothrombin times by 27.8%.^{13,14} A worldwide literature search by the manufacturers of fluvoxamine identified only 11 reported interactions between **warfarin** and fluvoxamine by 1995, all with clinical signs that included prolonged prothrombin times.¹⁵ An 80-year-old woman who had recently started taking **warfarin**, digoxin and 'colchicine', (p.397), had an increase in her INR from 1.8 to about 10 within a week of starting to take fluvoxamine 25 mg daily. Both the **warfarin** and fluvoxamine were stopped, but her INR only stabilised on the original dose of **warfarin** after the colchicine was withdrawn.¹⁶ Another report describes a 79-year-old woman admitted to hospital because of suicidal thoughts. She was taking **warfarin** (INR 1.6 to 1.8) and citalopram 10 mg at night and other medications including paracetamol with dextropropoxyphene. On the third day in hospital the citalopram dose was increased to 30 mg at bedtime and after 2 days it was discontinued and fluvoxamine 50 mg daily was started to treat depression and possibly obsessive thoughts. Within 4 days the patient's INR had increased to 3.7. Fluvoxamine was replaced with venlafaxine and **warfarin** was omitted for 1 day. The INR gradually decreased to the normal range over about 7 days.¹⁷

A further isolated report describes a woman stabilised on **fluidione** whose INR rose to 7.13 (from a normal value of about 2.5) within 13 days of starting to take fluvoxamine 100 mg daily. She had received fluoxetine, dosulepin and lorazepam for 15 days before fluvoxamine was started.¹⁸

Conversely, in a case-control study in patients stabilised on **warfarin**, the increase in risk of hospitalisation for an upper gastrointestinal bleed after starting either fluvoxamine or fluoxetine was higher than for other SSRIs (relative risk 1.2) but this did not reach statistical significance (95% confidence interval 0.9 to 1.6).¹² Note that these drugs were not considered separately, and the number given each individual SSRI was not stated.

(e) Paroxetine

Paroxetine 30 mg daily, given to healthy subjects with **warfarin** 5 mg daily, did not significantly increase mean prothrombin times, but mild, clinically significant bleeding was seen in 5 out of 27 subjects given the combination. Two withdrew from the study because of increased prothrombin times, and another because of haematuria. The pharmacokinetics of the **warfarin** and the paroxetine remained unchanged by concurrent use.¹⁹ In a brief retrospective review, 4 patients taking **warfarin** were said to have had an increase in INR by an average of 3 points (increases of nearly 100% in some cases) associated with the use of paroxetine and sertraline.²⁰

A single case report²¹ describes severe bleeding (abdominal haematoma) in a patient taking **acenocoumarol** and paroxetine when given phenytoin, but it is by no means clear whether the paroxetine had any part to play in what happened (see 'Phenytoin + Coumarins and related drugs', p.555).

(f) Sertraline

In a placebo-controlled study in healthy subjects, sertraline, in increasing doses up to 200 mg daily for 22 days, increased the prothrombin time AUC in response to a single 0.75-mg/kg dose of **warfarin** by 7.9%. This was statistically significant, but regarded as too small to be clinically relevant.²²

In a brief retrospective review, 4 patients taking **warfarin** were said to have had an increase in INR by an average of 3 points (increases of nearly 100% in some cases) associated with the use of paroxetine and sertraline.²⁰

Mechanism

Pharmacokinetic interactions. Fluvoxamine is a moderate inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which *S*-**warfarin** is metabolised, and is also a potent inhibitor of CYP1A2 and CYP2C19, by which the less active *R*-**warfarin** is metabolised. Consequently, fluvoxamine would be expected to increase warfarin effects. *In vitro*, fluoxetine, paroxetine, sertraline, and citalopram had little or no inhibitory effect on CYP2C9 mediated *S*-**warfarin** hydroxylation.²³ In addition, these SSRIs do not inhibit CYP1A2 or

Table 12.6 Summary of pharmacological studies of the effect of statins on warfarin

Study type	Group	Warfarin	Statin dose	Findings		Refs
				Pharmacokinetics	Anticoagulant effects	
Atorvastatin						
Prospective	12 patients	Stable therapy	80 mg daily for 14 days	NR	Prothrombin time decreased from 18.6 to 17 seconds on days 3 to 5, but was not changed on other days	1
Fluvastatin						
Placebo-controlled	Healthy subjects	Single 30-mg dose	40 mg daily for 8 days	No change in racemic warfarin levels	No change in prothrombin complex activity	2
Crossover	18 Healthy subjects	Single 10-mg dose	40 mg twice daily for 18 days	Increase in AUC of S-warfarin of 42% in smokers and 26% in non-smokers	NR	3
Lovastatin						
NR	Patients	Stable therapy	NR	NR	No change in prothrombin time	4
Crossover, placebo-controlled	8 patients	Stable therapy	40 mg daily for 7 days	NR	INR increased from 2.6 to 3 (17%) by day 7	5
Pravastatin						
Prospective	Healthy subjects	5 mg daily	20 mg twice daily	17% increase in warfarin AUC*	No change in prothrombin time on concurrent use for 6 days	6
Crossover, placebo-controlled	8 patients	Stable therapy	20 mg daily for 7 days	NR	No change in INR over the 7 days	5
NR	Elderly healthy subjects	Stable therapy	40 mg	NR	No change in prothrombin time	14
Rosuvastatin						
Placebo-controlled, crossover	18 healthy subjects	Single 25-mg dose	40 mg daily for 10 days	No change in pharmacokinetics of S- or R-warfarin	INR AUC increased by 10%, and maximum INR increased by 19%	7
Prospective	7 patients	Stable therapy	10 mg daily for up to 14 days then 80 mg daily for up to 14 days	NR	With 10 mg daily, 2 patients had INR increases of 1.5 and 3.7 to values greater than 4. With 80 mg daily, 4 of 5 patients had increases of 1.5 to 2.6 to values greater than 4.	7
Placebo-controlled, crossover	12 healthy subjects	5 mg daily for 14 days	40 mg daily for 7 days	NR	No change in steady-state warfarin pharmacodynamics	8
Simvastatin						
Retrospective analysis of a placebo-controlled study	23 patients	NR	20 mg or 40 mg daily	NR	INR increased from a mean of 2.6 to 3.4 in the simvastatin group without changes in warfarin dose, compared with a decrease from 2.6 to 2.4 in the placebo group	9
NR	Healthy subjects	NR	20 mg or 40 mg daily	NR	INR increased from a mean of 1.7 to 1.8	10, 11
Retrospective cohort	46 patients	Stable with no change	Switch from pravastatin to simvastatin	NR	Mean INR increased from 2.42 to 2.74. Eleven patients had a warfarin dose adjustment after the INR change, 7 a decrease and 4 an increase	12
Retrospective	29 patients	Stable therapy	NR	NR	Warfarin dose decreased from a mean of 4.2 mg daily before to 3.8 mg daily after, while INR increased from a mean of 2.5 to 3.15	13

NR = not reported.

*Attributed to warfarin being nearer steady state by the combined phase of this longitudinal study, in which there was no washout between phases, and sequence of phases was pravastatin alone for 3.5 days, warfarin alone for 6 days, and then both drugs for 6 days.

CYP2C19, therefore they would not be anticipated to increase warfarin levels.

Pharmacodynamic interactions. Serotonin release by platelets plays an important role in haemostasis, and epidemiological studies and case reports suggest that SSRIs alone are rarely associated with bleeding events.²⁴ There is no firm evidence that the risk of bleeding is increased if SSRIs are given with anticoagulants.

Importance and management

A pharmacokinetic interaction between fluvoxamine and warfarin that leads to increased anticoagulant effects is established. Therefore, the response should be monitored when fluvoxamine is first added, being alert for the need to decrease the anticoagulant dosage.

None of the other SSRIs studied (citalopram, fluoxetine, paroxetine) have been shown to alter the pharmacokinetics of warfarin, and neither fluoxetine nor paroxetine increased the prothrombin time. However, citalopram and sertraline caused a less than 10% increase in prothrombin time, and a few patients taking paroxetine with warfarin had bleeds. However, in general, these effects would generally not be expected to be clinically relevant. Nevertheless, because SSRIs alone can rarely cause bleeding, some predict that this may result in additive effects with coumarins and indanediones, and recommend caution with all SSRIs. Note that there are case reports of interactions with warfarin for many of the SSRIs (citalopram, fluoxetine, paroxetine, sertraline).

Coumarins and related drugs + Statins

Studies have suggested that fluvastatin and rosuvastatin can increase warfarin levels and/or effects. Other studies with atorvastatin, lovastatin, pravastatin, and simvastatin suggest that they do not usually significantly alter the effects of warfarin, although cases of bleeding have been seen when these statins were given with coumarins and fluindione.

Clinical evidence

Pharmacological studies of the effect of statins on **warfarin** are summarised in 'Table 12.6', (p.449), and case reports of interactions between statins and coumarins are summarised in 'Table 12.7', (p.451). An early report, from the first 7 months after lovastatin became available in the USA, notes that the manufacturers had received 10 spontaneous reports of bleeding and/or increased prothrombin times in patients taking **warfarin** with lovastatin.^{1,2}

An analysis of the use of simvastatin and warfarin found a 12% lower **warfarin** maintenance dose in patients taking simvastatin,³ and a trend towards a lower dose with lower 10-hydroxywarfarin (a metabolite of **R-warfarin**) levels in patients taking simvastatin or lovastatin.⁴ However, an early case report described a patient stabilised on **warfarin** with type III hyperlipoproteinaemia who had no changes in her INR over 20 weeks when treated with simvastatin 10 mg daily for 3 weeks then 20 mg daily.⁵ At the other extreme, an isolated report⁶ describes rhabdomyolysis with acute renal failure in an 82-year-old man taking simvastatin 20 mg daily within 7 days of starting **warfarin** 5 mg daily; his INR was raised to 4.3.

Mechanism

Fluvastatin is a modest inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which the more potent *S*-warfarin is metabolised. Evidence from an interaction study with the CYP2C9 substrate diclofenac suggests that this interaction is most likely with higher and sustained fluvastatin levels,⁷ which might explain why, with warfarin, it was demonstrated in healthy subjects with the maximum recommended daily dose of 80 mg daily, but not the usual clinical dose of 40 mg daily, and why it has not been seen in all patients. Lovastatin and simvastatin appear less likely to interact via CYP2C9,⁸ although it is possible they might interact via other

Table 12.7 Summary of the case reports of interactions between statins and coumarins

Year of study	Patient	Coumarin	Statin dose (duration before event)	INR or PT* before	INR or PT after	Bleeding complications	Longer-term management	Refs
Fluvastatin								
1996	68-year-old	Warfarin	20 mg daily (6 weeks)	3	4.8	None	Warfarin dose decreased by 14%	1
			40 mg daily (2 months)	2.9	3.81	None	Warfarin dose decreased by 12.5%	
	61-year-old	Warfarin	20 mg daily (4 weeks ^{**})	2.29	3.54	None	Warfarin dose decreased by 10%	
	71-year-old	Warfarin	20 mg daily (3 weeks ^{**})	2.92	4.45	None	Warfarin dose decreased by 14%	
1997	68-year-old	Warfarin	20 mg daily (2 weeks)	2.11 to 2.99	4.17	None	Warfarin dose decreased by 18%, then increased back again on withdrawal of fluvastatin	2
	83-year-old	Warfarin	20 mg daily (1 week)	1.84 to 2.73	3.47	None	Warfarin dose decreased by 36%, then increased back again on withdrawal of fluvastatin	
	51-year-old	Warfarin	20 mg daily (1 week)	1.95 to 3.4	4.2	Minor rectal bleeding	Warfarin dose decreased by 13%	
2004	67-year-old	Warfarin	80 mg daily (5 weeks [†])	2 to 3	6.6	None	Fluvastatin switched back to atorvastatin, and warfarin reestablished at a 14% lower dose	3
Lovastatin								
1990	48-year-old	Warfarin	20 mg daily (3 weeks)	PT 18 to 24 seconds	PT 48 seconds	Minor rectal bleeding	Warfarin dose decreased by 60%	4
	58-year-old	Warfarin	20 mg daily (10 days)	PT 19 to 22 seconds	PT 42 seconds	Epistaxis and haematuria	Warfarin dose decreased by 60%	
1992	85-year-old	Warfarin	20 mg daily (2 weeks)	PT 15 to 17 seconds	PT 24 seconds	None	Lovastatin discontinued	5
1995	78-year-old	Warfarin	40 mg daily (2 months)	1.9 to 3.1	12.3	Gross haematuria, haematoma	Lovastatin discontinued	6
Pravastatin								
1996	64-year-old	Fluindione [‡]	10 mg daily (5 days)	2.5 to 3.5	10.2	Haematuria	Not reported	7
Rosuvastatin								
2004	74-year-old	Warfarin	Not reported (4 weeks)	2	8	Bruising, haematuria	Not reported	8
2005	36-year-old	Acenocoumarol	10 mg daily (about 45 days)	2 to 3	5.8	Haematoma	Rosuvastatin discontinued	9
Simvastatin								
1996	70-year-old	Acenocoumarol	20 mg daily (3 weeks)	2 to 3.5	9	Not reported	Simvastatin discontinued	10

isoenzymes. It may be that because warfarin has multiple routes of metabolism that other isoenzymes can 'pick up' warfarin metabolism if competition for metabolism occurs. Interactions may therefore only occur if other confounding factors are present. Rosuvastatin clearly shows a dose related increase in warfarin effects, but this was not due to an increase in *R*- or *S*-warfarin levels, and the mechanism for this effect is currently unknown.⁹

Importance and management

Data are limited, which is surprising given the widespread use of statins and warfarin, and are sometimes contradictory, all of which complicates making firm recommendations. Recent evidence suggests that a modest pharmacokinetic interaction occurs between **fluvastatin** and warfarin at high doses, and this would explain the case reports of an interaction with this statin. The clinical evidence suggests that only some patients develop an important interaction (3 of 25 evaluable patients in one analysis). In the UK, the manufacturer states that concurrent use of fluvastatin and warfarin may commonly cause significant increases in prothrombin time.¹⁰ Clearly, with **fluvastatin**, increased monitoring is required when starting or stopping the statin, or changing the dose. Similar advice also applies to **rosuvastatin**, which has the best pharmacological data on concurrent use in patients, clearly showing that clinically important increases in INR can occur. In contrast to fluvastatin, this interaction does not appear to have a pharmacokinetic basis.

Data for **simvastatin** appear to be limited to retrospective analyses. In general these show that simvastatin can cause a minor increase in warfarin effects. This would appear to be supported by the fact that there is only one full published report of an interaction in a patient taking acenocoumarol. Some consider that any interaction is of limited clinical importance, and that statin therapy may be switched to simvastatin without any additional monitoring over and above that usually practised for warfarin therapy.¹¹ However, others,¹² including the manufacturer^{13,14} recommend increased monitoring when starting or stopping the statin, or changing the dose, and this may be prudent. There are even less data for **lovastatin**, an analogue of simvastatin, but it appears to interact similarly to simvastatin, and the manufacturer also recommends increased monitoring.¹⁵ There appear to be no data on the effect of lovastatin or simvastatin on the pharmacokinetics of coumarins.

In one pharmacological study, **atorvastatin** did not interact with warfarin, and no cases of an interaction have been published. This suggests that with this statin, no increased monitoring is necessary. In the US, the manufacturer does not give any advice on monitoring,¹⁶ but in the UK, the manufacturer does recommend close monitoring,¹⁷ which seems over-cautious. Limited data for **pravastatin** also suggest that no interaction occurs with warfarin, although there is one isolated case report with the in-danedione fluidione. No increased monitoring would appear to be necessary on concurrent use.

Coumarins + Sucralfate

The simultaneous administration of warfarin and sucralfate did not alter the anticoagulant effect of warfarin in studies in patients on stable therapy. However, case reports describe a marked reduction in the effects of warfarin in four patients taking sucralfate.

Clinical evidence

In an open, crossover study in 8 elderly patients taking **warfarin**, their anticoagulant response (thromboplastin time) and plasma **warfarin** levels remained unchanged while taking sucralfate 1 g three times a day over a 2-week period.¹ Similarly, in a preliminary report of another study, sucralfate 1 g four times daily for 2 weeks had no effect on prothrombin time or plasma **warfarin** levels in 5 patients on stable **warfarin** therapy.² In both these studies, the daily **warfarin** dose was taken simultaneously with one of the sucralfate doses.^{1,2}

However, there are four case reports of reduced **warfarin** effects with sucralfate. In one of these, a man taking several drugs (digoxin, furosemide, chlorpropamide, potassium chloride) had serum **warfarin** levels that were about two-thirds lower when he was given sucralfate (dose not stated). When the sucralfate was withdrawn, his serum **warfarin** levels rose to their former levels accompanied by a prolongation of prothrombin times.³ Another patient taking sucralfate had subtherapeutic prothrombin times on starting **warfarin**, despite **warfarin** doses of up to 17.5 mg daily. When the sucralfate was stopped his prothrombin time rose to 1.5 times the control, even though the **warfarin** dose was reduced to 10 mg daily.⁴ One other patient appeared to have reduced responses to **warfarin** while taking sucralfate, despite separation of administration.⁵ However, another patient taking **warfarin** and sucralfate had a reduced response to **warfarin** only when it was taken simultaneously with sucralfate, but not when administration was separated.⁶

Mechanism

Unknown. It is suggested that the sucralfate may possibly adsorb the warfarin so that its bioavailability is reduced.⁴

Importance and management

The documentation appears to be limited to the reports cited. Any interaction would therefore seem to be uncommon. Concurrent use need not be avoided, but bear this interaction in mind if a patient has a reduced anticoagulant response to warfarin.

Coumarins + Sucrose polyesters

Short-term, moderate consumption of potato crisps containing sucrose polyesters (Olestra, Olean), which include vitamin K₁, did not alter the INR in response to warfarin.

Clinical evidence

In a randomised, double-blind, placebo-controlled study in 36 patients stabilised on **warfarin**, sucrose polyester 12 g daily (as *Pringles Original Flavor Fat Free Potato Crisps with Olean* 42 g) for one week did not significantly alter the anticoagulant effects of **warfarin** (mean INR increase of 0.02, versus 0.17 for placebo). After one week, greater than expected numbers of patients from both the placebo and sucrose polyester groups had INRs outside the therapeutic range of 2 to 3 (3 sucrose polyester recipients and 3 placebo recipients had an INR above 3 (max 4.1) and 2 in the sucrose polyester group and one in the placebo group had an INR less

than 2). Two of each group also withdrew because of diarrhoea: their INRs were therapeutic. Only 22 patients entered the second week of the study, and there was no important effect on INR in these patients after the second week.¹

Mechanism

Sucrose polyesters are non-absorbable, non-calorific fat replacements. It has been concluded that sucrose polyesters are unlikely to reduce the absorption of oral drugs in general, however, they are known to reduce the absorption of some fat-soluble vitamins, and therefore might lower vitamin K stores.² Because of this, snacks containing *Olestra* are supplemented with vitamin K₁ at a level of 8 micrograms per gram of *Olestra*.³ It is possible that this supplementation could be insufficient to offset the vitamin K-lowering effect and increase patient sensitivity to warfarin, or it could be too much and result in an antagonism of warfarin.

Importance and management

No evidence was found in the above study to suggest that short-term moderate consumption of a snack containing sucrose polyesters (12 g daily, including 96 micrograms of vitamin K daily) altered the anticoagulant effect of warfarin. In 1996, the US FDA considered that the changes in dietary vitamin K intake attributable to eating vitamin-K compensated *Olestra* would likely be within the normal range of dietary variation.³ However, an intake similar to this of a 'vitamin K₁ supplement', (p.401) has altered coagulation status in some subjects, and pure vitamin K₁ is much more bio-available than that from 'plant sources', (p.409). Some consider that the snacks may have an impact on serum vitamin K levels.⁴ Given these concerns, further study is probably needed.

Coumarins + Sulfinpyrazone

The anticoagulant effects of warfarin are markedly increased by sulfinpyrazone, and there are case reports of moderate to serious bleeding on concurrent use. Acenocoumarol is modestly affected. Phenprocoumon does not appear to be significantly affected. Bear in mind that the antiplatelet effects of sulfinpyrazone might increase the risk of bleeding with coumarins.

