Antidiabetics + Azoles; Miscellaneous

Hypoglycaemia has been seen in few diabetics taking tolbutamide, glibenclamide or gliclazide when they were given miconazole. Posaconazole slightly enhanced the blood glucose-lowering effects of glipizide in healthy subjects, but did not affect the metabolism of a single dose of tolbutamide. Voriconazole is predicted to increase the levels of the sulphonylureas. Clotrimazole used intravaginally appears not to interact with gliclazide or glibenclamide.

Clinical evidence

(a) Clotrimazole

A group of 15 postmenopausal diabetic women with vulvovaginal candidiasis taking either **gliclazide** or **glibenclamide (glyburide)** were treated with intravaginal clotrimazole 100 mg daily for 14 days. None of the patients developed symptoms of hypoglycaemia and their glycosylated haemoglobin and fructosamine concentrations were unchanged. No pharmacokinetic data were reported.¹

(b) Miconazole

A diabetic patient taking **tolbutamide** was hospitalised with severe hypoglycaemia about 10 days after starting to take miconazole.² In 1983 the French Commission Nationale de Pharmacovigilance reported 6 cases of hypoglycaemia in diabetics taking sulphonylureas (5 with **gliclazide** and one with **glibenclamide (glyburide)**), which occurred within 2 to 6 days of miconazole being started.² The same organisation reported a further 8 cases in the 1985 to 1990 period but individual sulphonylureas were not named.³ Three other cases of hypoglycaemia (two with **gliclazide** and one with **glibenclamide**) are reported elsewhere, in patients given miconazole up to 750 mg daily.⁴ Miconazole has been predicted to interact with **nateglinide**, see 'fluconazole', (p.479).

(c) Posaconazole

A study in 12 healthy subjects found that posaconazole 400 mg twice daily for 10 days had no significant effects on the steady-state pharmacokinetics of **glipizide** 10 mg daily, but there was a small significant decrease in blood glucose levels following concurrent use. **Glipizide** did not affect the pharmacokinetics of posaconazole.⁵

In a study using **tolbutamide** as a probe drug for CYP2C9, posaconazole 200 mg once daily for 10 days had no effect on **tolbutamide** metabolism.⁶

(d) Voriconazole

The manufacturers of voriconazole predict that it will raise the levels of the sulphonylureas.^{7,8}

Mechanism

Miconazole and voriconazole are inhibitors of the cytochrome P450 isoenzyme CYP2C9, by which many of the sulphonylureas are metabolised. Inhibition of this isoenzyme would therefore be expected to lead to an accumulation of the sulphonylurea and therefore an increase in its ef-

fects, as seen with miconazole. Clotrimazole is probably not absorbed in sufficient quantities to cause an interaction.

Importance and management

The interaction between miconazole and the sulphonylureas is established and clinically important, but of uncertain incidence. Concurrent use need not be avoided but it should be monitored and the dosage of the sulphonylurea reduced if necessary. Patients should be warned. Information about other sulphonylureas not cited is lacking but it seems possible that they may interact similarly with miconazole.

Posaconazole slightly enhanced the blood glucose-lowering effects of glipizide in healthy subjects, but the clinical relevance of this is not known. Posaconazole does not appear to affect tolbutamide metabolism.

The manufacturers of voriconazole advise increased blood-glucose monitoring in patients taking sulphonylureas, and until more is known this seems prudent.

Information about intravaginal clotrimazole is very sparse, but it appears not to interact with gliclazide or glibenclamide, and probably not with any of the other oral antidiabetics, not least because its absorption from the vagina is very small.

Antidiabetics + Benzodiazepines

No adverse interaction normally occurs between antidiabetics and benzodiazepines, but an isolated case of hyperglycaemia has been seen in an insulin-treated patient with type 2 diabetes associated with the use of chlordiazepoxide. The effects of lorazepam were found to be increased in patients given beef/pork insulin rather than human insulin. Pioglitazone caused a minor decrease in the AUC of midazolam, which is probably not clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Insulin

A woman with long-standing type 2 diabetes, which was stabilised with 45 units of **isophane insulin suspension** daily, had a rise in her mean fasting blood glucose from about 12 to 21 mmol/L during a 3-week period while taking **chlordiazepoxide** 40 mg daily.¹ A preliminary report in 8 healthy type 1 diabetics given **lorazepam** 2 mg suggested that while they were taking **human insulin** they were more alert and less sedated than when taking **beef/pork insulin**.²

There seems to be nothing in the literature to suggest that a clinically important adverse interaction normally takes place between insulin and the benzodiazepines. No special precautions would appear to be necessary.

(b) Oral antidiabetics

Four patients with type 2 diabetes, two diet-controlled and two taking **tolbutamide**, had no changes in blood glucose levels while taking **chlordiazepoxide**.¹ In another study **diazepam** did not change the half-life of **chlorpropamide**.³ The manufacturer notes that **pioglitazone** 45 mg once daily for 15 days reduced the AUC and maximum level of a single dose of **midazolam** syrup by 26% in healthy subjects.⁴ This is possibly because **pioglitazone** is a weak inducer of the cytochrome P450 isoenzyme CYP3A4,⁴ by which **midazolam** is metabolised. The clinical relevance of this small decrease in **midazolam** levels has not been assessed, but it is likely to be minor.

Antidiabetics + Beta blockers

In diabetics using insulin, the normal recovery reaction (blood sugar rise) if hypoglycaemia occurs may be impaired to some extent by propranolol, but serious and severe hypoglycaemia seems rare. Cardioselective beta blockers seem less likely to interact. The blood glucose-lowering effects of the sulphonylureas may possibly be reduced by the beta blockers. Whether insulin or oral antidiabetic drugs are given, patients should be made aware that some of the familiar warning signs of hypoglycaemia (tachycardia, tremor) may not occur, although sweating may be increased. Hypoglycaemia in patients taking beta blockers has been noted to result in significant increases in blood pressure and possibly bradycardia in some studies. Miglitol has been found to reduce the bioavailability of propranolol by 40%.

Clinical evidence

(a) Insulin

1. **Hypoglycaemia.** Although **propranolol** has occasionally been associated with spontaneous episodes of hypoglycaemia in non-diabetics,¹ and a number of studies in diabetic patients² and healthy subjects^{3–6} have found that **propranolol** impairs the normal blood sugar rebound if blood sugar levels fall, there appear to be few reports of severe hypoglycaemia or coma in diabetics receiving insulin and **propranolol**. Marked hypoglycaemia and/or coma occurred in 5 diabetic patients receiving insulin due to the use of **propranolol**,^{1,7,8} **pindolol**,⁸ or **timolol** eye-drops.⁹ Other contributory factors (fasting, haemodialysis, etc.) probably had some part to play.⁸ **Metoprolol** interacts like **propranolol** but to a lesser extent,^{3,5,10} whereas **acebutolol**,^{2,5} **alprenolol**,¹¹ **atenolol**,^{2,12,13} **oxprenolol**,¹⁰ **penbutolol**,⁶ and **pindolol**¹⁴ have been found to interact minimally or not at all. The situation with **pindolol** is therefore not clear. **Carvedilol** has been associated with the onset of diabetes mellitus in one patient.¹⁵ **Propranolol** (a peripheral vasoconstrictor) has also been found to reduce the rate of absorption of subcutaneous insulin by almost 50%, but the importance of this is uncertain.¹⁶

However, a large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in patients over 65 years old receiving insulin and taking either cardioselective beta blockers (**atenolol** and **metoprolol**) or non-selective beta blockers (**propranolol** and **nadolol**) when compared with patients taking no antihypertensive drugs. Overall, of the different antihypertensive drug classes, the risk of hypoglycaemia was lowest with cardioselective beta blockers and highest with non-selective beta blockers, although none of the changes were statistically significant when controlled for demographic factors and markers of comorbidity.¹⁷ Similarly, in 2 other case-control studies, there was no increase in the risk of hypoglycaemia in patients with diabetes receiving insulin and also taking a beta blocker.^{18,19}

2. **Hypertension.** Marked increases in blood pressure and bradycardia may develop if hypoglycaemia occurs in diabetics receiving **insulin** and a beta blocker.²⁰ In one study in diabetics, insulin-induced hypoglycaemia resulted in blood pressure rises of 38.8/14.3 mmHg in those taking **propranolol** 80 mg twice daily, 27.9/0 mmHg in those taking **atenolol** 100 mg daily and in those taking placebo the systolic blood pressure rose by 15.2 mmHg whereas the diastolic blood pressure fell by 9.9 mmHg.²¹ In another study, **insulin**-induced hypoglycaemia resulted in blood pressure rises of 27/14 mmHg in those taking **alprenolol** 200 to 800 mg daily, but no rise occurred in those taking **metoprolol** 100 to 400 mg daily.²² A report describes a blood pressure rise to 258/144 mmHg in a patient having a hypoglycaemic episode within 2 days of starting **propranolol**.⁷ Another patient taking **metoprolol** 50 mg twice daily experienced a rise in blood pressure from 190/96 to 230/112 mmHg during a hypoglycaemic episode.²⁰

(b) Oral antidiabetics

1. *Effects on blood glucose.* The sulphonylurea-induced insulin-release from the pancreas can be inhibited by beta blockers so that the blood glucose-lowering effects are opposed to some extent.

- **Acebutolol** appears to inhibit the effects of **glibenclamide**,²³ but has no effect on **tolbutamide**.²⁴ Also, two isolated cases of hypoglycaemia have been seen with acebutolol, in one patient taking **gliclazide** and one patient taking **chlorpropamide**.²⁵
- **Betaxolol** had no effect on the response to **glibenclamide** or **metformin** in one study.²⁶
- **Metoprolol** did not affect the insulin-response to **tolbutamide** in one study.²⁷
- **Propranolol** inhibits the effects of **glibenclamide (glyburide)**,²³ and **chlorpropamide**²⁸ and reduced the insulin-response to **tolbutamide** in one study,²⁹ but not in another.²⁷ Also, an isolated report describes hyperosmolar non-ketotic coma in a patient taking **tolbutamide** and propranolol.³⁰

It is worth noting that the United Kingdom Prospective Diabetes Study Group (UKPDS) used **atenolol** 50 to 100 mg daily or captopril 25 to 50 mg twice daily for hypertension in diabetics taking a range of antidiabetics. Those given **atenolol** showed a slightly greater increase in glycosylated haemoglobin levels, and gained slightly more weight (3.4 kg for the **atenolol** group compared with 1.6 kg for the captopril group over 9 years). However, both drugs were equally effective in reducing the risk of predefined clinical end points (e.g. diabetic complications, death related to diabetes, heart failure). The number of patients experiencing hypoglycaemic attacks did not differ between the two antihypertensives.³¹ This would suggest that beta blockers are generally useful in the treatment of diabetics. Another large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in elderly patients taking sulphonylureas with either cardioselective beta blockers (**atenolol** and **metoprolol**) or non-selective beta blockers (**propranolol** and **nadolol**) when compared with patients taking no antihypertensive drugs.¹⁷

2. *Pharmacokinetic studies.* **Acarbose** 300 mg daily for one week had no effect on the pharmacokinetics or pharmacodynamics of a single 80-mg dose of **propranolol** in healthy subjects.³² Conversely, the manufacturer of **miglitol** notes that it reduced the bioavailability of **propranolol** by a modest 40%.³³

No pharmacokinetic interaction was seen in a study in healthy subjects given a single 1.75-mg dose of **glibenclamide** with **carvedilol** 25 mg daily for 6 days.³⁴

Mechanism

One of the normal physiological responses to a fall in blood sugar levels is the mobilisation of glucose from the liver under the stimulation of adrenaline from the adrenals. This sugar mobilisation is blocked by non-selective beta blockers (such as propranolol) so that recovery from hypoglycaemia is delayed and may even proceed into a full-scale episode in a hypoglycaemia-prone diabetic. Normally the adrenaline would also increase the heart rate, but with the beta-receptors in the heart already blocked this fails to occur. A rise in blood pressure occurs because the stimulant effects of adrenaline on the beta-2 receptors (vasodilation) are blocked leaving the alpha (vasoconstriction) effects unopposed.

Non-selective beta blockers can also block beta-2 receptors in the pancreas concerned with insulin-release, so that the effects of the sulphonylureas may be blocked.

Importance and management

Extremely well-studied interactions. Concurrent use can be uneventful but there are some risks.

Diabetics receiving insulin may have a prolonged or delayed recovery response to hypoglycaemia while taking a beta blocker, but very severe hypoglycaemia and/or coma is rare. If hypoglycaemia occurs it may be accompanied by a sharp rise in blood pressure. The risk is greatest with propranolol and possibly other non-selective blockers and least with the cardio-selective blockers. The cardioselectivity of a number of beta blockers is given in 'Table 22.1', (p.833). Monitor the effects of concurrent use well, avoid the non-selective beta blockers where possible, and check for any evidence that the insulin dosage needs some adjustment. Warn all patients that some of the normal premonitory signs of a hypoglycaemic at-

tack may not appear, in particular tachycardia and tremors, whereas the hunger, irritability and nausea signs may be unaffected and sweating may even be increased.

Diabetics taking oral sulphonylureas rarely seem to have serious hypoglycaemic episodes caused by beta blockers, and any reductions in the blood glucose-lowering effects of the sulphonylureas normally appear to be of little clinical importance. The selective beta blockers are probably safer than those that are non-selective. Nevertheless, always monitor concurrent use to confirm that diabetic control is well maintained, adjusting the dose of antidiabetic as necessary, and warn all patients (as above) that some of the premonitory signs of hypoglycaemia may not occur.

One experimental study indicated that no interaction occurred between betaxolol and **metformin**,²⁶ but direct information about other beta blockers seems to be lacking.

There is also a hint from one report that the peripheral vasoconstrictive effects of non-selective beta blockers and the poor peripheral circulation in diabetics could be additive,⁷ which is another possible reason for avoiding this type of beta blocker in diabetics.

Antidiabetics + Bile-acid binding resins

A report suggests that the hypocholesterolaemic effect of colestipol is unaffected in insulin-treated diabetics but it may be ineffective in those taking phenformin and sulphonylureas. Diabetic control was not affected. Colestyramine may enhance the effect of acarbose, and insulin levels may rebound if both drugs are stopped at the same time. There is evidence that the absorption of glipizide may be reduced by about 30% if it is taken at the same time as colestyramine, but tolbutamide does not appear to be affected.

Clinical evidence

(a) Colestipol

The concurrent use of phenformin and a sulphonylurea (chlorpropamide, tolbutamide or tolazamide) inhibited the normal hypocholesterolaemic effects of the colestipol in 12 diabetics with elevated serum cholesterol levels. No such antagonism was seen in two patients with type 2 diabetes receiving insulin. The control of diabetes was not affected by the colestipol.¹

(b) Colestyramine

1. *Acarbose.* Colestyramine 12 g daily for 6 days, given to 8 healthy subjects taking acarbose 100 mg three times daily, improved the reduction in postprandial insulin levels.² The mean serum insulin levels fell by 23% while taking both drugs, but showed a 'rebound' 31% increase above baseline when both were stopped.²

2. *Glipizide.* Colestyramine 8 g in 150 mL of water reduced the absorption of a single 5-mg dose of glipizide in 6 healthy subjects by a mean of 29%. One subject had a 41% reduction in glipizide levels. Peak serum levels were reduced by 33%. The AUC₀₋₁₀ was used to measure absorption.³

3. *Tolbutamide.* A single-dose study indicated that colestyramine 8 g, given 2 minutes before, and 6 and 12 hours after a 500-mg dose of tolbutamide, did not reduce the amount of tolbutamide absorbed, although the rate of absorption may have changed.⁴

Mechanism

Colestyramine is an anion-exchange resin, intended to bind to bile acids within the gut, but it can also bind with some acidic drugs thereby reducing the amount available for absorption.

Importance and management

Information about glipizide is limited to a single-dose study so that the clinical importance of the reduction in glipizide levels with colestyramine is unknown, but it would seem prudent to monitor the effects of concurrent use in patients. It has been suggested³ that the glipizide should be taken 1 to 2 hours before the colestyramine to minimise admixture in the gut, but this may only be partially effective because it is believed that glipizide undergoes some entero-hepatic circulation (i.e. after absorption it is excreted in the bile and reabsorbed). The effect of colestyramine on other sulphonylureas is uncertain, with the exception of tolbutamide, which is reported not to interact. The clinical importance of the effects of colestyramine on acarbose in diabetics is uncertain, although the manufacturers note that some enhancement of the effects of acarbose may occur, and they suggest care if both drugs are stopped at the same time because of the possible rebound phenomenon with respect to insulin levels.⁵

The study with colestipol suggests that it may not be suitable for lowering the blood cholesterol levels of diabetics taking chlorpropamide, tolbutamide, or tolazamide or phenformin, but more study is needed to confirm these findings. Phenformin has been withdrawn from many countries because of severe, often fatal, lactic acidosis.

Antidiabetics + Calcium-channel blockers

Calcium-channel blockers are known to have effects on insulin secretion and glucose regulation, but significant disturbances in the control of diabetes appear to be rare. A report describes a patient whose diabetes worsened, requiring an increase in the dose of insulin when diltiazem was given, and a similar case has occurred in a patient taking nifedipine. Deterioration in glucose tolerance has also occurred during nifedipine use. Hypoglycaemia occurred in a patient taking gliclazide and nifedipine. No clinically important changes in nifedipine pharmacokinetics have been seen with acarbose, miglitol, pioglitazone or rosiglitazone; in glibenclamide pharmacokinetics with nimodipine or verapamil; in glipizide or repaglinide pharmacokinetics with nifedipine; or between tolbutamide and diltiazem.

Clinical evidence

A. Dihydropyridines

(a) Effect on glucose tolerance

A study in 20 patients with type 2 diabetes (5 taking metformin and 15 diet-controlled) found that both nifedipine 10 mg every 8 hours and nifedipine 30 mg every 8 hours for 4 weeks did not affect either glucose tolerance tests or the control of the diabetes, but both systolic and diastolic blood pressures were reduced by 4 to 7 mmHg.¹ No important changes in glucose metabolism occurred in six type 2 diabetic patients taking glibenclamide (glyburide) when they were given nifedipine 20 to 60 mg daily for 12 to 25 weeks.² Similarly, other studies have found no important changes in glucose tolerance or control of diabetes in patients taking chlorpropamide,³ glibenclamide,⁴ gliclazide,⁵ glipizide^{3,6} or unspecified antidiabetics^{7,8} while also taking nifedipine,^{3,5-7} nimodipine⁴ or nitrendipine.⁸ No change in insulin dose was seen in one patient taking nifedipine⁹ and in 4 patients taking nitrendipine.⁸

However, there are reports of a deterioration in glucose tolerance during the use of nifedipine in a total of 12 subjects with impaired glucose tolerance.^{10,11} A further case report describes a 30% increase in the insulin requirements of a diabetic man after he took nifedipine 60 mg daily.¹² An isolated case of hypoglycaemia has been described in a patient taking gliclazide when nifedipine was given.¹³ However, a large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in patients over 65 years old taking insulin or sulphonylureas, who were also taking calcium-channel blockers (nifedipine and verapamil were the most frequently used), when compared with patients not taking antihypertensive drugs.¹⁴

(b) Pharmacokinetic studies

1. *Alpha-glucosidase inhibitors.* The manufacturers of acarbose say that in a pilot study of a possible interaction with nifedipine, no significant or reproducible changes were seen in plasma nifedipine profiles.^{15,16} Similarly, the manufacturers of miglitol note that it had no effect on the pharmacokinetics and pharmacodynamics of nifedipine.¹⁷

2. *Insulin.* One study found that nifedipine 10 mg increased the rate of absorption of subcutaneous insulin by about 50%.¹⁸

3. *Pioglitazone or Rosiglitazone.* Rosiglitazone 8 mg daily for 2 weeks was found to have no clinically relevant effect on the pharmacokinetics of nifedipine in 28 healthy subjects.¹⁹ The manufacturer notes that pioglitazone 45 mg once daily for 7 days given with nifedipine extended-release 30 mg once daily for 4 days resulted in a small but highly variable change in nifedipine pharmacokinetics.²⁰

4. *Repaglinide.* A three-period cross-over open-label study in healthy subjects found that nifedipine 10 mg daily decreased the maximum plasma level of repaglinide 2 mg three times daily by 2.7% and increased the bioavailability of repaglinide by 11%, but this was not statistically significant. There was a higher incidence of adverse effects during concurrent use.²¹

5. *Sulphonylureas.* A study in six type 2 diabetics found that a single 20-mg dose of nifedipine had no effect on the pharmacokinetics of glipizide 5 to 30 mg daily.⁶ Similarly, nimodipine caused no change in the pharmacokinetics of glibenclamide in 11 patients.⁴

B. Diltiazem

A patient with type 1 diabetes developed worsening and intractable hyperglycaemia (mean serum glucose levels above 13 mmol/L) when given diltiazem 90 mg every 6 hours. Her **insulin** requirements dropped when the diltiazem was withdrawn. When she started taking diltiazem 30 mg every 6 hours her blood glucose levels were still high, but she needed less **insulin** than when taking the higher diltiazem dosage.²²

A study in 12 healthy subjects found that diltiazem 60 mg three times daily had no effect on the secretion of **insulin** or glucagon, or on plasma glucose levels.²³ Similarly, diltiazem 120 mg three times daily for 3 days had no effect on **insulin** and glucose levels during an oral glucose tolerance test in 10 patients taking **gliclazide**.⁵

A study in 8 healthy subjects found that a single 500-mg dose of **tolbutamide** had no effect on the serum levels of a single 60-mg dose of diltiazem. There was a minor increase of about 10% in the AUC₀₋₂₄ and maximum serum levels of **tolbutamide** in the presence of diltiazem but the blood glucose-lowering effects of **tolbutamide** were not significantly changed.²⁴

C. Verapamil

A study in 23 type 2 diabetics, 7 of whom were taking **glibenclamide (glyburide)**, found that verapamil improved the response to an oral glucose tolerance test but did not increase the blood glucose-lowering effects of the **glibenclamide**.²⁵ Two studies in type 2 diabetics found that verapamil improved the response to glucose tolerance tests,^{26,27} but in one of the studies, no alterations in the blood glucose-lowering effects of **glibenclamide** were found.²⁶ A study in healthy subjects found that verapamil modestly raised the **glibenclamide** AUC by 26% but plasma glucose levels were unchanged.²⁸ A large case-control study found no statistically significant increase or decrease in the risk of a serious hypoglycaemic episode in patients over 65 years old taking insulin or sulphonylureas, who were also taking calcium-channel blockers (**nifedipine** and **verapamil** were the most frequently used), when compared with patients not taking antihypertensive drugs.¹⁴

Mechanism

The changes that occur are not fully understood. Suggestions include: inhibition of insulin secretion by the calcium-channel blockers and inhibition of glucagon secretion by glucose; changes in glucose uptake by the liver and other cells; blood glucose rises following catecholamine release after vasodilation, and changes in glucose metabolism. In contrast, one study in non-diabetics suggested that long-acting nifedipine could improve insulin sensitivity.²⁹

Importance and management

Very extensively studied, but many of the reports describe single-dose studies or multiple-dose studies in healthy subjects (only a few are cited here), which do not give a clear picture of what may be expected in diabetic patients. Those studies that have concentrated on diabetics indicate that the control of the diabetes is not usually adversely affected by calcium-channel blockers, although isolated cases with diltiazem, nifedipine and nifedipine have been reported.^{12,13,22} Similarly, there appear to be no important pharmacokinetic interactions with any of the combinations studied. However, if an otherwise unexplained worsening of diabetic control occurs it may be prudent to consider the use of a calcium-channel blocker as a possible cause. Therefore, in general, no particular precautions normally seem necessary.

Antidiabetics + Cibenzoline (Cifenline)

Hypoglycaemia has been seen in a few patients taking cibenzoline alone, and in one case with gliclazide. The risk factors appear to be age, renal insufficiency, malnutrition and high dosage.

Clinical evidence, mechanism, importance and management

Cibenzoline occasionally and unpredictably causes hypoglycaemia, which may be severe. Marked hypoglycaemia was seen in a 67-year-old non-diabetic patient when cibenzoline was given.¹ A further case report describes hypoglycaemia in an 84-year-old, in whom age, renal impairment and/or malnutrition acted as facilitating factors.² The authors of this report noted that hypoglycaemia has been reported in another 20 cases, where the dose was not corrected for age and renal function.² A more recent report describes an elderly patient with type 2 diabetes controlled by diet who developed hypoglycaemia and associated dementia-like symptoms during treatment with low dose cibenzoline.³ Hypoglycaemia also occurred in a 61-year-old patient with renal insufficiency taking **gliclazide** and cibenzoline.⁴

The reasons are not understood. However, in a controlled study in patients with abnormal glucose tolerance and ventricular arrhythmias, cibenzoline exerted a hypoglycaemic effect by facilitating insulin secretion.⁵

This appears to be a drug-disease rather than a drug-drug interaction and diabetic patients do not seem to be more at risk than non-diabetics, but good monitoring is advisable if cibenzoline is given.

Antidiabetics + Clonidine

There is evidence that clonidine may possibly suppress the signs and symptoms of hypoglycaemia in diabetic patients. Marked hyperglycaemia occurred in a child using insulin when clonidine was given. However, the effect of clonidine on carbohydrate metabolism appears to be variable, as other reports have described both increases and decreases in blood glucose levels. Clonidine premedication may decrease or increase the hyperglycaemic response to surgery.

Clinical evidence, mechanism, importance and management

(a) Non-diabetic patients

Studies in healthy subjects and patients with hypertension found that their normal response to hypoglycaemia (tachycardia, palpitations, perspiration) caused by a 0.1 unit/kg dose of **insulin** was markedly reduced when they were taking clonidine 450 to 900 micrograms daily.^{1,2} In contrast, a study in healthy subjects and non-diabetic patients found that clonidine raises blood glucose levels, apparently by reducing **insulin** secretion,³ and hypoglycaemia was associated with clonidine testing for growth hormone deficiency in 4 children.⁴

(b) Diabetic patients

A 9-year-old girl with type 1 diabetes stabilised with **insulin** 4 units daily, developed substantial hyperglycaemia and needed up to 56 units of **insulin** daily when she began to take clonidine 50 micrograms daily for Tourette's syndrome. When the clonidine was stopped, she had numerous hypoglycaemic episodes, and within a few days it was possible to reduce her daily dosage of **insulin** to 6 units.⁵ A patient with type 2 diabetes and hypertension experienced elevated blood glucose levels and decreased **insulin** secretion when clonidine was given.⁶ However, a study in 10 diabetic patients with hypertension found that although clonidine impaired the response to an acute glucose challenge, it did not significantly affect diabetic control over a 10-week period.⁷

In contrast, a placebo-controlled, crossover study in 20 patients with type 2 diabetes found that transdermal clonidine significantly reduced mean fasting plasma glucose levels by 9%.⁸

(c) Hyperglycaemia during surgery

Forty patients with type 2 diabetes (controlled by diet alone, **sulphonylureas**, **biguanides**, or **insulin**), having eye surgery under general anaesthesia, were given either clonidine 225 to 375 micrograms or flunitrazepam as premedication. In diabetic patients there is an increase in blood glucose during stress because of an increase in catecholamine release. Therefore the patients were also given a continuous infusion of **insulin** to maintain blood glucose at 5.5 to 11.1 mmol/L. Clonidine decreased the **insulin** requirement because of improved blood glucose control due to inhibition of catecholamine release.⁹ Contrasting results were found in a study in 16 non-diabetic women undergoing abdominal hysterectomy. Eight were given intravenous clonidine 1 microgram/kg and 8 control patients were given saline. Intraoperative plasma glucose levels were higher in the clonidine group and these patients also had lower insulin levels.¹⁰

Mechanism

The suggested reason for a reduced response to hypoglycaemia is that clonidine depresses the output of the catecholamines (adrenaline, noradrenaline), which are secreted in an effort to raise blood glucose levels, and which are also responsible for these signs.² It seems possible that clonidine will similarly suppress the signs and symptoms of hypoglycaemia that can occur in diabetics, but there seem to be no reports confirming this.

Importance and management

The effect of clonidine on carbohydrate metabolism in diabetic patients appears to be variable and the general importance of these interactions is uncertain. In diabetic patients there is an increase in blood glucose during stress because of an increase in catecholamine release. The influence of clonidine on the surgical stress response appears to vary depending on the dose of clonidine and the type of surgery.¹⁰ Thus, clonidine at about 4 micrograms/kg may attenuate the hyperglycaemic response to neurosurgical and non-abdominal procedures, but low-dose clonidine accentuates

the hyperglycaemic response to lower abdominal surgery, which results from a decrease in plasma insulin.^{9,10}

Antidiabetics + Corticosteroids

The blood glucose-lowering effects of the antidiabetics are opposed by corticosteroids with glucocorticoid (hyperglycaemic) activity and significant hyperglycaemia has been seen with systemic corticosteroids. A report also describes deterioration in diabetic control with *inhaled* high-dose fluticasone, then high-dose budesonide, in a patient taking glibenclamide and metformin. High doses of high-potency corticosteroid creams may also, rarely, cause hyperglycaemia.

Clinical evidence, mechanism, importance and management

(a) Local corticosteroids

1. *Inhaled*. A 67-year-old man with diabetes taking **glibenclamide** 5 mg daily and **metformin** 1.7 g daily had a deterioration in diabetic control (glycosuria and an increase in glycosylated haemoglobin) 3 weeks after starting inhaled **fluticasone** 2 mg daily, by metered dose inhaler with a spacer device, for asthma. The **fluticasone** dose was gradually decreased to 500 micrograms daily after about 3 months, with an improvement in diabetic control. Subsequently, the **fluticasone** dose was increased from 0.5 to 1 mg, and within a week he again developed glycosuria.¹ This same patient was later given inhaled high-dose **budesonide** 2 mg daily and he again developed glycosuria and increased glycated haemoglobin levels, which improved as the dose was gradually decreased to 800 micrograms daily.² The adverse effects of *systemic* corticosteroids on glucose tolerance are well known. Although only one case appears to have been reported, it suggests that high-dose inhaled corticosteroids may have a similar effect. It may be prudent to increase monitoring of diabetic control in patients requiring high-dose corticosteroids and consider reducing the dose of the inhaled corticosteroid if possible, or adjusting the dose of the antidiabetic medication as necessary.

2. *Topical*. Two patients with an abnormal response to the glucose tolerance test, but without overt signs of diabetes mellitus, developed postprandial hyperglycaemia and one developed glycosuria when they used topical corticosteroids for severe psoriasis. These patients were given 15 g of **halcinonide** 0.1% or **betamethasone** 0.1% cream, applied every 12 hours for 15 days under occlusive dressings.³ These cases appear to be rare, and were associated with high doses of potent or very potent corticosteroids, used under occlusive dressings, which increases systemic absorption. No additional special precautions would generally appear to be necessary in diabetics using moderate amounts of topical corticosteroids.

(b) Systemic corticosteroids

Systemic corticosteroids with glucocorticoid activity can raise blood glucose levels and induce diabetes.⁴ This can oppose the blood glucose-lowering effects of the antidiabetics used in the treatment of diabetes mellitus. For example, a disturbance of the control of diabetes is very briefly described in a patient given with **insulin** and **hydrocortisone**.⁵ A study in 5 patients with type 2 diabetes taking **chlorpropamide** found that a single 200-mg dose of **cortisone** modified their glucose tolerance. The blood

glucose levels of 4 of them rose (3 showed an initial fall), whereas in a previous test with **chlorpropamide** alone the blood glucose levels of 4 of them had fallen.⁶ This almost certainly reflects a direct antagonism between the pharmacological effects of the two drugs. Another glucocorticoid, **prednisone**, had no significant effect on the metabolism or clearance of **tolbutamide** in healthy subjects.⁷

There are very few studies of this interaction, probably because the hyperglycaemic activity of the **corticosteroids** has been known for such a long time that the outcome of concurrent use is self-evident. A case-control study found that in patients taking glucocorticoids, the relative risk for development of hyperglycaemia requiring treatment was 2.23, when compared with controls. Risk increased with an increasing daily dose of **hydrocortisone**: doses of 1 to 39 mg were associated with a 1.77-fold increase in risk, doses of 40 to 79 mg were associated with a 3.02-fold increase in risk, doses of 80 to 119 mg were associated with a 5.82-fold increase in risk, and doses of greater than 120 mg were associated with a 10.34-fold increase in risk.⁸ Similarly, another study, in healthy subjects, found dose-related decreases in glucose tolerance and higher serum insulin levels associated with single intravenous doses of **hydrocortisone** and **methylprednisolone**, but these changes were more marked with **methylprednisolone** than **hydrocortisone**.⁹ **Dexamethasone** has also been shown to induce deterioration in glucose tolerance with an incidence of about 35% in non-diabetic, first-degree relatives of patients with type 2 diabetes, primarily due to reduced insulin secretory capacity.¹⁰

The effects of systemic corticosteroid treatment in diabetics should be closely monitored and the dosage of the antidiabetic raised as necessary. Antidiabetics are sometimes needed in non-diabetic patients taking **corticosteroids** to reduce blood glucose levels.

Antidiabetics + Danazol

Danazol causes insulin resistance. Therefore, on theoretical grounds, danazol would be expected to oppose the effects of antidiabetics, but the practical clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

Danazol can disturb glucose metabolism. A study in 14 non-diabetic subjects found that 3 months of treatment with danazol 600 mg daily caused a mild but definite deterioration in glucose tolerance, associated with high insulin levels. Insulin resistance was also seen in 5 subjects taking danazol when they were given intravenous **tolbutamide**.¹ Similarly, another study in 9 non-diabetic women found that danazol 600 mg daily raised insulin levels in response to glucose or intravenous **tolbutamide**.² A further study in 9 non-diabetic women also found that danazol caused a mild deterioration in glucose tolerance and a marked increase in the insulin response to glucose loading.³ Other studies have found that danazol causes marked resistance to both insulin^{4–6} and glucagon,^{5,6} which could be due to receptor down-regulation resulting from hypersecretion of insulin and glucagon.^{5,6}

There is also a report of danazol-associated type 1 diabetes in a patient with endometriosis who took danazol 400 mg twice daily for 8 weeks. The diabetes resolved on withdrawal of danazol, but the development of hyperglycaemia about 5 months later suggested a predisposition to diabetes.⁷ However, it has been suggested that the patient probably had type 2 diabetes precipitated by danazol-induced insulin resistance, which would pos-

sibly have responded to dietary restriction. Danazol-associated hyperglucagonaemia may have exacerbated the symptoms.^{8,9}

For these reasons the manufacturers of danazol advise caution if danazol is given to diabetic patients.¹⁰ Danazol would be expected to oppose the actions of antidiabetics to some extent, but there do not appear to be any studies assessing the clinical relevance of this.

Antidiabetics + Dextropropoxyphene (Propoxyphene)

Dextropropoxyphene does not appear to affect the pharmacokinetics of tolbutamide. Hypoglycaemia was seen in a patient taking an unnamed sulphonylurea with co-proxamol, and has also been reported in non-diabetic patients given dextropropoxyphene alone.

Clinical evidence, mechanism, importance and management

After 6 healthy subjects took dextropropoxyphene 65 mg every 8 hours for 4 days, the clearance of a 500-mg intravenous dose of **tolbutamide** was not affected.¹ There is an isolated case of hypoglycaemia in a patient taking an unnamed **sulphonylurea** with **co-proxamol** (dextropropoxyphene with paracetamol (acetaminophen)).² There are also several reports of hypoglycaemia in non-diabetic patients taking dextropropoxyphene alone,^{3–7} sometimes associated with renal failure,^{3,4} advanced age,⁵ or with high doses or in overdose.⁶ The general importance of these isolated reports is uncertain, and there would normally seem to be little reason for avoiding the concurrent use of antidiabetics and dextropropoxyphene, or for taking particular precautions.

Antidiabetics + Disopyramide

Disopyramide occasionally causes hypoglycaemia, which may be severe. Isolated reports describe severe hypoglycaemia when disopyramide was given to diabetic patients taking gliclazide, or metformin and/or insulin.

Clinical evidence, mechanism, importance and management

Disopyramide occasionally and unpredictably causes hypoglycaemia, which may be severe.^{1–7} The reasons are not fully understood, but *in vitro* studies suggest that disopyramide and its main metabolite may enhance insulin release from the pancreas.⁸ There is a report of severe hypoglycaemia in an 82-year-old woman with diabetes who was taking **gliclazide**,

which occurred 6 months after she started disopyramide 300 mg daily.⁹ A further case of hypoglycaemia associated with disopyramide occurred in a 70-year-old woman who had been taking **metformin** 500 mg twice daily and **insulin** 62 units daily. Within 3 months of starting disopyramide 250 mg twice daily her **insulin** dose was reduced to 24 units daily, she stopped taking **metformin** and was eating 'substantial snacks' to avoid hypoglycaemia.¹⁰ The **insulin** requirements of another patient with type 2 diabetes were markedly reduced when disopyramide was started.¹¹

The manufacturers note that patients at particular risk for hypoglycaemia are the elderly, the malnourished, and diabetics, and that impaired renal function and impaired cardiac function may be predisposing factors.^{12,13} They advise close monitoring of blood glucose levels^{12,13} and withdrawal of disopyramide if problems arise.¹² This is not simply a problem for diabetics, but certainly within the context of diabetes the blood glucose-lowering effects of disopyramide may possibly cause particular difficulties. Although not strictly an interaction, the concurrent use of disopyramide and antidiabetics should be well monitored because of the potential for severe hypoglycaemia, as the cases show.

Antidiabetics + Disulfiram

Disulfiram appears not to affect the control of diabetes mellitus. Disulfiram does not appear to affect the pharmacokinetics of tolbutamide and there appears to be no evidence that disulfiram interacts with any other antidiabetics.

Clinical evidence, mechanism, importance and management

The manufacturers of disulfiram say that caution should be exercised if it is used in diabetics,¹ but a reviewer² who had given disulfiram to over 20 000 alcoholics said that he had prescribed disulfiram for several hundred patients with diabetes mellitus over 20 years without any apparent adverse effects and therefore any theoretical interaction is rarely, if ever, applicable to clinical practice. It would be reasonable to assume that many of these patients were also taking **insulin** or one of the older oral antidiabetics. There do not appear to be any reported cases in the literature of adverse interactions between disulfiram and any of the antidiabetics. In a study in 5 healthy subjects, disulfiram (400 mg three times daily for one day, then once daily for one day, then 200 mg daily for 2 days) had no significant effect on the half-life or clearance of intravenous **tolbutamide** 500 mg.³

The conclusion to be drawn from all of this is that any reaction is very rare (if it ever occurs), and no special precautions would normally appear to be necessary.

Antidiabetics + Diuretics; Loop

The control of diabetes is not usually disturbed to a clinically relevant extent by etacrynic acid, furosemide, or torasemide. However, there are a few reports showing that etacrynic acid and furosemide can, rarely, raise blood glucose levels.

Clinical evidence

(a) Etacrynic acid

A double-blind study in 24 hypertensive patients, one-third of whom were diabetics, found that etacrynic acid 200 mg daily for 6 weeks impaired their glucose tolerance and raised the blood glucose levels of the diabetics to the same extent as those diabetics and non-diabetics taking hydrochlorothiazide 200 mg daily.¹ In another study no change in carbohydrate metabolism was seen in 6 diabetics given etacrynic acid 150 mg daily for a week.²

(b) Furosemide

Although furosemide can elevate blood glucose levels,³ worsen glucose tolerance⁴ and occasionally cause glycosuria or even acute diabetes in individual patients,^{5,6} the general picture is that the control of diabetes is not usually affected by furosemide.⁷ No clinically relevant changes in the control of diabetes were seen in a 3-month study of 29 patients with type 2 diabetes taking furosemide 40 mg daily and an average of 7 mg of **glibenclamide (glyburide)** daily.⁸

(c) Torasemide

A three-month study in 32 patients with congestive heart failure and type 2 diabetes mellitus taking **glibenclamide** found that torasemide 5 mg daily caused a small but clinically insignificant fall in blood glucose levels.⁸

Mechanism

Uncertain.

Importance and management

Information is limited. Some impairment of glucose tolerance may possibly occur, but there seems to be a lack of evidence in the literature to show that any loop diuretic has much effect on the control of diabetes in most patients.

Antidiabetics + Diuretics; Thiazide and related

By raising blood sugar levels, the thiazide and related diuretics can reduce the effects of the antidiabetics and impair the control of diabetes. However, this effect appears to be dose related, and is less frequent at the low doses now more commonly used for hypertension. Hyponatraemia has rarely been reported when chlorthalidone was given with a thiazide and potassium-sparing diuretic. An isolated report describes severe hypoglycaemia in a patient taking glibenclamide (glyburide) shortly after metolazone was started. Voglibose had no important effect on the pharmacokinetics of hydrochlorothiazide.

Clinical evidence

(a) Effects on glucose control

Chlorothiazide, the first of the thiazide diuretics, was found within a year of its introduction in 1958 to have hyperglycaemic effects.¹ Since then a very large number of reports have described hyperglycaemia, the precipitation of diabetes in prediabetics, and the disturbance of blood sugar control in diabetics taking thiazides. One example from many:

A long-term study in 53 patients with type 2 diabetes found that **chlorothiazide** 500 mg or 1 g daily or **trichlormethiazide** 4 or 8 mg daily caused a mean rise in blood glucose levels from about 6.7 to 7.8 mmol/L. Only 7 patients needed a change in their treatment: 4 required more of their oral antidiabetic, 2 an increase in **insulin** dose, and one was transferred from **tolbutamide** to **insulin**. The oral antidiabetics used included **tolbutamide**, **chlorpropamide**, **acetohexamide** and **phenformin**.²

A rise in blood sugar levels has been observed with **bendroflumethiazide**,^{3,4} **benzthiazide**,⁵ **hydrochlorothiazide** 100 to 300 mg daily,³ and **chlortalidone** 50 to 100 mg daily.⁶ A study in hypertensive patients found that **chlortalidone** 50 mg daily increased glucose and insulin levels, but **hydrochlorothiazide** 50 mg daily alone or as part of a potassium and/or magnesium conserving regimen did not.⁷

More recent data suggest that the effects of thiazides on blood glucose may be dose related. In a double-blind randomised study comparing the effects of 1.25 or 5 mg of **bendroflumethiazide** on blood glucose, the lower dose had no effects on insulin action, whereas when the higher dose was given, there was evidence of impaired glucose tolerance.⁸ A review of the literature on **hydrochlorothiazide** similarly reports that low doses (6.25 to 12.5 mg) lack significant effects on blood glucose levels.⁹

A man with type 2 diabetes, stable taking **glibenclamide** (**glyburide**) 10 mg daily and hospitalised for congestive heart failure, became clinically hypoglycaemic (blood glucose levels unmeasurable by *Labstix*) within 40 hours of starting **metolazone** 5 mg daily. He was treated with intravenous glucose. Although both **glibenclamide** and **metolazone** were stopped, he had 4 further hypoglycaemic episodes over the next 30 hours.¹⁰ The reasons are not understood. *In vitro* studies failed to find any evidence that **metolazone** displaces **glibenclamide** from its protein binding sites, which might possibly have provided some explanation for what happened.¹⁰

The hypoglycaemic responses of 10 healthy subjects were studied following an intravenous infusion of **tolbutamide** 3 mg/kg, given 3 days before and one hour after the last dose of oral **cicletanine** 100 mg daily for a week.¹¹ No clinically relevant changes were seen. Note that, studies in *animals* and in non-diabetic hypertensive patients found that, at therapeutic doses, **cicletanine** did not affect glycoregulation.¹² The conclusion to be drawn is that **cicletanine** is unlikely to affect the control of diabetes in patients, but this needs confirmation from longer-term clinical studies.

(b) Hyponatraemia

A hospital report describes 8 cases of low serum sodium concentrations observed over a 5-year period in patients taking **chlorpropamide** and *Moduretic* (**hydrochlorothiazide** 50 mg with **amiloride** 5 mg).¹³

(c) Pharmacokinetics

A study in 12 healthy subjects given a single 25-mg dose of **hydrochlorothiazide** before and after taking **voglibose** 5 mg three times daily for 11 days found that the **hydrochlorothiazide** plasma levels were slightly increased by the **voglibose** (AUC increased 7.5%, maximum plasma levels increased 15%) but these changes were considered to be clinically irrelevant. The combination was well tolerated and adverse events were unchanged.¹⁴

Mechanism

Not understood. One study suggested that the hyperglycaemia is due to the inhibition of insulin release by the pancreas.¹⁵ Another suggestion is that the peripheral action of insulin is affected in some way.^{5,16} There is also evidence that the effects may be related in part to potassium depletion.¹⁷ The hyponatraemia appears to be due to the additive sodium-losing effects of chlorpropamide, the thiazide and amiloride. Obese patients may be more sensitive to the effects of hydrochlorothiazide on insulin metabolism.⁷

Importance and management

The reduction in hypoglycaemic effect is extremely well documented (not all references are given here) but of only moderate practical importance, particularly since much of the data relates to higher doses of thiazides than are now used clinically for hypertension. Low doses of thiazides have a lesser effect on plasma glucose, and recent guidelines on the treatment of hypertension in diabetes recommend the use of thiazides.¹⁸ If higher doses are used, increased monitoring of diabetic control would seem prudent. There is evidence that the full effects may take many months to develop in some patients.⁴ Most patients respond to a modest increase in the dosage of the antidiabetics. This interaction may be expected to occur with all thiazides and possibly related diuretics, such as clopamide and metolazone. Hyponatraemia is a rare but recognised adverse effect of the thiazides and no additional precautions would therefore seem necessary.

Antidiabetics + Fenfluramine

Fenfluramine has inherent blood glucose-lowering activity that can add to, or in some instances replace, the effects of conventional antidiabetic drugs.

Clinical evidence, mechanism, importance and management

A study of the substitution of fenfluramine (initially 40 mg daily, increased to 120 mg daily) for a biguanide antidiabetic found that diabetes was equally well controlled by either drug in 4 of 6 patients.¹ The blood glucose-lowering effects of fenfluramine have also been described elsewhere.^{2,3} It seems that fenfluramine increases the uptake of glucose into skeletal muscle, thereby lowering blood glucose levels.^{3,4}

This is a well established and, on the whole, an advantageous rather than an adverse reaction, but it would be prudent to check on the extent of the response if fenfluramine is added or withdrawn from the treatment being received by diabetics. However, note that fenfluramine was generally withdrawn in 1997 because its use was found to be associated with a high incidence of abnormal echocardiograms indicating abnormal functioning of heart valves.

Antidiabetics + Fibrates

A number of reports describe hypoglycaemia and/or an enhancement of the effects of antidiabetic drugs (mostly insulin and sulphonylureas) in patients given fibrates. The combination of gemfibrozil and repaglinide should be avoided, because a marked pharmacokinetic interaction can result in serious hypoglycaemia. Gemfibrozil also causes large increases in the AUCs of pioglitazone and rosiglitazone, and caution is therefore warranted until more is known. Only a modest pharmacokinetic interaction occurs between gemfibrozil and nateglinide. The antidiuretic effects of clofibrate in the treatment of diabetes insipidus are opposed by glibenclamide (glyburide).

Clinical evidence

A. Bezafibrate

(a) Repaglinide

In a study in healthy subjects bezafibrate 400 mg once daily for 5 days had no effect on the pharmacokinetics of a single 250-microgram dose of repaglinide, and did not alter the glucose-lowering effect of repaglinide.¹

(b) Sulphonylureas and Biguanides

Three elderly patients with type 2 diabetes and mild renal impairment taking **glibenclamide (glyburide)** developed hypoglycaemia when they were given bezafibrate: one of them needed a 60% dosage reduction, another was given **tolbutamide** instead, and the third was able to stop both **glibenclamide** and **bufornin**.² The French Centres Régionaux de Pharmacovigilance recorded 7 cases of hypoglycaemia during the period 1985 to 1990, which developed in patients taking unnamed sulphonylureas when they were given fibrates (one case with bezafibrate).³

B. Ciprofibrate

The French Centres Régionaux de Pharmacovigilance recorded 7 cases of hypoglycaemia during the period 1985 to 1990, which developed in patients taking unnamed **sulphonylureas** when they were given fibrates (3 cases with ciprofibrate).³

C. Clofibrate

(a) Hypoglycaemia

Over a 5-day period while taking clofibrate 2 g daily, the control of diabetes was improved in 6 out of 13 patients with type 2 diabetes taking various unnamed sulphonylureas. Hypoglycaemia (blood glucose levels of about 1.7 to 2.2 mmol/L) was seen in 4 patients.⁴ Other studies confirm that some, but not all, patients have a fall in blood glucose levels while taking clofibrate and the control of the diabetes can improve.⁵⁻¹² In one study¹³ the half-life of **chlorpropamide** ranged from 40 to 62 hours in 5 subjects taking clofibrate compared with a mean of about 36 hours in control subjects.

(b) Reduced antidiuretic effects

Clofibrate 2 g daily reduced the volume of urine excreted by 2 patients with pituitary diabetes insipidus, but when **glibenclamide** was also given the volume increased once again. Without treatment they excreted 5.8 and 6.5 litres of urine daily, and this reduced to only 2.4 and 1.7 litres while taking clofibrate, whereas with **glibenclamide** and clofibrate they excreted 3.6 and 3.7 litres daily, respectively.¹⁴

D. Fenofibrate

(a) Repaglinide

In a study in healthy subjects, fenofibrate 200 mg once daily for 5 days had no effect on the pharmacokinetics of a single 250-microgram dose of repaglinide, and did not alter the glucose-lowering effect of repaglinide.¹

(b) Sulphonylureas

The French Centres Régionaux de Pharmacovigilance recorded 7 cases of hypoglycaemia during the period 1985 to 1990, which developed in patients taking unnamed sulphonylureas when they were given fibrates (3 with cases fenofibrate).³

E. Gemfibrozil

(a) Nateglinide or Repaglinide

In a randomised crossover study, 12 healthy subjects were given gemfibrozil 600 mg twice daily for 3 days, with a 250-microgram dose of repa-

glinide on day 3. Gemfibrozil raised the AUC of repaglinide eightfold and increased the plasma levels nearly 29-fold.¹⁵ Itraconazole (which may interact, see 'Antidiabetics + Azoles; Itraconazole or Ketoconazole', p.479) given with gemfibrozil and repaglinide further increased these effects. The blood glucose-lowering effects of repaglinide were considerably enhanced and prolonged, both by gemfibrozil alone and in combination with itraconazole.¹⁵ In 2003, the European Agency for the Evaluation of Medicinal Products had received five reports of serious hypoglycaemic episodes with gemfibrozil and repaglinide.¹⁶

In contrast, in a very similar study by the same research group, the combination of gemfibrozil and itraconazole caused only a modest 47% increase in the AUC of a single dose of nateglinide 30 mg, and did not significantly alter the blood glucose response to nateglinide in healthy subjects.¹⁷

(b) Pioglitazone or Rosiglitazone

Gemfibrozil 600 mg twice daily for 4 days increased the mean AUC of a single dose of rosiglitazone 4 mg by 2.3-fold, the peak plasma level by 1.2-fold and the 24-hour plasma level by almost tenfold in a study in healthy subjects.¹⁸ In the same way, gemfibrozil increased the mean AUC of a single dose of pioglitazone 3.2-fold without altering its maximum level, but raised the 48-hour plasma level by approximately 15-fold.¹⁹ A similar increase in pioglitazone AUC was reported in another study.²⁰ In these studies, the effects of these pharmacokinetic changes on the pharmacodynamics of rosiglitazone or pioglitazone were not assessed.¹⁸⁻²⁰

(c) Sulphonylureas or Insulin

Fasting blood glucose levels decreased in 10 diabetic patients, and increased in 4 of 14 diabetic patients receiving insulin, **acetoexamide**, **chlorpropamide** or **glipizide** who were given gemfibrozil (800 mg daily initially, reduced later to 400 to 600 mg daily).²¹ Another study found that of 20 patients, 9 required a slight increase in the dosage of insulin or sulphonylurea (**glibenclamide** or **chlorpropamide**), and one a decreased dosage, when they were given gemfibrozil 800 mg to 1.6 g daily.²² A single report describes hypoglycaemia, which occurred in a diabetic taking **glibenclamide** when they were given gemfibrozil 1.2 g daily.²³ The **glibenclamide** dosage was reduced from 5 to 1.25 mg daily with satisfactory diabetic control. When the gemfibrozil was later stopped and restarted, the dosage of the **glibenclamide** had to be increased and then reduced. A placebo-controlled study in 10 healthy subjects found that gemfibrozil 600 mg twice daily for 5 doses increased the AUC of a single 500-microgram dose of **glimepiride** by 23%, but there were no significant changes in serum insulin or blood glucose.²⁴

Mechanism

The suggested reasons for the alteration in diabetic control with fibrates include the displacement of the sulphonylureas from their plasma protein binding sites,⁷ alterations in their renal excretion,¹³ and a decrease in insulin resistance.^{6,25} Clofibrate has also been shown to have a blood glucose-lowering action of its own, which improves the glucose tolerance of diabetics.¹² It is thought that gemfibrozil inhibits the metabolism of repaglinide by the cytochrome P450 isoenzyme CYP2C8, and that inhibition of CYP3A4 (its other main route of metabolism) by itraconazole further blocks repaglinide metabolism.¹⁵ Gemfibrozil also inhibits the CYP2C8-mediated metabolism of rosiglitazone and pioglitazone.^{18,19} In addition, gemfibrozil may inhibit CYP2C9-mediated metabolism of glimepiride and other sulphonylureas such as glipizide, glibenclamide or **gliclazide**,²⁴ and also nateglinide.¹⁷ It seems possible that any or all of these mechanisms might contribute towards enhanced hypoglycaemia.

Importance and management

The interaction between the sulphonylureas and clofibrate is established and well documented. The incidence is uncertain, but what is known suggests that between about one-third and one-half of patients may be affected. Alteration in diabetic control, most usually hypoglycaemia, has been seen in diabetics taking sulphonylureas with bezafibrate, ciprofibrate, fenofibrate, and gemfibrozil. There would seem to be no good reason for avoiding the concurrent use of sulphonylureas and fibrates, but be aware that the dosage of the antidiabetic may need adjustment. Patients should be warned that excessive hypoglycaemia occurs occasionally and unpredictably.

Note that on the basis of the study,¹⁵ and following five reports of serious hypoglycaemic episodes with gemfibrozil and repaglinide, the European

Agency for the Evaluation of Medicinal Products decided to contraindicate concurrent use.¹⁶

Marked increases in the AUC of rosiglitazone and pioglitazone have been demonstrated with gemfibrozil, but the clinical relevance of these has not been assessed. Until further experience is gained, caution is warranted. Only modest increases in plasma levels of nateglinide have been demonstrated with gemfibrozil, but the manufacturer recommends caution if nateglinide is given with CYP2C9 inhibitors including gemfibrozil.²⁶

Information about reduced diuretic effects is limited. It would seem prudent to avoid the concurrent use of drugs with actions that are antagonistic.

Antidiabetics + Glucosamine ± Chondroitin

In a controlled study, glucosamine supplements with chondroitin had no effect on glycaemic control in patients taking oral antidiabetic drugs but one report notes that unexpected increases in blood glucose levels have occurred.

Clinical evidence, mechanism, importance and management

In 2000, the Canadian Adverse Drug Reaction Monitoring Programme (CADRMP) briefly reported that unexpected increases in blood glucose levels had occurred in diabetic patients taking glucosamine sulfate, or glucosamine with chondroitin.¹ However, in a well controlled study, *Cosamin DS* (glucosamine hydrochloride 1.5 g daily plus chondroitin sulfate sodium 1.2 g) daily for 90 days had no effect on the control of diabe-

tes (glycosylated haemoglobin) in 22 patients with type 2 diabetes, 18 of whom were receiving oral antidiabetics [specific drugs not named] and 4 who were diet controlled.²

Endogenous glucosamine has a role in glucose metabolism, and may increase insulin resistance. In one case, glucosamine also reduced hypoglycaemic episodes in a patient with metastatic insulinoma.³

The interaction is not established, and the results of the controlled trial suggest that glucosamine supplements are unlikely to affect diabetes control. However, it has been suggested that the results may not be applicable to patients with later stages of diabetes.⁴ Therefore, it may be prudent to increase monitoring of blood glucose in these patients if glucosamine supplements are taken. Also, if glucose control unexpectedly deteriorates, bear in mind the possibility of self-medication with supplements such as glucosamine.

Antidiabetics + Guanethidine and related drugs

Limited evidence suggests that guanethidine has blood glucose-lowering activity, which may possibly add to the effects of conventional antidiabetics. One case report suggests soluble insulin may exaggerate the hypotensive effects of debrisoquine.

Clinical evidence

(a) Debrisoquine

An man with type 1 diabetes taking debrisoquine 20 mg twice daily developed severe postural hypotension within an hour of receiving 28 units of a short-acting **insulin** (soluble insulin) plus 20 units of **isophane insulin**. He became dizzy and was found to have a standing blood pressure of 97/72 mmHg. The postural fall in systolic pressure was 65 mmHg. He had no evidence of hypoglycaemia and no hypotension when using 48 units of **isophane insulin** without the soluble insulin.¹ **Insulin** can cause hypotension but this is only seen in those with an impaired reflex control of blood pressure.¹

(b) Guanethidine

A diabetic needed an **insulin** dose increase from 70 to 94 units daily when guanethidine was withdrawn.² A later study in 3 patients with type 2 diabetes found that guanethidine 50 to 90 mg daily caused a significant improvement in their glucose tolerance.³ Two other reports also suggest that guanethidine has blood glucose-lowering effects.^{4,5}

Mechanism

It has been suggested that the interaction between insulin and guanethidine occurs because guanethidine can impair the homeostatic mechanism concerned with raising blood glucose levels, by affecting the release of catecholamines. The balance of the system thus impaired tends to be tipped in favour of a reduced blood glucose level, resulting in a reduced requirement for the antidiabetic. The interaction between debrisoquine and insulin is not understood.

Importance and management

Information about both of these interactions is very limited, and their general importance is uncertain. Increase the frequency of blood glucose monitoring if guanethidine or related drugs are started or stopped. Also check patients given debrisoquine (no longer generally available) and insulin, particularly if they are taking vasodilators, to ensure that excessive hypotension does not develop.

Antidiabetics + Guar gum or Glucomannan

Guar gum appeared not to affect the absorption of glipizide or glibenclamide (glyburide) to a clinically relevant extent. Although guar gum modestly reduced the absorption of metformin, it enhanced its postprandial hypoglycaemic effect. Glucomannan appeared to reduce the initial absorption of glibenclamide, but also enhanced its hypoglycaemic effect.

Clinical evidence, mechanism, importance and management

(a) Glucomannan

Glucomannan 3.9 g reduced the plasma levels of a single 2.5-mg dose of **glibenclamide (glyburide)** in 9 healthy subjects. Four samples taken over 30 to 150 minutes found that the plasma levels of **glibenclamide** were reduced by about 50%.¹ Despite this, plasma glucose levels were lower with the combination than with **glibenclamide** alone. Because plasma samples were not taken beyond 150 minutes, it is unclear what effect glucomannan has on the extent of **glibenclamide** absorption. The clinical relevance of these changes is unclear, but they seem unlikely to be important.

(b) Guar gum

In one study in 10 healthy subjects guar gum was found to have no effect on the AUC or maximum serum levels of a single 2.5-mg dose of **glipizide**. In this study **glipizide** was given alone, or 30 minutes before breakfast, and this treatment was compared with guar gum granules (4.75 g guar gum) given either with the breakfast or with the **glipizide**.²

In one comparative study, guar gum was found to reduce the AUC of **glibenclamide** from one formulation (*Semi-Euglucon*) by about 30%, but not another newer formulation (*Semi-Euglucon-N*),³ possibly because the latter preparation is more rapidly and completely absorbed. Similarly, in a double-blind crossover study in 9 patients with type 2 diabetes, guar gum granules 5 g three times daily with meals did not significantly affect the AUC or maximum serum level of **glibenclamide** 3.5 mg twice daily from the newer formulation. In addition, the combination slightly reduced fasting blood glucose when compared with baseline values.⁴

In a single-dose study, guar gum 10 g reduced the absorption rate of **metformin** 1.7 g and reduced the AUC by 39% in healthy subjects, but the total reduction in postprandial blood glucose levels was increased.⁵

It seems doubtful if any of these modest pharmacokinetic interactions has much, if any, clinical relevance because guar gum can improve the metabolic control and decrease serum lipids in patients with type 2 diabetes.⁴

Antidiabetics + H₂-receptor antagonists

On the whole cimetidine and ranitidine do not appear to significantly alter diabetic control with sulphonylureas, although cases of adverse effects have been seen when glibenclamide was given with ranitidine, and when gliclazide or glipizide were given with cimetidine.

Cimetidine appears to reduce the clearance of metformin, and may have contributed to a case of metformin-associated lactic acidosis. Cimetidine did not alter repaglinide pharmacokinetics, and ranitidine did not alter pioglitazone or rosiglitazone pharmacokinetics. Acarbose did not alter ranitidine pharmacokinetics, but miglitol decreased the AUC of ranitidine by 60%.

Clinical evidence

A. Alpha-glucosidase inhibitors

The manufacturer of **acarbose** notes that it had no effect on the pharmacokinetics or pharmacodynamics of **ranitidine** in healthy subjects.¹ Conversely, the manufacturer of **miglitol** notes that it reduced the bioavailability of **ranitidine** by 60%.²

B. Biguanides

Cimetidine 800 mg daily was found to reduce the renal clearance of **metformin** in 7 healthy subjects by 27% and increase the AUC by 50%.³ A 59-year-old woman with type 2 diabetes taking long-term **metformin** 500 mg three times daily developed severe metabolic acidosis with cardiovascular collapse and acute renal failure. Three months previously she had started orlistat 120 mg three times daily, which caused chronic diarrhoea. During the 4 days before hospital admission, she was prescribed **cimetidine** 400 mg twice daily for her abdominal pain. The **metformin**-associated lactic acidosis was considered to have been precipitated by the 'orlistat', (p.498) and **cimetidine**.⁴

C. Sulphonylureas

(a) Chlorpropamide

Cimetidine had no effect on the pharmacokinetics of chlorpropamide in healthy subjects,⁵ and in another study the blood glucose-lowering effects of chlorpropamide remained unaltered when **cimetidine** was given.⁶

(b) Glibenclamide (Glyburide)

A study in healthy subjects reported that the blood glucose-lowering effects of glibenclamide were slightly reduced by **cimetidine** and **ranitidine**. This occurred despite the fact that **cimetidine** increased the AUC of glibenclamide by 37% and ranitidine had no significant pharmacokinetic effect on glibenclamide.⁷ Marked hypoglycaemia was seen in a patient taking glibenclamide 5 mg daily when **ranitidine** 150 mg twice daily was also taken.⁸ Conversely, a study in healthy subjects found that the blood glucose-lowering effects of glibenclamide remained unaltered by **cimetidine**.⁶

(c) Gliclazide

An elderly type 2 diabetic taking gliclazide 160 mg daily developed very low blood glucose levels (1 mmol/L) after starting to take **cimetidine** 800 mg daily.⁹

(d) Glimepiride

In a study in healthy subjects no relevant interactions, either pharmacokinetic or pharmacodynamic, were seen when glimepiride was given with either **cimetidine** or **ranitidine**.¹⁰

(e) Glipizide

Six patients with type 2 diabetes were given **cimetidine** 400 mg one hour before taking a dose of glipizide (average dose 5.8 mg) and then 3 hours later they were given a standard meal with **cimetidine** 200 mg. The expected rise in blood glucose levels after the meal was reduced by 40% and in two of the patients plasma glucose levels fell to less than 3 mmol/L. **Cimetidine** increased the glipizide AUC by 23%.^{11,12} However, a study in healthy subjects found that the hypoglycaemic activity of glipizide remained unaltered by **cimetidine**.⁶

Two studies in type 2 diabetics found that **ranitidine** 150 mg increased the AUC of glipizide by 29% and 34%,^{12,13} and reduced the expected rise in blood sugar levels after a meal by 22%.¹² However, another study by the same research group reported that **ranitidine** 300 mg had no significant effects on either the pharmacokinetics or the effects of glipizide, except that the absorption was delayed.¹⁴

(f) Tolbutamide

The pharmacokinetics of tolbutamide 250 mg daily for 4 days were not significantly changed in 7 healthy subjects when **cimetidine** 800 mg daily was added for a further 4 days.¹⁵ Other studies also found no pharmacokinetic interaction between tolbutamide and **cimetidine**,^{16,17} or between tolbutamide and **ranitidine**,¹⁷ and the hypoglycaemic activity of tolbutamide remained unaltered by **cimetidine**.⁶

In contrast, in another study in healthy subjects, the AUC of tolbutamide was found to be slightly increased by 20% and the elimination half-life decreased by 17% by **cimetidine** 1.2 g daily, but plasma glucose levels were not significantly changed. **Ranitidine** 300 mg had no effect.¹⁸ A later study found effectively the same results.¹⁹

(g) Unnamed sulphonylureas

A report briefly describes hypoglycaemia in 2 patients on unnamed sulphonylureas given **cimetidine**.²⁰

D. Other oral antidiabetics

(a) Pioglitazone

A study in healthy subjects found that when pioglitazone 45 mg daily was given with **ranitidine** 150 mg twice daily the pharmacokinetics of both drugs were not significantly affected.²¹

(b) Repaglinide

An open label crossover trial in 14 healthy subjects found that **cimetidine** 400 mg twice daily had no effect on the pharmacokinetics of repaglinide 2 mg three times daily.²²

(c) Rosiglitazone

A crossover study in 12 healthy subjects found that pre-treatment with **ranitidine** 150 mg twice daily for 4 days had no effect on the pharmacokinetics of either a single 4-mg oral dose or a single 2-mg intravenous dose of rosiglitazone.²³

Mechanism

Where an interaction occurs¹⁸ it may be because the cimetidine inhibits the metabolism of the sulphonylurea by the liver, thereby increasing its effects. Cimetidine appears to inhibit the excretion of metformin by the kidneys,³ and this may have contributed to the case of metformin-associated lactic acidosis described.⁴

Importance and management

The many studies cited here show that cimetidine generally causes no important changes in the pharmacokinetics or pharmacodynamics of the sulphonylureas (chlorpropamide, glimepiride and tolbutamide). Similarly, ranitidine did not interact with glimepiride or tolbutamide. Only a few isolated cases of hypoglycaemia have been reported with ranitidine or cimetidine and sulphonylureas (glibenclamide, gliclazide and unnamed), and only one research group has shown a possible increase in blood glucose lowering effect of glipizide with cimetidine and ranitidine.

It has been suggested that the dosage of metformin may need to be reduced if cimetidine is used, bearing in mind the possibility of lactic acidosis if levels become too high,³ and there is one case where cimetidine may have contributed to lactic acidosis.

The only other possible interaction of significance appears to be that between miglitol and ranitidine, although the clinical relevance of this has not been assessed.

Antidiabetics + Hormonal contraceptives or HRT

Some women may require small increases or decreases in their dosage of antidiabetic while taking oral contraceptives or HRT, but it is unusual for the control of diabetes to be seriously disturbed. Irrespective of diabetic control, HRT or oral contraceptives should be used with caution in patients with diabetes because of the increased risk of arterial disease. Pioglitazone, rosiglitazone and repaglinide do not appear to alter the pharmacokinetics of contraceptive steroids, and ethinylestradiol/levonorgestrel do not appear to have an important effect on the pharmacokinetics of repaglinide.

Clinical evidence

(a) HRT

1. *Insulin*. More than half of a group of 30 menopausal diabetics had abnormal glucose tolerance when given **noretynodrel** 5 mg with **mestranol** 75 micrograms, but the changes in their requirements of **insulin** or oral antidiabetic drug were rare and slight.¹ A 3-year, placebo-controlled, randomised study involving 875 postmenopausal women found that HRT (unopposed **conjugated oestrogens**, or **conjugated oestrogens plus medroxyprogesterone** or **progesterone**) had little, if any, harmful effect on carbohydrate metabolism.²

2. *Pioglitazone*. The pharmacokinetics of **ethinylestradiol** and **estrone** were not affected when *Premarin* (**conjugated oestrogens**) 0.625 mg and *Provera* (**medroxyprogesterone**) 5 mg was given for 28 days, with pioglitazone 45 mg daily for an additional 14 days.³

(b) Oral contraceptives

There are numerous reports of the effect of contraceptive steroids on glucose tolerance in non-diabetics. More recent reports from studies using newer, low-dose oral contraceptives, support the suggestion that changes in glucose metabolism are minimal.^{4,5} Problems with glucose metabolism seem very unlikely when the dose of oestrogen is less than 50 micrograms.⁶ The progestogen in the oral contraceptive may also be important.^{6–9} Progestogens with androgenic properties, such as **norgestrel**, **levonorgestrel** and to a lesser extent **norethisterone** (**norethindrone**), may affect carbohydrate metabolism. **Etinodiol** (**etynodrel**), which has weak androgenic activity, was found to cause smaller reductions in glucose tolerance, and **noretynodrel** was found to have no effect.^{6–8} Studies of healthy, non-diabetic women using oral contraceptives containing **ethinylestradiol** 20 to 40 micrograms with third generation progestogens (**gestodene**, **desogestrel** or **norgestimate**) found no effect on carbohydrate metabolism in women using monophasic oral contraceptives, but impaired glucose tolerance developed in 10% of the women taking triphasic oral contraceptives. It was considered that the clinical consequences of impaired glucose tolerance and reduced **insulin** sensitivity induced by oral contraceptives are probably confined to risk groups e.g. women with ovarian hyperandrogenism, obesity, previous gestational diabetes mellitus, perimenopausal women, or women with a family history of diabetes.¹⁰

A study in 11 **insulin**-dependent diabetics, free of vascular complications, taking low-dose oral contraceptives (**ethinylestradiol/gestodene** 30/75 micrograms) found that although the plasma levels of most haemostatic variables were comparable to those of non-diabetics using the same oral contraceptive preparation, the rate of fibrin formation was increased and the fibrinolytic response attenuated. This implies that women with diabetes can have a higher sensitivity to the thrombogenic effects of oral contraceptives.¹⁰

1. *Insulin*. In one study in 179 diabetic women, 34% needed an increase and 7% needed a decrease in their insulin dose when they were given an oral contraceptive.¹¹ There are also a few scattered reports of individual diabetics who experienced a marked disturbance of their diabetic control when given an oral contraceptive, some of which were low dose.¹²⁻¹⁵

However, in a study of 38 insulin-dependent diabetics it was found that progestogen-only and combined oral contraceptives had little effect on the control of diabetes,¹⁶ and another report¹⁷ about women taking *Orthonovin* (norethisterone with mestranol) stated that no insulin dose changes were necessary. Similarly, no change in glycaemic control was found in 22 women with well-regulated insulin-dependent diabetes mellitus who took a monophasic combination of ethinylestradiol and gestodene for 1 year.¹⁰

2. *Pioglitazone*. A randomised double-blind study in 35 healthy women given pioglitazone 45 mg once daily with either a combined oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg) or placebo for 21 days found that pioglitazone does not affect systemic exposure to the oral contraceptive, as measured by AUC.¹⁸ Similar results were reported in another study.³

3. *Repaglinide*. A three-period, cross-over, open-label study in healthy subjects found that a combined oral contraceptive (ethinylestradiol/levonorgestrel 30/150 micrograms) increased the maximum plasma level of repaglinide 2 mg three times daily by 17%, although the bioavailability of repaglinide was not altered.¹⁹ Repaglinide did not significantly alter the bioavailability of ethinylestradiol or levonorgestrel.¹⁹

4. *Rosiglitazone*. Rosiglitazone 8 mg daily, given for the first two weeks of two cycles in 32 women taking an oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg, *Ortho-Novum*), was found to have no effect on the pharmacokinetics of either steroid.²⁰

Mechanism

The reasons for changes in glucose metabolism are not understood. Many mechanisms have been considered including changes in cortisol secretion, alterations in tissue glucose utilisation, production of excessive amounts of growth hormone, and alterations in liver function.²¹

Importance and management

Moderately well documented. Concurrent use need not be avoided, but some patients may need a small adjustment in their dosage of antidiabetic (increases or decreases). However, it seems likely that routine blood glucose monitoring will identify any problems. Serious disturbances of diabetic control seem extremely rare. Bear in mind that the lowest-strength combined oral contraceptive preparations (20 micrograms of oestrogen) are recommended for patients with risk factors for circulatory disease (such as diabetics), so the potential for interference with their diabetic control will be minimised if this recommendation is followed. The choice of progestogen may also be important, with levonorgestrel having the most detrimental effect.