Clinical evidence

(a) Acenocoumarol

In a placebo-controlled, crossover study in 22 patients taking acenocoumarol, sulfinpyrazone 800 mg daily for 2 weeks led to a drop in the mean prothrombin time requiring a reduction in anticoagulant dosage by an average of 20%. Four patients withdrew because of bleeding episodes, 3 while taking sulfinpyrazone and one while taking placebo.¹

(b) Phenprocoumon

In a study in 6 healthy subjects, sulfinpyrazone 400 mg daily for 17 days had little effect on phenprocoumon levels after a single 0.6-mg/kg dose of phenprocoumon given on day 4. The AUC of prothrombin time increased in 4 subjects and decreased in 2, for an overall non-significant mean increase of 16%.² Similar findings were reported in another study of similar design.³

(c) Warfarin

In a double-blind, placebo-controlled study in 11 patients stabilised on warfarin, sulfinpyrazone 200 mg four times daily for 6 to 12 months reduced the average warfarin dose requirement by 44% from 7.3 to 4.1 mg week, compared with no change in the placebo group. There were 4 episodes of bleeding (haematoma, epistaxes and bleeding gums) in 3 patients receiving sulfinpyrazone and one in the placebo group. The authors noted it was difficult to regulate anticoagulant control in the patients taking

sulfinpyrazone.^{4,5} Similarly, in another study, the prothrombin ratios of 5 patients taking warfarin rose rapidly over 2 to 3 days after sulfinpyrazone 200 mg every 6 hours was added. The average warfarin requirements fell by 46% and 2 patients needed vitamin K to combat the excessive hypoprothrombinaemia. When the sulfinpyrazone was withdrawn, the warfarin requirements returned to their former levels within 1 to 2 weeks.⁶

A number of case reports have described increased effects of warfarin in patients starting sulfinpyrazone,^{7–12} or an exaggerated anticoagulant response in patients taking sulfinpyrazone and then starting warfarin.¹³ This interaction has been described in numerous studies and case reports in those taking warfarin.^{4,5,7–14} Moderate to severe bleeding occurred in some instances.^{8,10,11} An increased anticoagulant effect of warfarin in the first 15 days after starting sulfinpyrazone, followed by an unexplained progressive increased warfarin dose requirement has been described in one report.¹⁴ However, this may have had other explanations, since a constant potentiation of warfarin is usually seen on long-term sulfinpyrazone use.⁵

In subsequent studies in healthy subjects, sulfinpyrazone 200 mg twice daily for 10 days was shown to augment the effect of warfarin (99% or 83% increase in the AUC of the prothrombin time) by inhibiting the clearance of *S*-warfarin (by 51% or 40%) when a single dose of warfarin was given on day 4. In contrast, sulfinpyrazone did not alter the effect of *R*-warfarin, and actually increased its clearance by 30% or 42%.^{15,16}

Mechanism

Sulfinpyrazone inhibits the metabolism of the more potent *S*-isomer of warfarin, probably because its sulfide metabolite inhibits the cytochrome P450 isoenzyme CYP2C9.¹⁷ It probably interacts by a similar mechanism with acenocoumarol. It could be speculated that sulfinpyrazone induces the metabolism of *R*-warfarin via CYP1A2, since it modestly induces the metabolism of 'theophylline', (p.1199). Some early *in vitro* evidence¹⁸ suggested that plasma protein binding displacement might explain this interaction, but a study in healthy subjects found that sulfinpyrazone did not alter the free fraction of either *R*- or *S*-warfarin.¹⁹ Sulfinpyrazone also has antiplatelet effects, so might be expected to increase the risk or severity of bleeding should over-anticoagulation occur.

Importance and management

The increased effect of warfarin with sulfinpyrazone is a well established interaction of clinical importance. If sulfinpyrazone is added, the prothrombin time should be well monitored and suitable anticoagulant dosage reductions made. Halving the dosage of warfarin^{4,6,20} has proven to be adequate in patients taking sulfinpyrazone 600 to 800 mg daily. The interaction with acenocoumarol¹ is less marked, and a 20% dose reduction appears adequate in patients taking sulfinpyrazone 600 to 800 mg daily. Phenprocoumon is reported not to have a pharmacokinetic interaction with sulfinpyrazone. Bear in mind that the antiplatelet effects of sulfinpyrazone might increase the risk of bleeding with coumarins.

Coumarins + Tamoxifen or Toremifene

In one retrospective analysis, 5 patients taking tamoxifen were very sensitive to warfarin, and, in a second, 5 of 22 patients had problems with over-anticoagulation. Case reports also describe over-anticoagulation in three women taking warfarin and one woman taking acenocoumarol when they also took tamoxifen. It has been suggested that a similar interaction may occur with toremifene.

Clinical evidence

A woman who had been taking **warfarin** for 11 years after a heart valve replacement (prothrombin time of 23 to 34 seconds taking **warfarin** 27 to 28.5 mg weekly), was given tamoxifen 10 mg twice daily as adjuvant therapy after mastectomy for early breast cancer. Three days later her prothrombin time was 39 seconds, and 3 weeks later it was 75.6 seconds, although this was attributed to a 5-day course of co-trimoxazole, and so the warfarin dose was unchanged. Six weeks later she developed haematemesis, abdominal pain and haematuria, and her prothrombin time was found to be 206 seconds. She was restabilised on a little over half the **warfarin** dosage (17.5 mg weekly) while continuing to take the tamoxifen.¹ In another case, a 43-year-old woman was given **warfarin** for a deep vein thrombosis. Seven weeks later tamoxifen 40 mg daily was started, and her prothrombin time increased from 19 to 38 seconds. A warfarin dose reduction from 5 to 1 mg daily was eventually needed to keep her prothrombin time within the range of 20 to 25 seconds. A subsequent retrospective study of the records of women with breast cancer who had been admitted to hospital for serious thromboembolism from 1981 to 1986 revealed 5 other patients taking tamoxifen when **warfarin** was started, and 13 patients not taking tamoxifen. Of the 5 taking tamoxifen, 2 had shown marked increases in prothrombin times, and bleeding, shortly after receiving loading doses of **warfarin** (three daily doses of 10 mg, 10 mg and 5 mg). The other 3 needed daily **warfarin** doses of 2 mg, 2 mg and 3 mg, respectively, which were about one-third of those taken by the 13 other patients not on tamoxifen (mean 6.25 mg).²

In another retrospective analysis of hospital admissions from 1980 to 1988, 22 patients were identified who had been given tamoxifen with **warfarin**. Of these, 17 had no problems, but 2 developed grossly elevated British Comparative Ratios and 3 haemorrhaged.³ In 1987, the manufacturers of tamoxifen had one report of this interaction on their files.¹

A 53-year-old woman who had been taking **acenocoumarol** for 2 years after a heart valve replacement died after a massive brain haemorrhage about 3 weeks after starting to take tamoxifen 20 mg daily for a benign breast condition.⁴

Mechanism

Unknown. Tamoxifen can *increase* the risk of thrombosis, particularly when it is used with 'antineoplastics', (p.616).

Importance and management

Evidence is limited to the above reports, but it appears that a clinically important interaction between tamoxifen and warfarin can occur, which apparently affects some but not all patients. Monitor the effects closely if tamoxifen is added to treatment with warfarin or acenocoumarol and reduce the dosage as necessary. The reports cited here indicate a reduction of between one-half to two-thirds for warfarin. In the US, when tamoxifen is being used for the primary prevention of breast cancer, the manufacturer specifically contraindicates concurrent use with warfarin or other coumarins.⁵

Consider also that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, warfarin is generally in-

ferior (higher risk of major bleeds and recurrent thrombosis) to low molecular weight heparins.⁶

Because of the data with tamoxifen, the manufacturers of **toremifene** (indicated for hormone-dependent metastatic breast cancer in postmenopausal women) contraindicate the concurrent use of coumarin anticoagulants in the UK,⁷ but just recommend careful monitoring of prothrombin time in the US.⁸ However, there appear to be no published reports of any interaction between **toremifene** and warfarin.

Coumarins + Terbinafine

Terbinafine did not interact with warfarin in a study in healthy subjects, and patients have received the combination without apparent problems. However, two isolated cases describe reduced and increased anticoagulation, respectively. A cohort study found no increased risk of over-anticoagulation when acenocoumarol or phenprocoumon were given with terbinafine.

Clinical evidence

In a randomised, placebo-controlled, double-blind study in 16 healthy subjects, terbinafine 250 mg daily for 14 days did not alter the pharmacokinetics or anticoagulant effects of a single 30-mg oral dose of **warfarin** given on day 8.¹ In a post-marketing surveillance study of terbinafine, 26 patients were identified who were also taking **warfarin** and there was no evidence to suggest an interaction in these patients.^{2,3} In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, the concurrent use of oral terbinafine (n=49) or cutaneous terbinafine (n=29) was not associated with an increased risk of over-anticoagulation (INR greater than 6).⁴ However, an isolated report describes a 68-year-old woman taking long-term **warfarin** whose INR fell from 2.1 to 1.1 within a month of starting a 3-month course of terbinafine 250 mg daily for tinea unguium. It was necessary to raise her **warfarin** dosage from 5.5 mg daily to a range of 7.5 to 8 mg daily while taking the terbinafine, and to reduce it stepwise to 5.5 mg over the 4 weeks after the terbinafine was stopped.⁵ In contrast, another isolated case report describes an elderly woman stabilised on **warfarin** and cimetidine who developed gastrointestinal bleeding about a month after starting to take terbinafine 250 mg daily.⁶

Mechanism

The isolated cases are not understood, and have been questioned.⁷

Importance and management

Normally no interaction occurs between coumarins and terbinafine, while the two isolated cases cited are rarities, and unexplained. There appears therefore to be no reason for avoiding concurrent use, but bear these cases in mind if terbinafine is given to patients taking warfarin.

Coumarins + Tetracyclid and related antidepressants

In one study mirtazapine caused a slight increase in INR in subjects given warfarin. In studies in patients, maprotiline did not alter the anticoagulant effect of acenocoumarol, and mianserin did not alter the anticoagulant effect of phenprocoumon. In isolated case reports, an increased effect of warfarin and a decreased effect of acenocoumarol was seen when mianserin was given.

Clinical evidence

(a) Maprotiline

The anticoagulant effects of **acenocoumarol** were not affected by maprotiline 50 mg three times daily for 2 weeks in 20 patients stabilised on **acenocoumarol**.¹

(b) Mianserin

In a randomised, double-blind study in 60 patients taking **phenprocoumon** for 5 weeks, there was no difference in anticoagulant control and **phenprocoumon** dose between placebo recipients and those receiving either mianserin up to 30 mg daily or up to 60 mg daily for 20 days.²

A single case report describes a man stabilised on **warfarin** whose British standard ratio rose from 1.8 to 4.6 (prothrombin time rise from 20 to 25 seconds) after taking mianserin 10 mg daily for 7 days.³ However, another patient taking **warfarin** received mianserin in doses varying between 0 and 120 mg daily for 22 weeks without any change in prothrombin ratio.⁴ A further patient stabilised on **acenocoumarol** and amidarone needed an *increase* in his **acenocoumarol** dosage after starting mianserin, and a decrease when this drug was stopped.⁵

(c) Mirtazapine

In a study in healthy subjects stabilised on individual doses of **warfarin**,⁶ mirtazapine 15 mg for 2 days then 30 mg daily for 5 days increased the mean INR from 1.6 to 1.8. This small increase was not considered clinically relevant by the authors of the study or one of the UK manufacturers.^{6,7} One UK manufacturer comments that a more pronounced effect cannot be excluded at higher doses of mirtazapine.⁸ However, there do not appear to be any published reports of interactions.

Mechanism

Not understood.

Importance and management

Maprotiline does not interact with acenocoumarol and mianserin does not interact with phenprocoumon. The isolated cases of an increase in warfarin effects and a decrease in acenocoumarol effects with mianserin are unexplained, and probably of little general relevance. One UK manufacturer of mirtazapine very cautiously advises that the prothrombin time should be controlled if mirtazapine is given with warfarin.⁸ However, there do not appear to be any reports of problems with this combination, and another manufacturer does not consider monitoring to be necessary.⁷

Coumarins and related drugs + Thyroid and Antithyroid compounds

Hypothyroidism and hyperthyroidism, respectively, decrease and increase the metabolism of the clotting factors. Correction of these disease states therefore alters anticoagulant requirements. Bleeding has been seen in patients given thyroid hormones without an adjustment of their warfarin dose, and increased warfarin requirements have been seen in a patient given thiamazole. This is more of a drug-disease interaction rather than a direct drug-drug interaction and is therefore likely to occur with any coumarin or indanedione given with any drug that affects thyroid function.

Clinical evidence

(a) Hypothyroidism and Thyroid compounds

In a study in 7 patients with myxoedema (hypothyroidism), the response to a single dose of **warfarin** was increased after 3 months of treatment with **liothyronine** (when euthyroid), when compared with before treatment, without a change in plasma warfarin levels.¹ Various case reports describe similar effects. In one report, brief mention is made of one patient who showed an increased response to **warfarin** after an increase in dose of thyroid replacement therapy, and of another patient on long-term **warfarin** who had a bleeding episode when thyroid replacement therapy was started.² Another patient taking **warfarin** developed oral mucosal bleeding with an INR of greater than 11 when her hypothyroidism was overcorrected with **levothyroxine**, although she had no clinical signs of hyperthyroidism.³ In another case, a subdural haematoma occurred in a child stabilised on **warfarin** when **levothyroxine** was started, and her dose of **warfarin** was eventually reduced from 7.5 mg daily to 5 mg daily.⁴

A patient with myxoedema required a gradual reduction in his dosage of **phenindione** from 200 to 75 mg daily as his thyroid status was corrected by **liothyronine**.⁵ A similar patient required a reduction in **acenocoumarol** dose from 16 mg daily to 5 mg daily when hypothyroidism was corrected with **liothyronine**.⁵

(b) Hyperthyroidism and Antithyroid compounds

In 5 patients with hyperthyroidism, the response to a single dose of **warfarin** was decreased 3 months after treatment with **iodine-131** (when euthyroid), when compared with before treatment. In addition, the plasma half-life and levels of **warfarin** were higher after treatment.⁶ A hyperthyroid patient taking **warfarin** had a marked increase in his prothrombin times on two occasions when his treatment with **thiamazole** (**methimazole**) was stopped and he became hyperthyroid again.⁷ Another similar case has been described where the required dose of **warfarin** increased from 35 mg weekly to 65 mg weekly as the patient's hyperthyroid state was corrected with **thiamazole** 30 mg daily. However, the patient then became hypothyroid and required up to 85 mg weekly of **warfarin**. When the **thiamazole** dose was withheld for 5 days and then reduced to 5 mg daily, the patient rapidly developed a markedly raised INR of 7 without bleeding complications.⁸ In another report, a patient required just 0.5 mg of **warfarin** daily while hyperthyroid.³ Another case of possible enhanced response to **warfarin** in a hyperthyroid patient has been reported.^{9,10}

Mechanism

In hypothyroid patients the catabolism (destruction) of the blood clotting factors (II, VII, IX and X) is low and this tends to cancel, to some extent, the effects of the anticoagulants, which reduce blood clotting factor synthesis. Conversely, in hyperthyroid patients in whom the catabolism is increased, the net result is an increase in the effects of the anticoagulants.¹¹ In studies in healthy subjects, **dextrothyroxine** (which has weak thyroid activity compared with **levothyroxine**) potentiated the anticoagulant effect of **dicoumarol**¹² and **warfarin**¹³ without altering the half-life and plasma levels of the anticoagulants, and without altering vitamin K-dependent clotting activity.¹² Because of this, it was suggested that the thyroid hormones might increase the affinity of the anticoagulants for its receptor sites.^{12,13}

Importance and management

A well documented and clinically important interaction occurs if oral anticoagulants and thyroid hormones are taken concurrently.

Hypothyroid patients taking an anticoagulant who are subsequently treated with thyroid hormones as replacement therapy will need a downward adjustment of the anticoagulant dosage as treatment proceeds if excessive hypoprothrombinaemia and bleeding are to be avoided. All of the oral anticoagulants may be expected to behave similarly. Conversely, as the thyroid status of hyperthyroid patients returns to normal by the use of antithyroid drugs (e.g. **carbimazole**, thiamazole, **propylthiouracil**) an increase in the anticoagulant requirements would be expected. Close anticoagulant monitoring and dose adjustment are required, particularly while thyroid hormone levels are being stabilised. Note that, in one case the authors commented that the magnitude and clinical complexity of the interaction between the drugs and disease state was unexpected.⁸

Note that propylthiouracil in the absence of an anticoagulant has very occasionally been reported to cause hypoprothrombinaemia and bleeding.^{14,15}

Some drugs can alter thyroid status as an unwanted effect, and this will also alter the response to the oral anticoagulants. For example, 'amiodarone', (p.363) can cause thyrotoxicosis, which decreases warfarin requirements. Also, use of **dextrothyroxine** for hypercholesterolaemia decreased the required dose of warfarin^{16,17} and dicoumarol,¹⁸ presumably because it has weak thyroid activity.

Coumarins + Tiabendazole

An isolated case report describes a marked increase in the anticoagulant effects of acenocoumarol in a patient given tiabendazole.

Clinical evidence, mechanism, importance and management

An increase in the anticoagulant effects of **acenocoumarol** occurred in a patient with nephrotic syndrome undergoing dialysis, who was given tiabendazole 8 g daily for 2 days on two occasions about 7 weeks apart.¹ On both occasions, his INR rose from 2.9 to more than 5 without any clinical consequence. The reasons are not understood, nor is the general importance of this interaction known. There seem to be no other reports.

Coumarins + Tobacco

In one study in healthy subjects, stopping smoking caused a minor 13% increase in steady-state warfarin levels. Two cases have been reported of patients who required 14% and 23% reductions in warfarin dose, respectively, on stopping smoking. However, one analysis did not find any significant difference in warfarin dose by smoking status. One patient who stopped chewing tobacco had an increase in INR.

Clinical evidence

(a) Chewing tobacco

In a patient using smokeless tobacco (chewing tobacco) for greater than 85% of waking hours, the INR was found to have increased from 1.1 to 2.3 six days after discontinuation of the tobacco use. This patient had generally had an INR of 1.1 to 1.9 since restarting warfarin 4 months earlier, despite gradually increasing the warfarin dose from 10 mg daily to 25 mg daily alternating with 30 mg daily. However, during this time, he did have two INR spikes of 2.5 and 4.2, which were attributed to dietary changes,¹ but see mechanism below.

(b) Smoking tobacco

In a controlled study in 9 healthy subjects who normally smoked at least one pack of cigarettes daily (size unknown) and who were given **warfarin** to steady-state, smoking abstinence for about 6 weeks increased the average steady-state **warfarin** levels by 13%, decreased **warfarin** clearance by 13% and increased the **warfarin** half-life by 23%, but no changes in the prothrombin time occurred.² An 80-year-old man taking **warfarin** had a steady rise in his INR (from a range of 2 to 2.8 up to 3.7) over a 3-month period when he gave up smoking. No bleeding occurred. His dose of **warfarin** was reduced by 14%, and the INR stabilised at 2.3 to 2.8 over the next 9 months.³ Similarly, another patient required a 23% reduction in **warfarin** dose after stopping smoking following recovery from bacterial meningitis.⁴

In contrast, in one retrospective study of patients who had undergone cardiac valve replacement, there was no statistically significant difference between the **warfarin** dosage requirements of 117 non-smokers, 23 light smokers (20 or less cigarettes daily) or 34 heavy smokers (greater than 20 cigarettes daily).⁵

Mechanism

Some of the components of tobacco smoke act as cytochrome P450 isoenzyme inducers, which might cause a small increase in the metabolism of the warfarin. When smoking stops, the enzymes are no longer stimulated, the metabolism of the warfarin falls slightly and its effects are correspondingly slightly increased. Tobacco smoke is known to induce CYP1A2, which has a partial role in the metabolism of the less active *R*-warfarin enantiomer. Note that smoking status had no effect on the *S*-warfarin AUC in one study.⁶

The possible case of an interaction with smokeless tobacco was attributed to the very high 'vitamin-K', (p.458), content of tobacco resulting in relative warfarin resistance. However, there were two previous INR spikes in this patient, which were attributed to dietary changes,¹ an explanation that seems unlikely if there was a high background vitamin K intake from the tobacco. This case is therefore unclear.

Importance and management

The overall picture seems to be that smoking (or giving up smoking) only has a slight to moderate effect on the response to warfarin, and only the occasional patient will need a small dosage alteration. This should easily be detected in the course of routine INR checks. Note that tobacco smoking increases cardiovascular disease risk, and patients requiring anticoagulants should be encouraged and helped to stop smoking.

The isolated case with smokeless tobacco is unclear, but consider the possibility that vitamin K from chewing tobacco may reduce warfarin effects. Further study is needed.

Coumarins + Tolterodine

In healthy subjects, tolterodine did not alter the pharmacokinetics or pharmacodynamics of warfarin, but isolated cases of raised INRs have been reported.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in healthy subjects, tolterodine 2 mg twice daily for 7 days did not affect the pharmacokinetics of *R*- or *S*-warfarin after a single 25-mg dose of **warfarin** given on day 4, nor were the pharmacokinetics of tolterodine altered by **warfarin**. In addition, the prothrombin time and factor VII activity were not altered by tolterodine.¹

However, a report describes two patients on stable **warfarin** doses who had elevated INRs shortly after tolterodine 2 mg daily was started and stopped: one had an INR of 6.1 one day after stopping 13 days of tolterodine, and the other had an INR of 7.4 two days after stopping 8 days of tolterodine. In both cases no bleeding occurred and **warfarin** was withheld for three doses and successfully reinstated at the original dose.² Another case has been reported of a patient who required a 15% reduction in **warfarin** dose while taking tolterodine 4 mg daily. Her maximum INR had been 3.9. However, she had undergone several warfarin dose increases over the previous 2 months and her INR had been fluctuating.³

The controlled study suggests that no **warfarin** dose adjustment would be expected to be needed when tolterodine is added to **warfarin** therapy. However, the 3 cases introduce a note of caution. Although additional monitoring would seem over-cautious on the basis of these cases, bear them in mind in the case of an unexpected response to warfarin.

Coumarins + Topical salicylates

Increased warfarin effects have been seen when methyl salicylate or trolamine salicylate were used on the skin.

Clinical evidence

Methyl salicylate, in the form of gels, oil, or ointment applied to the skin, has been found to increase the effects of **warfarin**. Bleeding and bruising and/or raised INRs have been seen with both high^{1–3} and low doses⁴ of **methyl salicylate**. One report⁵ described the possible additive effects of **methyl salicylate oil** (*Kwan Loong Medicated Oil*) and a decoction of *Danshen* (the root of *Salvia miltiorrhiza*) on the response to **warfarin** (see also 'Coumarins and related drugs + Herbal medicines; Danshen (*Salvia miltiorrhiza*)', p.415). A raised prothrombin time has also been reported with topical **trolamine salicylate**.³

Mechanism

Methyl and trolamine salicylates possibly interact like high-dose 'aspirin', (p.385), because they are absorbed through the skin.¹

Importance and management

Although the evidence is limited, it appears that topical methyl salicylate and trolamine salicylate can increase the effect of warfarin.

Coumarins + Tricyclic antidepressants

Amitriptyline and nortriptyline do not appear to alter the half-life of warfarin, but may possibly increase that of dicoumarol. Limited evidence from analyses of patients taking phenprocoumon or warfarin suggests that use of tricyclics is associated with greater variability in prothrombin times, which can make stable anticoagulation difficult. An isolated case of the potentiation of warfarin by lofepramine has been reported.

Clinical evidence

(a) Dicoumarol

A study in 6 healthy subjects given **nortriptyline** 200 micrograms/kg three times daily for 8 days indicated that the mean half-life of dicoumarol was increased from 35 to 106 hours. In a parallel group, the same dose of **nortriptyline** also increased the half-life of antipyrine.¹ However, in later identical studies by the same research group, **nortriptyline** decreased the half-life of antipyrine in one study, and had no effect in another.² The authors were unable to explain these disparate findings with antipyrine,² and they cast doubt on the results seen with dicoumarol. In a later study by another group, both **amitriptyline** 75 mg daily and **nortriptyline** 40 mg daily had no consistent effect on the half-life of a single dose of dicoumarol, although there was some evidence of increased bioavailability.³

(b) Phenprocoumon

In a retrospective analysis of 7 patients taking phenprocoumon and **amitriptyline**, unpredictable and 'massive fluctuations' in prothrombin times (increases and decreases) were noted, which were not seen in a control group of 7 other patients not taking amitriptyline. Note that the **amitriptyline** dose was not stable. Anticoagulant control improved on stopping the amitriptyline in 5 of the patients.⁴ The same authors reported another similar case in a patient taking phenprocoumon and **amitriptyline**.⁵

(c) Warfarin

In a study in 12 healthy subjects,³ neither **amitriptyline** 75 mg daily nor **nortriptyline** 40 mg daily for 13 days affected the plasma half-life of a single dose of warfarin given on day 9.

However, in the preliminary report of an analysis of 500 patients taking warfarin, a statistically significant difference in the warfarin dose index (prothrombin time prolongation/cumulative warfarin dose) before, during and after therapy was detected for a number of unexpected drugs including **amitriptyline**. However, no further details were given.⁶ In another analysis of the stability of anticoagulant control in 277 patients, use of tricyclics (**imipramine**, **amitriptyline**, **nortriptyline**) in 16 patients was associated with an increased need for anticoagulant dose modifications (average 3.56 over 6 months). Most of the patients were taking warfarin.⁷ Another report briefly lists that potentiation of warfarin occurred in a patient given **lofepramine**.⁸

Mechanism

Not understood. One suggestion is that the tricyclic antidepressants inhibit the metabolism of the anticoagulant (seen in *animals* with nortriptyline or amitriptyline and warfarin,⁹ but not with **desipramine** and **acenocoumarol**¹⁰), but tricyclics are not established known inhibitors of the metabolism of any drug so this seems unlikely. Another idea is that the tricyclics slow gastrointestinal motility thereby increasing the time available for the dissolution and absorption of dicoumarol.³

Importance and management

Information about interactions between anticoagulants and tricyclic antidepressant is limited, patchy and inconclusive. It appears that amitriptyline and nortriptyline do not alter the half-life of warfarin, but might increase that of dicoumarol. A greater fluctuation in anticoagulant control was noted in two analyses, one with warfarin and one with phenprocoumon. However, these were uncontrolled studies, and the findings need confirming in a randomised study. Moreover, there do not appear to be any

published case reports of an interaction between tricyclics and warfarin. Thus, there is insufficient evidence to recommend any special precautions in patients stabilised on coumarins requiring tricyclics. Bear the possibility of an interaction in mind in the event of unexpected responses to treatment.

Coumarins + Valproate

An isolated case describes a patient who had an increase in her INR the day after starting valproic acid, but was eventually restabilised on the original dose of warfarin while still taking the valproic acid. Valproic acid did not alter the anticoagulant effects of phenprocoumon in one patient. Valproate alone can cause altered bleeding time, bruising, haematoma, epistaxis and haemorrhage.

Clinical evidence

A woman was given **warfarin** for a deep vein thrombosis, and was stabilised on 5 mg alternating with 2.5 mg daily with an INR between 1.8 and 2.6. Valproic acid 250 mg twice daily and fluphenazine 5 mg once daily were then added. The morning after her first dose of valproic acid, the INR increased to 3.9, and **warfarin** dosage was decreased to 2.5 mg daily. Four days later the valproic acid dosage was doubled, and numerous **warfarin** dosage adjustments were needed to keep the INR therapeutic. However, 3 weeks after starting the valproic acid she was discharged on the same **warfarin** dose as before the valproic acid was started.¹

In one patient taking **phenprocoumon**, valproic acid 500 mg to 1 g daily did not alter the prothrombin time ratio.²

Mechanism

There is *in vitro* evidence that the serum binding of warfarin is decreased by sodium valproate so that free warfarin levels rise,^{1,3,4} by 32% according to one study.¹ The increase in free warfarin levels is transient until a new equilibrium is reached, but theoretically could result in a transient increase in INR, as is seen with 'cloral hydrate', (p.396).

Valproate inhibits the second stage of platelet aggregation, and a reversible prolongation of bleeding times and thrombocytopenia has been reported, usually with high doses, which can result in spontaneous bruising and bleeding.

Importance and management

There seem to be no other reports of problems associated with concurrent use nor any other direct evidence that an interaction of clinical importance normally occurs. It may be that any interaction occurs only transiently when valproate is added, and the situation rapidly restabilises without any real need to adjust the warfarin dosage. However, some manufacturers recommend closely monitoring the prothrombin time because of the possibility of warfarin protein binding displacement.^{5,6} Note that valproate alone can cause spontaneous bruising or bleeding, and if these effects occur, some manufacturers recommend withdrawing valproate pending investigations.^{5–7} A reduction of valproate dosage or permanent withdrawal of valproate may be required.⁶

Coumarins and related drugs + Viloxazine

A single report describes three cases where viloxazine possibly increased the anticoagulant effects of acenocoumarol and fluidione.

Clinical evidence

An 82-year-old woman with angina, hypertension and atrial fibrillation, who was taking **acenocoumarol**, molsidomine and flunitrazepam, had a rise in her INR from 3.3 to 7.9 when she started to take viloxazine (dose not stated) for depression. Five days after stopping the viloxazine her INR had fallen to 2.6. This report also briefly describes 2 other cases where viloxazine possibly caused an increase in the anticoagulant effects of **acenocoumarol** and **fluidione**.¹

Mechanism

Not understood. The authors of the report suggest that viloxazine possibly inhibits cytochrome P450 within the liver, resulting in a reduction in the metabolism and loss of the anticoagulants from the body.¹

Importance and management

Information seems to be limited to this report so that its general importance is uncertain. Be alert for the need to reduce the dosage of acenocoumarol and fluidione if viloxazine is added to established anticoagulant treatment. Take the same precautions with any of the other coumarin or indanedione anticoagulants, but so far there seems to be no direct evidence that they interact.

1. Chiffolleau A, Delavaud P, Spreux A, Fialip J, Kergueris MF, Chichmanian RM, Lavarenne J, Bourin M, Larousse C. Existe-t-il une interaction métabolique entre la viloxazine et les antivitamines K? *Thérapie* (1993) 48, 492–3.

Coumarins + Vinpocetine

In healthy subjects, the anticoagulant effect of warfarin was slightly reduced by vinpocetine, and the warfarin AUC was also slightly reduced.

Clinical evidence, mechanism, importance and management

In a study in 18 healthy subjects taking vinpocetine 10 mg three times daily for 19 days, the anticoagulant effects and pharmacokinetics of a single 25-mg dose of **warfarin** were compared when given before vinpocetine was started, and on day 15.¹ A small 14.6% reduction in the mean prothrombin time occurred, and also an 8.4% reduction in the AUC of **warfarin**. More study is needed to find out whether these small changes are clinically important. Be aware of the small potential for interaction on concurrent use.

1. Hitzenberger G, Sommer W, Grandt R. Influence of vinpocetine on warfarin-induced inhibition of coagulation. *Int J Clin Pharmacol Ther Toxicol* (1990) 28, 323–8.

Coumarins and related drugs + Vitamin K substances

The effects of the coumarin and indanedione anticoagulants can be reduced or abolished by vitamin K₁ (phytonadione). This is used as an effective antidote for excessive anticoagulation. However, unintentional and unwanted antagonism can occur in patients unknowingly taking vitamin K₁. There is also a case of

antagonism of acenocoumarol in a patient using a proprietary chilblain product containing the vitamin K₄ substance acetomenaphthone.

Clinical evidence

A woman taking **acenocoumarol** had a fall in her British Corrected Ratio to 1.2 (normal range 1.8 to 3) within 2 days of starting to take a non-prescription chilblain preparation (*Gon*) containing **acetomenaphthone** 10 mg per tablet. She took a total of 50 mg of vitamin K₄ over 48 hours.¹

Mechanism

The coumarin and indanedione oral anticoagulants are vitamin K antagonists, and probably inhibit the enzyme vitamin K epoxide reductase so reducing the synthesis of vitamin K-dependent blood clotting factors by the liver. If the intake of vitamin K₁ increases, the competition swings in favour of the vitamin and the synthesis of the blood clotting factors begins to return to normal. As a result the prothrombin time also begins to fall to its normal value. The role of other vitamin K substances, such as K₄ and K₂, in coagulation is less clear.

Importance and management

The interaction with vitamin K₁ is very well established and clinically important, and is expected to occur with every coumarin and indanedione oral anticoagulant because they have a common mode of action as vitamin K antagonists. The drug intake and diet of any patient who shows 'warfarin resistance' should be investigated for the possibility of this interaction. It can be accommodated either by increasing the anticoagulant dosage, or by reducing the intake of vitamin K₁. However, the role of other vitamin K substances in coagulation is less clear. The case report with acetomenaphthone, a vitamin K₄ substance suggests that this can also antagonise the effect of vitamin K antagonists. It may be prudent for patients to avoid preparations containing this substance. Consider also 'dietary supplements', (p.401), 'enteral feeds', (p.406), 'vitamin K₁-rich foods', (p.409), and 'fermented soya bean', (p.408).

1. Heald GE, Poller L. Anticoagulants and treatment for chilblains. *BMJ* (1974) 1, 455.

Coumarins + Zileuton

Zileuton slightly increases the anticoagulant effects of warfarin and slightly increases R-warfarin levels, but this probably has little clinical relevance.

Clinical evidence

In a placebo-controlled study, zileuton 600 mg every 6 hours for 6 days or placebo was given to healthy subjects who had been stabilised on racemic **warfarin** to achieve prothrombin times of 14 to 18 seconds for one week. The zileuton had no effect on the pharmacokinetics of *S*-warfarin, but the *R*-warfarin AUC rose by 22%, and its clearance fell by 15%. The mean prothrombin times increased by 2.3 seconds (morning) and 2 seconds (evening) in the zileuton group. The corresponding increases in the placebo group were 0.7 and 0.2 seconds, respectively.¹

Mechanism

It seems likely that zileuton inhibits the metabolism of *R*-warfarin, probably by the cytochrome P450 isoenzyme CYP1A2.²

Importance and management

Information seems to be limited to this study, but the pharmacokinetic interaction appears to be established. The clinical significance of a 2 second rise in prothrombin times is unclear, but it seems likely to be small. The lack of any published reports of problems with the combination would tend to support this.

Drotrecogin alfa + Other drugs that affect coagulation

The manufacturers of drotrecogin alfa contraindicate its use with therapeutic doses of heparin (15 units/kg/hour or more), but state that prophylactic heparin doses may be used concurrently. They also say that the risk benefit ratio of drotrecogin alfa should be carefully assessed in patients who have received thrombolytics in the last 3 days, or oral anticoagulants, aspirin or platelet inhibitors within 7 days.

Clinical evidence, mechanism, importance and management

The manufacturers of drotrecogin alfa note that no formal drug interaction studies have been conducted.^{1,2} However, because drotrecogin alfa increases the risk of bleeding, they have a number of cautions and contraindications regarding its use with other drugs affecting haemostasis.^{1,2} Nevertheless, they say that in phase III studies of drotrecogin alfa, two-thirds of patients received prophylactic doses of **heparin** or **low-molecular-weight heparin**, and there was no observed increase in the risk of serious bleeding events reported in patients receiving the combination.¹ Therefore, in the US, they specifically state that low-dose **heparin** may be given for the prophylaxis of venous thromboembolic events in patients receiving drotrecogin alfa.² However, they state that the increased risk of bleeding should be carefully considered when deciding to use drotrecogin alfa with therapeutic doses of **heparin** for treating an active thromboembolic event.² In the UK, the manufacturers specifically contraindicate use with **heparin** at doses of 15 units/kg per hour or more.¹

Because of the possible increased risk of bleeding, the manufacturers also state that the risks of giving drotrecogin alfa should be weighed against the benefits in patients who have received **thrombolytics** within 3 days, **oral anticoagulants** within 7 days, or **aspirin** (US information specifies greater than 650 mg daily) or other **antiplatelet drugs** within 7 days.^{1,2}

Fondaparinux + Antiplatelet drugs and NSAIDs

Neither aspirin nor piroxicam altered the pharmacokinetics of fondaparinux, and there was no significant change in bleeding time during concurrent use. Nevertheless, the manufacturer recommends close monitoring if antiplatelet drugs or NSAIDs are used with fondaparinux, because of the increased risk of bleeding.

Clinical evidence

A single 975-mg dose of **aspirin** given on day 4 of an 8-day course of subcutaneous fondaparinux 10 mg daily had no effect on fondaparinux pharmacokinetics in 16 healthy subjects. The increase in bleeding time with fondaparinux and **aspirin** was greater than with **aspirin** alone, but this was not statistically significant. **Aspirin** had no effect on the small prolongation of aPTT seen with fondaparinux.¹

In another study, **piroxicam** 20 mg daily for 10 days was given to 12 healthy subjects with fondaparinux 10 mg daily starting on day 7. Both drugs were also given alone. **Piroxicam** had no effect on fondaparinux pharmacokinetics, and had no effect on the small prolongation of aPTT seen with fondaparinux. There was no difference in bleeding time between the treatments.¹

Mechanism

Fondaparinux commonly causes bleeding as a consequence of its action.² Since antiplatelet drugs and NSAIDs also increase the risk of bleeding, the risk and severity of bleeding is likely to be increased with the combination.

Importance and management

The pharmacological studies described show that the pharmacokinetics of fondaparinux are not changed by aspirin and piroxicam, and that there is only a minor increase in bleeding time. Nevertheless, the manufacturers of

fondaparinux say that antiplatelet drugs (**aspirin, dipyridamole, sulfipyrazone, ticlopidine or clopidogrel**) and NSAIDs should be used with caution because of the possible increased risk of haemorrhage. They recommend that if concurrent use is essential, close monitoring is necessary.^{2,3} This is considered particularly important in patients undergoing peridural or spinal anaesthesia or spinal puncture, in whom antiplatelet drugs, NSAIDs and fondaparinux are possible risk factors for epidural or spinal haematoma resulting in prolonged or permanent paralysis.³

3. Arixtra (Fondaparinux sodium). GlaxoSmithKline. US Prescribing information, October 2005.

Fondaparinux + Miscellaneous

In the UK, the manufacturer recommends avoiding other drugs that may enhance the risk of haemorrhage with fondaparinux. They specifically name, desirudin, fibrinolytic drugs, glycoprotein IIb/IIIa-receptor antagonists, heparin, heparinoids and low-molecular-weight heparins.¹ Similarly, in the US, the manufacturer states that agents that may enhance the risk of haemorrhage should be discontinued prior to starting fondaparinux. They say that if concurrent use is essential, close monitoring may be appropriate.² See also ‘warfarin’, (p.406), and ‘antiplatelet drugs and NSAIDs’, (p.459).

Heparin and LMWHs + Antiplatelet drugs

In a pharmacodynamic study, the dose of heparin did not need changing when clopidogrel was also given, and the antiplatelet effects of clopidogrel were unaltered. Nevertheless concurrent use of heparin or low molecular weight heparins and antiplatelet drugs such as clopidogrel and ticlopidine has the potential to increase the risk of bleeding and increased monitoring would be prudent.

Clinical evidence

(a) Clopidogrel

In a placebo-controlled study in 12 healthy subjects, the dosage of heparin given over 4 days did not need modification when clopidogrel 75 mg daily was also given, and the inhibitory effects of clopidogrel on platelet aggregation were unchanged on concurrent use.¹

The manufacturers of clopidogrel note that in various large clinical studies in patients with acute coronary syndrome or myocardial infarction, most patients received heparin or LMWHs without an obvious difference in the rate of bleeding or the incidence of major bleeding.^{2,3}

In one case the use of enoxaparin with clopidogrel was considered to be a contributing factor in a case of spinal epidural haematoma occurring after spinal anaesthesia.⁴ Another similar case occurred in a patient taking clopidogrel and given dalteparin.⁵

Serious retroperitoneal bleeding occurred in a patient with acute coronary syndrome receiving enoxaparin, clopidogrel and aspirin.⁶

(b) Ticlopidine

The manufacturer of ticlopidine notes that it has been used concurrently with heparin for about 12 hours in studies of cardiac stenting, but that longer-term safety has not been established.⁷

Mechanism

Antiplatelet drugs increase the risk of bleeding, and the risk is likely to be increased further in patients who are anticoagulated with heparin or LMWHs.