Similarly, irrespective of control of diabetes, menopausal HRT should be used with caution in diabetics because of the increased risk of arterial disease. See also 'Antidiabetics + Tibolone', p.509.

Antidiabetics + Imatinib

An improvement in diabetic control with a reduction in dose of insulin or oral antidiabetics was seen in 6 of 7 diabetics given imatinib for chronic myelogenous leukaemia. A further patient with type 2 diabetes was able to stop all antidiabetic medication during treatment with imatinib.

Clinical evidence, mechanism, importance and management

Use of imatinib 400 or 600 mg daily for the treatment of chronic myelogenous leukaemia was associated with improved glycaemic control in 6 of 7 diabetic patients. This allowed a reduction in **insulin** dose in 2 patients and **oral antidiabetic** drug dosage in 4 patients.¹ A case report describes a 70-year-old woman with type 2 diabetes who needed a reduction in her **insulin** dose when she was given imatinib for chronic myeloid leukaemia. Later, while still taking imatinib, she was able to stop the **insulin** completely.²

It was thought that imatinib may have a direct effect on glycaemic control,^{1,2} rather than an indirect effect via improvement in leukaemia.¹

These preliminary findings suggest that diabetic therapy should be well monitored in those given imatinib. Further study is needed.

Antidiabetics + Isoniazid

Some reports suggest that isoniazid causes an increase in blood glucose levels in diabetics, whereas another suggests it causes a decrease.

Clinical evidence

A study in 6 diabetics taking **insulin** found that isoniazid 300 to 400 mg daily increased their fasting blood glucose levels by 40% (from an average of 255 to 357 mg%), and their glucose tolerance curves rose and returned to normal levels more slowly. After 6 days of treatment the average rise was only 20%. Two other patients needed an increased dosage of **insulin** while taking isoniazid 200 mg daily, but this was reduced again when the isoniazid was withdrawn.¹

Another report describes glycosuria and the development of frank diabetes in 3 out of 50 patients given isoniazid 300 mg daily,² and hyperglycaemia has been seen in cases of isoniazid poisoning.³

In contrast, another study found that isoniazid had a hypoglycaemic effect in 6 out of 8 diabetics.⁴ A 500-mg dose of isoniazid caused an 18% (range 5 to 34%) reduction in blood glucose levels after 4 hours; 3 g of **tolbutamide** caused a 28% (19 to 43%) reduction, and together they caused a 35% (17 to 57%) reduction. However, one patient had a 10% increase in blood glucose levels after taking isoniazid, a 41% decrease after **tolbutamide**, and a 30% decrease after taking both drugs. The diabetic control of another patient was not affected by either drug.⁴

Mechanism

Not understood.

Importance and management

The major documentation for these reactions dates back to the 1950s, since when the literature has been virtually (and perhaps significantly) silent. The outcome of concurrent use is therefore somewhat uncertain. Nevertheless it would be prudent for diabetics given isoniazid to be monitored for changes in the control of the diabetes. Appropriate dosage adjustments of the antidiabetic should be made where necessary.

Antidiabetics + Karela (*Momordica charantia*)

The blood glucose-lowering effects of chlorpropamide and other antidiabetics can be increased by karela.

Clinical evidence

A report of a patient whose diabetes was poorly controlled on diet and **chlorpropamide**, but much better controlled when she ate curry containing karela, provides evidence that the blood glucose-lowering effects of karela and conventional oral antidiabetics can be additive.¹ Other small non-controlled studies have subsequently shown that karela produces a significant improvement in glucose tolerance in patients with type 2 diabetes, both when they are taking **chlorpropamide**,² **tolbutamide**,² **glibenclamide**,^{2,3} **glymidine**² or **metformin**,³ and when they are not taking antidiabetics.^{4–6} In these studies, karela was given orally as a juice from the fruit,^{2,4} dried powdered fruit,^{5,6} fried fruits,² aqueous extract,⁶ or solvent extract from the fruit.³

Hypoglycaemic coma and seizures occurred in two young non-diabetic children after they were given bitter melon (karela) tea.⁷

Mechanism

Karela (also known as bitter melon, bitter gourd, balsam pear, cundeamor) is the fruit of *Momordica charantia* which is indigenous to Asia and South America. The blood glucose-lowering effects of karela may be due to its content of polypeptide P, a blood glucose-lowering peptide,⁸ also known as vegetable insulin (v-insulin).⁹ This substance is effective when given subcutaneously,⁹ but its oral activity is uncertain.¹⁰ Other blood glucose-lowering compounds isolated from karela include charantin (sterol glucoside mixture in the fruit) and vicine a pyrimidine nucleoside found in the seeds). Karela fruit may have both insulin-like effects and stimulate insulin secretion.¹⁰

Importance and management

Karela is available in the UK and elsewhere, and is used to flavour foods such as curries, and also used as a herbal medicine for the treatment of diabetes mellitus. Its blood glucose-lowering activity is clearly established. Health professionals should therefore be aware that patients may possibly be using karela as well as more orthodox drugs to control their diabetes. Irregular consumption of karela as part of the diet could possibly contribute to unexplained fluctuations in diabetic control.

Antidiabetics + Ketotifen

The concurrent use of sulphonylureas or biguanides and ketotifen appears to be well tolerated, but a fall in the number of platelets has been seen in one study in patients taking biguanides with ketotifen.

Clinical evidence, mechanism, importance and management

A study in 30 hospitalised diabetics (10 diet controlled, 10 taking unnamed **sulphonylureas**, 10 taking unnamed **biguanides**) found that the concurrent use of ketotifen 4 mg daily for 14 days was generally well tolerated. However, those taking **biguanides** had a significant decrease in platelet counts and 3 had a marked fall on day 14 to slightly below $100 \times 10^9/L$, which returned to normal after a few days.¹ This finding underlies the precaution issued by the manufacturers of ketotifen,² that the combination should be avoided until this effect is explained. However, no other studies appear to have confirmed the fall in thrombocyte count so that its importance still remains uncertain.³

Antidiabetics + Lithium

An isolated report describes a diabetic patient receiving insulin who developed hyperglycaemia when his serum-lithium levels were high, but not when the lithium dose was reduced. Lithium can raise blood glucose levels and in some instances this has been associated with the development of diabetes mellitus, but the association is unclear and there is little or no evidence that its use normally causes significant changes in diabetic control.

Clinical evidence, mechanism, importance and management

It has been suggested that both lithium and affective disorders may lead to the development of diabetes mellitus or precipitate its appearance, and the incidence of diabetes in manic depressive patients is higher than in the general population; an overall prevalence of 10% has been reported, compared with 3% and 1.8% in other psychiatric patients and the general population, respectively. However, other factors such as weight gain, age, and other medications may also contribute.¹ A study in 10 psychiatric patients found that lithium carbonate for 2 weeks raised their blood glucose levels and impaired their glucose tolerance.² There are also a few case reports of hyperglycaemia, impaired glucose tolerance and diabetes mellitus in patients taking lithium.^{3–5} However, a long-term investigation over a period of 6 years, involving 460 patients, found that the mean blood glucose levels remained the same before and after treatment with lithium. One patient did develop diabetic ketoacidosis after 4 years of uneventful lithium treatment, but the authors concluded that long-term lithium treatment did not increase the risk of developing diabetes mellitus.⁶

One patient with mania and diabetes developed hyperglycaemia, in the presence of a constant **insulin** dose, when his serum lithium levels were high (approximately 1.4 mmol/L), but reducing the lithium level to 1.1 mmol/L led to a lowering of the fasting blood glucose.⁷ However, a study in 6 patients, with type 2 diabetes controlled by diet alone, found that lithium, taken for one week did not alter the metabolic response to a standard 50 g carbohydrate breakfast.⁸

Although there is only the one report of disturbed diabetic control in a diabetic patient taking lithium, it would seem prudent to bear this interaction in mind if lithium is added to the treatment being received by diabetic patients.

Antidiabetics + Macrolides

An isolated report describes severe liver damage with prolonged cholestasis in a patient taking chlorpropamide and erythromycin. Isolated cases of hypoglycaemia have been described in patients taking glibenclamide (glyburide) or glipizide with clarithromycin or erythromycin. A study in healthy subjects found that hypoglycaemia may occur if tolbutamide and clarithromycin are given concurrently and another pharmacokinetic study suggests that clarithromycin may enhance the effects of repaglinide.

Clinical evidence, mechanism, importance and management

(a) Effects on the liver

A man with type 2 diabetes taking chlorpropamide was given erythromycin ethylsuccinate 1 g daily for 3 weeks for a respiratory infection. Two weeks later he complained of increasing fatigue and fever. A short episode of pruriginous skin rash was followed by the appearance of dark urine, jaundice and hepatomegaly. The picture over the next 2 years was that of profound cholestasis, complicated by steatorrhea and marked hyperlipidaemia with disappearance of interlobular bile ducts. He died of ischaemic cardiomyopathy.¹ The reasons for this serious reaction are not understood, but the authors point out that liver damage occurs in a very small number of patients given sulphonylureas, such as chlorpropamide, and also with erythromycin. They suggest that there may have been an interaction between the two drugs. This case is also complicated by the prior long-term use of phenformin, which is known to be hepatotoxic.¹ No general conclusions can be drawn from this unusual case.

(b) Hypoglycaemia

1. *Repaglinide*. Clarithromycin 250 mg twice daily given to healthy subjects increased the AUC and maximum plasma concentrations of a single 250-microgram dose of repaglinide, given on day 5, by 40 and 67%, respectively. Clarithromycin may inhibit the metabolism of repaglinide by inhibition of cytochrome P450 isoenzyme CYP3A4. There was a similar corresponding rise in circulating insulin levels.² The effect of concurrent administration of these drugs should therefore be monitored. Other macrolides that inhibit CYP3A4 (such as erythromycin) would be expected to interact in a similar manner.

2. *Sulphonylureas*. Two isolated cases of severe hypoglycaemia occurred in elderly, type 2 diabetic patients, with renal impairment, given glibenclamide or glipizide and clarithromycin.³ A further case of hypoglycaemia occurred when an elderly diabetic patient, with normal renal function, taking glibenclamide 5 mg daily also took clarithromycin 1 g daily as part of an *Helicobacter pylori* eradication regimen.⁴ It was thought that the clarithromycin might have displaced glibenclamide and glipizide from protein binding sites.^{3,4}

A case of hypoglycaemia was reported in a patient taking glibenclamide and erythromycin.⁵ However, an earlier single-dose study in 12 patients with type 2 diabetes found that erythromycin had little effect on glibenclamide pharmacokinetics or on its blood glucose-lowering effects.⁶ A placebo-controlled study involving 34 patients with type 2 diabetes (most of whom were treated with glibenclamide or glipizide) found that oral erythromycin 400 mg three times daily for a week reduced fructosamine and fasting blood glucose concentrations and increased insulin secretion. Glycaemic control was also improved in a similar study using oral erythromycin 200 mg three times daily for 4 weeks.⁷ Further studies have shown that erythromycin increases gastric motility, which results in better control of blood glucose in patients with type 2 diabetes.^{8,9}

A single-dose study in 9 healthy subjects found that clarithromycin 250 mg increased the rate of absorption of tolbutamide 500 mg by about 20% and increased its bioavailability by 26%. Hypoglycaemia, reported as

uneasiness and giddiness, occurred on taking the combination.¹⁰ The general importance of these cases is uncertain, but some caution may be warranted with concurrent use,³ and the dose of the sulphonylurea may need to be reduced.

Antidiabetics + MAOIs or RIMAs

The blood glucose-lowering effects of insulin and the oral antidiabetics can be increased by MAOIs. This may improve the control of blood glucose levels in most diabetics, but in a few it may cause undesirable hypoglycaemia. Moclobemide appears not to interact.

Clinical evidence

(a) Moclobemide

A study in healthy subjects given glibenclamide 2.5 mg daily found that moclobemide 200 mg three times daily for a week had no effect on glucose or insulin concentrations after oral glucose tolerance tests.¹ In clinical trials, 8 diabetics taking glibenclamide (glyburide), gliclazide, metformin or chlorpropamide received moclobemide, and there was no effect on blood glucose levels or any other evidence of an interaction.¹

(b) Non-selective irreversible MAOIs

A diabetic patient receiving insulin experienced postural syncope and hypoglycaemia, which required a reduction in insulin dose, when mebanazine was also taken.² Other reports in diabetics indicate that mebanazine increases the blood glucose-lowering effects of insulin, tolbutamide and chlorpropamide, and improves diabetic control.^{3–6}

Mechanism

Not fully understood. Mebanazine,⁴ iproniazid,⁷ isocarboxazid,⁸ phenelzine,⁴ and tranlycypromine⁹ have all been shown to reduce blood glucose levels in the absence of conventional antidiabetics, possibly due to some direct action on the pancreas, which causes the release of insulin.⁹ It would seem that this can be additive with the effects of the conventional hypoglycaemics.

Importance and management

The interaction of the non-selective MAOIs is an established interaction of only moderate clinical importance. It can benefit the control of diabetes in many patients, but some individuals may need a reduction in the dose of their antidiabetic to avoid excessive hypoglycaemia. The effects of concurrent use should be monitored. This interaction would seem possible with any antidiabetic/MAOI combination, but this requires confirmation.

No clinically important interaction seems to occur between antidiabetics and moclobemide.

Antidiabetics + Nicotinic acid (Niacin)

Nicotinic acid causes a deterioration in glucose tolerance, which may be dose-related, and can result in the need for an adjustment in antidiabetic medication. Nevertheless, its benefits on lipids may outweigh its effects on glucose tolerance in some diabetics. Concurrent use should be closely monitored.

Clinical evidence

It is well recognised that nicotinic acid can cause deterioration in blood glucose tolerance. For example, in a small randomised crossover study, immediate-release nicotinic acid 1.5 g three times daily caused a 16% increase in mean plasma glucose and a 21% increase in glycosylated haemoglobin levels in 13 patients with type 2 diabetes.¹ In a retrospective study of patients taking controlled-release nicotinic acid (average dose approximately 1.5 g daily), nicotinic acid was discontinued in 106 out of 160 patients who were diabetics; of these, 43 patients (about 40%) had the nicotinic acid discontinued because of poor glycaemic control. Furthermore, 14 patients required the addition of oral antidiabetic drugs to control their diabetes.²

In contrast, in another placebo-controlled study including 125 patients with diabetes, immediate-release nicotinic acid 3 g daily (or maximum tolerated dose) only modestly increased plasma glucose levels in patients with diabetes. Moreover, there were no significant differences in antidiabetic medication in diabetics taking nicotinic acid versus placebo, although insulin use was increased by 13% in the nicotinic acid group, when compared with 4% in the placebo group.³ In a placebo-controlled study in patients with type 2 diabetes taking controlled-release nicotinic acid 1 g or 1.5 g daily, glycosylated haemoglobin marginally increased by 0.29% in the group receiving 1.5 g daily. There was an initial rise in fasting blood glucose between weeks 4 and 8, but this had returned to baseline by week 16. This was probably because some adjustment was made in antidiabetic therapy; 29% of patients taking nicotinic acid 1.5 g required an increase in antidiabetic therapy compared with 16% taking placebo (difference not significant). Only one patient (2%) taking nicotinic acid 1 g and 3 patients (6%) taking nicotinic acid 1.5 g discontinued treatment because of inadequate glucose control.⁴ However, it has been noted that patients enrolled in both these studies had good glycaemic control, and that the findings may not be applicable to those with poor glycaemic control.⁵

Mechanism

Nicotinic acid reduces glucose tolerance, possibly by causing or aggravating insulin resistance.

Importance and management

It is well known that nicotinic acid can cause deterioration in glycaemic control in patients with diabetes, but the incidence and clinical relevance of this is more controversial. The beneficial lipid-modifying effects of nicotinic acid directly improve the main lipid disorders observed in diabetes, which are considered an important contributing factor to the high incidence of cardiovascular disease seen in diabetics. The question then is, do the lipid-regulating benefits of nicotinic acid outweigh its adverse effects on glucose homeostasis? Some consider that they do especially if low doses of nicotinic acid (2 g or less) are used, and recommend the use of nicotinic acid in diabetics in some situations.^{6,7} Whenever nicotinic acid is used, diabetic control should be closely monitored, recognising that adjustment of antidiabetics may be needed.

Antidiabetics + NSAIDs

No adverse interaction normally occurs between most NSAIDs and antidiabetics. However, there are isolated cases of hypoglycaemia in patients given fenclofenac with chlorpropamide and metformin, ibuprofen with glibenclamide, indometacin with chlorpropamide, and naproxen with glibenclamide and metformin. Rofecoxib may have been a precipitating factor in a case of acute renal failure and metformin-associated lactic acidosis. The risk of fluid retention with pioglitazone or rosiglitazone is increased by the NSAIDs.

Consider also 'azapropazone, phenylbutazone, and oxyphenbutazone', (p.498) and the 'salicylates', (p.502) for related drugs that do have adverse interactions with antidiabetics.

Clinical evidence

A. Metformin

A 58-year-old woman with longstanding type 2 diabetes taking metformin 500 mg twice daily developed serious acute renal failure and lactic acidosis one month after starting **rofecoxib**. She made a full recovery. **Rofecoxib** could have precipitated acute renal failure, which would lead to the accumulation of metformin, and metformin-associated lactic acidosis.¹ For a case of hypoglycaemia attributed to ramipril and **naproxen**-induced renal failure in a patient taking metformin and glibenclamide, see Glibenclamide, below.

B. Nateglinide

In a randomised crossover study, 18 healthy subjects were given modified-release **diclofenac** 75 mg on the same day as two 120-mg doses of nateglinide, given 4 hours apart. The pharmacokinetics of both drugs were unaltered by concurrent use.²

C. Pioglitazone or Rosiglitazone

The manufacturers say that pioglitazone and rosiglitazone can cause fluid retention, which may exacerbate or precipitate heart failure, particularly in those with limited cardiac reserve.^{3,4} Because NSAIDs can also cause fluid retention, the manufacturers issue a warning that concurrent use may possibly increase the risk of oedema.⁴

D. Sulphonylureas

(a) Chlorpropamide

Ibuprofen 1.2 g daily for 4 weeks had no significant effect on the blood glucose levels of ten type 2 diabetic patients taking chlorpropamide 62.5 to 375 mg daily.⁵

A woman whose type 2 diabetes was well controlled with chlorpropamide 500 mg and metformin 1.7 g daily, developed hypoglycaemia within 2 days of exchanging **flurbiprofen** 150 mg daily and **indometacin** 150 mg daily for **fenclofenac** 1.2 g daily. The antidiabetic drugs were withdrawn the next day, but later in the evening she went into a hypoglycaemic coma. The reason for this is not understood, but it was attributed to a protein binding interaction between chlorpropamide and **fenclofenac**.⁶ Conversely, another isolated report briefly describes hyperglycaemia with chlorpropamide possibly due to **indometacin**.⁷

(b) Glibenclamide

Acemetacin. No changes in the control of diabetes were seen in 20 patients with type 2 diabetes taking glibenclamide when they were given acemetacin 60 mg three times daily.⁸

2. **Bromfenac.** The blood glucose levels of 12 diabetics taking glibenclamide 10 mg daily were unchanged by bromfenac 50 mg three times daily for 3 days, and the pharmacokinetics of glibenclamide were also unaltered.⁹

3. **Diclofenac.** The blood glucose levels of 12 diabetics with rheumatic diseases taking glibenclamide were unchanged by diclofenac 150 mg daily for 4 days.¹⁰

4. **Diflunisal.** An isolated case of hypoglycaemia has been reported in a patient taking glibenclamide with diflunisal.¹¹

5. **Etodolac.** Etodolac does not appear to affect the pharmacokinetics of glibenclamide.¹²

6. **Ibuprofen.** A study in 16 healthy subjects found that ibuprofen produced no significant changes in the pharmacokinetics of glibenclamide. However, ibuprofen with glibenclamide caused a greater blood glucose-lowering effect than glibenclamide alone, but the clinical significance of this was uncertain.¹³ A 72-year-old man with longstanding type 2 diabetes, well-controlled with glibenclamide 2.5 mg daily took a single 150-mg dose of ibuprofen, and 30 minutes later experienced severe nausea, sweating and palpitations, which were immediately relieved by taking sugar. The symptoms occurred again the next morning after a second dose of ibuprofen and after a further dose in the afternoon he became unconscious and was given intravenous glucose. Ibuprofen was withdrawn and there were no further episodes of hypoglycaemia. It was also noted that hypoglycaemia had not occurred when he had previously taken **aspirin**, **paracetamol** or **diclofenac**.¹⁴

7. **Lornoxicam.** Lornoxicam 4 mg twice daily for 6 days had no effect on the pharmacokinetics of a single 5-mg dose of glibenclamide in 15 healthy subjects. The pharmacokinetics of lornoxicam also remained unchanged. However, concurrent use significantly increased plasma insulin levels (AUC 47%) and lowered serum glucose levels (8%), but this is probably not clinically important.¹⁵

8. **Naproxen.** A case of severe hypoglycaemia in a diabetic patient was attributed to the accumulation of glibenclamide and **metformin** due to deterioration in renal function caused by the concurrent use of ramipril and naproxen.¹⁶

9. **Nimesulide.** Although a preliminary report suggested that nimesulide slightly increased the effects of glibenclamide,¹⁷ a later study using various [unnamed] **sulphonylureas** failed to find that it affected fasting blood glucose levels or the glucose tolerance of diabetic patients.¹⁷

10. **Parecoxib.** Valdecoxib, the active metabolite of parecoxib, does not appear to affect either the pharmacokinetics of glibenclamide or its effects on insulin or blood glucose levels.¹⁸

11. **Piroxicam.** Healthy subjects and type 2 diabetics had an increased hypoglycaemic response to glibenclamide (blood glucose levels down by 13 to 15%) when they were given piroxicam 10 mg.¹⁹

12. **Tenoxicam.** Tenoxicam 20 mg daily was found not to affect the glycoregulation of 8 healthy subjects given glibenclamide 2.5 mg daily.²⁰

13. **Tolmetin.** No changes were seen in the blood glucose levels of 40 diabetics taking glibenclamide when they were given either tolmetin 1.2 g or placebo daily for 5 days.²¹

(c) **Glibornuride**

A study in healthy subjects found that **tenoxicam** 20 mg daily did not affect the pharmacokinetics of glibornuride or its effect on plasma insulin and blood glucose levels.²²

(d) **Glipizide**

In a study in 6 healthy subjects, **indobufen** 200 mg twice daily for 5 days caused a 25% rise in the AUC of a single 5-mg dose of glipizide and a non-significant reduction in their blood glucose levels.²³ No important changes in blood glucose levels occurred in 24 type 2 diabetic patients taking tolbutamide or glipizide when they took **indoprofen** 600 mg daily for 5 days.²⁴ A study found that although **indoprofen** (200 mg on day 1, then 600 mg daily on days 3 to 8) lowered the plasma levels of a single 5-mg dose of glipizide, the blood glucose levels remained unaffected.²⁵

(e) **Tolbutamide**

A report briefly states that no changes in blood tolbutamide or in fasting blood glucose levels were seen in diabetics given **diflunisal** 375 mg twice daily.²⁶ In a study in 12 type 2 diabetic patients, **sulindac** 400 mg daily did not affect the half-life, plasma levels, time-to-peak levels or AUC of tolbutamide. An unimportant reduction in fasting blood glucose levels was

seen.²⁷ **Naproxen** 375 mg every 12 hours for 3 days had no effect on the pharmacokinetics or pharmacological effects of tolbutamide in ten type 2 diabetics.²⁸ The pharmacokinetics of a single 500-mg dose of tolbutamide were unaffected in 7 healthy subjects after they took **tenoxicam** 20 mg daily for 14 days, and blood glucose concentrations were not altered.²⁹ No important changes in blood glucose levels occurred in 24 type 2 diabetic patients taking tolbutamide or glipizide when they were given **indoprofen** 600 mg daily for 5 days.²⁴ In other patients taking tolbutamide it was found that **ibuprofen** lowered fasting blood glucose levels, but not below the lower limits of normal.³⁰

Mechanism, importance and management

The reports briefly quoted here indicate that no adverse or clinically relevant interaction normally occurs between the oral antidiabetics and the NSAIDs cited. The general silence in the literature would seem to add confirmation. Caution is appropriate with pioglitazone or rosiglitazone and NSAIDs, and patients should be monitored for signs of heart failure. Note that the NSAIDs, including coxibs, can cause renal failure, which can precipitate metformin-associated lactic acidosis. In addition, a reduction in the renal clearance of antidiabetic drugs can result in hypoglycaemia. Adverse interactions can certainly occur between antidiabetics and azapropazone, phenylbutazone, oxyphenbutazone and the salicylates, see 'Antidiabetics + NSAIDs; Phenylbutazone and related drugs', p.498 and 'Antidiabetics + Salicylates', p.502.

Antidiabetics + NSAIDs; Phenylbutazone and related drugs

The blood glucose-lowering effects of acetohexamide, chlorpropamide, carbutamide, glymidine, glibenclamide (glyburide) and tolbutamide can be increased by phenylbutazone. Severe hypoglycaemia has occurred in a few patients. Similarly, azapropazone can increase the effects of tolbutamide and cause severe hypoglycaemia. Oxyphenbutazone may be expected to behave similarly. Metamizole (dipyrone) and mofebutazone did not interact with glibenclamide.

Clinical evidence

(a) Azapropazone

A woman whose diabetes was well controlled for 3 years with **tolbutamide** 500 mg twice daily, became confused and semi-comatose 4 days after starting to take azapropazone 900 mg daily. She complained of having felt agitated since starting the azapropazone, so it was withdrawn on suspicion of causing hypoglycaemia. Later that evening she became semi-comatose and was found to have a plasma glucose level of 2 mmol/L.¹ A subsequent study in 3 healthy subjects found that azapropazone 900 mg daily increased the plasma half-life of **tolbutamide** 500 mg threefold (from 7.7 to 25.2 hours) and reduced its clearance accordingly.¹ Acute hypoglycaemia occurred in another patient taking **tolbutamide** 500 mg three times daily, 5.5 hours after a single 600-mg dose of azapropazone was taken.²

(b) Metamizole (Dipyrone)

One randomised, placebo-controlled, crossover study in 12 diabetic patients taking **glibenclamide**, suggested that metamizole 1 g daily for 2 days did not interact with **glibenclamide**; no relevant alteration in blood glucose levels was found.³

(c) Mofebutazone

Mofebutazone 900 mg daily has not been found to cause any clinically important changes in blood glucose levels in patients taking **glibenclamide**.⁴

(d) Oxyphenbutazone

Oxyphenbutazone has been found to alter⁵ or raise **glymidine** levels⁶ and **tolbutamide** levels.^{7,8}

(e) Phenylbutazone

A man with type 2 diabetes taking **tolbutamide** experienced an acute hypoglycaemic episode 4 days after starting phenylbutazone 200 mg three times daily, although there was no change in his diet or in the dosage of **tolbutamide**. He was able to control the hypoglycaemia by eating a large bar of chocolate.⁹

There are numerous other case reports and studies of this interaction involving phenylbutazone with **acetohexamide**,¹⁰ **carbutamide**,¹¹ **chlorpropamide**,¹²⁻¹⁴ **glibenclamide (glyburide)**,¹⁵ **glymidine**,¹⁶ and **tolbutamide**.^{13,17-23} Some of which describe acute hypoglycaemic episodes.^{10,12,13,18,20} Several of these interactions have been fatal.^{13,23} There is a report suggesting that the interaction between **glibornuride** and phenylbutazone may not be clinically important.²⁴ In contrast to these reports, a single study describes a paradoxical *rise* in blood glucose levels in 3 African patients taking **tolbutamide** and phenylbutazone.²⁵ In addition to these reports there is some evidence that **tolbutamide** increases the metabolism of phenylbutazone by 42%,²² but the extent to which this affects its therapeutic effects is uncertain.

Mechanism

Not fully resolved. Some evidence suggests that phenylbutazone can inhibit the renal excretion of **glibenclamide (glyburide)**,¹⁵ **tolbutamide**,¹⁹ and the active metabolite of acetohexamide¹⁰ so that they are retained in the body longer and their blood glucose-lowering effects are increased and prolonged. It has also been shown that phenylbutazone can inhibit the metabolism of the sulphonylureas^{7,22} as well as causing their displacement from protein binding sites.²⁶ Azapropazone also possibly inhibits the metabolism of **tolbutamide**,¹ as well as maybe causing displacement from plasma protein binding sites.²

Importance and management

The interactions between the antidiabetics and phenylbutazone are well documented and potentially clinically important. Blood glucose levels may be lowered, but the number of reports of acute hypoglycaemic episodes seems to be small. Concurrent use should therefore be well monitored. A reduction in the dosage of the sulphonylurea may be necessary if excessive hypoglycaemia is to be avoided. Not all sulphonylureas have been shown to interact (**glibornuride** probably does not do so) but it would be prudent to assume that they all interact until there is good evidence to suggest otherwise. Oxyphenbutazone may be expected to interact like phenylbutazone (it is a metabolite of phenylbutazone) but, unexpectedly, possibly not mofebutazone although more study would be needed to confirm this.

The information regarding an interaction between azapropazone and the sulphonylureas seems to be limited to the cases and small study involving **tolbutamide**. Nevertheless, the manufacturers of azapropazone say that the concurrent use of sulphonylureas is not recommended.²⁷

Antidiabetics + Orlistat

Orlistat improved glycaemic control, which resulted in the need to reduce the dose of glibenclamide (glyburide) or glipizide in almost half the patients in one study. In other studies, orlistat also reduced the dose requirement for metformin and for insulin. Orlistat did not alter the pharmacokinetics of glibenclamide or metformin. Orlistat and cimetidine may have contributed to a case of metformin-associated lactic acidosis. The manufacturers recom-

mend avoiding the concurrent use of acarbose and orlistat because of the lack of interaction studies.

Clinical evidence

(a) Acarbose

The manufacturer of orlistat says that in the absence of pharmacokinetic studies its concurrent use with acarbose should be avoided.¹

(b) Insulin

In a randomised, placebo-controlled, double-blind study in patients with type 2 diabetes receiving insulin with or without metformin or a sulphonylurea, orlistat 120 mg three times daily for one year combined with a reduced-calorie diet improved glycaemic control and allowed a greater reduction in insulin dose (mean reduction of 8.1 units daily versus 1.6 units daily for placebo). Hypoglycaemic episodes occurred in about 17% of orlistat recipients and about 10% of placebo recipients—three orlistat recipients and one placebo recipient required medical intervention due to hypoglycaemia.²

(c) Metformin

In a randomised study, 21 healthy subjects were given metformin 500 mg daily for 6 days, with or without orlistat 120 mg three times daily. Orlistat had no effect on the pharmacokinetics of metformin, and the combination was well-tolerated.³ In a randomised, placebo-controlled, double-blind study in patients with type 2 diabetes taking metformin with or without a sulphonylurea (mainly glibenclamide (glyburide) or glipizide), orlistat 120 mg three times daily for one year improved glycaemic control and allowed a small reduction in the dose of metformin (mean daily reduction of 16 mg versus a mean increase of 49 mg for placebo). Twice as many patients in the orlistat group either reduced or discontinued one or more antidiabetics (17% versus 8% with placebo). Hypoglycaemic episodes (mild to moderate and not requiring treatment) occurred in 10% of orlistat recipients and 4% of placebo recipients.⁴ Similarly, improvement in glycaemic control and reduced requirement for oral antidiabetic medication was reported in another study.⁵

A 59-year-old woman with type 2 diabetes taking long-term metformin 500 mg three times daily, developed severe metabolic acidosis with cardiovascular collapse and acute renal failure. Three months previously she had started orlistat 120 mg three times daily, which caused abdominal pain and chronic diarrhoea. During the 4 days before hospital admission, she was prescribed cimetidine 400 mg twice daily for her abdominal pain. The metformin-associated lactic acidosis⁶ was considered to have been precipitated by the orlistat and 'cimetidine', (p.491).

(d) Sulphonylureas

A placebo-controlled study in 12 healthy subjects found that orlistat 80 mg three times daily for a little over 4 days had no effect on the pharmacokinetics of a single 5-mg oral dose of **glibenclamide (glyburide)** and the blood glucose lowering effects remained unchanged.⁷ A later 1-year, randomised, placebo-controlled, double-blind trial in obese patients with type 2 diabetes in which 139 patients took orlistat found that orlistat reduced fasting blood glucose and glycosylated haemoglobin levels. In addition, 43% of patients taking orlistat 120 mg three times daily were able to decrease their sulphonylurea dosage (**glibenclamide** or **glipizide**), and 11.7% of them were able to discontinue the sulphonylurea. The average dose decrease was 23% compared with 9% in the placebo group.⁸

Mechanism

The benefits of orlistat are likely to be as a result of the beneficial effects of weight reduction on glycaemic control, although in some studies the reduction in glycosylated haemoglobin was not entirely dependent on the magnitude of weight loss.²

Importance and management

The benefits of orlistat on glycaemic control in overweight or obese patients with diabetes are established. Antidiabetic treatment should be more closely monitored in patients taking orlistat, and the dose adjusted as necessary.

Antidiabetics + Pentoxifylline

The manufacturer notes that, rarely, high-dose injections of pentoxifylline have intensified the blood glucose-lowering effects of insulin and oral antidiabetic drugs. This effect has not been seen with oral pentoxifylline.¹ For example, in one study oral pentoxifylline 600 mg daily for 9 months did not affect glycosylated haemoglobin levels in type 2 diabetic patients.²

Antidiabetics + Phenylephrine

Type 1 (insulin-dependent) diabetics can develop elevated blood pressures if they are given phenylephrine eye drops.

Clinical evidence, mechanism, importance and management

A comparative study of 14 type 1 diabetics, who over a period of 2 hours before ocular surgery were given phenylephrine 10% eye drops (a total of 4 doses of one or two drops), found that they had an average blood pressure rise of 34/17 mmHg, whereas another 176 non-diabetic patients similarly treated had no increases in blood pressure.¹ The reason for this pressor reaction is not understood but it would seem that enough phenylephrine is absorbed systemically to stimulate the adrenoceptors of the sympathetic nervous system, which innervates the cardiovascular system. The concentration of phenylephrine in the plasma is a balance between the amount absorbed and rate at which it is then inactivated. The inactivation in diabetics can be reduced (due to sympathetic denervation) so that their phenylephrine levels may rise higher than they would in normal subjects. The authors of this report say that they readily controlled these hypertensive reactions with halothane and by neuroleptanalgesia accompanying regional block with anaesthesia standby. Strictly speaking this is not a drug interaction, but a drug-disease reaction. The mydriatic dosage of phenylephrine should be reduced in type 1 diabetics but whether this is also true for type 2 diabetics is uncertain.

Antidiabetics + Quinolones

A number of reports describe severe hypoglycaemia in diabetic patients treated with gatifloxacin and various antidiabetics including insulin, metformin, pioglitazone, repaglinide, rosiglitazone, some sulphonylureas, or voglibose. In contrast, another report describes hyperglycaemia when a diabetic taking metformin and glipizide was given gatifloxacin. A retrospective review reported that almost one quarter of adverse events associated with gatifloxacin involved abnormal glucose homeostasis, which was at least tenfold higher than with other quinolones. Interaction studies have shown that gatifloxacin may cause hypoglycaemia and hyperglycaemia, whereas studies using cipro-

floxacin and levofloxacin with glibenclamide suggest plasma glucose levels are not usually affected to a clinically relevant extent. However, isolated reports describe hypoglycaemia in diabetic patients taking glibenclamide, when ciprofloxacin, levofloxacin, or norfloxacin was given, and deaths associated with abnormal glucose homeostasis have been reported in patients taking ciprofloxacin or levofloxacin.

Clinical evidence

A search of the FDA database for adverse drug events associated with **gatifloxacin, ciprofloxacin, levofloxacin, and moxifloxacin** between November 1997 and September 2003 found 10 025 unique adverse events, including 568 involving glucose homeostasis abnormalities, of which 25 were fatal. **Gatifloxacin** use was associated with 453 (80%) of the adverse events involving glucose homeostasis, and 17 of these were fatal compared with 3, 5, and 0 fatalities with **ciprofloxacin, levofloxacin, and moxifloxacin**, respectively. Of all the adverse events associated with **gatifloxacin**, 24% involved glucose homeostasis, compared with **ciprofloxacin** (1.3%), **levofloxacin** (1.6%) and **moxifloxacin** (1.3%). The risk of adverse events involving glucose homeostasis was higher in older patients, in patients taking medications for diabetes (almost 70% of those taking **gatifloxacin** were also using **insulin** or **oral antidiabetics**) and in patients with renal dysfunction whose dosage had not been appropriately adjusted.¹

(a) Ciprofloxacin

A study in 12 patients with type 2 diabetes mellitus taking **glibenclamide (glyburide)** 10 mg in the morning, plus in some instances 5 mg in the evening, found that ciprofloxacin 1 g daily for a week caused rises in maximum serum **glibenclamide** levels of 20 to 30%, and a rise in the AUC of 25 to 36%. However, none of these changes were statistically significant, and more importantly blood glucose levels were not altered.²

Nevertheless, an elderly patient who had been taking **glibenclamide** 5 mg daily for over 2 years was found to be confused, with slurred speech and diaphoresis within a week of starting ciprofloxacin 250 mg twice daily for acute cystitis, and was found to have a serum **glibenclamide** level several times greater than that normally seen.³ She needed treatment with intravenous glucose to correct the hypoglycaemia. Two further similar cases have been reported, in which hypoglycaemia developed after the first or second dose of ciprofloxacin, for either a wound infection⁴ or a urinary tract infection.⁵

(b) Gatifloxacin

In a study in patients with type 2 diabetes controlled by diet and exercise, gatifloxacin 400 mg daily for 10 days had no significant effect on glucose tolerance or most aspects of glucose homeostasis, but did cause a brief increase in serum insulin levels.⁶ In contrast, the manufacturer of gatifloxacin notes that in another study in patients with type 2 diabetes taking **metformin** with or without **glibenclamide**, oral gatifloxacin 400 mg daily for 14 days was associated with initial hypoglycaemia followed by hyperglycaemia.⁷

Moreover, there is a report of 3 cases of hypoglycaemia in elderly type 2 diabetic patients given gatifloxacin. In one of these cases a patient taking **glibenclamide** 5 mg daily and **pioglitazone** 30 mg daily experienced severe, persistent hypoglycaemia within an hour of the first dose of oral gatifloxacin 200 mg. It resolved on withdrawal of all three drugs and she had no further episodes of hypoglycaemia when **glibenclamide** and **pioglitazone** were restarted.⁸ Another case describes a patient taking **glimepiride** 2 mg before breakfast and 1 mg before dinner who developed severe hypoglycaemia 12 hours after the first dose of intravenous gatifloxacin 400 mg. Both drugs were discontinued and **glimepiride** was later restarted without further hypoglycaemia.⁸ In the remaining case, a patient taking **repaglinide** 500 micrograms every 8 hours was given oral gatifloxacin 400 mg daily for a urinary-tract infection. **Repaglinide** was discontinued 6 hours after the first dose of gatifloxacin because of the patient's lack of appetite. Two hours after the second dose of gatifloxacin, he developed severe hypoglycaemia and also experienced a tonic-clonic seizure. Gatifloxacin was discontinued but hypoglycaemia persisted for 32 hours. **Repaglinide** was restarted 4 days later without further hypoglycaemia.⁸ Other case reports have described severe hypoglycaemia when gatifloxacin was given to patients with diabetes taking **insulin** with **repaglinide** and **voglibose**,⁹ **glibenclamide**,¹⁰⁻¹² **glibenclamide** with **metformin**,¹³ **glibenclamide** with **rosiglitazone**,¹² or **glipizide**.¹⁰

In contrast, an 82-year-old woman taking **metformin** and **glipizide** who

was discharged from hospital taking gatifloxacin 200 mg daily developed severe **hyperglycaemia** within 48 hours. Her serum glucose rapidly reduced with low-dose intravenous **insulin**, but increased again the following day after she took oral gatifloxacin while receiving subcutaneous **insulin**.¹⁰ Hyperglycaemia has also been noted in 2 non-diabetic patients within 48 to 72 hours of starting gatifloxacin.^{9,10} See also the FDA findings, above.

(c) Levofloxacin

A study in 24 healthy subjects found that oral levofloxacin had no effect on the pharmacokinetics of a single oral dose of **glibenclamide** nor its effect on plasma glucose levels.¹⁴ No recurrence of hypoglycaemia occurred in a patient taking **gliclazide** and oral levofloxacin who had a severe hypoglycaemic episode while receiving **glibenclamide** and gatifloxacin.¹¹ However, a fatal case of hypoglycaemia related to intravenous levofloxacin occurred in an elderly patient with diabetes who was taking **glibenclamide**.¹⁵

(d) Moxifloxacin

The manufacturer notes that the concurrent use of moxifloxacin and **glibenclamide** resulted in an approximate 21% decrease in the peak plasma level of **glibenclamide** in diabetic subjects, but this did not alter blood glucose and endogenous insulin.¹⁶ A pooled analysis from clinical and post-marketing studies suggested that moxifloxacin had no clinically relevant effect on blood glucose homeostasis, even in patients with diabetes mellitus.¹⁷

(e) Norfloxacin

The manufacturer notes that the concurrent use of norfloxacin with **glibenclamide** has resulted in severe hypoglycaemia.¹⁸

Mechanism

Unknown. The authors of one report suggest that the ciprofloxacin may have inhibited the metabolism of the glibenclamide, thereby raising its serum levels.³ This may possibly be exaggerated in elderly patients whose liver function may be reduced. However, it has also been postulated that quinolones may affect insulin secretion.^{5,15} Gatifloxacin can cause disturbances in blood glucose levels;⁷ initiation of treatment with gatifloxacin has been associated with increased insulin release and a decrease in blood glucose levels; but from the third day of treatment, an increase in blood glucose levels has also been reported.^{1,7} This severe effect of gatifloxacin on glucose homeostasis does not appear to be a class effect of the quinolones.⁸

Importance and management

Gatifloxacin has been much more frequently associated with disturbances of blood glucose than other fluoroquinolones. The manufacturer notes that when gatifloxacin is used in diabetic patients, blood glucose should be closely monitored. Signs and symptoms of **hypoglycaemia** should be monitored, especially in the first 3 days of therapy, and signs and symptoms of **hyperglycaemia** should be monitored, especially with continued treatment beyond 3 days.⁷ Alternatives to gatifloxacin should be considered in patients with diabetes.

Isolated cases of hypoglycaemia in patients with diabetes have also been reported for ciprofloxacin, levofloxacin and norfloxacin. The general clinical relevance of these cases is uncertain but probably minor. However, it may be prudent to consider increasing the frequency of blood glucose monitoring in the elderly, who appear more at risk.

Antidiabetics + Rifampicins

Rifampicin (rifampin) reduces the serum levels and blood glucose lowering effects of tolbutamide, gliclazide, chlorpropamide (single case) and glibenclamide (glyburide), and to a lesser extent glimepiride, glipizide and glymidine. Rifampicin also reduces the effects of repaglinide, and possibly also nateglinide. Rifampicin reduces the AUC of rosiglitazone, which could be clinically relevant. An isolated report describes an increased insulin requirement in a patient with type 1 diabetes taking rifampicin.

Clinical evidence

(a) Insulin

A case report describes a 54-year-old woman with type 1 diabetes whose insulin requirements increased from 36 units to 48 units daily when she took **rifampicin**. Immediately on discontinuing her antituberculous therapy, she developed frequent hypoglycaemic attacks, which persisted until her insulin dose was reduced back to 36 units daily.¹

(b) Nateglinide

In a randomised crossover study, 10 healthy subjects were given a single 60-mg dose of nateglinide the day after a 5-day course of **rifampicin** 600 mg daily. **Rifampicin** reduced the AUC_{0–7} of nateglinide by 24% (range 5 to 53%) and decreased the nateglinide half-life from 1.6 to 1.3 hours. Overall **rifampicin** did not significantly decrease the blood glucose-lowering effects of nateglinide.² However, because of the high degree of intersubject variation, the authors suggest that the blood glucose-lowering effects of nateglinide may be reduced in some subjects.²

(c) Repaglinide

In one study in healthy subjects, a single 4-mg dose of repaglinide was given one hour after the final dose of **rifampicin** 600 mg daily for 7 days. **Rifampicin** decreased the AUC and the mean maximum plasma concentration of repaglinide by 31% and 26%, respectively, but the blood glucose-lowering effect of repaglinide was not affected.³ In another study,⁴ pretreatment with **rifampicin** 600 mg daily for 5 days increased the AUC and maximum level of a single 500-microgram dose of repaglinide given on day 6 by 57% and 41%, respectively. In this study, **rifampicin** reduced the blood glucose-lowering effect of repaglinide by 35%. A third study investigated the effect of **rifampicin** 600 mg daily for 7 days on a single 4-mg dose of repaglinide given at the same time as the last **rifampicin** dose on day 7 or 24 hours later. When **rifampicin** was given simultaneously, the median AUC of repaglinide was reduced by almost 50%, but when the repaglinide was given 24 hours after the last **rifampicin** dose, the median AUC was reduced by 80%. The size of the effect of **rifampicin** on repaglinide may therefore depend on the administration schedule.⁵

(d) Rosiglitazone

Rifampicin 600 mg daily for 5 days reduced the AUC of a single 4-mg dose of rosiglitazone by 54% and reduced the maximum plasma level by 28%, in a study in healthy subjects. **Rifampicin** increased the formation of *N*-desmethylrosiglitazone.⁶ Very similar findings were reported in a study in healthy Korean subjects.⁷

Sulphonylureas

(a) Chlorpropamide

A single case report describes a man with type 2 diabetes who needed an increase in his dosage of chlorpropamide from 250 to 400 mg daily when he was given **rifampicin** 600 mg daily. His serum chlorpropamide levels rose dramatically 12 months later when the **rifampicin** was withdrawn.⁸

(b) Glibenclamide (Glyburide)

A study in 29 type 2 diabetics, stable taking glibenclamide, found that when they were also given **rifampicin** 450 or 600 mg daily for 10 days, their blood glucose levels, both fasting and after meals, were raised. Glibenclamide dosage changes were needed in 15 out of 17 patients in whom the diabetes became uncontrolled. Their blood glucose levels normalised 6 days after stopping the **rifampicin**.⁹ Another patient with type 2 diabetes taking glibenclamide had a deterioration in diabetic control, over the 8 months after she started **rifampicin**, which required an increase in glibenclamide dose and the addition of insulin. On stopping **rifampicin**, she had a marked rise in trough serum glibenclamide levels, from 40 to 200 nanograms/mL, but no appreciable change in blood glucose concentrations.¹⁰ A study in 10 healthy subjects found that **rifampicin** 600 mg daily for 5 days decreased the AUC and peak plasma level of a single 1.75-mg dose of glibenclamide given on day 6 by 39% and 22%, respectively. The elimination half-life was shortened from 2 to 1.7 hours. The maximum reduction in blood glucose level was decreased by 36% by **rifampicin**.¹¹

(c) Gliclazide

A 65-year-old patient with type 2 diabetes taking gliclazide 80 mg daily for 2 years without problem was given **rifampicin** 450 mg daily, isoniazid, ethambutol and clarithromycin for an atypical mycobacteriosis. Fasting blood glucose levels became elevated requiring an increase in the dose of gliclazide to 120 mg then 160 mg daily. The plasma level of gliclazide on day 75 was 1.4 micrograms/mL, 2 hours after an 80-mg dose. When **rifampicin** was discontinued the gliclazide level increased to 4.7 micrograms/mL and the dose was reduced back to 80 mg daily.¹² A study in 9 healthy subjects found that pre-treatment with **rifampicin** 600 mg for 6 days decreased the AUC of a single 80-mg dose of gliclazide given on day 7 by 70%. The mean elimination half-life of gliclazide was reduced from 9.5 to 3.3 hours and the gliclazide oral clearance was increased by about fourfold. The blood glucose-lowering effects of gliclazide were significantly reduced by **rifampicin**.¹³

(d) Glimepiride

A placebo-controlled study in 10 healthy subjects found that **rifampicin** 600 mg daily for 5 days decreased the AUC of a single 1-mg dose of glimepiride given on day 6 by 34%. **Rifampicin** reduced the elimination half-life of glimepiride by 25%. However, no significant differences in blood glucose were found between the **rifampicin** and placebo regimens.¹⁴

(e) Glipizide

A placebo-controlled study in 10 healthy subjects found that **rifampicin** 600 mg daily for 5 days decreased the AUC of a single 2.5-mg dose of glipizide given on day 6 by 22%. The elimination half-life was shortened from 3 to 1.9 hours by **rifampicin**. However, no significant differences in blood glucose concentrations were found.¹¹

(f) Glymidine

In one study the half-life of glymidine was reduced by about one-third by the concurrent use of **rifampicin**.¹⁵

(g) Tolbutamide

After treatment for 4 weeks with **rifampicin** the half-life of tolbutamide in 9 diabetic patients with tuberculosis was reduced by 43%, and the serum concentrations measured at 6 hours were halved, when compared with other patients not taking **rifampicin**.¹⁶ Similar results have been found in other studies in patients with cirrhosis or cholestasis,¹⁷ in healthy subjects¹⁸ and in other patients.¹⁹

Mechanism

Rifampicin is a potent inducer of the liver microsomal enzymes concerned with the metabolism of tolbutamide (cytochrome P450 isoenzyme CYP2C9), which hastens its clearance from the body, thereby reducing its effects.^{16–18} The interaction between rifampicin and glibenclamide, gliclazide, glimepiride, glipizide, and nateglinide is probably also due to induction of CYP2C9.^{2,11–13} Induction of P-glycoprotein may also play a part.^{11,13} The interaction of rifampicin with repaglinide is probably due to induction of CYP3A4,^{3,4} and that with rosiglitazone is probably due to induction of CYP2C8 and to a lesser extent CYP2C9.^{6,7} The case report with insulin is unexplained.

Importance and management

Information is limited, but the interactions of tolbutamide, glibenclamide (glyburide) and gliclazide with rifampicin appear to be established. Patients taking these sulphonylureas may need an increase in the dosage while taking rifampicin. This also seems possibly true for chlorpropamide, but the documentation for this interaction is even more limited. The effect of rifampicin on the blood glucose-lowering effects of glimepiride, glipizide or glymidine may be of only limited clinical significance, but it should be noted that these were single-dose studies and it is possible that some effect may occur with multiple dosing. Caution is warranted. Similarly although the information regarding nateglinide and repaglinide is limited, a significant interaction is possible, especially with repaglinide, and so an increase in blood glucose monitoring would be prudent. Similarly, the effect on the AUC of rosiglitazone also indicates that diabetic control should be closely monitored if rifampicin is used.

The isolated case of increased insulin requirement suggests that rifampicin may possibly affect the glycaemic control of patients with type 1 diabetes, but this needs further investigation.

There does not seem to be any information regarding the other rifamycins, **rifabutin** (a weak enzyme inducer) and **rifapentine** (a moderate enzyme inducer). However, the manufacturers and the UK Committee on Safety of Medicines warn that rifabutin may possibly reduce the effects of a number of drugs, including oral antidiabetics.^{20,21}

Antidiabetics + Salicylates

Aspirin and other salicylates can lower blood glucose levels, but small analgesic doses do not normally have an adverse effect on patients taking antidiabetics. Larger doses of salicylates may have a more significant effect, and caution is warranted.

Clinical evidence

(a) Insulin

Twelve children with type 1 diabetes receiving insulin had a reduction in blood glucose levels averaging 15% (from about 10.4 to 8.8 mmol/L)

when they were given **aspirin** (patients under 27.2 kg given 1.2 g daily, patients over 27.2 kg given 2.4 g daily) for a week. No significant changes in insulin requirements were necessary.¹

Eight patients receiving 12 to 48 units of insulin zinc suspension daily required no insulin when they were treated for 2 to 3 weeks with **aspirin** in doses of 3.5 to 7.5 g daily, which were large enough to give maximum therapeutic serum salicylate levels of about 2.5 to 3.3 mmol/L. Six other patients were able to reduce their insulin requirements by between about 20 and 65%.²

(b) Chlorpropamide

The blood glucose-lowering effects of chlorpropamide and **sodium salicylate** were found to be additive in 5 healthy subjects. A further study in 6 healthy subjects found that chlorpropamide 100 mg given with **sodium salicylate** 1.5 g lowered blood glucose levels by the same amount as either chlorpropamide 200 mg or **sodium salicylate** 3 g alone.³

The blood glucose levels of a patient taking chlorpropamide 500 mg daily were lowered about two-thirds by **aspirin** in doses sufficient to give serum salicylate levels of about 1.9 mmol/L.⁴

(c) Glibenclamide (Glyburide)

Sixteen healthy subjects took a single 5-mg dose of glibenclamide both before and on the fourth day of taking **aspirin** 975 mg four times daily for 4 days. It was found that the **aspirin** reduced the AUC_{0–4} of the glibenclamide by 68% and reduced its mean peak serum levels by 35%. The effects of this on glucose tolerance tests and insulin responses were difficult to interpret, but there was no clear evidence that any clinically relevant changes occurred.⁵

Mechanism

It has been known for over 100 years that aspirin and salicylates have hypoglycaemic properties and in relatively large doses can be used on their own in the treatment of diabetes.^{6–10} The simplest explanation for this interaction with antidiabetics is that the blood glucose lowering effects are additive,³ but there is some evidence that other mechanisms may come into play.¹⁰ In addition aspirin can raise serum chlorpropamide levels, possibly by interfering with renal tubular excretion, and therefore the effects of chlorpropamide are enhanced.⁴

Importance and management

The interaction between the sulphonylureas or insulin and the salicylates is established but of limited importance. Considering the extremely wide use of aspirin it might reasonably be expected that any generally serious interaction would have come to light by now. The data available, coupled with the common experience of diabetics,¹¹ is that excessive and unwanted hypoglycaemia is very unlikely with small to moderate analgesic doses. Some downward readjustment of the dosage of the antidiabetic may be appropriate if large doses of salicylates are used. Information about other antidiabetics and salicylates appears to be lacking, but they are expected to behave similarly.

Antidiabetics + Somatostatin analogues

Octreotide decreases insulin resistance so that the dosage of insulin used by diabetics can be reduced. Fatal diabetic ketoacidosis

occurred in one patient when octreotide was withdrawn. Octreotide appears to have no benefits in those with intact insulin reserves (type 2 diabetes), and it may reduce insulin secretion and affect glucose tolerance in non-diabetic patients. In addition, octreotide has been reported to reduce sulphonylurea-induced hypoglycaemia. Lanreotide may also affect glucose levels in diabetic patients.

Clinical evidence

Changes in glucose tolerance may occur in patients with acromegaly who are given somatostatin analogues. In a prospective study, in 24 acromegalic patients given long-acting octreotide or lanreotide, insulin resistance was reduced, but insulin secretion was impaired resulting in deterioration of glucose homeostasis in non-diabetic patients. Of 16 patients with normal glucose tolerance before octreotide treatment, 4 developed impaired glucose tolerance, and of 7 patients with impaired glucose tolerance, 4 improved, 1 remained stable and 2 deteriorated to diabetes mellitus; the status of one diabetic patient remained the same.¹ In another study in patients with acromegaly given octreotide, impaired glucose tolerance or frank diabetes developed in approximately half of the 55 patients who initially had normal glucose tolerance, but glucose tolerance improved in 3 of the 11 patients who were diabetic.² Similar results were reported in a further study, although octreotide appeared to be more detrimental to glucose metabolism than lanreotide.³

(a) Insulin

When 7 patients with type 1 diabetes with poor metabolic control were given octreotide 50 micrograms subcutaneously three times daily (at 8, 15 and 23 hours) or by continuous subcutaneous infusion (62.5 or 112.5 micrograms over 24 hours), their blood glucose levels were about 50% lower than when they were given insulin alone. The effects of octreotide on blood glucose levels were virtually the same regardless of route of administration or dose.⁴ Another study in 6 patients with type 1 diabetes also found that octreotide 50 micrograms subcutaneously before meals reduced their daily insulin requirements by about 50%,⁵ and other studies confirm that octreotide behaves in this way.^{6,7} An isolated report describes clinical and biochemical improvement with lanreotide 30 mg intramuscularly every 10 days, in a diabetic acromegalic man whose glucose levels were poorly controlled with insulin. However, he experienced hypoglycaemia when the lanreotide was replaced with intramuscular octreotide 20 mg (depot preparation) and he had to reduce his insulin dose by 30 to 50% for the first week after each octreotide injection.⁸ Another report describes deterioration in glucose tolerance leading to death from diabetic ketoacidosis when octreotide was stopped in a patient with acromegaly and insulin-resistant diabetes mellitus.⁹ Eight obese type 2 diabetic patients whose diabetes was not controlled with oral antidiabetics and who needed insulin, had no significant increases in blood glucose levels following a meal when they were given subcutaneous octreotide 25 micrograms.¹⁰ Octreotide reduced insulin requirements in 6 type 2 diabetic patients with chronic renal failure, but did not significantly affect the glycaemic profile of similar diabetic patients with normal renal function. This effect was thought to be due to a greater reduction in glucagon levels, which are elevated in renal failure.¹¹

(b) Oral antidiabetics

Octreotide does not appear to have a clinically relevant beneficial or harmful effect on the blood glucose-lowering effects of oral antidiabetics such as glibenclamide (glyburide) in patients with type 2 diabetes, although some metabolic changes can occur including suppression of postprandial serum insulin levels.^{12,13} A retrospective study of 9 patients with hypoglycaemia occurring as a result of a sulphonylurea overdose (with glibenclamide or glicipide) found that there was a dramatic and significant reduction in the number of episodes of hypoglycaemia after octreotide was given (29 episodes before versus 2 episodes after octreotide).¹⁴

Mechanism

Octreotide is an analogue of the natural hormone somatostatin, and similarly has blood glucose-lowering effects because it inhibits the actions of glucagon and growth hormone (which raise blood glucose levels), and because it also delays the absorption of carbohydrate from the gut. However, somatostatin is also diabetogenic, because it suppresses insulin release. In type 1 diabetes, because there is no endogenous insulin, the blood glucose-lowering effects predominate. In non-diabetics and type 2 diabetics, the

actions may cancel out, or there may be poorer glycaemic control. Octreotide is thought to cause less suppression of insulin release than somatostatin, but this may still be important in those with insulin-secreting reserves.

Lanreotide, like somatostatin and its analogues, may produce a transient inhibition of the secretion of insulin and glucagon,¹⁵ but lanreotide may have less affinity for receptors found in the pancreas and so possibly produces a different response to that of octreotide.^{1,8}

Sulphonylureas lower blood glucose levels primarily by facilitating preformed insulin release from pancreatic beta cells, and octreotide may oppose this by directly inhibiting insulin secretion from the pancreas.¹⁴

Importance and management

The interaction between insulin and octreotide is established and hypoglycaemia has been reported. If both drugs are used, anticipate the need to reduce the insulin dosage. The studies cited above^{4,5} suggest that about a 50% reduction is possible.

The manufacturers of octreotide say that octreotide may also reduce the requirements of oral antidiabetics in patients with type 1 diabetes mellitus. However, there do not appear to be any studies on this. Conversely, they state that in patients with type 2 diabetes, octreotide may result in prandial increases in glycaemia,¹⁶ but two clinical studies in patients with type 2 diabetes given glibenclamide (glyburide) did not show any deterioration (or benefit) in glycaemia.^{12,13} However, octreotide has been reported to reduce sulphonylurea-induced hypoglycaemia. Octreotide may affect insulin secretion, and therefore glucose tolerance, and so it would certainly be prudent to monitor the effects of giving octreotide with any of the oral antidiabetics. The manufacturer of lanreotide also recommends that blood glucose levels should be checked in diabetic patients to determine whether antidiabetic treatment needs to be adjusted.¹⁵

Antidiabetics + SSRIs

Hypoglycaemia has occurred in patients with diabetes when given fluoxetine or sertraline and hypoglycaemia unawareness has also been reported with fluoxetine. Conversely, two isolated reports describe hyperglycaemia in patients given fluvoxamine or sertraline. Fluvoxamine slightly reduces the clearance of tolbutamide

and increases the maximum plasma levels of glimepiride, but these changes are unlikely to be clinically relevant in most patients. Fluoxetine did not alter the pharmacokinetics of tolbutamide, and sertraline did not significantly affect the pharmacokinetics of glibenclamide (glyburide) or tolbutamide.

Clinical evidence

(a) Fluoxetine

One study found that single, or multiple doses of fluoxetine for 8 days, did not affect the pharmacokinetics or the blood glucose-lowering effects of **tolbutamide** 1 g.¹ However, studies in obese patients with type 2 diabetes receiving oral antidiabetics have shown that fluoxetine can cause significant weight loss, reduce fasting plasma glucose levels and improve glycaemic control (decrease in glycosylated haemoglobin levels),^{2,3} and in those receiving **insulin**, decrease the daily **insulin** dose.⁴ The manufacturers of fluoxetine say that hypoglycaemia has occurred in diabetic patients when they took fluoxetine alone, and hyperglycaemia has developed following discontinuation.^{5,6}

An **insulin**-dependent diabetic experienced symptoms of hypoglycaemia (nausea, tremor, sweating, anxiety, lightheadedness) after starting to take fluoxetine 20 mg each night. The symptoms disappeared when the fluoxetine was stopped and reappeared when it was restarted. However, blood glucose levels were found to be normal (9 to 11 mmol/L), so it is likely that the effects were purely adverse effects of fluoxetine that were mistaken for symptoms of hypoglycaemia.⁷ In contrast, another patient with type 1 diabetes experienced a loss of hypoglycaemic awareness while taking fluoxetine 40 mg daily. Approximately one month after fluoxetine was started, he reported an increased incidence of hypoglycaemia, but these episodes were not accompanied by typical adrenergic symptoms (which he had previously experienced). After 3 grand mal seizures which occurred with blood glucose readings ranging from 1.9 to 2.2 mmol/L, the dose of fluoxetine was gradually decreased. Hypoglycaemic unawareness resolved when the fluoxetine dosage was reduced to 10 mg every second day. Within weeks of discontinuing fluoxetine, blood glucose levels had risen considerably and hypoglycaemia did not recur.⁸

(b) Fluvoxamine

Hyperglycaemia occurred in a 60-year-old woman with type 2 diabetes controlled with **insulin**, 5 days after fluvoxamine was started. Blood glucose levels, which had approximately doubled, decreased when the fluvoxamine was stopped, but increased and then decreased again when the fluvoxamine was restarted and then stopped.⁹

A study in 14 healthy subjects given fluvoxamine 75 or 150 mg daily for 5 days, with a single 500-mg dose of **tolbutamide** on the third day, found that the clearance of **tolbutamide** was modestly reduced by 19% by the 75 mg dose and by 33% by the 150 mg dose of fluvoxamine. The clearance of its metabolites (4-hydroxytolbutamide and carboxytolbutamide) was also significantly decreased.¹⁰

A randomised, double-blind, crossover study in 12 healthy subjects given fluvoxamine 100 mg or placebo daily for 4 days, with a single 500-microgram dose of **glimepiride** on the fourth day, found the AUC of **glimepiride** was not significantly affected by fluvoxamine. Peak plasma levels of **glimepiride** were increased by 43% and the elimination half-life was prolonged from 2 to 2.3 hours, but there was no significant change in the effects of **glimepiride** on blood glucose concentrations.¹¹

(c) Sertraline

After taking sertraline 200 mg daily for 22 days the clearance of a single intravenous dose of **tolbutamide** was decreased by 16% in 25 healthy subjects.¹² In another study in 11 healthy subjects, the pharmacokinetics of a single 5-mg dose of **glibenclamide** (**glyburide**) were found to be unaffected by sertraline, taken in increasing doses up to 200 mg daily over 15 days. Blood glucose levels were also unchanged.¹³ However, there is a report of a patient with schizoaffective disorder and type 2 diabetes who developed hypoglycaemia during treatment with sertraline, risperidone and **glibenclamide**.¹⁴ In contrast, another report describes a patient with diet-controlled, type 2 diabetes, whose glucose levels increased after initiation of sertraline treatment.¹⁵

Mechanism

Fluvoxamine probably decreases the clearance of tolbutamide by inhibition of its metabolism by the cytochrome P450 isoenzyme CYP2C9. This mechanism may also partly explain the increase in plasma levels of

glimepiride. However, as the glimepiride AUC was not increased and the half-life was only slightly increased, the increase in plasma levels may also be due to an increased rate of glimepiride absorption caused by the SSRI.^{10,11} The effects of other SSRIs may also be associated with enzyme inhibition.¹⁴

Importance and management

There would seem to be little reason for avoiding concurrent use of fluoxetine, fluvoxamine or sertraline with sulphonylureas, but until more is known it would seem prudent to monitor diabetic control. The manufacturers of fluoxetine, **paroxetine** and sertraline warn that dosages of insulin or oral antidiabetics may need adjustment during concurrent use.^{5,6,16,17}

Antidiabetics + St John's wort (*Hypericum perforatum*)

St John's wort modestly decreases the AUC of rosiglitazone. Repaglinide is similarly metabolised and may therefore be expected to interact similarly. St John's wort did not affect the metabolism of tolbutamide.

Clinical evidence

(a) Rosiglitazone

A preliminary report of a pharmacokinetic study¹ states that St John's wort 900 mg daily decreased the AUC of a single dose of rosiglitazone by 26% and increased its clearance by 35%.

(b) Tolbutamide

In a study using tolbutamide as a probe drug for CYP2C9 activity, St John's wort 900 mg daily had no effect on the metabolism of a single dose of tolbutamide either after one day or after 2 weeks of use.² Similarly, in another study, a St John's wort preparation with low hyperforin content (*Esbericum*) at a dose of 240 mg daily had no effect on tolbutamide metabolism.³

Mechanism

Rosiglitazone is known to be metabolised principally by the cytochrome P450 isoenzyme CYP2C8, and it was therefore concluded that St John's wort induces CYP2C8. The magnitude of the effect of St John's wort was

not influenced by CYP2C8 genotype.¹ St John's wort has no effect on the metabolism of tolbutamide via CYP2C9.

Importance and management

The clinical relevance of the modest reduction in rosiglitazone levels has not been assessed, but it would seem unlikely to be important. However, the authors state that St John's wort use should be monitored when patients are given CYP2C8 substrates. Of the antidiabetics, in addition to rosiglitazone, this would also include **repaglinide**. Note that **repaglinide** is also a substrate for CYP3A4, of which St John's wort is an established inducer. Further study is needed. No special precautions would appear to be necessary if tolbutamide and St John's wort are used together.

Antidiabetics + Statins

No clinically relevant adverse interactions appear to have been reported between the statins and the sulphonylureas. One study reported an increased incidence of adverse effects with repaglinide and simvastatin, the clinical relevance of which is unclear.

Most studies have shown no pharmacokinetic interaction or increased incidence of adverse effects when pioglitazone or rosiglitazone were used with atorvastatin or simvastatin. Subcutaneous exenatide modestly decreased the AUC of lovastatin, but no clear pattern of altered efficacy of statins was noted in exenatide clinical trials.