Importance and management

The combined use of heparin or LMWHs with antiplatelet drugs such as clopidogrel has been used in specific situations such as acute coronary syndrome. However, unless specifically indicated, concurrent use of heparin or LMWHs with antiplatelet drugs should probably be avoided because of the likely increase in haemorrhagic risk. If they are used together, the manufacturers of the LMWHs (**bemiparin, dalteparin, enoxaparin, tinzaparin**) recommend caution or careful clinical and laboratory monitoring. Heparin and some LMWHs have rarely caused epidural or spinal haematomas resulting in long-term or permanent paralysis when used for thromboprophylaxis in procedures involving spinal/epidural anaesthesia or spinal puncture. The risk of this may be increased if they are used concurrently with other drugs affecting haemostasis such as antiplatelet drugs, and extreme caution is needed if combined use is considered appropriate in these situations.

Heparin + Aprotinin

The activated clotting time (ACT) may not be a reliable method to monitor heparin therapy when aprotinin is used concurrently. This is because aprotinin increases the ACT monitored by some methods, without actually increasing anticoagulation.

Clinical evidence, mechanism, importance and management

Aprotinin prolongs the activated clotting time (ACT) as measured by a celite surface activation method, although the kaolin ACT is much less affected.¹ Therefore, if the ACT is used to monitor the effectiveness of heparin anticoagulation during cardiopulmonary bypass incorporating aprotinin, this may lead to an overestimation of the degree of anticoagulation. This may result in patients not receiving additional necessary heparin during extended extracorporeal circulation, or receiving excess protamine to reverse the effects of heparin at the end of the procedure. The UK manufacturer of aprotinin notes that it is not necessary to adjust the usual heparin/protamine regimen used in cardiopulmonary bypass procedures when aprotinin is also used.² The US manufacturer provides additional detailed information on appropriate methods to monitor heparin anticoagulation in the presence of aprotinin.¹

Heparin and LMWHs + Aspirin

The combined use of aspirin with heparin or low-molecular-weight heparins slightly increases the risk of haemorrhage. Combined use may be a contributing factor to the very rare complication of epidural or spinal haematoma.

Clinical evidence

(a) Heparin

Eight out of 12 patients with hip fractures developed serious bleeding when they were given heparin 5000 units subcutaneously every 12 hours and aspirin 600 mg twice daily as perioperative prophylaxis for deep vein thrombosis. Haematomas of the hip and thigh occurred in 3 patients, bleeding through the wound in 4, and uterine bleeding in the other patient.¹ In a large, randomised, placebo-controlled study, aspirin 500 mg three times daily, subcutaneous heparin 5000 units twice daily, and the combi-

nation were compared for prophylaxis of deep vein thrombosis in 1210 patients undergoing surgery. Haemorrhage severe enough to discontinue the prophylaxis occurred in significantly more patients in the combination group (11 of 402 patients versus 3 of 404 patients in the heparin and aspirin alone groups). In addition, minor haemorrhage occurred more frequently in the combination group (89 patients) compared with aspirin alone (41 patients) or heparin alone (30 patients).² In another randomised study in patients with acute unstable angina, the combination of aspirin 325 mg twice daily and an intravenous infusion of heparin 1000 units/hour resulted in slightly greater incidence of serious bleeding than either drug alone (3.3% versus 1.7% and 1.7%).³

In an epidemiological study of hospitalised patients receiving heparin, the incidence of bleeding was almost 2.4 times higher in 302 patients also receiving aspirin than in 2354 patients not given aspirin (doses not stated). Surgical patients were excluded from this analysis, as were patients with a discharge diagnosis of cancer or haematological disease.⁴

(b) LMWHs

In a crossover study in 9 healthy subjects, bleeding time was prolonged by the use of aspirin 300 mg daily and subcutaneous **reviparin** 6300 units daily, when compared with either drug alone (9.6 minutes versus 5.5 minutes and 5 minutes, respectively). However, the effect of aspirin on platelet aggregation and the effect of **reviparin** on aPTT were not altered by the combination.⁵

During a 5-year period in one hospital, 3 elderly patients had presented with sudden severe abdominal pain after coughing, which was found to be due to a rectus muscle sheath haematoma. These patients had been receiving subcutaneous **enoxaparin** 40 mg once daily for an average of 6 days with aspirin 100 mg daily.⁶ Other cases of retroperitoneal haematoma have been reported with **enoxaparin** in which aspirin may have been one of various contributing factors.⁷⁻¹⁰ Similarly, the use of aspirin may have been one of a number of contributing factors in a case of spinal epidural haematoma occurring with **enoxaparin**.¹¹

Mechanism

Aspirin inhibits platelet aggregation and prolongs bleeding times, and increases the risk of upper gastrointestinal haemorrhage, even at doses of 300 mg daily and less.¹² This risk is likely to be higher in patients also taking anticoagulants. See also 'Coumarins and related drugs + Aspirin', p.385.

Importance and management

The combined use of heparin or LMWHs with aspirin is indicated in specific situations such as the prophylaxis of ischaemic complications of unstable angina.¹³ However, unless specifically indicated, it may be prudent to avoid the combined use of aspirin with these drugs, because of the likely increased risk of bleeding. If they are used together, the manufacturers of the LMWHs (**bemiparin**, **dalteparin**, **enoxaparin**, **tinzaparin**) recommend caution or careful clinical and laboratory monitoring. Heparin and some LMWHs have rarely caused epidural or spinal haematomas resulting in long-term or permanent paralysis when used for thromboprophylaxis in procedures involving spinal/epidural anaesthesia or spinal puncture. The risk of this may be increased if they are used concurrently with other drugs affecting haemostasis such as aspirin, and extreme caution is needed if combined use is considered appropriate in these situations.

Heparin + Dextran

Additive effects on coagulation occur when heparin is given with dextran.

Clinical evidence, mechanism, importance and management

A study in 9 patients with peripheral vascular disease given 500 mL of dextran showed that the mean clotting time 1 hour after an infusion of 10 000 units of heparin was increased from 36 to 69 minutes. Dextran alone had no effect, but the mean clotting time after 5000 units of heparin with dextran was almost the same as after 10 000 units of heparin alone.^{1,2} This study would seem to support two other reports^{3,4} of an increase in the incidence of bleeding in those given both heparin and dextran 70. Uneventful concurrent use^{5,6} has been described with dextran 40. Note that this is probably of little clinical significance if these drugs are given for their anticoagulant effects; however, increased anticoagulation may be undesirable if dextran 40 is given as a volume expander to a patient already receiving heparin. In this situation some caution is warranted.

Heparin + LMWHs

There is some evidence that patients receiving enoxaparin preoperatively require more heparin during surgery.

Clinical evidence, mechanism, importance and management

In a clinical study, 30 patients with unstable coronary disease treated preoperatively with **enoxaparin** needed more heparin to maintain an activated clotting time above 480 seconds during surgery than 31 stable control patients not treated with enoxaparin. In addition, the **enoxaparin** recipients had higher heparin levels and lower antithrombin values compared with control patients. All patients were taking low-dose aspirin until the day before surgery, and received tranexamic acid as a bolus dose before cardiopulmonary bypass.¹

Reasons for these differences are unclear, and their clinical relevance is uncertain. Further study is needed.

Heparin + Miscellaneous

Changes in the protein binding of diazepam, propranolol, quindine and verapamil caused by heparin do not appear to be of clinical importance.

Clinical evidence, mechanism, importance and management

A number of studies have found that heparin reduces the plasma protein binding of several drugs including **diazepam**,^{1,2} **propranolol**,¹ **quinidine**³ and **verapamil**⁴ in man and in *animals*. For example, 3 patients taking oral **propranolol** and 5 patients given intramuscular **diazepam** 10 mg were given 3000 units of heparin just before cardiac catheterisation. Five minutes after the heparin was given, the free fraction of **diazepam** was found to have risen fourfold (from 1.8 to 7.9%) while the free **diazepam** levels had risen from 2 to 8.4 nanograms/mL. The free fraction of the **propranolol** rose from 7.4 to 12.5% and the free levels rose from 1.7 to 2.7 nanograms/mL.¹

It was suggested that these changes occur because heparin displaces these drugs from their binding sites on the plasma albumins and that these changes in protein binding might possibly have some clinical consequences. For example, there could, theoretically, be sudden increases in sedation or respiratory depression because of the rapid increase in the active (free) fraction of **diazepam**.

However, these changes are unlikely to be of clinical importance (see 'Protein-binding interactions', (p.3)). One study even suggested that the heparin-induced protein binding changes are an artefact of the study methods used,⁵ and this would seem to be supported by an experimental study, which found that heparin did not have any effect on the beta-blockade caused by **propranolol**.⁶ Moreover there seem to be no other reports confirming that these interactions are of real clinical importance. No special precautions would seem to be necessary.

Heparin + Nitrates

The effects of heparin were reduced by the infusion of glyceryl trinitrate in some studies, but other studies have failed to confirm this interaction. On balance, the evidence favours there being no clinically important interaction. No interaction has been seen with heparin and isosorbide dinitrate or molsidomine.

Clinical evidence

(a) Glyceryl trinitrate (Nitroglycerin)

An interaction between heparin and glyceryl trinitrate was originally reported¹ in 1985. They found a lower aPTT value in patients receiving both intravenous glyceryl trinitrate and heparin, when compared with control patients receiving heparin alone. In a study in healthy subjects, they found the same effect with the propylene glycol diluent alone, so attributed the interaction to the diluent.¹ However, in another study, the same interaction was noted in 2 patients receiving a glyceryl trinitrate preparation without propylene glycol. In this study, while receiving intravenous glyceryl trinitrate, 7 patients with coronary artery disease needed an increased dose of intravenous heparin to achieve satisfactory aPTT ratios of 1.5 to 2.5 on eight occasions. When the glyceryl trinitrate was stopped, in 6 out of 8 occasions there was a marked increase in aPTT values to 3.5. One patient had transient haematuria.²

Four other studies have also shown a reduction in the effects of heparin in the presence of intravenous glyceryl trinitrate.^{3–6} In one of these, the PT of 27 patients given heparin was more than halved (from 130 to about 60 seconds) when they were given intravenous glyceryl trinitrate 2 to 5 mg/hour. The PT rose again when the glyceryl trinitrate was stopped.³ In one study, there was some evidence that the effect might occur only at higher doses of intravenous glyceryl trinitrate (above 350 micrograms/minute),⁵ whereas in another, an effect was seen at low doses of 25 to 50 micrograms/minute.⁶

In contrast to the above studies, a total of 12 other studies have found no changes in aPTT in patients^{7–16} or healthy subjects^{17,18} given intravenous

glyceryl trinitrate with heparin. In the randomised, placebo-controlled studies in healthy subjects, a 60-minute infusion of glyceryl trinitrate 5 mg had no effect on the aPTT or PT following a 5000 unit intravenous injection of heparin,¹⁷ and a 100 micrograms/minute infusion of glyceryl trinitrate did not alter the anticoagulant effect of a 40 units/kg bolus of heparin in 7 healthy subjects.¹⁸ Two randomised, placebo-controlled studies in patients have also failed to find an effect of intravenous glyceryl trinitrate on a heparin infusion titrated to a given effect,¹² or on an intravenous heparin bolus dose.¹⁴ In the first of these studies, the glyceryl trinitrate preparation contained propylene glycol.¹²

(b) Isosorbide dinitrate

In a randomised, placebo-controlled study in 12 patients receiving a stable infusion of heparin, the use of isosorbide dinitrate 4.8 ± 0.8 mg/hour for 24 hours did not alter the AUC of PT values, when compared with placebo, nor was there any change in PT values in the 5 hours after stopping the nitrate.¹² Similarly, other studies have failed to find an important change in anticoagulation when intravenous isosorbide dinitrate is given with heparin.^{8,14,16}

(c) Molsidomine

In a study in 15 patients treated with intravenous heparin then given intravenous molsidomine 2 mg/hour, molsidomine had no effect on the PT.¹⁹

Mechanism

Not understood. One study suggests that what occurs is related to a glyceryl trinitrate-induced antithrombin III abnormality, and is apparent at doses above 350 micrograms/minute.⁵ One study found that heparin levels were lowered,⁶ whereas another reported unchanged heparin levels.³

Importance and management

The discord between these reports is not understood. However, the best controlled studies in the largest number of patients have failed to find evidence of an interaction. On balance therefore, it appears that a clinically relevant interaction is generally unlikely to be seen. Moreover, given that heparin is routinely monitored, it is likely that if any interaction occurs, it will be rapidly detected and compensated for. No special precautions would appear to be needed if heparin is given with molsidomine or isosorbide dinitrate.

Heparin and LMWHs + NSAIDs

The bleeding time was prolonged by the concurrent use of dalteparin and ketorolac in healthy subjects, but not by the use of heparin and ketorolac. Parecoxib did not alter the effect of heparin on aPTT. In a small clinical study, intramuscular ketorolac and subcutaneous enoxaparin appeared not to increase measures of postoperative bleeding when compared with opioids. Cases of spinal haematomas have been reported with concurrent use of heparin or low-molecular-weight heparins and NSAIDs. Note that ketorolac may possibly cause serious gastrointestinal bleeding and in the UK it is considered to be contraindicated in patients taking anticoagulants.

Clinical evidence

(a) Ibuprofen

Use of heparin and ibuprofen were considered to be contributing factors in a case of spinal haematoma occurring after epidural anaesthesia.¹

(b) Ketorolac

1. *Heparin*. In a crossover, placebo-controlled study in healthy subjects, there was no evidence of an interaction between ketorolac and heparin in terms of prolongation of skin bleeding time, platelet aggregation, anti-factor Xa activity, or kaolin-cephalin clotting time. In this study, two doses of oral ketorolac were given (the previous evening, and in the morning), then two 10-mg intramuscular doses of ketorolac were given at 10 am and 2 pm, with simultaneous doses of subcutaneous heparin 5000 units.²

2. *Low-molecular-weight heparins*. In a crossover, placebo-controlled study in healthy subjects, giving ketorolac with dalteparin resulted in prolongation of the skin bleeding time, when compared with ketorolac alone (13.95 minutes versus 10.55 minutes). Dalteparin alone had no effect on the bleeding time when compared with placebo. In this study, two doses of oral ketorolac 30 mg were given the day before, and one dose an hour after a single 5000-unit subcutaneous dose of dalteparin. The combination did not have any greater effect on platelet aggregation, anti-factor Xa activity or aPTT time than the individual drugs alone.³

However, a study in hip replacement patients given subcutaneous enoxaparin 40 mg once daily found that there were no significant differences in intra-operative blood loss, post-operative drainage, transfusion requirements, bruising, wound oozing, and leg swelling between 34 patients given intramuscular ketorolac 30 mg on induction of anaesthesia then once daily for 4 days postoperatively and 26 patients given unnamed opioids. Patients in this study had any previous NSAID medication stopped 4 weeks before admission, and were not taking aspirin.⁴

The use of enoxaparin, ketorolac, and aspirin were considered to be contributing factors in a case of spinal haematoma occurring after lumbar puncture, which resulted in paraplegia.⁵ Another case has also been briefly described.⁶ In an analysis of reports from the FDA in the US, 16 of 43 patients who developed spinal or epidural haematoma after receiving enoxaparin had received concurrent drugs known to prolong bleeding, such as ketorolac or other NSAIDs.⁷

(c) Parecoxib

In an open-label, crossover study in 18 healthy subjects, administration of heparin on day 5 of treatment with 40 mg of intravenous parecoxib twice daily for 6 days produced no clinically or statistically significant differences in coagulation parameters (PT, aPTT and platelet counts), when compared with heparin alone (bolus dose of heparin 4000 units then a 36-hour infusion of 10 to 14 units/kg). Use of these drugs together was well tolerated. However, prolongation of bleeding time was not assessed.⁸

Mechanism

NSAIDs, to a greater or lesser extent irritate the stomach lining, which can result in gastrointestinal bleeding, which will be more severe in anticoagulated patients. Many also have antiplatelet activity, which can prolong bleeding times.

Importance and management

The CSM in the UK and the UK manufacturers say that ketorolac is contraindicated with anticoagulants, including low-dose heparin.^{9,10} Con-

versely, the US manufacturers of ketorolac advise that physicians should carefully weigh the benefits against the risks and use concurrent heparin only extremely cautiously.¹¹

If NSAIDs and LMWHs are used together, the manufacturers of the LMWHs (bemiparin, dalteparin, enoxaparin, tinzaparin) recommend caution or careful clinical and laboratory monitoring. Heparin and some LMWHs have rarely caused epidural or spinal haematomas resulting in long-term or permanent paralysis when used for thromboprophylaxis in procedures involving spinal/epidural anaesthesia or spinal puncture. The risk of this may be increased if they are used concurrently with other drugs affecting haemostasis such as ketorolac or other NSAIDs, and extreme caution is needed if combined use is considered appropriate in these situations.

Heparin + Probenecid

An isolated case report from the 1950s suggests that the effects of heparin may be possibly increased by probenecid, and bleeding may occur.

Clinical evidence, mechanism, importance and management

In 1950 (but not reported until 1975) a woman with subacute bacterial endocarditis was given probenecid orally and penicillin by intravenous drip, which was kept open with minimal doses of heparin. After a total of about 20 000 units of heparin had been given over a 3-week period, increasing epistaxes developed and the clotting time was found to be 24 minutes (normal 5 to 6 minutes). This was controlled with protamine.¹ However, no reports of this interaction appear to have been made subsequently. This interaction seems unlikely to be of general significance.

- Sanchez G. Enhancement of heparin effect by probenecid. *N Engl J Med* (1975) 292, 48.

Heparin and LMWHs + SSRIs

Severe bleeding was attributed to the use of tinzaparin in an elderly woman with renal impairment taking fluoxetine.

Clinical evidence, mechanism, importance and management

A 78-year-old woman taking fluoxetine was started on once-daily subcutaneous injections of weight-adjusted tinzaparin for treatment of deep vein thrombosis. Five days later she suffered a massive intraperitoneal and parietal haematoma. Poor renal function in this patient could have led to accumulation of the low-molecular-weight heparin, but fluoxetine was also considered a contributing factor because SSRIs have antiplatelet effects and can contribute to bleeding.¹ Consider also 'Coumarins and related drugs + SSRIs', p.448.

- de Maistre E, Allart C, Lecompte T, Bollaert P-E. Severe bleeding associated with use of low molecular weight heparin and selective serotonin reuptake inhibitors. *Am J Med* (2002) 113, 530–2.

Heparin + Tobacco

In one study, patients who smoked tobacco had a shorter heparin half-life. However, smoking status is probably not important in predicting heparin dose.

Clinical evidence, mechanism, importance and management

In a study of the factors affecting the sensitivity of individuals to heparin, the heparin half-life in **smokers** was 0.62 hours compared with 0.97 hours in non-smokers. The dosage requirements of the smokers were slightly increased (18.8 compared with 16 units/hour per lean body weight). However, when lean body weight was taken into account, smoking status was no longer related to heparin clearance.¹ Therefore, smoking status is probably not important in predicting heparin dose.

Heparinoids; Danaparoid + Antiplatelet drugs and NSAIDs

No haemostatic interaction was noted between danaparoid and aspirin in healthy volunteers. However, caution is recommended on combined use because of the possibility of increased bleeding risk.

Clinical evidence

In a randomised, crossover study in healthy subjects, there were no important alterations in coagulation tests and plasma anti-Xa activity when danaparoid (3250 anti-Xa units intravenous bolus followed by 750 units subcutaneously twice daily for 8 days) was given with **aspirin** 500 mg, 14 and 2 hours before the intravenous danaparoid. Similarly, danaparoid did not alter the effects of **aspirin** on platelet function, but the prolongation in bleeding time tended to be longer after the combination.¹

Mechanism

The manufacturer notes that, in general, combination with antithrombotics that act by other mechanisms, such as aspirin, would be additive.²

Importance and management

Any effects in the study with aspirin were not considered to be clinically relevant.^{1,2} The manufacturer notes that danaparoid may be used with drugs that interfere with platelet function, such as aspirin and NSAIDs, but considers that caution remains necessary.^{2,3} This is considered particularly important in patients undergoing peridural or spinal anaesthesia or spinal puncture, in whom the use of NSAIDs, and probably also danaparoid, are risk factors for epidural or spinal haematoma resulting in prolonged or permanent paralysis.^{2,3}

3. Orgaran (Danaparoid sodium). Organon Laboratories Ltd. UK Summary of product characteristics, July 2003.

Heparinoids; Danaparoid + Diuretics

Chlortalidone had no clinically relevant effect on the anti-Xa activity of danaparoid in healthy volunteers, but caused an increase in the volume of distribution of antithrombin activity of uncertain relevance. Nevertheless, in clinical use danaparoid is frequently used with a number of other drugs including diuretics, and there is no evidence of an interaction.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study in healthy subjects, a slight decrease in clearance (7%) and volume of distribution (19%) of the anti-Xa activity of

danaparoid (3250 anti-Xa units intravenous bolus) occurred when it was given about 12 hours after a single 100-mg dose of chlortalidone. Conversely, the apparent volume of distribution of antithrombin activity showed an 80% increase. However, chlortalidone did not change the effect of danaparoid on clotting tests, except for a 4% increase in prothrombin time, which was thought to be a spurious finding.¹ The reasons for these changes are uncertain.