Clinical evidence

A. Exenatide

The manufacturer notes¹ that subcutaneous exenatide 10 micrograms twice daily decreased the AUC of a single dose of **lovastatin** by 40%, and the maximum level by 28%. However, they also note that in clinical trials of exenatide, the use of exenatide for 30 weeks in patients already taking statins was not associated with consistent changes in lipid profiles.¹

B. Repaglinide

A three-period, crossover, open-label study in healthy subjects found that **simvastatin** 20 mg daily increased the maximum plasma level of repaglinide 2 mg three times daily by 26%, although there was high variability and the mean bioavailability of repaglinide was increased by 8%. There was a higher incidence of adverse effects during concurrent use.²

C. Sulphonylureas

(a) Chlorpropamide

A study in 7 patients with type 2 diabetes and hypercholesterolaemia, taking chlorpropamide 125 to 750 mg daily, found that **lovastatin** 20 mg twice daily for 6 weeks reduced low-density lipoprotein cholesterol by 28%, total cholesterol by 24% and apolipoprotein B by 24%. The chlorpropamide plasma levels were unchanged, and the diabetic control remained unaltered.³

(b) Glibenclamide (Glyburide)

Groups of 16 healthy subjects taking **fluvastatin** 40 mg or **simvastatin** 20 mg daily were given single 3.5-mg oral doses of glibenclamide on days 1, 8 and 15. The maximum plasma concentration and the AUC of glibenclamide were increased by about 20% by the statins. The blood glucose-lowering effects of the glibenclamide remained virtually unchanged by both **fluvastatin** and **simvastatin** in these subjects, and also when **fluvastatin** was tested in a group of 32 patients with type 2 diabetes.⁴ The manufacturers of **fluvastatin** report a study in which **fluvastatin** 40 mg twice daily was given to diabetic patients stable taking glibenclamide 5 to 20 mg daily. **Fluvastatin** increased the AUC of glibenclamide by 1.7-fold, and increased the maximum serum levels by 1.6-fold, without causing significant changes in glucose levels.⁵

(c) Tolbutamide

A single 1-g oral dose of tolbutamide was given to two groups of 16 healthy subjects taking **fluvastatin** 40 mg or **simvastatin** 20 mg. The pharmacokinetics of the tolbutamide were affected only to a very minor extent, and the blood glucose-lowering effects of the tolbutamide were unchanged.⁴

D. Thiazolidinediones

One review suggested that patients receiving thiazolidinediones (95% taking **troglitazone**) were more likely to develop hepatotoxicity if taking **atorvastatin** than when taking **simvastatin**.⁶ However, **troglitazone** has now been withdrawn due to its hepatotoxic effects. The same authors more recently conducted a similar study. They analysed the FDA adverse event reporting database for reactions affecting muscle, liver, pancreas, or bone marrow where **simvastatin** or **atorvastatin** were implicated. They then looked for events where antidiabetic drugs also featured. Of the 3767 events identified for atorvastatin, 40 also involved rosiglitazone and 20 also involved pioglitazone. Of the 3651 events identified for simvastatin, 10 also involved rosiglitazone and 9 also involved pioglitazone. About half of these events involving pioglitazone or rosiglitazone resulted in hospitalisation or death. Although the data did not allow for an assessment of whether this rate was greater than that expected, the authors say that if simvastatin is used as the control, the data suggest that the number of cases of adverse events with atorvastatin and a thiazolidinedione are greater than would be expected by chance alone.⁷

However, in a study in healthy subjects, **pioglitazone** 45 mg daily did not significantly affect the pharmacokinetics of **simvastatin** 80 mg daily and concurrent use was well tolerated.⁸ Similarly, there was no pharmacokinetic interaction between **pioglitazone** 45 mg daily and **atorvastatin** 80 mg daily.⁹ Moreover, clinical use of **rosiglitazone** with **atorvastatin** in patients with type 2 diabetes for 16 weeks was well tolerated,¹⁰ as was the clinical use of **rosiglitazone** or **pioglitazone** with **simvastatin**.¹¹

Mechanism

The small changes in the pharmacokinetics of glibenclamide caused by fluvastatin and simvastatin are not understood, but they do not appear to be clinically significant. The interaction between atorvastatin or simvastatin and the thiazolidinediones is thought to involve the cytochrome P450 isoenzyme CYP3A4, although this is as yet unconfirmed.

Importance and management

There is little evidence to suggest that special precautions appear to be needed by diabetic patients taking any of the pairs of sulphonylureas and statins cited here (chlorpropamide with lovastatin, or glibenclamide or tolbutamide with fluvastatin or simvastatin). However, the manufacturers of fluvastatin suggest that a serious interaction cannot be ruled out and therefore advise that the use of glibenclamide should be avoided wherever possible.⁵

The clinical significance of the increased incidence of adverse effects with repaglinide and simvastatin is unclear and so an element of caution would seem prudent.

Most studies have shown no pharmacokinetic interaction or increased incidence of adverse effects when pioglitazone or rosiglitazone were used with atorvastatin or simvastatin. The clinical relevance of the apparent increased incidence of adverse muscle and liver effects with the use of pioglitazone or rosiglitazone together with atorvastatin is unclear. Further study is needed. The clinical relevance of the decrease in lovastatin levels with exenatide is also unclear. But experience in clinical studies suggests that it is unlikely to be significant.

Note that a number of the large-scale trials of the use of lipid-regulating drugs in primary or secondary prevention of cardiovascular events included patients with diabetes. A review of these subgroups concluded that statins were the drug of choice for lipid-lowering therapy in patients with type 2 diabetes and known coronary artery disease or other cardiovascular risk factors. There was no evidence to recommend one statin over another.¹²

Antidiabetics + Sucralfate

Sucralfate appears not to affect the pharmacokinetics of chlorpropamide or rosiglitazone.

Clinical evidence, mechanism, importance and management

(a) Chlorpropamide

A two-way crossover study in 12 healthy subjects found that sucralfate 1 g four times daily, given 1 hour before meals, had no significant effect on the pharmacokinetics of a single 250-mg dose of chlorpropamide.¹ No additional precautions would therefore seem to be necessary on concurrent use.

(b) Rosiglitazone

A single-dose study found that sucralfate 2 g taken 45 minutes before rosiglitazone 8 mg had no significant effect on the pharmacokinetics of rosiglitazone. No special precautions are needed during concurrent use.²

Antidiabetics + Sugar-containing pharmaceuticals

Some pharmaceutical preparations may contain sufficient amounts of sugar to affect the control of diabetes. Diabetics should be warned and advised of sugar-free alternatives where appropriate.

Clinical evidence, mechanism, importance and management

Pharmaceuticals, especially liquid formulations, may contain sugar in significant amounts. The extent to which the use of preparations like these will affect the control of diabetes clearly depends upon the amounts ingested, but the problem is by no means merely theoretical. One report describes the loss of diabetic control (glycosuria) in a woman with type 1 diabetes receiving insulin when given psyllium effervescent powder (*Metamucil* instant-mix), which contains sugar.¹

The range of other sugar-containing preparations is far too extensive to be listed here. Because of concerns over sugar-containing medicines and dental caries, in children in particular, the number of sugar-free preparations has grown considerably over recent years. In the UK the BNF and MIMS provide guidance as to which preparations are sugar-free. Diabetics should be warned about sugar-containing medicines, and given guidance about the terminology used in labelling. Sweetening agents of note to diabetics include: **invert sugar** (dextrose and fructose), **invert syrup** (67% w/w invert sugar), **syrup BP** (66% w/w sucrose), **glucose liquid**

(dextrose content 10 to 20%), **glucose syrup** (33.3% liquid glucose in syrup) and **honey** (70 to 80% glucose and fructose).²

- Greenwood J. Sugar content of liquid prescription medicines. *Pharm J* (1989) 243, 553–7.

Antidiabetics + Sulfapyrazone

Sulfapyrazone has no effect on the insulin requirements of diabetics, nor does it affect the control of diabetes in patients taking glibenclamide (glyburide). Increased blood glucose-lowering effects might occur if sulfapyrazone is given with tolbutamide, but as yet there appear to be no case reports of this interaction. Sulfapyrazone modestly increased the AUC of nateglinide, but this is unlikely to be clinically relevant.

Clinical evidence

(a) Insulin

A double-blind study in 41 adult diabetics found that sulfapyrazone 600 to 800 mg daily had no clinically significant effects on insulin requirements over a 12-month period.¹

(b) Nateglinide

In a crossover study in healthy subjects, sulfapyrazone 200 mg twice daily for 7 days increased the mean AUC of a single 120-mg dose of nateglinide by 28%, but did not change the mean maximum plasma level.²

(c) Sulphonylureas

A study in 19 type 2 diabetics taking **glibenclamide** found that sulfapyrazone 800 mg daily did not affect diabetic control.³

A detailed study of the pharmacokinetics of **tolbutamide** in 6 healthy subjects found that sulfapyrazone 200 mg every 6 hours for a week, almost doubled the half-life of a 500-mg intravenous dose of **tolbutamide**, from 7.3 to 13.2 hours, and reduced the plasma clearance by 40%.⁴

Mechanism

Sulfapyrazone is an inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which tolbutamide and nateglinide are metabolised.

Importance and management

Information about an interaction between tolbutamide and sulfapyrazone appears to be limited to the report cited. So far there appear to be no reports of adverse interactions in patients, but what is known suggests that increased blood glucose-lowering effects, and possibly hypoglycaemia could occur if the dosage of tolbutamide is not reduced. Such an interaction has been described with phenylbutazone, which has a close structural similarity to sulfapyrazone (see 'Antidiabetics + NSAIDs; Phenylbutazone and related drugs', p.498). Patients should be warned if sulfapyrazone is added to established treatment with tolbutamide. The modest increase in nateglinide exposure when given with sulfapyrazone has not been assessed in diabetics, but it seems unlikely to be clinically relevant. There seems to be nothing documented about any other clinically important interactions between antidiabetics and sulfapyrazone.

Antidiabetics + Sulfonamides

The blood glucose-lowering effects of some of the sulphonylureas are increased by some, but not all, sulfonamides, due to inhibition of their metabolism. However, sulfaphenazole, which was shown to have an important pharmacokinetic interaction with tolbutamide, is no longer used clinically, and other sulfonamides appear less likely to interact. Nevertheless, occasionally and unpredictably

bly acute hypoglycaemia has occurred in individual patients taking various combinations of sulfonamides and sulphonylureas. There appear to be no reports of a serious adverse interaction between insulin and the sulfonamides. Co-trimoxazole alone may rarely cause hypoglycaemia.

Clinical evidence

'Table 13.3', (p.508) summarises the information on the interactions between sulphonylureas and sulfonamides. For a report of the combined use of co-trimoxazole and fluconazole causing hypoglycaemia with **gliclazide**, see 'Antidiabetics + Azoles; Fluconazole', p.479.

Mechanism

The sulfonamides may inhibit the metabolism of the sulphonylureas so that they accumulate in the body. In this way their serum levels and blood glucose-lowering effects are enhanced.¹⁻⁴ Greater understanding of metabolic mechanisms has led to the realisation that some sulfonamides are inhibitors of the cytochrome P450 isoenzyme CYP2C9 by which many of the sulphonylureas are metabolised. Tolbutamide, in particular, is now recognised as an important substrate of CYP2C9.^{5,6} Of the sulfonamides, *in vitro* data suggest that sulfaphenazole is a potent inhibitor of CYP2C9, with sulfadiazine, sulfamethizole, sulfafurazole (sulfisoxazole) and sulfamethoxazole being moderate to minor inhibitors, and sulfapyridine, sulfadimethoxine and sulfamonomethoxine having little inhibitory activity.⁶ CYP2C9 shows genetic polymorphism, therefore any interaction might only be clinically relevant in a subgroup of the population. There is also some evidence that the sulfonamides can displace the sulphonylureas from their protein binding sites.⁴

Where some of the cases of hypoglycaemia cannot be predicted on pharmacokinetic grounds, it is worth noting that hypoglycaemia induced by co-trimoxazole, in the absence of a conventional antidiabetic,⁷⁻¹¹ and sometimes associated with renal failure,⁹ high dose of sulfonamide,^{7,11} advanced age,^{8,10} or malnutrition,⁷ has been described. Note that trimethoprim alone may cause interactions mediated via inhibition of CYP2C8 and CYP2C9, see 'Antidiabetics + Trimethoprim', p.510.

Importance and management

Information is very patchy and incomplete. Most sulfonamides seem to have caused marked problems (acute hypoglycaemia) in only a few patients and serious interactions are uncommon. When a sulfonamide is first added to established treatment with a sulphonylurea, warn the patient that increased blood glucose-lowering effects, sometimes excessive, are a possibility, but that problems appear to be uncommon or rare. Nevertheless, the cautious approach would be to increase the frequency of blood glucose monitoring. In one study, co-trimoxazole did not appear to cause any significant changes in blood glucose or insulin concentrations in patients receiving **insulin**.¹² However, note that co-trimoxazole alone may rarely cause hypoglycaemia (see Mechanism above). For the interactions of trimethoprim alone, see 'Antidiabetics + Trimethoprim', p.510.

Antidiabetics + Terbinafine

Terbinafine is reported not to interact with tolbutamide, and did not affect glucose control in a study in patients treated with insulin or oral antidiabetics.

Clinical evidence

A large-scale post-marketing survey did not find any interaction in patients taking terbinafine with **tolbutamide** [number unknown].¹ In a 154 patient subgroup of this survey no additional risk was noted in patients taking antidiabetics with terbinafine.² In a clinical trial in 89 patients with diabetes and toenail fungal infections, oral terbinafine 250 mg daily for 12 weeks had no effect on blood glucose levels in 83% of patients. Eleven (12.4%) of the patients had an elevated blood glucose level at baseline, which was normal at the end of the study, and 4 patients had a normal baseline blood glucose, which became elevated at the end of the study. No episodes of hypoglycaemia were reported. Patients in this study were treated with **insulin** or **oral antidiabetics** (not specified).³

Mechanism

On the basis of studies with human liver microsomes, terbinafine is unlikely to alter the metabolism of tolbutamide.⁴

Importance and management

Terbinafine does not appear to interact with tolbutamide or affect glucose control in patients treated with insulin or oral antidiabetics. No special precautions are required on concurrent use.

Antidiabetics + Tetracyclines

A few early reports indicated that the blood glucose-lowering effects of insulin and the sulphonylureas may sometimes be increased by oxytetracycline. There is also a case of hypoglycaemia involving insulin and doxycycline. Phenformin-induced lactic acidosis may be precipitated by tetracyclines.

Clinical evidence

(a) Insulin

A diabetic with poorly controlled blood glucose levels needed a marked reduction in his insulin dosage from 208 to 64 units daily in order to control the hypoglycaemia that developed when **oxytetracycline** 250 mg four times daily was given. This reaction was also seen when the patient was given a second course of antibacterials, and in another patient.¹ A report briefly lists a case of hypoglycaemia when a patient receiving insulin was given **doxycycline**,² and another case describes doxycycline-induced hypoglycaemia in an elderly diabetic patient treated by diet alone.³

(b) Phenformin

There are now at least 6 cases on record of lactic-acidosis in patients taking phenformin that were apparently precipitated by the concurrent use of **tetracycline**.⁴⁻⁷

(c) Sulphonylureas

Marked hypoglycaemia occurred in an elderly patient taking **tolbutamide** when **oxytetracycline** was given,⁸ and another study in diabetic patients similarly found that **oxytetracycline** could reduce blood glucose levels.⁹ The half-life of **glymidine** has been found to be prolonged from 4.6 to 7.6 hours by **doxycycline**,¹⁰ whereas a brief comment in another report

Table 13.3 Interactions between antidiabetics and sulfonamides

Drugs	Information documented	Refs
Chlorpropamide		
+ sulfafurazole (sulfisoxazole)	1 case of acute hypoglycaemia	1
+ sulfadimidine	1 case of acute hypoglycaemia	2
+ co-trimoxazole	2 cases of acute hypoglycaemia	3, 4
Glibenclamide		
+ co-trimoxazole	In a large review of glibenclamide-associated hypoglycaemia 6 of 57 patients were also taking co-trimoxazole	5
	1 case of hypoglycaemia	6
	No pharmacokinetic interaction in 8 patients	7
Glibornuride		
+ sulfaphenazole	Half-life increased by 34% in 4 subjects (2 diabetic, 2 healthy)	8
Gliclazide		
+ co-trimoxazole	4 cases of acute hypoglycaemia	6
Glipizide		
+ co-trimoxazole	1 case of acute hypoglycaemia	9
	No pharmacokinetic interaction, or change in blood glucose-lowering effects in 8 healthy subjects	10
Insulin		
+ co-trimoxazole	No overall changes in blood glucose or insulin concentrations in 8 patients	11
Tolbutamide		
+ co-trimoxazole	Clearance of intravenous tolbutamide reduced by 25%, half-life increased by 30% in 7 healthy subjects	12
+ sulfafurazole (sulfisoxazole)	3 cases of severe hypoglycaemia	13, 14
	No pharmacokinetic interaction	15, 16
+ sulfamethizole	Half-life of tolbutamide increased 60%. Metabolic clearance reduced by about 40%	17
+ sulfaphenazole	Two cases of severe hypoglycaemia	16
	Half-life of tolbutamide increased three to sixfold	15, 16, 18, 19, 20
+ sulfadiazine	Half-life of tolbutamide increased by about 57%	18
+ sulfadimethoxine	No pharmacokinetic interaction	15, 16
+ sulfamethoxazole	Clearance reduced 14%, half-life increased 20% after intravenous use	12
	Half-life increased by about 65%	15
+ sulfamethoxy-pyridazine	No pharmacokinetic interaction	16
Unnamed sulphonylurea		
+ co-trimoxazole	1 case of acute hypoglycaemia	11

suggests that **demeclocycline** and **doxycycline** may not affect **chlorpropamide** disposition.¹¹

Mechanism

Not understood. Several mechanisms have been suggested including prolongation of the half-life of insulin and interference with adrenaline-induced glycaemia.³

Importance and management

Information about the interactions between the sulphonylureas or insulin and the tetracyclines is very limited indeed, and clinically important interactions appear to be very uncommon. Concurrent use need not be avoided, but be aware of this interaction in case of an unexpected response to treatment.

Phenformin was withdrawn in some countries because it was associated with a high incidence of lactic acidosis; where available, concurrent use with tetracyclines should be avoided. However, there is nothing to suggest that there is an increased risk if tetracyclines are given with **metformin**.

Antidiabetics + Thioctic acid

Thioctic acid is reported not to interact with acarbose, metformin or glibenclamide (glyburide).

Clinical evidence, mechanism, importance and management

A study in 24 healthy subjects given tablets containing thioctic acid 200 mg and **metformin** 500 mg found that the pharmacokinetics of the **metformin** were unchanged by the presence of the thioctic acid, and the authors of the report say that there was also no pharmacodynamic interaction.¹ The report gives very few details. A further study in 24 healthy subjects found that a single 600-mg dose of thioctic acid given with **glibenclamide (glyburide)** 3.5 mg did not result in any clinically relevant pharmacokinetic interaction, and thioctic acid did not alter the effect of **glibenclamide** on glucose or insulin levels.² Similarly, there was no evidence of a change in thioctic acid pharmacokinetics or pharmacodynamics when it was given to healthy subjects with **acarbose**.²

No special precautions seem to be required if thioctic acid is given to patients taking **acarbose, metformin** or **glibenclamide**.

Antidiabetics + Tibolone

Tibolone may slightly impair glucose tolerance and therefore possibly reduce the effects of the antidiabetics.

Clinical evidence, mechanism, importance and management

One woman developed diabetes 14 weeks after starting tibolone 2.5 mg daily. However, she had a high normal fasting blood glucose level before starting tibolone, and the diabetes did not resolve on withdrawing the drug.¹ The manufacturers of tibolone noted that on their adverse drug event database they had only 3 cases of diabetes occurring during the use of tibolone, and 3 cases of aggravation of diabetes during its use, which they considered a very low number in relation to the extent of tibolone use.²

A metabolic study in 10 women with type 2 diabetes given tibolone 2.5 mg daily and stabilised with diet and oral antidiabetics found there were no changes in glycaemic control, as measured by glycosylated haemoglobin levels.³ Conversely, a longer 12-month study in 14 women with type 2 diabetes given tibolone found a slight deterioration in glycaemic control (as measured by serum fructosamine),⁴ and an early study found that tibolone caused a slight decrease in glucose tolerance in non-diabetic patients.⁵

The manufacturers of tibolone say that patients with diabetes should be closely supervised.^{6,7} It would therefore seem prudent to increase the frequency of blood glucose monitoring if tibolone is started or stopped.

Antidiabetics + Tobacco or Nicotine

Diabetics who smoke tobacco may need more subcutaneous insulin than non-smokers. Smoking or, to a lesser extent, nicotine patches may increase insulin resistance, and stopping smoking can improve glycaemic control in both type 1 and type 2 diabetics. However, the effects of smoking on diabetes appear to be complex, as some studies have reported that smoking does not affect insulin sensitivity or glycaemic control. Preliminary evidence shows that smoking increases the absorption of inhaled insulin.

Clinical evidence, mechanism, importance and management

A study in 163 patients with type 1 diabetes found that, on average, the 114 who smoked needed 15 to 20% more subcutaneous **insulin** than the non-smokers, and up to 30% more **insulin** if they smoked heavily.¹ Possible mechanisms include decreased absorption of **insulin** from the subcutaneous tissue because of peripheral vasoconstriction,² and a significant rise (40 to 100%) in the levels of the hormones that oppose the actions of **insulin**.^{3,4}

Serum **insulin** levels during the first 6 hours after inhaled **insulin** were 58% higher in smokers than in non-smokers, and peak **insulin** levels were about threefold higher. Minor hypoglycaemia requiring a glucose infusion occurred in 12 smokers but in only one non-smoker. The increased absorption was possibly due to cigarette smoke increasing the permeability of the alveolar-capillary barrier.⁵ It should be noted that use of inhaled **insulin** is contraindicated in patients who smoke, or have smoked within the past 6 months.⁶

In a double-blind, crossover study in 12 smokers with type 2 diabetes, stabilised with diet alone or with **oral antidiabetics**, the effect of smoking one cigarette every hour for 6 hours compared with transdermal nicotine (30 cm² patch) or a placebo patch. Cigarette smoking and the nicotine patch did not affect endogenous insulin secretion, when compared with placebo, but smoking impaired peripheral insulin action, and resulted in lower rates of glucose utilisation and greater hepatic glucose production. The nicotine patch similarly impaired insulin action, but this was much less pronounced than after cigarette smoking, possibly due to the lower plasma levels of nicotine attained with the patch.⁷

In another study, glycaemic control (as measured by glycosylated haemoglobin) was modestly improved in 7 subjects with type 1 diabetes and 27 subjects with type 2 diabetes, one year after they had stopped smoking. This improved control was considered clinically significant.⁸ In a study in patients with type 2 diabetes stabilised with diet alone or diet plus **sulphonylureas** with or without **metformin**, insulin resistance was higher in the 28 smokers than the 12 non-smokers.⁹ Further studies have reported that smoking in diabetics is associated with poor glycaemic control,¹⁰ microalbuminuria,¹⁰ and impaired insulin clearance.¹¹ However, other studies have suggested that smoking does not affect **insulin** requirement in type 1 diabetics¹² or have a significant effect on glycaemic control in type 1 or type 2 diabetics.^{3,12,13} There are numerous other studies on the relationship between smoking and diabetes or insulin resistance in non-diabetics, and only a few are cited here as examples. Some studies have indicated that smoking could increase the risk of type 2 diabetes (relative risk of 2.6) and that tobacco use is associated with a low insulin response.¹⁴ However, other studies suggest that a causal relationship between smoking and insulin resistance is unlikely,^{15,16} although in one of the studies¹⁶ exposure to environmental tobacco smoke was associated with lower insulin sensitivity.

Glycaemic control is not the only factor of importance with smoking in diabetics. Cigarette smoking may also accelerate progression of atherosclerosis, increase blood pressure, and increase macrovascular complications.^{7,16,17} Diabetics who smoke should be given all the help they need to stop smoking.^{10,17}

Antidiabetics + Tricyclic and related antidepressants

Interactions between antidiabetics and tricyclic or tetracyclic antidepressants appear to be rare, but four isolated cases of hypoglycaemia have been reported.

Clinical evidence, mechanism, importance and management

A study in 4 patients suggested that **amitriptyline** 75 mg daily for 9 days did not affect the half-life of a single 500-mg dose of **tolbutamide**.¹ Although there is some evidence of a change in glucose metabolism during treatment with **mianserin**,^{2,4} the alteration failed to affect the control of diabetes in a study in 10 patients and there appear to be no reports of adverse effects caused by concurrent use.³ In contrast there are four case reports describing interactions:

- A patient taking **tolazamide** became hypoglycaemic 11 days after starting to take **doxepin** 250 mg daily. The patient was eventually stabilised on a daily dose of **tolazamide** that was only 10% of that used before the **doxepin** was given.⁵
- A patient taking **chlorpropamide** (initially 25 mg increased to 75 mg daily) developed marked hypoglycaemia 3 days after starting **nortriptyline** 125 mg daily. The **chlorpropamide** was stopped.⁵
- A patient receiving **insulin** developed violent and agitated behaviour (but no adrenergic symptoms) and hypoglycaemia when she started to take **amitriptyline** 25 mg at bedtime.⁶
- An elderly diabetic woman taking **glibenclamide (glyburide)** and **phenformin** developed hypoglycaemia when given **maprotiline**. She was restabilised on half the dose of **glibenclamide** and **phenformin**.⁷

Apart from these isolated cases^{5–7} the literature seems to be silent about interactions between these antidiabetics and the tricyclic or tetracyclic antidepressants. Bearing in mind the length of time these groups of drugs have been available, the risk of a clinically important interaction would seem to be very small.

Antidiabetics + Trimethoprim

Trimethoprim increases the AUC of repaglinide and would be expected to increase its effects in some patients. The effect of trimethoprim on the AUC of rosiglitazone is more modest and less likely to be clinically relevant. Trimethoprim does not appear to significantly affect the pharmacokinetics of intravenous tolbutamide.

Clinical evidence

(a) Repaglinide

In a study in 9 healthy subjects trimethoprim 160 mg twice daily for 3 days increased the AUC and the maximum plasma level of a single 250-microgram dose of repaglinide by 61% and 41%, respectively. However, the blood glucose-lowering effect of repaglinide was unchanged.¹

(b) Rosiglitazone

In a study in 10 healthy subjects trimethoprim 160 mg twice daily for 4 days increased the AUC of a single 4-mg dose of rosiglitazone given on day 3 by 37%. The half-life of rosiglitazone was increased by 26% but the peak plasma level was only slightly affected (14% increase).² Similarly, in another study, trimethoprim 200 mg twice daily for 5 days increased the AUC of a single 8-mg dose of rosiglitazone by 31% and increased the half-life by 27%.³

(c) Tolbutamide

Trimethoprim 150 mg twice daily for 7 days prolonged the elimination half-life of a single intravenous 500-mg dose of tolbutamide by 19% in a study in 7 healthy subjects.⁴

Mechanism

Data suggest that trimethoprim inhibits the metabolism of repaglinide and rosiglitazone by the cytochrome P450 isoenzyme CYP2C8. Tolbutamide is metabolised by CYP2C9, and it is thought possible that trimethoprim may have a slight inhibitory effect on this isoenzyme, although there is very little information about this.⁵

Importance and management

The clinical relevance of the pharmacokinetic changes have not been assessed. However, the changes seen with repaglinide suggest that some patients might experience an increase in the effects of this drug. The UK manufacturers of repaglinide⁶ suggest that the concurrent use of trimethoprim should be avoided as the effect of larger doses of both drugs are unknown. The US manufacturers suggest that repaglinide dosage adjustments may be necessary.⁷ If both drugs are used it would seem prudent to increase the frequency of blood glucose monitoring until the effects are known.

The more modest increase in AUC of rosiglitazone is less likely to be clinically important, but, until more experience is gained, some caution is warranted. No interaction would be expected between trimethoprim and tolbutamide, although note that co-trimoxazole has rarely caused hypoglycaemia alone or combined with various sulphonylureas, see 'Antidiabetics + Sulphonamides', p.506.

Exenatide + Miscellaneous

The rate and extent of paracetamol (acetaminophen) absorption are reduced by exenatide, even when the paracetamol is given up to four hours after the exenatide. The manufacturer therefore recommends that exenatide be used with caution with drugs that require rapid gastrointestinal absorption or drugs that require a threshold level for efficacy (such as the oral contraceptives and some antibacterials). Further study is necessary to establish the clinical relevance of any of these potential interactions.

Clinical evidence, mechanism, importance and management

In a study using paracetamol (acetaminophen) as a marker of gastric emptying, subcutaneous exenatide 10 micrograms delayed and reduced the maximum plasma levels of paracetamol from 0.6 to 4.2 hours and by 37% to 56%, respectively. The overall extent of absorption was slightly reduced (14% to 24% reduction in AUC). This effect was seen when paracetamol was given simultaneously with exenatide, or one, two, and

four hours after exenatide. It was not seen when paracetamol was given one hour before exenatide.¹

This study demonstrates that exenatide slows gastric emptying, and has the potential to delay the absorption of other drugs. The manufacturer recommends that exenatide should be used with caution in patients receiving oral drugs that require rapid gastrointestinal absorption. They do not give any specific examples.² However, they do note that exenatide does not affect the absorption of lisinopril.

Because exenatide delays gastric emptying and may reduce the rate and extent of absorption of orally administered drugs the manufacturer suggests that it should be used with caution in patients receiving oral drugs that are dependent on threshold concentrations for efficacy. They give antibacterials and oral contraceptives as an example (but no drugs are specifically named), and recommend that they should be taken at least one hour before exenatide.² Whether this is clinically necessary remains to be shown.

2. Byetta (Exenatide). Amylin Pharmaceuticals, Inc. US Prescribing information, February 2007.

Insulin + Naltrexone

The insulin requirements of a patient rose by about 30% when naltrexone was given.

Clinical evidence, mechanism, importance and management

A patient with type 1 diabetes was given naltrexone in an experimental study of the treatment of anorexia nervosa. During two periods of 5 days while taking the naltrexone (dosage not stated), the blood glucose levels of the patient remained unchanged but the insulin dosage requirements rose from 52.8 and 61.4 units daily to 71.4 and 76 units daily (a rise of about 30%). The reason is not known but the authors of this report point out that this apparent interaction must have been due to the actions of insulin rather than on its release because this patient had no endogenous insulin.¹

The general clinical importance of this interaction is not known but it would be prudent to be alert for any evidence of increased insulin requirements if naltrexone is used in any patient.

1. Marrazzi MA, Jacober S, Luby ED. A naltrexone-induced increase in insulin requirement. *J Clin Psychopharmacol* (1994) 14, 363-5.

Metformin + Cefalexin

Cefalexin modestly increased the serum levels of metformin in a single-dose study.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 12 healthy subjects cefalexin 500 mg increased the AUC and maximum serum levels of a single 500-mg dose of metformin by 24% and 34%, respectively. Cefalexin reduced the renal clearance of metformin by 14% by inhibiting metformin tubular secretion via the organic cation system.¹ The clinical relevance of these small changes is uncertain, but they could be greater with longer-term use. The authors recommend that patients receiving metformin with cefalexin should have metformin levels monitored or an alternative antibacterial to cefalexin should be considered.¹ However, based on the available evidence this seems somewhat overcautious.

1. Jayasagar G, Krishna Kumar M, Chandrasekar K, Madhusudan Rao C, Madhusudan Rao Y. Effect of cephalexin on the pharmacokinetics of metformin in healthy human volunteers. *Drug Metabol Drug Interact* (2002) 19, 41-8.

Metformin + Iodinated contrast media

Parenteral administration of iodinated contrast media may cause renal failure, which could result in lactic acidosis in patients taking metformin.

Clinical evidence, mechanism, importance and management

Parenteral administration of iodinated contrast media to patients taking metformin may result in lactic acidosis. However, the problem is reported to occur only if the contrast media causes renal failure and metformin use is continued. This is because metformin is mainly excreted by the kidneys and in renal failure toxic levels may accumulate,¹ which may result in lactic acidosis. A literature search identified 18 cases of lactic acidosis after the use of contrast media in patients taking metformin.² Of these 18 cases, 14 or 15 were associated with pre-existing renal impairment and 2 cases with other contraindications to metformin (sepsis and cirrhosis). The remaining case was in an elderly woman with neurological disease.

The manufacturers of metformin say that it should be stopped before, or at the time of giving the contrast media and not restarted until 48 hours later, and then only after renal function has been re-checked and found to be normal.³ Guidelines issued by the Royal College of Radiologists are based on this statement and they say that referring clinicians should assess renal function before the test.⁴ Similar guidelines have been issued by the European Society for Urogenital medicine.^{5,6} Nevertheless, some consider that metformin need not be stopped for 48 hours in those patients with normal renal function.² However, a more recent analysis supports the guidelines. Of 97 patients taking metformin who were given intravenous contrast media, 4 developed contrast media-associated nephropathy (all 4 had baseline normal renal function). These patients could have been at increased risk of metformin-associated lactic acidosis had the metformin not been stopped and withheld, as suggested by the guidelines.⁷

Pioglitazone + Fexofenadine

A study in healthy subjects indicated that the pharmacokinetics of pioglitazone 45 mg daily are not significantly affected by fexofenadine 60 mg twice daily, and that pioglitazone does not affect the pharmacokinetics of fexofenadine.¹

1. Robert M. Pharmacokinetics of coadministration of pioglitazone with fexofenadine. *Diabetes* (2001) 50 (Suppl 2), A443.

Pioglitazone or Rosiglitazone + Insulin

Pioglitazone and rosiglitazone may cause fluid retention and peripheral oedema, which can worsen or cause heart failure. There is evidence that the incidence of these effects is higher when combined with insulin. The incidence of hypoglycaemia may also be increased.

Clinical evidence

(a) Pioglitazone

It has been noted that in patients receiving insulin the dose may need to be reduced by 10 to 25% if pioglitazone 15 or 30 mg daily is given.¹ In one 16-week, randomised, double-blind, placebo-controlled study,² pioglitazone 15 or 30 mg with insulin was compared with insulin alone in 566 patients with long-standing diabetes. Oedema was reported in 15.3% of the patients receiving pioglitazone plus insulin (12.6% and 17.6% with pioglitazone 15 mg and 30 mg, respectively) compared with 7% when insulin was given alone. Four of the 379 patients given with pioglitazone and insulin developed congestive heart failure compared with none of the 187 patients given insulin alone; all 4 had a history of cardiovascular disease. Analysis of this study did not identify specific factors that predict this possible increased risk of congestive heart failure.¹ One case report describes

a 57-year-old obese man with type 2 diabetes, no history of heart failure and excellent exercise tolerance, who was given insulin and pioglitazone 30 mg daily. Over the first 4 weeks after starting pioglitazone he developed significant weight gain and subsequently developed heart failure and pulmonary oedema.³

(b) Rosiglitazone

A randomised, double-blind, placebo-controlled study in patients with poorly-controlled type 2 diabetes receiving insulin twice daily found that the addition of rosiglitazone 2 or 4 mg twice daily for 26 weeks improved the control of their blood glucose levels and they needed less insulin.⁴ Mean total daily insulin reductions were 12% for the 4 mg dose, 5.6% for the 2 mg dose, and 0.6% for placebo. Symptoms consistent with hypoglycaemia also occurred more frequently with the combination; 67% with the 4 mg rosiglitazone dose, 53% with the 2 mg dose, and 38% with placebo. The incidence of oedema was about threefold higher in those patients given insulin and rosiglitazone; 16.2% with the 4 mg dose, and 13.1% with the 2 mg dose, compared with 4.7% in those given placebo. Congestive heart failure occurred in 4 of 209 patients receiving the combination compared with 1 of 104 receiving placebo. However, 2 of the patients receiving rosiglitazone had a prior history of coronary heart disease.⁴

From results of clinical studies, the UK manufacturer has reported an incidence of heart failure of 1.1% with insulin monotherapy and 2.4% when combined with rosiglitazone.⁵ In a pilot study in 8 massively obese patients with type 2 diabetes, taking large doses of insulin, the use of rosiglitazone 8 mg daily allowed a 22% reduction in the median insulin dose, and improved glycaemic control. However, 5 of the 8 patients (63%) developed peripheral oedema.⁶ One case report described 2 patients receiving insulin who developed congestive heart failure 6 to 12 months after starting rosiglitazone. They recovered when rosiglitazone was withdrawn and diuretic doses increased.⁷ Another patient taking metformin, glimepiride, rosiglitazone and insulin unusually developed unilateral oedema 2 years after starting rosiglitazone, which resolved on stopping the rosiglitazone, and reappeared within 5 days of restarting it.⁸

Mechanism

Pioglitazone or rosiglitazone alone can exacerbate or precipitate heart failure because they can cause fluid retention and weight gain.^{1,5,9,10} The incidence appears to be greatly increased in patients who are also receiving insulin. An estimated 2 to 5% of patients receiving thiazolidinedione monotherapy and 5 to 15% receiving concurrent insulin therapy experience peripheral oedema.¹¹ Fluid retention and tissue oedema appear to be part of a vascular 'leak' syndrome but, additionally, thiazolidinediones may potentiate the renal effects of insulin on sodium and water retention. It is conceivable that increased fluid retention caused by thiazolidinediones may alter the already precarious volume status in patients with underlying cardiac or renal dysfunction thus leading to congestive heart failure.¹¹ However, congestive heart failure has been estimated to occur in as many as 12% of patients who have type 2 diabetes¹¹ and whether the incidence of heart failure in patients given thiazolidinediones and insulin is simply a reflection of other factors that increase the risk in these patients, or due to some specific interaction with insulin, remains to be established.

Importance and management

The fact that rosiglitazone and pioglitazone can cause weight gain and peripheral oedema, and that the incidence of this is greater in patients who are also using insulin is well established. However, the relevance of this appears to be controversial. In the UK, the manufacturers of the combination product of rosiglitazone with metformin¹² caution the concurrent use of insulin, however rosiglitazone itself is still contraindicated⁵ (although note that the summary of product characteristics for rosiglitazone with metformin has been updated more recently. However, in the US both rosiglitazone¹⁰ and pioglitazone¹ are licensed for use with insulin, and in the UK pioglitazone is licensed for use with insulin.⁹ The American Heart Association and American Diabetes Association have issued guidelines on the use of thiazolidinediones which take into account risk factors for, or severity of, heart failure. Pioglitazone or rosiglitazone may be used cautiously at low dosage in patients with symptomatic heart disease (New York Heart Association (NYHA) class I or II), but should not be used in patients with class III or IV cardiac functional status. If oedema occurs in a patient taking a thiazolidinedione they recommend that the possible causes be assessed. If symptoms and signs suggest congestive heart failure, they recommend that a dosage change and temporary or permanent

discontinuance of the thiazolidinedione should be considered. If there is no evidence of heart failure, they suggest that the thiazolidinedione may be continued, with consideration of dosage reduction or addition of diuretics, and with continued observation of the oedema.¹³

Pioglitazone or Rosiglitazone + Other oral antidiabetics

The pharmacokinetics of metformin are not altered by pioglitazone or rosiglitazone. Pioglitazone does not alter glipizide pharmacokinetics. Rosiglitazone does not have an important effect on glibenclamide (glyburide) pharmacokinetics, and does not alter glimepiride pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Metformin

In healthy subjects, **pioglitazone** 45 mg daily for 7 days did not alter the pharmacokinetics of a single 1-g dose of metformin.^{1,2}

The steady-state pharmacokinetics of metformin 500 mg twice daily and **rosiglitazone** 2 mg twice daily were not affected when they were given to healthy subjects for 4 days.^{3,4}

No special precautions appear to be needed if metformin is used with the thiazolidinediones.

(b) Sulphonylureas

In healthy subjects, **pioglitazone** 45 mg daily for 7 days did not alter the steady-state pharmacokinetics of **glipizide** 5 mg daily.^{1,2}

Rosiglitazone 2 mg twice daily for 7 days did not alter the mean steady-state 24-hour plasma glucose levels in diabetics taking **glibenclamide** (**glyburide**) 3.75 to 10 mg daily. However, **rosiglitazone** 8 mg daily for 8 days caused a decrease of about 30% in the AUC of **glibenclamide** in healthy Caucasian subjects, and a slight increase in the AUC of **glibenclamide** in Japanese subjects.³ These changes are not considered clinically relevant.^{3,5} No pharmacokinetic interaction appears to occur between **glimepiride** and **rosiglitazone**.³

No special precautions appear to be needed if these sulphonylureas are used with the thiazolidinediones.

Pramlintide + Miscellaneous

Pramlintide slows gastric emptying, and therefore the manufacturer recommends that it should not be used with other drugs that alter gastrointestinal motility.

Clinical evidence, mechanism, importance and management

In a study using **paracetamol** (**acetaminophen**) as a marker of gastric emptying, pramlintide increased the time to maximum plasma **paracetamol** levels by up to 72 minutes and reduced the maximum **paracetamol** level by about 29%, without altering the overall extent of absorption. This effect was seen when **paracetamol** was given simultaneously with pramlintide, or for up to two hours after pramlintide. It was not seen when **paracetamol** was given one to two hours before pramlintide.¹

This study demonstrates that pramlintide slows gastric emptying, and has the potential to delay the absorption of other drugs. The manufacturer notes that if a rapid onset of action is required (for example when giving an oral **analgesic**), the drug should be given at least one hour before, or two hours after pramlintide.¹

Furthermore, because of this delay in gastric emptying, the manufacturer recommends that pramlintide should not be used in patients taking drugs that alter gastrointestinal motility. They specifically name **antimuscarinics** such as **atropine**,¹ which delays gastric emptying. Note that pramlintide could, theoretically, oppose the effects of **metoclopramide**, which increases gastric emptying.

Sitagliptin + Miscellaneous

Single-dose ciclosporin slightly increased the absorption of sitagliptin, although this was not considered clinically relevant. Sitagliptin does not have a clinically relevant effect on the pharmacokinetics of digoxin, oral contraceptives, simvastatin or warfarin.

Clinical evidence, mechanism, importance and management

(a) Ciclosporin

A crossover study in 8 healthy subjects found that when a single 100-mg dose of sitagliptin was given with a single 600-mg dose of ciclosporin there was a 68% increase in the maximum plasma levels of sitagliptin, with a slight increase in overall exposure to sitagliptin (AUC increased by 28%). It is likely that ciclosporin enhances the absorption of sitagliptin via inhibition of P-glycoprotein. However, these changes were considered unlikely to be clinically meaningful, because of the apparent wide therapeutic index of sitagliptin.¹

(b) Digoxin

The manufacturers describe a study in which digoxin 250 micrograms daily was given with sitagliptin 100 g daily for 10 days. The AUC and maximum plasma levels of digoxin were increased by 11% and 18%, respectively, which was not considered to be clinically significant.^{2,3} Therefore it is unlikely that the dose of digoxin will need to be altered on concurrent use.

(c) Hormonal contraceptives

Sitagliptin did not appear to alter the pharmacokinetics of norethisterone (norethindrone) or ethinylestradiol given as part of an oral contraceptive.^{2,3}

(d) Simvastatin

Sitagliptin did not appear to alter the pharmacokinetics of a single dose of simvastatin.^{2,3}

(e) Warfarin

Sitagliptin did not appear to affect the pharmacokinetics of either *S*- or *R*-warfarin, or the INR in response to warfarin.^{2,3}

Sulphonylureas + Chloramphenicol

The blood glucose-lowering effects of tolbutamide and chlorpropamide can be increased by chloramphenicol and acute hypoglycaemia can occur.

Clinical evidence

A man taking chloramphenicol 2 g daily started taking **tolbutamide** 2 g daily. Three days later he had a typical hypoglycaemic collapse and was found to have serum **tolbutamide** levels three to fourfold higher than expected.¹

Studies in diabetics have shown that chloramphenicol 2 g daily can increase the serum level and half-life of **tolbutamide** twofold, and two to threefold, respectively.^{1,2} Blood glucose levels were reduced by about 25 to 30%.^{2,3} Hypoglycaemia, acute in one case, developed in two other patients taking **tolbutamide** with chloramphenicol.^{4,5} In another study chloramphenicol 1 to 2 g daily caused an average twofold increase in the half-life of **chlorpropamide**.⁶

Mechanism

Chloramphenicol inhibits the liver enzymes concerned with the metabolism of tolbutamide, and probably chlorpropamide as well, leading to their accumulation in the body. This is reflected in prolonged half-lives, reduced blood glucose levels and occasionally acute hypoglycaemia.^{1-4,6}

Importance and management

The interaction between tolbutamide and chloramphenicol is well established and of clinical importance. The incidence is uncertain, but increased blood glucose-lowering effects should be expected if both drugs are given. The interaction between chlorpropamide and chloramphenicol is less well documented. Nevertheless, monitor concurrent use carefully and reduce the dosage of the sulphonylureas as necessary. Some patients may show a particularly exaggerated response. The manufacturers of other sulphonylureas often list chloramphenicol as an interacting drug, based on its interactions with tolbutamide and chlorpropamide, but direct information of an interaction does not appear to be available. No interaction would be expected with chloramphenicol eye drops, because the systemic absorption is likely to be small.

Sulphonylureas + Heparin

Isolated reports describe hypoglycaemia in two diabetic patients, one taking glipizide, the other taking glibenclamide (glyburide). The effects were attributed to the concurrent use of heparin.

Clinical evidence, mechanism, importance and management

A diabetic, taking **glipizide** 5 mg daily for 6 months, with fair control was hospitalised for the treatment of a foot ulcer. Over a period of 4 days he experienced recurring episodes of hypoglycaemia after taking a routine 5-mg dose of **glipizide**. It was suggested that this might possibly have been due to an interaction with subcutaneous heparin calcium 5000 units every 12 hours which, it is suggested, might have displaced the **glipizide** from its protein binding sites.¹ Another report mentions that hypoglycaemia developed in a patient taking **glibenclamide** (**glyburide**) and

heparin.² No other information seems to be available. The general importance of these reports is unknown, but seems likely to be small.

- McKillop G, Fallon M, Slater SD. Possible interaction between heparin and a sulphonylurea a cause of prolonged hypoglycaemia? *BMJ* (1986) 293, 1073.
- Beeley L, Daly M, Stewart P. *Bulletin of the West Midlands Centre for Adverse Drug Reaction Reporting* (1987) 24, 24.

Sulphonylureas + Methysergide

A preliminary study indicated that methysergide may enhance the effects of tolbutamide.

Clinical evidence, mechanism, importance and management

Pretreatment with methysergide 2 mg every 6 hours for 2 days increased the amount of insulin secreted in response to a 1-g intravenous dose of **tolbutamide** by almost 40% in 8 patients with type 2 diabetes.¹ Whether in practice the addition or withdrawal of methysergide adversely affects the control of diabetes is uncertain, but the possibility should be borne in mind.

- Baldrige JA, Quickel KE, Feldman JM and Lebovitz HE. Potentiation of tolbutamide-mediated insulin release in adult onset diabetics by methysergide maleate. *Diabetes* (1974) 23, 21-4.

Sulphonylureas + Probenecid

The clearance of chlorpropamide is reduced by probenecid, but the clinical importance of this is uncertain. Tolbutamide appears not to interact.

Clinical evidence, mechanism, importance and management

A study in 6 patients given single oral doses of **chlorpropamide** found that probenecid 1 to 2 g daily increased the **chlorpropamide** half-life from about 36 to 50 hours.¹ It seems that the probenecid reduces the renal excretion of **chlorpropamide**. Another report in healthy subjects suggested that the half-life of **tolbutamide** was also prolonged by probenecid,² but this was not confirmed by a further controlled study.³

Information is very limited but it may possibly be necessary to reduce the dosage of **chlorpropamide** in the presence of probenecid. It seems unlikely that a clinically important interaction will occur with **tolbutamide**. Information about other sulphonylureas appears to be lacking.

Sulphonylureas; Chlorpropamide + Urinary acidifiers or alkalinisers

On theoretical grounds the response to chlorpropamide may be decreased if the urine is made alkaline, and increased if urine is acidified.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects given a 250-mg oral dose of chlorpropamide found that when the urine was made alkaline (pH 7.1 to 8.2) with **sodium bicarbonate**, the half-life of the chlorpropamide was reduced from 50 to 13 hours, and the 72-hour clearance was increased fourfold. In contrast, when the urine was acidified (pH 5.5 to 4.7) with **ammonium chloride**, the chlorpropamide half-life was increased from 50 to 69 hours and the 72-hour urinary clearance was decreased to 5%, and non-renal (i.e. metabolic) clearance predominated.¹ Another study found that the renal clearance of chlorpropamide was almost 100 times greater at pH 7 than at pH 5.² The reasons are that changes in urinary pH affect the ionisation of the chlorpropamide, and this affects the ability of the kidney to reabsorb it from the kidney filtrate (see more details under 'Drug excretion interac-

tions', (p.7)). Thus, urinary pH determines the relative contribution of renal and metabolic clearance.

There appear to be no reports of adverse interactions between chlorpropamide and drugs that can alter urinary pH, but prescribers should be aware of the possibilities: a reduced response if the pH is raised significantly and renal clearance predominates (e.g. with **sodium bicarbonate**, **acetazolamide**, some **antacids**); an increased response if the pH is made more acid than usual and metabolic clearance predominates (e.g. with **ammonium chloride**). Perhaps more importantly, the effects of drugs that alter the hepatic clearance of chlorpropamide are likely to be more significant when its renal clearance is low (i.e. when the urine is acid).²

Sulphonylureas; Glibenclamide (Glyburide) + Bosentan

There appears to be an increased risk of liver toxicity if bosentan is given with glibenclamide, and the combination should probably be avoided. Glibenclamide modestly reduces the plasma levels of bosentan, and bosentan reduces the plasma levels of glibenclamide.

Clinical evidence, mechanism, importance and management

In clinical studies, bosentan was noted to be associated with dose-related asymptomatic elevations in liver enzymes in some patients, and these elevations were higher in patients also receiving glibenclamide.¹ Study in *rats* confirmed that combined use of bosentan and glibenclamide caused increases in serum bile salt levels that were greater than with either drug alone.¹ In addition, *in vitro* study showed bosentan inhibits the bile salt export pump.¹ Glibenclamide also inhibits this pump. Because of the possibility that there may be a pharmacokinetic component to the interaction, the pharmacokinetics of both bosentan and glibenclamide were determined in a crossover study in 12 healthy subjects. However, glibenclamide actually reduced the maximum plasma levels and AUC of bosentan by 24 and 29%, respectively, while bosentan reduced the maximum plasma levels and AUC of glibenclamide by 22 and 40%, respectively. Two subjects had asymptomatic elevated liver enzyme levels while taking bosentan with glibenclamide.²

Based on the limited evidence available about the increased risk of liver toxicity, the UK manufacturer of bosentan recommends that it should not be used with drugs that are inhibitors of the bile salt export pump, such as glibenclamide. They suggest that an alternative antidiabetic drug should be used.³ The US manufacturer contraindicates concurrent use because of the potential for raised liver enzymes.⁴ This seems a sensible precaution. Note also that a decrease of 40% in the AUC of glibenclamide may possibly decrease its blood glucose-lowering effects to a clinically relevant extent.²

4. Tracleer (Bosentan). Pantheon, Inc. US Prescribing information, February 2007.

Sulphonylureas; Glibenclamide (Glyburide) + Naftidrofuryl oxalate

One report briefly lists a case of severe hypoglycaemia, which occurred when glibenclamide was given with naftidrofuryl oxalate.¹ No details are given.

1. Beeley L, Magee P, Hickey FM. *Bulletin of the West Midlands Centre for Adverse Drug Reaction Reporting* (1990) 30, 17.

Sulphonylureas; Glibenclamide (Glyburide) + Pantoprazole

There is no pharmacokinetic interaction between glibenclamide (glyburide) and pantoprazole, and pantoprazole does not alter the glucose-lowering effect of glibenclamide.

Clinical evidence, mechanism, importance and management

Pantoprazole 40 mg daily or placebo were given to 20 healthy subjects for 5 days. On day 5 the subjects were additionally given 3.5 mg of a micronised preparation of glibenclamide. The pharmacokinetics of the glibenclamide and the pharmacodynamic profiles of glucose and insulin serum concentrations were not significantly altered, and the pharmacokinetics of pantoprazole were not affected. It was concluded that dosage changes of the micronised preparation of glibenclamide are not needed during treatment with pantoprazole.¹

1. Walter-Sack IE, Bliesath H, Stötzer F, Huber R, Steinijans VW, Ding R, Mascher H, Wurst W. Lack of pharmacokinetic and pharmacodynamic interaction between pantoprazole and glibenclamide in humans. *Clin Drug Invest* (1998) 15, 253–60.

Sulphonylureas; Glibenclamide (Glyburide) + Vinpocetine

Vinpocetine does not alter the pharmacokinetics or efficacy of glibenclamide.

Clinical evidence, mechanism, importance and management

A study in 18 elderly patients with type 2 diabetes and symptoms of dementia, taking glibenclamide (glyburide), found that 4 days of treatment with vinpocetine 10 mg three times daily did not affect either the pharmacokinetics of the glibenclamide or the control of blood glucose levels.¹ There would seem to be no reason for avoiding concurrent use.

1. Grandt R, Braun W, Schulz H-U, Lüthmann B, Frercks H-J. Glibenclamide steady-state plasma levels during concomitant vinpocetine administration in type II diabetic patients. *Arzneimittelforschung* (1989) 39, 1451–4.

Sulphonylureas; Glymidine + Phenobarbital

A study in one subject found that the blood glucose-lowering effects of glymidine were unaffected by phenobarbital.¹ No special precautions would appear necessary on concurrent use.

1. Gerhards E, Kolb KH, Schulze PE. Über 2-Benzolsulfonylamino-5(β-methoxy-äthoxy) pyrimidin (Glycodiazin). V. In vitro- und in vivo-Versuche zum Einfluß von Phenyläthylbarbitursäure (Luminal) auf den Stoffwechsel und die blutzuckersenkende Wirkung des Glycodiazins. *Naunyn-Schmiedeberg's Arch Pharmacol Exp Pathol* (1966) 255, 200–20.

Sulphonylureas; Tolbutamide + Aprepitant

Aprepitant slightly reduces tolbutamide levels.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects aprepitant (125 mg on day one, then 80 mg daily on days 2 and 3) decreased the AUC of a single 500-mg dose of tolbutamide by 23%, 28%, 15%, when given on days 4, 8, and 15, respectively, when compared with 12 subjects not given aprepitant.¹

Aprepitant is an inducer of the cytochrome P450 isoenzyme CYP2C9 by which tolbutamide is metabolised. It therefore increases tolbutamide metabolism, which leads to a reduction in tolbutamide levels. However, the clinical relevance of these small changes has not been assessed. The manufacturer recommends caution when both drugs are given.²

2. Emend (Aprepitant). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, February 2007.

Sulphonylureas; Tolbutamide + Echinacea

Echinacea does not have a clinically relevant effect on the pharmacokinetics of tolbutamide.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 12 healthy subjects were given *Echinacea purpurea* root 400 mg four times daily for 8 days with a single 500-mg dose of tolbutamide on day 6. The AUC of tolbutamide was increased by 14%, and the time to maximum levels was increased from 4 to 6 hours.¹ The oral clearance was decreased by a mean of 11%, although 2 subjects had a 25% or greater reduction. These minor to modest changes are unlikely to be clinically relevant.

1. Gorski JC, Huang S-M, Pinto A, Hamman MA, Hilligoss JK, Zaheer NA, Desai M, Miller M, Hall SD. The effect of echinacea (*Echinacea purpurea* root) on cytochrome P450 activity in vivo. *Clin Pharmacol Ther* (2004) 75, 89–100.

Sulphonylureas; Tolbutamide + Tolcapone

Tolcapone did not alter tolbutamide pharmacokinetics in a single-dose study.

Clinical evidence, mechanism, importance and management

In a single-dose study in 12 healthy subjects, tolcapone 200 mg had no effect on the pharmacokinetics of tolbutamide 500 mg, and did not alter the glucose-lowering effect of tolbutamide.¹ This study was conducted since *in vitro* evidence showed that tolcapone inhibits the cytochrome P450 isoenzyme CYP2C9, by which tolbutamide is metabolised. However, the findings in healthy subjects suggest that no clinically relevant changes in pharmacokinetics of tolbutamide are likely.

Antiepileptics

The antiepileptic drugs find their major application in the treatment of various kinds of epilepsy, although some of them are also used for other conditions, such as pain management.

Drug interactions

The drugs used as antiepileptics are a disparate group, and their interactions need to be considered individually. Carbamazepine and phenytoin have established ranges of therapeutic plasma levels and these are typically fairly narrow. Modest changes in plasma levels may therefore be clinically important.

(a) Carbamazepine or oxcarbazepine

Carbamazepine is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4 to the active metabolite, carbamazepine-10,11-epoxide, which is then further metabolised. Concurrent use of CYP3A4 inhibitors or inducers may therefore lead to toxicity or reduced efficacy. However, importantly, carbamazepine also induces CYP3A4 and so induces its own metabolism (autoinduction). Because of this, it is important that drug interaction studies are multiple-dose and carried out at steady state. Auto-induction also means that moderate inducers of CYP3A4 may have less of an effect on steady-state carbamazepine levels than expected. Oxcarbazepine is a derivative of carbamazepine, but has a lesser effect on CYP3A4. However, both carbamazepine and oxcarbazepine can act as inhibitors of CYP2C19, see 'Phenytoin + Carbamazepine', p.554.

(b) Phenobarbital

Phenobarbital is an inducer of a wide range of cytochrome P450 isoenzymes, and may increase the metabolism of a variety of drugs. It may, itself, also be affected by some enzyme inducers or inhibitors, although these interactions are less established.

(c) Phenytoin

Phenytoin is extensively metabolised by hydroxylation, principally by CYP2C9, although CYP2C19 also plays a role. These isoenzymes show 'genetic polymorphism', (p.4), and CYP2C19 may assume a greater role in individuals who have a poor metaboliser phenotype of CYP2C9. The concurrent use of inhibitors of CYP2C9, and sometimes also CYP2C19, can lead to phenytoin toxicity. In addition, phenytoin metabolism is satu-

table (it shows non-linear pharmacokinetics), and therefore small changes in metabolism or phenytoin dose can result in marked changes in plasma levels. Moreover, phenytoin is highly protein bound, and drugs that alter its protein binding may alter its levels. Although protein binding interactions are usually not clinically relevant (unless metabolism is also inhibited, see 'Phenytoin + Valproate', p.568), they can be important in interpreting drug levels.

(d) Valproate

Valproate is a generic name that is applied in this section to cover valproic acid and its salts and esters. Valproate undergoes glucuronidation and β -oxidation, and possibly also some metabolism via CYP2C isoenzymes. It can therefore undergo drug interactions via a variety of mechanisms. It acts as an inhibitor of glucuronidation and so may affect other drugs that undergo glucuronidation. Valproate also has non-linear pharmacokinetics due to saturation of plasma protein binding, and so may interact with drugs that alter its protein binding. However, note that, although protein binding interactions are usually not clinically relevant unless metabolism is also inhibited, they can be important in interpreting drug levels.

(e) Newer antiepileptics

Of the newer antiepileptics, both felbamate and topiramate are weak inducers of CYP3A4. They may also inhibit CYP2C19. They are also partially metabolised by the cytochrome P450 isoenzyme system, so may have their metabolism altered by other drugs such as the older enzyme-inducing antiepileptics.

Gabapentin, lamotrigine, levetiracetam, tiagabine, vigabatrin, and zonisamide do not appear to act as inhibitors or inducers of cytochrome P450 isoenzymes, and so appear to cause less drug interactions than the older antiepileptics. Moreover, gabapentin, levetiracetam, and vigabatrin do not appear to be metabolised by the cytochrome P450 system, so appear to be little affected by drug interactions that result from this mechanism. Tiagabine and zonisamide are metabolised by the cytochrome P450 system, so may have their metabolism altered by other drugs such as the older enzyme-inducing antiepileptics. Lamotrigine is metabolised by glucuronidation, and may be affected by inhibitors (e.g. valproate) or inducers (e.g. the older enzyme-inducing antiepileptics) of this process. Lamotrigine may also act as an inducer of glucuronidation.

Antiepileptics + Acetazolamide

Severe osteomalacia and rickets have been seen in a few patients taking phenytoin, phenobarbital, or primidone with acetazolamide. A marked reduction in serum primidone levels with a loss in seizure control, rises in serum carbamazepine levels with toxicity, and rises in phenytoin levels have also been described in a very small number of patients given acetazolamide.

Clinical evidence

(a) Osteomalacia

Severe osteomalacia developed in 2 women taking **phenytoin** or **primidone** and **phenobarbital** when they were given acetazolamide 750 mg daily, despite a normal intake of calcium. When the acetazolamide was withdrawn, the hyperchloraemic acidosis that had been seen in both patients abated and their high urinary excretion of calcium fell by 50%.^{1,2}

Similar cases have been described in 3 children given acetazolamide, **phenytoin** and **primidone**, with **phenobarbital** and/or metharbital,³ who developed rickets.

(b) Reduced serum primidone levels

A patient taking primidone had an increase in seizure-frequency and a virtual absence of primidone (or phenobarbital) in the serum while taking acetazolamide 250 mg daily. Primidone levels rose when the acetazolamide was withdrawn, probably due to improved absorption. A subsequent study in 2 other patients found that acetazolamide had a small effect on primidone absorption in one, and no effect in the other.⁴

(c) Increased serum carbamazepine levels

A 9-year-old girl and two teenage boys, all of them taking the highest dosages of carbamazepine tolerable (without adverse effects), developed signs of toxicity after taking acetazolamide 250 to 750 mg daily. Their serum carbamazepine levels were found to have increased by about 25 to 50%. In one instance toxicity appeared within 48 hours.⁵

The seizure control of 54 children with grand mal and temporal lobe epilepsy was improved when acetazolamide 10 mg/kg daily was added to carbamazepine. Serum carbamazepine levels rose by 1 to 6 mg/L in 60% of the 33 patients sampled. Adverse effects developed in 10 children, and in 8 children this was within 1 to 10 days of starting the acetazolamide. The adverse effects responded to a reduction in the carbamazepine dosage.⁶

(d) Increased serum phenytoin levels

When acetazolamide was added to phenytoin treatment in 6 children, 5 of them had an increase in the phenytoin level (range 20 to 132%, representing an increase of 3 to 12.5 mg/L), and one had a slight decrease (20% or 3 mg/L) [values estimated from figure].⁷

Mechanism

Uncertain. Mild osteomalacia induced by antiepileptics is a recognised phenomenon⁸ (see also 'Vitamin D substances + Phenytoin and Barbiturates', p.1291). It seems that this is exaggerated by acetazolamide, which increases urinary calcium excretion, possibly by causing systemic acidosis, which results from the reduced absorption of bicarbonate by the kidney. The changes in the antiepileptic levels are not understood.

Importance and management

The documentation of all of these interactions is very limited, and their incidence is uncertain. Concurrent use should be monitored for the possible development of osteomalacia or altered antiepileptic levels and steps taken to accommodate them. Withdraw the acetazolamide if necessary, or adjust the dosage of the antiepileptic appropriately. In the case of the children with rickets³ the acetazolamide was withdrawn and high doses of vitamin D was given. It seems possible that other carbonic anhydrase inhibitors may behave like acetazolamide.

Antiepileptics + Aciclovir

Isolated reports describe a marked reduction in serum phenytoin and valproate levels in two children given aciclovir. Seizure frequency increased.

Clinical evidence, mechanism, importance and management

A 7-year-old boy with epilepsy taking **phenytoin**, **valproate** and nitrazepam was given oral aciclovir 1 g daily for 6 days. After 4 days his trough serum **phenytoin** levels had fallen from 17 to 5 micrograms/mL, and his trough **valproate** levels similarly fell, from 32 to 22 micrograms/mL. When the aciclovir was stopped the serum levels of both antiepileptics rose over a period of 3 to 6 days. During the period when the antiepileptic levels were restablising, the seizure frequency markedly increased and his EEG worsened. The reason for this apparent interaction is not known, but the authors of the report suggest that the aciclovir may possibly have reduced the absorption of the antiepileptics, in some way not understood.¹ Reduced phenytoin and valproate levels during treatment with aciclovir have been reported in another child.²

There appears to be only these isolated reports of an interaction between these drugs. Its general clinical importance is not known. More study is needed.

Antiepileptics + Antineoplastics; Cytotoxic

Carbamazepine, phenytoin and valproate serum levels can be reduced by several antineoplastic drug regimens and seizures can occur if the antiepileptic dosages are not raised appropriately. In contrast, phenytoin toxicity has occurred when fluorouracil and fluorouracil prodrugs, such as capecitabine, doxifluridine and tegafur, were given. The effects of many antineoplastics are reduced or changed by enzyme-inducing antiepileptics. Increased haematological toxicity may occur if valproate is given with fotemustine and cisplatin.

Clinical evidence

(a) Antiepileptic levels reduced

There are a number of reports (mainly case reports) that implicate a variety of types of chemotherapy in reducing the levels of **carbamazepine**, **phenytoin**, and **valproate**. See 'Table 14.1', (p.519) for details.

(b) Antiepileptic levels raised

Two epileptic patients taking **phenytoin** developed **phenytoin** toxicity when they were given **fluorouracil** to treat colon cancer.^{1,2} Three patients with malignant brain tumours developed acute **phenytoin** toxicity associated with raised serum **phenytoin** levels when they were given **UFT** (**uracil** and **tegafur**, a prodrug of **fluorouracil**).³ Another case of **phenytoin** toxicity has been reported with **UFT**.⁴ **Phenytoin** toxicity was also seen in a woman treated with combination therapy that included the fluorouracil prodrug **doxifluridine**.⁵ Similarly, **phenytoin** toxicity has occurred in a patient given **capecitabine** (another prodrug of **fluorouracil**).⁶ Although in one report,³ no interaction occurred in one of the patients when the **UFT** was replaced by **fluorouracil**, cases of **phenytoin** toxicity have been reported in 3 patients receiving **fluorouracil** with **folinic acid**.^{6,7}

Table 14.1 Reduced antiepileptic levels during antineoplastic therapy

Antiepileptic	Antineoplastic	Malignancy	Outcome	Refs
Phenytoin	Cisplatin Carmustine	Brain tumours	A retrospective study reviewed the effects of 3 or more cycles of 72 hours of carmustine and cisplatin chemotherapy in 19 patients who did not vomit. A phenytoin dose increase was required in three-quarters of patients, which was, on average, 40% of the original dose (range 20 to 100%). The effect on phenytoin levels persisted after the chemotherapy had finished, with levels returning to normal 2 to 3 weeks later.	1
Phenytoin	Cisplatin Vinblastine Bleomycin	Metastatic germ cell tumour	Estimated phenytoin level 15 micrograms/mL, but level only reached 2 micrograms/mL. Patient fitted.	2
Phenytoin Primidone	Cisplatin Vinblastine Bleomycin	Metastatic embryonal cell cancer	Phenytoin 800 mg daily gave a level of 15 micrograms/mL whilst receiving chemotherapy. After chemotherapy the same dose produced a toxic level of 42.8 micrograms/mL. Phenobarbital levels unaffected.	3
Phenytoin Phenobarbital	Vinblastine Carmustine Methotrexate	Lung cancer with brain metastases	Phenytoin levels fell from 9.4 to 5.6 micrograms/mL 24 hours after vinblastine. Patient fitted. Phenytoin levels returned to normal 2 weeks after chemotherapy. Phenobarbital levels unaffected.	4
Phenytoin Carbamazepine Sodium valproate	Doxorubicin Cisplatin Cyclophosphamide Altretamine	Papillary adenocarcinoma of the ovaries	Seizures occurred 2 to 3 days after starting chemotherapy. All drug levels dropped to one-third or lower. Doses increased to compensate, which led to phenytoin toxicity when the chemotherapy finished.	5
Phenytoin	Carboplatin	Small cell lung cancer with brain metastases	Phenytoin level dropped from 9.7 to 4.6 micrograms/mL 10 days into chemotherapy, resulting in seizures. Phenytoin dose had to be increased by 35% to achieve a level of 10.7 micrograms/mL.	6
Phenytoin	Dacarbazine Carmustine Cisplatin Tamoxifen	Malignant melanoma with brain metastases	Phenytoin level of only 2.5 micrograms/mL despite a loading 1-g dose and a daily dose of 500 mg phenytoin.	7
Phenytoin followed by Carbamazepine	Vincristine Cytarabine Hydroxycarbamide Daunorubicin Methotrexate Tioguanine Cyclophosphamide Carmustine	Stage IV T-cell lymphoma	Phenytoin failed to reach therapeutic levels and so was substituted with carbamazepine. Chemotherapy caused carbamazepine levels to drop below therapeutic levels resulting in seizures. Increasing the dose from 30 to 50 mg/kg per day prevented subtherapeutic levels.	8
Phenytoin	Methotrexate Mercaptopurine Vincristine	Acute lymphoblastic leukaemia	Phenytoin levels dropped from 19.8 micrograms/mL on the day before chemotherapy to 3.6 micrograms/mL on the 6th day of chemotherapy.	9
Phenytoin	Cisplatin Carmustine Etoposide	CNS tumours	Dose of phenytoin had to be increased by 50 to 300% in 10 patients to maintain phenytoin levels in the therapeutic range.	10
Sodium valproate	Methotrexate (high dose)	Acute lymphoblastic leukaemia	A child had a seizure a few hours after methotrexate. Serum valproate levels reduced by 75%. The valproate dose was increased by 50% and clonazepam added.	11
Sodium valproate	Methotrexate Cytarabine Nimustine (by CSF perfusion)	Glioblastoma	CSF valproic acid levels reduced by 70% during the perfusion, but returned to normal levels within 7 hours.	12
Sodium valproate Phenytoin	Cisplatin Etoposide Bleomycin	Testicular cancer	Serum valproate levels reduced by 50% after the first cycle and generalised tonic-clonic seizures occurred. There was no effect on phenytoin levels.	13

(d) Miscellaneous

One report found **valproate** increased haematological toxicity in patients taking **valproate** with **fotemustine** and **cisplatin**.⁸

Mechanism

Not fully understood, but a suggested reason for the fall in serum antiepileptic levels is that these antineoplastics damage the intestinal wall, which reduces the absorption of the antiepileptic. Other mechanisms may also have some part to play. The raised serum phenytoin levels possibly occur because the liver metabolism of the phenytoin is reduced by these antineoplastics. Changes in plasma protein binding may also have been involved.

Importance and management

Information is scattered and incomplete. However, it appears that both altered antiepileptic levels and altered antineoplastic levels can occur, possibly leading to loss of efficacy or toxicity. Where possible, it may be prudent to avoid concurrent use of enzyme-inducing antiepileptics and antineoplastics. If this is not possible, serum antiepileptic levels should be closely monitored during treatment with any of these antineoplastics, making dosage adjustments as necessary, and the efficacy of the antineoplastics should also be closely monitored.

Antiepileptics + Calcium carbimide or Disulfiram

Phenytoin serum levels are markedly and rapidly increased by disulfiram. Phenytoin toxicity can develop. There is evidence that phenobarbital and carbamazepine are not affected by disulfiram, and that phenytoin is not affected by calcium carbimide.