The minor changes in anti-Xa activity are unlikely to be clinically relevant.^{1,2} However, the authors considered that relevance of the change in antithrombin activity was uncertain.¹ Nevertheless, the manufacturer notes that in clinical use danaparoid has frequently been used with a variety of drugs, including diuretics, and that there is no evidence of any direct interaction with danaparoid.²

1. de Boer A, Stiekema JC, Danhof M, Breimer DD. Influence of chlortalidone on the pharmacokinetics and pharmacodynamics of Org 10172 (Lomoparan®), a low molecular weight heparinoid, in healthy volunteers. *J Clin Pharmacol* (1991) 31, 611–17.
2. Orgaran (Danaparoid). Organon Canada Ltd. Canadian product monograph, June 2001.

Heparinoids; Danaparoid + Penicillins

Cloxacillin and ticarcillin caused an increase in elimination half-life of anti-Xa activity of danaparoid, which was not considered clinically relevant. Ticarcillin had no effect on haemostasis, but cloxacillin appeared to have some pro-coagulant effects, which were not likely to be due to an interaction with danaparoid. The manufacturer notes that in clinical use danaparoid is frequently used with a number of other drugs, including antibacterials, and there is no evidence of a direct interaction.

Clinical evidence

(a) Cloxacillin

In a randomised, crossover study in 6 healthy subjects, there was a 74% increase in the elimination half-life of the plasma anti-Xa activity of danaparoid (3250 anti-Xa units intravenous bolus) when combined with oral cloxacillin 500 mg four times daily for 3 days beginning 24 hours before the danaparoid. Unexpectedly, there were slight decreased effects on thrombin time and bleeding time, and increased effects on aPTT with the combination, effects that were attributed to cloxacillin alone.¹

(b) Ticarcillin

In a randomised, crossover study in 12 healthy subjects, there was a 56% increase in the elimination half-life of the plasma anti-Xa activity of danaparoid (3250 anti-Xa units intravenous bolus) when combined with intravenous ticarcillin 4 g four times daily for 2 days beginning immediately before the danaparoid. There were no changes in haemostatic parameters when ticarcillin was given with danaparoid.¹

Mechanism

Uncertain, but penicillins might compete with danaparoid for renal tubular secretion.¹

Importance and management

The pharmacokinetic changes seen in the studies with cloxacillin and ticarcillin were not considered clinically relevant.^{1,2} In addition, the haemostatic changes seen in the study with cloxacillin were unlikely to be due to an interaction.¹ The manufacturer notes that in clinical use danaparoid has frequently been used with a variety of drugs, including antibacterials, and that there is no evidence of any direct interaction with danaparoid.²

2. Orgaran (Danaparoid). Organon Canada Ltd. Canadian product monograph, June 2001.

Indanediones + Haloperidol

A single case report describes a marked reduction in the anticoagulant effects of phenindione in a patient given haloperidol.

Clinical evidence, mechanism, importance and management

A man stabilised on **phenindione** 50 mg daily was given haloperidol by injection (5 mg every 8 hours for 24 hours) followed by 3 mg twice daily by mouth. Adequate anticoagulation was not achieved even when the **phenindione** dosage was increased to 150 mg daily. When the haloperidol dosage was halved, the necessary dose of anticoagulant was reduced to 100 mg daily, and only when the haloperidol was withdrawn was it possible to achieve adequate anticoagulation with the original dosage.¹ The reasons for this are not understood. This appears to be the only report of an interaction, and its general importance is therefore limited. Bear it in mind in the event of an unexpected response to treatment.

1. Oakley DP, Lauth H. Haloperidol and anticoagulant treatment. *Lancet* (1963) ii, 1231.

Indanediones + Oxaceprol

An isolated report describes a marked fall in the response to flui-dione in a patient given oxaceprol.

Clinical evidence, mechanism, importance and management

A 77-year-old woman with hypertension and atrial fibrillation, taking propafenone, furosemide, enalapril and **fluidione** 15 mg daily, started taking oxaceprol 300 mg daily. Within 2 days her Quick Time had risen from 26 to 57% and by the end of the week to 65%. When the oxaceprol was withdrawn, her Quick value returned to its previous values of 23 to 30%.¹ The mechanism is not understood. The general importance of this interaction is not known but bear it in mind when prescribing oxaceprol and **fluidione**. Be alert for the need to modify the anticoagulant dosage.

1. Bannwarth B, Tréchet P, Mathieu J, Froment J, Netter P. Interaction oxaceprol-fluidione. *Thérapie* (1990) 45, 162–3.

Thrombin inhibitors + Antiplatelet drugs and Thrombolytics

Low-dose aspirin did not alter the pharmacokinetics or pharmacodynamic effects of argatroban. Neither abciximab nor eptifibatide appeared to alter argatroban pharmacokinetics. There is no pharmacodynamic interaction between bivalirudin and aspirin, ticlopidine, clopidogrel, abciximab, eptifibatide or tirofiban. Nevertheless, the manufacturers warn of the increased bleeding risks if argatroban, bivalirudin or lepirudin are used with antiplatelet drugs or thrombolytics.

Clinical evidence, mechanism, importance and management

(a) Argatroban

1. *Antiplatelet drugs.* In a study in healthy subjects, pretreatment with oral **aspirin** 162.5 mg, given 26 and 2 hours prior to argatroban 1 microgram/kg per minute over 4 hours, caused no changes in the pharmacokinetics or pharmacodynamic effects of the argatroban.¹

In a large clinical study of the combination of argatroban and a glycoprotein IIb/IIIa-receptor antagonist (**abciximab** or **eptifibatide**) in patients undergoing percutaneous coronary intervention, using a population model assessment, the pharmacokinetics of argatroban were similar to those previously seen in healthy subjects. This suggests that neither **abciximab** nor **eptifibatide** alter argatroban pharmacokinetics.² Nevertheless, the manufacturer warns that the use of argatroban with **antiplatelet drugs** may increase the risk of bleeding.³

2. *Thrombolytics.* The manufacturer notes that, in patients with acute myocardial infarction, the incidence of intracranial bleeding was 1% (8 out of 810 patients) in patients receiving both argatroban and thrombolytic therapy (**streptokinase** or **alteplase**).³ They therefore state that the safety and effectiveness of argatroban with thrombolytics has not been established, and that concurrent use may increase the risk of bleeding.³

(b) Bivalirudin

1. *Antiplatelet drugs.* The UK manufacturer says that no pharmacodynamic interactions were detected when bivalirudin was used with platelet inhibitors, including **aspirin**, **ticlopidine**, **clopidogrel**, **abciximab**, **eptifibatide**, or **tirofiban**.⁴ The US manufacturer states that bivalirudin is intended for use with **aspirin** 300 to 325 mg daily, and has been studied only in patients receiving **aspirin**.⁵ Both manufacturers state that bivalirudin may be used with a glycoprotein IIb/IIIa-receptor antagonist^{4,5} (e.g. **abciximab**, **eptifibatide**, **tirofiban**). Nevertheless, the US manufacturer states that in clinical studies, the concurrent use of bivalirudin with these inhibitors was associated with increased risks of major bleeding events compared to patients not receiving them.⁵ The UK manufacturer recommends regular monitoring of haemostasis when bivalirudin is used with platelet inhibitors.⁴

2. *Thrombolytics.* In the US, the manufacturers state that the concurrent use of bivalirudin with thrombolytics was associated with increased risks of major bleeding events.⁵

(c) Lepirudin

The manufacturers of lepirudin say that no formal interaction studies have been done but they reasonably warn that the concurrent use of lepirudin and other thrombolytics (they name **alteplase** and **streptokinase**) may increase the risk of bleeding complications and considerably enhance the effect of lepirudin on the aPTT. They also warn about the increased risks of bleeding if antiplatelet drugs such as **clopidogrel**, **ticlopidine**, **abciximab**, **eptifibatide** or **tirofiban** are used concurrently.^{6,7}

Thrombin inhibitors + Other anticoagulants

Use of argatroban with warfarin and related oral anticoagulants has an effect on the measurement of the INR, and the manufacturer provides equations to adjust for this. Argatroban does not alter warfarin pharmacokinetics. The manufacturers warn of the increased bleeding risks if argatroban, bivalirudin or lepirudin are used with other anticoagulants.

Clinical evidence, mechanism, importance and management

(a) Argatroban

In 12 healthy subjects, argatroban 1.25 micrograms/kg per minute was given for 100 hours, with a single 7.5-mg dose of **warfarin** given at hour 4. Neither drug affected the pharmacokinetics of the other. The single dose of **warfarin** in this study did not add to the anticoagulant effect of argatroban.¹ However, a previous study found that the INR and prothrombin time were increased when **warfarin** (7.5 mg on day one, then 3 to 6 mg for 9 days) was used with argatroban (1 to 4 micrograms/kg per minute for 5 hours daily for 11 days), but without any additional effect on vitamin K-dependent factor Xa activity.² A similar finding was reported in a study using **acenocoumarol** or **phenprocoumon** and argatroban.³ This means that the INR reading needs to be corrected before it can be used as a clinical indicator of coagulation status when **warfarin** or other vitamin K antagonists (i.e. the **indanediones**) are used with argatroban. The manufacturer provides detailed information on how this should be done while switching from argatroban to **warfarin**.⁴

Argatroban is currently licensed for use in patients with or at risk of heparin-induced thrombocytopenia, hence it is unlikely to be used with heparin. Nevertheless, the manufacturer states that if **heparin** is to be switched to argatroban, allow sufficient time for heparin's effect on the aPTT to decrease before starting argatroban.⁴

(b) Bivalirudin

In the US, the manufacturers state that concurrent use of bivalirudin with **heparin** or **warfarin** was associated with increased risks of major bleeding events, when compared to patients not receiving these concurrent drugs.⁵ In the UK, the manufacturers state that bivalirudin can be started

30 minutes after stopping intravenous **heparin**, but 8 hours should be left after stopping a **low-molecular-weight heparin** given subcutaneously.⁶ They recommend regular monitoring of haemostasis when bivalirudin is used with other anticoagulants.⁶

(c) *Lepirudin*

The manufacturers of lepirudin say that no formal interaction studies have been done but they reasonably warn about the increased risks of bleeding if vitamin K antagonists (i.e. **coumarins** and **indanediones**) are used concurrently.^{7,8} Their recommendation^{7,8} for changing from lepirudin to an oral anticoagulant is to reduce the lepirudin dosage gradually to reach an aPTT ratio just above 1.5 before beginning the oral anticoagulant, which should be started at the intended maintenance dose without a loading dose. They suggest that parenteral anticoagulation should be continued for 4 to 5 days, and then stopped when the INR stabilises within the target range.

Thrombin inhibitors; Argatroban + Erythromycin

Erythromycin has no effect on the pharmacokinetics or activity of argatroban.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects, erythromycin 500 mg four times daily was given for 7 days with a 5-hour intravenous infusion of argatroban 1 microgram/kg per minute given before erythromycin and on day 6. Erythromycin had no effect on the pharmacokinetics of argatroban, and had no effect on the argatroban-induced prolongation of aPTT.¹ No special precautions are likely to be required on concurrent use of argatroban and erythromycin or other inhibitors of the cytochrome P450 isoenzyme CYP3A4 (for a list, see 'Table 1.4', (p.6)).

1. Tran JQ, Di Cicco RA, Sheth SB, Tucci M, Peng L, Jorkasky DK, Hursting MJ, Benincosa LJ. Assessment of the potential pharmacokinetic and pharmacodynamic interactions between erythromycin and argatroban. *J Clin Pharmacol* (1999) 39, 513–19.

Thrombin inhibitors; Argatroban + Lidocaine

There was no pharmacokinetic interaction between argatroban and lidocaine, and no further change in coagulation parameters when both drugs were given together in a study.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, lidocaine 2 mg/kg per hour was infused for 16 hours (after a loading dose of 1.5 mg/kg over 10 minutes) alone, then in combination with intravenous argatroban 1.5 micrograms/kg per minute for 16 hours. Concurrent use did not affect the pharmacokinetics of either drug. Lidocaine did not alter the effect of argatroban on aPTT.¹

No special precautions appear likely to be necessary on concurrent use of lidocaine and argatroban.

1. Inglis AML, Sheth SB, Hursting MJ, Tenero DM, Graham AM, DiCicco RA. Investigation of the interaction between argatroban and acetaminophen, lidocaine, or digoxin. *Am J Health-Syst Pharm* (2002) 59, 1257–66.

Thrombin inhibitors; Argatroban + Paracetamol (Acetaminophen)

There was no pharmacokinetic interaction between argatroban and paracetamol, and no further change in coagulation parameters when both drugs were given together in a study.

Clinical evidence, mechanism, importance and management

In 11 healthy subjects, paracetamol 1 g every 6 hours for 5 doses had no effect on the pharmacokinetics of a 19-hour infusion of argatroban 1.5 micrograms/kg per minute, started with the second dose of paracetamol. In addition, argatroban had no effect on paracetamol pharmacokinetics. Paracetamol did not alter the effect of argatroban on aPTT.¹

No special precautions appear necessary on concurrent use of paracetamol and argatroban.

1. Inglis AML, Sheth SB, Hursting MJ, Tenero DM, Graham AM, DiCicco RA. Investigation of the interaction between argatroban and acetaminophen, lidocaine, or digoxin. *Am J Health-Syst Pharm* (2002) 59, 1257–66.

Thrombin inhibitors; Ximelagatran + Miscellaneous

Aspirin did not alter the pharmacokinetics of melagatran, the active metabolite of ximelagatran, or its effects on the aPTT, but the combination had additive effects on bleeding time. Erythromycin increases the AUC of melagatran, the active metabolite of ximelagatran, and causes a small additional effect on coagulation parameters. The concurrent use of amiodarone and ximelagatran caused a slight increase in the AUC of melagatran and a slight decrease in the AUC of amiodarone, but the clinical relevance of this is unknown.

No pharmacokinetic interaction occurs between ximelagatran and atorvastatin or digoxin, and concurrent use does not change coagulation status. No pharmacokinetic interaction appears to occur between ximelagatran and diazepam, diclofenac or nifedipine. This suggests that ximelagatran has no clinically relevant effect on drugs that are substrates for the cytochrome P450 isoenzymes CYP2C9, CYP2C19, and CYP3A4.

Clinical evidence, mechanism, importance and management

(a) *Amiodarone*

In a placebo-controlled study in 26 healthy subjects, ximelagatran 36 mg was given every 12 hours for 8 days with a single 600-mg dose of amiodarone on day 4. On combined use there was a slight 21% increase in the AUC of melagatran (the active metabolite of ximelagatran), and a slight 15% decrease in the AUC of amiodarone. Amiodarone did not alter the effect of melagatran on aPTT.¹

The mechanism of this interaction is unknown. The pharmacokinetic changes seen were not considered to be clinically relevant.

(b) *Aspirin*

In young healthy subjects, aspirin 450 mg the day before, and 150 mg just before melagatran had no effect on the pharmacokinetics of intravenous melagatran 4.12 mg. In addition, aspirin did not alter the increases seen in aPTT or activated clotting time seen with melagatran. Both aspirin and melagatran increased bleeding time, and the increase with the combination was additive.²

(c) *Atorvastatin*

In 15 healthy subjects, ximelagatran 36 mg twice daily was given for 5 days with a single 40-mg dose of atorvastatin on day 4. There was no change in the pharmacokinetics of either drug or their active metabolites. Atorvastatin did not alter the effect of melagatran on aPTT.³

No special precautions are expected to be needed if ximelagatran is used in patients taking atorvastatin.

(d) *Diazepam*

In 24 healthy subjects, ximelagatran 24 mg twice daily was given for 8 days with a single 100-microgram/kg intravenous dose of diazepam on day 3. There was no change in the pharmacokinetics of either drug or of *N*-desmethyl-diazepam.⁴

Metabolism of diazepam to *N*-desmethyl-diazepam occurs via the cytochrome P450 isoenzyme CYP2C19, and *in vitro* studies had shown that melagatran was a weak inhibitor of this isoenzyme.⁴ However, the lack of a pharmacokinetic interaction with diazepam suggests that no clinically relevant interaction occurs, and is also unlikely with other CYP2C19 substrates⁴ (for a list see 'Table 1.3', (p.6)).

(e) *Diclofenac*

In a single-dose study in 24 healthy subjects, simultaneous administration of ximelagatran 24 mg and enteric-coated diclofenac 50 mg caused no change in the pharmacokinetics of either drug. In this study, there was also no additional effect of the combination on activated partial thromboplastin time or capillary bleeding time, suggesting that no pharmacodynamic interaction occurs.⁴

Diclofenac is a substrate for the cytochrome P450 isoenzyme CYP2C9, and *in vitro* study has shown that ximelagatran and melagatran are weak inhibitors of this isoenzyme.⁴ However, the lack of a pharmacokinetic interaction with diclofenac suggests that no clinically relevant interaction occurs, and is also unlikely with other CYP2C9 substrates⁴ (for a list see 'Table 1.3', (p.6)).

(f) *Digoxin*

In a double-blind, crossover study, 16 healthy subjects were given oral ximelagatran 36 mg twice daily or placebo for 8 days and a single 500-microgram oral dose of digoxin on day 4. Ximelagatran had no effects on the pharmacokinetics of digoxin. Similarly, digoxin had no effects on the pharmacokinetics of melagatran (the active metabolite) when ximelagatran was given orally. The anticoagulant effect of melagatran (measured as aPTT prolongation) was not altered by digoxin.⁵

(g) *Erythromycin*

In 16 healthy subjects, erythromycin 500 mg three times daily was given for 5 days with a single 36-mg oral dose of ximelagatran given before

erythromycin, and on day 5. Erythromycin increased the AUC of melagatran (the active metabolite of ximelagatran) 1.8-fold, and the maximum plasma level 1.7-fold. This resulted in a small increase in peak aPTT from 41 to 44 seconds.⁶

Ximelagatran is not metabolised by cytochrome P450 isoenzymes, so the known inhibitory effect of erythromycin on CYP3A4 is not thought to be the mechanism for this interaction.

The findings of a pharmacokinetic interaction with a small pharmacodynamic effect indicate that further study is needed. Until more is known, it would certainly be prudent to be cautious if ximelagatran is used in patients taking erythromycin, although note that the pharmacodynamic effect was small and all patients tolerated the combination well.⁶

(h) *Nifedipine*

In a single-dose study in 34 healthy subjects, giving ximelagatran 24 mg four hours after slow-release nifedipine 60 mg caused no change in the pharmacokinetics of either drug.⁴

Nifedipine is a substrate for the cytochrome P450 isoenzyme CYP3A4, and *in vitro* studies had shown that ximelagatran metabolites might be weak inhibitors of this isoenzyme.⁴ However, the lack of a pharmacokinetic interaction with nifedipine suggests that no clinically relevant interaction occurs, and is also unlikely with other CYP3A4 substrates⁴ (for a list see 'Table 1.4', (p.6)).

Antidiabetics

The antidiabetics are used to control diabetes mellitus, a disease in which there is total or partial failure of the beta-cells within the pancreas to secrete enough insulin, one of the hormones concerned with the handling of glucose. In some cases there is evidence to show that the disease results from the presence of factors that oppose the activity of insulin.

With insufficient insulin, the body tissues are unable to take up and utilise the glucose that is in circulation in the blood. Because of this, glucose, which is derived largely from the digestion of food, and which would normally be removed and stored in tissues throughout the body, accumulates and boosts the glucose in the blood to such grossly elevated proportions that the kidney is unable to cope with such a load and glucose appears in the urine. Raised blood glucose levels (hyperglycaemia) with glucose and ketone bodies in the urine (glycosuria and ketonuria) are among the manifestations of a serious disturbance in the metabolic chemistry of the body, which, if untreated, can lead to the development of diabetic coma and death.

There are two main types of diabetes: one develops early in life and occurs when the ability of the pancreas suddenly, and often almost totally, fails to produce insulin. This type is called type 1, juvenile, or insulin-dependent diabetes (IDDM), and requires insulin replacement therapy. The other form is type 2, maturity-onset, or non-insulin dependent diabetes mellitus (NIDDM), which is most often seen in those over 40 years old. This occurs when the pancreas gradually loses the ability to produce insulin over a period of months or years and/or resistance to the action of insulin develops. It is often associated with being overweight and can sometimes be satisfactorily controlled simply by losing weight and adhering to an appropriate diet. This may then be augmented with oral antidiabetic drugs, and eventually insulin. A classification of the antidiabetics is given in 'Table 13.1', (p.469).

Modes of action of the antidiabetics

A. Parenteral antidiabetics

(a) Amylin analogues

Pramlintide is a synthetic analogue of amylin, a pancreatic hormone involved in glucose homeostasis. It slows the rate of gastric emptying and reduces appetite. It is given subcutaneously immediately prior to meals, and is used in patients already receiving insulin.

(b) Incretin mimetics

Exenatide is an incretin mimetic that acts as a glucagon-like peptide-1 (GLP-1) receptor agonist. This increases insulin secretion when glucose levels are high. It is given subcutaneously as an adjunct in type 2 diabetes in patients already receiving metformin, a sulphonylurea, or both.

(c) Insulin

Insulin extracted from the pancreatic tissue of pigs and cattle is so similar to human insulin that it can be used as a replacement. However, human insulin, manufactured by genetically engineered microorganisms, is more commonly used. Insulin is usually given by injection in order to bypass the enzymes of the gut, which would digest and destroy it like any other protein. The onset and duration of action of insulin may be prolonged by complexing with zinc or protamine. More recently, various insulin analogues have been developed, which have specific pharmacokinetic profiles. Insulin aspart and lispro have a faster onset and shorter duration of action than

soluble insulin. Insulin glargine and detemir both have a prolonged duration of action.

An inhaled form of insulin has been approved by The European Medicines Agency for use in adult patients with diabetes mellitus.

B. Oral antidiabetics

(a) Aldose reductase inhibitors

Epalrestat inhibits the enzyme aldose reductase, which converts glucose to sorbitol. The accumulation of sorbitol may play a role in some diabetic complications.

(b) Alpha-glucosidase inhibitors

Acarbose, miglitol and voglibose act against alpha glucosidases and specifically against sucrase in the gut to delay the digestion and absorption of monosaccharides from starch and sucrose.

(c) Biguanides

The mode of action of the biguanides, such as metformin, is obscure, but they do not stimulate the pancreas like the sulphonylureas to release insulin, but appear to facilitate the uptake and utilisation of glucose by the cells in some way. Their use is restricted to type 2 diabetes because they are not effective unless insulin is present.

(d) Meglitinides

The meglitinides (e.g. repaglinide) increase endogenous insulin secretion, and so are used in type 2 diabetes.

(e) Sulphonylureas

The sulphonylurea and other sulfonamide-related compounds such as chlorpropamide and tolbutamide were the first synthetic compounds used in medicine as antidiabetics. Among their actions they stimulate the remaining beta-cells of the pancreas to grow and secrete insulin which, with a restricted diet, controls blood glucose levels and permits normal metabolism to occur. Clearly they can only be effective in those diabetics whose pancreas still has the capacity to produce some insulin, so their use is confined to type 2 diabetes.

(f) Thiazolidinediones

The thiazolidinediones (e.g. rosiglitazone) appear to decrease insulin resistance through activation of gamma-PPAR (peroxisome proliferator-activated receptor). They are used in type 2 diabetes.

(g) Other oral antidiabetics

Outside orthodox Western medicine, there are herbal preparations which are used to treat diabetes and which can be given by mouth. Blueberries were traditionally used by the Alpine peasants, and bitter gourd or karela (*Momordica charantia*) is an established part of herbal treatment in the Indian subcontinent and elsewhere. Traditional Chinese medicine also has herbal medicines for diabetes. As yet it is not known how these herbal medicines act and their efficacy awaits formal clinical evaluation.

Interactions

The commonest interactions with antidiabetic drugs are those that result in a rise or fall in blood glucose levels, thereby disturbing the control of diabetes. These are detailed in this section. Other interactions where the antidiabetic drug is the affecting drug are described elsewhere.

Table 13.1 Drugs used in the management of diabetes

<i>Group</i>	<i>Drugs</i>	
Parenteral antidiabetics		
Amylin analogues	Pramlintide	
Incretin mimetics (Glucagon like peptide-1 (GLP-1) receptor agonist)	Exenatide	
Insulins	Short-acting	Soluble insulin
	Intermediate- and long-acting	Insulin zinc suspension, Isophane insulin, Protamine zinc insulin
	Short-acting analogues	Insulin aspart, Insulin glulisine, Insulin lispro
	Intermediate to long-acting analogues	Insulin aspart protamine, Insulin detemir, Insulin glargine, Insulin lispro protamine
Oral antidiabetics		
Aldose reductase inhibitors	Epalrestat	
Alpha glucosidase inhibitors	Acarbose, Miglitol, Voglibose	
Biguanides	Buformin, Metformin, Phenformin	
Meglitinides	Nateglinide, Repaglinide	
Sulphonylureas	Acetohexamide, Carbutamide, Chlorpropamide, Glibenclamide (Glyburide), Glibornuride, Gliclazide, Glimepiride, Glipizide, Gliquidone, Glisentide, Glisolamide, Glisoxepide, Glycyclamide, Tolazamide, Tolbutamide	
Thiazolidinediones (Gamma-PPAR (peroxisome proliferator-activated receptor) agonists)	Pioglitazone, Rosiglitazone	
Other drugs	Guar gum	

Acarbose + Miscellaneous

Neomycin may increase the efficacy and the gastrointestinal adverse effects of acarbose. There is some indirect evidence that acarbose with alcohol may increase the hepatotoxicity of paracetamol (acetaminophen). Paralytic ileus has been reported in a Japanese patient treated with acarbose and promethazine, an antimuscarinic drug.

Clinical evidence, mechanism, importance and management

(a) Antimuscarinics

A 69-year-old man with a partial gastrectomy and type 2 diabetes, treated with insulin 24 units and acarbose 300 mg daily, was admitted to hospital with diabetic gangrene. After developing cold symptoms he was given *PL granules* (salicylamide, paracetamol, caffeine, **promethazine** methylene disalicylate). The next day he experienced sudden abdominal pain, nausea and vomiting, which was diagnosed as paralytic ileus. He was given intravenous fluids and piperacillin. Oral intake and acarbose were withheld and the ileus resolved after 2 days. The authors note that there are several reports of ileus developing in Japanese patients within 3 months of treatment with alpha-glucosidase inhibitors such as acarbose. The risk seems to be increased with age, a history of abdominal surgery, and a Japanese diet (high in carbohydrates and fibre) rather than Western diet. However, in this case the patient had been taking acarbose for 15 months without problem and it is possible that the antimuscarinic effects of **promethazine** in the *PL granules* may have contributed to the development of ileus.¹ The general clinical relevance of this case is uncertain. However, the authors consider that patients at risk should be monitored if they are given alpha-glucosidase inhibitors, especially if the dose is increased or if antimuscarinics are also given.¹

(b) Neomycin

Neomycin alone can reduce postprandial blood glucose levels and may enhance the reduction in postprandial glucose levels associated with acarbose.² Neomycin 1 g three times daily increased the unpleasant gastrointestinal adverse effects (flatulence, cramps and diarrhoea) of acarbose 200 mg three times daily in 7 healthy subjects.³ The manufacturers suggest that if these adverse effects are severe the dosage of acarbose should be reduced.⁴

(c) Paracetamol

Studies in *rats* have found that acarbose alone or in combination with alcohol may potentiate the hepatotoxicity of paracetamol.⁵ However, it is not known whether this has any clinical relevance.

Alpha-glucosidase inhibitors + Charcoal or Digestive enzymes

The manufacturers of acarbose^{1,2} and miglitol³ reasonably suggest that intestinal adsorbents (e.g. charcoal) or digestive enzyme preparations (such as amylase, pancreatin) should be avoided because, theoretically, they would be expected to reduce the effects of these alpha glucosidase inhibitors.

Alpha-glucosidase inhibitors + Other antidiabetics

Some minor decreases in the plasma levels of glibenclamide (glyburide), metformin, and rosiglitazone have been seen with acarbose or miglitol, but these are not clinically relevant. Voglibose had no effect on glibenclamide pharmacokinetics. Alpha glucosidase inhibitors cause a moderate additional blood glucose-lowering effect when used with other antidiabetics, and a possible increased risk of hypoglycaemia should be borne in mind. In patients taking alpha-glucosidase inhibitors, treatment of hypoglycaemia should be with a monosaccharide such as glucose (dextrose) or glucagon, not a disaccharide such as sucrose. The manufacturer of pramlintide recommends that it should not be used in patients taking alpha-glucosidase inhibitors.

Clinical evidence

(a) Glibenclamide (glyburide)

Voglibose had no effect on the pharmacokinetics of glibenclamide in a double-blind crossover trial in 12 healthy male subjects. In this study, subjects were given either **voglibose** 5 mg or a placebo three times daily for 8 days and a single 1.75-mg dose of glibenclamide on the morning of day 8, taken at the same time as the first dose of the **voglibose** or placebo.¹ Similarly, the manufacturers of **acarbose** note that it had no effect on the absorption or disposition of glibenclamide in diabetic patients.²

However, in a randomised, double-blind, placebo-controlled study in 28 patients with type 2 diabetes mellitus, **miglitol** reduced the maximum plasma glibenclamide levels and its AUC by 16 and 19%, respectively. The patients were given glibenclamide 2.5 mg twice daily with either **miglitol** 100 mg three times daily or placebo for 2 days. Nevertheless, the average blood glucose levels were reduced more by the drug combination than by the glibenclamide alone: over 5 hours there was a 15% greater reduction, and over 10 hours a 9% greater reduction.³

(b) Metformin

A study in 6 healthy subjects found that **acarbose** 50 to 100 mg three times daily reduced the maximum serum levels and the AUC₀₋₉ of metformin 1 g by about 35%, but the 24-hour urinary excretion was unchanged.⁴

Another study in 19 diabetic patients given **acarbose** 50 or 100 mg three times daily and metformin 500 mg twice daily, also found that **acarbose** lowered metformin levels (AUC reduced by 12 to 13%, maximum plasma levels reduced by 17 to 20%). Nevertheless, the drug combination reduced the postprandial glucose concentration at 3 hours by 15% more than metformin alone.⁵ Similarly, the manufacturer notes that, in a study in healthy subjects, **miglitol** 100 mg three times daily for 7 days reduced the AUC and maximum level of a single 1-g dose of metformin by 12% and 13%, respectively, although this difference was not statistically significant.⁶

(c) Pramlintide

The manufacturer of pramlintide suggests that it should not be used in patients taking drugs that slow the intestinal absorption of nutrients, such as the alpha-glucosidase inhibitors.⁷ This is because pramlintide slows gastric emptying (see also 'Pramlintide + Miscellaneous', p.513). Clinical study is needed to see if there is any important effect if the drugs are used together.

(d) Rosiglitazone

A study in 16 healthy subjects found that **acarbose** 100 mg three times daily for a week slightly reduced the absorption of a single 8-mg oral dose of rosiglitazone (AUC reduced by 12%), but this was not considered to be clinically relevant.⁸

Mechanism

The reason for the minor pharmacokinetic changes is uncertain.

Importance and management

The pharmacokinetic changes seen are minor and unlikely to be clinically relevant. The manufacturers say that while alpha glucosidase inhibitors such as acarbose and miglitol do not cause hypoglycaemia when given alone, they may increase the blood glucose-lowering effects of **insulin** and

the **sulphonylureas**, for which reason it may be necessary to reduce their dosages. Monitor the outcome when acarbose, miglitol, or voglibose is first given. Any hypoglycaemic episodes should be treated with glucose (dextrose), not sucrose, because alpha glucosidase inhibitors delay the digestion and absorption of disaccharides such as sucrose, but do not affect monosaccharides.^{2,6,9} Patients taking alpha-glucosidase inhibitors should not be given pramlintide until the combination has been studied clinically.

Antidiabetics + ACE inhibitors

The concurrent use of ACE inhibitors and antidiabetics normally appears to be uneventful but hypoglycaemia, marked in some instances, has occurred in a small number of diabetics taking insulin or sulphonylureas with captopril, enalapril, lisinopril or perindopril. This has been attributed, but not proved, to be due to an interaction. The United Kingdom Prospective Diabetes Study Group (UKPDS) found no difference in the incidence of hypoglycaemia between patients taking atenolol and those taking captopril. No pharmacokinetic interaction has been found to occur between spirapril and glibenclamide. Subcutaneous exenatide has no important effect on the pharmacokinetics of lisinopril, and does not alter its efficacy.

Clinical evidence

Numerous case reports, small case-control studies, and a pharmacological study in healthy subjects suggest that ACE inhibitors increase the risk of hypoglycaemia in patients receiving insulin or oral antidiabetics, and these are summarised in 'Table 13.2', (p.472). Conversely several larger case-control studies and two randomised controlled studies have not found a significantly increased risk of hypoglycaemia with ACE inhibitors, and these are also summarised in Table 13.2. It is worth highlighting that one of these, the United Kingdom Prospective Diabetes Study Group (UKPDS), found that the number of patients experiencing hypoglycaemic attacks did not differ between patients receiving atenolol 50 to 100 mg daily or **captopril** 25 to 50 mg twice daily for hypertension.¹

A brief report states that **spirapril** does not have a pharmacokinetic interaction with **glibenclamide**.² The manufacturer of exenatide notes that, in a study in hypertensive patients exenatide 10 micrograms twice daily did not alter the steady-state AUC or maximum level of **lisinopril** 5 to 20 mg daily, but it did delay the time to maximum level by 2 hours. However, exenatide did not alter the blood-pressure lowering effect of **lisinopril**.³

Mechanism

Not understood. An increase in glucose utilisation and increased insulin sensitivity have been suggested.^{4,5} Other possibilities (e.g. altered renal function) are discussed in a series of letters in *The Lancet*.^{6–11} There is also an isolated report of persistent severe hypoglycaemia in a non-diabetic patient associated with both **captopril** and **ramipril** therapy.¹² Conversely, high natural ACE activity has been associated with a higher risk of severe hypoglycaemia.¹³

Importance and management

This interaction is not well established nor understood, and it remains the subject of considerable study and debate. However, some cases of severe hypoglycaemia have undoubtedly occurred due to the use of ACE inhibitors

by diabetic patients. Nevertheless, some authors consider the risk of severe hypoglycaemia in diabetic patients treated with ACE inhibitors to be very low and negligible compared with the benefits of this class of drugs in diabetes.¹⁴ Moreover, some recent guidelines on the treatment of hypertension in diabetes recommend that all patients with diabetes and hypertension should be treated with an ACE inhibitor.^{15,16} To be on the safe side, it would be prudent to warn all patients receiving insulin or oral antidiabetics who are just starting any ACE inhibitors (although only captopril, enalapril, lisinopril and perindopril have been implicated) that excessive hypoglycaemia has been seen very rarely and unpredictably. The problem has been resolved in some patients by reducing the sulphonylurea dosage by a half to three-quarters.^{17,18}

Subcutaneous exenatide has no important pharmacokinetic interaction with lisinopril, and would therefore not be expected to have a pharmacokinetic interaction with any other ACE inhibitor, although this needs confirmation.

A false positive urine ketone test can also occur with captopril when using the alkaline-nitroprusside test (*Ketodistix*), which may affect the monitoring of diabetic control.¹⁹

Antidiabetics + Alcohol

Diabetic patients stabilised with insulin, oral antidiabetics or diet alone need not abstain from alcohol, but they should drink only in moderation and accompanied by food. Epidemiological evidence suggests that heart disease may be less common in diabetic patients who drink in moderation. However, alcohol makes the signs of hypoglycaemia less clear and delayed hypoglycaemia can occur. The CNS depressant effects of alcohol plus hypoglycaemia can make driving or the operation of dangerous machinery much more hazardous. A flushing reaction is common in patients taking chlorpropamide who drink alcohol, but is less common with other sulphonylureas. Limited evidence suggests that alcoholic patients may require above-average doses of tolbutamide.

Clinical evidence

(a) Antidiabetics, general

1. *Effect on glucose levels.* The blood glucose levels of diabetics may be reduced, remain unchanged, or increased by alcohol, depending on the amount drunk at one time, if it is drunk with food or not, and if use is chronic and excessive.¹ In one early study, 2 out of 7 diabetics receiving **insulin** became severely hypoglycaemic after drinking the equivalent of about 3 measures of spirits.² In a hospital study over a 3-year period, 5 type I diabetics were hospitalised with severe hypoglycaemia after binge-drinking. Two of them died without recovery from the initial coma and the other 3

Table 13.2 Interactions between antidiabetics and ACE inhibitors

<i>Patients</i>	<i>ACE inhibitor</i>	<i>Antidiabetic</i>	<i>Notes</i>	<i>Refs</i>
Evidence for hypoglycaemia				
1 case	Captopril 50 mg/day	Glibenclamide (glyburide) 10.5 mg/day Metformin 1.7 g/day	Blood glucose 2.2 mmol/L 24 hours after the addition of captopril.	1
1 case	Captopril	Glibenclamide 10.5 mg/day Metformin 1.7 g/day	Blood glucose of 2.9 mmol/L 48 hours after starting captopril. Antidiabetic drugs stopped.	1
3 cases	Captopril	Glibenclamide	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
1 case	Captopril 12.5 mg/day	Glibenclamide 2.5 mg/day	Hypoglycaemia 7 hours after first dose, blood glucose 2.1 mmol/L, glibenclamide stopped.	3
1 case	Captopril	Unspecified oral antidiabetic	Hypoglycaemia, oral antidiabetic withdrawn.	4
5 cases	Captopril	Unspecified sulphonylureas	Hypoglycaemia reported to Centres Regionaux de Pharmacovigilance in France.	5
3 cases case control study	Captopril	Unspecified oral antidiabetics	Risk of hypoglycaemia increased 3.1-fold.	6
9 cases case control study	Captopril	Insulin	Risk of hypoglycaemia increased 3.7-fold.	6
4 cases	Captopril	Insulin	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
3 cases	Captopril	Insulin	Unexplained hypoglycaemia.	4
1 case	Enalapril 5 mg/day	Glibenclamide 5 mg/day	Hypoglycaemia, blood glucose 2.3 mmol/L. Dose of glibenclamide reduced to 2.5 mg/day.	3
2 cases	Enalapril 5 mg/day	Glibenclamide 5 mg/day	Hypoglycaemic attacks, glibenclamide reduced to 1.25 mg/day.	7
9 healthy subjects (double-blind, crossover study)	Enalapril 5 mg/day, then 10 mg/day	Glibenclamide 3.5 mg single dose	Hypoglycaemic effects of glibenclamide temporarily enhanced between 2 and 4 hours after enalapril was taken.	8
4 cases	Enalapril	Glibenclamide	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
1 case	Enalapril	Gliclazide 80 mg/day	Hypoglycaemia when enalapril dose increased from 5 to 10 mg/day.	9
4 cases	Enalapril	Unspecified sulphonylureas	Hypoglycaemia reported to Centres Regionaux de Pharmacovigilance in France.	5
1 case	Enalapril	Unspecified sulphonylurea	Recurrent hypoglycaemia, sulphonylurea withdrawn.	10
10 cases case control study	Enalapril	Unspecified sulphonylurea Insulin	2.4-fold increase in the risk of hypoglycaemia with sulphonylureas. However, no increased risk was seen in insulin users. In addition when all ACE inhibitors were considered together, no significant increase in risk was seen.	11
2 cases case control study	Enalapril	Unspecified oral antidiabetics	Non-significant 5.4-fold increase in the risk of hypoglycaemia.	6
3 cases case control study	Enalapril	Insulin	Non-significant 1.7-fold increase in the risk of hypoglycaemia.	6
1 case	Enalapril	Insulin	Reduced insulin requirements.	10
11 cases	Enalapril	Insulin	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
1 case	Lisinopril	Glibenclamide and metformin	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
1 case	Lisinopril 10 mg/day	Gliclazide	Hypoglycaemia resolved on stopping gliclazide.	9
1 case	Perindopril	Glibenclamide	Hypoglycaemia reported to a Spanish Regional Pharmacosurveillance centre.	2
1 case	Ramipril 2.5 mg/day	Glibenclamide 5 mg/day Metformin 1.7 g/day	Patient also on naproxen, renal function deteriorated causing hypoglycaemia due to accumulation of oral antidiabetics.	12