Clinical evidence

The serum **phenytoin** levels of 4 patients rose by 100 to 500% over a 9-day period when they were given disulfiram 400 mg daily. **Phenytoin** levels were still rising even 3 to 4 days after the disulfiram was withdrawn, and had still not returned to normal after 14 days. Two patients developed signs of mild **phenytoin** toxicity.¹ In a follow-up study in two of the patients, one developed ataxia and both had a rise in serum **phenytoin** levels, of 25% and 50%, respectively, during 5 days of disulfiram treatment.²

Disulfiram increased the half-life of **phenytoin** from 11 to 19 hours in 10 healthy subjects.³ There are also other case reports describing this interaction.⁴⁻⁸

Phenobarbital levels (from **primidone** in 3 patients and **phenobarbital** in one patient) fluctuated by about 10% (which is unlikely to be clinically significant) when disulfiram was given for 9 days.^{1,2}

A case report suggested that **carbamazepine** did not interact with disulfiram,⁶ and this has been confirmed in a study of 5 epileptic, non-alcoholic patients.⁹

A study in 4 patients found that calcium carbimide 50 mg daily for a week followed by 100 mg daily for 2 weeks had no effect on serum **phenytoin** levels.²

Mechanism

Disulfiram inhibits the liver enzymes concerned with the metabolism of phenytoin (possibly the cytochrome P450 isoenzyme CYP2C9) thereby prolonging its stay in the body and resulting in a rise in its serum levels, to toxic concentrations in some instances. One study concluded that the inhibition was non-competitive.⁷

Importance and management

The interaction between phenytoin and disulfiram is established, moderately well documented, clinically important and potentially serious. It seems to occur in most patients and develops rapidly. Recovery may take 2 to 3 weeks after the disulfiram is withdrawn. It has been suggested that the dosage of phenytoin could be reduced to accommodate the interaction, but it may be difficult to maintain the balance required. Monitor very closely if both drugs are given.²

Carbamazepine and phenobarbital do not appear to interact with disulfiram and calcium carbimide does not appear to interact with phenytoin.

Antiepileptics + Chinese herbal medicines

A study in epileptics found that **Saiko-ka-ryukotsu-borei-to** enhanced the antiepileptic effects of carbamazepine. **Paeoniae Radix** does not appear to affect the pharmacokinetics of valproic acid.

Clinical evidence

(a) Carbamazepine

A study in epileptic patients found the antiepileptic effects of carbamazepine were enhanced by concurrent **Saiko-ka-ryukotsu-borei-to**;¹ patients experienced fewer seizures and improved neurological symptoms.²

(b) Valproate

The pharmacokinetics of a single 200-mg dose of valproic acid were unaffected by 1.2 g of a powder extract of **Paeoniae Radix** daily for 7 days in 6 healthy subjects.³

Mechanism

Not fully understood. As a pharmacokinetic interaction has not been found between **Saiko-ka-ryukotsu-borei-to** and carbamazepine, the enhanced effects found in the patients with epilepsy may therefore have been due to a pharmacodynamic interaction.²

Paeoniae Radix (the dried root of *Paeonia lactiflora*³) is reported to reduce the rate of gastric emptying.⁴ However, this does not appear to affect the rate of absorption of valproate.

Importance and management

Evidence is limited, but there appears to be no evidence of an adverse effect when using **Paeoniae radix** with valproate, or **Saiko-ka-ryukotsu-borei-to** with carbamazepine: concurrent use may even be beneficial. More study is needed to confirm all these findings. Note that adulteration of Chinese medicines with various antiepileptics may lead to unexpected toxicity.⁵

Antiepileptics + Folates

If folate supplements are given to treat folate deficiency, which can be caused by the use of antiepileptics (phenytoin, phenobarbital, primidone and possibly pheneturide), the serum antiepileptic levels may fall, leading to decreased seizure control in some patients.

Clinical evidence

A study in 50 folate-deficient epileptics (taking phenytoin, phenobarbital and primidone in various combinations) found that after one month of

treatment with folic acid 5 mg daily, the plasma **phenytoin** levels of one group of 10 patients had fallen from 20 to 10 micrograms/mL. In another group of patients taking folic acid 15 mg daily the levels of **phenytoin** fell from 14 to 11 micrograms/mL. Only one patient (in the 5-mg folic acid group) had a marked increase in seizure frequency and severity. No alterations were seen in the **phenobarbital** levels.¹

Another long-term study was conducted in 26 patients with folic acid deficiency (serum folate less than 5 nanograms/mL), and treated with two or more drugs (**phenytoin**, **phenobarbital**, **primidone**). The mental state of 22 of them (as shown by increased alertness, concentration, sociability etc.) improved to a variable degree when they were given folic acid 5 mg three times daily. However, the frequency and severity of seizures in 13 patients (50%) increased to such an extent that the vitamin had to be withdrawn from 9 of them.²

Similar results, both of increased seizure activity and decreased serum folate levels, have been described in other studies and reports in patients taking **phenytoin**, **phenobarbital**, **primidone** and **pheneturide**.^{3–6}

Another report describes lack of **phenytoin** efficacy in a patient receiving **UFT** with **folinic acid**, which was attributed to the effect of the **folinic acid** on **phenytoin** levels.⁷

Mechanism

Patients taking antiepileptics may have subnormal serum folic acid levels. Frequencies of 27 to 76% have been reported for phenobarbital, primidone, and phenytoin alone or in various combinations.⁸ One possible explanation is that this is due to the enzyme-inducing characteristics of these antiepileptics, which makes excessive demands on folate for the synthesis of the enzymes concerned with drug metabolism. Ultimately drug metabolism becomes limited by the lack of folate, and patients may also develop a reduction in their general mental health² and even frank megaloblastic anaemia.^{8,9} If folic acid is then given to treat this deficiency, the metabolism of the antiepileptic increases once again,¹⁰ resulting in a reduction in serum antiepileptic levels, which in some instances may become so low that seizure control is partially or totally lost.

Importance and management

A very well documented and clinically important interaction, which has been the subject of review.¹¹ Reductions in serum phenytoin levels of 16 to 50% have been described in patients taking 5 to 15 mg folic acid daily for 2 to 4 weeks.^{1,3,12} If folic acid supplements are given to folate-deficient epileptics taking phenytoin, phenobarbital, primidone and possibly pheneturide, their serum antiepileptic levels should be well monitored so that suitable dosage increases can be made.

Antiepileptics + Mefloquine

A woman whose epilepsy was controlled with sodium valproate developed convulsions when she took mefloquine. Note that mefloquine is normally contraindicated in epilepsy.

Clinical evidence, mechanism, importance and management

An isolated report describes a 20-year-old woman, with a 7-year history of epilepsy (bilateral myoclonus and generalised tonic-clonic seizures) controlled with **sodium valproate** 1.3 g daily, who developed tonic-clonic seizures 8 hours after taking the second of 3 prophylactic doses of mefloquine 250 mg.¹ It is not clear whether this resulted from a drug-drug or a drug-disease interaction. The manufacturers of mefloquine advise its avoidance in those with a history of convulsions as it may increase the risk of convulsions. In these patients mefloquine should be used only for curative treatment if compelling reasons exist.²

Antiepileptics + Quinine

Preliminary evidence suggests that the effects of carbamazepine and phenobarbital may be increased by quinine, possibly leading to toxicity. An isolated report suggests that phenytoin may reduce the levels of quinine but the levels of phenytoin do not appear to be affected by quinine.

Clinical evidence, mechanism, importance and management

Single doses of **carbamazepine** 200 mg, **phenobarbital** 120 mg or **phenytoin** 200 mg were given to 3 groups of 6 healthy subjects with and without a single 600-mg dose of quinine sulfate. The AUC of **carbamazepine** and **phenobarbital** were increased by 104% and 57%, respectively, and the peak plasma levels were increased by 81% and 53%, respectively. **Phenytoin** was not significantly affected. The reasons for these effects are not known but the authors suggest that quinine inhibits the metabolism of **carbamazepine** and **phenobarbital** (but not **phenytoin**) by the liver, so that their levels become raised.¹

In an earlier study, **phenobarbital** 125 mg daily for 4 days caused only a small reduction in the plasma half-life of quinine in 2 healthy subjects.²

Information seems to be limited to these studies. The importance of the interactions with either **carbamazepine** and **phenobarbital** awaits assessment in a clinically realistic situation (i.e. in patients taking multiple doses) but in the meantime it would seem prudent to monitor the effects of **carbamazepine** or **phenobarbital** for evidence of increased effects and possible toxicity if quinine is also taken.

An isolated report describes a 22-month-old girl treated with **phenytoin**, **sodium valproate** and **topiramate** for epilepsy and then with quinine sulfate (initially intravenously, then orally) followed by a single dose of sulfadoxine/pyrimethamine for malaria. Her malaria film became negative after 4 days of the 7-day quinine course. About 1 month later she was found to have recrudescence of falciparum malaria, which was treated with quinine sulfate and then atovaquone/proguanil. Although it is possible that quinine resistance may have occurred, the authors also considered that enzyme induction by **phenytoin** may have led to suboptimal quinine levels.³

Although quinine does not appear to affect **phenytoin** levels, the isolated case report suggests that levels of quinine may be reduced in the presence of **phenytoin** and it would seem prudent to monitor carefully concurrent use.

Antiepileptics + Quinolones

Studies suggest that ciprofloxacin, clinafloxacin, and enoxacin do not usually have a clinically significant effect on phenytoin levels. However, case reports describe both a rise and a fall in phenytoin levels in patients given ciprofloxacin. Quinolones alone very occasionally cause convulsions, therefore they should be used with caution in patients with epilepsy.

Clinical evidence

(a) Ciprofloxacin

In a study in 4 healthy subjects there was no difference in the pharmacokinetics of **phenytoin** 200 mg daily when it was given with ciprofloxacin 500 mg twice daily. However, one of the 4 subjects experienced a 30% decrease in the **phenytoin** maximum serum levels when ciprofloxacin was added.¹ In another study in 7 patients taking **phenytoin**, ciprofloxacin 500 mg twice daily for 10 days caused no significant change in **phenytoin** levels, although there was a tendency for an increase (mean 24% rise).² Four case reports describe falls of 50% or more in **phenytoin** serum levels when ciprofloxacin was added, accompanied by seizures in 3 instances.^{3–6} Another report describes unexpectedly low **phenytoin** levels (measured after a loading dose) in a woman taking ciprofloxacin.⁷ Conversely, **phenytoin** levels rose in an elderly woman, possibly as a result of the ciprofloxacin she was taking.⁸ In one report, blood levels of **phenytoin** and **valproic acid** were not affected by ciprofloxacin although a seizure occurred on the fourth day of therapy.⁹ Other cases describe seizures in patients taking **phenytoin** when given ciprofloxacin, but with little or no information on **phenytoin** levels.¹⁰

(b) Clinafloxacin

Phenytoin 300 mg daily was given to healthy subjects for 10 days, then clinafloxacin 400 mg twice daily was added for a further 2 weeks. The maximum serum **phenytoin** levels rose by 18%, from 6.74 to 7.95 mg/L, the AUC rose by 20% and the clearance fell by 17%.¹¹

(c) Enoxacin

In a study in healthy subjects, enoxacin did not appear to alter **phenytoin** serum levels, nor were multiple-dose serum enoxacin levels significantly altered by **phenytoin**.¹²

Mechanism

Fluoroquinolones alone rarely cause convulsions both in patients with and without a history of seizures. The mechanism for the effect of ciprofloxacin on phenytoin levels is unknown, and is unlikely to be due to effects on hepatic metabolism or oral absorption.^{13,14} However, ciprofloxacin decreased phenytoin levels in an *animal* study, and a suggested reason for this was increased urinary excretion.¹⁵

Importance and management

The known potential for quinolones to induce seizures suggests that these antibacterials should either be avoided in epileptics, or only used when the benefits of treatment outweigh the potential risks of seizures. Some of the reactions seem to be drug-disease interactions rather than drug-drug interactions, the usual outcome being that the control of epilepsy is worsened. However, it appears that ciprofloxacin may also alter (usually decrease) phenytoin levels, and if this combination is used it would be prudent to consider monitoring phenytoin levels. Enoxacin appears not to alter phenytoin levels.

Antiepileptics + St John's wort (*Hypericum perforatum*)

St John's wort modestly increased the clearance of single-dose carbamazepine, but had no effect on multiple-dose carbamazepine pharmacokinetics. Carbamazepine does not appear to significantly affect the pharmacokinetics of hypericin or pseudohypericin (constituents of St John's wort). St John's wort is predicted to reduce the blood levels of phenytoin and phenobarbital, but this awaits clinical confirmation.

Clinical evidence, mechanism, importance and management

In a multiple-dose study, St John's wort had no effect on the pharmacokinetics of carbamazepine or its metabolite (carbamazepine-10,11-epoxide) in 8 healthy subjects. In this study, subjects took carbamazepine 200 mg increased to 400 mg daily alone for 20 days, then with St John's wort 300 mg (standardised to 0.3% hypericin) three times daily for a further 14 days.¹ In contrast, the AUC of a single 400-mg dose of carbamazepine was reduced by 21% after St John's wort 300 mg was given three times daily for 14 days, and the AUC of the 10,11-epoxide metabolite was increased by 26%.²

St John's wort is a known enzyme inducer, and the results with single-dose carbamazepine are as predicted. However, carbamazepine is also an enzyme inducer, which induces its own metabolism (autoinduction). It is suggested that St John's wort is not sufficiently potent an inducer to further induce carbamazepine metabolism when autoinduction has occurred,¹ and therefore a small interaction is seen with single doses but no interaction is seen with multiple doses.

A double-blind, placebo-controlled study in healthy subjects found that, apart from a modest 29% decrease in the AUC of pseudohypericin, carbamazepine did not significantly affect the pharmacokinetics of either hypericin or pseudohypericin, which are both constituents of St John's wort.³ The available evidence therefore suggests that a clinically significant interaction between carbamazepine and St John's wort is unlikely. Prior to the publication of the above reports, the CSM in the UK had advised that patients taking a number of drugs including the antiepileptics carbamazepine, phenytoin and phenobarbital should not take St John's wort.⁴ This advice was based on predicted pharmacokinetic interactions. In the light of the above studies, this advice no longer applies to carbamazepine, but until more is known, it should probably still apply to phenytoin and phenobarbital.

Antiepileptics + Terbinafine

An isolated report describes the development of fatal toxic epidermal necrolysis shortly after a patient taking phenobarbital and carbamazepine started taking terbinafine.

Clinical evidence, mechanism, importance and management

An isolated report describes a 26-year-old woman with cerebral palsy who had been taking phenobarbital 15 mg with carbamazepine 400 mg daily for 12 years to control epilepsy, and who developed fatal toxic epidermal necrolysis 2 weeks after starting oral terbinafine 250 mg daily for tinea corporis. The reasons are not understood, but the authors point out that all three drugs can cause adverse skin reactions (erythema multiforme) and suggest that some synergism may have occurred.¹ It is uncertain whether this was a true interaction or a terbinafine adverse effect.

1. White SI, Bowen-Jones D. Toxic epidermal necrolysis induced by terbinafine in a patient on long-term anti-epileptics. *Br J Dermatol* (1996) 134, 188–9.

Antiepileptics + Tobacco

Smoking tobacco appears to have no important effect on the serum levels of phenytoin, phenobarbital or carbamazepine.

Clinical evidence, mechanism, importance and management

A comparative study in 88 epileptic patients taking antiepileptics (phenobarbital, phenytoin and carbamazepine alone or in combination) found that although smoking had a tendency to lower the steady-state serum levels of these drugs, a statistically significant effect on the concentration-dose ratios was only found in the patients taking phenobarbital.¹ However, in another study in healthy subjects, there was no difference in the pharmacokinetics of a single 60-mg dose of phenobarbital between smokers and non-smokers.² In practical terms smoking appears to have only a negligible effect on the serum levels of these antiepileptics and epileptics who smoke are unlikely to need higher doses than non-smokers.

1. Benetello P, Furlanut M, Pasqui L, Carmillo L, Perlotto N, Testa G. Absence of effect of cigarette smoking on serum concentrations of some anticonvulsants in epileptic patients. *Clin Pharmacokinet* (1987) 12, 302–4.
2. Mirfazaelian A, Jahanzad F, Tabatabaei-far M, Farsam H, Mahmoudian M. Effect of smoking on single dose pharmacokinetics of phenobarbital. *Biopharm Drug Dispos* (2001) 22, 403–6.

Antiepileptics + Vitamin B substances

High daily doses of pyridoxine can cause 35% reductions in phenytoin levels and 50% reductions in phenobarbital levels in some patients. Some evidence suggests that high doses of nicotinamide reduce the conversion of primidone to phenobarbital, and increase carbamazepine levels.

Clinical evidence

(a) Nicotinamide

Nicotinamide 41 to 178 mg/kg daily increased the levels of primidone and decreased the levels of primidone-derived phenobarbital in 3 children. Although two of the children had refractory seizures, seizure frequency decreased while on nicotinamide. Two of the children on carbamazepine had increases in their carbamazepine levels.¹

(b) Pyridoxine

Pyridoxine 200 mg daily for 4 weeks reduced the phenobarbital serum levels of 5 epileptics by about 50%. Reductions in serum phenytoin levels of about 35% (range 17 to 70%) were also seen when patients were given pyridoxine 80 to 400 mg daily for 2 to 4 weeks. However, no interaction occurred in a number of other patients taking these drugs.²

Mechanism

It is suggested that the pyridoxine increases and nicotinamide decreases the activity of the liver enzymes concerned with the metabolism of these antiepileptics.^{1,2}

Importance and management

Information seems to be limited, but what is known suggests that concurrent use should be monitored if large doses of pyridoxine or nicotinamide are used, being alert for the need to modify the antiepileptic dosage. It seems unlikely that small doses (as in multivitamin preparations) will interact to any great extent.

2. Hansson O, Sillanpää M. Pyridoxine and serum concentration of phenytoin and phenobarbital. *Lancet* (1976) i, 256.

Carbamazepine + Allopurinol

There is some evidence to suggest that high-dose allopurinol (15 mg/kg or 600 mg daily) can gradually raise serum carbamazepine levels by about a third. It appears that allopurinol 300 mg daily has no effect on carbamazepine levels.

Clinical evidence

In a 6-month study, 7 epileptic patients taking antiepileptics, which included carbamazepine, were also given allopurinol 100 mg three times daily for 3 months then 200 mg three times daily for 3 months. The mean trough steady-state serum carbamazepine levels of 6 of the patients rose by 30% or more and the carbamazepine clearance fell by 32% during the second 3-month period. A reduction in the carbamazepine dosage was needed in 3 patients because of the symptoms that developed.¹ Similarly, in another study allopurinol 10 mg/kg increased to 15 mg/kg daily for 12 weeks increased carbamazepine levels by 29% in 11 patients taking antiepileptics, which included carbamazepine.² Conversely, in another study, allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients) for 4 months had no effect on carbamazepine levels in 53 patients taking antiepileptics, which included carbamazepine.³

Mechanism

Uncertain. A possible explanation is that allopurinol can act as a liver enzyme inhibitor, which reduces the metabolism and clearance of carbamazepine.

Importance and management

Information is limited to these studies, but be alert for the need to reduce the dosage of carbamazepine if high doses of allopurinol are used long-term. This interaction apparently takes several weeks or even months to develop fully. More study is needed.

Carbamazepine + Amiodarone

Amiodarone does not appear to affect the pharmacokinetics of carbamazepine.

Clinical evidence, mechanism, importance and management

A single 400-mg dose of carbamazepine was given to 9 patients with cardiac disease (premature ventricular contractions, supraventricular tachycardia, sinus arrhythmia) before and after they took amiodarone 200 mg twice daily for a month. The pharmacokinetics of carbamazepine were found to be unchanged by the amiodarone. This certainly suggests that no clinically important interaction occurs, but it needs confirmation in patients who are given both drugs long term. Furthermore, the authors postulate that a higher amiodarone dose may inhibit the metabolism of the carbamazepine by the liver.¹

1. Leite SAO, Leite PJM, Rocha GA, Routledge PA, Bittencourt PRM. Carbamazepine kinetics in cardiac patients before and during amiodarone. *Arg Neuropsiquiatr* (1994) 52, 210–15.

Carbamazepine + Antipsychotics

An increase in the serum levels of carbamazepine or its epoxide metabolite has been reported in patients given loxapine, haloperidol, quetiapine, risperidone, or chlorpromazine with amoxapine. Toxicity has occurred. Thioridazine appears not to raise carbamazepine-10,11-epoxide levels. Isolated cases of Stevens-Johnson syndrome have occurred in patients taking antipsychotics with carbamazepine. Carbamazepine may reduce levels of many of the antipsychotics. A case of neuroleptic malignant syndrome had been described in a patient taking antipsychotics and carbamazepine. See also 'Antipsychotics + Antiepileptics', p.707.

Clinical evidence, mechanism, importance and management

(a) Raised carbamazepine or carbamazepine-10,11-epoxide levels

Two patients, one taking **loxapine** 500 mg daily and the other taking **chlorpromazine** 350 mg and **amoxapine** 300 mg daily, developed toxicity (ataxia, nausea, anxiety) when given carbamazepine 600 to 900 mg daily,

even though their serum carbamazepine levels were low to normal.¹ In another case, neurotoxicity (ataxia, lethargy, visual disturbances) developed in a man given carbamazepine and **loxapine**.² In all 3 cases, the toxicity appeared to be due to elevated carbamazepine-10,11-epoxide levels (the metabolite of carbamazepine).^{1,2} The problem resolved when the carbamazepine dosages were reduced. Raised carbamazepine-10,11-epoxide levels have also been reported in 2 patients after they were given **quetiapine**, with toxicity in one of the patients.³ **Risperidone** 1 mg daily for 2 weeks raised carbamazepine levels by about 20% in 8 patients.⁴ Raised serum carbamazepine levels have also been seen with 'haloperidol', (p.707).

It is relatively well documented that carbamazepine can reduce the levels of many of the antipsychotics (discussed in individual monographs elsewhere). The above reports show that the effect of the antipsychotic on carbamazepine should also be considered. The levels of both carbamazepine and its metabolite should be monitored if toxicity develops.

(b) No changes to carbamazepine-10,11-epoxide levels

Thioridazine 100 to 200 mg daily was found to have no effect on the steady-state levels of carbamazepine or carbamazepine-10,11-epoxide in 8 epileptic patients,⁵ and also carbamazepine had no significant effect on **thioridazine** plasma levels in 6 patients.⁶

(c) Stevens-Johnson syndrome

Three patients treated with various antipsychotics (**fluphenazine**, **haloperidol**, **trifluoperazine**, **chlorpromazine**) developed Stevens-Johnson syndrome within 8 to 14 days of starting to take carbamazepine. All 3 had erythema multiforme skin lesions and at least two mucous membranes were affected. After treatment, all 3 were restarted on all their previous drugs, except carbamazepine, without problems.⁷ Another case of Stevens-Johnson syndrome has been reported in a patient taking carbamazepine, **lithium carbonate**, **haloperidol** and **trihexphenidyl**.⁸ The reasons are not understood. Stevens-Johnson syndrome with carbamazepine alone is rare, and the risk appears to be mostly confined to the first 8 weeks of treatment.⁹ It may be more common in patients being treated for conditions other than epilepsy.¹⁰ It is not possible to say whether the concurrent use of antipsychotics increases the risk of its development, but until more is known it would be prudent to monitor the outcome, particularly during the first 2 weeks of combined use.

(d) Neuroleptic malignant syndrome

A 54-year old man living in a psychiatric hospital, who had been taking **haloperidol**, **levomepromazine**, **sultopride**, and metixene long-term was prescribed carbamazepine 400 mg daily for impulsive behaviour. The following day he became unstable on his feet, and after 3 days could no longer walk by himself. He had a fever of 40°C, muscle rigidity, diaphoresis, and serum creatine phosphokinase was elevated to 923 units/L. He was diagnosed as having neuroleptic malignant syndrome (NMS), and recovered after body cooling and administration of fluids, with symptoms resolving over 12 days. Before carbamazepine was given, his **haloperidol** level was 19 nanograms/mL and after 3 days of carbamazepine it was reduced to 10.9 nanograms/mL.¹¹

Carbamazepine alone is not associated with NMS. It was suggested that carbamazepine may have reduced levels of the antimuscarinic (anticholinergic) antipsychotics (**levomepromazine** and **sultopride**), resulting in cholinergic rebound, and inducing NMS.¹¹ The general applicability of this case is unknown.

Carbamazepine + Aspirin or NSAIDs

Carbamazepine levels are unaffected by aspirin or tolafenamic acid.

Clinical evidence, mechanism, importance and management

No changes in carbamazepine serum levels were seen in 10 patients who took aspirin 1.5 g daily for 3 days.¹ It would appear that no precautions are necessary if aspirin is used in patients on carbamazepine.

Tolafenamic acid 300 mg for 3 days had no significant effect on the serum levels of carbamazepine in 11 patients.¹ No special precautions seem necessary if these drugs are taken concurrently.

1. Neuvonen PJ, Lehtovaara R, Bardy A, Elomaa E. Antipyretic analgesics in patients on anti-epileptic drug therapy. *Eur J Clin Pharmacol* (1979) 15, 263–8.

Carbamazepine + Azoles

Ketoconazole causes a small to moderate rise in serum carbamazepine levels. A marked rise in carbamazepine levels has been seen in two patients taking fluconazole, with toxicity in one. Adverse effects were seen in another patient when carbamazepine was given with miconazole. Carbamazepine may markedly reduce the levels of itraconazole and possibly voriconazole, and is predicted to lower the levels of posaconazole.

Clinical evidence

(a) Fluconazole

A 33-year-old man whose seizures were stabilised by carbamazepine became extremely lethargic after taking fluconazole 150 mg daily for 3 days. His carbamazepine level was found to have risen from 11.1 to 24.5 micrograms/mL. Symptoms resolved when both drugs were stopped, and carbamazepine was later re-introduced without problem.¹ Another well-documented case report describes a threefold increase in carbamazepine levels (without any signs of toxicity) 10 days after fluconazole 400 mg daily was started.²

(b) Itraconazole

About 14 days after starting carbamazepine 400 mg daily, a patient taking itraconazole 200 mg daily was noted to have low itraconazole levels (0.15 mg/L), and about 2 months later they were undetectable. About 3 weeks after stopping the carbamazepine, itraconazole levels had reached the therapeutic range (0.36 mg/L).³ For mention of 2 patients taking carbamazepine with phenytoin, who had undetectable or very low itraconazole levels, and who relapsed or did not respond to itraconazole therapy, see 'Phenytoin + Azoles', p.552.

(c) Ketoconazole

A study in 8 patients with epilepsy taking carbamazepine found that oral ketoconazole 200 mg daily for 10 days increased their serum carbamazepine levels by 28.6% (from 5.6 to 7.2 micrograms/mL) without affecting carbamazepine-10,11-epoxide levels. When the ketoconazole was stopped the serum carbamazepine levels returned to their former levels.⁴

(d) Miconazole

A patient receiving long-term treatment with carbamazepine 400 mg daily developed malaise, myoclonia and tremor within 3 days of being given oral miconazole 1.125 g. The same reaction occurred on each subsequent occasion that miconazole was given. These toxic effects disappeared when the miconazole was withdrawn.⁵

Mechanism

Carbamazepine levels are thought to rise because azole antifungals inhibit the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of carbamazepine. Different azoles affect CYP3A4 to varying degrees, see 'azole antifungals', (p.207). Carbamazepine is an enzyme inducer, and appears to decrease the levels of azole antifungals by increasing their metabolism.

Importance and management

Evidence for these interactions is limited and in some cases the effects are only modest. Nevertheless, it would seem prudent to monitor the outcome of adding azole antifungals to established carbamazepine treatment, being alert for any evidence of increased carbamazepine adverse effects.

Note also that carbamazepine may reduce the levels of azole antifungals: a marked reduction in itraconazole levels has been reported, and some manufacturers of itraconazole consequently say that concurrent use of potent enzyme inducers such as carbamazepine is not recommended.^{6,7} Based on the interaction with 'phenytoin', (p.552), which results in reduced **posaconazole** levels, the manufacturer of **posaconazole** suggests that concurrent use of **posaconazole** and carbamazepine should be avoided, unless the benefits outweigh the risks.⁸ If both drugs are given it would seem sensible to consider increasing the **posaconazole** dose, and increase monitoring of carbamazepine levels. Based on the interaction with 'phenytoin', (p.552), the manufacturers of **voriconazole** also contraindicate the concurrent use of carbamazepine and **voriconazole**.^{9,10}

Carbamazepine + Bile-acid binding resins

Colestyramine 8 g did not affect the absorption of carbamazepine 400 mg in 6 healthy subjects, whereas colestipol 10 g reduced it by 10%. Both colestyramine and colestipol were given as a single dose 5 minutes after the carbamazepine.¹ This small reduction is unlikely to be clinically important.

Carbamazepine or Oxcarbazepine + Calcium-channel blockers

Both diltiazem and verapamil can increase serum carbamazepine levels causing toxicity. Limited evidence suggests that amlodipine and nifedipine do not affect carbamazepine levels. A single case report describes neurological toxicity in a patient taking phenytoin and carbamazepine with isradipine. The plasma levels of felodipine, nifedipine, nilvadipine, and nimodipine are reduced by carbamazepine. Felodipine levels are modestly reduced by oxcarbazepine.

Clinical evidence

(a) Diltiazem

An epileptic patient taking carbamazepine 400 mg in the morning and 600 mg in the evening developed symptoms of toxicity (dizziness, nausea, ataxia and diplopia) within 2 days of starting to take diltiazem 60 mg three times daily. His serum carbamazepine levels had risen by about 40% to 21 mg/L, but fell once again when the diltiazem was stopped. No interaction occurred when the diltiazem was replaced by **nifedipine** 20 mg three times daily.¹ Other case reports describe carbamazepine toxicity and a rise in serum levels of up to fourfold in a total of 11 patients given diltiazem.^{2–7} One patient required a 62% reduction in the carbamazepine dose.² Another patient had a marked fall in serum carbamazepine levels of 54% when diltiazem was stopped.⁸ For a further case report involving diltiazem, see *Nifedipine*, below.

(b) *Felodipine*

After taking felodipine 10 mg daily for 4 days, 10 epileptics (including 4 taking carbamazepine alone and 3 taking carbamazepine with phenytoin) had markedly reduced plasma felodipine levels (peak levels of 1.6 nanomol/L compared with 8.9 nanomol/L in 12 control subjects). The felodipine bioavailability was reduced to 6.6%.⁹ A study in 8 subjects found that the AUC of felodipine was reduced by only 28% by oxcarbazepine 600 to 900 mg daily for a week.¹⁰

(c) *Isradipine*

A man taking carbamazepine and phenytoin developed neurological toxicity while taking isradipine, which was attributed to an interaction between the phenytoin and isradipine.¹¹ However, although carbamazepine levels remained within normal limits, a commentator suggested that an interaction between carbamazepine and isradipine was plausible.¹²

(d) *Nifedipine*

Nifedipine 20 mg twice daily for 2 weeks did not affect the steady-state carbamazepine levels in 12 epileptic patients.¹³ Similarly, a retrospective study of 5 patients suggested that nifedipine does not usually raise carbamazepine levels or cause toxicity.⁴ A man had a marked rise in serum carbamazepine levels when nifedipine was replaced by **diltiazem**. When **diltiazem** was replaced by **amlodipine**, his carbamazepine levels returned to normal, suggesting that neither nifedipine nor **amlodipine** interact with carbamazepine.¹⁴ Another patient had no change in carbamazepine levels when also given nifedipine.¹

A study in 12 epileptics receiving long-term treatment with carbamazepine found that the AUC of concurrent nifedipine 20 mg was only 22% of the values seen in 12 healthy subjects not taking carbamazepine.¹³

(e) *Nilvadipine*

A 59-year-old man taking nilvadipine 8 mg daily for hypertension and haloperidol for psychotic symptoms was given carbamazepine because haloperidol alone did not control symptoms of mania. The carbamazepine dosage was gradually increased from 100 mg to 600 mg daily. Although the manic symptoms were improved, his blood pressure rose to 230/140 mmHg after 3 days of treatment with carbamazepine 600 mg daily. Blood pressure was temporarily controlled by **nifedipine** 10 mg sublingually. Retrospective analyses found that plasma levels of nilvadipine were reduced during the use of carbamazepine 100 and 300 mg daily and undetectable when the carbamazepine dose was increased to 600 mg daily. Plasma levels of nilvadipine rose after carbamazepine was discontinued and blood pressure returned to normal after about 2 weeks.¹⁵

(f) *Nimodipine*

A study in 8 epileptic patients receiving long-term treatment (including 2 taking carbamazepine with phenobarbital, 1 taking carbamazepine with clobazam, and 1 taking carbamazepine with phenytoin) found that the AUC of a single 60-mg oral dose of nimodipine was only about 15% of that achieved in a group of healthy subjects,¹⁶ suggesting that carbamazepine lowers nimodipine exposure.

(g) *Verapamil*

Carbamazepine toxicity developed in 6 epileptic patients within 36 to 96 hours of them starting to take verapamil 120 mg three times daily. The symptoms disappeared when the verapamil was withdrawn. Total carbamazepine plasma levels had risen by 46% (a 33% rise in free plasma carbamazepine levels). Rechallenge of two of the patients who only found mild toxicity with a lower dose of verapamil 120 mg twice a day caused a similar rise in serum verapamil levels, again with mild toxicity. This report also describes another patient who had elevated serum carbamazepine levels while also taking verapamil.¹⁷ Carbamazepine toxicity is described in 3 other patients, again caused by verapamil.^{18,19} The verapamil was successfully replaced by **nifedipine** in one patient.¹⁸

Oxcarbazepine 450 mg twice daily was given to 10 healthy subjects who were then also given verapamil 120 mg twice daily for 5 days. The AUC of the monohydroxy derivative of the oxcarbazepine (the active metabolite) fell by about 20% but oxcarbazepine levels were unaltered.²⁰

Mechanism

It would appear that diltiazem and verapamil inhibit the metabolism of carbamazepine by the cytochrome P450 isoenzyme CYP3A4, thereby reducing its loss from the body and increasing serum levels. In contrast, car-

bamazepine is an enzyme inducer, which increases the metabolism of the calcium-channel blockers by the liver, resulting in a very rapid loss from the body.

Importance and management

Information about the effects of calcium-channel blockers on carbamazepine is limited, but what is known indicates that if carbamazepine is given with verapamil or diltiazem, the carbamazepine dosage may possibly need to be reduced to avoid toxicity. A 50% reduction in the dose of carbamazepine has been suggested if diltiazem is to be used.⁵ Nifedipine and amlodipine normally appear to be non-interacting alternatives. Oxcarbazepine appears to be a non-interacting alternative for carbamazepine.

Carbamazepine has been shown to lower the levels of a number of calcium-channel blockers. Given that the majority are metabolised by CYP3A4 (see 'calcium-channel blockers', (p.860)) most calcium-channel blockers would be expected to interact similarly. If a calcium-channel blocker is given to a patient taking carbamazepine expect to need to use a larger dose. If carbamazepine is added to existing treatment with a calcium-channel blocker monitor the blood pressure and expect to need to increase the dose. Note that the manufacturer of nimodipine²¹ contraindicates its use with carbamazepine.

Oxcarbazepine interacts to a lesser extent than carbamazepine and it may therefore be a suitable alternative in some patients.

Carbamazepine + Danazol

Serum carbamazepine levels can be doubled by danazol and carbamazepine toxicity may occur.

Clinical evidence

The serum carbamazepine levels of 6 epileptic patients approximately doubled within 7 to 30 days of taking danazol 400 to 600 mg daily. Acute carbamazepine toxicity (dizziness, drowsiness, blurred vision, ataxia, nausea) was experienced by 5 out of the 6 patients.¹

Other reports similarly describe rises in serum carbamazepine levels of 50 to 100% (with toxicity seen in some instances) when danazol was given.^{2–4}

Mechanism

Danazol inhibits the metabolism (by the epoxide-trans-diol pathway) of carbamazepine by the liver, thereby reducing its loss from the body.^{2,5} During danazol treatment the clearance of carbamazepine has been found to be reduced by 60%.²

Importance and management

An established and clinically important interaction. If concurrent use is necessary carbamazepine serum levels should be monitored and the dosage reduced as necessary.

Carbamazepine + Dantrolene and Oxybutynin

Carbamazepine toxicity has been reported in a patient given oxybutynin and dantrolene.

Clinical evidence

A woman with incomplete tetraplegia who had taken carbamazepine 1 g daily for neuropathic pain for 2 years was given dantrolene in a gradually increasing dose and oxybutynin 5 mg twice daily. Two weeks after starting oxybutynin and while receiving dantrolene 125 mg daily, she experienced dizziness and vomiting, drowsiness, confusion, slurred speech, and nystagmus, and was found to have a raised carbamazepine level of 16 micrograms/mL. All drugs were stopped and the plasma carbamazepine level fell to 8.3 micrograms/mL (therapeutic range 4 to 12 micrograms/mL). Because of pain, urinary frequency and spasticity, daily doses of carbamazepine 600 mg, oxybutynin 10 mg and dantrolene 100 mg were restarted which resulted in a carbamazepine level of 9.2 micrograms/mL. The dantrolene dosage was increased to 125 mg daily because of continuing spasticity, but after one day, symptoms of carbamazepine toxicity occurred and the carbamazepine plasma level was 29 micrograms/mL. Carbamazepine and oxybutynin were discontinued and the dantrolene dose was reduced to 25 mg. In order to relieve the patient's symptoms of pain and spasticity, carbamazepine 400 mg daily and dantrolene 25 mg daily were given (carbamazepine levels of 8.4 micrograms/mL at 7 days). The addition of oxybutynin 5 mg daily was associated with an increase in the carbamazepine level to 32 micrograms/mL and symptoms of toxicity. Carbamazepine was replaced by **valproate** 600 mg daily, which appeared to be beneficial and without an interaction with dantrolene or oxybutynin.¹

Mechanism, importance and management

In the reported case, oxybutynin was being taken on each occasion when carbamazepine levels increased. This increase was probably due to the inhibition by oxybutynin of the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of carbamazepine. Dantrolene was also being taken and the second episode of carbamazepine toxicity occurred after the dantrolene dose was increased. The exact mechanism of dantrolene metabolism is not known but it may decrease the activity of cytochrome P450 isoenzymes in a dose-dependent manner. Valproate, which is mainly metabolised by glucuronide conjugation, was not affected by concurrent oxybutynin or dantrolene. The authors recommend careful monitoring and, if necessary, dose adjustments if carbamazepine is given with dantrolene and/or oxybutynin.¹

1. Vander T, Odi H, Bluvstein , Ronen J, Catz A. Carbamazepine toxicity following oxybutynin and dantrolene administration; a case report. *Spinal Cord* (2005) 43, 252–5.

Carbamazepine + Dextromethorphan

Dextromethorphan appears not to affect the serum levels of carbamazepine.

Clinical evidence, mechanism, importance and management

A double-blind, crossover study in 5 epileptic patients with severe complex partial seizures found that dextromethorphan 120 mg daily in liquid form (*DelSYM*) over 3 months had no effect on their serum carbamazepine levels. There was a non-significant alteration in the complex partial seizure and tonic-clonic seizure frequency.¹

1. Fisher RS, Cysyk BJ, Lesser RP, Pontecorvo MJ, Ferkany JT, Schwerdt PR, Hart J, Gordon B. Dextromethorphan for treatment of complex partial seizures. *Neurology* (1990) 40, 547–9.

Carbamazepine or Oxcarbazepine + Dextropropoxyphene (Propoxyphene)

Carbamazepine serum levels can be raised by dextropropoxyphene. Toxicity may develop unless suitable dosage reductions are made. Oxcarbazepine appears not to interact with dextropropoxyphene.

Clinical evidence

(a) Carbamazepine

The observation of toxicity (headache, dizziness, ataxia, nausea, tiredness) in patients taking both carbamazepine and dextropropoxyphene prompted further study. Five carbamazepine-treated patients given dextropropoxyphene 65 mg three times daily had a mean rise in serum carbamazepine levels of 65%, and 3 showed evidence of carbamazepine toxicity. Carbamazepine levels were not taken in a further 2 patients because they withdrew from the study after 2 days of treatment due to adverse effects.^{1,2} In a further study a 66% rise in carbamazepine levels was seen after 6 days of treatment with dextropropoxyphene.³

Carbamazepine toxicity due to this interaction is reported elsewhere,^{4–7} and rises in trough serum carbamazepine levels of 69% to 600% have been described.⁸ A study in the elderly compared groups of patients taking either carbamazepine or dextropropoxyphene alone, with patients taking both drugs (21 subjects). The carbamazepine dose was about a third lower in those receiving combined treatment, yet the mean serum carbamazepine levels were still 25% higher than in the patients not taking dextropropoxyphene. The prevalence of adverse effects was also higher in patients taking both drugs.⁹

(b) Oxcarbazepine

Dextropropoxyphene 65 mg three times daily for 7 days did not affect the steady-state levels of the active metabolite of oxcarbazepine in 7 patients with epilepsy or trigeminal neuralgia.¹⁰

Mechanism

Uncertain. It is suggested that dextropropoxyphene inhibits the metabolism of carbamazepine by the liver, leading to its accumulation in the body.^{1,2}

Importance and management

The interaction between carbamazepine and dextropropoxyphene is very well established and clinically important. If concurrent use is necessary reduce the dosage of carbamazepine appropriately to prevent the development of toxicity. In many cases it may be simpler to use a non-interacting analgesic, although the occasional single dose of dextropropoxyphene probably does not matter. No special precautions seem necessary with oxcarbazepine.

Carbamazepine + Diuretics

Two patients taking carbamazepine developed hyponatraemia when they were also given hydrochlorothiazide or furosemide. Another patient developed hyponatraemia while taking carbamazepine, hydrochlorothiazide and paroxetine.

Clinical evidence, mechanism, importance and management

Two epileptic patients taking carbamazepine developed symptomatic hyponatraemia while also taking **hydrochlorothiazide** or **furosemide**.¹ Another case has been described in a patient taking carbamazepine when also given **hydrochlorothiazide** and paroxetine.² The reasons are uncertain but all these drugs can cause sodium to be lost from the body. This seems to be an uncommon interaction, but be aware that it can occur.

Carbamazepine + Felbamate

Felbamate modestly reduces serum carbamazepine levels but increases the levels of the active metabolite, carbamazepine-10,11-epoxide. Carbamazepine may reduce felbamate levels. The importance of these changes is uncertain but it is likely to be small.

Clinical evidence

The serum carbamazepine levels of 22 patients, with doses adjusted to keep levels in the range of 4 to 12 micrograms/mL, fell by 25% (range 10 to 42%) when they were given felbamate 3 g daily. The decrease occurred within a week, reaching a plateau after 2 to 4 weeks, and returning to the original levels within 2 to 3 weeks of stopping the felbamate.¹ Other studies in epileptics have found reductions in carbamazepine levels of between 18 and 31% when felbamate was given.^{2–7} Some of these studies also found that the serum levels of the active carbamazepine metabolite carbamazepine-10,11-epoxide rose by 33% to 57%.^{1,4,5}

Carbamazepine increases the clearance of felbamate by up to 49%.^{8–10}

Mechanism

Not established. Felbamate does not induce the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of carbamazepine, but appears to alter the interaction of carbamazepine with CYP3A4.¹¹

Importance and management

This interaction is established, but its clinical importance is uncertain because the modest fall in serum carbamazepine levels would seem to be offset by the rise in levels of its metabolite, carbamazepine-10,11-epoxide, which also has anticonvulsant activity. However, monitor carbamazepine levels carefully, reducing the dose as necessary, and be alert for any changes in the anticonvulsant control. The importance of the increased felbamate clearance is uncertain. More study is needed.

Carbamazepine + Gemfibrozil

Two patients had a modest rise in their carbamazepine serum levels after they took gemfibrozil.

Clinical evidence, mechanism, importance and management

Two patients stable taking carbamazepine had rises in their serum carbamazepine levels when they were given gemfibrozil for type IV hyperlipoproteinaemia. One patient had a rise from 8.8 to 11.4 micrograms/mL within 4 days of starting gemfibrozil 300 mg daily, and the other patient had a rise from 8.3 to 13.7 micrograms/mL three months after gemfibrozil 300 mg twice daily was started.¹ It was suggested that the clearance of carbamazepine is increased in those with elevated cholesterol and total lipids. Thus, when the condition is treated with gemfibrozil, the clearance becomes more normal, which results in a rise in the serum carbamazepine levels.² The clinical importance of this interaction is uncertain but be alert for any evidence of carbamazepine toxicity (nausea, vomiting, ataxia and drowsiness) if gemfibrozil is given.

Carbamazepine + Grapefruit and other fruit juices

Grapefruit juice increases carbamazepine levels. A case of possible carbamazepine toxicity has been seen when a man taking carbamazepine started to eat grapefruit.

Clinical evidence

A 58-year-old man, taking carbamazepine 1 g daily for epilepsy developed visual disturbances with diplopia, and was found to have a carbamazepine level of 11 micrograms/mL (therapeutic range 4 to 10 micrograms/mL). Previous levels had not exceeded 5.4 micrograms/mL. The patient said that one month previously he had started to eat one whole grapefruit each day. The levels restabilised at 5.1 micrograms/mL after the carbamazepine dose was reduced to 800 mg daily.¹

A randomised, crossover study in 10 epileptic patients taking carbamazepine 200 mg three times daily found that a single 300-mL drink of grapefruit juice increased the plasma levels and AUC of carbamazepine by about 40%.²

Mechanism

The cytochrome P450 isoenzyme CYP3A4 is the main enzyme involved in the metabolism of carbamazepine.³ Components of grapefruit juice are known to inhibit CYP3A4, which in this case would lead to a reduction in the metabolism of carbamazepine, and therefore an increase in levels.^{1,2,4} Preliminary *in vitro* and *animal* studies suggest that **pomegranate juice** may also contain components that inhibit the CYP-mediated metabolism of carbamazepine.⁵

Importance and management

Although the information is sparse, the interaction has been predicted, demonstrated in a study, and has also occurred in practice. The authors of the study,² suggest that grapefruit juice should be avoided in patients taking carbamazepine. In the case report,¹ the patient continued to eat grapefruit, and this was successfully managed by a reduction in the

carbamazepine dose. However, it should be noted that intake of a set amount of grapefruit would need to be maintained for this approach to work. The manufacturers advise carbamazepine dosage adjustment and monitoring of carbamazepine levels in patients taking substances that may raise carbamazepine levels, such as grapefruit juice.³ If monitoring is not practical, or regular intake of grapefruit is not desired, it would seem prudent to avoid grapefruit/grapefruit juice.

What is of particular interest in the case cited is that the interaction apparently occurred with whole grapefruit, which is not usually considered to be a problem, although it is known that the fruit content of possible active components (e.g. flavonoids) do vary considerably. The juice (as opposed to the whole fruit) more commonly interacts, as the juicing process can increase the flavonoid content.⁴ The evidence with **pomegranate juice** is currently too sparse to predict its effects in practice.

Carbamazepine or Oxcarbazepine + H₂-receptor antagonists

The serum levels of those taking long-term carbamazepine may transiently increase, possibly accompanied by an increase in adverse effects, for the first few days after starting to take cimetidine, but these adverse effects rapidly disappear. Cimetidine does not appear to have this effect on oxcarbazepine levels. Ranitidine appears not to interact with carbamazepine.

Clinical evidence

(a) Carbamazepine

The steady-state carbamazepine levels of 8 healthy subjects taking carbamazepine 300 mg twice daily were increased by 17% within 2 days of them starting to take **cimetidine** 400 mg three times daily. Adverse effects occurred in 6 patients, but after 7 days of treatment the carbamazepine levels had fallen again and the adverse effects disappeared.¹

Conversely, the steady-state carbamazepine levels of 7 epileptic patients receiving long-term treatment remained unaltered when they were given **cimetidine** 1 g daily for a week.² Another study also showed a lack of an interaction in 11 epileptic patients.³ However, an 89-year-old woman taking carbamazepine 600 mg daily developed symptoms of carbamazepine toxicity within 2 days of starting to take **cimetidine** 400 mg daily, and had a rise in serum carbamazepine levels, which fell when the **cimetidine** was withdrawn.⁴ The effects of **cimetidine** may be additive with those of isoniazid, see 'Carbamazepine + Isoniazid or Rifampicin (Rifampin)', below.

The results of these studies in patients and subjects taking carbamazepine long term differ from single-dose studies and short-term studies in healthy subjects. For example, a 33% rise in serum carbamazepine levels,⁵ a 20% fall in clearance⁶ and a 26% increase in the AUC⁷ have been reported, which would indicate that there is some potential for a clinically significant interaction (see 'Mechanism' below).

In 8 healthy subjects **ranitidine** 300 mg daily did not affect the pharmacokinetics of a single 600-mg dose of carbamazepine.⁸

(b) Oxcarbazepine

No changes in the pharmacokinetics of a single 600-mg oral dose of oxcarbazepine were seen in 8 healthy subjects who took **cimetidine** 400 mg twice daily for 7 days.⁹

Mechanism

Not fully understood. It is thought that cimetidine can inhibit the activity of the liver enzymes concerned with the metabolism of carbamazepine (such as the cytochrome P450 isoenzyme CYP3A4), resulting in its reduced clearance from the body, but the effect is short-lived because the auto-inducing effects of the carbamazepine oppose it. This would possibly explain why the single-dose and short-term studies in healthy subjects

suggest that a clinically important interaction could occur, but in practice the combination causes few problems in patients receiving long-term treatment.

Importance and management

The interaction between carbamazepine and cimetidine is established but of minimal importance. Patients receiving long-term treatment with carbamazepine should be warned that for the first few days after starting to take cimetidine they may possibly experience some increase in carbamazepine adverse effects (nausea, headache, dizziness, fatigue, drowsiness, ataxia, an inability to concentrate, a bitter taste). However, because the serum levels are only transiently increased, these effects should subside and disappear by the end of a week. Ranitidine appears to be a non-interacting alternative to cimetidine.

Carbamazepine + Influenza vaccines

In one study carbamazepine levels rose modestly 14 days after an influenza vaccine was given. A case report describes carbamazepine toxicity and markedly increased carbamazepine levels in a teenager 13 days after she was given an influenza vaccine.

Clinical evidence, mechanism, importance and management

The serum carbamazepine levels of 20 children rose by 47% from 6.17 to 9.04 micrograms/mL 14 days after they were given 0.5 mL of influenza vaccine USP, types A and B, whole virus (Squibb). Levels remained elevated on day 28.¹ A teenager taking carbamazepine 400 mg in the morning and 600 mg at night with gabapentin 600 mg three times daily developed signs of carbamazepine toxicity (unsteady, lethargic, slurred speech) 13 days after she was given an influenza vaccination (*Fluzone*, Aventis Pasteur). Her serum carbamazepine level was 27.5 micrograms/mL (previous levels 8.2 to 12.4 micrograms/mL), and she required ventilation for 19 hours. A urine drug screen was positive for tricyclic antidepressants and cocaine, but it was eventually concluded that these were likely to represent false-positive results.²

It has been suggested that the vaccine inhibits the liver enzymes concerned with the metabolism of carbamazepine, and therefore raising its levels. The moderate increase in serum carbamazepine levels seen in the first study is unlikely to have much clinical relevance. However, the case report of markedly increased carbamazepine levels introduces a note of caution. Further study is needed.

Carbamazepine + Isoniazid or Rifampicin (Rifampin)

Carbamazepine serum levels are markedly and very rapidly increased by isoniazid and toxicity can occur. Rifampicin has been reported both to augment and negate this interaction. There is evidence to suggest that carbamazepine may potentiate isoniazid hepatotoxicity.

Clinical evidence

Disorientation, listlessness, aggression, lethargy and, in one case, extreme drowsiness developed in 10 out of 13 patients taking carbamazepine when they were given isoniazid 200 mg daily. Serum carbamazepine levels were measured in 3 of the patients and they were found to have risen above the normal therapeutic range (initial level not stated).¹

Carbamazepine toxicity, associated with marked rises in serum carbamazepine levels, has been described in other reports.²⁻⁶ Some of the patients were also taking sodium valproate, which does not seem to be implicated in the interaction, and in one case cimetidine, which was thought to have potentiated the interaction.⁶ See also 'Carbamazepine or Oxcarbazepine + H₂-receptor antagonists', p.529.

One report describes carbamazepine toxicity in a patient given isoniazid, but only when rifampicin was present as well. Usually the enzyme-inducing effects of rifampicin would be expected to counteract any enzyme inhibition by isoniazid, so this report is somewhat inexplicable.⁷ Conversely, a case report describes reduced carbamazepine levels in a woman given rifampicin and isoniazid, which resulted in reduced carbamazepine efficacy (symptoms of hypomania).⁸

Isoniazid-induced fulminant liver failure occurred in a 16-year-old girl taking carbamazepine and clonazepam, within 5 days of starting isoniazid, rifampicin and pyrazinamide. She recovered with supportive measures and later tolerated the antiepileptics with concurrent rifampicin and pyrazinamide.⁹ Isoniazid hepatotoxicity has also occurred in a 74-year-old woman¹⁰ and a 10-year-old boy¹¹ taking carbamazepine, shortly after treatment with isoniazid, rifampicin, and ethambutol, with or without pyrazinamide, was started.

Mechanism

It seems probable that isoniazid inhibits the activity of the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of carbamazepine, causing it to accumulate in the body.¹² Rifampicin is a potent enzyme inducer, and would be expected to negate the effects of isoniazid, and to induce the metabolism of carbamazepine. This is supported by one report, but not another.

Importance and management

The documentation is limited, but a clinically important and potentially serious interaction is established between isoniazid and carbamazepine. Toxicity can develop quickly (within 1 to 5 days) and also seems to disappear quickly if the isoniazid is withdrawn. Concurrent use should not be undertaken unless the effects can be closely monitored and suitable downward dosage adjustments made (a reduction to between one-half or one-third was effective in 3 patients¹). It seems probable that those who are 'slow' metabolisers of isoniazid may show this interaction more quickly and to a greater extent than fast metabolisers.²

The effect of concurrent rifampicin on the interaction between isoniazid and carbamazepine is unclear. One report showed negation of the interaction, whereas another showed potential augmentation. Limited evidence suggests that carbamazepine may potentiate isoniazid hepatotoxicity.

Carbamazepine + Isotretinoin

A study in one patient found that isotretinoin modestly reduced the serum levels of both carbamazepine and its active metabolite.

Clinical evidence, mechanism, importance and management

The carbamazepine AUC in an epileptic patient taking carbamazepine 600 mg daily was reduced by 11% when isotretinoin 500 micrograms/kg daily, was taken, and by 24% when 1 mg/kg daily was taken. The AUC of carbamazepine-10,11-epoxide (the active metabolite of carbamazepine) was reduced by 21 and 44% by the small and large doses of isotretinoin, respectively. The patient had no adverse effects.¹ Although the author of the report suggests that monitoring may be necessary in patients given both drugs changes of this magnitude, especially those seen with the lower dose, are not usually clinically significant.

1. Marsden JR. Effect of isotretinoin on carbamazepine pharmacokinetics. *Br J Dermatol* (1988) 119, 403-4.

Carbamazepine + Lamotrigine

Most studies have found that lamotrigine has no effect on the pharmacokinetics of carbamazepine or its epoxide metabolite. However, some studies have found that lamotrigine raises the serum levels of carbamazepine-10,11-epoxide. Carbamazepine reduces lamotrigine levels. Symptoms of toxicity have been seen irrespective of changes in levels.

Clinical evidence

(a) Effects on carbamazepine

The addition of lamotrigine increased the serum levels of carbamazepine-10,11-epoxide, the active metabolite of carbamazepine, in 3 epileptic patients, but carbamazepine levels remained unchanged. One of the patients had carbamazepine-10,11-epoxide serum levels of 2 to 2.2 micrograms/mL while taking carbamazepine 1.1 g daily. The levels rose to 4.7 to 8.7 micrograms/mL when lamotrigine was added. Symptoms of toxicity occurred in 2 patients (dizziness, double vision, sleepiness, nausea).¹ In another study in 9 patients, the addition of lamotrigine 200 mg increased the mean serum carbamazepine-10,11-epoxide levels by 45%. Toxicity was seen in 4 patients (dizziness, nausea, diplopia).² The addition of lamotrigine resulted in cerebellar toxicity (nausea, vertigo, nystagmus, ataxia) in 8 out of 9 patients taking subtoxic and just-tolerated doses of carbamazepine when lamotrigine was added. Analysis showed that in all 8 cases at least one of the levels of carbamazepine, carbamazepine-10,11-epoxide or lamotrigine had become unusually high, but the authors concluded the interaction was likely to be pharmacodynamic rather than pharmacokinetic.³

In contrast other studies have found that the concurrent use of lamotrigine and carbamazepine does not result in any clinically significant pharmacokinetic changes. Lamotrigine caused no changes in carbamazepine levels in two clinical studies,^{4,5} and another pharmacokinetic study found that lamotrigine 200 to 300 mg daily had no effect on the disposition of a single dose of oral carbamazepine-epoxide.⁶ Another study in 47 patients taking carbamazepine, to which lamotrigine was added, found no significant changes in carbamazepine or carbamazepine-10,11-epoxide levels. Despite this 9 cases of diplopia or dizziness were recorded, predominantly in those whose carbamazepine levels were already high before the lamotrigine was added, even though there was no change in carbamazepine or carbamazepine-10,11-epoxide levels.⁷ A further well-designed study in healthy subjects found that lamotrigine 100 mg twice daily for a week had no effect on the pharmacokinetics of carbamazepine or carbamazepine-10,11-epoxide after a single 200-mg dose of carbamazepine.⁸ Similarly, lamotrigine had no effect on mean carbamazepine levels, and actually decreased mean carbamazepine-10,11-epoxide levels by 23% in a study in 14 children. Two children developed diplopia, which was unrelated to drug levels, but responded to a reduction in lamotrigine dose in one, and a reduction in carbamazepine dose in the other.⁹

(b) Effects on lamotrigine

In a retrospective study, the lamotrigine serum concentration-to-dose ratio was much lower in patients also taking carbamazepine than in those taking

lamotrigine monotherapy (0.38 versus 0.84).¹⁰ Other studies have reported similar findings.^{11,12} In another study, mean increases in lamotrigine levels of about 60% occurred in patients taking lamotrigine with carbamazepine when the carbamazepine was withdrawn.¹³ Similarly, a case report describes a rapid increase in lamotrigine levels when carbamazepine was withdrawn.¹⁴ A review of patients taking antiepileptics found that carbamazepine increased the clearance of lamotrigine by 30 to 50%.¹⁵

Mechanism

The apparent contradiction between the results described is not understood. One suggestion to account for the toxic symptoms seen in some patients is that it occurs at the site of action (a pharmacodynamic interaction) rather than because lamotrigine increases the carbamazepine-10,11-epoxide serum levels.^{3,7} Carbamazepine may induce the glucuronidation of lamotrigine.

Importance and management

Overall lamotrigine does not appear to significantly alter carbamazepine levels. However, toxicity has occurred, and therefore patients should be well monitored if lamotrigine is added, and the carbamazepine dose reduced if CNS adverse effects occur. Carbamazepine induces the metabolism of lamotrigine, and the recommended starting dose and long-term maintenance dose of lamotrigine in patients already taking carbamazepine is twice that of patients taking lamotrigine monotherapy.¹⁶ However, if they are also taking valproate in addition to carbamazepine, the lamotrigine dose should be reduced.¹⁶ See 'Lamotrigine + Valproate', p.542.

Carbamazepine + Macrolides

Carbamazepine serum levels are markedly and rapidly increased by erythromycin or troleandomycin, and toxicity can often develop within 1 to 3 days. Telithromycin is predicted to interact similarly. Clarithromycin also raises carbamazepine levels, but to a lesser extent. Studies suggest that azithromycin, flurithromycin, josamycin, midecamycin, and roxithromycin have no interaction, or no clinically significant interaction, with carbamazepine, but note that a case of carbamazepine toxicity has been reported in a patient given roxithromycin.

Clinical evidence

(a) Azithromycin

Azithromycin 500 mg once daily for 3 days had no effect on the pharmacokinetics of carbamazepine 200 mg twice daily or its active metabolite, carbamazepine-10,11-epoxide, in healthy subjects.¹

(b) Clarithromycin

A pharmacokinetic study² in healthy subjects found that clarithromycin 500 mg every 12 hours for 5 days increased the AUC of a single 400-mg dose of carbamazepine by 26%. A retrospective study of 5 epileptic patients found that when they were given clarithromycin (dosage not stated) their serum carbamazepine levels rose by 20 to 50% within 3 to 5 days, despite 30 to 40% reductions in the carbamazepine dosage in 4 of them. Carbamazepine levels in the toxic range were seen in 3 of them, and their carbamazepine dosages were then even further reduced.³ A number of case reports have described carbamazepine toxicity following the addition of clarithromycin in adults,^{4–6} and children.^{7,8} Two other epileptic patients had marked rises in serum carbamazepine levels when they were given clarithromycin 500 mg three times daily and omeprazole.⁹ It is not clear whether the omeprazole also had some part to play.^{10,11} See also 'Carbamazepine + Proton pump inhibitors', p.534.

(c) Erythromycin

An 8-year-old girl taking phenobarbital 50 mg and carbamazepine 800 mg daily was given 500 mg, then later 1 g of erythromycin daily. Within 2 days she began to experience balancing difficulties and ataxia, which were eventually attributed to carbamazepine toxicity. Her serum carbamazepine levels were found to have risen from a little below 10 micrograms/mL to over 25 micrograms/mL (therapeutic range 2 to 10 micrograms/mL). The levels rapidly returned to normal after carbamazepine was withheld for 24 hours and the erythromycin stopped.¹²

A study in 7 healthy subjects confirmed that erythromycin can cause significant increases in carbamazepine levels,¹³ and a study in 8 healthy subjects found that the clearance of carbamazepine is reduced by an average of 20% (range 5 to 41%) by erythromycin 1 g daily for 5 days.¹⁴ Another study, in healthy subjects given erythromycin 500 mg three times daily for 10 days, found that the clearance of a single dose of carbamazepine was reduced by about 20% and the maximum serum levels of carbamazepine-10,11-epoxide were reduced by about 40% by erythromycin.¹⁵

Marked rises in serum carbamazepine levels (up to fivefold in some cases) and/or toxicity (including cases of hepatorenal failure and AV block as well as more typical signs of carbamazepine toxicity) have been described in over 30 cases involving both children and adults. Symptoms commonly began within 24 to 72 hours of starting erythromycin, although in some cases it was as early as 8 hours. In most cases toxicity resolved within 3 to 5 days of stopping the erythromycin.^{7,16–34}

(d) Flurithromycin

Flurithromycin 500 mg three times daily for a week increased the AUC of a single 400-mg dose of carbamazepine by about 20% and moderately reduced the production of carbamazepine-10,11-epoxide in healthy subjects.³⁵

(e) Josamycin

Josamycin 1 g twice daily for a week reduced the clearance of carbamazepine by about 20% in healthy subjects and in patients.^{36–38}

(f) Midecamycin acetate

A single-dose study in 14 subjects found that after taking midecamycin acetate 800 mg twice daily for 8 days the AUC of a single 200-mg dose of carbamazepine was increased by 15%, and the AUC of its active metabolite (carbamazepine-10,11-epoxide) was reduced by 26%.³⁹ Another study in patients taking carbamazepine found that the addition of midecamycin acetate 600 mg twice daily caused a small increase in the trough serum levels of carbamazepine, and only an 11.6% increase in the AUC.⁴⁰

(g) Roxithromycin

Roxithromycin 150 mg twice daily for 8 days did not affect the pharmacokinetics of a single 200-mg dose of carbamazepine in healthy subjects.⁴¹ However, there is an isolated report of carbamazepine toxicity (levels increased to 21.7 mg/L) in a patient taking carbamazepine and atorvastatin the day after she started to take roxithromycin 150 mg twice daily. Roxithromycin and atorvastatin were stopped and carbamazepine levels fell to 12.5 mg/L within a day. The increased carbamazepine levels were attributed to the concurrent use of roxithromycin.⁴²

(h) Telithromycin

The manufacturer predicts that carbamazepine will reduce the levels of telithromycin, with possible loss of efficacy, because carbamazepine induces the cytochrome P450 isoenzyme CYP3A4. Telithromycin is an inhibitor of CYP3A4, and may therefore raise carbamazepine levels.⁴³

(i) Troleandomycin

Symptoms of carbamazepine toxicity (dizziness, nausea, vomiting, excessive drowsiness) developed in 8 epileptic patients taking carbamazepine within 24 hours of starting to take troleandomycin. The 2 patients available for examination had a sharp rise in serum carbamazepine levels, from about 5 to 28 micrograms/mL over 3 days, and a rapid fall following withdrawal of the troleandomycin.^{44,45}

Another report by the same authors describes a total of 17 similar cases of carbamazepine toxicity caused by troleandomycin.¹⁶ Some of the patients had three or fourfold increases in serum carbamazepine levels. Another case has been described elsewhere.¹² In most instances the serum carbamazepine levels returned to normal within about 3 to 5 days of withdrawing the macrolide.¹⁶

Mechanism

It seems probable that clarithromycin, erythromycin and troleandomycin, and to a lesser extent some of the other macrolides, slow the rate of metabolism of the carbamazepine by the cytochrome P450 isoenzyme CYP3A4 so that the anticonvulsant accumulates within the body.^{46,47} Telithromycin is predicted to interact similarly.⁴³ It was suggested that the carbamazepine toxicity seen with roxithromycin may have been mediated by P-glycoprotein inhibition, which occurred as a result of an interaction between roxithromycin and atorvastatin.

Importance and management

The interaction between carbamazepine and troleandomycin is established, clinically important and potentially serious. The incidence is high. The rapidity of its development (within 24 hours in some cases) and the extent of the rise in serum carbamazepine levels suggest that it would be difficult to control carbamazepine levels by reducing the dosage. Concurrent use should probably be avoided.

The interaction between carbamazepine and erythromycin is also very well documented, well established and of clinical importance. Concurrent use should be avoided unless the effects can be very closely monitored by measurement of serum carbamazepine levels and suitable dosage reductions made. Toxic symptoms (ataxia, vertigo, drowsiness, lethargy, confusion, diplopia) can develop within 24 hours, but serum carbamazepine levels can return to normal within 8 to 12 hours of withdrawing the antibacterial.³⁶

The interaction between carbamazepine and clarithromycin is also established, clinically important and potentially serious. However, the extent of the interaction is less with clarithromycin than with erythromycin or troleandomycin (i.e. the rise in carbamazepine levels is less).⁴⁸ It has been recommended that carbamazepine dosages should be reduced by 30 to 50% during treatment with clarithromycin, with monitoring within 3 to 5 days, and patients should be told to tell their doctor of any symptoms of toxicity (dizziness, diplopia, ataxia, mental confusion).

Analysis of the macrolide/carbamazepine interactions has shown that patients requiring high doses of carbamazepine to reach therapeutic levels are likely to have a greater rise in their carbamazepine levels.⁴⁸ The extent of the interactions is also correlated with the macrolide dose.⁴⁸

Josamycin, flurithromycin and midecamycin acetate appear to be safer alternatives to either clarithromycin, erythromycin or troleandomycin. Nevertheless a small or moderate reduction in the dosage of the carbamazepine may be needed, with subsequent good monitoring. Pharmacokinetic data suggest that azithromycin and roxithromycin do not interact. However, there is an isolated report of carbamazepine toxicity in a patient taking roxithromycin, but this was complicated by the presence of atorvastatin. Telithromycin is predicted to interact, and the manufacturer advises avoidance of the combination, and suggests that telithromycin should not be used within 2 weeks of stopping carbamazepine.⁴³

Carbamazepine + MAOIs

Phenelzine, moclobemide and tranlycypromine appear not to interact adversely with carbamazepine.

Clinical evidence, mechanism, importance and management

There appear to be no reports of adverse reactions during the concurrent use of MAOIs and carbamazepine. However, the manufacturers of carbamazepine¹ say that concurrent use should be avoided because of the close structural similarity between carbamazepine and the tricyclic antidepressants (and therefore the theoretical risk of an adverse interaction). They suggest that MAOIs should be discontinued at least 2 weeks before carbamazepine is started. Several reports describe successful use of carbamazepine and MAOIs, namely **tranlycypromine**,^{2,3} **phenelzine**,⁴ and **moclobemide**.⁵ Bearing in mind that the MAOIs and the tricyclics can be given together under certain well controlled conditions (see 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1149), the warning about the risks may possibly prove to be overcautious. Note that, rarely, the MAOIs have been seen to cause convulsions.

Carbamazepine + Melatonin

Melatonin does not affect the serum levels of carbamazepine or its 10,11-epoxide metabolite.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study on the effects of melatonin on antioxidant enzymes, melatonin 6 to 9 mg/kg daily for 14 days was given with carbamazepine to children with epilepsy. The addition of melatonin increased the antioxidant activity of glutathione reductase, compared with a decrease in the placebo group; similar trends which did not reach statistical significance were found with glutathione peroxidase. Carbamazepine may cause reactive oxygen species (ROS) accumulation and the effect may be antagonised by melatonin. ROS can interact with other molecules within the body, causing damage to cell structures. This results in oxidative stress, which may contribute to the development of some disease states. Serum levels of carbamazepine and its metabolite carbamazepine-10,11-epoxide were not affected by concurrent melatonin which suggests a pharmacokinetic interaction is unlikely.¹

Carbamazepine + Metronidazole

Increased serum carbamazepine levels and toxicity have been seen in a patient given metronidazole.

Clinical evidence, mechanism, importance and management

A woman taking carbamazepine 1 g daily started taking co-trimoxazole twice daily and metronidazole 250 mg three times daily for diverticulitis. After 2 days the co-trimoxazole was stopped, she was changed to intravenous metronidazole 500 mg three times daily, and cefazolin 500 mg every 8 hours. After 2 days she complained of diplopia, dizziness and nausea, and her serum carbamazepine levels were found to have risen from 9 to 14.3 micrograms/mL. A month later (presumably after the metronidazole had been withdrawn) her serum carbamazepine levels had fallen to 7.1 micrograms/mL. The reasons for this reaction are not understood.¹

This appears to be the first and only report of an interaction between car-

bamazepine and metronidazole, so its general importance is uncertain. More study is needed.

1. Patterson BD. Possible interaction between metronidazole and carbamazepine. *Ann Pharmacother* (1994) 28, 1303-4.

Carbamazepine + Nefazodone

Five patients developed elevated serum carbamazepine levels and toxicity when nefazodone was given. A study in healthy subjects using lower carbamazepine doses found only modest increases in carbamazepine levels, and no evidence of toxicity when nefazodone was given. Carbamazepine markedly reduces nefazodone levels.

Clinical evidence

A patient taking carbamazepine 1 g daily developed evidence of toxicity (light-headedness, ataxia) within 15 days of starting to take nefazodone (initially 100 mg twice daily increasing to 150 mg twice daily after a week). Her serum carbamazepine levels had risen from below 8.3 micrograms/mL up to 10.8 micrograms/mL. It was found necessary to reduce the carbamazepine dosage to 600 mg daily to eliminate these adverse effects and to achieve a serum level of 7.4 micrograms/mL.¹ In 4 other patients taking carbamazepine 800 mg or 1 g daily the addition of nefazodone caused up to threefold rises in carbamazepine levels. The carbamazepine dose was reduced by 25 to 60%.^{1,2} In a study in 12 healthy subjects no evidence of toxicity was seen when carbamazepine 200 mg twice daily was given with nefazodone 200 mg twice daily for 5 days. However, the levels of carbamazepine were slightly increased (23% increase in AUC) and the levels of nefazodone markedly decreased (93% decrease in AUC). The authors suggest that there may be a greater effect with higher doses of carbamazepine.³

Mechanism

Both drugs are metabolised by the cytochrome P450 isoenzyme CYP3A4. Nefazodone is known to inhibit CYP3A4, whereas carbamazepine is a potent inducer of CYP3A4. Hence concurrent use reduces carbamazepine metabolism, leading to raised levels, and increases nefazodone levels, leading to lowered levels.

Importance and management

Information is limited, but it would seem prudent to monitor for signs of carbamazepine toxicity if nefazodone is added to established treatment, especially with doses of carbamazepine above 800 mg. The nefazodone dosage may need to be increased in the presence of carbamazepine, so be alert for a reduced effect. Nefazodone has largely been withdrawn, but the US manufacturer of nefazodone did contraindicate its concurrent use with carbamazepine.⁴

Carbamazepine + Phenobarbital

Carbamazepine serum levels are reduced to some extent by phenobarbital, and carbamazepine-10,11-epoxide levels are raised. In children, phenobarbital clearance is decreased by carbamazepine.

Clinical evidence

A comparative study found that on average patients taking both carbamazepine and phenobarbital (44 patients) had carbamazepine serum levels that were 18% lower than those taking carbamazepine alone (43 patients).¹ Similar results were found in other studies in both adult and paediatric patients taking both drugs.²⁻⁵ Levels of the active metabolite, carbamazepine-10,11-epoxide, were increased.³⁻⁶ However, one study

found that the clearance of a single dose of carbamazepine-10,11-epoxide was higher and the plasma half-life shorter in epileptic patients taking phenobarbital when compared with healthy subjects not taking phenobarbital.⁷

In a prospective study the clearance of phenobarbital in 222 patients receiving monotherapy was compared to that in 63 patients who were also taking carbamazepine. During phenobarbital monotherapy, clearance was highest in the very young, decreased with increasing weight, and was lowest in adults. The pattern was similar for carbamazepine, except that its clearance was decreased by phenobarbital. Further, the effects of carbamazepine on phenobarbital clearance were maximal in young children (about 54%) and minimal in adults.⁸

Mechanism

Phenobarbital and carbamazepine are both known enzyme inducers, and may therefore increase each others metabolism. Phenobarbital may also induce the metabolism of carbamazepine-10,11-epoxide.⁷

Importance and management

An established interaction. It would be prudent to monitor phenobarbital levels in children also given carbamazepine, as changes in clearance may affect dose requirements. The small fall in serum carbamazepine levels probably has little practical importance, especially since the metabolite carbamazepine-10,11-epoxide also has anticonvulsant activity. Consider also 'Carbamazepine + Primidone', below.

Carbamazepine + Primidone

A single case report suggests that primidone can reduce the effects of carbamazepine. There is other evidence that carbamazepine may reduce primidone serum levels and increase primidone-derived phenobarbital levels.

Clinical evidence

A 15-year-old boy had complex partial seizures that were not controlled despite treatment with primidone 12 mg/kg daily in three divided doses and carbamazepine 10 mg/kg daily in three divided doses. Even when the carbamazepine dosage was increased to 20 and then 30 mg/kg daily his serum carbamazepine levels only reached 4.8 micrograms/mL, and his seizures continued. When the primidone was gradually withdrawn his serum carbamazepine levels increased to 12 micrograms/mL and his seizures completely disappeared.¹

An analysis of serum levels of anticonvulsants in children found that the serum levels of primidone tended to be lower in those also taking carbamazepine, but no details were given.² Another study found that levels of phenobarbital derived from primidone were 42 micrograms/mL in patients taking primidone, carbamazepine and phenytoin, 24.7 micrograms/mL in patients taking phenytoin and primidone, and just 9.9 micrograms/mL in patients taking primidone alone.³ A further study found that primidone levels were lower in patients also taking carbamazepine, but there were no significant changes in phenobarbital levels. Carbamazepine-10,11-epoxide levels were increased by primidone.⁴ In a retrospective study, the plasma level to dose ratio for primidone was lower in patients also taking carbamazepine than in those taking primidone alone, and the derived phenobarbital levels were higher.⁵

Mechanism

When the primidone was stopped in the single case cited, the clearance of the carbamazepine decreased by about 60%.¹ This is consistent with the known enzyme-inducing effects of primidone (converted in the body to phenobarbital), which can increase the metabolism of other drugs by the liver. There is some evidence to suggest that carbamazepine may increase the metabolism of primidone to phenobarbital.

Importance and management

Direct information seems to be limited to these reports. It may be prudent to monitor combined treatment, and adjust doses if necessary. Consider also 'Carbamazepine + Phenobarbital', p.533.

Carbamazepine + Proton pump inhibitors

Omeprazole markedly raised the levels of a single dose of carbamazepine, but had no significant effect on carbamazepine taken long-term. Some anecdotal reports suggest that carbamazepine serum levels may possibly be reduced by lansoprazole. Pantoprazole did not affect the pharmacokinetics of carbamazepine in one study.

Clinical evidence

(a) Lansoprazole

In 2001 the manufacturers of lansoprazole had on record 5 undetailed case reports of apparent interactions between lansoprazole and carbamazepine. One of them describes the development of carbamazepine toxicity when lansoprazole was added, but there is some doubt about this case because it is thought that the patient may have started to take higher doses of carbamazepine.

The other 4 cases are consistent, in that carbamazepine levels fell shortly after lansoprazole was added, and/or the control of seizures suddenly worsened. One patient had a fall in carbamazepine serum levels from 11.5 to 7.7 mg/L. The carbamazepine levels of another patient returned to normal when the lansoprazole was stopped.¹

(b) Omeprazole

Omeprazole 20 mg daily for 14 days was found to increase the AUC of a single 400-mg dose of carbamazepine in 7 patients by 75%. The clearance was reduced by 40% and the elimination half-life was more than doubled (from 17.2 to 37.3 hours).² However, a retrospective study of the records of 10 patients who had been taking omeprazole 20 mg daily with long-term carbamazepine (rather than a single dose) found a non-significant reduction in carbamazepine serum levels.³

(c) Pantoprazole

Pantoprazole 40 mg daily for 5 days had no effect on the AUC of carbamazepine or carbamazepine-10,11-epoxide after a single 400-mg dose of carbamazepine in healthy subjects.⁴

Mechanism

Omeprazole may inhibit the oxidative metabolism of single doses of carbamazepine. However, when carbamazepine is taken continuously it induces its own metabolism by the cytochrome P450 isoenzyme CYP3A4, thereby possibly opposing the effects of this interaction.³

Importance and management

It seems that in practice no clinically relevant interaction is likely to occur between omeprazole and carbamazepine. For lansoprazole, information seems to be limited to this handful of reports from which no broad general conclusions can be drawn, but they do suggest that this interaction should be considered if **lansoprazole** is added to established treatment with carbamazepine. Pantoprazole appears not to affect the pharmacokinetics of carbamazepine.

Carbamazepine + SSRIs

Some, but not all, reports indicate that carbamazepine serum levels can be increased by fluoxetine and fluvoxamine. Toxicity may develop. Citalopram, paroxetine and sertraline do not normally affect carbamazepine, but there is an isolated case of raised carbamazepine levels with sertraline. Citalopram, paroxetine and sertraline levels may be reduced by carbamazepine. The use of carbamazepine with an SSRI has, rarely, led to effects such as hyponatraemia, the serotonin syndrome, and parkinsonism. Consideration should be given to the fact that SSRIs have been known to cause seizures.

Clinical evidence

(a) Citalopram

In a study in 12 healthy subjects citalopram 40 mg daily for 2 weeks caused no change in the pharmacokinetics of carbamazepine 400 mg once daily.¹ An approximate 30% decrease in citalopram levels occurred in 6 patients taking citalopram 40 to 60 mg daily when they were given carbamazepine 200 to 400 mg daily for 4 weeks. Despite this decrease, the combination was considered clinically useful.² Similarly, two patients with epilepsy, major depression, and panic disorder had increased citalopram levels (one had an improved antidepressant response, but the other patient experienced tremor and increased anxiety) when their treatment with carbamazepine was replaced by oxcarbazepine.³

(b) Fluoxetine

Two patients developed carbamazepine toxicity (diplopia, blurred vision, tremor, vertigo, nausea, tinnitus etc.) within 7 and 10 days of starting to take fluoxetine 20 mg daily. Their serum carbamazepine levels were found to have risen by about 33% and 60%, respectively. The problem was resolved in one of them by reducing the carbamazepine dosage from 1 g to 800 mg daily, and in the other by stopping the fluoxetine.⁴ The effects seen in these cases are supported by a study in 6 healthy patients, where adding fluoxetine 20 mg daily to steady-state carbamazepine caused a rise in the AUC of carbamazepine and carbamazepine-10,11-epoxide (its active metabolite) of about 25 to 50%.⁵

In contrast, fluoxetine 20 mg daily for 3 weeks was found to have no effect on the serum levels of carbamazepine or carbamazepine-10,11-epoxide in 8 epileptic patients stabilised on carbamazepine.⁶

Aside from these pharmacokinetic changes two cases of parkinsonism developed within 3 and 9 days of adding fluoxetine to carbamazepine treatment. In both cases carbamazepine levels were unaffected.⁷ A case of the serotonin syndrome (shivering, agitation, myoclonic-like leg contractions, diaphoresis etc.) has also been seen, in a woman taking carbamazepine 200 mg daily and fluoxetine 20 mg daily.⁸

(c) Fluvoxamine

Increased serum levels and signs of carbamazepine toxicity (nausea, vomiting) were seen in 3 patients taking long-term carbamazepine when they were given fluvoxamine. The carbamazepine level almost doubled in one of them within 10 days of starting fluvoxamine 50 to 100 mg daily. The interaction was accommodated by reducing the carbamazepine dosage by 200 mg daily in all three (from 1 g to 800 mg in one of them, and from 800

to 600 mg daily in the other two).^{9,10} An approximate doubling of carbamazepine levels has also been seen in other patients given fluvoxamine.^{11–14}

In contrast, fluvoxamine 100 mg daily for 3 weeks was found to have no effect on the serum levels of carbamazepine or carbamazepine-10,11-epoxide in 7 epileptic patients stabilised on carbamazepine.⁶

(d) Paroxetine

In epileptic patients, paroxetine 30 mg daily for 16 days caused no changes in the plasma levels or therapeutic effects of carbamazepine. Steady-state paroxetine plasma levels were lower in those taking phenytoin (16 nanograms/mL) than in those taking carbamazepine (27 nanograms/mL) or sodium valproate (73 nanograms/mL).¹⁵

An elderly patient taking carbamazepine 200 mg daily then 400 mg daily for neuropathic pain associated with herpes zoster infection was given paroxetine 20 mg daily to treat depression. He developed vertigo, bradycardia and syncope and his plasma sodium was found to be low (120 mmol/L). Sodium levels returned to normal (135 mmol/L) over several weeks after carbamazepine was withdrawn.¹⁶

(e) Sertraline

A double blind, placebo-controlled, parallel group study in 13 healthy subjects (7 taking sertraline, 6 taking placebo) found that sertraline 200 mg daily for 17 days had no effect on the pharmacokinetics of carbamazepine 200 mg twice daily, nor on the pharmacokinetics of carbamazepine-10,11-epoxide. In addition, sertraline did not potentiate the cognitive effects of carbamazepine.¹⁷

However, an isolated report describes a woman who had taken carbamazepine 600 mg and flecainide 100 mg daily for 2 years, who had a rise in her trough serum carbamazepine levels from 4.7 to 8.5 micrograms/mL within 4 weeks of starting sertraline 100 mg daily. After 3 months of treatment, carbamazepine levels were 11.9 micrograms/mL. At the same time she developed pancytopenia (interpreted as a toxic bone marrow reaction to the increased carbamazepine), which improved when the carbamazepine and sertraline were stopped.¹⁸

An isolated report describes a woman with schizoaffective disorder successfully treated for 3 years with haloperidol and carbamazepine who was given sertraline 50 mg daily for depression. When she failed to respond, the sertraline dosage was progressively increased to 300 mg daily but her sertraline plasma levels remained low (about 17 to 25% of those predicted). Another patient on carbamazepine similarly failed to respond to the addition of sertraline and had low sertraline levels.¹⁹ In an analysis of plasma sertraline levels the concentration to daily dose ratio of sertraline was significantly lower in patients who had taken sertraline with carbamazepine compared with those who had taken sertraline without carbamazepine,²⁰ suggesting that carbamazepine lowered sertraline levels.

Mechanism

The evidence suggests that fluoxetine and fluvoxamine inhibit the metabolism of carbamazepine by the liver (presumably by inhibiting the cytochrome P450 isoenzyme CYP3A4) so that its loss from the body is reduced, leading to a rise in its serum levels.^{5,12}

Citalopram, sertraline and possibly paroxetine serum levels may be reduced because carbamazepine induces their metabolism by CYP3A4, which results in lower levels of these SSRIs. Oxcarbazepine appears not to interact. Both carbamazepine and paroxetine may cause hyponatraemia so the reduced sodium levels could be due to the effects of both drugs.¹⁶

Importance and management

Information for fluoxetine and fluvoxamine appears to be limited to these reports. It is not clear why they are inconsistent, but be alert for an increase in carbamazepine serum levels and toxicity if fluoxetine or fluvoxamine is added. The interaction appears rare. A literature search²¹ by the manufacturers of fluvoxamine only identified 8 cases of an interaction between fluvoxamine and carbamazepine up until 1995. However, because of the unpredictability of this interaction it would be prudent to monitor concurrent use, particularly in the early stages, so that any patient affected can be quickly identified. Be alert for the need to reduce the carbamazepine dosage. The manufacturers of fluoxetine suggest that carbamazepine should be started at or adjusted towards the lower end of the dosage range in those taking fluoxetine. They additionally suggest caution if fluoxetine has been taken during the previous 5 weeks.²²

There would seem to be no particular need to monitor carbamazepine levels in patients taking citalopram, paroxetine, or sertraline. However, be

aware that the SSRIs may be less effective in the presence of carbamazepine. Consider increasing the dose if necessary.

Note that SSRIs may increase seizure frequency and should therefore be used with caution in patients with epilepsy, and avoided in those with unstable epilepsy.

Carbamazepine + Terfenadine

Carbamazepine toxicity, attributed to the use of terfenadine, has been described in one case report but the interaction is not established.

Clinical evidence, mechanism, importance and management

A 18-year-old woman taking carbamazepine after treatment for brain metastases, developed confusion, disorientation, visual hallucinations, nausea and ataxia shortly after starting terfenadine 60 mg twice daily for rhinitis. The symptoms were interpreted as carbamazepine toxicity. However, her total carbamazepine serum levels of 8.9 mg/L were within the normal range. An interaction due to protein binding displacement was suspected and measurement of free carbamazepine revealed levels of 6 mg/L, almost three times the upper limit of normal. All the symptoms disappeared when the terfenadine was stopped. The authors speculate that the terfenadine had displaced the carbamazepine from its plasma protein binding sites, thereby increasing the levels of free and active carbamazepine.¹ The report is very brief and does not say whether any other drugs were being taken concurrently, so that this interaction is not established.

- Hirschfeld S, Jarosinski P. Drug interaction of terfenadine and carbamazepine. *Ann Intern Med* (1993) 118, 907–8.

Carbamazepine + Ticlopidine

One case report suggests that ticlopidine may have caused increased carbamazepine levels, with associated toxicity.

Clinical evidence, mechanism, importance and management

A 67-year-old man taking carbamazepine 600 mg twice daily developed symptoms of carbamazepine toxicity (drowsiness, dizziness, ataxia) within a week of starting to take ticlopidine 250 mg twice daily. His carbamazepine level one week after starting the ticlopidine was 17.7 [micrograms/mL], but it had been only 10.1 [micrograms/mL] five weeks earlier. The carbamazepine dose was reduced to 500 mg twice daily, with resolution of symptoms, and producing a level of 12.5 [micrograms/mL] one week later. After stopping the ticlopidine, carbamazepine levels fell to 9.9 [micrograms/mL]. It was suggested that ticlopidine may interfere with carbamazepine metabolism.¹ However, carbamazepine is principally metabolised by the cytochrome P450 isoenzyme CYP3A4, and ticlopidine is not usually considered an inhibitor of this isoenzyme. This is the only report so far, and its general relevance is uncertain.

- Brown RIG, Cooper TG. Ticlopidine-carbamazepine interaction in a coronary stent patient. *Can J Cardiol* (1997) 13, 853–4.

Carbamazepine + Trazodone

A single case report describes a moderate rise in serum carbamazepine levels in a patient given trazodone. Carbamazepine may moderately decrease trazodone levels.

Clinical evidence, mechanism, importance and management

A 53-year-old man who had been taking carbamazepine 700 mg daily for 7 months (serum levels 7.2 and 7.9 mg/L) started taking trazodone 100 mg daily. Two months later his serum carbamazepine levels were 10 mg/L and the concentration/dose ratio had increased by about 26%, but no signs or symptoms of carbamazepine toxicity were seen. The reasons for this interaction are not known but the authors suggest that it might occur because trazodone inhibits the cytochrome P450 isoenzyme CYP3A4 resulting in a reduction in the metabolism of the carbamazepine.¹

This seems to be the first and only report of raised carbamazepine levels with trazodone, and its general importance is unknown. The rise was only moderate and in this case was clinically irrelevant, but a carbamazepine serum rise of 26% might possibly be of importance in those patients with serum levels already near the top end of the therapeutic range.

In 6 patients taking trazodone 150 or 300 mg daily, the addition of carbamazepine 400 mg daily for 4 weeks decreased the plasma levels of trazodone by 24%, and of the active metabolite of trazodone by 40%.² However, the combination was considered clinically useful in three of the cases.² In another study, when carbamazepine 400 mg daily was given with trazodone 100 to 300 mg daily, the plasma levels of trazodone and its active metabolite were reduced by 76% and 60%, respectively.³ The FDA in the US and the manufacturer of trazodone recommend that patients should be closely monitored and trazodone doses increased if necessary when both drugs are given.⁴

- Molipaxin (Trazodone hydrochloride). Sanofi-Aventis. UK Summary of product characteristics, July 2005.

Carbamazepine + Valnoctamide

Carbamazepine toxicity may develop if valnoctamide is also taken.

Clinical evidence

A study in 6 epileptic patients taking carbamazepine 800 to 1200 mg daily found that valnoctamide 200 mg three times daily for 7 days caused a 1.5 to 6.5-fold increase in the serum levels of carbamazepine-10,11-epoxide (an active metabolite). Clinical signs of carbamazepine toxicity (drowsiness, ataxia, nystagmus) were seen in 4 of them. Two patients were also taking phenobarbital or phenytoin, and the serum levels of these drugs were unaffected by valnoctamide.¹ A further study in 6 healthy subjects found

that valnoctamide 600 mg daily for 8 days increased the half-life of a single 100-mg dose of carbamazepine-10,11-epoxide threefold, from 6.7 to 19.7 hours, and decreased its oral clearance fourfold.²

Mechanism

Valnoctamide inhibits the enzyme epoxide hydrolase, which is concerned with the metabolism and elimination of carbamazepine and its active epoxide metabolite.^{1,2}

Importance and management

Information is limited but the interaction appears to be established. Patients taking carbamazepine who also take valnoctamide could rapidly develop carbamazepine toxicity because the metabolism of its major metabolite, carbamazepine-10,11-epoxide, is inhibited. This interaction is very similar to the interaction that occurs between carbamazepine and valpromide (an isomer of valnoctamide), see 'Carbamazepine + Valproate', below. Concurrent valnoctamide should be avoided unless the carbamazepine dosage can be reduced appropriately.

1. Pisani F, Fazio A, Artesi C, Oteri G, Spina E, Tomson T, Perucca E. Impairment of carbamazepine-10,11-epoxide elimination by valnoctamide, a valpromide isomer, in healthy subjects. *Br J Clin Pharmacol* (1992) 34, 85-7.
2. Pisani F, Haj-Yehia A, Fazio A, Artesi C, Oteri G, Perucca E, Kroetz DL, Levy RH, Bialer M. Carbamazepine-valnoctamide interaction in epileptic patients: in vitro/in vivo correlation. *Epilepsia* (1993) 34, 954-9.

Carbamazepine + Valproate

The serum levels of carbamazepine are usually only slightly affected by sodium valproate, valproic acid or valpromide but a moderate to marked rise in the levels of its active metabolite, carbamazepine-10,11-epoxide may occur.

Carbamazepine may reduce the serum levels of sodium valproate by 60% or more. Concurrent use may possibly increase the incidence of sodium valproate-induced hepatotoxicity.

Clinical evidence

(a) Carbamazepine

1. *Sodium valproate or valproic acid.* A study in 7 adult epileptic patients who had been taking carbamazepine 8.3 to 13.3 mg/kg for more than 2 months found that their steady-state serum carbamazepine levels fell by an average of 24% (range 3 to 59%) over a 6-day period when they were given sodium valproate 1 g twice daily. The carbamazepine levels were reduced in 6 of the patients and remained unchanged in one. The levels of the active metabolite, carbamazepine-10,11-epoxide, increased by a mean of 38%, with small decreases or no change in 4 patients and 24 to 150% increases in the remaining 3 patients.^{1,2} Other reports state that falls,^{3,4} no changes^{3,5-7} and even a slight rise⁴ in carbamazepine levels have been seen in some patients also taking sodium valproate or valproic acid. The serum levels of carbamazepine-10,11-epoxide are reported to be increased by about 50 to 100%.^{6,8-10} This active metabolite may cause the development of marked adverse effects such as blurred vision, dizziness, vomiting, tiredness and even nystagmus.^{6-8,11} Acute psychosis, tentatively attributed to elevated epoxide levels, occurred in one patient when carbamazepine was added to sodium valproate treatment.¹²

2. *Valpromide.* Symptoms of carbamazepine toxicity developed in 5 out of 7 epileptic patients taking carbamazepine when concurrent treatment with sodium valproate was replaced by valpromide, despite the fact that their serum carbamazepine levels did not increase.¹³ The toxicity appeared to be connected with a fourfold increase in the serum levels of the metabolite of carbamazepine, carbamazepine-10,11-epoxide, which rose to 8.5 micrograms/mL.¹³

In another study in 6 epileptic patients the serum levels of carbamazepine-10,11-epoxide rose by 330% (range 110 to 864%) within a week of starting valpromide, and two of the patients developed confusion, dizziness and vomiting. The symptoms disappeared and serum carbamazepine-10,11-epoxide levels fell when the valpromide dosage was reduced by one-third.⁶

A study in healthy subjects given a single 100-mg oral dose of carbamazepine-10,11-epoxide confirmed that valpromide 300 mg twice daily

for 8 days reduced carbamazepine-10,11-epoxide clearance by 73%, and increased peak levels by 62%.¹⁴

(b) Valproate levels

A pharmacokinetic study in 6 healthy subjects found that carbamazepine, 200 mg daily, over a 17-day period increased the sodium valproate clearance by 30%.¹⁵

Other reports have described reductions in serum sodium valproate levels of 34 to 38% when carbamazepine was added,¹⁶⁻¹⁸ and rises of 50 to 65% when the carbamazepine was withdrawn.^{19,20} The rise appears to reach a plateau after about 4 weeks.²⁰ A pharmacokinetic model has been devised to estimate valproate clearance when given with carbamazepine.²¹

(c) Other effects

Evidence from epidemiological studies suggests that the risk of fatal hepatotoxicity is higher when sodium valproate is given with other antiepileptics than when it is given alone, especially in infants.^{22,23} A single case report describes hepatocellular and cholestatic jaundice and a reversible Parkinsonian syndrome in a woman taking sodium valproate and carbamazepine, which reversed when the carbamazepine was withdrawn. Levels of both drugs did not exceed the therapeutic range at any stage. The Parkinsonian syndrome was attributed to a drug interaction, whereas the hepatotoxicity was considered most likely to be due to the carbamazepine, although the valproate may have contributed.²⁴

Mechanism

The evidence suggests that carbamazepine increases the metabolism of valproate, so that it is cleared from the body more quickly. Carbamazepine may also possibly increase the formation of a minor but hepatotoxic metabolite of sodium valproate (2-propyl-4-pentenoic acid or 4-ene-VPA).^{25,26}

The latter stages of carbamazepine metabolism appear to be inhibited by both valproate and its amide derivative, valpromide.²⁷ The levels of the metabolite carbamazepine-,10,11-epoxide increase during concurrent use, probably by inhibition of its metabolism to carbamazepine-10,11-trans-diol,²⁸⁻³⁰ by epoxide hydrolase. Valpromide was found to be about 100 times more potent an inhibitor of this enzyme than sodium valproate *in vitro*³¹ and caused a threefold higher rise in epoxide levels than valproate in one study.⁶ The carbamazepine-10,11-epoxide metabolite has anticonvulsant activity, but it may also cause toxicity if its serum levels become excessive.^{6,32}

It has also been suggested that valproate is not a selective inhibitor of epoxide hydrolase but that it inhibits all the steps of the epoxide-diol pathway.³³ The trans-diol metabolite is then further converted by glucuronidation, and it seems that this step is also inhibited.³⁰

Importance and management

Moderately well documented interactions, which are established.

A minor to modest fall in carbamazepine levels may occur, but there may be a moderate to marked rise in the active epoxide metabolite. Therefore, be alert for signs of toxicity, which may indicate high levels of carbamazepine-10,11-epoxide and a need to reduce the carbamazepine dose.

Be alert for falls in the serum levels of valproate if carbamazepine is added, and rises if carbamazepine is withdrawn. Sodium valproate has been associated with serious hepatotoxicity, especially in children aged less than 3 years, and this has been more common in those receiving other antiepileptics. Sodium valproate monotherapy is to be preferred in this group.

There is also some debate about whether the combination of valproate (especially valpromide) and carbamazepine should be avoided, not only because of the risk of toxicity but also because inhibition of epoxide hydrolase may be undesirable.¹³ This enzyme is possibly important for the detoxification of a number of teratogenic, mutagenic and carcinogenic epoxides.^{6,13} More study is needed.

Carbamazepine + Vigabatrin

Vigabatrin does not normally alter carbamazepine levels, although one study has shown a modest increase, and one a modest decrease.

Clinical evidence

In an early clinical study, vigabatrin 2 to 3 g daily did not change the serum levels of carbamazepine in 12 patients.¹ Similarly, other studies found that carbamazepine levels were not significantly altered by the addition of vigabatrin.^{2,3} However, in one study in which 59 patients taking carbamazepine received vigabatrin, 34 patients had an increase in carbamazepine levels, 3 had no change, and 22 had a decrease, resulting in a mean overall increase of 6%, which was not significant.⁴ Similarly, in another study 46 out of 66 patients had an increase in carbamazepine level of at least 10% (mean increase about 24%), and in 24 of these patients the carbamazepine level exceeded the therapeutic level.⁵ In this study, the increase in carbamazepine level was greater the lower the initial car-

bamazepine level.⁵ In contrast, one study in 15 patients reported a mean 18% decrease in carbamazepine levels when vigabatrin was added.⁶

Mechanism

Not understood.

Importance and management

The studies seem to suggest that any change in carbamazepine levels with vigabatrin is of borderline clinical significance and therefore the majority of patients will not be affected. Any change is likely to be more important in patients at the top of the therapeutic carbamazepine range. It would therefore seem prudent to be alert for any increase in carbamazepine adverse effects (such as nausea and vomiting, ataxia, and drowsiness) and consider taking carbamazepine levels if these develop.

Carbamazepine + Viloxazine

Viloxazine can cause a marked rise in serum carbamazepine levels and toxicity has been seen, but it does not appear to alter oxcarbazepine levels.

Clinical evidence

(a) Carbamazepine

The serum carbamazepine levels of 7 patients rose by 50%, from 8.1 to 12.1 micrograms/mL, after they took viloxazine 100 mg three times daily for 3 weeks.¹ Signs of mild toxicity (dizziness, ataxia, fatigue, drowsiness) developed in 5 of them. These symptoms disappeared and the serum carbamazepine levels fell when the viloxazine was withdrawn.¹ Another report found a 2.5-fold increase in serum carbamazepine levels in one patient within 2 weeks of starting to take viloxazine 300 mg daily.² Another report found an average 55% rise in plasma carbamazepine levels and toxicity in 4 of 7 patients taking viloxazine.³ Yet another patient developed choreoathetosis and increased serum carbamazepine levels, which was attributed to the use of viloxazine.⁴ In one study, the pharmacokinetics of a single dose of viloxazine were reported to be unaffected by carbamazepine,⁵ but in the case report cited above, which was at steady-state, the viloxazine levels were found to be reduced.²

(b) Oxcarbazepine

In 6 patients with simple or partial seizures the steady-state serum levels of oxcarbazepine (average dose 1500 mg daily) were unaffected by the addition of viloxazine 100 mg twice daily for 10 days. No adverse effects were seen.⁶

Mechanism

Uncertain. What is known suggests that viloxazine inhibits the metabolism of carbamazepine, thereby reducing its clearance and raising its serum levels.

Importance and management

Information seems to be limited to the reports cited. If concurrent use is undertaken, serum carbamazepine levels should be monitored closely and suitable dosage reductions made as necessary to avoid possible toxicity. No special precautions seem necessary with oxcarbazepine.

Ethosuximide + Isoniazid

A single report describes a patient who developed psychotic behaviour and signs of ethosuximide toxicity when given isoniazid.

Clinical evidence, mechanism, importance and management

An epileptic patient, who had been stable taking ethosuximide and sodium valproate for 2 years, developed persistent hiccuping, nausea, vomiting, anorexia and insomnia within a week of starting to take isoniazid 300 mg daily. Psychotic behaviour gradually developed over the next 5 weeks and so the isoniazid was stopped. The appearance of these symptoms appeared to be related to the sharp rise in serum ethosuximide levels (from about 50 up to 198 micrograms/mL).¹ It is suggested that the isoniazid may have inhibited the metabolism of the ethosuximide, leading to accumulation and toxicity. The general importance of this case is uncertain.

- van Wieringen A, Vrijlandt CM. Ethosuximide intoxication caused by interaction with isoniazid. *Neurology* (1983) 33, 1227–8.

Ethosuximide + Other antiepileptics

Minor to modest falls in serum ethosuximide levels may occur if carbamazepine, primidone or phenytoin are also given, whereas methylphenobarbital or sodium valproate may cause a rise in ethosuximide levels. The effect of all these changes on seizure control is uncertain. Lamotrigine appears not to affect ethosuximide levels.

Ethosuximide is reported to have caused phenytoin toxicity in a few cases, and it appears that ethosuximide can reduce valproate serum levels.

Clinical evidence

(a) Barbiturates

In a retrospective analysis, the level to dose ratio of ethosuximide was 33% lower in 29 epileptic patients taking ethosuximide and **primidone** than in 39 patients taking ethosuximide alone,¹ suggesting that primidone reduces ethosuximide levels.

Similarly, in another study, which compared the pharmacokinetics of a single dose of ethosuximide in 10 epileptic patients taking **phenobarbital**, phenytoin and/or carbamazepine with 12 healthy controls, the epileptic group had markedly shorter (about halved) ethosuximide half-lives.² Conversely, another report stated that ethosuximide levels tended to rise [amount not stated] when **methylphenobarbital** was used (the opposite effect to that which would be expected), but did not appear to be affected by **phenobarbital** or **primidone**.³ Phenobarbital levels (from **primidone**) do not appear to be affected by ethosuximide.⁴

(b) Carbamazepine

A study in 6 healthy subjects taking ethosuximide 500 mg daily found that the mean plasma levels of ethosuximide were reduced by 17%, from 32 to 27 mg/mL by carbamazepine 200 mg daily for 18 days. One individual had a 35% reduction in ethosuximide levels.⁵ Another study, which compared 10 epileptic patients (taking enzyme-inducing antiepileptic drugs, including 4 taking carbamazepine) with 12 healthy controls found that the epileptic group had markedly shorter (about halved) ethosuximide half-lives.²

In contrast, the concurrent use of carbamazepine did not affect the correlation between ethosuximide dose and levels in another study.³

(c) Lamotrigine

Five children taking ethosuximide and various other antiepileptics had no change in their plasma ethosuximide levels when lamotrigine was also given.⁶

(d) Phenytoin

A study compared the pharmacokinetics of a single dose of ethosuximide in 10 epileptic patients taking phenobarbital, phenytoin and/or carbamazepine with 12 healthy controls. The epileptic group had markedly shorter (about halved) ethosuximide half-lives.² In contrast, the concurrent use of phenytoin did not affect the correlation between ethosuximide levels and dose in another study.³

Three cases have occurred in which ethosuximide appeared to have been responsible for increasing phenytoin levels,^{7–9} leading to the development of phenytoin toxicity in 2 patients.^{8,9}

(e) Sodium valproate

Four out of 5 patients taking ethosuximide (average dose 27 mg/kg) had an increase in their serum levels of about 50% (from 73 to 112 micrograms/mL), within 3 weeks of starting to take sodium valproate (adjusted to the maximum tolerated dose). Sedation occurred and ethosuximide dose reductions were necessary.¹⁰ In a single-dose study in 6 healthy subjects, treatment with sodium valproate for 9 days was reported to have increased the ethosuximide half-life and reduced the clearance by 15%.¹¹ However, other studies have described no changes^{12,13} or even lower serum ethosuximide levels (level to dose ratio reduced by 36%).¹

One study in 13 children found that ethosuximide can lower valproate serum levels. In the presence of ethosuximide the valproate levels were lower than with valproate alone (87 versus 120 micrograms/mL). After stopping ethosuximide the valproate levels rose by about 40%.¹⁴

Mechanism

The most probable explanation for the fall in ethosuximide levels is that the carbamazepine and the other enzyme-inducing antiepileptics increase the metabolism and clearance of ethosuximide, which is known to be metabolised by the cytochrome P450 isoenzyme CYP3A.²

Importance and management

The concurrent use of antiepileptics is common and often advantageous. Information on these interactions is sparse and even contradictory and their clinical importance is uncertain. Nevertheless, good monitoring would clearly be appropriate if these drugs are used with ethosuximide to monitor for potential toxicity and to ensure adequate seizure control.

Felbamate + Antacids

An aluminium/magnesium hydroxide-containing antacid had no effect on the absorption of felbamate.

Clinical evidence, mechanism, importance and management

Felbamate 2.4 g daily was given to 9 epileptic women for 2 weeks. For a third week the felbamate was taken with an antacid containing **aluminium/magnesium hydroxide (Maalox Plus)**. No significant changes in the plasma levels or AUC were seen.¹ No special precautions would seem to be needed if felbamate is taken with this or any other similar antacid.

1. Sachdeo RC, Narang-Sachdeo SK, Howard JR, Dix RK, Shumaker RC, Perhach JL, Rosenberg A. Effect of antacid on the absorption of felbamate in subjects with epilepsy. *Epilepsia* (1993) 34 (Suppl 6), 79–80.

Felbamate + Erythromycin

Erythromycin does not alter felbamate pharmacokinetics.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 12 epileptic patients were given felbamate 3 g or 3.6 g daily, either alone or with erythromycin 333 mg every 8 hours for 10 days. The pharmacokinetics of felbamate were unchanged by erythromycin.¹ There would therefore seem no reason for avoiding erythromycin in patients taking felbamate.

1. Sachdeo RJ, Narang-Sachdeo SK, Montgomery PA, Shumaker RC, Perhach JL, Lyness WH, Rosenberg A. Evaluation of the potential interaction between felbamate and erythromycin in patients with epilepsy. *J Clin Pharmacol* (1998) 38, 184–90.

Felbamate + Gabapentin

There is some evidence that the half-life of felbamate may be prolonged by gabapentin.

Clinical evidence, mechanism, importance and management

In a retrospective examination of clinical data from patients taking felbamate, its half-life was found to be 24 hours in 40 patients taking felbamate alone, whereas in 18 other patients also taking gabapentin (including 7 taking a third drug), the half-life was extended to 32.7 hours.¹ The practical clinical importance of this is uncertain but be alert for the need to reduce the felbamate dosage. More study is needed.

Fosphenytoin + Miscellaneous

Fosphenytoin is a prodrug of phenytoin, which is rapidly and completely hydrolysed to phenytoin in the body. It is predicted to interact with other drugs in the same way as phenytoin.^{1,2} No drugs are known to interfere with the conversion of fosphenytoin to phenytoin.²

Gabapentin + Antacids

Aluminium/magnesium hydroxide slightly reduces the absorption of gabapentin.

Clinical evidence, mechanism, importance and management

An **aluminium/magnesium hydroxide** antacid (*Maalox TC*) reduced the bioavailability of gabapentin 400 mg by about 20% when given either at the same time or 2 hours after gabapentin. When the antacid was given 2 hours before the gabapentin, the bioavailability was reduced by about 10%.¹ These small changes are unlikely to be of clinical importance. How-

ever, the manufacturer does recommend that gabapentin is taken about 2 hours after **aluminium/magnesium-containing antacids.**²

2. Neurontin (Gabapentin). Pfizer Ltd. UK Summary of product characteristics, August 2006.

Gabapentin + Cimetidine

A brief report notes that cimetidine decreased the renal clearance of gabapentin by 12%, which was not expected to be clinically important. No study details were given.¹

1. Busch JA, Bockbrader HN, Randinitis EJ, Chang T, Welling PG, Reece PA, Underwood B, Sedman AJ, Vollmer KO, Türk D. Lack of clinically significant drug interactions with Neurontin (Gabapentin). 20th International Epilepsy Congress. Oslo, Norway, July 1993. Abstract 013958.

Gabapentin + Food

Food, including protein and enteral feeds, does not have a clinically important effect on the absorption of gabapentin.

Clinical evidence, mechanism, importance and management

A high-protein meal (80 g of total protein) increased the maximum serum levels of a single 800-mg dose of gabapentin by 36% in healthy subjects. The AUC was increased by 11%, which was not statistically significant. These findings were the opposite of those expected, since L-amino acids compete for gabapentin intestinal transport *in vitro*.¹

In another single-dose study, the absorption of gabapentin capsules did not differ when opened and mixed with either **apple sauce** or **orange juice**, but tended to be higher (AUC increased by 26%) when mixed with a protein-containing vehicle (**chocolate pudding**).² Similarly, no change in absorption was found when gabapentin syrup was mixed with tap water, **grape juice**, or an **enteral feed (Sustacal)**, but a modest 31% increase in AUC was seen when it was mixed with **chocolate milk**.³

These small changes are unlikely to be of clinical importance, so it does not matter when gabapentin is taken in relation to food.

Gabapentin + Other antiepileptics

Gabapentin does not normally affect the pharmacokinetics of carbamazepine, phenytoin, phenobarbital or sodium valproate, and no dosage adjustments are needed on concurrent use. However, isolated reports describe increased phenytoin levels and toxicity in two patients given gabapentin.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of both **phenytoin** and gabapentin remained unchanged in 8 epileptics who were given gabapentin 400 mg three times daily for 8 days, in addition to **phenytoin**, which they had been taking for at least 2 months.¹ Other studies confirm that the steady-state pharmacokinetics of **phenytoin** are unaffected by gabapentin, and that the pharmacokinetics of gabapentin are similarly unaffected by **phenytoin**.^{2,3} These reports contrast with an isolated report of a patient taking **phenytoin, carbamazepine** and **clobazam** whose serum **phenytoin** levels increased three to fourfold, with symptoms of toxicity, on two occasions when gabapentin 300 to 600 mg daily was given. **Carbamazepine** serum levels remained unchanged. The author suggests that this differing reaction may be because the patient was taking more than one antiepileptic, unlike previous studies where only single drugs had been used.⁴ However, another case of **phenytoin** toxicity possibly attributable to gabapentin has been described in a patient who was not taking any other antiepileptics.⁵

Gabapentin does not affect **phenobarbital** levels, nor is it affected by **phenobarbital**.^{2,3,6} Other studies confirm that the steady-state pharmacokinetics of **carbamazepine** and **sodium valproate** are unaffected by gabapentin, and that the pharmacokinetics of gabapentin are similarly unaffected by these antiepileptics.^{2,3,7}

It would seem therefore that no dosage adjustments are normally needed if gabapentin is added to treatment with most of these antiepileptics. However, if gabapentin is added to **phenytoin** it may be wise to bear the possibility of raised **phenytoin** levels in mind. For mention that gabapentin may prolong the half-life of **felbamate**, see 'Felbamate + Gabapentin', p.540. For mention of the lack of interaction between **levetiracetam** and gabapentin, see 'Levetiracetam + Other antiepileptics', p.543.

Gabapentin + Probenecid

A brief report notes that probenecid had no effect on the renal clearance of gabapentin. No study details were given.¹

1. Busch JA, Brockbrader HN, Randinitis EJ, Chang T, Welling PG, Reece PA, Underwood B, Sedman AJ, Vollmer KO, Türck D. Lack of clinically significant drug interactions with Neurontin (Gabapentin). 20th International Epilepsy Congress. Oslo, Norway, July 1993. Abstract 013958.

Lamotrigine + Antimycobacterials

Rifampicin markedly increased the clearance of lamotrigine in a pharmacokinetic study. A case report has described a similar finding, and also included some limited evidence suggesting that isoniazid may inhibit lamotrigine metabolism.

Clinical evidence

Rifampicin 600 mg daily for 5 days increased the clearance of a single 25-mg dose of lamotrigine by 97% and decreased the AUC by 44% in 10 healthy subjects. The amount of lamotrigine glucuronide recovered in the urine was increased by 36%.¹ Similarly, a case report² describes a 56-year-old woman taking lamotrigine 150 mg daily who had unexpectedly low serum lamotrigine levels of 1.3 mg/L after starting **rifampicin**, **isoniazid** and pyrazinamide. The lamotrigine dosage was therefore increased to 250 mg daily. After treatment was changed to **isoniazid** and ethambutol, the lamotrigine serum levels rose to 12.4 mg/L. Levels less than 10 mg/L are associated with less toxicity; however, in this patient no toxicity was seen.

Mechanism

Rifampicin increases the loss of lamotrigine from the body, probably by inducing glucuronidation via UDP-glucuronyl transferases.¹ It was suggested that isoniazid may have inhibited lamotrigine metabolism.²

Importance and management

Information appears to be limited to these reports, but the interaction between lamotrigine and rifampicin would appear to be established. Be aware that rifampicin could reduce the efficacy of lamotrigine, and that increased lamotrigine doses are likely to be required.

The case report also raises the possibility of an interaction between lamotrigine and isoniazid. If isoniazid is added to or withdrawn from lamotrigine treatment, be alert for the need to adjust the lamotrigine dosage.

2. Armijo JA, Sánchez B, Peralta FG, Cuadrado A, Leno C. Lamotrigine interaction with rifampicin and isoniazid. A case report. *Methods Find Exp Clin Pharmacol* (1996) 18 (Suppl C), 59.

Lamotrigine + Cimetidine

Cimetidine 400 mg twice daily for 5 days had no effect on the pharmacokinetics of a single 25-mg dose of lamotrigine in 10 healthy subjects. No change in lamotrigine dose appears to be needed during concurrent use.¹

1. Ebert U, Thong NQ, Oertel R, Kirch W. Effects of rifampicin and cimetidine on pharmacokinetics and pharmacodynamics of lamotrigine in healthy subjects. *Eur J Clin Pharmacol* (2000) 56, 299–304.

Lamotrigine + Felbamate

Felbamate appears not to affect the pharmacokinetics of lamotrigine.

Clinical evidence, mechanism, importance and management

In 21 healthy subjects felbamate 1.2 g twice daily had minimal effects on the pharmacokinetics of lamotrigine 100 mg twice daily when they were given together for 10 days. A 14% increase in the lamotrigine AUC was seen, which was not considered clinically relevant.¹ Similarly, there was no difference between lamotrigine pharmacokinetics in 6 patients receiving lamotrigine and felbamate and 5 patients taking lamotrigine alone.² Therefore the dose of lamotrigine does not need to be adjusted if felbamate is given.

2. Gidal BE, Kanner A, Maly M, Rutecki P, Lensmeyer GL. Lamotrigine pharmacokinetics in patients receiving felbamate. *Epilepsy Res* (1997) 27, 1–5.

Lamotrigine + Phenobarbital or Primidone

Phenobarbital has been associated with reduced lamotrigine serum levels. Phenobarbital and primidone levels were unchanged.

Clinical evidence, mechanism, importance and management

In a retrospective study, the lamotrigine serum concentration-to-dose ratio was lower in patients also taking phenobarbital than in those receiving lamotrigine monotherapy (0.52 versus 0.99),¹ suggesting that phenobarbital lowers lamotrigine levels. Similar findings have been reported in another study.² No changes in the serum levels of phenobarbital or primidone were seen in a study in 12 patients given lamotrigine 75 to 400 mg daily.³

Phenobarbital induces the metabolism of lamotrigine, and the recommended starting dose and long-term maintenance dose of lamotrigine in patients already taking phenobarbital or primidone is twice that of patients receiving lamotrigine monotherapy.^{4,5} However, note that if they are also taking valproate in addition to phenobarbital, the lamotrigine dose should be reduced, see 'Lamotrigine + Valproate', p.542. The lamotrigine dosage may need to be reduced if phenobarbital is withdrawn.

Lamotrigine + Phenytoin

Phenytoin has been associated with reduced lamotrigine serum levels. Lamotrigine has no effect on phenytoin levels.

Clinical evidence, mechanism, importance and management

In a retrospective study, the lamotrigine serum concentration-to-dose ratio was much lower in patients receiving concomitant phenytoin than in those taking lamotrigine monotherapy (0.32 versus 0.98),¹ suggesting that phenytoin lowers lamotrigine levels. Other studies in patients taking lamotrigine with phenytoin have reported similar findings.^{2,3} In another study, the mean lamotrigine levels were approximately doubled when phenytoin was withdrawn.⁴ In contrast one study suggests that the serum level of phenytoin was unchanged in patients given lamotrigine 75 to 400 mg daily.⁵

Phenytoin is a known hepatic enzyme inducer, which increases lamotrigine metabolism. The recommended starting dose and long-term maintenance dose of lamotrigine in patients already taking phenytoin is twice that of patients receiving lamotrigine monotherapy.^{6,7}

However, note that if they are also taking valproate in addition to phenytoin, the lamotrigine dose should be reduced, see 'Lamotrigine + Valproate', below. The lamotrigine dosage may need to be reduced if phenytoin is withdrawn.

Lamotrigine + Sertraline

A report describes two cases, which suggest that sertraline may increase lamotrigine levels and cause toxicity.

Clinical evidence, mechanism, importance and management

A patient's lamotrigine levels were found to have doubled and symptoms of toxicity were noted (confusion, cognitive impairment) 6 weeks after sertraline 25 mg daily was started.¹ The lamotrigine dose was halved, and the sertraline dose titrated to 50 mg daily. Symptoms of toxicity resolved, but the lamotrigine levels were still 24% higher than before sertraline was started. In another patient taking sertraline and lamotrigine with signs of lamotrigine toxicity, a 33% reduction in sertraline dose resulted in a halving of the lamotrigine level even though the lamotrigine dose was increased by 33%.

The authors suggest that sertraline may competitively inhibit the glucuronidation of lamotrigine. Evidence so far appears limited to this case report. In view of the increased risk of rash with increased lamotrigine levels (see also 'Lamotrigine + Valproate', below), it may be prudent to monitor the combination. Further study is needed.

1. Kaufman KR, Gerner R. Lamotrigine toxicity secondary to sertraline. *Seizure* (1998) 7, 163–5.

Lamotrigine + Topiramate

Topiramate does not appear to alter the pharmacokinetics of lamotrigine, although one study suggested that it reduced lamotrigine levels. Lamotrigine has no effect on topiramate levels.

Clinical evidence, mechanism, importance and management

In the preliminary report of one study, it was found that serum lamotrigine levels decreased by 40 to 50% in 4 of 7 patients stable taking lamotrigine 350 to 800 mg daily when they were given topiramate, titrated to 800 mg

daily.¹ In contrast, other authors reported that the addition of topiramate 75 to 800 mg daily had little effect on the steady state serum levels of lamotrigine 100 to 950 mg daily in 24 patients. The mean lamotrigine level before topiramate was 10.4 mg/L and during topiramate was 9.7 mg/L. Only 2 of the patients had reductions of greater than 30% (40% and 43%).² A further study by the same research group confirmed the lack of effect of topiramate on lamotrigine pharmacokinetics.³ The authors of the second study² note that there is some evidence that peak-to-trough variations of as much as 30 to 40% can occur during lamotrigine therapy, and therefore timing of blood sampling might be a factor in the findings of the first study.¹

Lamotrigine had no effect on topiramate pharmacokinetics in one study in 13 patients. The oral clearance of topiramate 400 mg daily was 2.6 L/hour when given alone, and 2.7 L/hour when given with lamotrigine, and the AUC and plasma levels of topiramate were also similar.³

The balance of the evidence suggests that there is no important pharmacokinetic interaction between topiramate and lamotrigine. No special precautions appear to be necessary during concurrent use.

Lamotrigine + Valproate

The serum levels of lamotrigine can be markedly increased by valproate. Concurrent use has been associated with skin rashes, tremor and other toxic reactions. Lamotrigine has been found to cause small increases, decreases or no changes in valproate levels.

Clinical evidence

(a) Effects on lamotrigine levels

In 6 healthy subjects sodium valproate 200 mg every 8 hours reduced the clearance of lamotrigine by 20%, and increased its AUC by 30%.¹ In another study, in 18 healthy subjects receiving valproate 500 mg twice daily, the clearance of lamotrigine 50, 100 or 150 mg daily was also markedly reduced, and the half-life increased.² In a retrospective study, the lamotrigine serum concentration-to-dose ratio was markedly higher in patients also taking valproate than in those receiving lamotrigine monotherapy (3.57 versus 0.98), suggesting that valproate increases lamotrigine levels. In patients also taking phenytoin, the effects of valproate on lamotrigine were offset (0.99 versus 0.98). However, the effects of valproate on lamotrigine were not completely offset by either carbamazepine or phenobarbital (1.67 or 1.8, respectively versus 0.98).³ Other studies have reported broadly similar findings.^{4–6} Three studies have found that the effect of valproate on lamotrigine was independent of the valproate dose or serum level (that is, it is maximal within the usual therapeutic dose range of valproate).^{6–8} Another study has shown that the inhibition of lamotrigine clearance by valproate begins at very low valproate dosages (less than 125 mg daily), and is maximal at doses of about 500 mg daily.⁹

(b) Effects on valproate levels

In one study, 18 healthy subjects taking valproate 500 mg twice daily were also given lamotrigine 50, 100 or 150 mg daily. The lamotrigine caused a 25% decrease in valproate serum levels and a 25% increase in valproate oral clearance.² A study in 11 children taking valproate and other antiepileptics noted that no clinically important changes in valproate serum levels occurred when lamotrigine was added.¹⁰ A retrospective analysis found that lamotrigine was associated with only a 7% reduction in valproate levels, which would not be expected to be clinically significant.¹¹

(c) Toxic reactions

1. *Tremor*. In 3 patients severe and disabling tremor (sometimes preventing them from feeding themselves) occurred when they were given lamotrigine and sodium valproate. The problem resolved when the dosages were reduced.¹² In a study of 13 adult patients, all developed upper limb tremor when given lamotrigine with valproate, which could be minimised by reducing the dosage of either or both drugs.¹³ Other studies have found similar effects.^{7,14,15}

2. *Rash*. In a survey of adult epileptics who had lamotrigine added to their existing treatment, 33 were also taking valproate. Of these, 10 patients (30%) developed a rash, whereas only 6 of the 70 (8%) not taking valproate did so.¹⁶ In another analysis of skin rash in patients taking lamotrigine, 11 of 12 patients with serious rash were also taking sodium valproate, and all but one had a lamotrigine starting dose that is higher than currently recommended.¹⁷ However, in another study in which patients taking valproate were given lower initial doses of lamotrigine, there was no difference in incidence of rash in those taking lamotrigine and valproate, when compared with those taking lamotrigine and other antiepileptics (13% versus 14.2%).¹⁸

3. *Other*. Severe multiorgan dysfunction and disseminated intravascular coagulation was seen in 2 children when they took lamotrigine with valproate.¹⁹ Three patients taking lamotrigine developed neurotoxicity (confusion, lethargy) after starting to take valproate (an intravenous bolus dose of valproic acid then oral therapy). Lamotrigine levels had risen by 2.9 to 6.9 times those before valproic acid.¹⁴ Confusion, disorientation, visual disturbances and behavioural changes were reported in another patient 4 days after valproate was added to her treatment with lamotrigine. Lamotrigine levels were found to be 22.9 micrograms/mL (normal range 1 to 13 micrograms/mL). She recovered within 2 days of the discontinuation of both drugs.²⁰

One study reported that the formation of hepatotoxic metabolites of valproate was unaffected by lamotrigine.²

Mechanism

Not fully understood. It is thought that valproate reduces lamotrigine glucuronidation by competitive inhibition, which results in a decreased lamotrigine clearance.^{1,2,21} Raised lamotrigine levels have been implicated in the development of rash.^{18,22} Increased valproate clearance may be due to enzyme induction. Tremor may be the result of a pharmacodynamic interaction.^{7,13}

Importance and management

A well documented interaction. Concurrent use can be therapeutically valuable, but the lamotrigine dosage should be reduced by about half when valproate is added to avoid possible toxicity (sedation, tremor, ataxia, fatigue, rash).^{2,7-9,12,18,23} In patients already taking valproate, the manufacturer of lamotrigine recommends a lamotrigine starting dose that is half that of lamotrigine monotherapy, irrespective of whether they are also receiving enzyme-inducing anticonvulsants, and a very gradual dose-escalation rate.²⁴ The outcome should be very well monitored. The CSM in the UK has suggested that the concurrent use of sodium valproate is one of the main risk factors for the development of serious skin reactions to lamotrigine, because it prolongs the half-life of lamotrigine.²² Rashes are potentially serious and should be evaluated promptly.^{18,24,25} The reports cited above^{12,19} also suggest that sometimes other serious reactions (disabling tremor, multiorgan dysfunction) can occur.

Levetiracetam + Food

The oral absorption of levetiracetam is not significantly affected by food.

Clinical evidence, mechanism, importance and management

In a study, 10 healthy subjects were given a 500-mg levetiracetam tablet with 120 mL of water or crushed and mixed with either 4 oz apple sauce or 120 mL of an enteral nutrition formulation (*Sustacal*). The overall rate and extent of absorption of oral levetiracetam were not significantly affected by crushing and mixing the tablet with either apple sauce or an enteral nutrition preparation, although the peak serum level of levetiracetam may be slightly reduced if it is mixed with enteral nutrition.¹

Levetiracetam + Other antiepileptics

There is some evidence that the enzyme-inducing antiepileptics (carbamazepine, phenobarbital, phenytoin and primidone) may modestly reduce levetiracetam levels, but this is not thought to be clinically relevant. Levetiracetam does not usually alter the levels of these antiepileptics. However, some studies have found modestly raised phenytoin levels, and cases of possible carbamazepine toxicity have also been reported. There appears to be no pharmacokinetic interaction between levetiracetam and gabapentin, lamotrigine, or valproate.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine

Evidence from clinical studies suggests that levetiracetam does not affect the serum levels of carbamazepine.¹⁻³ There is also some evidence that patients taking levetiracetam and also receiving enzyme-inducing antiepileptics such as carbamazepine had modestly (24%) lower levetiracetam levels than those also receiving antiepileptics not considered to be enzyme-inducers, but this was not considered clinically relevant, see (d) below.⁴ Similarly, another retrospective analysis of patient data found that the serum levetiracetam level to dose ratio was modestly lower in patients also receiving carbamazepine than those receiving monotherapy (0.32 versus 0.52).⁵ suggesting that carbamazepine moderately lowers levetiracetam levels. One report describes 4 patients who experienced disabling symptoms compatible with carbamazepine toxicity when levetiracetam was added. The symptoms resolved after a decrease in the carbamazepine dosage or withdrawal of the levetiracetam. A pharmacodynamic interaction was suggested, because levels of carbamazepine and its metabolite, carbamazepine-10,11-epoxide, were not affected.⁶

In general, there is no need to modify the dose of either carbamazepine or levetiracetam when used together. However, the report of possible toxicity suggests that some caution is warranted.

(b) *Phenytoin*

There is some evidence that patients taking levetiracetam with enzyme-inducing antiepileptics such as phenytoin had modestly (24%) lower levetiracetam levels than those taking other antiepileptics not considered to be enzyme inducers, but this was not considered clinically relevant, see (d) below.⁴ Similarly, another retrospective analysis of patient data found that the serum levetiracetam level-to-dose ratio was modestly lower in patients also receiving phenytoin than those receiving monotherapy (0.32 versus 0.52),⁵ suggesting that phenytoin modestly lowers levetiracetam levels.

However, evidence from clinical studies suggests that levetiracetam does not affect the serum levels of phenytoin.¹⁻³ Similarly, in another study, levetiracetam 1.5 g twice daily for 12 weeks had no effect on the steady-state pharmacokinetics of phenytoin in 6 subjects with epilepsy who were taking stable doses of phenytoin.⁷ In one clinical study the addition of levetiracetam increased phenytoin levels by 27% to 52% in 4 patients. A further patient had a 75% increase in phenytoin levels [estimated from figure] and experienced signs of toxicity (sedation, ataxia) and required a reduction in his phenytoin dose. Another patient with raised phenytoin levels [estimated increase of 47%] had the dose of levetiracetam reduced.⁸

In general therefore, there is no need to modify the dose of either phenytoin or levetiracetam when they are used together. However, the report of raised phenytoin levels suggests that some caution is warranted.

(c) *Valproate*

There was no difference in the pharmacokinetics of a single 1.5-g dose of levetiracetam given to healthy subjects before or after sodium valproate 500 mg twice daily for 8 days. In addition, levetiracetam did not affect the pharmacokinetics of valproate.⁹ In an analysis of clinical study data, the AUC of levetiracetam in 57 patients also taking valproic acid was slightly (11%) higher than in 28 patients also taking antiepileptics not thought to affect microsomal enzymes (gabapentin, lamotrigine, vigabatrin), but this was not thought to be clinically relevant.⁴ In another retrospective analysis of patient data, the serum levetiracetam level-to-dose ratio was the same in patients also receiving valproic acid than those receiving monotherapy (0.53 versus 0.52),⁵ suggesting that valproate does not alter levetiracetam levels. Furthermore, evidence from clinical studies suggests that levetiracetam does not affect the serum levels of valproate.^{1,3} There appears to be no need to adjust the doses of either sodium valproate or levetiracetam if these drugs are used together.

(d) *Other antiepileptics*

The AUC of levetiracetam tended to be lower in 436 patients also taking enzyme-inducing antiepileptics (carbamazepine, phenobarbital, phenytoin, **primidone**) than in 28 patients also taking antiepileptics not thought to affect microsomal enzymes (**gabapentin, lamotrigine, vigabatrin**), but the difference was modest (24%).⁴ Another retrospective analysis of patient data found that the serum levetiracetam level-to-dose ratio did not differ significantly between patients also taking **lamotrigine** and those taking levetiracetam alone (0.45 versus 0.52), but was modestly lower in those taking **oxcarbazepine** (0.34 versus 0.52).⁵

Furthermore, evidence from clinical studies suggests that levetiracetam does not affect the serum levels of **gabapentin, lamotrigine, phenobarbital, or primidone**.¹⁻³ In general therefore, no dosage adjustments would seem to be needed if levetiracetam is used as add-on therapy with any of these drugs.

Levetiracetam + Probenecid

Probenecid increased the plasma levels of an inactive metabolite of levetiracetam.

Clinical evidence, mechanism, importance and management

Probenecid 500 mg four times daily did not affect the renal excretion of levetiracetam. However, the renal excretion of its primary and pharmacologically inactive metabolite (ucb L057) was reduced by 61%, and plasma concentrations increased 2.5-fold,¹ although the manufacturer notes that these levels were still low.² The clinical relevance of elevated levels of ucb L057 is not known, therefore some have suggested caution is warranted.¹ The effect of levetiracetam on probenecid has not been studied.^{2,3}

Mesuximide + Other antiepileptics

Phenobarbital, phenytoin, and possibly felbamate increase the levels of the active metabolite of mesuximide, *N*-desmethylmesuximide. Mesuximide increases the serum levels of phenobarbital and phenytoin, and decreases the levels of lamotrigine, and to a lesser extent, valproate.

Clinical evidence

(a) *Felbamate*

Three adolescent epileptic patients taking mesuximide developed mild adverse effects within 3 days of starting to take felbamate, which became more serious after one month (decreased appetite, nausea, weight loss, insomnia, dizziness, hiccups, slurred speech). During this time the levels of the active metabolite of mesuximide, *N*-desmethylmesuximide, rose by 26% and 46% in two patients, respectively. The adverse effects disappeared and *N*-desmethylmesuximide levels fell when the mesuximide dosage was reduced. Other antiepileptics being taken were carbamazepine, ethosuximide and valproate.¹

(b) *Lamotrigine*

In 6 patients taking mesuximide, lamotrigine levels were 53% lower (range 36 to 72%), when compared with lamotrigine levels before starting or after stopping mesuximide. In some patients deterioration in seizure control was seen while taking mesuximide, and an improvement in seizure control occurred after mesuximide was stopped.² In another study, lamotrigine levels were about 70% lower in 13 patients also taking mesuximide than in 64 patients taking lamotrigine alone, when corrected for dose. Note that in patients also taking valproate, the reduction in lamotrigine levels caused by mesuximide was compensated for by the increase caused by valproate, see also 'Lamotrigine + Valproate', p.542.³

(c) *Phenobarbital or primidone*

A study in hospitalised patients with petit mal epilepsy found that when mesuximide was given to 8 patients taking phenobarbital and 13 patients taking primidone, the mean serum levels of phenobarbital rose by 38% and 40%, respectively. Dose reductions were needed in 50% and 62% of patients, respectively. It was also found that the concurrent use of phenobarbital increased the serum levels of the active metabolite of mesuximide, *N*-desmethylmesuximide.⁴

(d) *Phenytoin*

Mesuximide was given to 17 patients taking phenytoin, which resulted in a 78% rise in the phenytoin serum levels requiring dose reductions in about 30% of the patients. It was also found that the concurrent use of phenytoin increased the serum levels of the active metabolite of mesuximide, *N*-desmethylmesuximide.⁴

(e) *Valproate*

A retrospective analysis of serum valproate levels was carried out in 17 patients who started and/or stopped taking mesuximide and whose concurrent medication remained unaltered. In the 14 patients starting mesuximide, a mean decrease in valproate levels of 32% was seen. In the 8

patients who stopped mesuximide a 30% increase in valproate levels occurred.³ Note that the related drug, ethosuximide, has also been reported to lower valproate levels, see 'Ethosuximide + Other antiepileptics', p.539.

Mechanism

It has been suggested that phenobarbital, phenytoin and felbamate compete with mesuximide for the same metabolic mechanisms (hydroxylation) in the liver. As a result each one is metabolised more slowly and therefore their levels increase. Mesuximide appears to increase the clearance of valproate, and lamotrigine (which is principally via glucuronidation).

Importance and management

Information about these interactions is limited. Nevertheless, concurrent use should be monitored. Anticipate the need to reduce the dose of phenytoin, phenobarbital or primidone if mesuximide is given. The dose of lamotrigine may need to be increased if mesuximide is given. There is also some evidence that the dose of valproate may need to be increased.

The activity of mesuximide is thought to be due to its active metabolite, *N*-desmethylmesuximide. Therefore, it has been suggested that levels of this metabolite should also be monitored. Anticipate the need to reduce the dose of mesuximide if felbamate is added. Other antiepileptics such as phenobarbital and phenytoin may also increase levels of *N*-desmethylmesuximide.⁴

Oxcarbazepine + Erythromycin

Erythromycin does not appear to affect the pharmacokinetics of oxcarbazepine.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects the pharmacokinetics of a single 600-mg dose of oxcarbazepine was unaffected by erythromycin 500 mg twice daily for 7 days.¹ Erythromycin appears not to interact with oxcarbazepine, and no special precautions therefore seem to be required during concurrent use.

1. Keränen T, Jolkkonen J, Jensen PK, Menge GP, Andersson P. Absence of interaction between oxcarbazepine and erythromycin. *Acta Neurol Scand* (1992) 86, 120-3.

Oxcarbazepine + Felbamate

Felbamate has no clinically relevant effect on the pharmacokinetics of oxcarbazepine, but concurrent use appears to increase the incidence of adverse effects.

Clinical evidence, mechanism, importance and management

A double-blind, randomised study in 8 healthy subjects found that oxcarbazepine 300 to 600 mg every 12 hours, given with felbamate 600 to 1200 mg every 12 hours for 10 days had no effect on the plasma levels of the major active metabolite of oxcarbazepine (monohydroxyoxcarbazepine). However, the levels of dihydroxyoxcarbazepine (a minor, inactive metabolite) were reduced, and the maximum serum levels of oxcarbazepine were reduced, by about 20%. Although these changes were considered to be clinically irrelevant, the incidence of some adverse effects (dizziness, somnolence, nausea, diplopia) rose during concurrent use.¹

1. Hulsman JARJ, Rentmeester TW, Banfield CR, Reidenberg P, Colucci RD, Meehan JW, Radwanski E, Mojaverian P, Lin C-C, Nezamis J, Afrime MB, Glue P. Effects of felbamate on the pharmacokinetics of the monohydroxy and dihydroxy metabolites of oxcarbazepine. *Clin Pharmacol Ther* (1995) 58, 383-9.

Oxcarbazepine + Other antiepileptics

Oxcarbazepine appears not to affect the pharmacokinetics of carbamazepine, phenobarbital or valproate to a clinically relevant extent, but may modestly reduce lamotrigine levels. High doses of oxcarbazepine increase phenytoin levels, and a reduction in the phenytoin dose may be required. Phenytoin and phenobarbital can increase the loss of the active metabolite of oxcarbazepine, monohydroxyoxcarbazepine, although this is probably not clinically relevant. Lamotrigine may increase levels of monohydroxyoxcarbazepine, although one study found no pharmacokinetic interaction.

Clinical evidence

(a) Effects of oxcarbazepine on other antiepileptics

A double-blind, crossover comparison of oxcarbazepine and carbamazepine in 42 epileptic patients found that when carbamazepine was replaced by oxcarbazepine, the serum levels of valproate rose by 32%, and the serum levels of phenytoin rose by 23%. In patients taking both valproate and phenytoin together, oxcarbazepine caused a rise in the serum levels of 21% and 25% respectively. The study extended over 12 weeks to establish steady-state levels.¹ Another study in 4 young epileptic patients (aged 13 to 17) found that the level to dose ratio of free valproate rose when switched from concurrent carbamazepine to oxcarbazepine, with an increase in valproate adverse effects, which resolved when the valproate dose was decreased.²

A later study in 35 epileptic patients found that when oxcarbazepine 300 mg three times daily was added to treatment with carbamazepine, sodium valproate or phenytoin for 3 weeks there were no clinically relevant changes in the pharmacokinetics of any of these anticonvulsants.³ However, analysis of data from clinical studies found that oxcarbazepine decreased carbamazepine levels by about 15 to 22%, increased phenobarbital levels by about 14%, and at high doses increased phenytoin levels by up to 40%.^{4,5} In another analysis, lamotrigine levels were about 34% lower in 14 patients also taking oxcarbazepine than in 64 patients taking lamotrigine alone, when corrected for dose. In this study, the effect of oxcarbazepine was less than that of carbamazepine (34% versus 47%).⁶ Similarly, in another analysis, the addition of oxcarbazepine to lamotrigine reduced lamotrigine levels by 15 to 75%.⁷ However in contrast to these findings, one study in healthy subjects found that oxcarbazepine had no effect on the pharmacokinetics of lamotrigine, although adverse effects were reported to be more frequent and severe during concurrent treatment.⁸

(b) Effects of other antiepileptics on oxcarbazepine

The AUCs of oxcarbazepine and its active metabolite (monohydroxyoxcarbazepine) were reduced by phenobarbital, by 43% and 25%, respectively. There were no other significant effects on the pharmacokinetics of oxcarbazepine.⁹ Another study found that phenytoin caused a 29% reduction in the AUC of monohydroxyoxcarbazepine.³ Another study found that the serum levels of monohydroxyoxcarbazepine were not affected by phenobarbital or phenytoin but its further conversion to dihydroxyoxcarbazepine was increased.¹⁰ Since the conversion to dihydroxyoxcarbazepine is a minor step in the metabolism of monohydroxyoxcarbazepine, the overall antiepileptic action of oxcarbazepine is unlikely to be altered. Correspondingly, a study found that phenytoin 100 to 375 mg daily increased the clearance of the active metabolite, monohydroxyoxcarbazepine by almost 40%.¹¹ The AUC of monohydroxyoxcarbazepine was also 40% lower in the presence of carbamazepine.³ Similarly, carbamazepine, phenobarbital, and phenytoin were found to increase the apparent clearance of monohydroxyoxcarbazepine by 31 to 35% in a study in children.¹²

A retrospective analysis found that monohydroxyoxcarbazepine levels to oxcarbazepine dose ratios were higher in 7 patients also taking lamotrigine than in those taking oxcarbazepine alone,¹³ suggesting that lamotrigine decreased oxcarbazepine metabolism. However in contrast to these findings, one study in healthy subjects found that lamotrigine had no effect on the pharmacokinetics of oxcarbazepine or monohydroxyoxcarbazepine although adverse effects were reported to be more frequent and more severe during concurrent treatment.⁸

Mechanism

Unlike carbamazepine, oxcarbazepine appears not to have marked enzyme-inducing properties so that it would not be expected to have as great an effect on the metabolism of other antiepileptics. However, oxcarbazepine does appear to act as an inhibitor of the cytochrome P450 isoenzyme CYP2C19 at high concentrations and therefore may raise phenytoin levels (see 'Phenytoin + Carbamazepine', p.554, for more on this mechanism). Other antiepileptics can increase the metabolism of the active metabolite of oxcarbazepine, monohydroxyoxcarbazepine. The situation with lamotrigine is not clear. In one study lamotrigine appeared to decrease the metabolism of oxcarbazepine but another study found no pharmacokinetic interaction.