Continued

Table 13.2 Interactions between antidiabetics and ACE inhibitors (continued)

Patients	ACE inhibitor	Antidiabetic	Notes	Refs
7 cases case control study	Unspecified ACE inhibitor	Insulin or oral antidiabetics	3.2-fold increase in the risk of hypoglycaemia leading to hospitalisation.	13
Evidence of no interaction				
8 cases	Captopril 37.5 mg/day	Insulin	No change to daily insulin requirements. No evidence of symptomatic hypoglycaemia.	14
38 cases	Captopril 50 to 100 mg/day or Enalapril 20 to 40 mg/day	Insulin or oral antidiabetics	Antidiabetic treatment unaltered, no evidence of unusual or unexplained hypoglycaemia.	15
18 cases double blind controlled study	Enalapril 20 to 40 mg/day	Insulin	No change to daily insulin requirements. No evidence of unexplained hypoglycaemia.	15
428 patients randomised controlled study	Lisinopril 10 to 20 mg/day or placebo	Insulin	No difference in the number of hypoglycaemic episodes between lisinopril and placebo recipients.	16
22 cases case control study	Captopril or Enalapril	Insulin or oral antidiabetics	Data from Centres Regionaux de Pharmacovigilance in France used. No increased risk of hypoglycaemia detected.	17
598 cases of hypoglycaemia in a retrospective study	Captopril or Enalapril or other classes of antihypertensive	Insulin or oral antidiabetics	No statistically significant increase or decrease in the risk of serious hypoglycaemia among users of ACE inhibitors or any other class of antihypertensives compared with non users of antihypertensives.	18
758 patients randomised controlled study	Captopril 50 to 100 mg/day or atenolol	Insulin or oral antidiabetics or diet alone	The proportion of patients with hypoglycaemic attacks did not differ between the captopril and atenolol groups.	19

suffered permanent damage to the nervous system.³ In another study it was found that alcohol was involved in about 4% of hypoglycaemic episodes requiring hospitalisation.⁴ In contrast to these alcohol-induced hypoglycaemic episodes, it was found in two other studies^{5,6} that pure alcohol and dry wine had little effect on blood glucose levels. In a recent review of six studies, it was concluded that consumption of a moderate amount of alcohol does not acutely impair glycaemic control in diabetic patients, and may in fact result in a small decrease in plasma glucose concentration.⁷ However, another study found that 46 patients with type 2 diabetes and a mean age of 67 years who were regular chronic alcohol users (mean 45 g/day) had a reversible deterioration in metabolic control (higher fasting and postprandial

glucose levels and higher glycosylated haemoglobin levels), when compared with 35 non-alcohol users.⁸ Another study reported similar findings.⁹

2. *Effect on diabetic complications.* A review of 4 epidemiological studies concluded that heart disease is less common in people with diabetes who drink moderate amounts of alcohol than in those who do not.⁷

(b) Biguanides

A controlled study in 5 ketosis-resistant patients with type 2 diabetes taking **phenformin** 50 to 100 mg daily found that the equivalent of about 85 mL (3 oz) of whiskey markedly raised their blood lactate and lactate-pyruvate levels. Two of them had blood-lactate levels of more than

50 mg%, and one of these patients had previously experienced nausea, weakness and malaise while taking **phenformin** and alcohol.¹⁰ The ingestion of alcohol is described in other reports as having preceded the onset of **phenformin**-induced lactic-acidosis.¹¹⁻¹³ Some patients have complained that alcohol tastes metallic.

(c) Rosiglitazone

An 8-week study in type 2 diabetics taking rosiglitazone 8 mg daily or a placebo found that 0.6 g/kg of alcohol taken with a meal did not have a clinically relevant effect on plasma glucose levels and no episodes of hypoglycaemia were seen.¹⁴

(d) Sulphonylureas

About one-third of those taking **chlorpropamide** who drink alcohol, even in quite small amounts, experience a warm, tingling or burning sensation of the face, and sometimes the neck and arms as well. It may also involve the conjunctivae. This can begin within 5 to 20 minutes of drinking, reaching a peak within 30 to 40 minutes, and may persist for 1 to 2 hours. Very occasionally headache occurs, and light-headedness, palpitations, wheezing and breathlessness have also been experienced.^{15,16}

This disulfiram-like flushing reaction has been described in numerous reports (far too many to list here) involving large numbers of patients taking **chlorpropamide**. These reports have been extensively reviewed.^{15,17-19} A similar reaction can occur, but much less frequently, with other sulphonylureas including **carbutamide**,²⁰ **glibenclamide (glyburide)**,^{16,21} **gliclazide**,²² **glipizide**,¹⁶ **tolazamide**,²³ and **tolbutamide**.^{24,25} In one crossover study, evident flushing phenomenon, after an oral ethanol-loading test, was seen in 6 of 10 patients taking **chlorpropamide**, 3 of 10 taking **tolbutamide**, 2 of 10 taking **glibenclamide**, one of 10 taking **glibornuride** and none of 10 taking **glipizide**.²⁶

A study found that the mean half-life of **tolbutamide** in alcoholics was about one-third lower than in control subjects.²⁷ Alcohol is also reported to prolong but not increase the blood glucose-lowering effects of **glipizide**.²⁸ Another study found that intravenous infusion of ethanol (equivalent to 1 to 2 units of alcoholic drinks) significantly decreased the nadir plasma glucose level during a fast in 10 elderly patients (age range 60 to 75 years) with type 2 diabetes taking **glibenclamide** 20 mg daily.²⁹

Mechanism

The exacerbation of hypoglycaemia by alcohol is not fully understood. However, it is known that if hypoglycaemia occurs when liver glycogen stores are low, the liver turns to the formation of new glucose from amino acids (gluconeogenesis). This gluconeogenesis is inhibited by the presence of alcohol so that the fall in blood glucose levels may not be prevented and a full-scale hypoglycaemic episode can result.

The chlorpropamide-alcohol flush reaction, although extensively studied, is by no means fully understood. It seems to be related to the disulfiram-alcohol reaction, and is accompanied by a rise in blood-acetaldehyde levels (see also 'Alcohol + Disulfiram', p.61). It also appears to be genetically determined¹⁶ and may involve both prostaglandins and endogenous opioids.³⁰ The decreased half-life of tolbutamide in alcoholics is probably due to the inducing effects of alcohol on liver microsomal enzymes.^{27,31,32}

The reasons for the raised blood lactate levels seen during the concurrent use of phenformin and alcohol are not clear, but one suggestion is that it may possibly be related to the competitive demands for isoenzymes by the reactions that convert alcohol to acetaldehyde, and lactate to pyruvate.¹⁰ A study in healthy subjects found that moderate alcohol consumption both improves insulin action, without affecting non-insulin mediated glucose uptake, and decreases lactate clearance. The increase in blood lactate with alcohol is therefore mainly due to inhibition of clearance. Alcohol did not appear to significantly affect beta-cell function.³³

Importance and management

The documentation of the interactions between antidiabetic drugs and alcohol is surprisingly patchy (with the exception of chlorpropamide and alcohol) but they are of recognised clinical importance.

General comments

The following contains the main recommendations of Diabetes UK (formerly The British Diabetic Association) based on a review of what is currently known:^{34,35} Most diabetics need not avoid alcohol totally, but they are advised not to exceed 2 drinks (for women) or 3 drinks (for men) daily. A drink (or unit) is defined in 'Table 3.1', (p.41). The intake of drinks with

high-carbohydrate content (sweet sheries, sweet wines, most liqueurs, and low alcohol wines) should be limited. Diabetics should not drink on an empty stomach and they should know that the warning signs of hypoglycaemia may possibly be obscured by the effects of the alcohol. Driving or handling dangerous machinery should be avoided because the CNS depressant effects of alcohol plus hypoglycaemia can be particularly hazardous. Warn patients of the risks of hypoglycaemia occurring several hours after drinking. Those with peripheral neuropathy should be told that alcohol may aggravate the condition and they should not have more than one drink daily. Provided drinking is restricted as suggested, and drinks containing a lot of carbohydrate are avoided, there is no need to include the drink in the dietary allowance. However, diabetics on a weight-reducing diet should try to limit intake to the occasional drink and should include it in their daily calorie allowance.

The advice of the American Diabetes Association is similar: If individuals choose to drink alcohol, daily intake should be limited to 1 drink (for women) or 2 drinks (for men). To reduce the risk of hypoglycaemia, alcohol should be consumed with food.¹

There is some evidence that heart disease in patients with diabetes may be less common in patients who consume moderate amounts of alcohol, but this is currently not sufficient to recommend that patients who do not drink alcohol should begin to drink in moderation.⁷

Specific comments about oral antidiabetics

The chlorpropamide-alcohol interaction (flushing reaction) is very well documented, but of minimal importance. It is a nuisance and possibly socially embarrassing but normally requires no treatment. Patients should be warned. The incidence is said to lie between 13 and 33%^{36,37} although one study claims that it may be as low as 4%.³⁸ Since it can be provoked by quite small amounts of alcohol (half a glass of sherry or wine) it is virtually impossible for sensitive patients to avoid it if they drink. Most manufacturers issue warnings about the possibility of this reaction with other sulphonylureas, but it is very rarely seen and can therefore almost always be avoided by replacing chlorpropamide with another sulphonylurea. Alcoholic subjects may need above-average doses of tolbutamide.

Metformin does not carry the same risk of lactic acidosis seen with phenformin and it is suggested in a paper³⁴ prepared for and approved by The British Diabetic Association [now Diabetes UK] that one or two drinks a day are unlikely to be harmful in patients taking **metformin**. However, the drug should not be given to alcoholic patients because of the possibility of liver damage.

Antidiabetics + Allopurinol

Allopurinol adversely affected glycaemic control in a patient with type 2 diabetes receiving insulin. Allopurinol caused an increase in the half-life of chlorpropamide, and a minor decrease in the half-life of tolbutamide, but the effect of these changes on the hypoglycaemic response of patients is uncertain. Marked hypoglycaemia and coma occurred in one patient taking gliclazide and allopurinol.

Clinical evidence

A. Insulin

A case report describes improved glycaemic control in a type 2 diabetic patient after allopurinol was stopped. Despite restricted food intake and an increasing dose of insulin, his glycaemic control was poor (fasting blood glucose 14.8 mmol/L) when he took allopurinol 100 mg twice daily. However, within a few days of stopping the allopurinol, an unexpected improvement in glycaemic control was observed (fasting blood glucose reduced to less than 11 mmol/L). He was later rechallenged with allopurinol, which resulted in reduced glucose tolerance, but increased insulin response, suggesting increased insulin resistance. Hyperuricaemia was later controlled with **probenecid**, which did not adversely affect glycaemic control.¹

B. Sulphonylureas

(a) Chlorpropamide

A brief report describes 6 patients taking chlorpropamide with allopurinol. The half-life of chlorpropamide in one patient with gout and normal renal function exceeded 200 hours (normally 36 hours) after allopurinol had been taken for 10 days, and in 2 others the half-life was extended to 44 and 55 hours. The other 3 patients were given allopurinol for only 1 or 2 days and the half-life of chlorpropamide remained unaltered.²

(b) Gliclazide

Severe hypoglycaemia (1.6 mmol/L) and coma occurred in a patient with renal impairment taking gliclazide and allopurinol.³ Hypoglycaemia has been seen in another patient taking both drugs, but an interaction is less clear, as enalapril and ranitidine, which may also (rarely) interact were also involved.³

(c) Tolbutamide

Allopurinol 2.5 mg/kg twice daily for 15 days reduced the half-life of intravenous tolbutamide in 10 healthy subjects by 25%, from 360 to 267 minutes.^{4,5}

Mechanism

Not understood. In the case of chlorpropamide it has been suggested that it possibly involves some competition for renal tubular mechanisms.²

Importance and management

Information is very limited. Only gliclazide has been implicated in severe hypoglycaemia with allopurinol and there seem to be no reports of either grossly enhanced hypoglycaemia with chlorpropamide and allopurinol, or a reduced effect with tolbutamide and allopurinol. More study is needed to find out whether any of these interactions has general clinical importance, but it seems unlikely.

Antidiabetics + Anabolic steroids

Nandrolone, methandienone, testosterone and stanozolol can enhance the blood glucose-lowering effects of insulin.

Clinical evidence

In a study in 54 diabetics taking **nandrolone phenylpropionate** 25 mg weekly or **nandrolone decanoate** 50 mg given every 3 weeks by intramuscular injection, it was found necessary to reduce the insulin dosage by an average of 36% (reduction range 4 to 56 units) in about one-third of the patients.¹

Other reports similarly describe an enhanced reduction in blood glucose levels in diabetics receiving insulin and **nandrolone**,^{2,3} **methandienone**,⁴ **testosterone propionate**⁵ or **stanozolol**.⁶ A reduction in blood glucose levels has also been seen in healthy subjects given **testosterone propionate**.⁷ No changes were seen when **ethylestrenol** was used.^{1,2}

Mechanism

Uncertain.

Importance and management

Established interactions but the total picture is incomplete because not all of the anabolic steroids appear to have been studied and they may not necessarily behave identically. A fall in the dosage requirements of insulin may be expected in many patients with the steroids cited. An average reduction of a third is reported.¹ Given these results, and the fact that anabolic steroids have been shown to *impair* glucose tolerance it would seem prudent to closely monitor the concurrent use of any antidiabetic drug.

Antidiabetics + Angiotensin II receptor antagonists

Glibenclamide (glyburide) causes a small reduction in valsartan plasma levels, but this is unlikely to be of any clinical significance. No clinically relevant pharmacokinetic interaction occurs between glibenclamide and candesartan or telmisartan, or between tolbutamide and irbesartan. Eprosartan does not alter the efficacy of glibenclamide. Losartan and possibly eprosartan may reduce awareness of hypoglycaemic symptoms.

Clinical evidence and mechanism

A. Insulin

(a) Eprosartan

A study in 16 healthy subjects found that a single 600-microgram dose of eprosartan did not significantly affect adrenaline (epinephrine) release in response to insulin-induced hypoglycaemia, but the eprosartan tended to blunt some of the haemodynamic responses to hypoglycaemia.¹ Theoretically, therefore, hypoglycaemic symptoms could be reduced in some diabetic patients.

(b) Losartan

Three patients with type 1 diabetes spontaneously reported reduced awareness of hypoglycaemic symptoms (tremor, palpitations, nervousness) after initiation of losartan therapy. A placebo-controlled study in 16 healthy subjects given losartan 50 mg daily for 8 days confirmed an attenuation of the symptomatic and hormonal responses to hypoglycaemia.²

B. Glibenclamide (Glyburide)

(a) Candesartan

Glibenclamide 3.5 mg daily did not significantly affect the pharmacokinetics of candesartan 16 mg daily, both given for 7 days, although the maximum plasma concentration of candesartan was slightly increased by 12%. The pharmacokinetics of glibenclamide were not altered by the candesartan.³

(b) Eprosartan

Fifteen type 2 diabetics stabilised taking glibenclamide 3.75 to 10 mg daily for at least 30 days had no changes in their 24-hour plasma glucose concentrations when eprosartan 200 mg twice daily was added, for a further 7 days. Concurrent use was safe and well tolerated and it was concluded that there is no clinically relevant interaction between these two drugs.⁴

(c) Valsartan

In a randomised, crossover study, 12 healthy subjects were given single oral doses of valsartan 160 mg and glibenclamide 1.75 mg alone and together.⁵ Glibenclamide appeared to decrease the valsartan AUC by 16%, but the plasma concentrations of valsartan showed wide variations between subjects. The pharmacokinetics of glibenclamide were not affected.⁵ The changes in valsartan pharmacokinetics seen with glibenclamide appear to have little or no clinical relevance.

C. Tolbutamide

A study in 18 healthy subjects given **irbesartan** 300 mg daily and tolbutamide 1 g daily, either alone or in combination, found that no clinically important pharmacokinetic interactions occurred.⁶

Importance and management

No special precautions would appear to be needed if candesartan, eprosartan, telmisartan or valsartan are given with glibenclamide, or if irbesartan is given with tolbutamide. However, symptoms of hypoglycaemia may be reduced by losartan and possibly other angiotensin II receptor antagonists. Further clinical study is needed, but note that this is similar to the effect of 'ACE inhibitors', (p.471).

Antidiabetics + Antacids

The rate of absorption of some antidiabetics is increased by some antacids, but there appear to be no reports of adverse responses in diabetic patients as a result of any of these interactions.

Clinical evidence

(a) Acarbose

A placebo-controlled study found that 10 mL of **Maalox 70 (aluminium/magnesium hydroxide)** had no effect on the blood glucose- and insulin-lowering effects of acarbose 100 mg in 24 healthy subjects given a 75-g dose of sucrose. It was concluded that no special precautions are needed if this or similar antacids are used with acarbose.¹

(b) Chlorpropamide

Magnesium hydroxide 850 mg increased the rate of absorption of chlorpropamide 250 mg in healthy subjects, but the insulin and glucose responses were unaffected.²

(c) Glibenclamide (Glyburide)

A single-dose study in healthy subjects found that **magnesium hydroxide** 850 mg had little effect on the rate or extent of absorption of a micronised glibenclamide preparation (**Semi-Euglucon**), but it caused a threefold increase in the peak plasma concentration and the bioavailability of a non-micronised preparation (**Gilemid**).³ **Maalox (aluminium/magnesium hydroxide)** increased the AUC of glibenclamide (given as **Daonil**) by one-third, and its maximum serum level by 50%.⁴

Sodium bicarbonate 1 to 3 g very markedly increased the early bioavailability of non-micronised glibenclamide in healthy subjects, but its activity remained unaltered.⁵

(d) Glipizide

Sodium bicarbonate 3 g significantly increased the absorption of glipizide 5 mg and enhanced its effects to some extent, but the total absorption was unaltered.⁶ The AUCs from 0 to 30 minutes, 1-hour, and 2-hours, were increased six-, four- and twofold, respectively, and the time to reach the peak serum level fell from 2.5 to 1 hour. **Aluminium hydroxide** 1 g did not appear to affect the absorption of glipizide 5 mg.⁶ **Magnesium hydroxide** 850 mg considerably increased the rate of absorption of glipizide 5 mg, the AUCs from 0 to 30 minutes and 1-hour being increased by 180 and 69%, respectively.⁷

(e) Miglitol

The manufacturer notes that an antacid (not specified) did not alter the pharmacokinetics of miglitol in healthy subjects.⁸

(f) Tolbutamide

Magnesium hydroxide 850 mg increased the 0 to 1-hour and 2-hour AUCs of a single 500-mg dose of tolbutamide 5-fold and 2.5-fold, respectively, in healthy subjects. The total AUC was unaffected. The maximum insulin response was increased fourfold and occurred about an hour earlier, and the glucose responses were also larger and occurred earlier.²

Mechanism

Uncertain. The small increase in gastric pH caused by these antacids possibly increases the solubility of these sulphonylureas and therefore increases their absorption.⁹

Importance and management

Although some interactions certainly occur in healthy subjects, their clinical importance in patients with diabetes is uncertain. No reports of adverse reactions appear to have been published, but note that patients taking glipizide with sodium bicarbonate or magnesium hydroxide, or tolbutamide with magnesium hydroxide may experience transient hypoglycaemia. Generally no action seems necessary, but if a problem does occur, separating the dosages as much as possible would probably minimise any

effects. Giving glibenclamide half to one hour before the antacid has been suggested.⁴

Antidiabetics + Antimalarials

Hydroxychloroquine may reduce insulin requirements by about 25%, and a case of hypoglycaemia has been reported. Similarly, hypoglycaemia has occurred in a patient taking chloroquine and insulin. Reduced glucose levels or hypoglycaemia have been reported with mefloquine, quinidine, quinine, and sulfadoxine-pyrimethamine. Note that falciparum malaria *per se* can result in severe hypoglycaemia, and quinine in particular may contribute to this.