Importance and management

Information about the concurrent use of oxcarbazepine and other antiepileptics is limited, but growing. The overall picture seems to be that, oxcarbazepine is a less potent enzyme inducer than carbamazepine, and therefore it does not markedly affect the serum levels of other antiepileptics. If oxcarbazepine is substituted for carbamazepine, be aware that drug levels of some other antiepileptics may rise. High oxcarbazepine doses may increase phenytoin levels, and the manufacturer notes that a decrease in the phenytoin dose may be required.⁴ The clinical relevance of the modest reductions in lamotrigine levels is uncertain. For mention of modestly reduced levetiracetam levels, see 'Levetiracetam + Other antiepileptics', p.543.

Any changes in the pharmacokinetics of oxcarbazepine brought about by other antiepileptics seem to be of minimal clinical relevance. However, the clinical relevance of the increase in the active metabolite monohydroxyoxcarbazepine with lamotrigine requires further study. In addition, there is the theoretical risk that monohydroxyoxcarbazepine levels might rise to toxic levels if carbamazepine or phenytoin were withdrawn.³ For mention that there may be an increase in adverse effects if oxcarbazepine is used with felbamate, see 'Oxcarbazepine + Felbamate', p.545.

Paraldehyde + Disulfiram

Animal data suggest that disulfiram can increase paraldehyde levels and prolong its effects. There is a theoretical potential for a disulfiram reaction.

Clinical evidence, mechanism, importance and management

It is thought that paraldehyde is depolymerised in the liver to acetaldehyde, and then oxidised by acetaldehyde dehydrogenase.¹ Since disulfiram inhibits this enzyme, concurrent use would be expected to result in the accumulation of acetaldehyde and result in a modified disulfiram reaction.² However, studies in *animals* given disulfiram and paraldehyde

found increases in paraldehyde levels and hypnotic effect, with only small increases in acetaldehyde and no increase in toxicity.^{2,3} In addition, there appear to be no reports of a disulfiram reaction involving paraldehyde in humans. Three cases of mental confusion have been reported in patients receiving disulfiram and paraldehyde.⁴ Note that, patients with liver disease are at greater risk of adverse effects of paraldehyde, and the addition of disulfiram results in a further risk. Therefore it may be prudent to avoid concurrent use.

Phenobarbital or Primidone + Allopurinol

Allopurinol appears not to alter phenobarbital levels, including those derived from primidone.

Clinical evidence, mechanism, importance and management

In a study of add-on therapy, allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients) for 4 months, had no effect on phenobarbital levels in 46 patients taking antiepileptics including phenobarbital.¹ In another similar study, allopurinol 10 mg/kg increased to 15 mg/kg daily for 12 weeks had no effect on serum phenobarbital levels in 11 patients taking primidone or phenobarbital with or without other antiepileptics.² Therefore phenobarbital or primidone dosage alterations are unlikely to be required if allopurinol is used.

Phenobarbital + Azoles

Limited evidence suggests phenobarbital causes a marked decrease in itraconazole levels, and might decrease ketoconazole levels. Phenobarbital is also predicted to decrease posaconazole levels and markedly decrease voriconazole levels.

Clinical evidence, mechanism, importance and management

(a) Itraconazole

The serum levels of itraconazole 200 mg daily were very low (0.01 to 0.03 mg/L, therapeutic range 0.25 to 2 mg/L) in a patient taking **phenobarbital**. Two months after stopping the **phenobarbital** they were higher (0.15 mg/L), but still below the therapeutic range, apparently because carbamazepine had been recently started.¹ For mention of two other patients who had very low itraconazole levels while taking both phenytoin and phenobarbital, see 'Phenytoin + Azoles', p.552. Some makers of itraconazole say that concurrent use of potent enzyme inducers such as phenobarbital is not recommended.^{2,3}

(b) Ketoconazole

Low ketoconazole levels in a patient with leukaemia receiving various antineoplastics was attributed to the concurrent use of phenytoin and phenobarbital therapy.⁴ It may be prudent to monitor the effects of ketoconazole if phenobarbital is also given.

(c) Posaconazole

Based on the evidence with 'phenytoin', (p.552), the manufacturer of posaconazole predicts that phenobarbital will reduce posaconazole levels, and therefore suggests avoiding the combination unless the benefits outweigh the risks.⁵ If concurrent use is necessary monitor for posaconazole efficacy.

(d) Voriconazole

Based on the evidence with 'phenytoin', (p.552), the manufacturer of voriconazole predicts that phenobarbital will reduce voriconazole levels, and

therefore contraindicates their concurrent use.^{6,7} In the US the manufacturer extends this contraindication to all long-acting barbiturates.⁷

Phenobarbital + Dextropropoxyphene (Propoxyphene)

An average 20% rise was seen in the serum phenobarbital levels of 4 epileptic patients after they took dextropropoxyphene 65 mg three times a day for a week.¹ This rise is unlikely to be clinically significant in most patients.

1. Hansen BS, Dam M, Brandt J, Hvidberg EF, Angelo H, Christensen JM, Lous P. Influence of dextropropoxyphene on steady state serum levels and protein binding of three anti-epileptic drugs in man. *Acta Neurol Scand* (1980) 61, 357–67.

Phenobarbital or Primidone + Felbamate

Felbamate causes a moderate increase in plasma phenobarbital levels (including those derived from primidone), which has resulted in phenobarbital toxicity.

Clinical evidence

When 24 healthy subjects taking phenobarbital 100 mg daily were also given felbamate 1.2 g twice daily for 10 days, the AUC and the maximum plasma levels of phenobarbital were raised by 22% and 24%, respectively. Concurrent use was said to be safe and well tolerated.¹ A 30% increase in phenobarbital plasma concentrations was seen in another 19 patients taking phenobarbital or primidone (which is metabolised to phenobarbital) when given felbamate (average dose 2458 mg daily).² A phenobarbital dosage reduction of about 30% was needed in another 6 patients when they started to take felbamate.³ A man taking sodium valproate and phenobarbital had an almost 50% increase in phenobarbital serum levels over a 5-week period after felbamate 50 mg/kg was added, despite an initial phenobarbital dosage reduction from 230 mg to 200 mg daily. He was hospitalised because of increased lethargy, anorexia and ataxia and was eventually discharged on a phenobarbital dosage of 150 mg daily.⁴

It was noted that felbamate levels were lower in patients taking phenobarbital than in historical control patients who were not taking phenobarbital.¹ However, in a modelling study, phenobarbital apparently had little or no effect on the pharmacokinetics of felbamate.⁵

Mechanism

Not established. It seems possible that the felbamate may inhibit more than one pathway in the metabolism of the phenobarbital, resulting in a reduction in its loss from the body. The cytochrome P450 isoenzyme CYP2C19 may be involved.^{1,6}

Importance and management

An established interaction. If felbamate is added to established treatment with phenobarbital or primidone, particularly in patients already taking substantial doses, monitor well for any evidence of increased adverse effects (drowsiness, lethargy, anorexia, ataxia) and reduce the dosages of the phenobarbital or primidone if necessary.

Phenobarbital + Influenza vaccines

Influenza vaccine can cause a moderate rise in serum phenobarbital levels.

Clinical evidence, mechanism, importance and management

Serum phenobarbital levels rose by about 30% in 11 out of 27 children when given 0.5 mL of a whole virus influenza vaccine USP, types A and B, (Squibb). Levels remained elevated 28 days after vaccination.¹

It was suggested that the vaccine inhibits the liver enzymes concerned with the metabolism of phenobarbital, thereby reducing its loss from the body. Information is very limited. Note that, a similar 30% increase in phenobarbital levels with felbamate has eventually required a dosage adjustment; however with this interaction the increase will eventually be self-limiting. Therefore it seems unlikely that this moderate increase in phenobarbital levels will be of clinical significance..

Phenobarbital + Troleandomycin

Troleandomycin caused a modest fall in the plasma phenobarbital levels of one patient.

Clinical evidence, mechanism, importance and management

A patient phenobarbital and carbamazepine had a modest fall in plasma phenobarbital levels from about 40 to 31 micrograms/mL, and a rise in carbamazepine levels, when given troleandomycin.¹ The general importance of this single report is uncertain, but this modest is probably of limited clinical importance. For a discussion of the rise in carbamazepine levels with troleandomycin, see 'Carbamazepine + Macrolides', p.531.

Phenobarbital + Valproate

Serum phenobarbital levels can be increased by valproate, which may result in excessive sedation and lethargy. Small reductions in valproate levels have also been reported. Combined use of phenobarbital and valproate may cause an increase in serum liver enzymes.

Clinical evidence

A 6-month study in 11 epileptic patients taking phenobarbital 90 to 400 mg daily found that when they were also given valproic acid 11.2 to 42.7 mg/kg daily sedation developed. On average the dosage of phenobarbital was reduced to 54% of the original dose with continued good seizure control. Another 2 patients who did not have their phenobarbital dose reduced had an increase in their phenobarbital levels of 12% and 48%, respectively, when valproic acid was added.¹

Another study found that sodium valproate 1.2 g daily raised serum phenobarbital levels in 20 patients by an average of 27%. Signs of toxicity occurred in 13 patients, but the dose only needed to be reduced in 3 patients.² This interaction has been described in numerous other reports, and dose reductions of the phenobarbital were almost always necessary to avoid excessive drowsiness.^{3–17} In one study the rise in phenobarbital levels was much greater in children (over 100%) than in adults (about 50%).¹⁸

A reduction in sodium valproate levels of about 25% has also been reported, but the effect on seizure control was not mentioned.¹⁹ A reduction

in valproate levels caused by phenobarbital has also been reported elsewhere.²⁰

The incidence of increased liver enzyme activity was found to be higher in 41 patients receiving phenobarbital with valproate than in 40 patients taking valproate alone (ALT 7.3% versus 0%). When phenytoin was also given an even greater incidence of increases (ALT 26.1% and AST 28.3% versus about 20%) occurred. However, the increases were mild and were not considered clinically important.²¹

Mechanism

The evidence indicates that valproate inhibits three steps in the metabolism of phenobarbital by the liver, leading to its accumulation in the body. The inhibited steps are the formation of *p*-hydroxyphenobarbital by the cytochrome P450 isoenzyme CYP2C9,²² the *N*-glucosidation of phenobarbital²³ and the *O*-glucuronidation of *p*-hydroxyphenobarbital.²³

Importance and management

An extremely well documented and well established interaction of clinical importance. The incidence seems to be high. The effects of concurrent use should be well monitored and suitable phenobarbital dosage reductions made as necessary to avoid toxicity. The dosage may need to be reduced by a third to a half.¹ The significance of the modest reduction in valproate levels is not clear, especially as valproate levels do not correlate well with efficacy of treatment. Valproate has been associated with serious hepatotoxicity, especially in children aged less than 3 years, and this has been more common in those receiving other anticonvulsants. Valproate monotherapy is to be preferred in this group.

Phenytoin + Allopurinol

A case report describes phenytoin toxicity in a boy given allopurinol. Another study found raised phenytoin levels in 2 of 18 patients given allopurinol.

Clinical evidence, mechanism, importance and management

A 13-year-old boy with Lesch-Nyhan syndrome who was taking phenobarbital, clonazepam, valproic acid and phenytoin 200 mg daily became somnolent within 7 days of starting to take allopurinol 150 mg daily. His serum phenytoin levels were found to have increased from 7.5 to 20.8 micrograms/mL.¹ In another study, 2 patients had a marked increase in phenytoin levels when given allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients) for 4 months, which in one case led to withdrawal from the study, and in the other to a phenytoin dosage reduction. However, 16 other patients had no change in phenytoin levels while taking this dose of allopurinol.²

The reason for this reaction is not known. An *animal* study confirmed that 50 mg/kg, but not 20 mg/kg, of allopurinol reduced phenytoin elimination, but was unable to work out the mechanism.³

Although information is limited, it appears that allopurinol may raise phenytoin levels in some patients. It would therefore be prudent to monitor for phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness) when allopurinol is added.

Phenytoin + Amiodarone

Serum phenytoin levels can be raised by amiodarone, markedly so in some individuals, and phenytoin toxicity may occur. Amiodarone serum levels are reduced by phenytoin.

Clinical evidence

(a) Phenytoin serum levels increased

Three patients had a marked rise in serum phenytoin levels 10 days to 4 weeks after being given amiodarone 400 mg to 1.2 g daily. One of them developed phenytoin toxicity (ataxia, lethargy, vertigo) within 4 weeks of starting to take amiodarone and had a serum phenytoin level of 40 micrograms/mL, representing a three to fourfold rise. Levels re-established when the phenytoin dosage was withheld and then reduced from 300 to 200 mg daily. The serum phenytoin levels of the other 2 patients were approximately doubled by the amiodarone.¹

A study in healthy subjects found that amiodarone 200 mg daily for 3 weeks increased the AUC of a single 5-mg/kg intravenous dose of phenytoin by 40%.² Another pharmacokinetic study found that amiodarone 200 mg daily for 6 weeks raised the AUC and steady-state peak serum levels of phenytoin by 40% and 33%, respectively. Phenytoin 2 to 4 mg/kg daily was given orally for 14 days before and during the last 2 weeks of amiodarone therapy.³ Other case reports describe 3 patients who had two to threefold rises in serum phenytoin levels, and toxicity, 2 to 6 weeks after starting amiodarone.^{4–6}

(b) Amiodarone serum levels reduced

A study in 5 healthy subjects given amiodarone 200 mg daily found that over a 5-week period the serum amiodarone levels gradually increased. When phenytoin 3 to 4 mg/kg daily was added for a period of 2 weeks, the serum amiodarone levels fell to concentrations that were between about 50 and 65% of those predicted.⁷

Mechanism

Uncertain. It seems possible that amiodarone inhibits the liver enzymes concerned with the metabolism of phenytoin, resulting in a rise in its serum levels.³ It seems unlikely that drug displacement from protein binding sites had a part to play as free and bound levels of phenytoin remained constant.³

Phenytoin is an enzyme-inducing drug that possibly increases the metabolism of the amiodarone by the liver.

Importance and management

Information seems to be limited to the reports cited, but both interactions appear to be clinically important. Concurrent use should not be undertaken unless the effects can be well monitored.

The phenytoin dosage should be reduced as necessary. A 25 to 30% reduction has been recommended for those taking phenytoin 2 to 4 mg/kg daily, but it should be remembered that small alterations in phenytoin dose may result in a large change in phenytoin levels, as phenytoin kinetics are non-linear.^{3,8,9} Note that the phenytoin levels in some individuals were doubled after only 10 days of concurrent use.¹ Amiodarone has a long half-life so that this interaction will persist for weeks after its withdrawal. Continued monitoring is important. Be aware that ataxia due to phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness) may be confused with amiodarone-induced ataxia.^{1,5}

It is not clear whether or not the amiodarone dosage should be increased to accommodate this interaction because the metabolite of amiodarone (*N*-desethylamiodarone) also has important antiarrhythmic effects.⁷

Phenytoin + Antacids

Some studies have shown that antacids can reduce phenytoin serum levels and this may have been responsible for some loss of seizure control in a few patients. However other studies have shown no interaction, and it seems that usually no clinically important interaction occurs.

Clinical evidence

(a) Evidence of an interaction

A review briefly mentions that 3 patients taking phenytoin were found to have low serum phenytoin levels of 2 to 4 micrograms/mL when they were given phenytoin at the same time as antacids (unnamed), but when the antacid administration was delayed by 2 to 3 hours the serum phenytoin levels rose two to threefold.¹

Elsewhere, 2 epileptic patients are reported to have had inadequate seizure control, which coincided with the ingestion of **aluminium/magnesium hydroxide** antacids for dyspepsia.² The AUC of a single dose of phenytoin was reduced by about 25% in 8 healthy subjects given either **aluminium/magnesium hydroxide** or **calcium carbonate**.³

(b) Evidence of no interaction

A study in 6 healthy subjects given **aluminium** or **magnesium hydroxide** failed to show any change in the rate or extent of absorption of a single dose of phenytoin,² and a similar study found **calcium carbonate** also had no effect on the absorption of phenytoin.⁴ A controlled study in 6 epileptic patients found that a **magnesium trisilicate** and **aluminium hydroxide** antacid (*Gelusil*) caused a slight 12% reduction in steady-state serum phenytoin levels, which would not be expected to be clinically significant. Seizure frequency was not affected.⁴ A study in 2 subjects found that the

absorption of phenytoin was not altered by a mixture of **aluminium/magnesium hydroxide** and **magnesium trisilicate**, or **calcium carbonate**.⁵ In another study, no statistically significant decrease in absorption was seen in 6 healthy subjects given a **dimeticone, aluminium hydroxide** and **magnesium oxide** antacid (*Asilone*).⁶

Mechanism

Not understood. One suggestion is that diarrhoea and a general increase in peristalsis caused by some antacids may cause a reduction in phenytoin absorption. Another is that antacids may cause changes in gastric acid secretion, which could affect phenytoin solubility.

Importance and management

This possible interaction is fairly well documented, but the results are conflicting. In practice it appears not to be important in most patients, although some loss of seizure control has been seen to occur in isolated cases. The interaction is unpredictable because it seems to depend on the individual patient and the antacid being taken. Concurrent use need not be avoided but if there is any hint that phenytoin levels are reduced, separation of the dosages by 2 to 3 hours may, as with other interactions caused by antacids, minimise the effects.

Phenytoin + Antidiabetics

Large and toxic doses of phenytoin have been observed to cause hyperglycaemia, but normal therapeutic doses do not usually affect the control of diabetes. Two isolated cases of phenytoin toxicity have been attributed to the use of tolazamide or tolbutamide. Miglitol does not affect the bioavailability of phenytoin.

Clinical evidence

(a) Response to antidiabetics

Phenytoin has been shown in a number of reports^{1–6} to raise the blood glucose levels of both diabetics and non-diabetics. However, in all but one of these cases the phenytoin dosage was large (at least 8 mg/kg) or even in the toxic range (70 to 80 mg/kg). There is little evidence that a hyperglycaemic response to usual doses of phenytoin is normally large enough to interfere with the control of diabetes, either with diet alone or with conventional antidiabetic drugs. In the one case where the interaction occurred with a therapeutic dose of phenytoin (1.2 g in the 24 hours following status epilepticus), the situation was complicated by the use of many other drugs and by renal impairment.²

(b) Response to phenytoin

Tolbutamide 500 mg two or three times daily was given to 17 patients taking phenytoin 100 to 400 mg daily.⁷ The patients had a transient 45% rise in the amount of non-protein-bound phenytoin by day 2, which had disappeared by day 4. The introduction to this report briefly mentions a man given phenytoin and **tolazamide** who developed phenytoin toxicity, which disappeared when the **tolazamide** was replaced by **insulin**.⁷ A woman previously uneventfully treated with phenytoin and **tolbutamide** developed toxicity on a later occasion when she took **tolbutamide** with twice the previous dose of phenytoin.⁸ One study in healthy subjects found that **miglitol** 100 mg three times daily for 5 days did not affect the bioavailability of a single 400-mg dose of phenytoin.⁹

Mechanism

Studies in *animals* and man^{10–12} suggest that phenytoin-induced hyperglycaemia occurs because the release of insulin from the pancreas is impaired. This implies that no interaction is possible without functional

pancreatic tissue. Just why the phenytoin appeared to interact with tolazamide and tolbutamide is uncertain, but it is possible that these antidiabetics competitively inhibit phenytoin hydroxylation¹³ by the cytochrome P450 isoenzyme CYP2C9.¹⁴

Importance and management

The weight of evidence shows that no interaction of clinical importance normally occurs between phenytoin and the antidiabetic drugs (most of the studies involved sulphonylureas). No special precautions seem normally to be necessary.

Phenytoin + Antimycobacterials

Serum phenytoin levels are markedly reduced by rifampicin, but can be raised by isoniazid. Those who are slow acetylators (slow metabolisers) of isoniazid may develop phenytoin toxicity if the dosage of phenytoin is not reduced appropriately. If rifampicin and isoniazid are given together, serum phenytoin levels may fall in patients who are fast acetylators of isoniazid, but may occasionally rise in those who are slow acetylators. Clofazimine may reduce serum phenytoin levels.

Clinical evidence

(a) Isoniazid

A study in 32 patients given phenytoin 300 mg daily found that within a week of starting to take isoniazid 300 mg daily and aminosalicylic acid 15 g daily, 6 of them had phenytoin levels almost 5 micrograms/mL higher than the rest of the group. On the following days when the phenytoin levels of these 6 patients rose above 20 micrograms/mL the typical signs of phenytoin toxicity were seen. All 6 had unusually high serum isoniazid levels and were identified as slow acetylators of isoniazid.¹

Rises in serum phenytoin levels and toxicity induced by the concurrent use of isoniazid has been described in numerous other reports,^{2–15} involving large numbers of patients, one of which describes a fatality.⁸

(b) Rifampicin

A study in 6 patients found that the clearance of intravenous phenytoin 100 mg doubled, from 46.7 to 97.8 mL/minute, when rifampicin 450 mg daily was taken for 2 weeks.¹⁶

A man taking phenytoin 400 mg daily experienced a seizure 3 days after starting rifampicin 600 mg daily. His phenytoin level was low (5.1 micrograms/mL) so the rifampicin was stopped and the phenytoin dose increased to 500 mg daily. His level increased slowly over the next 2 weeks, eventually ranging between 16 and 25 micrograms/mL.¹⁷ Another man taking phenytoin needed a dosage reduction from 375 to 325 mg daily to keep his serum phenytoin levels within the therapeutic range when he stopped taking rifampicin.¹⁸ See also, *Rifampicin and Clofazimine*, below.

(c) Rifampicin and Clofazimine

A man with AIDS taking a large number of drugs (rifampicin, clofazimine, ciprofloxacin, ethambutol, clarithromycin, diphenoxylate, bismuth, octreotide, co-trimoxazole, amphotericin, flucytosine, amikacin, zalcitabine) was also given phenytoin to control a right-sided seizure disorder. Despite taking phenytoin 1.6 g daily, and a trial of intravenous treatment, his trough phenytoin plasma levels remained almost undetectable until the rifampicin was withdrawn, when they rose to 5 micrograms/mL with the oral dose. When the clofazimine was withdrawn the levels rose even further to 10 micrograms/mL.¹⁹

(d) Rifampicin and Isoniazid

A patient taking phenytoin 300 mg daily developed progressive drowsiness (a sign of phenytoin toxicity) during the first week of taking isoniazid, rifampicin and ethambutol. His serum phenytoin levels rose to 46.1 micrograms/mL. He slowly recovered when the phenytoin was stopped, and he was later stabilised taking only 200 mg of phenytoin daily. He proved to be a slow acetylator of isoniazid.²⁰ Another patient taking phenytoin 300 mg daily was also given isoniazid, rifampicin and ethambutol but, in anticipation of the response seen in the previous patient, his phenytoin dosage was reduced to 200 mg daily. Within 3 days he developed seizures because his serum phenytoin levels had fallen to only 8 micrograms/mL. He needed a daily dosage of 400 mg of phenytoin to keep the serum levels within the therapeutic range. He was a fast acetylator of isoniazid.²⁰

The clearance of phenytoin was doubled in 14 patients given rifampicin 450 mg, isoniazid 300 mg and ethambutol 900 mg to 1.2 g daily for 2 weeks. No further changes occurred in the pharmacokinetics of phenytoin after 3 months of antimycobacterial treatment. In this study, the interaction was of a similar magnitude in both the 8 slow and the 6 fast acetylators.¹⁶

Mechanism

Rifampicin (a known potent liver enzyme inducer) increases the metabolism and clearance of the phenytoin from the body so that a larger dose is needed to maintain adequate serum levels. Isoniazid inhibits the liver microsomal enzymes that metabolise phenytoin, and as a result the phenytoin accumulates and its serum levels rise.²¹ Only those who are slow acetylators (slow metabolisers) of isoniazid normally attain blood levels of isoniazid that are sufficiently high to cause extensive inhibition of the phenytoin metabolism. Fast acetylators (fast metabolisers) remove the isoniazid too quickly for this to occur. Acetylator status is genetically determined. Thus some individuals will show a rapid rise in phenytoin levels, which eventually reaches toxic concentrations, whereas others will show only a relatively slow and unimportant rise to a plateau within, or only slightly above the therapeutic range.

If isoniazid and rifampicin are given together, the enzyme inhibitory effects of isoniazid may oppose the effects of rifampicin in those who are slow acetylators of isoniazid, but in those who are fast acetylators, the isoniazid will be cleared too quickly for it effectively to oppose the rifampicin effects. However, in one study isoniazid did not counter the effects of rifampicin in slow acetylators.¹⁶

The interaction involving clofazimine is not understood.

Importance and management

Direct information seems to be limited to these reports, but the interactions appear to be of clinical importance. Monitor the serum phenytoin levels and increase the dosage appropriately if rifampicin alone is started. Reduce the dosage if the rifampicin is stopped. If both rifampicin and isoniazid are given, the outcome may depend on the isoniazid acetylator status of the patient. Those who are fast acetylators will probably also need an increased phenytoin dosage. Those who are slow acetylators may need a smaller phenytoin dosage if toxicity is to be avoided. All patients should be monitored very closely as, unless acetylator status is known, the outcome is unpredictable.

The interaction with phenytoin and isoniazid alone is well documented, well established, clinically important and potentially serious. About 50% of the population are slow or relatively slow metabolisers of isoniazid,¹ but not all of them develop serum phenytoin levels in the toxic range. The reports indicate that somewhere between 10 and 33% of patients are at risk.^{1–4,10} This adverse interaction may take only a few days to develop fully in some patients, but several weeks in others. Therefore concurrent use should be very closely monitored, making suitable dosage reductions as

necessary. One patient was reported to have had better seizure control with fewer adverse effects while taking both drugs than with phenytoin alone.²²

Information about clofazimine seems to be limited to one report. Monitor concurrent use, anticipating the need to increase the phenytoin dosage.

Phenytoin + Aspirin or NSAIDs

Serum phenytoin levels can be markedly increased by azapropazone and toxicity can develop rapidly. It is inadvisable for patients to take these drugs together. Phenytoin serum levels can also be increased by phenylbutazone and phenytoin toxicity may occur. It seems likely that oxyphenbutazone will interact similarly. Phenytoin toxicity has been seen in one patient taking ibuprofen, although no pharmacokinetic interaction was found in a study. Phenytoin toxicity occurred in a patient taking celecoxib. High-dose aspirin can cause protein-binding displacement of phenytoin, but this does not usually seem to be clinically important. No clinically significant interaction occurs between phenytoin and bromfenac, etodolac or tolfenamic acid.

Clinical evidence, mechanism, importance and management

(a) Aspirin

It has been suggested that if a patient has been taking large quantities of aspirin, phenytoin is 'potentiated'.¹ This comment remains unconfirmed, although a study in 10 healthy subjects did find that aspirin 975 mg every 4 hours caused protein binding displacement of phenytoin, resulting in a 16% rise in free salivary phenytoin levels and a 24% decrease in serum levels. However, these changes were considered unlikely to be clinically significant, and aspirin doses of 325 and 650 mg every 4 hours had no appreciable effect on phenytoin.² Similar effects on protein binding displacement have been seen in other studies.^{3–7} However, although the ratios of free and bound phenytoin may change, there does not appear to be a clinical effect, possibly because the extra free phenytoin is metabolised by the liver.⁶ A study in 10 epileptics taking phenytoin found that when they were also given aspirin 500 mg three times daily for 3 days, no significant changes in serum phenytoin levels or antiepileptic effects occurred.⁸ The extremely common use of aspirin, and the almost total silence in the literature about an adverse interaction between phenytoin and aspirin implies that no special precautions are likely to be needed.

(b) Azapropazone

A patient taking phenytoin developed phenytoin toxicity within 2 weeks of starting azapropazone 600 mg twice daily. Further study in 5 healthy subjects given phenytoin 125 to 250 mg daily found that azapropazone 600 mg twice daily, briefly decreased their mean serum phenytoin levels from 5 to 3.7 micrograms/mL before they rose steadily over the next 7 days to 10.5 micrograms/mL.^{9,10} An extension of this study is described elsewhere.¹¹

Another report describes phenytoin toxicity in a woman taking phenytoin and primidone when fenclofenac was replaced by azapropazone 1.2 g daily.¹²

The most likely explanation is that azapropazone inhibits the liver enzymes concerned with the metabolism of phenytoin, resulting in its accumulation. It also seems possible that azapropazone displaces phenytoin from its plasma protein binding sites so that levels of unbound (and active) phenytoin are increased. Information seems to be limited to the reports cited, but it appears to be a clinically important interaction. The incidence is uncertain, but an interaction occurred in all 5 of the subjects in the study cited.^{9,11} The manufacturers contraindicate azapropazone in patients taking phenytoin.¹³

(c) Bromfenac

Twelve healthy subjects were given bromfenac 50 mg three times daily for 4 days and then phenytoin 300 to 330 mg for up to 14 days (to achieve stable levels), and then both drugs for 8 days. It was found that the peak phenytoin serum levels and AUC were increased by 9% and 11%, respectively, while the bromfenac peak levels and AUC were reduced by 42%. The suggested reason for the reduction in bromfenac levels is that the phenytoin increases its metabolism by the liver.¹⁴ In practical terms these results indicate that there is no need to adjust the dosage of phenytoin if bromfenac is added, nor any need to increase the bromfenac dosage unless there is any evidence that its efficacy is diminished.

(d) Celecoxib

An elderly woman taking phenytoin 300 mg daily who had also been taking celecoxib for the previous 6 months, developed signs of phenytoin toxicity. She was found to have a phenytoin level of 42 micrograms/mL, and a very slow rate of elimination.¹⁵ It was thought that celecoxib may have competed with phenytoin for elimination via the cytochrome P450 isoenzyme CYP2C9. Further study is needed. Until then, it may be prudent to warn patients to monitor for signs of phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness), if celecoxib is started, or consider monitoring phenytoin levels.

(e) Etodolac

A three-way crossover study in 16 healthy subjects found that etodolac 200 mg every 12 hours for 3 days had no effect on the pharmacokinetics or the pharmacological effects of phenytoin (100 mg twice daily for 2 days, 100 mg on day three).¹⁶ There would seem to be no reason for avoiding the concurrent use of these drugs.

(f) Ibuprofen

Studies in healthy subjects found that the pharmacokinetics of single 300- or 900-mg doses of phenytoin were not significantly altered by ibuprofen 300 or 400 mg every 6 hours.^{17,18} However, a single report describes a woman stabilised on phenytoin 300 mg daily who developed phenytoin toxicity within a week of starting to take ibuprofen 400 mg four times daily.¹⁹ Her serum phenytoin levels had risen to about 25 micrograms/mL. The phenytoin was stopped for 3 days and the ibuprofen withdrawn, and within 10 days the phenytoin level had dropped to about 17 micrograms/mL. The reasons for this interaction are not understood.

Both phenytoin and ibuprofen have been available for many years and this case seems to be the first and only report of an adverse interaction. No special precautions would normally seem to be necessary.

(g) Oxyphenbutazone or Phenylbutazone

Six epileptic patients taking phenytoin 200 to 350 mg daily who were then also given phenylbutazone 100 mg three times daily had a mean fall in their phenytoin serum levels from 15 to 13 micrograms/mL over the first 3 days, after which the levels rose steadily to 19 micrograms/mL over the next 11 days. One patient developed symptoms of toxicity. His levels of free phenytoin more than doubled.⁸ Another study found that phenylbutazone increased the steady state half-life of phenytoin from 13.7 to 22 hours.²⁰

The predominant effect of phenylbutazone seems to be the inhibition of

the enzymes concerned with the metabolism of phenytoin,²⁰ leading to its accumulation in the body and a rise in its serum levels. The initial transient fall may possibly be related in some way to the displacement by the phenylbutazone of the phenytoin from its plasma protein binding sites.²¹ An established interaction, although the documentation is very limited. Monitor the outcome of adding phenylbutazone and reduce the phenytoin dosage as necessary. There is no direct evidence that oxyphenbutazone interacts like phenylbutazone, but since it is the main metabolic product of phenylbutazone in the body and has been shown to prolong the half-life of phenytoin in *animals*²² it would be expected to interact similarly.

(h) Tolfenamic acid

Tolfenamic acid 300 mg daily for 3 days had no significant effect on the serum levels of phenytoin in 11 patients.⁸ No special precautions seem necessary if these drugs are taken concurrently.

Phenytoin + Atovaquone

In 12 healthy subjects, atovaquone (1 g, given both twelve hours before and with a single 600-mg dose of phenytoin) did not affect the pharmacokinetics of phenytoin. It was concluded that a clinically important pharmacokinetic interaction is unlikely.¹

1. Davis JD, Dixon R, Khan AZ, Toon S, Rolan PE, Posner J. Atovaquone has no effect on the pharmacokinetics of phenytoin in healthy male volunteers. *Br J Clin Pharmacol* (1996) 42, 246–8.

Phenytoin + Azoles

Phenytoin levels are raised by fluconazole (toxicity seen). Posaconazole, voriconazole and possibly miconazole interact similarly. Itraconazole (and therefore probably ketoconazole) have little effect on phenytoin levels.

Phenytoin decreases itraconazole and possibly ketoconazole levels (treatment failures seen). Posaconazole and voriconazole are similarly affected. Fluconazole levels are not usually affected by phenytoin, although there is one report of reduced efficacy.

Clinical evidence

(a) Fluconazole

In a randomised, placebo-controlled study, 10 subjects given phenytoin 200 mg daily for the last 3 days of a 14-day course of fluconazole 200 mg daily were compared with 10 other subjects taking phenytoin alone. Fluconazole caused the phenytoin AUC to rise by 75%, and the trough phenytoin levels to rise by 128%. Phenytoin appeared not to affect fluconazole trough levels.¹ Two other studies reported similar findings.^{2,3}

There are reports describing at least 7 cases of phenytoin toxicity caused by fluconazole.^{4–7}

A brief report noted that 3 of 9 patients taking fluconazole and phenytoin required an increase in fluconazole dose or the substitution of another antifungal due to a lack of efficacy. It was suggested that phenytoin may reduce fluconazole levels in some patients.⁸ However, in the controlled studies cited above,^{1,3} fluconazole serum levels were unaltered by phenytoin.

(b) Itraconazole

After taking oral phenytoin 300 mg daily for 15 days, the AUC of a single 200-mg dose of itraconazole was reduced more than 90% in 13 healthy subjects. The half-life of itraconazole fell from 22.3 to 3.8 hours. A parallel study⁹ in another group found that itraconazole 200 mg for 15 days increased the phenytoin AUC by 10.3%.

Two patients taking phenytoin and two taking phenytoin with carbamazepine either did not respond to treatment with itraconazole 400 mg daily for aspergillosis, coccidioidomycosis or cryptococcosis, or suffered a relapse. All of them had undetectable or substantially reduced serum itraconazole levels compared with other patients taking itraconazole alone.¹⁰ Two other patients also had very low itraconazole serum levels while taking phenytoin and phenobarbital.¹¹

(c) Ketoconazole

A study in 9 healthy subjects found that ketoconazole 200 mg twice daily for 6 days did not significantly alter the AUC_{0–48h} of a single 250-mg dose of phenytoin.²

A man being treated for coccidioidal meningitis with ketoconazole 400 mg daily relapsed when he was given phenytoin 300 mg daily. A pharmacokinetic study found that his peak serum ketoconazole levels and AUC were reduced compared with the values seen before the phenytoin was started. Even though the ketoconazole dose was increased to 600 mg, and later 1.2 g, his serum levels remained low compared with other patients taking only 400 or 600 mg of ketoconazole.¹² Coccidioidomycosis progressed in another patient taking phenytoin despite the use of ketoconazole.¹⁰ Low serum ketoconazole levels were seen in one patient taking phenytoin and phenobarbital.¹³

(d) Miconazole

A man with epilepsy, well controlled with phenytoin, developed symptoms of phenytoin toxicity within one day of starting *intravenous* miconazole 500 mg every 8 hours and flucytosine. After one week of concurrent treatment his serum phenytoin levels had risen by 50%, from 29 to 43 micrograms/mL. He had some symptoms of very mild phenytoin toxicity before the antifungal treatment was started.¹⁴ Another patient developed symptoms of toxicity (nystagmus, ataxia) within 5 days of starting to take oral miconazole 500 mg daily. His serum phenytoin level rose to 40.8 micrograms/mL. After discontinuation of the miconazole the same dose of phenytoin resulted in a level of 14.5 micrograms/mL.¹⁵

(e) Posaconazole

In a study in healthy subjects the concurrent use of posaconazole 200 mg daily and phenytoin 200 mg daily for 10 days decreased the AUC of posaconazole by 50%, when compared to controls. Although there was no statistically significant change in phenytoin pharmacokinetics, some subjects had increases in phenytoin levels that could be clinically relevant.¹⁶

(f) Voriconazole

Studies in healthy subjects found that phenytoin 300 mg daily decreased the maximum serum levels and AUC of voriconazole by 49% and 69%, respectively. Also, voriconazole 400 mg twice daily increased the maximum serum levels and AUC of phenytoin 300 mg daily by 67% and 81%, respectively.¹⁷

Mechanism

Fluconazole inhibits the cytochrome P450 isoenzymes responsible for phenytoin metabolism (probably CYP2C9).² Voriconazole and miconazole

zole probably act similarly, but ketoconazole and itraconazole do not affect this isoenzyme and therefore do not significantly affect phenytoin levels. Phenytoin is an enzyme inducer, and appears to induce the metabolism of these azoles to varying degrees.

Importance and management

The increase in serum phenytoin levels with **fluconazole** is established and clinically important. Toxicity can develop within 2 to 7 days unless the phenytoin dosage is reduced. Monitor serum phenytoin levels closely and reduce the dosage appropriately. Also be alert for any evidence of reduced fluconazole effects.

The decrease in **itraconazole** levels with phenytoin is established, clinically important and its incidence appears to be high. Because such a marked fall in itraconazole levels occurs, it is difficult to predict by how much its dosage should be increased, for which reason the authors of one report advise using another antifungal instead.⁹ Similarly, the UK manufacturer of itraconazole says that use with potent enzyme inducers such as phenytoin is not recommended.¹⁸ The small rise in serum phenytoin levels caused by itraconazole is unlikely to be clinically important.

Information on the interaction between **ketoconazole** and phenytoin appears to be limited to these reports, but be alert for any signs of a reduced antifungal response. It may be necessary to increase the dosage of the ketoconazole. Ketoconazole probably does not have an important effect on phenytoin levels.

Evidence for increased phenytoin levels with **miconazole** is limited, even so it would be prudent to monitor serum phenytoin levels, including when the oral gel is used at a dose of 5 to 10 mL four times daily (15 mg/kg per day).¹⁹

Phenytoin halves **posaconazole** levels, and posaconazole might increase phenytoin levels. The manufacturer of posaconazole suggests that concurrent use should be avoided unless the benefits outweigh the risks.²⁰ If used together it would seem sensible to consider increasing the posaconazole dose, and increase monitoring of phenytoin adverse effects, taking levels as necessary, and adjusting the phenytoin dose as appropriate.

The interaction between phenytoin and **voriconazole** is established. The UK manufacturers say that concurrent use of voriconazole and phenytoin should be avoided unless the benefits outweigh the risks.²¹ If used together, the manufacturers recommend careful monitoring of phenytoin levels and adverse effects, and doubling the dose of oral **voriconazole** (from 200 to 400 mg twice daily and from 100 mg to 200 mg twice daily in patients less than 40 kg) or increasing the dose of intravenous **voriconazole** (from 4 to 5 mg/kg twice daily).^{21,22}

Phenytoin + Bile-acid binding resins

Neither colestyramine nor colestipol affect the absorption of phenytoin from the gut.

Clinical evidence, mechanism, importance and management

Neither colestyramine 5 g nor colestipol 10 g had a significant effect on the absorption of a single 500-mg dose of phenytoin in 6 healthy subjects. The resins were given 2 minutes before and 6 and 12 hours after the phenytoin.¹ Another study in 6 healthy subjects found that colestyramine 4 g four times daily for 5 days had no significant effect on the extent of the absorption of a single 400-mg dose of phenytoin (given on day 3, two minutes after the colestyramine).² No special precautions would seem to be necessary if either of these drugs and phenytoin is taken concurrently.

Phenytoin + Calcium-channel blockers

Diltiazem can increase serum phenytoin levels. A single case report describes phenytoin toxicity with nifedipine and another case report describes neurological toxicity when a patient taking phenytoin and carbamazepine was given isradipine.

The plasma levels of felodipine and nisoldipine are very markedly reduced by phenytoin (either alone or with carbamazepine). Case reports suggest that nimodipine and verapamil levels may be reduced by phenytoin, and that phenytoin levels may be raised by nifedipine.

Clinical evidence

(a) Diltiazem

Elevated serum phenytoin levels and signs of toxicity developed in 2 out of 14 patients taking phenytoin when they were also given diltiazem.¹ A patient taking phenytoin 250 mg twice daily developed signs of toxicity within 2 weeks of starting to take diltiazem 240 mg every 8 hours.²

(b) Felodipine

After taking felodipine 10 mg daily for 4 days, 10 epileptic patients (including 2 taking phenytoin alone and 3 taking phenytoin with carbamazepine) had markedly reduced plasma felodipine levels (peak levels of 1.6 nanomol/L compared with 8.9 nanomol/L in 12 control subjects). The felodipine bioavailability was reduced to 6.6%.³

(c) Isradipine

A man taking carbamazepine and phenytoin developed neurological toxicity while also taking isradipine, which the authors attributed to a pharmacokinetic or pharmacodynamic interaction between the phenytoin and isradipine.⁴ However, a commentator considered that an interaction between the carbamazepine and isradipine was more plausible.⁵

(d) Nifedipine

An isolated report describes phenytoin toxicity in a man taking phenytoin, 3 weeks after he started to take nifedipine 30 mg daily. His serum phenytoin level was 30.4 micrograms/mL. The nifedipine was stopped, and over the next 2 weeks his serum phenytoin levels fell to 10.5 micrograms/mL. A further 2 weeks later all the symptoms had resolved.⁶ However, a retrospective study of 8 patients suggested that nifedipine does not usually interact.¹ One of the manufacturers of nifedipine notes that the bioavailability of nifedipine may be reduced by concurrent phenytoin.⁷

(e) Nimodipine

A study in 8 epileptic patients one of whom was taking phenytoin with carbamazepine found that the AUC of a single 60-mg oral dose of nimodipine was only about 15% of that obtained from a group of healthy subjects.⁸

(f) Nisoldipine

Twelve epileptic patients receiving long-term phenytoin treatment and 12 healthy subjects were given single 40- or 20-mg doses of nisoldipine. The mean nisoldipine AUCs (normalised for a 20-mg dose) were 1.6 micrograms/L per hour for the epileptics, and 15.2 micrograms/L per hour for the healthy subjects.⁹

(g) Verapamil

A woman taking phenytoin who was then also given verapamil had persistently subnormal plasma verapamil levels (less than 50 nanograms/mL) despite increases in the verapamil dosage from 80 mg twice daily to 160 mg three times daily. When the phenytoin was stopped, her plasma verapamil levels rose to the expected concentrations.¹⁰

Mechanism

Diltiazem may inhibit the metabolism of phenytoin. In contrast, the antiepileptics are well recognised as enzyme inducers, which can increase the metabolism of the calcium-channel blockers by the liver, resulting in a very rapid loss from the body.

Importance and management

Information about the effects of calcium-channel blockers on phenytoin is limited, but what is known indicates that if diltiazem is given with phenytoin, the dosage of phenytoin may possibly need to be reduced to avoid toxicity. The case report of phenytoin toxicity with nifedipine is isolated, and of unknown importance. Phenytoin markedly reduces felodipine, verapamil and possibly nifedipine levels. Although not all calcium-channel blockers have been studied, most would be expected to interact with phenytoin similarly, as they are metabolised by the same isoenzymes (see 'Calcium-channel blockers', (p.860)). A considerable increase in the dosage of any calcium-channel blocker will probably be needed in the presence of phenytoin. Note that the manufacturers of nimodipine¹¹ and nisoldipine¹² contraindicate the concurrent use of phenytoin because of the possibility of a large reduction in their levels.

Phenytoin + Carbamazepine

Some reports describe rises in serum phenytoin levels, with toxicity, whereas others describe falls in phenytoin levels. Genetic differences in the metabolism of these drugs may be an explanation for the differences. Falls in carbamazepine serum levels, sometimes with rises in carbamazepine-10,11-epoxide levels, have been described.

Clinical evidence*(a) Reduced serum phenytoin levels*

Carbamazepine 600 mg daily for 4 to 14 days reduced the serum phenytoin levels of 3 out of 7 patients, from 15 to 7 micrograms/mL, from 18 to 12 micrograms/mL and from 16 to 10 micrograms/mL, respectively. Phenytoin serum levels rose again 10 days after carbamazepine was withdrawn.¹

Reduced serum phenytoin levels in patients given carbamazepine have been described in other reports.^{2–5}

(b) Raised serum phenytoin levels

A study in 6 epileptic patients taking phenytoin 350 to 600 mg daily found that over a 12-week period the addition of carbamazepine 600 to 800 mg daily increased the phenytoin serum levels by 35%, increased its half-life by 41% and reduced its clearance by 36.5%. Neurotoxicity increased by 204%, with additional symptoms of toxicity (sedation, ataxia, nystagmus, etc.) developing in 5 of the 6 patients. The phenytoin dosage remained unchanged throughout the period of the study.⁶

Other reports have also described increases in serum phenytoin levels,^{7–12} which were as large as 81%, and even up to 100% in some cases.^{8,10}

(c) Reduced serum carbamazepine levels

A series of multiple regression analyses on data from a large number of patients [the precise number is not clear from the report], showed that phenytoin reduced plasma carbamazepine, by, on average, 0.9 micrograms/mL for each 2 mg/kg per day of phenytoin.⁷

Reduced serum carbamazepine levels have been described in other studies and reports.^{3,11,13–16} Two studies found that phenytoin markedly increased the levels of the active metabolite of carbamazepine, carbamazepine-10,11-epoxide.^{17,18}

Mechanism

Not understood. Both carbamazepine and phenytoin are enzyme inducers, and might therefore be expected to decrease the metabolism of each other. However, more recently it has been shown that carbamazepine can inhibit the cytochrome P450 isoenzyme CYP2C19, which is one of the enzymes involved in phenytoin metabolism.¹⁹ Carbamazepine might therefore cause increases in phenytoin levels by this mechanism. Moreover, CYP2C19 shows genetic polymorphism (see 'Genetic factors in drug metabolism', (p.4), for a general discussion), so an interaction via this mechanism would not occur in all patients.

Importance and management

Phenytoin may decrease carbamazepine levels, but carbamazepine has variable effects on phenytoin levels, with both increases and decreases described. Monitor antiepileptic levels during concurrent use (where possible including the active metabolite of carbamazepine, carbamazepine-10,11-epoxide) so that steps can be taken to avoid the development of toxicity or lack of efficacy. Not all patients appear to have an adverse interaction, and, at present, it does not seem possible to identify those potentially at risk. The risk of carbamazepine-induced water intoxication is reported to be reduced in patients also taking phenytoin.¹⁴

Phenytoin + Chloramphenicol

Serum phenytoin levels can be raised by intravenous chloramphenicol and phenytoin toxicity may occur. Other evidence indicates that phenytoin may increase or decrease serum chloramphenicol levels in children.

Clinical evidence

(a) Effect on chloramphenicol

A child given a 6-week course of intravenous chloramphenicol 100 mg/kg daily in four divided doses had a reduction in chloramphenicol peak and trough serum levels of 46% and 74%, respectively, within 2 days of starting phenytoin 4 mg/kg daily. Levels were further reduced by 63% and 87%, respectively, by the addition of phenobarbital 4 mg/kg daily.¹ Consider also 'Chloramphenicol + Phenobarbital', (p.300). In contrast, 6 children (aged 1 month to 12 years) developed raised, toxic chloramphenicol levels while receiving phenytoin.²

(b) Effect on phenytoin

A man taking phenytoin 100 mg four times daily developed signs of toxicity within a week of also receiving intravenous chloramphenicol (1 g every 6 hours for 4 doses then 2 g every 6 hours). His serum phenytoin levels had risen by about threefold, from about 7 to 24 micrograms/mL.³

This interaction has been described in a number of other reports.^{4–12} One study found that intravenous chloramphenicol more than doubled the half-life of phenytoin.⁴ The AUC of phenytoin after a single intravenous dose of fosphenytoin was 23% higher (not significant) in children also given intravenous chloramphenicol when compared with those given intravenous cefotaxime. In addition, the phenytoin half-life was significantly prolonged by chloramphenicol (23.7 hours versus 15.5 hours).¹³

Mechanism

It seems probable that chloramphenicol, a known enzyme inhibitor,¹⁴ affects the liver enzymes (possibly cytochrome P450 isoenzyme CYP2C19¹⁵) concerned with the metabolism of phenytoin thereby reducing its rate of clearance from the body. The changes in the pharmacokinetics of chloramphenicol in children are not understood.

Importance and management

The rise in serum phenytoin levels with intravenous chloramphenicol in adults is well documented and clinically important. A two to fourfold rise can occur within a few days. Concurrent use should be avoided unless the effects can be closely monitored and appropriate phenytoin dosage reductions made as necessary. The use of a single prophylactic dose of phenytoin or fosphenytoin may be an exception to this.¹³ It seems very doubtful if enough chloramphenicol is absorbed from eye drops or ointments for an interaction to occur.

The general clinical importance of the changes in serum chloramphenicol levels in children is uncertain, but the effects of concurrent use should certainly be monitored. More study is needed.

Phenytoin + Chlorphenamine

In two patients phenytoin toxicity was attributed to the concurrent use of chlorphenamine.

Clinical evidence, mechanism, importance and management

A week or so after starting to take chlorphenamine 4 mg three times daily, a woman taking phenytoin and phenobarbital developed phenytoin toxicity with serum phenytoin levels of about 65 micrograms/mL. The toxic symptoms disappeared and phenytoin levels fell when the chlorphenamine was withdrawn.¹ Another woman taking antiepileptics, including phenytoin, developed slight grimacing of the face and involuntary jaw movements (but no speech slurring, ataxia or nystagmus) within 12 days of starting to take chlorphenamine 12 to 16 mg daily. Her serum phenytoin level had risen to 30 micrograms/mL but it fell when the chlorphenamine was withdrawn.²

The reason for these reactions is not clear but it has been suggested that chlorphenamine may have inhibited the metabolism of phenytoin by the liver. These are isolated cases, and their general relevance is uncertain, but it seems likely to be small.

Phenytoin + Coumarins and related drugs

The serum levels of phenytoin can be increased by dicoumarol (toxicity seen) and phenprocoumon, but they are usually unchanged by warfarin and phenindione. However, a single case of phenytoin toxicity has been seen with warfarin. Phenytoin would be expected to reduce the anticoagulant effects of coumarin anticoagulants, and this has been demonstrated for dicoumarol and warfarin. However, cases of increased effects of warfarin have been reported, and one study showed the effects of phenprocoumon were generally unaltered. A single case of severe bleeding has been described in a patient taking acenocoumarol, paroxetine and phenytoin.

Clinical evidence

The reports of interactions between phenytoin and various anticoagulants are summarised in 'Table 14.2', (p.556), and discussed in further detail below.

(a) Acenocoumarol

A 68-year-old woman with a double mitral valve lesion, atrial fibrillation and hypertension, taking digoxin and diuretics, was stabilised on acenocoumarol 17 mg per week in divided doses and paroxetine. Phenytoin 400 mg daily for 3 days then 300 mg daily was started because of a seizure, and 11 days later she developed ataxia, lethargy and nystagmus (free phenytoin levels of 12.5 micromol/L). At the same time her INR was found to have risen from a range of 2 to 4, up to 14.5 and a huge retroperitoneal haematoma was discovered. After appropriate treatment she was discharged taking acenocoumarol 13 mg per week in divided doses and half the phenytoin dosage.¹

(b) Dicoumarol

Phenytoin 300 mg daily was given to 6 subjects taking dicoumarol 40 to 160 mg daily for a week. No significant changes in the prothrombin-pro-

Table 14.2 Summary of interactions between phenytoin and anticoagulants

Concurrent treatment with phenytoin and anticoagulant	Effect on anticoagulant	Effect on serum phenytoin levels
Dicoumarol	Reduced ¹	Markedly increased ¹⁰⁻¹²
Phenprocoumon	Usually unchanged ²	Increased ¹¹
Acenocoumarol	Single case of increase ³	Uncertain
Warfarin	Increased ^{4-9,14} Single case of increase followed by decrease ⁷	Usually unchanged ¹¹ Increased in two cases ^{9,13}
Phenindione	Not documented	Usually unchanged ^{10,11}

convertin concentration occurred until 3 days after stopping the phenytoin. In the following 5 days it climbed from 20 to 50%, with an accompanying drop in the serum dicoumarol levels.² Four other subjects taking dicoumarol 60 mg daily were also given phenytoin 300 mg daily for the first week of treatment, and then 100 mg daily for 5 more weeks. The prothrombin-proconvertin concentration had risen from 20 to 70% after 2 weeks of concurrent treatment, representing an antagonism of the anticoagulant effect, and only fell to previous levels 5.5 weeks after stopping the phenytoin.²

A study in 6 subjects taking phenytoin 300 mg daily found that when they were also given dicoumarol (doses adjusted to give prothrombin values of about 30%) their serum phenytoin levels rose on average by almost 10 micrograms/mL (126%) over 7 days.³ In another study the half-life of phenytoin in 3 patients increased by about fivefold during dicoumarol treatment.⁴

A patient taking dicoumarol developed phenytoin toxicity within a few days of starting to take phenytoin 300 mg daily (dose based on a weight of 62 kg). Phenytoin was withdrawn, and re-introduced at 200 mg daily, which gave satisfactory phenytoin levels.⁵

(c) Phenindione

A study in 4 patients taking phenytoin 300 mg daily found that phenindione did not affect their serum phenytoin levels.⁴

(d) Phenprocoumon

An investigation in patients taking long-term phenprocoumon treatment found that in the majority of cases phenytoin had no significant effect on either serum phenprocoumon levels or the anticoagulant control, although a few patients had a fall and others a rise in serum anticoagulant levels, with consequent decreased or increased effect.⁶

A study in 4 patients taking phenytoin 300 mg daily found that when they were given phenprocoumon their serum phenytoin levels rose from about 10 micrograms/mL to 14 micrograms/mL over 7 days.⁴ The phenytoin half-life increased from 9.9 to 14 hours.

(e) Warfarin

The prothrombin time of a patient taking warfarin increased from 21 to 32 seconds over a month when phenytoin 300 mg daily was also given, despite a 22% reduction in the warfarin dosage. He was restabilised on the original warfarin dosage when the phenytoin was withdrawn. Six other reports describe this interaction.⁷⁻¹² One of them describes a patient who had

an increased anticoagulant response to warfarin for the first 6 days after phenytoin was added. The anticoagulant effect then declined to less than the level seen before the addition of phenytoin.¹⁰ Conversely, a population pharmacokinetic analysis reported that the clearance of warfarin was increased by 30% in 6 patients taking phenytoin or phenobarbital.¹³ However, the findings were not reported separately for the two drugs, and are therefore difficult to interpret (phenobarbital is a known inducer of warfarin clearance, see 'Coumarins + Barbiturates', p.390).

A study in 2 patients taking phenytoin 300 mg daily found that their serum phenytoin levels were unaffected by warfarin given for 7 days, and the half-life of phenytoin in 4 other patients was unaffected.⁴ However, a patient taking phenytoin 300 mg daily developed symptoms of toxicity shortly after starting to take warfarin.¹⁴ Another patient developed phenytoin toxicity 6 months after starting to take phenytoin with warfarin.¹²

Mechanism

Multiple, complex and poorly understood. Dicoumarol and phenprocoumon (but not normally warfarin) appear to inhibit the metabolism of phenytoin by the liver, so that its loss from the body is reduced. Phenytoin is an inducer of the cytochrome P450 isoenzyme CYP2C9, which is involved in metabolism of the coumarin anticoagulants. Phenytoin would therefore be expected to decrease the levels and effect of some coumarins, and this has been shown for dicoumarol. However, increased effects of warfarin have been noted, suggesting reduced metabolism of warfarin. Why this occurs is uncertain, but poor CYP2C9 metaboliser phenotype (see 'Genetic factors', (p.4)) may provide an explanation.¹⁵ Phenytoin possibly also has a diverse depressant effect on the liver, which lowers blood clotting factor production.¹⁶

Importance and management

None of these interactions has been extensively studied nor are they well established, but what is known suggests that the use of dicoumarol with phenytoin should be avoided or monitored very closely. Serum phenytoin levels and anticoagulant control should be well monitored if acenocoumarol, phenprocoumon or warfarin is given with phenytoin. Dosage adjustments may be needed to accommodate any interactions. Information about other anticoagulants (apart from phenindione, which had no effect

on phenytoin levels) appears to be lacking, but it would clearly be prudent to monitor the effects of concurrent use.

Phenytoin + Dextromethorphan

Dextromethorphan appears not to affect the serum levels of phenytoin.

Clinical evidence, mechanism, importance and management

A double-blind, crossover study in 4 epileptic patients with severe complex partial seizures found that dextromethorphan 120 mg daily in liquid form (*Delsym*) over 3 months had no effect on their serum phenytoin levels. There was a non-significant alteration in the complex partial seizure and tonic-clonic seizure frequency.¹

1. Fisher RS, Cysyk BJ, Lesser RP, Pontecorvo MJ, Ferkany JT, Schwerdt PR, Hart J, Gordon B. Dextromethorphan for treatment of complex partial seizures. *Neurology* (1990) 40, 547–9.

Phenytoin + Dextropropoxyphene (Propoxyphene)

Although no interaction generally appears to occur between phenytoin and dextropropoxyphene, a case report describes phenytoin toxicity in a patient given both drugs.

Clinical evidence, mechanism, importance and management

Only a very small rise in serum phenytoin levels occurred in 6 patients who took dextropropoxyphene 65 mg three times daily for 6 to 13 days.¹ In contrast, a review briefly mentions one patient who developed toxic serum phenytoin levels while taking dextropropoxyphene in doses of up to 600 mg daily on an as-required basis.²

Concurrent use need not be avoided, but since rises in the serum levels of phenytoin can occur it would be prudent to monitor the outcome. It is probably sufficient just to monitor for increased adverse effects (blurred vision, nystagmus, ataxia or drowsiness).

Phenytoin + Diazoxide

Three children and one adult had very marked reductions in serum phenytoin levels when diazoxide was given, and in one case

seizure control was lost. There is some evidence that the effects of diazoxide may also be reduced.

Clinical evidence

A child receiving phenytoin 29 mg/kg daily and an adult receiving phenytoin 1 g daily were unable to achieve therapeutic phenytoin serum levels while taking diazoxide. When the diazoxide was withdrawn, satisfactory serum phenytoin levels were achieved with dosages of only 6.6 mg/kg and 400 mg daily, in the child and the adult, respectively. When diazoxide was restarted experimentally in the adult, the serum phenytoin levels became undetectable after 4 days, and seizures occurred.¹ Two other reports describe this interaction.^{2,3} In addition it appears that the effects of the diazoxide can also be reduced.^{2,4}

Mechanism

What is known suggests that diazoxide increases the metabolism and the clearance of phenytoin from the body.^{1,2} The half-life of diazoxide is possibly reduced by phenytoin.⁴

Importance and management

Information is limited to these reports, but the interaction would appear to be established. Monitor the effects of concurrent use, being alert for the need to increase the phenytoin dosage. The clinical importance of the reduced diazoxide effects is uncertain.

Phenytoin + Dichloralphenazone

There is some evidence that serum phenytoin levels may be reduced by dichloralphenazone.

Clinical evidence, mechanism, importance and management

After taking dichloralphenazone 1.3 g each night for 13 nights the total body clearance of a single intravenous dose of phenytoin was doubled in 5 healthy subjects.¹ The phenazone component of dichloralphenazone is a known enzyme inducer and the increased clearance of phenytoin is probably due to an enhancement of its metabolism by the liver. There seem to be no additional reports of adverse effects in patients given both drugs, so that the clinical importance of this interaction is uncertain. However, it would seem prudent to watch for a reduction in serum phenytoin levels if dichloralphenazone is added to established treatment with phenytoin.

1. Riddell JG, Salem SAM, McDevitt DG. Interaction between phenytoin and dichloralphenazone. *Br J Clin Pharmacol* (1980) 9, 118P.

Phenytoin + Felbamate

Felbamate causes a moderate increase in plasma phenytoin levels. Felbamate plasma levels are reduced, but the importance of this is uncertain.

Clinical evidence

A pilot study in 4 patients noted that felbamate increased plasma phenytoin levels.¹ Therefore, in a further study the phenytoin dose was automatically reduced by 20% when felbamate was given. Of 5 patients, one needed a slight increase in phenytoin dosage, whereas 2 others needed a further reduction in their phenytoin dosage.² In a later full report of this study, it was noted that phenytoin dosage decreases of 10 to 30% were required to maintain stable levels.³ Another study in epileptic patients found that felbamate 1.2 or 1.8 g daily increased the maximum plasma phenytoin levels by 31% and 69%, respectively. Higher felbamate doses necessitated phenytoin dose reductions of 20 to 40%.⁴

Studies in children and adults have found that phenytoin increased the clearance of felbamate by about 40%,^{5,6} and decreased maximum felbamate levels by 56 to 60%, when compared with patients receiving felbamate alone.⁴ Another report suggested that this effect was dose-dependent.⁷

Mechanism

Uncertain but felbamate probably acts as a competitive inhibitor of phenytoin metabolism, thereby reducing its loss from the body and increasing its serum levels,^{2,8} whereas phenytoin induces felbamate metabolism, thereby increasing its clearance.⁷

Importance and management

Established interactions. The phenytoin dosage may need to be reduced (a 20 to 40% reduction seems to be about right^{2,4,8}) if felbamate is added, and to increase it if felbamate is withdrawn. However, note that as phenytoin pharmacokinetics are non-linear any dosage adjustments will need to be assessed in individual patients. The importance of the reduced felbamate levels is uncertain, but is probably less important because felbamate has a wide therapeutic range.⁴

Phenytoin + Food

The absorption of phenytoin can be affected by some foods. A very marked reduction in phenytoin absorption has been described when it was given with enteral feeds (e.g. *Isocal*, *Osmolite*), by nasogastric or jejunostomy tubes.

Clinical evidence

(a) Food by mouth

A study found that serum drug levels were lower than expected when phenytoin was disguised in **vanilla pudding** and given to children. However, when the phenytoin was mixed with **apple sauce**, 3 out of 10 patients developed serum phenytoin levels within the toxic range, and the mean levels were twice those seen when the tablets were mixed with the **vanilla pudding**.¹ The absorption of phenytoin as the acid in a micronised form (*Fenantoin*, ACO, Sweden) was faster and the peak serum levels were on average 40% higher when it was given after a **standardised breakfast**.² In a further study to investigate the effects of component parts of the **standardised breakfast**, the same authors found that **fat** had no measurable effect, but **carbohydrate** may enhance and **protein** reduce the absorption of phenytoin.³

Another study in 5 subjects found that the bioavailability of a single dose of phenytoin was enhanced when it was given immediately after a '**balanced**' meal. Administration after a **high-lipid meal** resulted in large inter-patient variability in phenytoin bioavailability.⁴ One single dose study found that, when taken with a **high-protein meal**, the total absorption of phenytoin was not affected, although it was slightly delayed.⁵

An epileptic had a marked fall in his serum phenytoin levels accompanied by an increased seizure frequency when phenytoin was given at bedtime with 8 oz of a food supplement (*Ensure*).⁶ Another patient had reduced phenytoin serum levels when phenytoin was given as an oral suspension with oral *Fresubin liquid food concentrate*.⁷

However, in contrast, a study in 10 healthy subjects found that when *Ensure* or *Vivonex TEN* was given every 4 hours for 24 hours, the absorption of a single 400-mg dose of phenytoin was unaffected.⁸ Similarly, a single-dose study in healthy subjects found that the bioavailability of phenytoin sodium 400 mg in a capsule formulation (*Dilantin Kapseals*) was not affected by concurrent enteral feeds (*Ensure*).⁹

A study in healthy subjects found phenytoin levels were reduced by enteral feeds, but that it was easier to attain therapeutic levels of phenytoin in those also receiving a **meat-based** formulation (*Compleat Modified*) rather than a **protein hydrolysate** formulation (*Osmolite*).¹⁰

(b) Food by nasogastric tube

A patient taking phenytoin 300 mg daily who was being fed with *Fortison* through a nasogastric tube, following a brain injury sustained in a road traffic accident, had a phenytoin serum level of only 1 mg/L. When phenytoin 420 mg was given diluted in water and separated from the food by 2 hours, a serum level of 6 mg/L was achieved.¹¹ This report describes a similar reaction in another patient with a cerebral tumour.¹¹

A study in 20 patients and 5 healthy subjects found that phenytoin absorption was reduced by about 70% when it was given by nasogastric tube with an **enteral feed** product (*Isocal*) at a rate of 100 to 125 mL/hour.¹² Other reports describe the same interaction in patients given *Ensure*,¹³ *Isocal*,^{14,15} or *Osmolite*.^{13,16-18}

However, another study in healthy subjects found the absolute bioavailability of phenytoin suspension or phenytoin sodium solution given by nasogastric tube was not affected by an enteral feed product (*Isocal*).¹⁹

(c) Food by jejunostomy tube

A woman with a history of seizures had acceptable serum phenytoin levels when phenytoin was given intravenously, but they fell from 19.1 micrograms/mL to less than 2.5 micrograms/mL when a comparable dose of phenytoin suspension was given in the presence of an **enteral feed** product (*Jevity*), given by jejunostomy tube.²⁰

Mechanism

Not fully resolved. Phenytoin can bind to some food substances, which reduces its absorption.^{21,22} One study in healthy subjects failed to find any difference in phenytoin bioavailability after fasting or with *Ensure* (given hourly or every 4 hours), suggesting that factors other than direct contact of phenytoin and feed contribute to decreased phenytoin bioavailability.²³ Phenytoin can also become bound to the nasogastric tubing²⁴ and may also be poorly absorbed if the tubing empties into the duodenum rather than the stomach.²⁴ Delivery into the jejunum appears to have an even greater detrimental effect on phenytoin absorption, because there is even less time for adequate absorption.²⁰ Other factors that could contribute to the interaction are gastrointestinal transit time, the nitrogen source in the feed, the calcium content and pH of the feed, the dose form of phenytoin or its dilution before administration.²⁵

Importance and management

Phenytoin is often taken orally with food to reduce gastric irritation. This normally appears not to have a marked effect on absorption, but the studies cited above show that some formulations and some foods can interact. If there are problems with the control of seizures or evidence of toxicity, review how and when the patient is taking the phenytoin.

Some studies in healthy subjects failed to find an interaction between phenytoin and enteral feeding.^{8,9,19,23} However, many studies in patients have found a clinically important interaction between phenytoin and enteral feeds given orally or by nasogastric tube. The markedly reduced bioavailability associated with the nasogastric route has been successfully managed by giving the phenytoin diluted in water 2 hours after stopping the feed, flushing with 60 mL of water, and waiting another 2 hours before restarting the feed,^{11,12} However, one limited study failed to confirm that this method is successful,¹³ and some sources suggest waiting 1 hour²⁶ or 6 hours¹⁴ after the phenytoin dose before restarting the feed. Some increase in the phenytoin dosage may also be needed. Monitor concurrent use closely. The same problem can clearly also occur when enteral feeds are given by jejunostomy tube. Approaches on how to minimise any potential interaction have been reported,^{25,27} including the development and use of an algorithm.²⁵

Phenytoin + H₂-receptor antagonists

Phenytoin serum levels are raised by the use of cimetidine and toxicity has occurred. Limited evidence suggests that low (non-prescription) doses of cimetidine may not interact. Very rarely bone marrow depression develops on concurrent use. Famotidine, nizatidine and ranitidine do not normally interact with phenytoin, although, rarely, cases of elevated phenytoin levels have been reported.

Clinical evidence

(a) Cimetidine

The serum phenytoin levels of 9 patients rose by 60% (from 5.7 to 9.1 micrograms/mL) when they were given cimetidine 200 mg three times daily and 400 mg at night for 3 weeks. The serum phenytoin level returned to its former levels within 2 weeks of stopping the cimetidine.¹

This interaction has been described in many reports and studies involving patients^{2–7} and healthy subjects.^{8–11} Phenytoin toxicity has developed in some individuals. The extent of the rise in serum levels is very variable being quoted as 13 to 33% over about 6 days in one report² and 22 to 280% over 3 weeks in others.^{4,12} There is some evidence that the effect may be dependent on cimetidine dose. One study found that the effect of cimetidine 2.4 g daily was greater than that of 1.2 g daily or 400 mg daily, which did not differ from each other.⁹ In another study, cimetidine 200 mg twice daily for 2 weeks had no effect on serum phenytoin levels in 9 patients taking stable doses of phenytoin.¹³

Severe and life-threatening agranulocytosis in 2 patients^{14,15} and thrombocytopenia in 6 other patients^{16–18} have been attributed to the concurrent use of phenytoin and cimetidine. Severe skin reactions have also been reported in 3 patients treated with phenytoin, cimetidine, and dexamethasone after resection of brain tumours, which resolved on discontinuing phenytoin.¹⁹ See also 'Corticosteroids + Phenytoin', p.1059 for the effects of dexamethasone on phenytoin levels.

(b) Famotidine

A study in 10 subjects found that famotidine 40 mg daily for 7 days did not alter the pharmacokinetics of a single dose of phenytoin.²⁰ However, a single case report describes phenytoin toxicity and an almost doubled serum level (increase from 18 to 33 micrograms/mL) in a patient given famotidine. This was managed by a reduction in the phenytoin dose.²¹

(c) Nizatidine

Nizatidine 150 mg twice daily for 9 doses had no effects on the pharmacokinetics of a single dose of phenytoin in 18 healthy subjects.²²

(d) Ranitidine

A study in 4 patients found that ranitidine 150 mg twice daily for 2 weeks did not alter phenytoin levels.^{4,12} Similarly, a double-blind, crossover study in healthy subjects found that ranitidine 150 mg twice daily for 6 days had no significant effect on steady state phenytoin levels.²³ However, one patient had a 40% increase in serum phenytoin levels over a month when ranitidine 150 mg twice daily was given,²⁴ and two others also developed elevated serum phenytoin levels and signs of toxicity, which were attributed to the use of ranitidine.^{25,26} Another patient developed a severe skin reaction when treated with phenytoin, ranitidine and dexamethasone after resection of a brain tumour, which resolved on discontinuing phenytoin.¹⁹

Mechanism

Cimetidine inhibits the activity of the liver enzymes concerned with the metabolism of phenytoin, thus allowing it to accumulate in the body and, in some instances, to reach toxic concentrations. Famotidine, nizatidine and ranitidine normally do not affect these enzymes. Agranulocytosis and thrombocytopenia are relatively rare manifestations of bone marrow depression caused by both phenytoin and the H₂-receptor antagonists.

Importance and management

The interaction between phenytoin and cimetidine is well documented and clinically important. It is not possible to identify individuals who will show the greatest response, but those with serum levels at the top end of the therapeutic range are most at risk. Do not give cimetidine to patients already taking phenytoin unless the serum levels can be monitored and suitable dosage reductions made as necessary. The results from one small study suggest that low doses of cimetidine (such as those available without a prescription in the UK) may not interact.¹³ Since there are only rare cases cited for famotidine, nizatidine, and ranitidine extra monitoring beyond that usually carried out in patients receiving phenytoin does not appear to be warranted but be alert for signs of phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness) when these H₂-receptor antagonists are first added to established treatment with phenytoin.

Phenytoin + Immunoglobulins

An isolated report describes an epileptic patient taking phenytoin who died, probably from hypersensitivity myocarditis, two days after receiving immunoglobulins for Guillain-Barré syndrome.

Clinical evidence, mechanism, importance and management

A man who had been taking phenytoin for 8 years was diagnosed as having Guillain-Barré syndrome for which intravenous immunoglobulin was started at 400 mg/kg daily. On day 2 the patient complained of abdominal pain, aching shoulders and backache. He subsequently developed hypotension and died, despite resuscitation attempts. A post-mortem suggested that he had died from hypersensitivity myocarditis, which the authors of the report suggest might have resulted from the long-term use of the phenytoin.¹ This hypersensitivity with phenytoin has been reported before.² Because this complication is so serious, the authors of this report suggest that leukocyte counts, in particular eosinophils, should be monitored if immunoglobulins and phenytoin are given concurrently.¹ The general importance of this alleged interaction is not known. However, note that subsequent to this report, intravenous immunoglobulin has successfully been used to treat a few cases of hypersensitivity syndrome to phenytoin,^{3–5} one including eosinophilia.³ Intravenous immunoglobulin alone has also been associated with causing myocarditis.⁶

Phenytoin + Influenza vaccines

Influenza vaccine is reported to increase, decrease or to have no effect on phenytoin serum levels. The efficacy of the vaccine remains unchanged.

Clinical evidence

(a) Phenytoin levels

The serum phenytoin levels of 8 epileptic children were increased by about 50%, from 9.5 to 15.16 micrograms/mL, 7 days after they were given 0.5 mL of an influenza virus vaccine USP, types A and B, whole virus (Squibb). The phenytoin levels returned to baseline over the following 7 days.¹ Temporary rises in the serum phenytoin levels of 3 patients, apparently caused by influenza vaccination, are briefly described in another report.²

In contrast, another study in 16 patients given 0.5 mL of an inactivated whole-virion trivalent influenza vaccine found that 7 and 14 days later their mean serum phenytoin levels were not significantly altered, although

4 of them showed a trend towards raised levels. Subsequently, these 4 patients had serum phenytoin increases ranging from 46 to 170%, which returned to baseline between week 4 and 17 after immunisation.³

In yet another study, within 4 days of receiving 0.5 mL of a subvirion, trivalent influenza vaccine, the serum phenytoin levels of 7 patients were reduced by 11 to 14%, which is unlikely to have much clinical significance.⁴ A further study⁵ measured both free and total phenytoin levels in 8 patients receiving phenytoin alone. Two days after receiving 0.5 mL of a trivalent influenza vaccine, the total phenytoin level had increased by 10%, and this then returned to baseline levels by day 7. However, the free phenytoin level gradually decreased after vaccination to a maximum of 25% less at day 14.

(b) Vaccine efficacy

The efficacy of influenza vaccine is reported to be unchanged by phenytoin.⁶

Mechanism

Where an interaction occurs it is suggested that it may be due to the inhibitory effect of the vaccine on the liver enzymes concerned with the metabolism of the phenytoin, resulting in a reduced clearance from the body.¹

Importance and management

The outcome of immunisation with influenza vaccine on phenytoin levels is uncertain. Concurrent use need not be avoided but it would be prudent to monitor the effects closely. Be aware that any alteration in levels may take a couple of weeks to develop and usually resolves spontaneously.

Phenytoin + Isotretinoin

A study in 7 healthy subjects taking phenytoin 300 mg daily found that the addition of isotretinoin 40 mg twice daily for 11 days had no effect on the steady-state pharmacokinetics of phenytoin.¹ No special precautions would seem to be needed if these drugs are given concurrently.

1. Oo C, Barsanti F, Zhang R. Lack of effect of isotretinoin on the pharmacokinetics of phenytoin at steady-state. *Pharm Res* (1997) 14 (11 Suppl), S-561.

Phenytoin + Loxapine

A single case report describes decreased serum phenytoin levels in a patient given loxapine.

Clinical evidence, mechanism, importance and management

The serum phenytoin levels of an epileptic patient were reduced by loxapine, and showed a marked rise when it was withdrawn.¹ The general importance of this case is uncertain, but bear this interaction in mind, particularly as loxapine can lower the convulsive threshold.

1. Ryan GM, Matthews PA. Phenytoin metabolism stimulated by loxapine. *Drug Intell Clin Pharm* (1977) 11, 428.

Phenytoin + Macrolides

Erythromycin appears not to interact with phenytoin. Limited evidence suggests that clarithromycin may possibly raise serum phenytoin levels.

Clinical evidence

(a) Clarithromycin

A retrospective study of serum phenytoin levels in a group of 21 patients with AIDS and a large control group of 557 subjects suggested that the concurrent use of clarithromycin (a total of 22 samples from at least 10 patients) was associated with higher serum phenytoin levels. The concentration/dose ratio of the phenytoin was 1.6 without clarithromycin and 3.9 with clarithromycin.¹

(b) Erythromycin

A single-dose study found that the mean clearance of phenytoin was unchanged by erythromycin 333 mg every 8 hours for 7 days in 8 healthy subjects. However, there were occasional large changes in phenytoin clearance.² Similarly, in another study erythromycin 250 mg every 6 hours for 7 days had no effect on the pharmacokinetics of a single dose of phenytoin in 8 healthy subjects.³

Mechanism

Not known, but it could be that clarithromycin inhibits the metabolism of the phenytoin by the liver. An *animal* study found that erythromycin, clarithromycin, and **roxithromycin** reduced the metabolism and increased levels of phenytoin.⁴

Importance and management

This seems to be the first and only evidence that clarithromycin possibly interacts like this. Given that the interaction was identified retrospectively any interaction seems unlikely to cause an acute problem. Erythromycin appears not to interact with phenytoin, but nevertheless caution has been recommended.²

Phenytoin + Methylphenidate

Although two small studies found that methylphenidate did not alter phenytoin levels, raised serum phenytoin levels and phenytoin toxicity have been seen in three patients given methylphenidate.

Clinical evidence

A 5-year-old hyperkinetic epileptic boy taking phenytoin 8.9 mg/kg and **primidone** 17.7 mg/kg daily, developed ataxia without nystagmus when he was also given methylphenidate 40 mg daily. Serum levels of both the antiepileptics were found to be at toxic levels and only began to fall when the methylphenidate dosage was reduced.¹

A further case of phenytoin toxicity occurred in another child given methylphenidate.² Only one other case has been reported, but this patient was later rechallenged with the two drugs and phenytoin toxicity was not seen.³

Furthermore, this interaction has not been seen in clinical studies and observations of 3 healthy subjects³ and more than 11 patients⁴ taking phenytoin and methylphenidate.

Mechanism

Not fully understood. The suggestion is that methylphenidate acts as an enzyme inhibitor, slowing the metabolism of the phenytoin by the liver and leading to its accumulation in those individuals whose drug metabolising system is virtually saturated by phenytoin.

Importance and management

These appear to be the only reports, and any interaction is not established. Concurrent use of phenytoin need not be avoided but be alert for any evi-

dence of toxicity, particularly if the phenytoin dosage is high. It would seem prudent to monitor for symptoms of phenytoin toxicity (e.g. blurred vision, nystagmus, ataxia or drowsiness) and take levels if necessary.

Phenytoin + Metronidazole

One study found that the half-life of phenytoin was modestly prolonged by metronidazole, whereas another found no change in phenytoin pharmacokinetics. An anecdotal report describes a few patients who developed toxic phenytoin levels when given metronidazole.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study¹ in 7 healthy subjects found that metronidazole 250 mg three times daily increased the half-life of a single 300-mg intravenous dose of phenytoin by about 40% (from 16 to 23 hours) and reduced the clearance by 15%. In contrast, another study in 5 healthy subjects found that the pharmacokinetics of a single 300-mg oral dose of phenytoin were unaffected by metronidazole 400 mg twice daily for 6 days.² An anecdotal report describes several patients (exact number not stated) who developed toxic phenytoin serum levels when given metronidazole.³ These appear to be the only reports of this potential interaction, and the reason for their discordant findings is not clear. It seems likely that few patients are likely to experience a clinically significant interaction.

1. Blyden GT, Scavone JM, Greenblatt DJ. Metronidazole impairs clearance of phenytoin but not of alprazolam or lorazepam. *J Clin Pharmacol* (1988) 28, 240–5.

3. Picard EH. Side effects of metronidazole. *Mayo Clin Proc* (1983) 58, 401.

Phenytoin + Nefazodone

Nefazodone did not affect the pharmacokinetics of phenytoin in healthy subjects.

Clinical evidence, mechanism, importance and management

Nefazodone 200 mg twice daily for 7 days had no effect on the pharmacokinetics of a single 300-mg dose of phenytoin in healthy subjects, and no changes in vital signs, ECGs or other physical measurements were seen. There was no evidence that a clinically significant interaction was likely.¹

1. Marino MR, Langenbacher KM, Hammett JL, Nichola P, Uderman HD. The effect of nefazodone on the single-dose pharmacokinetics of phenytoin in healthy male subjects. *J Clin Psychopharmacol* (1997) 17, 27–33.

Phenytoin + Nitrofurantoin

An isolated report describes a reduction in serum phenytoin levels and poor seizure control in a patient given nitrofurantoin.

Clinical evidence, mechanism, importance and management

A patient with seizures due to a brain tumour was taking phenytoin 300 mg daily. He had a seizure within a day of being given nitrofurantoin 200 mg for a urinary-tract infection and, despite a recent increase in the phenytoin dose to 350 mg, his serum phenytoin levels were found to be modestly reduced (from about 9 to 7.6 micrograms/mL). They continued to fall to 6.3 micrograms/mL despite a further increase in the phenytoin dosage to 400 mg daily. When the nitrofurantoin was stopped he was stabilised on his original dosage of phenytoin. The reasons are not understood but, on the basis of a noted rise in serum gamma glutamyltransferase levels during the use of the nitrofurantoin, the authors speculate that it

increased the metabolism of the phenytoin by the liver.¹ The general importance of this interaction is uncertain, but probably small.

1. Heipertz R, Pilz H. Interaction of nitrofurantoin with diphenylhydantoin. *J Neurol* (1978) 218, 297–301.

Phenytoin + Orlistat

Orlistat does not alter the pharmacokinetics of phenytoin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, randomised, crossover study, 12 healthy subjects were given a single 300-mg dose of phenytoin on day 4 of a 7-day course of orlistat 120 mg three times daily. The pharmacokinetics of phenytoin were unchanged by orlistat,¹ and no special precautions are therefore thought to be needed if these two drugs are given concurrently.

1. Melia AT, Mulligan TE, Zhi J. The effect of orlistat on the pharmacokinetics of phenytoin in healthy volunteers. *J Clin Pharmacol* (1996) 36, 654–8.

Phenytoin + Penicillins

An isolated case describes a marked reduction in serum phenytoin levels, resulting in seizures, which was attributed to the use of oxacillin.

Clinical evidence, mechanism, importance and management

An epileptic woman taking phenytoin 400 mg daily, hospitalised for second degree burns sustained during a generalised seizure, experienced brief clonic seizures and was found to have a marked reduction in her serum phenytoin levels, from 16.3 to 3.5 micrograms/mL, which was attributed to the concurrent use of oral **oxacillin** 500 mg every 6 hours. The phenytoin dose was increased, but seizures continued and progressed to status epilepticus, and intravenous phenytoin was given. Doses of oral phenytoin of about 600 mg daily were required to maintain minimum therapeutic levels, sometimes with supplementation of small intravenous doses. Just before the **oxacillin** was withdrawn the serum phenytoin level was 22.3 micrograms/mL, but 6 months later it had risen to 39.9 micrograms/mL, and the phenytoin dose was reduced.¹ Other studies have shown that penicillins such as **oxacillin**, **cloxacillin** and **dicloxacillin** can displace phenytoin from plasma protein binding, decreasing total serum levels but increasing the free fraction of phenytoin. If anything, this would be predicted to increase phenytoin toxicity.^{2,3} This seems to be only report of an adverse interaction between phenytoin and a penicillin. Its general importance is probably small.

Phenytoin + Pheneturide

Phenytoin serum levels can be increased by about 50% by pheneturide.

Clinical evidence, mechanism, importance and management

In 9 patients the steady-state half-life of phenytoin was prolonged from 32 to 47 hours by pheneturide. Mean serum levels were raised by about 50% but fell rapidly over the 2 weeks after pheneturide was withdrawn.¹ This study confirms a previous report of this interaction.² The reason for this interaction is uncertain, but since the two drugs have a similar structure it is possible that they compete for the same metabolising enzymes in the liver, thereby resulting, at least initially, in a reduction in the metabolism of the phenytoin. If concurrent use is undertaken the outcome should be well monitored. Reduce the phenytoin dosage as necessary.

2. Hulsman JW, van Heycop Ten Ham MW and van Zijl CHW. Influence of ethylphenacetamide on serum levels of other anticonvulsant drugs. *Epilepsia* (1970) 11, 207.

Phenytoin + Phenobarbital

The concurrent use of phenytoin and phenobarbital is normally advantageous and uneventful. Changes in serum phenytoin levels (often decreases but sometimes increases) can occur if phenobarbital is added, but seizure control is not usually affected. Phenytoin toxicity following phenobarbital withdrawal has been seen. Increased phenobarbital levels and possibly toxicity may result if phenytoin is given to patients taking phenobarbital.

Clinical evidence

A study in 10 epileptic patients taking phenytoin 2.8 to 6.8 mg/kg daily found that while taking phenobarbital 1.1 to 2.5 mg/kg daily their serum phenytoin levels were reduced. Five patients had a mean reduction of about 65%, from 15.7 to 5.7 micrograms/mL. In most cases phenytoin levels rose again when the phenobarbital was withdrawn. In one patient this was so rapid and steep that he developed ataxia and a cerebellar syndrome with phenytoin levels of up to 60 micrograms/mL, despite a reduction in the phenytoin dosage.¹

This reduction in phenytoin levels by phenobarbital has been described in other reports.^{2–7} However, some of these also described a very transient and small rise⁴ or no alteration^{4,5} in serum phenytoin levels in individual patients. Three other studies have found that phenobarbital does not alter phenytoin levels.^{8–10}

Elevated serum phenobarbital levels occurred in epileptic children when they were also given phenytoin. In 5 patients the phenobarbital levels were approximately doubled. In some cases mild ataxia was seen but the relatively high barbiturate levels were well tolerated.¹ A long-term study in 6 adult epileptics found that when phenytoin was added to phenobarbital, the level/dose ratio of the phenobarbital gradually rose by about 60% over one year, and then gradually fell again over the next 2 years.¹¹ This suggests that initially, phenytoin reduces phenobarbital metabolism. In another patient taking phenobarbital 100 mg and phenytoin 160 mg daily, serum levels of phenobarbital increased by about 53% within about 2 days when the dose of phenytoin was increased to 490 mg daily.¹²

Mechanism

Phenobarbital can have a dual effect on phenytoin metabolism: it may cause enzyme induction, which results in a more rapid clearance of the phenytoin from the body, or with large doses it may inhibit metabolism by competing for enzyme systems. The total effect will depend on the balance between the two drugs. The reason for the elevation of serum phenobarbital levels is not fully understood, but the extent may be dependent on the serum level of phenytoin.^{12,13}

Importance and management

Concurrent use can be therapeutically valuable. Changes in dosage or the addition or withdrawal of either drug need to be monitored to ensure that toxicity does not occur, or that seizure control is not worsened. The contradictory reports cited here do not provide a clear picture of what is likely to happen. Consider also 'Primidone + Phenytoin', p.570.

Phenytoin + Phenothiazines

The serum levels of phenytoin can be raised or lowered by the use of chlorpromazine, prochlorperazine or thioridazine. Phenytoin may reduce levels of the active metabolite of thioridazine.

Clinical evidence

(a) Chlorpromazine

The serum phenytoin levels of a patient taking phenytoin, primidone and sulthiame doubled after chlorpromazine 50 mg daily was taken for a month.¹ However, another 4 patients taking chlorpromazine 50 to 100 mg daily showed no interaction.¹ In another report, one out of 3 patients taking phenytoin and phenobarbital had a fall in their serum phenytoin levels when they were also given chlorpromazine.² A further very brief report states that in rare instances chlorpromazine has been noted to impair phenytoin metabolism.³

In a large study in patients taking phenytoin with various phenothiazines (chlorpromazine, **thioridazine** or **mesoridazine**), phenytoin levels were decreased by 44% when the phenothiazines were started, and by 33% when the phenothiazine dose was increased. A number of patients experienced an increased frequency of seizures. In patients who had these phenothiazines discontinued or the dosage *decreased*, the phenytoin levels increased by 55% and 71%, respectively, and toxic levels occurred in some patients.⁴

(b) Prochlorperazine

A single very brief report states that in rare instances prochlorperazine has been noted to impair phenytoin metabolism.³

(c) Thioridazine

One out of 6 patients taking phenytoin and phenobarbital had a marked rise in serum phenytoin levels when thioridazine was added, whereas 4 others had a fall in phenytoin levels.² Phenytoin toxicity has also been described in 2 patients after about 2 weeks of concurrent treatment with thioridazine.⁵ A retrospective study in 27 patients taking phenytoin found that when they were given thioridazine their serum phenytoin levels were increased by at least 4 micrograms/mL (4 patients), decreased by at least 4 micrograms/mL (2), or were unchanged (21).⁶ Another retrospective study comparing 28 patients taking both phenytoin and thioridazine with patients taking either drug alone found no evidence that thioridazine increased the risk of phenytoin toxicity.⁷ A further study found no changes in serum phenytoin or thioridazine levels in patients given both drugs, but serum levels of mesoridazine (the active metabolite of thioridazine) were reduced, suggesting higher doses of thioridazine may be necessary to achieve the same effect.⁸ See also the study⁴ in section (a), which found a decrease in phenytoin levels and an increase in seizure frequency when patients took phenothiazines including thioridazine.

Mechanism

Uncertain. Phenothiazines such as thioridazine are inhibitors of the cytochrome P450 isoenzyme CYP2D6, and as such would not be expected to affect phenytoin metabolism, at least by this mechanism.

Importance and management

A confusing situation as the results are inconsistent. The concurrent use of phenytoin and the phenothiazines cited need not be avoided, but it would be prudent to watch for any signs of changes in serum phenytoin levels that would affect antiepileptic control. It is also worth remembering that phenothiazines may decrease the seizure threshold. In one study a trend towards increased seizure frequency was noted after phenothiazines were added, or doses increased.⁴ Also note that phenytoin may reduce levels of some phenothiazines. Whether all phenothiazines interact similarly is uncertain.

Phenytoin + Proton pump inhibitors

A study in epileptic patients found that omeprazole 20 mg daily did not affect the serum levels of phenytoin, whereas earlier studies in healthy subjects suggested that phenytoin levels might be modestly raised by omeprazole 40 mg daily. A study with esomeprazole also suggests it may cause a minor rise in phenytoin levels. Lansoprazole does not normally affect phenytoin levels, but an isolated case report of toxicity is tentatively attributed to an interaction. Pantoprazole and rabeprazole appear not to interact.

Clinical evidence

(a) Esomeprazole

Esomeprazole inhibits the cytochrome P450 isoenzyme CYP2C19 so that the plasma levels of drugs metabolised by this enzyme might be expected to be increased by concurrent use. This is true for phenytoin, which the manufacturers say showed a 13% increase in trough plasma levels in patients given esomeprazole 40 mg.¹

(b) Lansoprazole

In a group of 12 healthy subjects lansoprazole 60 mg daily for 7 days caused only a very small and clinically irrelevant rise (less than 3%) in the AUC of a single intravenous dose of phenytoin.^{2,3} In contrast the manufacturer has received an isolated report of the development of blurred vision, diarrhoea, muscle pain, dizziness, abdominal pain, salivary hypersecretion, increased sweating and incoordination in a man taking phenytoin, which occurred within a day of stopping sustained-release propranolol 80 mg and starting lansoprazole.⁴ The phenytoin serum levels were not measured but the symptoms might possibly have been due to phenytoin toxicity, although it should be said that if an interaction with lansoprazole was responsible, it developed unusually quickly.

(c) Omeprazole

Omeprazole 20 mg daily for 3 weeks caused no changes in the mean steady-state serum phenytoin levels in 8 epileptic patients.⁵ Four patients had unchanged levels, 2 had falls and 2 had rises, but none of them was adversely affected by the omeprazole treatment.⁵

After taking omeprazole 40 mg daily for 7 days the AUC of a single 300-mg dose of phenytoin was increased by 25% in 10 healthy subjects.⁶ In another study the clearance of a 250-mg intravenous dose of phenytoin was reduced by 15% by omeprazole 40 mg given for 7 days.⁷ A further study found that 3 doses of omeprazole 40 mg had no effect on the pharmacokinetics of a single dose of phenytoin.⁸

(d) Pantoprazole

In a randomised, crossover study in 23 healthy subjects it was found that pantoprazole 40 mg daily for 7 days did not alter the pharmacokinetics (AUC, maximum serum levels, half-life) of a single 300-mg dose of phenytoin.⁹ This study has also been published elsewhere.¹⁰

(e) Rabeprazole

A preliminary report, which gives no details, states that when rabeprazole was used with phenytoin, no significant changes in the pharmacokinetics of phenytoin were seen.¹¹

Mechanism

Not understood. A possible explanation is that if the dosage of omeprazole is high enough, it may possibly reduce the metabolism of phenytoin by CYP2C19. However, CYP2C19 has only a minor role in phenytoin metabolism.¹² Esomeprazole may interact similarly. With lansoprazole, the overall picture is that it does not act as an enzyme inducer or inhibitor¹³

(or it is only very weak) so that it would not be expected to interact with phenytoin to a clinically relevant extent (confirmed by the study cited above²). The same appears to be true for pantoprazole and rabeprazole.

Importance and management

Information is very limited but it seems that omeprazole 20 mg daily does not affect serum phenytoin levels, whereas 40 mg daily may possibly cause a slight increase. No special precautions would normally seem necessary if lansoprazole or omeprazole is given with phenytoin, but until more is known it would be prudent to be aware of this possible interaction if concurrent use is necessary. Similarly, the manufacturers of esomeprazole suggest concurrent use should be monitored,¹ although the elevation in levels seen in the study would not usually be expected to be clinically significant. More study is needed. No special precautions would seem to be necessary if rabeprazole or pantoprazole and phenytoin are given concurrently.

Phenytoin + Shankhapushpi (SRC)

A case report, and an *animal* study, indicate that an antiepileptic Ayurvedic herbal preparation, *Shankhapushpi* (SRC), can markedly reduce plasma phenytoin levels, leading to an increased seizure frequency.

Clinical evidence

An epileptic man taking phenobarbital 120 mg daily and phenytoin 500 mg daily developed an increase in seizure frequency when *Shankhapushpi* (SRC) three times a day was given. His plasma phenytoin levels were found to have fallen from 18.2 to 9.3 micrograms/mL, whereas his phenobarbital levels were little changed. When the SRC was stopped the phenytoin plasma levels rose to 30.3 micrograms/mL, and toxicity was seen. A reduction in the dose of phenytoin to 400 mg daily resulted in levels of 16.2 micrograms/mL. Another possible case has also been reported.^{1,2}

Subsequent studies in *rats* found that SRC reduces the plasma levels of phenytoin by about half.³ These pharmacokinetic effects were only seen after multiple doses, not single doses of phenytoin. A pharmacodynamic interaction, resulting in reduced antiepileptic activity was also noted.^{1,3,4}

Mechanism

Not understood. There is evidence from *animal* studies that SRC may affect the pharmacokinetics of the phenytoin and possibly its pharmacodynamics as well,^{1,3} thereby reducing its antiepileptic activity. It is also suggested that one of the ingredients of SRC may have some antiepileptic activity.³

Importance and management

Information about this interaction appears to be limited to these reports. *Shankhapushpi* (SRC) is given because it has some antiepileptic activity (demonstrated in *animal* studies^{3,4}), but there is little point in combining it with phenytoin if the outcome is a fall in plasma phenytoin levels, accompanied by an increase in seizure frequency. For this reason concurrent use should be avoided. SRC is a syrup prepared from *Convolvulus pluricaulis* leaves, *Nardostachys jatamansi* rhizomes, *Onosma bracteatum* leaves and flowers and the whole plant of *Centella asiatica*, *Nepeta hindostana* and *Nepeta elliptica*.³ The first two of these plants appear to contain compounds with antiepileptic activity.⁵

It has been suggested that adulteration of traditional medicines with various antiepileptics^{6,7} may be an unexpected factor in these interactions.

Phenytoin + SSRIs

Phenytoin serum levels can be increased in some patients by fluoxetine and toxicity may occur. There are also isolated reports of phenytoin toxicity in patients taking fluvoxamine. Phenytoin and sertraline do not normally interact, but two patients have shown increased serum phenytoin levels. Sertraline and possibly paroxetine levels may be reduced by phenytoin. Note that SSRIs should be avoided in unstable epilepsy and used with care in other epileptics.

Clinical evidence

(a) Fluoxetine

A woman taking phenytoin 370 mg, diazepam 4 mg, and clonazepam 6 mg daily was given fluoxetine 20 mg for depression.¹ Five days later her serum phenytoin levels had risen from 18 to 26.5 mg/L, and a further 9 days later to 30 mg/L, accompanied by signs of toxicity (tremor, headache, abnormal thinking, increased partial seizure activity). Seven days after stopping the phenytoin the serum levels had fallen to 22 mg/L.

Two other patients, taking phenytoin 300 and 400 mg daily, respectively, had marked rises in serum phenytoin levels (from 15 to 35 micrograms/mL and from 11.5 to 47 micrograms/mL), accompanied by signs of phenytoin toxicity, within 5 to 10 days of starting fluoxetine 20 or 40 mg daily. The problem resolved when the fluoxetine was stopped or the phenytoin dosage reduced.² Another patient only developed this interaction after taking fluoxetine for about 9 months.³

A review initiated by the US Food and Drug Administration and the manufacturers of fluoxetine briefly describes another 23 anecdotal observations of suspected phenytoin/fluoxetine interactions (most of them incompletely documented). These suggest that a marked 1.5-fold increase in serum phenytoin levels, with accompanying toxicity, can occur within 1 to 42 days (mean onset time of 2 weeks) after starting fluoxetine.⁴ Another case describes raised phenytoin levels with improved efficacy when fluoxetine was started, and reduced levels and possible loss of efficacy when fluoxetine was stopped.⁵ Conversely, a retrospective review of 7 patients taking phenytoin and fluoxetine found no cases of an interaction.⁶

(b) Fluvoxamine

About one month after starting to take fluvoxamine 50 mg daily, a woman taking phenytoin 300 mg daily experienced ataxia and was found to have a threefold increase in her phenytoin levels (from 16.6 to 49.1 micrograms/mL). Fluvoxamine was subsequently discontinued, and the phenytoin dose reduced, with gradual recovery.⁷ Another report describes phenytoin toxicity (serum levels of 48 mg/L) in an 86-year-old woman after she took fluvoxamine 100 to 200 mg daily for 10 days.⁸

However the fluvoxamine was started only 2 days after the phenytoin, in a dose of 200 mg twice daily, had been started, and the serum phenytoin levels were not checked until the toxicity had actually developed. Both drugs were then stopped and the phenytoin later successfully reinstated without the fluvoxamine. A worldwide analysis of data up to 1995 by the manufacturers of fluvoxamine identified only 2 reported cases of interactions (clinical symptoms only) between phenytoin and fluvoxamine.⁹

(c) Paroxetine

In a group of epileptic patients, paroxetine 30 mg daily for 16 days caused no changes in the plasma levels or therapeutic effects of phenytoin. Steady-state paroxetine plasma levels were lower in those also taking phenytoin (16 nanograms/mL) than in those taking carbamazepine (27 nanograms/mL) or valproate (73 nanograms/mL).¹⁰

(d) Sertraline

A double-blind, randomised, placebo-controlled study in 30 healthy subjects taking phenytoin 100 mg three times daily, found that sertraline 50 to 200 mg daily did not affect the steady-state trough serum levels of phenytoin, nor was there any evidence that concurrent use impaired cognitive function.¹¹ However, another report describes 2 elderly patients whose serum phenytoin levels rose when they were given sertraline, but there was no evidence of toxicity. One of them had an almost fourfold rise in serum phenytoin levels whereas the other had a rise of only about one-third.¹²

In an analysis of plasma sertraline levels the concentration to daily dose ratio of sertraline was significantly lower in patients who had taken sertraline with phenytoin compared to those who had taken sertraline without phenytoin,¹³ which suggested that phenytoin increases sertraline metabolism.

Mechanism

An *in vitro* investigation found that fluoxetine and fluvoxamine inhibited the metabolism of phenytoin by the cytochrome P450 isoenzyme CYP2C9 in human liver tissue.¹⁴ This would presumably lead to a rise in serum phenytoin levels. In this study, sertraline was a weaker inhibitor of CYP2C9, and was considered less likely to interact with phenytoin.¹⁴ A similar study also suggested that the risk of interaction was greatest for fluoxetine, and less likely with sertraline and paroxetine.¹⁵ Sertraline plasma levels may be reduced because of enzyme induction by phenytoin which would increase its metabolism and clearance from the body.¹⁵

Importance and management

The interaction between phenytoin and fluoxetine appears to be established but its incidence is not known. Because of the unpredictable nature of this interaction, if fluoxetine is added to treatment with phenytoin in any patient be alert for the need to reduce the phenytoin dosage. Ideally the phenytoin serum levels should be monitored. Similarly, to be on the safe side phenytoin levels should be monitored when fluvoxamine is first added to treatment with phenytoin so that any patient affected can be quickly identified. Although an interaction with sertraline appears less likely, be alert for any evidence of an increase in phenytoin adverse effects (e.g. blurred vision, nystagmus, ataxia or drowsiness) if sertraline is given. More study of these interactions is needed. Note that SSRIs should be avoided in patients with unstable epilepsy, and those with controlled epilepsy should be carefully monitored, because of the potential increased seizure risk.

Phenytoin + Sucralfate

The absorption of single-dose phenytoin can be reduced by about 7 to 20% by sucralfate, but this effect was not seen in a multiple-dose study. The interaction is unlikely to be clinically relevant.

Clinical evidence

Sucralfate 1 g was found to reduce the absorption (measured over a 24-hour period) of a single 300-mg dose of phenytoin in 8 healthy subjects by 20%.¹ Peak serum phenytoin levels were also reduced, but this was not statistically significant. Another single-dose study found a reduction in phenytoin absorption of 7.7 to 9.5%.² However, sucralfate 1 g four times daily for 7 days had no effect on the steady-state levels of phenytoin 5 to 7 mg/kg daily in 6 healthy subjects. The fourth daily dose of sucralfate was taken simultaneously with the daily phenytoin dose at bedtime. After 7 days, all phenytoin levels were within 15% of the baseline values (range, 6% decrease to 15% increase).³

Mechanism

Uncertain. Reduced bioavailability has been demonstrated in a single-dose study in *dogs* when the drugs were used simultaneously, and this did not occur if the phenytoin was given 2 hours after the sucralfate.⁴

Importance and management

Information is limited. The reduction in absorption shown in single-dose studies was quite small, and was not seen in a multiple-dose study, suggesting it is unlikely to be clinically relevant.

Phenytoin + Sulfipyrazone

Some limited evidence indicates that phenytoin serum levels may be markedly increased by sulfipyrazone.

Clinical evidence

A review of the drug interactions of sulfipyrazone identified two studies that found interactions with phenytoin.¹ In the first, the serum phenytoin levels of 2 out of 5 patients taking phenytoin 250 to 350 mg daily were doubled from about 10 to 20 micrograms/mL within 11 days of starting to take sulfipyrazone 800 mg daily. One of the remaining patients had a small increase in phenytoin levels, but the other two had no changes at all. When the sulfipyrazone was withdrawn, the serum phenytoin concentrations fell to their former levels. The second study was a clinical study in epileptic patients that found that sulfipyrazone 800 mg daily for a week increased the phenytoin half-life from 10 to 16.5 hours and reduced the metabolic clearance from 59 to 32 mL/minute.

Mechanism

Uncertain. It seems probable that sulfipyrazone inhibits the metabolism of the phenytoin by the liver, thereby allowing it to accumulate in the body and leading to a rise in its serum levels. Displacement of phenytoin from its plasma protein binding sites may also have a small part to play.

Importance and management

Information seems to be limited to these studies, which await confirmation. A similar interaction with phenytoin has been reported with phenylbutazone, which has a very close chemical relationship with sulfinpyrazone (see 'Phenytoin + Aspirin or NSAIDs', p.551). Thus what is known suggests that concurrent use should be monitored and suitable phenytoin dosage reductions made where necessary.

Phenytoin + Sulfonamides and/or Trimethoprim

Phenytoin serum levels can be raised by co-trimoxazole, sulfamethizole, sulfamethoxazole, sulfadiazine and trimethoprim. Phenytoin toxicity may develop in some cases. A single case of liver failure has been described in a patient taking phenytoin with co-trimoxazole. Sulfamethoxy-pyridazine, and sulfafurazole (sulfisoxazole) are reported not to interact.

Clinical evidence

(a) Co-trimoxazole or Trimethoprim

A patient taking phenytoin 400 mg daily developed signs of toxicity (ataxia, nystagmus, loss of balance) within 2 weeks of starting to take co-trimoxazole 960 mg twice daily. His serum levels were found to have risen to about 38 micrograms/mL (normal range about 10 to 20 micrograms/mL).¹

A child who was stable taking phenytoin and sultiam developed phenytoin toxicity within 48 hours of starting co-trimoxazole. Toxicity resolved when the antibacterial was changed to amoxicillin.² A clinical study found that co-trimoxazole and trimethoprim can increase the phenytoin half-life by 39% and 51%, respectively, and decrease the mean metabolic clearance by 27% and 30%, respectively.³ Sulfamethoxazole alone had only a small effect on the half-life and did not affect the clearance of phenytoin.³ A case report describes fatal acute hepatic failure in a 60-year-old woman 10 days after starting co-trimoxazole and 14 days after starting phenytoin.⁴ This patient was also given cimetidine, which may raise phenytoin levels (see 'Phenytoin + H₂-receptor antagonists', p.559).

(b) Sulfadiazine

After taking sulfadiazine 4 g daily for a week, the half-life of a single intravenous dose of phenytoin was found to have increased by 80% in 8 patients. The mean metabolic clearance decreased by 45%.³

(c) Sulfamethizole

The development of phenytoin toxicity in a patient taking sulfamethizole prompted a study of this interaction in 8 patients given phenytoin. After the concurrent use of sulfamethizole 1 g four times daily for 7 days the phenytoin half-life had lengthened from 11.8 to 19.6 hours. Of the 4 patients receiving long-term treatment with phenytoin, 3 had rises in serum phenytoin levels from 22 to 33 micrograms/mL, from 19 to 23 micrograms/mL and from 4 to 7 micrograms/mL respectively. The phenytoin levels of the fourth patient were not affected.^{5,6} Another single-dose study found that the half-life of phenytoin was increased and the mean metabolic clearance reduced by 36%.³

(d) Other sulfonamides

Pretreatment for one week with **sulfamethoxy-pyridazine** or **sulfadimethoxine** did not significantly alter the pharmacokinetics of a single dose of phenytoin.³

Mechanism

The sulfonamides that interact appear to do so by inhibiting the metabolism of the phenytoin by the liver (possibly by the cytochrome P450 isoenzyme CYP2C9),⁷ resulting in its accumulation in the body. This would

also seem to be true for trimethoprim. Depletion of glucuronic acid by phenytoin may have increased the hepatotoxicity of co-trimoxazole.⁴

Importance and management

The documentation seems to be limited to the reports cited, but the interaction is established. Co-trimoxazole, sulfamethizole, sulfadiazine and trimethoprim can increase serum phenytoin levels. The interaction probably occurs in most patients, but the small number of adverse reaction reports suggests that the risk of toxicity is small. It is clearly most likely in those with serum phenytoin levels at the top end of the range. If concurrent use is thought appropriate, the serum phenytoin levels should be closely monitored and the phenytoin dosage reduced if necessary. Alternatively, if appropriate, use a non-interacting antibacterial (in some circumstances 'penicillins', (p.562), or 'macrolides', (p.560), may be appropriate). There seems to be no information about other sulfonamides but it would be prudent to be alert for this interaction with any of them.

Phenytoin + Sultiam

Serum phenytoin levels can be approximately doubled by sultiam and phenytoin toxicity may occur.

Clinical evidence

The serum phenytoin levels in 6 out of 7 epileptic patients approximately doubled within about 5 to 25 days of starting to take sultiam 400 mg daily. All experienced an increase in adverse effects and definite phenytoin toxicity occurred in 2 of them. In most of the patients, phenytoin serum levels fell back to baseline over the 2 months following the withdrawal of sultiam.¹ All of the patients were also taking **phenobarbital** and although greater variations in serum **phenobarbital** were seen, they were not considered to be clinically significant.¹

A number of other reports confirm this interaction,^{2–8} some of which describe the development of phenytoin toxicity.

Mechanism

The evidence suggests that sultiam interferes with the metabolism of the phenytoin by the liver, leading to its accumulation in the body.

Importance and management

A reasonably well-documented, established and clinically important interaction. The incidence seems to be high. If sultiam is added to established treatment with phenytoin, increases in serum phenytoin levels of up to 75% or more may be expected.^{3,7} Phenytoin serum levels should be closely monitored and appropriate dosage reductions made to prevent the development of toxicity. The changes in phenobarbital levels appear to be unimportant.

Phenytoin + Tamoxifen

Some preliminary evidence suggests that high-dose tamoxifen can cause the serum levels of phenytoin to rise, causing toxicity. Phenytoin may lower tamoxifen levels.

Clinical evidence, mechanism, importance and management

A man who had undergone an operation 10 years previously for a brain tumour and had since remained seizure-free while taking phenytoin 200 mg twice daily began to have breakthrough seizures. It was established that his brain tumour had recurred and so tamoxifen was started as experimental treatment. The dose of tamoxifen was slowly titrated to 200 mg daily over a 6-week period. He continued to receive phenytoin and was also given carbamazepine as his seizures were not controlled, but when the maximum dosage of tamoxifen (200 mg daily) was reached he began to develop symptoms of phenytoin toxicity with a serum level of 28 micrograms/mL. The toxicity disappeared and the phenytoin levels decreased when the phenytoin dosage was reduced. The carbamazepine serum levels remained unchanged throughout.¹

The authors of this report say that other patients of theirs similarly treated with tamoxifen also developed phenytoin toxicity, which disappeared when the phenytoin dosage was reduced by 15 to 20%. Another study of the pharmacokinetics of high dose tamoxifen in patients with brain tumours found that the mean tamoxifen levels in 15 patients taking phenytoin were about 60% lower than in patients not taking phenytoin, although this did not reach statistical significance due to high inter-patient variability.² The reasons for these possible interactions are not known, but it could be that tamoxifen and phenytoin both compete for the same metabolising enzymes.

The evidence for this interaction is very slim indeed and it may possibly only occur with high dose tamoxifen. Consider monitoring phenytoin levels if high-dose tamoxifen is added and monitor the efficacy of the tamoxifen. More study is needed.

Phenytoin + Terfenadine

A 1-day and a 2-week course of terfenadine 60 mg twice daily had no effect on the pharmacokinetics of phenytoin in 12 patients with epilepsy.¹ No special precautions are needed if both drugs are used.

- Coniglio AA, Garnett WR, Pellock JH, Tsidonis O, Hepler CD, Serafin R, Small RE, Driscoll SM, Karnes HT. Effect of acute and chronic terfenadine on free and total serum phenytoin concentrations in epileptic patients. *Epilepsia* (1989) 30, 611–16.

Phenytoin + Ticlopidine

Ticlopidine reduces the metabolism of phenytoin. A number of case reports describe patients who developed phenytoin toxicity when ticlopidine was added.

Clinical evidence

A 65-year-old man taking phenytoin 200 mg daily and clobazam developed signs of phenytoin toxicity (vertigo, ataxia, somnolence) within a week of starting ticlopidine 250 mg daily. His serum phenytoin levels had risen from 18 mg/L to 34 mg/L. When the phenytoin dosage was reduced to 200 mg daily the toxic symptoms disappeared within a few days and his serum phenytoin levels fell to 18 mg/L. To test whether an interaction had occurred, the ticlopidine was stopped, whereupon the serum phenytoin levels fell, within about 3 weeks, to 8 mg/L, during which time the patient

experienced his first seizure in 2 years. When the ticlopidine was restarted, his serum phenytoin levels rose again, within a month, to 19 mg/L.¹ A number of other case reports describe phenytoin toxicity, which occurred within 2 to 6 weeks of starting ticlopidine 250 mg once or twice daily.^{2–7} These were usually managed by reducing the phenytoin dose. One patient then experienced breakthrough seizures after the ticlopidine was stopped without re-adjusting the phenytoin dose.⁶ One case in a patient also taking phenobarbital reported that no change in phenobarbital levels occurred.⁴

A study in 6 patients taking phenytoin alone found that ticlopidine 250 mg twice daily approximately halved the steady-state phenytoin clearance.⁸

Mechanism

The metabolism of phenytoin to 5-(4-hydroxyphenyl)-5-phenylhydantoin (HPPH) by the cytochrome P450 isoenzyme CYP2C19, and to a lesser extent by CYP2C9, in the liver is inhibited by ticlopidine.^{1,3,4,9} Further metabolism of HPPH to dihydroxylated products is mediated mainly by CYP2C19 and this may also be inhibited by ticlopidine.⁹

Importance and management

The interaction is established and clinically important, but its incidence is unknown. It would now be prudent to monitor serum phenytoin levels very closely in any patient if ticlopidine is added to established treatment, being alert for the need to reduce the phenytoin dosage. If ticlopidine is discontinued, the phenytoin dose may need to be increased.

Phenytoin + Tizanidine

An isolated report describes a modest increase in serum phenytoin levels caused by tizanidine.

Clinical evidence, mechanism, importance and management

An isolated report describes a 59-year-old man whose phenytoin levels rose by one-third, from about 19 to 25.5 micrograms/mL, and who experienced drowsiness within a week of starting tizanidine 6 mg daily. The phenytoin was stopped for 3 days and restarted at a reduced dose, but the drowsiness recurred in 3 weeks (phenytoin level 20.5 micrograms/mL). Therefore, the tizanidine was withdrawn.¹ The general importance of this interaction is unclear, but it would seem prudent to remain aware of this interaction in case of an unusual response to treatment.

- Ueno K, Miyai K, Mitsuzane K. Phenytoin-tizanidine interaction. *DICP Ann Pharmacother* (1991) 25, 1273.

Phenytoin + Trazodone

An isolated case report describes phenytoin toxicity in a patient given trazodone.

Clinical evidence, mechanism, importance and management

A patient taking phenytoin 300 mg daily developed progressive signs of phenytoin toxicity after taking trazodone 500 mg daily for 4 months. His serum phenytoin levels had risen from 17.8 to 46 micrograms/mL.¹ Therapeutic phenytoin serum levels were restored by reducing the phenytoin dosage to 200 mg daily and the trazodone dosage to 400 mg daily. The

reasons for this apparent interaction are not understood, and this appears to be the only reported case of an interaction. No general conclusions can be drawn.

1. Dorn JM. A case of phenytoin toxicity possibly precipitated by trazodone. *J Clin Psychiatry* (1986) 47, 89–90.

Phenytoin + Tricyclic antidepressants

Evidence from two patients suggests that imipramine can raise serum phenytoin levels but nortriptyline and amitriptyline appear not to do so. Phenytoin possibly reduces serum desipramine levels. Note that the tricyclics also lower the convulsive threshold.

Clinical evidence

(a) Phenytoin levels

The serum phenytoin levels of 2 patients rose over a 3-month period when they were given **imipramine** 75 mg daily. One of them had an increase in phenytoin levels from about 7.6 to 15 micrograms/mL and developed mild toxicity (drowsiness and uncoordination). These signs disappeared and the phenytoin serum levels of both patients fell when the **imipramine** was withdrawn. One of them was also taking nitrazepam and clonazepam, and the other sodium valproate and carbamazepine, but were stable on these combinations before the addition of **imipramine**.¹

Other studies have shown that **nortriptyline** 75 mg daily had an insignificant effect on the serum phenytoin levels of 5 patients,² and that **amitriptyline** had no effect on the elimination of phenytoin in 3 subjects.³

(b) Tricyclic antidepressant levels

A report describes 2 patients who had low serum **desipramine** levels, despite taking standard dosages, while they were also taking phenytoin.⁴

Mechanism

One suggestion is that imipramine inhibits the metabolism of the phenytoin by the liver, which results in its accumulation in the body. *In vitro* study⁵ has shown that the tricyclics can inhibit the cytochrome P450 isoenzyme CYP2C19, but this isoenzyme usually has only a minor role in phenytoin metabolism (see 'Antiepileptics', (p.517)). The reduced desipramine levels may be a result of enzyme induction by the phenytoin.

Importance and management

The documentation is very limited indeed and none of these interactions is adequately established. The results of the *in vitro* study suggest that the interaction may only assume importance in those who are deficient in CYP2C9, the enzyme usually responsible for phenytoin metabolism.⁵ The tricyclic antidepressants as a group lower the seizure threshold,⁶ which suggests extra care should be taken if deciding to use them in epileptic patients. If concurrent use is undertaken the effects should be very well monitored.

Phenytoin + Valproate

The concurrent use of phenytoin and valproate is common and usually uneventful. Initially total serum phenytoin levels may fall but this is offset by a rise in the levels of free (and active) phenytoin, which may very occasionally cause some toxicity. After continued use the total serum phenytoin levels rise once again, and there might be sustained increases in free phenytoin levels. There is also some very limited evidence to suggest that concurrent use possibly increases the incidence of valproate hepatotoxicity.

Clinical evidence

(a) Phenytoin levels

A number of reports clearly show that total serum levels of phenytoin fall during the early concurrent use of valproate, while the concentrations of free phenytoin rise.^{1–5} In one report it was noted that within 4 to 7 days the total serum phenytoin levels had fallen from 19.4 to 14.6 micrograms/mL.¹ A study extending over a year in 8 patients taking phenytoin and valproate found that by the end of 8 weeks the total serum phenytoin levels of 6 of them had fallen by almost as much as 50%, but had returned to their original levels in all but one patient by the end of the year.⁶ Similar results were found in another study.⁷ However, in a further study, some patients had a sustained increase in the free fraction of phenytoin.⁴ Another regression analysis showed that valproate increased the free fraction of phenytoin.⁸ The occasional patient may have symptoms of phenytoin toxicity and the dosage may need to be reduced.⁹ Delirium and an increased seizure frequency were seen in one patient taking valproic acid with phenytoin.¹⁰

(b) Valproate levels

Valproate levels are reduced by the presence of phenytoin.^{11,12} Valproate levels increased by 30 to 200% when phenytoin was discontinued in 12 patients taking both drugs, which allowed dosage reductions in 6 patients. In these patients, there was no change in seizure control when phenytoin was stopped.¹³

(c) Hepatotoxicity

Epidemiological studies suggest that the risk of fatal hepatotoxicity is higher when valproate is given as polytherapy with enzyme inducers such as phenytoin than when it is given as monotherapy, especially in infants.^{14,15} For mention of raised liver enzymes with concurrent use of valproate, phenobarbital and phenytoin, see 'Phenobarbital + Valproate', p.547.

Mechanism

The initial fall in total serum phenytoin levels appears to result from the displacement of phenytoin from its protein binding sites by valproate,^{1–5,10} the extent being subject to the diurnal variation in valproate levels.¹⁶ This allows more of the unbound drug to be exposed to metabolism by the liver and the total phenytoin levels fall. After several weeks the metabolism of the phenytoin is inhibited by the valproate and phenytoin levels rise.^{2,4} This may result in sustained elevation of free (active) phenytoin levels.¹⁷ Phenytoin reduces valproate levels, probably because it increases its metabolism by the liver. Because phenytoin is an enzyme inducer it may also possibly increase the formation of a minor but hepatotoxic metabolite of valproate (2-propyl-4-pentenoic acid or 4-ene-VPA).¹⁸

Importance and management

An extremely well-documented interaction (only a selection of the references being listed here). Concurrent use is common and usually advantageous, the adverse effects of the interactions between the drugs usually being of only minor practical importance. However, the outcome should still be monitored. A few patients may experience mild toxicity if valproate is started, but most patients taking phenytoin do not need a dosage change. During the first few weeks total serum phenytoin levels may fall by 20 to 50%, but usually no increase in the dosage is needed, because it is balanced by an increase in the levels of free (active) phenytoin levels. In the following period, the total phenytoin levels may rise again. This may result in a sustained rise in free phenytoin levels.

When monitoring concurrent use it is important to understand fully the implications of changes in 'total' and 'free' or 'unbound' serum phenytoin concentrations. Where monitoring of free phenytoin levels is not available, various nomograms have been designed for predicting unbound phenytoin concentrations during the use of valproate.^{17,19} Bear in mind the evidence that the incidence of valproate induced liver toxicity may be increased, especially in infants.

Phenytoin + Vigabatrin

Vigabatrin causes a small to moderate fall in serum phenytoin levels.

Clinical evidence

In one early clinical study, the mean plasma phenytoin levels in 19 patients were about 30% lower when they were given vigabatrin 2 to 3 g daily: in 2 patients they fell below the therapeutic range. However, the change in phenytoin levels was not correlated with the change in seizure frequency.¹ Another clinical study found that vigabatrin reduced the mean serum phenytoin levels by 20% in 53 patients; 41 patients had a decrease in phenytoin levels and 12 had an increase. In this study, some of the patients (number not stated) with decreased phenytoin levels had an increase in seizure frequency and required a phenytoin dosage increase.^{2,3} In another analysis, the decrease in phenytoin levels did not occur until the fifth week of vigabatrin therapy.⁴ Three other studies have shown roughly similar decreases in phenytoin levels when vigabatrin was added.^{5–7}

Mechanism

Not understood. The decrease in phenytoin levels does not appear to be due to reduced metabolism or altered plasma protein binding.⁴ Similarly, it is not due to altered bioavailability, since the interaction occurred with intravenous phenytoin.⁵

Importance and management

The interaction between phenytoin and vigabatrin would appear to be established. Vigabatrin causes a modest decrease in phenytoin levels in some patients, which takes a number of weeks to become apparent. A small increase in the dosage of phenytoin may possibly be needed in some patients.

Phenytoin + Viloxazine

Viloxazine can cause a marked rise in serum carbamazepine levels and toxicity has been seen. Viloxazine can also raise serum phenytoin to toxic levels, but appears not to alter oxcarbazepine levels.

Clinical evidence

The serum phenytoin levels of 10 epileptic patients rose by 37%, from 18.8 to 25.7 micrograms/mL over the 3 weeks following the addition of viloxazine 150 to 300 mg daily. The rise ranged from 7 to 94%. Signs of toxicity (ataxia, nystagmus) developed in 4 of the patients 12 to 16 days after starting the viloxazine. Their serum phenytoin levels had risen to between 32.3 and 41 micrograms/mL.¹ When viloxazine was withdrawn the symptoms disappeared and phenytoin levels fell.¹ The pharmacokinetics of viloxazine were unaffected by phenytoin.²

Mechanism

Uncertain. What is known suggests that viloxazine inhibits the metabolism of phenytoin, thereby reducing its clearance and raising its serum levels.

Importance and management

Information seems to be limited to the reports cited. If concurrent use is undertaken, serum phenytoin levels should be monitored closely and suitable dosage reductions made as necessary to avoid possible toxicity.

Phenytoin + Zidovudine

Although one study found that zidovudine did not alter the pharmacokinetics of phenytoin, there is other evidence suggesting that some changes possibly occur, although these may actually be due to HIV infection.

Clinical evidence, mechanism, importance and management

Although there are said to have been 13 cases of a possible interaction between zidovudine and phenytoin, the details are not described in the report.¹ No significant changes in the pharmacokinetics of phenytoin 300 mg daily were seen in 12 asymptomatic HIV-positive patients who were taking zidovudine 200 mg every 4 hours.¹ Another study found that the mean phenytoin dose was higher in HIV-positive patients, when compared to epileptic subjects without the virus, while the mean phenytoin levels in the HIV-positive group were lower (i.e. a higher phenytoin dose resulted in lower serum levels in HIV-positive subjects). Zidovudine did not appear to affect the levels.^{2,3} The current evidence would suggest that it is HIV infection, rather than zidovudine that affects phenytoin levels, but more study is needed to confirm this.

Phenytoin + Zileuton

The pharmacokinetics of phenytoin are unchanged by zileuton.

Clinical evidence, mechanism, importance and management

A controlled study in 20 healthy subjects found that the pharmacokinetics of a single 300-mg dose of phenytoin were unaltered by zileuton 600 mg every 6 hours for 5 days.¹ An *in vitro* study found that zileuton had little effect on the isoenzymes responsible for the metabolism of phenytoin.² These studies suggest that zileuton is unlikely to affect phenytoin levels in clinical use.

Piracetam + Other antiepileptics

Piracetam does not appear to alter the levels of sodium valproate or primidone. No interaction has been found between piracetam and carbamazepine, clonazepam, phenobarbital, or phenytoin.

Clinical evidence, mechanism, importance and management

The addition of piracetam (2 to 4 g three times daily, increased to a maximum of 18 to 24 g daily) did not affect plasma levels of **sodium valproate** or **primidone** in patients with myoclonus. The exact number of patients taking these drugs is unclear, since the report just states that 28 patients were taking **clonazepam**, **sodium valproate**, or **primidone**, alone or in combination.¹ Another similar report, briefly noted the same finding.² The manufacturer notes that, although based on a small number of patients, no interaction has been found between piracetam and **clonazepam**, **carbamazepine**, **phenytoin**, **phenobarbital** and **sodium valproate**.³ No special precautions appear to be required if piracetam is used with these antiepileptics.

Pregabalin + Miscellaneous

There appears to be no pharmacokinetic interaction between pregabalin and carbamazepine, gabapentin, lamotrigine, phenobarbital, phenytoin, topiramate, valproate, alcohol, lorazepam, or oxycodone. However, the impairment of cognitive and gross motor function caused by oxycodone was additive with pregabalin, and pregabalin may potentiate the effects of alcohol and lorazepam.

Clinical evidence, mechanism, importance and management

(a) Alcohol or Lorazepam

The manufacturer notes that there was no clinically relevant pharmacokinetic interaction between pregabalin and lorazepam or alcohol, and that concurrent use caused no clinically important effect on respiration. However, they note that pregabalin may potentiate the effects of lorazepam and alcohol.¹

(b) Other antiepileptics

Pregabalin 200 mg three times daily for 7 days was added to monotherapy with various antiepileptics in patients with partial epilepsy. Pregabalin did not alter the steady-state levels of **phenytoin**, **carbamazepine** (and its active metabolite, carbamazepine-10,11-epoxide), **valproate** or **lamotrigine**. In addition, the steady-state pharmacokinetics of pregabalin were not different to those seen previously in healthy subjects taking pregabalin alone, suggesting that these antiepileptics do not alter pregabalin pharmacokinetics.² Similarly, population pharmacokinetic analyses of clinical studies found no important changes in the pharmacokinetics of **lamotrig-**

ine, **phenobarbital**, **phenytoin**, **topiramate** or **valproate** when they were given with pregabalin, and the pharmacokinetics of pregabalin were unaffected by these drugs.³ The manufacturer also notes that there is no pharmacokinetic interaction between pregabalin and **gabapentin**.¹

(c) Oxycodone

The manufacturer notes that there was no clinically relevant pharmacokinetic interaction between pregabalin and oxycodone, and that there was no clinically important effect on respiration. However, pregabalin appeared to cause an additive impairment in cognitive and gross motor function when given with oxycodone.¹ This suggests caution is warranted during combined use.

Primidone + Isoniazid

A single case report describes elevated serum primidone levels and reduced phenobarbital levels when primidone was given with isoniazid.

Clinical evidence, mechanism, importance and management

A patient taking primidone had raised serum primidone levels and reduced serum phenobarbital levels. This was attributed to the concurrent use of isoniazid, which inhibited the metabolism of the primidone by the liver. The half-life of primidone rose from 8.7 to 14 hours while taking isoniazid and steady-state primidone levels rose by 83%.¹ The importance of this interaction is uncertain but prescribers should bear this interaction in mind in case of an unexpected response to primidone.

1. Sutton G, Kupferberg HJ. Isoniazid as an inhibitor of primidone metabolism. *Neurology* (1975) 25, 1179–81.

Primidone + Miscellaneous

Primidone is substantially converted to phenobarbital within the body and it is therefore expected to interact with other drugs in the same way as phenobarbital. Some drugs may increase the conversion of primidone to phenobarbital.

Clinical evidence, mechanism, importance and management

Primidone is substantially converted to phenobarbital within the body. For example, a group of patients taking long-term primidone developed serum primidone levels of 9 micrograms/mL and serum phenobarbital levels of 31 micrograms/mL.¹ Primidone would therefore be expected to interact with other drugs in the same way as phenobarbital. Some enzyme-inducing drugs might increase the conversion of primidone to phenobarbital, and this has been demonstrated for ‘phenytoin’, below, and ‘carbamazepine’, (p.534). Some patients have been treated with a combination of phenobarbital and primidone. In this situation higher phenobarbital levels might be expected.

1. Booker HE, Hosokawa K, Burdette RD, Darcey B. A clinical study of serum primidone levels. *Epilepsia* (1970) 11, 395–402.

Primidone + Phenytoin

Primidone-derived serum phenobarbital levels are increased by phenytoin. This is normally an advantageous interaction, but phenobarbital toxicity occasionally occurs.

Clinical evidence

A study in 44 epileptic patients taking primidone and phenytoin found that their serum phenobarbital to primidone ratio was high (4.35) when compared with that in 15 other patients who were only taking primidone

(1.05).¹ This suggests that in the presence of phenytoin, primidone-derived phenobarbital levels are higher than when primidone is given alone. Similar results are described in other studies.²⁻⁷ A few patients may develop barbiturate toxicity.⁸

An initial marked decrease in phenytoin levels, then an increase to half the initial phenytoin level, was seen in the first few weeks after withdrawing primidone in an infant. Derived phenobarbital levels before discontinuing the primidone were very high, and were associated with marked sedation.⁹

Mechanism

Phenytoin increases the metabolic conversion of primidone to phenobarbital, while possibly depressing the subsequent metabolic destruction (hydroxylation) of the phenobarbital. The net effect is a rise in phenobarbital levels.¹⁰ Phenobarbital may increase or decrease phenytoin levels, see 'Phenytoin + Phenobarbital', p.562.

Importance and management

Well documented. This is normally an advantageous interaction since phenobarbital is itself an active antiepileptic. However, it should be borne in mind that phenobarbital serum levels could sometimes reach toxic concentrations,⁸ even if only a small dose of phenytoin is added. Changes in phenytoin levels may also occur (see 'Phenytoin + Phenobarbital', p.562).

Primidone + Valproate

Valproate has been reported to cause increases, decreases, and no change in serum primidone levels. Primidone-derived phenobarbital levels appear to be increased by valproate.

Clinical evidence

In a number of cases, patients taking primidone required a decrease in the primidone dosage after valproate was added.¹⁻⁴ In 6 cases this was due to an increase in the primidone-derived phenobarbital level,¹ and in the other cases phenobarbital levels were not measured, but the dosage reduction was needed to overcome the sedation that occurred when the valproate was added.²⁻⁴ Primidone levels were not measured in any of these cases.¹⁻⁴ In two other studies, primidone levels either decreased,⁵ or did not change when valproate was added.⁶ However, phenobarbital levels, where measured, had increased.⁶

In 7 children the serum levels of primidone 10 to 18 mg/kg daily rose two to threefold when valproate (dosage not stated) was also given. After 1 to 3 months of continued therapy the serum primidone levels fell in 3 of the patients but persisted in one. Follow-up primidone levels were not taken in the other 3 patients, and no patient had phenobarbital levels measured.⁷

In contrast, in a further study, neither phenobarbital levels nor primidone levels were significantly altered when valproate was given.⁸

Mechanism

It has been suggested that valproate decreases the conversion of primidone to phenobarbital, and decreases the metabolism of phenobarbital (see also 'Phenobarbital + Valproate', p.547). This would result in increased prim-

idone and phenobarbital levels. However, increased renal clearance of primidone may occur, resulting in no overall change to the primidone levels. Depending on the balance between these various effects a variety of levels may result.⁸ The results of one study suggest that this proposed inhibition of primidone metabolism caused by valproate may diminish over the first few months of concurrent use.⁷

Importance and management

There seems to be little consistency about the effect of valproate on primidone levels. However, in the majority of cases phenobarbital levels seem to be raised (see also 'Phenobarbital + Valproate', p.547). It would seem prudent not to measure primidone levels without corresponding phenobarbital levels. Monitor the patient for increased signs of sedation, which may be resolved by a reduction in the primidone dose.

Progabide + Other antiepileptics

Progabide may raise phenytoin levels and alter the serum levels of carbamazepine, clonazepam, phenobarbital. The effect of these antiepileptics on progabide levels appears to be only moderate or small.

Clinical evidence

(a) Phenytoin

Marked increases in serum phenytoin levels have been seen in a few patients also given progabide,¹⁻⁴ while smaller changes have been described in some studies,^{5,6} and negligible changes in others.⁷

In one study, 17 out of 26 epileptics needed a reduction in their phenytoin dosage to keep the levels within 25% of the serum levels achieved in the absence of progabide. Over half the patients needed a dose reduction within 4 weeks of starting concurrent treatment. Most of those needing a dosage reduction had a maximum increase in the serum level of 40% or more, which was sometimes accompanied by toxicity.^{2,8} In a later report of this study, of a total of 32 epileptic patients taking carbamazepine with phenytoin and then given progabide, 22 needed a reduction in phenytoin dosage to maintain serum levels within 25% of those achieved in the absence of progabide. In addition, it appeared this effect on phenytoin serum levels continued for a while after progabide was withdrawn.⁴

(b) Other antiepileptics

Information about antiepileptics other than phenytoin is limited, but progabide is reported to minimally reduce,^{1,9,10} minimally increase¹ or not to change **carbamazepine**^{2,3,5-7} serum levels. An increase of up to 24% in the levels of carbamazepine-10,11-epoxide (the active metabolite of **carbamazepine**) has also been reported.^{6,10} **Valproate**,^{3,5-7} and **clonazepam**¹¹ serum levels were not significantly affected by progabide. Progabide appears to cause a small increase in serum **phenobarbital** levels, which is of little clinical importance.^{1,5-7}

Mechanism

Uncertain.

Importance and management

Some small to moderate changes in the serum levels of carbamazepine, phenobarbital, valproate and clonazepam can apparently occur in the presence of progabide, but only the interaction with phenytoin appears to be

clinically relevant. Be alert for the need to reduce the dosage of phenytoin if progabide is used concurrently. The slight effects of the antiepileptics on progabide levels are of unknown, but probably minor, significance.

Remacemide + Other antiepileptics

Remacemide causes modest increases in carbamazepine and phenytoin serum levels. Carbamazepine, phenobarbital and phenytoin moderately reduce remacemide serum levels. Valproate and lamotrigine do not appear to interact with remacemide.

Clinical evidence

(a) Carbamazepine

When a group of 10 patients taking carbamazepine were also given up to 300 mg of remacemide twice daily for 2 weeks the minimum serum levels and AUC of carbamazepine were increased by 20% and 22%, respectively. No patients had symptoms of carbamazepine toxicity.¹ Another study of 11 patients taking carbamazepine found that remacemide caused a similar 20 to 30% increase in the AUC of carbamazepine, again without signs of toxicity. No consistent changes in the AUC of carbamazepine-10,11-epoxide, the main metabolite of carbamazepine, were seen.² Another study has reported a slight inhibitory effect of remacemide on carbamazepine metabolism, which is in line with these other findings.³ One of these studies also reported that the AUC of remacemide was decreased by 40 to 50% and the AUC of its main metabolite by about 70% in the presence of carbamazepine, when compared with healthy subjects (presumably not taking carbamazepine).²

However, a further study of the efficacy of remacemide and carbamazepine in combination found that about two-thirds of the 120 patients treated needed 14 to 50% reductions in their carbamazepine dose, to ensure levels remained in the therapeutic range.⁴

(b) Lamotrigine

There was no clinically relevant pharmacokinetic interaction between remacemide (200 mg daily increased to 200 mg three times daily) and lamotrigine (200 mg twice daily decreased to 100 mg daily) in healthy subjects.⁵

(c) Phenobarbital

Phenobarbital 30 mg daily increased to 90 mg daily increased the clearance of remacemide 200 mg twice daily by 67%, and slightly increased the plasma levels of phenobarbital (by 9%) in a study in healthy subjects.⁶

(d) Phenytoin

A group of 10 patients taking phenytoin were also given up to 300 mg remacemide twice daily for 2 weeks. On average remacemide did not affect phenytoin pharmacokinetics but 5 patients had an increase in mini-

um serum levels of 30% or more. No patients had symptoms of phenytoin toxicity.¹ In another study 10 epileptics, who had been taking phenytoin for at least 3 months, were given remacemide 300 mg twice daily for 12 days. Phenytoin maximum plasma levels were increased by 13.7% and the AUC was raised by 11.5%. Average concentrations of remacemide and its main metabolite were around only 40% and 30%, respectively, of those achieved in healthy subjects taking remacemide alone, at the same dosage.⁷ Another study reported a slight inhibitory effect of remacemide on phenytoin metabolism, which is in line with these other findings.³

(e) Sodium valproate

A group of 10 patients taking valproate were also given remacemide up to 300 mg twice daily for 14 days. The pharmacokinetics of valproate remained unchanged.¹ Another study in 17 patients confirmed these findings,⁸ and an earlier study by the same authors also noted no effect of remacemide on valproate metabolism.³

Mechanism

Not fully understood, but *in vitro* studies indicate that remacemide inhibits the cytochrome P450 isoenzyme CYP3A4, which in practice would be expected to result in a reduction in the metabolism of the carbamazepine resulting in an increase in its serum levels. Remacemide appears to inhibit CYP2C9 to a lesser extent, which is reflected in a smaller interaction with phenytoin. Valproate is metabolised by glucuronidation and is therefore unaffected.¹

Carbamazepine and phenytoin, known enzyme inducers, also seem to increase the metabolism of the remacemide.⁷

Importance and management

Information is limited, but the interactions of remacemide with carbamazepine, phenobarbital and phenytoin appear to be established, but so far only the carbamazepine interaction seems to have been shown to be of clinical importance. Even so, until more experience has been gained, monitor the effects of concurrent use with phenytoin or phenobarbital. No interaction occurs between remacemide and valproate or lamotrigine.

Retigabine + Other antiepileptics

The clearance of retigabine is increased by carbamazepine and phenytoin, but not by phenobarbital, topiramate, or valproate. Retigabine does not alter the pharmacokinetics of any of these antiepileptics. There is a modest pharmacokinetic interaction between retigabine and lamotrigine.

Clinical evidence, mechanism, importance and management

(a) Enzyme-inducing antiepileptics

The preliminary report of a study notes that the clearance of retigabine was increased (amount not stated) by **carbamazepine** and **phenytoin**, whereas retigabine did not alter **carbamazepine** or **phenytoin** pharmacokinetics in patients with epilepsy.¹ This is consistent with the known enzyme-inducing properties of **carbamazepine** and **phenytoin**, and the fact that retigabine has not been shown to induce hepatic enzymes. In contrast, in a study in healthy subjects, **phenobarbital** 90 mg daily did not affect the pharmacokinetics of retigabine 200 mg every 8 hours, and the pharmacokinetics

of **phenobarbital** were not altered by retigabine.² The clinical relevance of the effect of **carbamazepine** and **phenytoin** on retigabine remains to be assessed. No dosage adjustments seem to be necessary with **phenobarbital**.

(b) Lamotrigine

In a study in 14 healthy subjects lamotrigine 25 mg daily for 5 days increased the AUC of a single 200-mg dose of retigabine by 15% and decreased the clearance by 13%.³ In another 15 subjects, retigabine 200 mg twice daily increased to 300 mg twice daily over 15 days decreased the AUC of a single 200-mg dose of lamotrigine by 18% and increased clearance by 22%. It was suggested that lamotrigine competes for renal elimination with retigabine, but the mechanism behind the decreased lamotrigine levels is unknown.³ These modest changes are unlikely to be clinically important for most patients, but the authors suggest that the effects need to be assessed at the upper recommended dose ranges, and therefore advise caution.

(c) Topiramate

The preliminary report of a study notes that the pharmacokinetics of retigabine and topiramate were not altered by concurrent use in patients with epilepsy.¹ No special dosing precautions are necessary.

(d) Valproate

The preliminary report of a study notes that the pharmacokinetics of retigabine and valproic acid were not altered by concurrent use in patients with epilepsy.¹ No special dosing precautions are necessary.

Stiripentol + Other antiepileptics

Stiripentol causes marked rises in the serum levels of carbamazepine, phenobarbital and phenytoin. Stiripentol causes only a small rise in the serum levels of valproate.