Clinical evidence, mechanism, importance and management

(a) Effect on diabetic control

1. **Chloroquine.** A case report describes a patient with type 1 diabetes who had developed insulin resistance and was maintained on intravenous **insulin**, who showed a dramatic return of sensitivity to subcutaneous **insulin**, heralded by a series of hypoglycaemic attacks, within 15 days of starting to take chloroquine phosphate 200 mg every 8 hours.¹ Similarly, chloroquine phosphate (150 mg of chloroquine base) four times daily improved glucose tolerance in 5 out of 6 patients with type 2 diabetes controlled by diet, but had little effect on healthy subjects.² It has been suggested that chloroquine might inhibit insulin degradation or increase glucose utilisation in peripheral tissues.³

2. **Hydroxychloroquine.** The effect of hydroxychloroquine on diabetic control with **insulin** or **glibenclamide (glyburide)** was investigated in a randomised, double-blind, placebo-controlled study in 38 patients with poorly controlled type 2 diabetes. The addition of hydroxychloroquine 200 mg three times daily to **insulin** caused a significant improvement in the glycaemic profile and the daily **insulin** dose had to be reduced by about 25%. Patients taking **glibenclamide** with hydroxychloroquine also had a significant improvement in their plasma glucose levels. One patient receiving **insulin** and hydroxychloroquine had severe hypoglycaemia after 2 months of treatment, and it was necessary to drastically reduce the daily dose of **insulin**.³ The authors suggested that hydroxychloroquine might inhibit insulin degradation or increase glucose utilisation in peripheral tissues.³

(b) Treatment of malaria

Hypoglycaemia is a complication of falciparum malaria, which occurs mainly in severe life-threatening disease,^{4,5} in pregnant women⁴ or children,^{6,7} and in patients who are given **quinine** or **quinidine**.^{5,7-10} The reasons are not fully understood but renal impairment and poor nutrition, may be contributing factors. In severe malaria, hypoglycaemia may increase as the patient's glucose production becomes insufficient for the host/parasite demand because in this situation glucose utilisation can be increased by 50%.¹¹

Additionally, **quinine** reduces plasma glucose by stimulating the release of large amounts of **insulin** from the pancreas,¹² possibly associated with an increase in the sensitivity to **insulin** as the malaria improves,¹³ although other factors may also be involved. A study in 32 patients with malaria found that their pre-treatment capillary glucose was below normal in 12.5% of cases. One hour after intravenous **quinine** was given, glucose levels in all patients fell by an average of 11.4% and after 6 hours a further fall of 20.5% was found in 75% of patients (with an increase at 6 hours in

the remaining 25% of patients).¹⁰ **Quinidine** has been shown to have a similar effect.¹⁴ Whether these changes can also occur in patients with **quinine**- or **quinidine**-treated malaria and diabetes, despite their pancreatic beta cell impairment, seems not to have been studied, although one isolated report argues against significant **quinine**-mediated mechanisms. Profound and persistent hypoglycaemia was seen in a diabetic patient (type 2 diabetes) with severe falciparum malaria treated with **quinine**, but the hypoglycaemia evolved prior to **quinine** therapy and resolved as the parasitaemia was successfully eradicated, despite continuation of the **quinine**. Subsequently, as she had discontinued antidiabetic medication (chlorpropamide) prior to hospital admission, hyperglycaemia developed (blood glucose ranging from 7.5 to 16 mmol/L) despite continuing to take **quinine**.¹⁵ Any interpretation of disturbances in the control of the diabetes should take into account the severity of the malaria and the possible effects of these drugs.

An isolated report describes life-threatening hypoglycaemia in a 3-year-old boy, with uncomplicated malaria, 90 minutes after he took **sulfadoxine-pyrimethamine (Fansidar)**.¹⁶ **Mefloquine** has been reported to reduce plasma glucose levels in healthy subjects.¹⁷ **Artemisinin derivatives** such as **artemether** may be associated with fewer episodes of hypoglycaemia than **quinine** in children with severe malaria.⁷ **Chloroquine**, **amodiaquine** and **halofantrine** do not apparently stimulate the release of **insulin**.^{14,18}

(c) Treatment of cramps

A study in 12 patients (age 51 to 79 years) with type 2 diabetes taking **gliclazide**, and 10 similar, non-diabetic subjects, found that a single 600-mg dose of **quinine sulphate** at night reduced serum glucose levels in both groups, without affecting serum insulin concentrations.¹⁹ **Quinine** has been responsible for hypoglycaemia in non-diabetic patients, one of whom was taking **quinine sulphate** 325 mg four times daily for leg muscle cramps.²⁰ Two other non-diabetic patients, one with congestive heart failure and the other with terminal cancer, similarly developed hypoglycaemia when given **quinine** for leg cramps.^{21,22}

Antidiabetics + Antineoplastics

Asparaginase sometimes induces temporary diabetes mellitus. It seems possible that some diabetics will need changes in the dose of their antidiabetic drugs. There is also evidence that the control of diabetes can be severely disturbed in patients given cyclophosphamide. Capecitabine may cause hyperglycaemia and therefore could aggravate diabetes.

Clinical evidence and mechanism

(a) Asparaginase (*Colaspase*)

Three patients with acute lymphocytic leukaemia developed diabetes after receiving asparaginase with or without corticosteroids. In two of them this occurred 2 and 4 days after a single dose of asparaginase, and in another patient it occurred 2 days after the fourth dose. Plasma insulin was undetectable. A normal insulin response returned in one patient after 23 days, whereas the other 2 showed a suboptimal response 2 weeks, and 9 months afterwards.¹ In another study, 5 out of 39 patients (3 adults, 2 children) developed hyperglycaemia and glycosuria after treatment with asparaginase. This responded to **insulin**, and blood glucose levels returned to normal in about 2 weeks.² In a retrospective analysis, it was found that about 10% of 421 children with leukaemia treated with asparaginase and **prednisone** developed hyperglycaemia, which resolved in all patients. A family history of diabetes and obesity were found to be risk factors.³ Other cases have been described,⁴⁻⁶ including one who, unusually, developed persistent hyperglycaemia and required long-term treatment with oral antidiabetics.⁵ The reasons for this reaction are not understood but suggestions include inhibition of insulin synthesis,⁷ direct damage to the islets of Langerhans,¹ and reduced insulin binding.⁷ Hyperglycaemia can be caused by 'corticosteroids' (p.485), and their combined use with asparaginase is probably a contributing factor.

(b) Capecitabine

There appear to be no reports of adverse interactions between antidiabetics and capecitabine, but the manufacturer notes that the control of diabetes mellitus may be affected by capecitabine, for which reason they advise caution.⁸

(c) Cyclophosphamide

Acute hypoglycaemia has been described in 2 diabetic patients receiving **insulin** and **carbutamide** who were also given cyclophosphamide.⁹ Three cases of diabetes, apparently induced by the use of cyclophosphamide, have also been reported.¹⁰ The reasons are not understood.

Importance and management

Strictly speaking probably none of these reactions is an interaction, but they serve to underline the importance of monitoring the diabetic control of patients receiving asparaginase, capecitabine or cyclophosphamide.

Antidiabetics + Antipsychotics

Chlorpromazine may raise blood glucose levels, particularly in daily doses of 100 mg or more, and disturb the control of diabetes. Clozapine, olanzapine and risperidone are associated with an increased risk of glucose intolerance.

Clinical evidence

(a) Phenothiazines and Butyrophenones

A long-term study was undertaken over the period 1955 to 1966 in a large number of women treated for a year or longer with **chlorpromazine** 100 mg daily or more, or corresponding doses of **perphenazine**, **thioridazine**, **trifluoperazine**. This found that about 25% developed hyperglycaemia accompanied by glycosuria, compared with less than 9% in a control group who were not taking phenothiazines. Of those given a phenothiazine, about a quarter had complete remission of the symptoms when the drug was withdrawn or the dosage reduced. **Thioridazine** appeared to be less diabetogenic than the other phenothiazines used.¹

There are other reports of this response to **chlorpromazine**.²⁻¹¹ However, in contrast one study in 850 patients suggests that **chlorpromazine** has no effect on blood glucose levels; 22 diabetic patients in the study had no significant changes in their blood glucose levels. Five patients developed diabetes, but this was believed to be due to factors other than **chlorpromazine** treatment.¹² **Chlorpromazine** 50 to 70 mg daily does not affect blood glucose levels significantly.¹¹ Further, a more recent analysis discussed in (b) below did not find an increased risk of glucose intolerance with **chlorpromazine** or **haloperidol**, and notes that the number of reports of glucose intolerance with these drugs has remained small.¹³

(b) Atypical antipsychotics

An analysis of reports of glucose intolerance in the adverse reaction database of the WHO Collaborating Centre for International Drug Monitoring found that **clozapine**, **olanzapine** and **risperidone** were associated with an increased risk of glucose intolerance. It is uncertain whether this is a dose-related effect. Additional risk factors with these antipsychotics were an underlying diabetic condition, weight increase, male gender, or the concurrent use of valproic acid, SSRIs or buspirone.¹³

Mechanism

Although some studies found that drugs such as chlorpromazine and haloperidol were not associated with glucose intolerance,^{11,13} it seems that chlorpromazine can inhibit the release of insulin, and possibly cause adrenaline release from the adrenals, both of which could result in a rise in blood glucose levels. This may be a dose-related effect.¹¹ Further, chlorpromazine may cause aggregation and inactivation of insulin by reduction of disulfide bonds.¹⁴ Clozapine may induce insulin resistance and a compensatory increase in insulin secretion. Patients may develop diabetes if this compensatory increase is not achieved. Clozapine and olanzapine may cause weight gain and hypertriglyceridaemia.¹³ Schizophrenia itself may be associated with an increased risk of hyperglycaemia.

Importance and management

A long-established reaction first recognised in the early 1950s. The incidence of hyperglycaemia with chlorpromazine in doses of 100 mg or more is about 25%. Increases in the dosage requirements of the antidiabetic should be anticipated during concurrent use.¹ Smaller chlorpromazine doses, of 50 to 70 mg daily do not appear to cause hyperglycaemia. There seems to be little clinical evidence that other phenothiazines or butyrophenones significantly disturb blood glucose levels in diabetics. The atypical antipsychotics, clozapine, olanzapine and risperidone appear to be associated with an increased risk of glucose intolerance and regular monitoring is recommended in the presence of additional risk factors for diabetes mellitus.¹³

Antidiabetics + Azoles; Fluconazole

Fluconazole appears not to affect the diabetic control of most patients taking sulphonylureas, but isolated reports describe hypoglycaemic coma in one patient taking glipizide and hypoglycaemia and aggressive behaviour in a patient taking gliclazide. There is some evidence that the blood glucose-lowering effects of both glipizide and glibenclamide (glyburide) may be modestly increased. Fluconazole may cause increases in plasma levels of glimepiride (marked) and nateglinide (modest).

Clinical evidence

(a) Chlorpropamide

After taking fluconazole 100 mg daily for 7 days, the AUC of single 250-mg doses of chlorpropamide was increased by 28% in 18 healthy subjects but the maximum plasma levels and blood glucose levels were unchanged. There was no evidence of hypoglycaemia.¹

(b) Glibenclamide (Glyburide)

After taking fluconazole 100 mg daily for 7 days, the AUC of a single 5-mg dose of glibenclamide was increased by 44% and maximum plasma levels rose by 19% in 20 healthy subjects. The change in blood glucose levels was not statistically significant but the number of subjects who had symptoms of hypoglycaemia increased.² In another study, a group of 14 postmenopausal diabetic women with vulvovaginal candidiasis taking either gliclazide or glibenclamide were given fluconazole 50 mg daily for 14 days. In contrast, none of the patients in this study developed symptoms of hypoglycaemia and their glycosylated haemoglobin and fructosamine concentrations were unchanged. No pharmacokinetic data were reported.³

(c) Gliclazide

A group of 14 postmenopausal diabetic women with vulvovaginal candidiasis taking either gliclazide or glibenclamide were given fluconazole 50 mg daily for 14 days. None of the patients developed symptoms of hypoglycaemia and their glycosylated haemoglobin and fructosamine concentrations were unchanged. No pharmacokinetic data were reported.³

However, a 56-year-old HIV-positive patient (antiretroviral treatment refused) and type 2 diabetes who had been taking gliclazide for 2 years was given fluconazole 50 mg daily for 2 weeks for oral candidiasis, and prophylactic co-trimoxazole (sulfamethoxazole 400 mg and trimethoprim 80 mg daily). One week after the re-introduction of fluconazole at a higher dose of 200 mg daily he was hospitalised because of weakness and aggressive behaviour. His blood glucose level was 2.2 mmol/L and gliclazide was stopped. He experienced brief loss of consciousness 2 days later while driving his car, but his condition then improved and neurological symptoms did not recur during 3 months follow-up without gliclazide treatment.⁴ For the possible contribution of sulfamethoxazole to this interaction, see Mechanism, below.

(d) Glimepiride

A double-blind study in 12 healthy subjects found that fluconazole 400 mg on day one then 200 mg daily for a further 3 days increased the AUC and peak plasma level of a single 0.5-mg dose of glimepiride by about 2.5-fold and 1.5-fold, respectively. Fluconazole increased the mean elimination half-life of glimepiride from 2 to 3.3 hours.⁵

(e) Glipizide

After taking fluconazole 100 mg daily for 7 days, the AUC of a single 2.5-mg dose of glipizide was increased by 49% and their maximum serum levels rose by 17% in 13 healthy subjects. Although blood glucose levels were lowered the change was not statistically significant. However, the number of subjects who had symptoms suggestive of hypoglycaemia increased.⁶

A diabetic patient taking glipizide 2.5 mg three times daily went into a hypoglycaemic coma within 4 days of starting to take fluconazole 200 mg daily. Her blood glucose levels had fallen to less than about 0.05 mmol/L. She rapidly recovered when given glucose.⁷

(f) Nateglinide

In a randomised, double-blind, crossover study, 10 healthy subjects were given a single 30-mg dose of nateglinide on day 4 of a course of fluconazole (given as 400 mg on day one, then 200 mg daily). Fluconazole raised the AUC of nateglinide by 48% (range 20 to 73%) and increased the nateglinide half-life from 1.6 to 1.9 hours. Despite these pharmacokinetic changes fluconazole did not potentiate the blood glucose lowering effects of nateglinide.⁸ It was predicted that this interaction may occur with **micronazole** (which inhibits the same isoenzymes as fluconazole), but this needs confirmation.

(g) Tolbutamide

After taking a single 150-mg dose and a further 6 doses of fluconazole 100 mg daily, the AUC of a single 500-mg dose of tolbutamide was increased by about 50%, and the peak plasma levels were raised in 13 healthy subjects. The half-life of the tolbutamide was increased about 40%. Blood glucose levels remained unaltered and none of the subjects showed any evidence of hypoglycaemia.^{9,10} However, the authors caution against extrapolating this finding to diabetic patients taking tolbutamide regularly.^{9,10}

Mechanism

Fluconazole is an inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which many of the sulphonylureas are metabolised. Inhibition of this isoenzyme leads to an accumulation of the sulphonylurea and therefore an increase in its effects. The hypoglycaemia in the patient taking gliclazide and fluconazole may have been enhanced by sulfamethoxazole, which also inhibits CYP2C9 (see also 'sulfonamides' (p.506)).⁴ The moderate pharmacokinetic changes seen when fluconazole is given with nateglinide are also thought to be mediated by CYP2C9.

Importance and management

The almost total absence of adverse reports implies that fluconazole does not usually markedly disturb the control of diabetes in those taking sulphonylureas. For fluconazole the increased plasma levels of glipizide and glimepiride, and the single case of severe hypoglycaemia, as well as the hypoglycaemic symptoms shown by those taking glibenclamide (glyburide) or gliclazide suggest that patients taking these sulphonylureas in particular should be warned to be alert for any evidence of hypoglycaemia. However, there seems to be no reason for avoiding concurrent use. Note that in the study of fluconazole with nateglinide a sub-therapeutic dose was given to healthy subjects, so in clinical practice a greater blood glucose-lowering effect may possibly occur.

Antidiabetics + Azoles; Itraconazole or Ketoconazole

Itraconazole also appears not to affect diabetic control in most patients, but there are reports of hypoglycaemia or hyperglycaemia associated with its use. Itraconazole causes modest increases in repaglinide and nateglinide levels, but has no effect on pioglitazone pharmacokinetics. Ketoconazole increases the blood glu-

Glucose-lowering effects of tolbutamide in healthy subjects and possibly increases the AUC of rosiglitazone and pioglitazone.

Clinical evidence

(a) Itraconazole

Post-marketing surveillance over 10 years indicated that in most patients itraconazole given with either **insulin** or **oral antidiabetics** did not affect diabetic control. However, there were 15 reports suggesting hyperglycaemia and 9 reports suggesting hypoglycaemia when itraconazole was given to patients taking antidiabetics.¹ In clinical trials only one of 189 diabetic patients experienced aggravated diabetes when given itraconazole.¹ The patient in question was also receiving ciclosporin for a renal transplant.

Itraconazole 200 mg then 100 mg twice daily for 4 days did not alter the pharmacokinetics of a single 15-mg dose of **pioglitazone** in 12 healthy subjects.²

Itraconazole 200 mg then 100 mg twice daily for 3 days increased the AUC of a single 250-microgram dose of **repaglinide** by 40% in healthy subjects. No change was noted in blood glucose levels, when compared with **repaglinide** alone.³ However, itraconazole enhanced the pharmacokinetic interaction of gemfibrozil on **repaglinide**; itraconazole plus gemfibrozil increased the AUC of **repaglinide** nearly 20-fold and considerably enhanced the blood glucose-lowering effect of **repaglinide**. In a similar study in healthy subjects, itraconazole plus gemfibrozil increased the AUC of a single 30-mg dose of **nateglinide** by 47%, without causing any significant change in blood glucose response to **nateglinide**.⁴

(b) Ketoconazole

After an overnight fast and breakfast the next morning, 7 healthy subjects were given a single 500-mg dose of **tolbutamide** before and after taking ketoconazole 200 mg daily for a week. Ketoconazole increased the elimination half-life of **tolbutamide** more than threefold (from 3.7 to 12.3 hours) and increased its AUC by 77%. Ketoconazole increased the blood glucose-lowering effects of **tolbutamide** by about 10 to 15%, and 5 of the subjects experienced mild hypoglycaemic symptoms (weakness, sweating and a reeling sensation) at about 2 hours after the dose.⁵

Ketoconazole 200 mg for 5 days increased the AUC and maximum plasma levels of a single 2-mg dose of **repaglinide** by 15 and 8%, respectively, in healthy subjects.⁶

Ketoconazole 200 mg twice daily for 5 days increased the AUC of a single 8-mg dose of **rosiglitazone** by 47% in 10 healthy Korean subjects.⁷

The US manufacturer refers to a 7-day study in which ketoconazole 200 mg twice daily modestly increased the AUC of **pioglitazone**.⁸

Mechanism

The modest changes in repaglinide pharmacokinetics with ketoconazole and itraconazole may be because repaglinide is metabolised by both CYP2C8 and CYP3A4, and one pathway may have the capacity to compensate if the other is inhibited.⁹ Similarly, itraconazole modestly affects nateglinide metabolism via CYP3A4.⁴

Although it has been suggested that ketoconazole may inhibit the metabolism of rosiglitazone via CYP2C8 and CYP2C9, ketoconazole is normally only considered to be a significant inhibitor of CYP3A4.

Importance and management

Itraconazole does not usually disturb the control of diabetes, although there are rare reports of hyperglycaemia or hypoglycaemia associated with its use. The effect of itraconazole on repaglinide could potentially be important, especially if a drug which inhibits CYP2C8 such as gemfibrozil is given as well; so increased monitoring of glucose levels is advisable. Similarly, itraconazole may interact with nateglinide to a modest extent. Itraconazole is unlikely to interact with pioglitazone.

Information about ketoconazole and sulphonylureas appears to be limited to one study in healthy subjects. The reaction in diabetics is uncertain, but if ketoconazole is added to tolbutamide, patients should be warned to be alert for any evidence of increased hypoglycaemia. It may become necessary to reduce the tolbutamide dosage. Ketoconazole increases the AUC of rosiglitazone and pioglitazone, and more frequent blood glucose monitoring is recommended. The pharmacokinetic changes with ketoconazole and repaglinide are minor, and unlikely to be of any clinical relevance.