Clinical evidence

Epileptic patients taking two or three antiepileptics (**phenytoin**, **phenobarbital**, **carbamazepine**, **clobazam**, **primidone**, **nitrazepam**) were also given stiripentol, increasing from 600 mg to 2.4 g daily. The 5 patients taking **phenytoin** had an average 37% reduction in the **phenytoin** clearance when they took stiripentol 1.2 g daily, and a 78% reduction when they took stiripentol 2.4 g daily. These changes in clearance were reflected in marked rises in the steady-state serum levels of **phenytoin**: for example the serum **phenytoin** levels of one patient rose from 14.4 to 27.4 mg/L over 30 days while he was taking stiripentol, despite a 50% reduction in his **phenytoin** dosage. **Phenytoin** toxicity was seen in another two subjects.¹ The clearance of **carbamazepine** in one subject fell by 39% when stiripentol 1.2 g daily was taken and by 71% when stiripentol 2.4 g daily was taken. **Phenobarbital** clearance in two subjects fell by about 30 to 40% when they took stiripentol 2.4 g daily.¹ Three other studies in adults and children confirmed that stiripentol reduces the clearance of **carbamazepine** by between about 50% and 65%,^{2–4} and significantly increases carbamazepine levels.⁵ Another study found that the formation of carbamazepine-10,11-epoxide, the active metabolite of **carbamazepine** was markedly reduced in children taking **carbamazepine** with stiripentol.⁶

Valproate 1 g daily was given to 8 subjects with or without stiripentol 1.2 g daily. The stiripentol caused a 14% increase in the peak serum levels of **valproate**.⁷ In another 11 patients no adverse effects on motor, perceptual or attention tests were seen when stiripentol was given with other antiepileptic drugs, but the doses of **phenobarbital**, **phenytoin** and **carbamazepine** were reduced before the combination was taken.⁸

Mechanism

Stiripentol inhibits the activity of various cytochrome P450 liver isoenzymes including CYP1A2, CYP2C9, CYP2C19, CYP2D6 and CYP3A4,

some of which are concerned with the metabolism of other antiepileptics. As a result the loss of the antiepileptic from the body is reduced and the serum levels rise accordingly.^{3,9} In the case of valproate, cytochrome P450-mediated metabolism is only involved in minor valproate metabolic pathways and therefore only a small rise in serum levels occurs.⁷ However, there is evidence that stiripentol may reduce the formation of a minor but hepatotoxic metabolite of valproate (2-propyl-4-pentenoic acid or 4-ene-VPA).¹⁰

Importance and management

Established and clinically important interactions. The phenytoin, phenobarbital and carbamazepine dosages should be reduced to avoid the development of elevated serum levels and possible toxicity during the concurrent use of stiripentol. One study³ suggests that the carbamazepine dosage should be decreased incrementally over 7 to 10 days, beginning as soon as the stiripentol is started and, regardless of age, the maintenance dose of carbamazepine should aim to give serum levels of 5 to 10 micrograms/mL. Stiripentol causes only small changes in the serum levels of valproate and dosage adjustments are unlikely to be needed with this combination.

Tiagabine + Miscellaneous

The pharmacokinetics of tiagabine were not altered by cimetidine or erythromycin. No clinically relevant pharmacokinetic interactions occur between tiagabine and theophylline or warfarin.

Clinical evidence, mechanism, importance and management

Cimetidine 400 mg twice daily for 5 days increased the steady-state AUC of tiagabine 4 mg twice daily by just 5% in a study in 12 healthy subjects.^{1,2} This change would not be clinically relevant.

Erythromycin 500 mg twice daily had no clinically relevant effect on the steady-state pharmacokinetics of tiagabine 4 mg twice daily in a study in 14 healthy subjects.³ No dose adjustment would be required during concurrent use.

Multiple dose studies in healthy subjects have also excluded any clinically relevant pharmacokinetic interactions between tiagabine and **theophylline** or **warfarin** but no further study details were given.¹

Tiagabine + Other antiepileptics

Tiagabine plasma levels are reduced by enzyme-inducing antiepileptics (carbamazepine, phenytoin, phenobarbital and primidone).

done). Tiagabine doses may need to be lower in patients *not* taking these drugs. Tiagabine may cause a slight reduction in valproate levels (not clinically relevant), but has no effect on carbamazepine, phenytoin or vigabatrin levels.

Clinical evidence, mechanism, importance and management

In an early clinical study, tiagabine was reported to have no significant effect on the plasma levels of carbamazepine, phenytoin, valproate, and vigabatrin.¹ Similarly, tiagabine (titrated from 8 mg up to a maximum of 48 mg daily over 18 days) did not alter the steady-state pharmacokinetics of phenytoin or carbamazepine in 12 patients with epilepsy.² However, in another similar study, it reduced the AUC of valproate by 10%, but this reduction is not expected to be clinically significant.³

A study in patients taking 1 to 3 other enzyme-inducing antiepileptics (phenobarbital, phenytoin, carbamazepine, primidone) found that tiagabine half-lives were shorter (3.8 to 4.9 hours) when compared with historical values in healthy subjects taking tiagabine alone (7.1 hours).⁴ The manufacturers say that the plasma concentrations of tiagabine may be reduced 1.5 to 3-fold by these enzyme-inducing antiepileptics.⁵ Based on this, they recommend that the initial maintenance dose of tiagabine in patients *not* taking enzyme-inducing drugs should be lower (15 to 30 mg daily) than in those taking these drugs (30 to 45 mg daily).⁵

Topiramate + Carbamazepine

Topiramate plasma levels may be reduced by carbamazepine. Carbamazepine levels are not affected by topiramate. However, one report suggests that the toxicity seen when topiramate is added to maximum tolerated doses of carbamazepine may respond to a reduction in the carbamazepine dose.

Clinical evidence

(a) Carbamazepine levels

In a study in 12 epileptic patients topiramate titrated up to a maximum of 400 mg twice daily had no effect on the steady-state plasma levels of carbamazepine 300 to 800 mg every 8 hours or on its main metabolite, carbamazepine-10,11-epoxide.¹ An earlier study in epileptic patients also reported that topiramate does not affect the pharmacokinetics of carbamazepine.² In contrast, another report describes 2 patients taking a maximum tolerated dose of carbamazepine who started treatment with topiramate and subsequently developed symptoms suggestive of carbamazepine toxicity. In both these cases, the symptoms resolved when the carbamazepine dose was reduced, and this enabled continued titration of the topiramate dose in one. A review of the clinical use of these two drugs found another 23 cases that fitted this pattern. Carbamazepine levels were not reported.³

(b) Topiramate levels

The topiramate plasma levels and AUC were found to be about 40% lower in the presence of carbamazepine in a study in 12 epileptic patients.¹ A population pharmacokinetic study reported that patients taking carbamazepine had 32% lower morning topiramate level than patients not taking enzyme-inducing antiepileptics.⁴ In a study in healthy subjects carbamazepine 600 mg daily was found to cause a twofold increase the clearance of a single 200-mg dose of topiramate. The mean half-life of topiramate decreased from 29 to 19 hours. There was also a two- to threefold increase in the formation of the 2 major metabolites of topiramate (2,3-diol-TPM and 10-OH-TPM), although 41% of topiramate was excreted unchanged in the urine in the presence of carbamazepine.⁵ In contrast, an earlier study reported that carbamazepine did not have a major effect on the pharmacokinetics of topiramate.²

Mechanism

Carbamazepine appears to induce the metabolism of topiramate. Although topiramate can weakly induce CYP3A4 this does not usually appear to have a clinically relevant effect on carbamazepine metabolism, unless carbamazepine is already at the maximum tolerated dose.

Importance and management

Carbamazepine possibly results in a moderate reduction in topiramate plasma levels, but this is probably of limited clinical importance. There is some evidence that the toxicity seen when topiramate is added to maximum tolerated doses of carbamazepine may respond to a reduction in the carbamazepine dose.

Topiramate + Phenobarbital or Primidone

Topiramate appears not to alter the pharmacokinetics of phenobarbital or primidone. Phenobarbital reduces topiramate levels.

Clinical evidence, mechanism, importance and management

A review of data from double blind, placebo-controlled studies found that over periods of 8 to 12 weeks the plasma levels of phenobarbital or primidone in patients (number not stated) with partial seizures remained unchanged when they were also given topiramate.¹

A population pharmacokinetic study reported that patients taking phenobarbital had 31% lower morning topiramate levels than patients not taking enzyme-inducing antiepileptics.² Another study that grouped carbamazepine, phenobarbital and phenytoin reported that patients taking one or more of these drugs had 1.5-fold greater topiramate clearance than patients taking lamotrigine or valproate.³ Phenobarbital probably induces the metabolism of topiramate thereby reducing its levels.

When topiramate is added to existing treatment with phenytoin or phenobarbital its dose should be titrated to effect. If phenobarbital or primidone are withdrawn or added, be aware that the dose of topiramate may need adjustment.

- Doose DR, Walker SA, Pledger G, Lim P, Reife RA. Evaluation of phenobarbital and primidone/phenobarbital (primidone's active metabolite) plasma concentrations during administration of add-on topiramate therapy in five multicenter, double-blind, placebo-controlled trials in outpatients with partial seizures. *Epilepsia* (1995) 36 (Suppl 3), S158.

Topiramate + Phenytoin

In some patients the plasma levels of phenytoin are slightly raised by topiramate, and topiramate plasma levels may be reduced by phenytoin.

Clinical evidence

Topiramate, titrated to a maximum of 400 mg twice daily, was given to 12 epileptic patients taking phenytoin 260 to 600 mg daily. When the maximum tolerated dose of topiramate was reached, the phenytoin dose was then reduced, and in some cases the phenytoin was subsequently discontinued. Topiramate clearance was assessed in 2 patients and was found to be increased two to threefold by phenytoin.¹ Similarly, a population pharmacokinetic study reported that patients taking phenytoin and topiramate had 50% lower morning topiramate levels than patients not taking enzyme-inducing antiepileptics.²

In the first study above, 3 of the 12 patients had a decrease in phenytoin clearance and an increase of 25 to 55% in the AUC of phenytoin when taking topiramate: the other 9 had no changes.¹ This slight increase is said not to be clinically significant based on analyses from six add-on studies.³

Mechanism

An *in vitro* study using human liver microsomes found that topiramate does not inhibit most hepatic cytochrome P450 isoenzymes, except for CYP2C19 at high concentrations.¹ This isoenzyme plays a minor role in phenytoin metabolism, but it has been suggested this may become important at high doses of topiramate in patients who are poor CYP2C9 metabolisers,¹ (see 'genetic factors in drug metabolism', (p.4), for more information). Phenytoin appears to induce the metabolism of topiramate.

Importance and management

The interaction between topiramate and phenytoin appears to be established, and topiramate dose adjustments may be required if phenytoin is added or discontinued. No reduction in the phenytoin dosage seems necessary in the majority of patients, but be aware that a few patients may have increased phenytoin levels, particularly at high topiramate doses. Monitor phenytoin levels.

Topiramate + Valproate

Encephalopathy has been reported in patients given topiramate with or without valproate. One study found no clinically relevant pharmacokinetic interaction between topiramate and valproate.

Clinical evidence, mechanism, importance and management

Six patients with severe epilepsy developed stuporous encephalopathy with marked cognitive impairment when taking topiramate with valproate (5 patients) or when taking topiramate alone (1 patient). Four of the patients had hyperammonaemia which resolved when topiramate or valproate were withdrawn. The toxicity was possibly due to a synergistic effect of valproate and topiramate on liver ornithine metabolism resulting in hyperammonaemia. It was also possible that the encephalopathy was due to topiramate toxicity in at-risk patients such as those with pre-existing chronic encephalopathy.¹

In a study in 12 epileptic patients, the pharmacokinetics of both topiramate, titrated to 400 mg twice daily, and valproate 1 to 4.5 g daily were slightly changed by concurrent use. The topiramate AUC was raised by about 18%, and the valproate AUC was reduced by 11.3%, but these changes were not considered to be clinically relevant.² However, the proportion of various metabolites of valproate was altered by topiramate: metabolism to 4-ene-valproate (a putative hepatotoxin) and metabolism by oxidation increased, whereas conjugation decreased.² Similar changes have been seen with other enzyme-inducing antiepileptics (see Mechanism in 'Phenytoin + Valproate', p.568).

The pharmacokinetic study suggests that dosage adjustments and special precautions are not required during concurrent use.² However, the report of encephalopathy with topiramate and valproate indicates that particularly for at-risk patients such as those with pre-existing encephalopathy careful monitoring is advised in these patients.¹

1. Latour P, Biraben A, Polard E, Bentué-Ferrer D, Beauplet A, Tribut O, Allain H. Drug induced encephalopathy in six epileptic patients: topiramate? valproate? or both? *Hum Psychopharmacol Clin Exp* (2004) 19, 193–203.
2. Rosenfeld WE, Liao S, Kramer LD, Anderson G, Palmer M, Levy RH, Nayak RK. Comparison of the steady-state pharmacokinetics of topiramate and valproate in patients with epilepsy during monotherapy and concomitant therapy. *Epilepsia* (1997) 38, 324–33.

Valproate + Acarbose

An isolated case report describes reduced valproate levels in a patient taking acarbose.

Clinical evidence, mechanism, importance and management

An epileptic patient taking sodium valproate for 10 years had a 40% fall in his normally stable plasma levels from 67 to 40.5 micrograms/mL when acarbose was added. No other drugs were being taken. When the acarbose was stopped and then restarted, the valproate levels rose and then fell once again. The reason is not understood but the authors of the report suggest that the acarbose possibly reduces the absorption of valproate.¹ This is an isolated report and its general importance is unknown, but it would seem prudent to be alert for any evidence of reduced effects if acarbose is added to valproate treatment.

1. Serrano JS, Jiménez CM, Serrano MI, Garrido H, Balboa B. May acarbose impair valproate bioavailability? *Methods Find Exp Clin Pharmacol* (1996) 18 (Suppl C), 98.

Valproate + Allopurinol

Allopurinol appears not to alter valproate levels.

Clinical evidence, mechanism, importance and management

A study investigating allopurinol in refractory epilepsy found that allopurinol (150 mg daily in those less than 20 kg, and 300 mg daily for other patients for 4 months) had no effect on valproate levels in 28 patients taking antiepileptics including valproate.¹ In another similar study, allopurinol 10 mg/kg increased to 15 mg/kg daily for 12 weeks had no effect on serum valproate levels in 6 patients taking antiepileptics including valproate.² Therefore valproate dosage alterations are unlikely to be required if allopurinol is used.

1. Zagnoni PG, Bianchi A, Zolo P, Canger R, Cornaggia C, D'Alessandro P, DeMarco P, Pisani F, Gianelli M, Verzé L, Viani F, Zaccara G. Allopurinol as add-on therapy in refractory epilepsy: a double-blind placebo-controlled randomized study. *Epilepsia* (1994) 35, 107–12.
2. Coppola G, Pasotto A. Double-blind, placebo-controlled, cross-over trial of allopurinol as add-on therapy in childhood refractory epilepsy. *Brain Dev* (1996) 18, 50–2.

Valproate + Antacids

The absorption of valproate was slightly, but not significantly, increased by an aluminium/magnesium hydroxide suspension but not by magnesium trisilicate or a calcium carbonate suspension.

Clinical evidence, mechanism, importance and management

In 7 healthy subjects the AUC of a single 500-mg dose of valproic acid, given 1 hour after breakfast, was increased by 12% (range 3 to 28%) by 62 mL of an aluminium/magnesium hydroxide suspension (*Maalox*) given with and 2 hours after valproate. Neither magnesium trisilicate suspension (*Trisogel*) nor calcium carbonate suspension (*Titralac*) had a significant effect on absorption.¹ No special precautions would seem necessary during concurrent use.

Valproate + Aspirin or NSAIDs

Valproate toxicity developed in three patients given large and repeated doses of aspirin. Increased levels of free valproate were found in 5 children within hours of them taking aspirin. Conversely, a slightly reduced valproate level was reported in one patient who took ibuprofen. Modestly altered protein binding has been shown when sodium valproate was given with diflunisal or naproxen, but this appears unlikely to be clinically important.

Clinical evidence, mechanism, importance and management

(a) Aspirin

A 17-year-old girl taking valproate 21 mg/kg daily was prescribed aspirin 18 mg/kg daily for lupus arthritis. Within a few days she developed a disabling tremor which disappeared when the aspirin was stopped. Total serum valproate levels were not significantly changed, but the free fraction fell from 24% to 14% when the aspirin was withdrawn. Similar toxic reactions (tremor, nystagmus, drowsiness, ataxia) were seen in 2 children,

aged 6 and 4 years, given 12 and 20 mg/kg aspirin every 4 hours while taking valproate.¹ In 5 epileptic children taking valproate, free valproate levels increased by 31 to 66% (average 49%) 17 hours after starting aspirin 11.5 to 16.9 mg/kg four times daily.² One case report of fatal hyperammonaemia was speculated to have been induced by valproate, and the authors also considered that concurrent use of aspirin and 'cimetidine', (p.578) may have contributed.³

Aspirin displaces valproate from its protein binding sites^{2,4} and also alters its metabolism by the liver⁵ so that the levels of free (and pharmacologically active) valproate rise. This could temporarily increase both the therapeutic and toxic effects of the valproate. However, there is evidence that increased hepatic elimination of valproate counterbalances this effect.

Direct information seems to be limited to the studies cited. Clinically relevant interactions appear rare, probably because in most cases the effects of aspirin on free valproate levels cancel each other out. The combination need not necessarily be avoided, but it would seem prudent to be aware of this interaction if valproate and high-dose aspirin are used.

(b) Diflunisal

Diflunisal 250 mg twice daily for 7 days given with sodium valproate 200 mg twice daily caused a 20% increase in the unbound fraction of valproate in 7 healthy subjects. There was a 35% increase in the AUC of one of the oxidation metabolites of valproate, and a small decrease in the AUC of some of the diflunisal glucuronide metabolites. This was shown to be due to changes in renal clearance of these metabolites.⁶ Whether any of these modest changes have any clinical relevance remains to be seen, but it appears unlikely.

(c) Ibuprofen

A 15-year-old boy was found to have a subtherapeutic valproate level (43 micrograms/mL) 3 days after starting to take ibuprofen 600 mg every 6 hours for post-fracture analgesia. The ibuprofen was stopped, and after one week the valproate levels were within the therapeutic range (60 micrograms/mL).⁷ The general importance of this isolated case is unknown. More study is needed.

(d) Naproxen

A study in 6 healthy subjects found that naproxen 500 mg twice daily moderately decreased the AUC of a single 800-mg dose of sodium valproate by 11%.⁸ Similarly, in another study, when naproxen 500 mg twice daily was given with sodium valproate 500 mg twice daily the AUC of valproate was decreased by 20% and the AUC of naproxen was increased by 7%.⁹ It is suggested that naproxen and sodium valproate displace each other from their protein binding sites.^{8,9} The clinical relevance of these modest changes is uncertain, but is likely to be small.⁸

Valproate + Bile-acid binding resins

Colestyramine causes a very small reduction in the absorption of valproate. No interaction occurs if administration of the drugs is separated by 3 hours. Colesevelam does not interact.

Clinical evidence

(a) Colesevelam

Colesevelam 4.5 g had no effect on the pharmacokinetics of valproic acid 250 mg in a single-dose study in 26 healthy subjects.¹

(b) Colestyramine

A single 250-mg dose of valproic acid was given to 6 healthy subjects either alone, at the same time as colestyramine 4 g twice daily, or with the colestyramine taken 3 hours after the valproic acid. The bioavailability of valproate taken alone and when separated from the colestyramine by 3 hours remained the same. When the valproate was taken at the same time as the colestyramine the valproate AUC fell by 15% and the maximum serum levels fell by 21%.^{2,3}

Mechanism

Colestyramine is an ion-exchange resin intended to bind with bile acids in the gut, but it can also bind with drugs as well, leading to a reduction in their absorption. This apparently occurs to a limited extent with valproate.

Importance and management

Direct information about colestyramine and valproate appears to be limited to this single study, but what happened is consistent with the way colestyramine interacts with a number of other drugs. The fall in the bioavailability is small and probably of very limited clinical importance, but the interaction can be totally avoided by separating the dosages by 3 hours so that admixture in the gut is minimised. Colesevelam does not interact.

Valproate + Carbapenems

Panipenem/betamipron dramatically reduced the valproate serum levels of 6 patients. Imipenem and meropenem have similar effects and seizures have occurred when they were given to patients taking valproate. Ertapenem is predicted to interact similarly.

Clinical evidence

(a) Imipenem

A report describes a reduction in valproate levels from 80 micrograms/mL to 24 then 33 micrograms/mL in an epileptic patient 4 and 11 days after imipenem was given to treat a *Pseudomonas aeruginosa* infection.¹

(b) Meropenem

A report describes two patients whose valproate levels fell when meropenem and amikacin were given. The first patient had been maintained on intravenous valproate 1.2 to 1.6 g daily with valproate levels of between 50 and 100 mg/L. Two days after the addition of the antibacterials the levels had halved, and after 3 days of subtherapeutic levels, phenytoin was substituted for valproate. The other patient experienced a drop in valproate levels from 44 mg/L to 5 mg/L within 24 hours of being given meropenem, despite being given greater doses of valproic acid.² Other reports^{1,3-8} describe reductions in valproate levels in several other patients when they were also given meropenem: three of them developed seizures.^{1,7,8}

(c) Panipenem

A report describes 3 cases of Japanese children taking antiepileptic drugs who had marked reductions in valproate serum levels while receiving panipenem/betamipron for serious chest infections.⁹ An increased seizure-frequency occurred in 2 of the patients. In one case the serum valproate levels fell from 30.1 to 1.53 mg/L within 4 days of starting panipenem, and rose again when it was stopped. All 3 patients were also taking carbamazepine but its serum levels were unchanged by the panipenem/betamipron. In a further 3 cases, 60 to 100% reductions in valproate levels were reported, which occurred within 2 days of starting concurrent treatment. Increased seizure frequency occurred in 2 cases.¹⁰

Mechanism

Unknown, but the speed of the interaction is said to be inconsistent with enzyme induction, and accelerated renal excretion has been suggested.² Altered protein binding has been shown in *animal* and *in vitro* studies.¹¹

Importance and management

Although there is only an isolated report of an interaction between valproate and imipenem, there are now several reports of the interaction between valproate and meropenem or panipenem. Seizures or increased seizure frequency have been reported. It would therefore seem prudent to monitor the valproate levels in any patient also given carbapenems, being alert for the need to increase the valproate dosage, or to use another antibacterial, or an alternative to valproate. Carbamazepine⁹ and phenytoin² did not interact in the above reports. The manufacturers of **ertapenem** have no reports of an interaction on their files,¹² but prudently warn about a possible interaction with valproate¹³ because of the interactions seen with other carbapenems.

Valproate + Chlorpromazine

Valproate serum levels are slightly raised in patients given chlorpromazine, but this appears to be of minimal clinical importance. An isolated report describes severe hepatotoxicity on concurrent use.

Clinical evidence, mechanism, importance and management

The steady-state trough serum levels of valproate 400 mg daily rose by 22% when 6 patients taking valproate were given chlorpromazine 100 to 300 mg daily. The half-life increased by 14% and the clearance fell by 14% (possibly due to some reduction in its liver metabolism)¹. This interaction would normally seem to be of minimal importance. Severe hepatotoxicity occurred in another patient given both drugs,² but remember that both drugs independently can be hepatotoxic.

Valproate + Erythromycin

Two isolated reports describe valproate toxicity in a woman and a child given erythromycin. Another report describes vitamin K deficiency in a child given valproate and erythromycin.

Clinical evidence, mechanism, importance and management

A woman taking lithium and valproate 3.5 g daily developed fatigue and walking difficulties a day after starting to take erythromycin 250 mg four times daily. Within a week she had also developed slurred speech, confusion, difficulty in concentrating and a worsening gait. Her serum valproate levels had risen from 88 mg/L (measured 2 months before) to 260 mg/L. She recovered within 24 hours of the valproate and erythromycin being withdrawn. Her serum lithium levels remained unchanged.¹ A child taking sodium valproate had a threefold increase in serum valproate levels after taking erythromycin 150 mg every 8 hours and aspirin 250 mg every 6 hours for 3 days.² These case reports contrast with another study in a 10-year-old boy taking valproic acid 375 mg twice daily who had only very small and clinically unimportant changes in the pharmacokinetics of valproate, consistent with inhibition of cytochrome P450 metabolism, when given erythromycin 250 mg four times daily.³

Another child taking valproic acid developed a deficiency of prothrombin complex after taking erythromycin 300 mg three times daily. This resolved when the patient was given oral vitamin K. It was suggested that the effect was because the numbers of vitamin-K producing intestinal bacteria were reduced.⁴

The general relevance of these isolated reports is unclear, but probably small. Further study is needed.

Valproate + Felbamate

Felbamate can raise valproate serum levels causing toxicity. Valproate may slightly decrease the clearance of felbamate.

Clinical evidence

(a) Effect on sodium valproate

The average steady-state valproate serum levels in 7 epileptics were raised by 28%, from 66.9 to 85.4 micrograms/mL, by felbamate 1.2 g daily, and by 54%, from 66.9 to 103 micrograms/mL by felbamate 2.4 g daily. The AUC of valproate was raised by 28% and 54% by felbamate 1.2 and 2.4 g, respectively.¹ Valproate clearance was correspondingly reduced by felbamate.¹ Similar effects were seen in another study.^{2,3} It was suggested that in children the interaction may be more marked.³ Many of the patients experienced nausea. Other toxic effects included lethargy, drowsiness, headaches, cognitive disturbances and low platelet counts.^{1,2}

(b) Effect on felbamate

The clearance of felbamate was decreased 21% by valproate in one study,⁴ and another reported a significantly lower felbamate clearance in the presence of valproate.⁵ Yet another study noted only a minimal effect of valproate on felbamate clearance.⁶

Mechanism

Uncertain. Altered plasma protein binding of valproate is unlikely to be important.⁷ Felbamate may cause inhibition of the oxidative pathway of valproate metabolism.⁸

Importance and management

An established interaction. It may be necessary to reduce the valproate dosage to avoid toxicity if felbamate is given. The authors of one report suggest a 30 to 50% reduction. It may also be necessary to reduce the felbamate dosage as well. If both drugs are given monitor closely, particularly during the initial stages of treatment.

Valproate + Fluoxetine

Isolated reports describe marked increases or modest decreases in valproate levels in a small number of patients given fluoxetine. Valproate toxicity occurred in one patient.

Clinical evidence

A woman with an atypical bipolar disorder and 'severe mental retardation' taking semisodium valproate (divalproex sodium) 3 g daily had a rise in her serum valproic acid levels from 93.5 to 152 mg/L within 2 weeks of starting to take fluoxetine 20 mg daily. The valproate dosage was reduced to 2.25 g daily and 2 weeks later the serum valproic acid levels had fallen to 113 mg/L. No adverse effects were seen.¹ Another woman taking valproic acid developed elevated serum valproate levels (a rise from 78 to 126 mg/L) without any accompanying clinical symptoms within 1 month of starting to take fluoxetine 20 mg daily. Valproate levels fell again when the fluoxetine was stopped.² Similarly, a 17-year-old taking valproic acid and felbamate developed drowsiness and difficulty in being roused 2 weeks after starting fluoxetine 20 mg daily. His valproate level had increased to 141 micrograms/mL from a previous range of 100 to 110 micrograms/mL. His valproate dose was reduced by about 15%, and his consciousness improved.³

In contrast 2 cases of *reduced* valproate levels have also been reported in patients taking fluoxetine. In the first case, a 67-year-old woman taking valproic acid 2 g daily and fluoxetine 20 mg daily had a serum valproate level of 51.9 mg/L. This increased to 64.9 mg/L 9 days after fluoxetine was discontinued and fell to 32.6 mg/L 6 days after fluoxetine was restarted. In the second case, an 81-year-old woman was taking valproic acid 1 g with fluoxetine 20 mg daily and had serum valproate levels of 41.9 mg/L. The fluoxetine was stopped, and 6 days later valproate serum levels had risen to 56.2 mg/L. After re-introduction of fluoxetine her valproate levels fell to 45.6 mg/L.⁴

Mechanism

Not understood.

Importance and management

These reports are somewhat confusing and inconsistent, but the overall picture is that concurrent use need not be avoided, but that the outcome should probably be monitored (indicators of valproate toxicity include nausea, vomiting, and dizziness). More study is needed.

Valproate + Food

A study in 12 healthy subjects found that dietary fibre (citrus pectin 14 g) did not affect the rate or extent of absorption of a single 500-mg dose of valproate.¹

- Issy AM, Lanchote VL, de Carvalho D, Silva HC. Lack of kinetic interaction between valproic acid and citrus pectin. *Ther Drug Monit* (1997) 19, 516–20.

Valproate + H₂-receptor antagonists

Aside from one tentative case report, cimetidine and ranitidine do not appear to have a clinically significant interaction with valproate.

Clinical evidence, mechanism, importance and management

The clearance of a single oral dose of sodium valproate was reduced in 6 patients by 2 to 17% after a 4-week course of **cimetidine**, but was not affected by **ranitidine**.¹ It seems doubtful if the interaction between valproate and **cimetidine** is of clinical importance. However, a case of fatal hyperammonaemia in a patient with systemic lupus erythematosus was speculated to have been induced by valproate, and the authors also considered that the concurrent use of **cimetidine** and aspirin (see 'Valproate + Aspirin or NSAIDs', p.575) may have contributed.² The general importance of this case is unknown.

- Webster LK, Mihaly GW, Jones DB, Smallwood RA, Phillips JA, Vajda FJ. Effect of cimetidine and ranitidine on carbamazepine and sodium valproate pharmacokinetics. *Eur J Clin Pharmacol* (1984) 27, 341–3.

Valproate + Isoniazid

An isolated report describes the development of raised serum valproate levels and toxicity in a child given isoniazid while taking valproate. Another report describes raised hepatic enzymes and drowsiness in a patient taking both drugs.

Clinical evidence, mechanism, importance and management

A 5-year-old girl with left partial seizures, successfully treated with valproate 600 mg daily and clonazepam for 7 months, developed signs of valproate toxicity (drowsiness, asthenia) shortly after starting to take isoniazid 200 mg daily (because of a positive tuberculin reaction). Her serum valproate levels were found to have risen to around 121 to 139 mg/L (normal therapeutic range 50 to 100 mg/L).¹ Over the next few months various changes were made in her treatment, the most significant being a 62% reduction in the dosage of valproate, which was needed to maintain satisfactory therapeutic levels. Later when the isoniazid was stopped her valproate levels fell below therapeutic levels and seizures recurred. It was then found necessary to increase the valproate to its former dosage. The suggested explanation for this interaction is that the isoniazid inhibited the metabolism (oxidation) of valproate by the liver so that it accumulated. The child was found to be a very slow acetylator of isoniazid.¹

Another child who had been treated with valproate for several years was prescribed isoniazid for the treatment of tuberculosis. At the same time, seizures recurred, and the valproate was stopped and primidone 750 mg daily started. Seven months later seizures persisted, and she was admitted to hospital. Liver enzyme values were normal. Valproate 300 mg daily increased to 600 mg daily was added, and within 2 days she was vomiting and drowsy. After 5 days she had increased liver enzymes and her prothrombin time had fallen, so the valproate was stopped. Valproate levels were 81 micrograms/mL. It was speculated that the CNS effects and hepatic impairment were due to an interaction between the valproate and isoniazid.²

The general importance of these cases is uncertain, but bear them in mind in the event of an unexpected response to treatment.

- Jonville AP, Gauchez AS, Autret E, Billard C, Barbier P, Nsabiymva F, Breteau M. Interaction between isoniazid and valproate: a case of valproate overdosage. *Eur J Clin Pharmacol* (1991) 40, 197–8.

Valproate + Methylphenidate

Two children taking valproic acid rapidly developed severe dyskinesias and bruxism after the first and second dose of methylphenidate, respectively. Valproate appears to potentiate the effects of methylphenidate, possibly by a pharmacokinetic mechanism, or because of additive dopaminergic effects. The authors of the re-

port advise clinical observation while the dose of methylphenidate is being established.¹

1. Gara L, Roberts W. Adverse response to methylphenidate in combination with valproic acid. *J Child Adolesc Psychopharmacol* (2000) 10, 39–43.

Valproate + Propranolol

One patient had a reduction in valproate clearance when also given propranolol, but 12 other patients had no changes.

Clinical evidence, mechanism, importance and management

An isolated report describes a 28% reduction in valproate clearance in a patient taking valproate semisodium with propranolol 40 mg, and a 35% reduction with propranolol 80 mg. However, 12 other patients taking valproate had no changes in clearance, serum levels or half-life when given propranolol 60 or 120 mg daily for 3 weeks.¹ This interaction would therefore not appear to be of general importance. No special precautions would seem necessary.

1. Nemire RE, Toledo CA, Ramsay RE. A pharmacokinetic study to determine the drug interaction between valproate and propranolol. *Pharmacotherapy* (1996) 16, 1059–62.

Valproate + Theophylline

A study in 6 healthy subjects found that oral aminophylline 200 mg every 6 hours for 3 doses did not affect the pharmacokinetics of a single 400-mg dose of sodium valproate.¹

1. Kulkarni C, Vaz J, David J, Joseph T. Aminophylline alters pharmacokinetics of carbamazepine but not that of sodium valproate — a single dose pharmacokinetic study in human volunteers. *Indian J Physiol Pharmacol* (1995) 39, 122–6.

Vigabatrin + Clomipramine

An isolated case report describes mania in an epileptic patient taking vigabatrin and clomipramine.

Clinical evidence, mechanism, importance and management

An isolated report describes an epileptic man taking carbamazepine and clobazam who started taking clomipramine 35 mg daily for depression. About one month later, vigabatrin 2 g daily was added for better seizure control. After about a week, the patient then progressively showed signs of mania, requiring hospitalisation after about 10 weeks. The clomipramine was stopped, the vigabatrin continued (because of its efficacy), and haloperidol started. Within a week the patient's mood had stabilised. The authors of the report attributed the mania to an interaction between the vigabatrin and the clomipramine.¹ Note that both clomipramine and vigabatrin can cause psychiatric disorders including mania, and vigabatrin should be used with caution in patients with depression. No general conclusions can be based on this single report.

Vigabatrin + Felbamate

No clinically relevant pharmacokinetic interactions appear to occur between vigabatrin and felbamate.

Clinical evidence, mechanism, importance and management

In a study of 16 subjects, felbamate 2.4 g daily increased the AUC of vigabatrin 2 g daily by 13%, which is unlikely to be clinically significant. In a second study in a further 18 subjects, vigabatrin did not affect felbamate pharmacokinetics.¹ There would therefore seem to be no reason for avoiding concurrent use.

1. Reidenberg P, Glue P, Banfield C, Colucci R, Meehan J, Rey E, Radwanski E, Nomeir A, Lim J, Lin C, Guillaume M, Affrime MB. Pharmacokinetic interaction studies between felbamate and vigabatrin. *Br J Clin Pharmacol* (1995) 40, 157–60.

Vigabatrin + Phenobarbital or Primidone

Vigabatrin causes a trivial decrease in phenobarbital and primidone levels. There is some evidence that phenobarbital may reduce the efficacy of vigabatrin in infantile spasms.

Clinical evidence

In an early clinical study, vigabatrin 2 to 3 g daily did not change the serum levels of phenobarbital in 26 patients.¹ Similarly, another study found that phenobarbital levels were not significantly altered by vigabatrin.² Another study found that vigabatrin caused serum level reductions of 7% with phenobarbital and 11% with primidone.^{3,4} Alterations of this size would not be expected to be clinically significant.

There is some evidence that the efficacy of vigabatrin for infantile seizures may be reduced in those taking phenobarbital. The median time to response after starting vigabatrin was 3 days in 3 infants not taking phenobarbital and 34 days in 6 patients taking phenobarbital. Three patients did not respond to vigabatrin until after phenobarbital was withdrawn.⁵

Mechanism

Not understood.

Importance and management

There appears to be no change in phenobarbital levels with vigabatrin, but some suggestion that vigabatrin may be less effective for infantile spasms in the presence of phenobarbital. Bear this possibility in mind.

Vigabatrin + Valproate

No pharmacokinetic interaction appears to occur between vigabatrin and valproate, but one retrospective study found a correlation between valproate levels and vigabatrin levels.

Clinical evidence, mechanism, importance and management

Vigabatrin 40 to 80 mg/kg daily did not change the serum levels of sodium valproate in 11 children.¹ The combined use of vigabatrin and sodium valproate in 16 children with refractory epilepsy was found not to affect the steady-state serum levels of either drug and the combination reduced the frequency of seizures.² However, a retrospective analysis of serum samples from 53 patients found that the vigabatrin concentration-to-dose ratio was increased as the valproate trough steady state levels increased,³ suggesting that valproate slightly raises vigabatrin levels. However, no dosage adjustments usually appear to be necessary on combined use.

Zonisamide + Miscellaneous

Cimetidine does not alter zonisamide pharmacokinetics. Food has no effect on the absorption of zonisamide. A case of reduced zonisamide levels possibly caused by risperidone has been described.

Potent inhibitors of CYP3A4 are predicted to modestly decrease zonisamide clearance.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

When a single 300-mg oral dose of zonisamide was given to healthy subjects, it was found that cimetidine 300 mg four times daily for 13 days did not affect the zonisamide clearance, half-life, apparent volume of distribution or the amount of drug recovered from the urine. The drugs were well tolerated.^{1,2} No special precautions would seem to be needed if both drugs are used.

(b) Food

There was no difference in the pharmacokinetics of a single 300- or 400-mg dose of zonisamide when given in the fasted state or after breakfast in a study in healthy subjects. Zonisamide may be taken without regard to the timing of meals.³

(c) Risperidone

A 57-year-old man taking zonisamide was prescribed risperidone 2 mg daily, which was gradually increased to 10 mg daily. About 2 months after starting the risperidone, the zonisamide level had fallen from 23.7 to 10.7 micrograms/mL. The risperidone was stopped, and the zonisamide level had slightly increased again to 12.4 micrograms/mL about one month later. It was suggested that a metabolic interaction occurred.⁴ More study is needed to establish any interaction.

(d) Cytochrome P450 isoenzyme CYP3A4 inhibitors

In vitro studies have shown that the cytochrome P450 isoenzyme CYP3A4 is the principal enzyme involved in the metabolism of zonisamide.⁵ Based on *in vitro* data, it is predicted that **ketoconazole**, **ciclosporin**, **miconazole** and **fluconazole** may cause a modest to minor decrease in the clearance of zonisamide. Conversely, **itraconazole** and **triazolam** are not predicted to have an effect.⁵ *In vitro* predictions do not always mirror what happens in clinical use, therefore, further study is needed.

Zonisamide + Other antiepileptics

Phenobarbital, phenytoin and carbamazepine can cause a small to moderate reduction in the serum levels of zonisamide, while lamotrigine may increase zonisamide levels. Clonazepam and valproate have little or no effect. Zonisamide shows variable effects (a modest decrease, an increase, or no effect) on carbamazepine serum levels, but has no important effect on lamotrigine, phenobarbital, primidone or valproate levels. Most studies also suggest that zonisamide has no effect on phenytoin levels, but two showed a modest increase.

Clinical evidence

(a) Carbamazepine

In one study the ratio of plasma level to zonisamide dose was 39% lower in 17 patients taking carbamazepine than in 28 patients taking zonisamide alone, suggesting that carbamazepine modestly reduces zonisamide levels.¹ Similarly, in another study in 12 epileptic children taking zonisamide 8.6 to 13.6 mg/kg daily, carbamazepine 12.1 to 18.1 mg/kg daily reduced zonisamide plasma levels by about 35 to 37%.² In an early study in 2 groups of patients, one taking carbamazepine and the other phenytoin, it was noted that the zonisamide AUC following a single 400-mg dose was 40% higher in the carbamazepine group than the phenytoin group.³ However, in the first study, the plasma concentration-to-dose ratio was the same in patients taking carbamazepine as in those taking phenytoin.¹

Therefore the comparative effects of carbamazepine and phenytoin on zonisamide levels are unclear.

In one study, the ratio of carbamazepine-10,11-epoxide (the major active metabolite of carbamazepine) to carbamazepine in the plasma was 50% lower in patients also taking zonisamide, suggesting that zonisamide reduces carbamazepine metabolism. However, the plasma concentration-to-dose ratio of carbamazepine was only 20% higher, which was not significant.¹ An early pilot study had noted a consistent rise in carbamazepine plasma levels following initiation of zonisamide therapy in 7 patients (range 26 to 270%).⁴ The opposite effect was seen in a study of 16 paediatric patients in whom zonisamide reduced the ratio of carbamazepine serum levels to dose by up to 22% and increased the relative amount of its major metabolite in the serum by up to 100%, suggesting that zonisamide increases the metabolism of carbamazepine. However, the free fraction of carbamazepine remained unaltered.⁵

Contrasting with these three studies are four others that found no changes in the serum levels of carbamazepine or carbamazepine-10,11-epoxide when zonisamide was used,^{2,6-8} although in one of the studies, the renal clearance of carbamazepine-10,11-epoxide was significantly reduced by zonisamide.⁸ A further study similarly found no change in the plasma level of carbamazepine in 41 patients also given zonisamide (7.5 versus 7.4 micrograms/mL).⁹

(b) Clonazepam

In one study the ratio of plasma level to dose of zonisamide did not differ between 8 patients also taking clonazepam and 28 patients taking zonisamide alone, suggesting clonazepam has no effect on zonisamide levels.¹

(c) Lamotrigine

Zonisamide 100 mg daily increased to 200 mg twice daily did not alter the steady-state pharmacokinetics of lamotrigine in 18 patients.^{10,11} Further, the pharmacokinetics of zonisamide were unaffected by lamotrigine.¹¹ However, in 2 patients who were stable taking zonisamide 600 mg daily or 800 mg daily, the addition of lamotrigine (incremental doses up to 400 mg daily) caused about twofold increases in their zonisamide levels, with symptoms of toxicity that were maximal 40 to 60 minutes after taking a zonisamide dose.¹²

(d) Phenobarbital or Primidone

In one study the ratio of plasma level to dose of zonisamide was 29% lower in 11 patients also taking phenobarbital than in 28 patients taking zonisamide alone, suggesting that phenobarbital reduces zonisamide levels.¹ Similarly, another study in healthy subjects found that pretreatment with phenobarbital increased the clearance of a single dose of zonisamide by about twofold.¹³ A further study found no changes in the serum levels of phenobarbital or primidone in 34 and 13 patients, respectively, who were also given zonisamide.⁹

(e) Phenytoin

In one study the ratio of plasma level to dose of zonisamide was 39% lower in 14 patients also taking phenytoin than in 28 patients taking zonisamide alone, suggesting phenytoin modestly reduces zonisamide levels.¹ In an early study in 2 groups of patients, one taking carbamazepine and the other phenytoin, it was noted that the zonisamide AUC following a single 400-mg dose was 40% higher in the carbamazepine group than the phenytoin group.³ However, in the first study, the reduction in zonisamide level-to-dose ratio was the same for phenytoin as for carbamazepine.¹ Therefore the comparative effect of phenytoin and carbamazepine on zonisamide levels is unclear.

Zonisamide 300 to 600 mg daily did not affect the phenytoin serum levels in 10 patients.⁶ Another study found that zonisamide did not affect the serum levels of phenytoin in 9 children.¹⁴ A further study similarly found no change in the plasma level of phenytoin in 33 patients also given zonisamide.⁹ In contrast to these three studies, in a population pharmacokinetic analysis, the clearance of phenytoin at a given dose was 14% lower and the serum level 16% higher in 39 patients also taking zonisamide.¹⁵ Similarly, the preliminary results from 9 patients in another study showed that there was a 28% increase in the steady-state AUC of phenytoin when zonisamide 100 mg daily increased to 200 mg twice daily was given.¹⁶ However, a later study by the same authors, in 19 patients, found that zonisamide did not affect the pharmacokinetics of phenytoin to a clinically relevant extent.¹⁷

(f) Valproate

In one study the ratio of plasma level to dose of zonisamide was about 20% lower in 24 patients also taking valproate than in 28 taking zonisamide alone.

amide alone, suggesting that valproate has little effect on zonisamide levels.¹ Similarly, another study in 16 patients found that valproate did not affect the pharmacokinetics of zonisamide.¹⁸ Further, the steady-state pharmacokinetics of valproate did not change when zonisamide 100 mg daily increased to 200 mg twice daily was added to the therapy of 16 patients.^{18,19}

Another study found that zonisamide did not affect the serum levels of sodium valproate in 12 children.¹⁴ A further study similarly found no marked changes in the plasma level of valproic acid in 7 patients also given zonisamide.⁹

Mechanism

Uncertain. It seems possible that phenobarbital, phenytoin and carbamazepine can induce the metabolism of zonisamide thereby reducing its serum levels. The plasma protein binding of zonisamide is unaffected by other antiepileptics (phenobarbital, phenytoin, carbamazepine, valproate).²⁰

Importance and management

None of these studies reported any major problems during concurrent use of zonisamide and these other antiepileptic drugs. Zonisamide serum levels are lower with phenobarbital, phenytoin and carbamazepine, and there is the possibility of carbamazepine or phenytoin level changes, so it would be prudent to monitor patients taking any of these combinations.

Antihistamines

Antihistamines (histamine H₁-antagonists) vary in their interaction profiles by sedative potential, route of metabolism, and cardiotoxicity (QT interval prolongation).

(a) Additive sedative effects

The older antihistamines (e.g. chlorphenamine, diphenhydramine and hydroxyzine) are also referred to as sedating antihistamines or first-generation antihistamines. As the former name suggests they have the potential to cause additive sedative effects with other sedating drugs. This type of interaction is discussed elsewhere, see 'CNS depressants + CNS depressants', p.1253. The sedating antihistamines also tend to have antimuscarinic (also called anticholinergic) adverse effects and so therefore may interact additively with other antimuscarinic-type drugs. This is also discussed elsewhere, see 'Antimuscarinics + Antimuscarinics', p.674.

The newer (non-sedating antihistamines or second-generation antihistamines) have a low potential to cause sedative effects. This appears to be because they are substrates for P-glycoprotein, an efflux transporter found in many organs, which would have the effect of actively ejecting any drug molecules that crossed the blood-brain barrier. Nevertheless, sedation may occur on rare occasions and patients should be advised to be alert to the possibility of drowsiness if they have not taken the drug before. Any drowsiness is likely to become apparent after the first few doses, and would indicate that additive sedative effects with other sedating drugs might be expected. The antihistamines are listed, by sedative potential, in 'Table 15.1', (below).

(b) Metabolism

Some of the sedating antihistamines, such as diphenhydramine, are inhibitors of the cytochrome P450 isoenzyme CYP2D6. None of the non-sedating antihistamines are known to inhibit cytochrome P450 isoenzymes, but some are substrates for CYP3A4 including astemizole, desloratadine, ebastine, loratadine, mizolastine, and terfenadine, see 'Table 15.2', (p.583). This has important consequences for the potential cardiotoxicity of astemizole and terfenadine, see (c) below. Loratadine and desloratadine are also substrates for CYP2D6, and mizolastine is also metabolised by glucuronidation. Cetirizine, levocetirizine and fexofenadine are minimally metabolised. Where pharmacokinetic interactions occur with fexofenadine, these appear to be mediated via drug transporters such as P-glycoprotein and/or organic anion transport polypeptide (OATP). For more information see 'Drug transporter proteins', (p.8).

(c) QT interval prolongation and cardiac arrhythmias

Important drug interactions occur with the non-sedating antihistamines astemizole and terfenadine. Raised serum levels of these two antihista-

mines can block potassium channels, lengthening the QT interval and increasing the risk of potentially fatal cardiac arrhythmias (torsade de pointes). Therefore, dangerous interactions may result when other drugs reduce the metabolism of astemizole or terfenadine, usually by inhibition of the cytochrome P450 isoenzyme CYP3A4. Such drugs include the 'macrolides', (p.589) and the 'azoles', (p.584). Adverse interactions are also predicted when astemizole or terfenadine are used with drugs that prolong the QT interval, see 'Antihistamines + Drugs that prolong the QT interval', p.587. Due to these potentially fatal interactions, astemizole has been withdrawn from many countries, while terfenadine has been withdrawn in the US and reclassified as a prescription-only medicine in the UK. Apart from possibly ebastine, loratadine and mizolastine, where information is inconclusive, none of the other non-sedating antihistamines have been clearly shown to be associated with QT prolongation (see 'Table 15.2', (p.583)). Therefore, even when pharmacokinetic interactions result in increased levels, these are unlikely to be clinically important in terms of cardiotoxicity.

Table 15.1 Systemic antihistamines (classified by sedative potential) and topical antihistamines

Sedative potential	Antihistamine
Non-sedative	Acrivastine, Astemizole,* Cetirizine, Desloratadine, Ebastine,* Fexofenadine, Levocetirizine, Loratadine, Mizolastine,* Rupatadine, Terfenadine*
Sedating	Azatadine, Brompheniramine, Buclizine, Chlorphenamine, Cinnarizine, Clemastine, Cyclizine, Cyproheptadine, Dexchlorpheniramine, Flunarizine, Meclozine, Mepyramine, Mequitazine, Pheniramine, Tripelennamine, Triprolidine
Significantly sedating	Alimemazine, Bromazepam, Carbinoxamine, Dimenhydrinate, Diphenhydramine, Doxylamine, Hydroxyzine, Promethazine, Trimeprazine
Topical use (mainly)	Antazoline, Azelastine, Emedastine, Epinastine, Levocabastine, Olopatadine

*Important QT prolongation known to occur (astemizole, terfenadine), or may possibly occur (ebastine, mizolastine), see Table 15.2, p. 583

Table 15.2 Metabolism and cardiac effects of non-sedating antihistamines

Drug	Drug blocks the HERG [†] potassium channel in vitro	QTc interval prolongation shown in pharmacological studies with drug alone	QTc interval prolongation shown in pharmacological studies with CYP3A4 inhibitors	Case reports of torsade de pointes with drug alone	Case reports of torsade de pointes with CYP3A4 inhibitors
Metabolised by CYP3A4					
Astemizole	Yes ¹	Yes ²	Yes. See Azoles, p. 584	Several ²⁻⁸	Yes. See Azoles, p. 584, or Macrolides, p. 589

Antihistamines + Azoles

The azole antifungals raise the levels of astemizole and terfenadine, which can result in life-threatening arrhythmias. Arrhythmias have been reported for astemizole with ketoconazole, and terfenadine with itraconazole, ketoconazole, and even topical oxiconazole. Consequently all azoles are contraindicated with astemizole and terfenadine.

Ketoconazole increases mizolastine levels, which resulted in some QT prolongation in one study, therefore all azoles are contraindicated. The manufacturers of ebastine advise caution with ketoconazole and itraconazole as ketoconazole raises ebastine levels. The manufacturers of acrivastine advise caution with azoles due to a lack of data.

The situation with loratadine and ketoconazole is unclear as one study found that concurrent use caused a small increase in the QT interval.

Ketoconazole raises the levels of desloratadine, emedastine, fexofenadine but as no adverse cardiac effects were seen these combinations are considered safe. No interaction occurs between ketoconazole and azelastine, cetirizine, intranasal levocabastine, and none is expected with levocetirizine.

Clinical evidence

The effect of various azole antifungals on the plasma levels of the non-sedating antihistamines, and their cardiac effects from controlled studies are summarised in 'Table 15.3', (p.585). The subsections below include data from case reports and further studies.

A. Astemizole

(a) Ketoconazole

A 63-year old woman developed torsade de pointes arrhythmia and was found to have a prolonged QT interval after taking astemizole and ketoconazole. These two drugs were withdrawn and she was successfully treated with a temporary pacemaker, magnesium sulphate and lidocaine. She was later discharged with a normal ECG.¹

(b) Miconazole

An *in vitro* study using human liver microsomal enzymes and ¹⁴C-labelled compounds found that miconazole inhibits the metabolism of astemizole. On the basis of the values obtained it has been predicted that a clinically relevant interaction could occur *in vivo*.²

B. Desloratadine

A chemotherapy patient developed severe pruritus and was given desloratadine and clemastine. Because of a pyrexia of unknown origin she was treated with meropenem and then 48 hours later fluconazole was added. After about 36 hours severe hepatotoxicity was detected, and apart from the anti-infectives the other drugs were stopped. Liver parameters recovered over the following week. Because the patient had previously received clemastine and fluconazole without problems, this case was attributed to a possible interaction between fluconazole and desloratadine.³

C. Ebastine

One *animal* study showed that ebastine given with ketoconazole had a similar potential for QTc prolongation as terfenadine given with ketoconazole. The potential was greater than that for loratadine, which was not considered to have a significant effect.⁴ A review of the safety of ebastine cites two studies assessing the potential interaction between ebastine and ketoconazole. One, a single dose study, found that the combination did not affect the QTc interval, whereas in a multiple dose study the QTc interval was prolonged by 18.1 milliseconds by the combination.⁵

D. Fexofenadine

(a) Itraconazole

In a single dose study, administration of itraconazole 200 mg one hour prior to fexofenadine 180 mg increased the AUC of fexofenadine 2.3-fold, and 3-fold in two groups of subjects of different genotypes for the gene encoding P-glycoprotein. Itraconazole pretreatment increased the effect of fexofenadine on histamine-induced wheal and flare reaction.⁶

(b) Ketoconazole

Fexofenadine has no effect on the pharmacokinetics of ketoconazole.⁷

E. Loratadine

In one study⁸ the cardiac effects of loratadine were found to be similar to those of ebastine (see C. above), which caused a small increase in the QT interval. However, loratadine alone, given at 4 times the recommended dose for 90 days, had no effect on the QTc interval when compared with placebo,⁹ and *animal* studies suggest that the combination of ketoconazole and loratadine does not significantly affect the QTc interval.⁴ As at 1993, there had been no cases of torsade de pointes reported during worldwide clinical use of loratadine,⁹ but see also 'Table 15.2', (p.583).

F. Terfenadine

(a) Fluconazole

By January 1993 no clinically significant interactions between terfenadine and fluconazole had been reported to the FDA.¹⁰

(b) Itraconazole

A 26-year-old woman taking 60 mg terfenadine twice daily began to have fainting episodes on the third evening after starting to take itraconazole 100 mg twice daily for vaginitis. When admitted to hospital the next morning her ECG showed a QT interval of 580 milliseconds and her heart rate was 67 bpm. Several episodes of torsade de pointes were recorded, and she fainted during two of them. No arrhythmias were seen 20 hours after the last itraconazole dose, and her QT interval returned to normal after 3 days. She was found to have terfenadine levels of 28 nanograms/mL in the first sample of serum taken (normally less than 5 nanograms/mL) and she still had levels of 12 nanograms/mL about 60 hours after taking the last tablet.^{11,12} Two other similar cases have been reported,^{13,14} and the FDA has received four well-documented cases of severe cardiac complications due to this interaction.¹⁵

(c) Ketoconazole

A 39-year-old woman taking terfenadine 60 mg twice daily developed a number of episodes of syncope and light-headedness, preceded by palpitations, dyspnoea and diaphoresis, within 2 days of starting to take ketoconazole 200 mg twice daily. ECG monitoring revealed torsade de pointes and a QTc interval of 655 milliseconds. Her terfenadine serum levels were 57 nanograms/mL (levels expected to be 10 nanograms/mL or less). Other drugs being taken were cefaclor (stopped 3 to 4 days before the problems started) and medroxyprogesterone acetate. She had taken terfenadine and cefaclor on two previous occasions in the absence of ketoconazole without problems.^{16,17} Other cases of an interaction between terfenadine and ketoconazole have also been reported.^{18,19}

(d) Oxiconazole

A 25-year-old woman complained of palpitations and chest pain radiating down her left arm, and was also found to be having frequent ventricular premature beats in a pattern of bigeminy. On questioning it turned out that she was taking terfenadine and using topical oxiconazole for ringworm on her arm. Both drugs were stopped and her symptoms disappeared the following week.²⁰

Mechanism

In vitro studies have shown that ketoconazole inhibits the metabolism of astemizole.²¹ Ketoconazole, and to a lesser extent itraconazole and miconazole,^{2,21} also appear to reduce the metabolism of terfenadine by inhibition of the cytochrome P450 isoenzyme CYP3A.²¹⁻²³ High serum levels of astemizole and terfenadine (but not its metabolites) block cardiac potassium channels leading to prolongation of the QT interval, which may precipitate the development of torsade de pointes arrhythmia (see 'Table 15.2', (p.583)). The risk of cardiac arrhythmias with other non-sedating antihistamines appears to be non-existent or very much lower (see 'Table 15.2', (p.583)), so any pharmacokinetic interactions do not result in clinically relevant cardiac toxicity. In fact, studies have shown that desloratadine at nine times the recommended dose,²⁴ fexofenadine in overdose,^{7,25} and mizolastine at four times the recommended dose²⁶ do not affect the QT interval. However, some questions remain about loratadine and ebastine. Additionally, some studies have reported that ketoconazole alone is associated with a small increase in QT interval,⁸ and at least one case of torsade de pointes has been reported for ketoconazole alone.²⁷ Therefore the cardiac effects of ketoconazole may be additive with those of the antihistamines, and this may be important for ebastine and loratadine.

Table 15.3 Summary of the effects of azoles on the pharmacokinetics and cardiovascular effects of non-sedating antihistamines

Antihistamine (Oral unless specified)	Azole (Oral unless specified)	Duration of combined use (days)	Subjects	C _{max} increase [‡]	AUC increase	Effect on QTc	Refs
Astemizole* 10 mg single dose	Itraconazole 200 mg twice daily	Single dose	12 healthy subjects	No change	82%	No change	1
Azelastine* 4 mg twice daily	Ketoconazole 200 mg twice daily	7	12 healthy subjects	Not determined. In vitro tests suggest no change likely.	Not determined. In vitro tests suggest no change likely.	No change	2
Cetirizine 20 mg daily	Ketoconazole 400 mg daily	10	Healthy subjects	No change	No change	No change	3
Desloratadine 7.5 mg daily	Ketoconazole 200 mg twice daily	10	24 healthy subjects	27%	21%	No change	4
Ebastine 20 mg daily	Ketoconazole 400 mg daily	8	55 healthy subjects	16-fold	42-fold	Mean increase of 5.25 milliseconds when antihistamine added to ketoconazole. Mean increase of 12.21 milliseconds from baseline. QTc did not exceed 500 milliseconds in any subject. [†]	5
Emedastine 4 mg daily	Ketoconazole 200 mg twice daily	5	12 healthy subjects	37%	34%	No change	6
Fexofenadine 120 mg twice daily	Ketoconazole 400 mg daily	7	24 healthy subjects	135%	164%	No change	7
Levocabastine 200 micrograms twice daily intranasal	Ketoconazole 200 mg single dose	Single dose	37 subjects	No change	No change	No change	8
Loratadine 20 mg single dose	Ketoconazole 200 mg twice daily	Single dose	12 healthy subjects	144% Loratadine 33% Desloratadine	184% Loratadine 54% Desloratadine		9
Loratadine 10 mg daily	Ketoconazole 200 mg twice daily	10	24 healthy subjects	172% Loratadine 76% Desloratadine	247% Loratadine 82% Desloratadine	No change	10
Loratadine 10 mg daily	Ketoconazole 400 mg daily	8	62 healthy subjects	248% Loratadine 82% Desloratadine	346% Loratadine 94% Desloratadine	Mean increase of 3.16 milliseconds when antihistamine added to ketoconazole. Mean increase of 10.68 milliseconds from baseline. QTc did not exceed 500 milliseconds in any subject. [†]	5
Mizolastine 10 mg single dose	Ketoconazole 100 mg, 200 mg, 400 mg single doses	Single dose	12 healthy subjects		45%, 61% and 95% respectively		11
Mizolastine 10 mg daily	Ketoconazole 200 mg twice daily	5				Mean increase of 7 milliseconds over mizolastine or placebo alone. None exceeded 500 milliseconds	12
Terfenadine* 60 mg twice daily	Fluconazole 200 mg daily	6	6 healthy subjects		No change Terfenadine 34% Terfenadine acid metabolite	No change	13
Terfenadine* 60 mg twice daily	Fluconazole 800 mg daily	7	Note - 6 subjects previously found to have measurable terfenadine levels at steady state		52% Terfenadine 5% Terfenadine acid metabolite	Increase	14

Continued

Table 15.3 Summary of the effects of azoles on the pharmacokinetics and cardiovascular effects of non-sedating antihistamines (continued)

Antihistamine (Oral unless specified)	Azole (Oral unless specified)	Duration of combined use (days)	Subjects	C _{max} increase [‡]	AUC increase	Effect on QTc	Refs
Terfenadine* 120 mg single dose	Itraconazole 200 mg daily	Single dose	6 healthy subjects	Terfenadine 25%, 115%, 156% in the 3 subjects who had measurable levels prior to itraconazole	30% Terfenadine acid metabolite	Mean increase of 27 milliseconds when compared to terfenadine alone	15
Terfenadine* 120 mg single dose	Ketoconazole 400 mg daily	Single dose	12 healthy subjects	≥170% Terfenadine ↓71% Terfenadine acid metabolite		Prolongation by 10 to 20 milliseconds	16,17
Terfenadine* 60 mg twice daily	Ketoconazole 200 mg twice daily	4 to 7	6 healthy subjects	<5 to 7 nanograms/mL Terfenadine levels increased to 81 nanograms/mL in one subject	57% Terfenadine acid metabolite	Mean increase of 74 milliseconds	18

*Cases of torsade de pointes have been reported for this antihistamine

[†]QTc intervals calculated using the Fridericia cube root formula, rather than the more commonly used Bazett square root formula, which the authors suggest would lead to a 5 to 6 millisecond overestimation

[‡]Note that terfenadine levels are normally undetectable

Fexofenadine is not metabolised by CYP3A4, but it is a substrate for P-glycoprotein and OATP,²⁸ therefore azole antifungals may increase its levels by inhibiting drug transporter proteins.

Importance and management

The interactions of astemizole with ketoconazole, and terfenadine with itraconazole or ketoconazole are established and clinically important, although much of the evidence for them is indirect. Astemizole would also be expected to interact similarly with itraconazole. The risk of an interaction with terfenadine or astemizole and other azole antifungals seems smaller.

The incidence of an interaction is probably low, but because of the potential severity and unpredictability of this interaction, the concurrent use of astemizole and terfenadine is contraindicated with all azole antifungals

in all patients. This is a recommendation of the manufacturers^{29,30} and the CSM in the UK.³¹ The manufacturer of terfenadine extends this contraindication to the concurrent use of topical azoles.³⁰

The use of azole antifungals with mizolastine is also contraindicated,³² and the manufacturer of ebastine advises against the concurrent use of ketoconazole and itraconazole.³³ Because there are no data on **acrivastine** with ketoconazole, the manufacturer advises caution.³⁴

Ketoconazole markedly raises loratadine levels. In one study, this was associated with a small increase in QT interval, but no obvious alteration in adverse event profile. No special precautions appear to have been recommended for the use of loratadine with azoles.

Desloratadine, emedastine and fexofenadine levels are raised by ketoconazole but because this does not result in adverse cardiac effects concurrent use is considered safe. Azelastine, cetirizine (and therefore probably

its isomer **levocetirizine**) and levocabastine seem to be free from clinically significant pharmacokinetic interactions, and have no cardiac effects, and so may therefore provide suitable alternatives if a non-sedating antihistamine is needed in a patient taking azole antifungals.

Antihistamines + Benzodiazepines and related drugs

Benzodiazepines impair psychomotor performance, but neither ebastine nor mizolastine (both non-sedating antihistamines) further impair this. An enhanced sedative effect would be expected if known sedative antihistamines are given with benzodiazepines. Diphenhydramine did not alter the pharmacokinetics of zaleplon.

Clinical evidence

(a) Diphenhydramine

A randomised single dose three-period crossover study in healthy subjects found that diphenhydramine 50 mg had no significant effect on the pharmacokinetics of a single 10-mg dose of **zaleplon**, despite the fact diphenhydramine is a moderate inhibitor of the primary metabolic pathway [aldehyde oxidase] of **zaleplon**.¹

(b) Ebastine

Ebastine 20 mg daily did not impair the performance of a number of psychomotor tests in 12 healthy subjects, although body sway and flicker fusion tests were altered. When ebastine was given with a single 15-mg dose of **diazepam**, it did not further impair performance compared with diazepam alone, and did not alter plasma **diazepam** levels.²

(c) Mizolastine

Mizolastine appears to lack sedative effects, and does not have a detrimental effect on psychomotor performance.³ A single 2-mg dose of oral **lorazepam** was found to impair the performance of psychomotor tests in 16 healthy subjects, and caused some sedation and amnesia, but these effects were not changed when the subjects also took mizolastine 10 mg daily for 8 days.³

Mechanism, importance and management

A number of older antihistamines cause sedation, and this would be expected to be increased by some of the benzodiazepines by the simple addition of their CNS depressant effects. Non-sedating antihistamines would not be expected to have this effect (but see also 'Antihistamines', (p.582)), and this has been confirmed for ebastine and mizolastine.

Antihistamines + Drugs that prolong the QT interval

Astemizole and terfenadine should generally not be used with other drugs that can also prolong the QT interval. The manufacturer of mizolastine issues the same advice. One early study found that hydroxyzine caused ECG abnormalities in high doses. The authors suggested that its use with other drugs that can cause cardiac abnormalities might increase the likelihood of arrhythmias and sudden death, but there is no published evidence of this.

Clinical evidence, mechanism, importance and management

(a) Non-sedating antihistamines

The manufacturers of **astemizole**¹ and **terfenadine**² contraindicate the concurrent use of any other drugs that can also prolong the QT interval (for a list, see 'Table 9.2', (p.257)). However, note that the primary risk of QT prolongation and torsade de pointes arrhythmia with **astemizole** and **terfenadine** appears to be from drugs that significantly inhibit their metabolism (e.g. 'azoles', (p.584) and 'macrolides', (p.589)). Clinically relevant QT prolongation has not yet been shown conclusively for any of the other antihistamines (see 'Table 15.2', (p.583)), although the manufacturers of **mizolastine**³ still contraindicate its use with drugs that prolong the QT interval. Isolated cases have been described with other antihistamines: a case of torsade de pointes has been attributed to the concurrent use of amiodarone and '**loratadine**', (p.246); a case report of torsade de pointes with sotalol and '**terfenadine**', (p.859) was attributed solely to additive effects of QT prolongation with these drugs; and a small additional QT-prolonging effect has also been shown when **terfenadine** was given with 'sparfloxacin', (p.593).

Consider also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

(b) *Sedating antihistamines*

A study, conducted in 1958, in 25 elderly psychotic patients taking high-dose **hydroxyzine** 300 mg daily over a 9-week period found that ECG changes were mild, except for an alteration in T waves, which were definite in 9 patients. In each case the T waves were lower in altitude, broadened and flattened and sometimes notched. The QT interval was usually prolonged. A repeat of the study in a few patients, at least one given **hydroxyzine** 400 mg, found similar effects, the most pronounced change being a marked attenuation of cardiac repolarisation. On the basis of these observations the authors suggest that other drugs that cause ECG abnormalities such as thioridazine might aggravate and exaggerate these **hydroxyzine**-induced changes and increase the risk of sudden death.⁴ However, note that in the decades of use of **hydroxyzine** since this study was conducted there appear to be only a few isolated reports of arrhythmias (tachycardia) associated with its use.^{5,6} Note also that some manufacturers do not give any warnings regarding the use of **hydroxyzine** in patients with cardiac disorders, nor are any cardiac adverse effects mentioned, even for overdose.^{7,8} However, one manufacturer does suggest that caution is necessary in patients pre-disposed to arrhythmias, or on drugs that may cause arrhythmias.⁹

Antihistamines + Grapefruit and other fruit juices

Grapefruit juice raises terfenadine levels, increasing the risk of QT interval prolongation and torsade de pointes arrhythmias. Grapefruit juice does not appear to alter the pharmacokinetics of astemizole and desloratadine. The absorption of fexofenadine is modestly reduced by grapefruit juice, orange juice and apple juice.

Clinical evidence

(a) *Astemizole*

In a study in 12 healthy subjects the steady-state pharmacokinetics of astemizole (30 mg daily for 4 days, then 10 mg daily for the next 20 days), were unaffected by 800 mL of **grapefruit juice** (given as 200 mL every 4 hours).¹

(b) *Desloratadine*

The bioavailability of a single 5-mg dose of desloratadine was unaffected by 8 oz (240 mL) of double-strength **grapefruit juice**, which was given three times daily for 2 days preceding the desloratadine and then 5 minutes before and 2 hours after the dose.²

(c) *Fexofenadine*

In a study in 23 healthy subjects the AUC of fexofenadine 60 mg was reduced by 30% by double-strength **grapefruit juice** (8 oz or 240 mL), which was given three times daily for 2 days before the fexofenadine and then 5 minutes before and 2 hours after the dose.² Similarly, another study found that **grapefruit juice** at normal strength decreased the AUC of a single 120-mg dose of fexofenadine by 67%. Dilute **grapefruit juice** (25%) caused a smaller reduction of 23%. Normal strength **orange juice** and **apple juice** similarly decreased the AUC of fexofenadine by 72% and 77% respectively.³ In this study, 300 mL of juice was given with the fex-

ofenadine, followed by 150 mL every half an hour to a total volume of 1.2 L. A subsequent study found that a single 300 mL dose of normal strength **grapefruit juice** reduced the AUC of a single 120-mg dose of fexofenadine by 42% when they were given simultaneously.⁴ An effect was apparent for 300 mL of **grapefruit juice** given up to 10 hours prior to fexofenadine 120 mg in at least some of 12 subjects involved in this study.⁵

(d) *Terfenadine*

Terfenadine 60 mg was given to 6 healthy subjects every 12 hours for 14 days, given simultaneously with 240 mL of double-strength **grapefruit juice** every 12 hours for the final 7 days. Terfenadine was only detectable in the plasma when **grapefruit juice** was taken. The mean QTc interval was found to have risen from 420 to 434 milliseconds,⁶ which is not of a magnitude usually considered to be clinically significant. The effects were less pronounced in a further 6 subjects who took the **grapefruit juice** 2 hours after the terfenadine.⁶ Several other reports confirm these pharmacokinetics findings, although some did not find any changes in the QTc interval.^{7–9}

Mechanism

Not fully understood, but it seems likely that some component of grapefruit juice inhibits the metabolism of the terfenadine to its active metabolite (by the cytochrome P450 isoenzyme CYP3A4), so that the parent drug accumulates.⁸ Terfenadine, but not its metabolite, causes QTc prolongation. Increased QTc intervals are associated with the development of ventricular tachycardia and torsade de pointes arrhythmias, which are potentially life-threatening.

Fexofenadine is a substrate for P-glycoprotein, and organic anion transporting polypeptide (OATP), both of which affect fexofenadine uptake. OATP in particular may be inhibited by grapefruit juice, apple juice, and orange juice, so these juices may reduce fexofenadine levels by preventing its absorption.³

Importance and management

The interaction between terfenadine and grapefruit juice is established and potentially clinically important. However, the serious cardiac effects may only occur in a small subset of individuals. As of 1996 neither the FDA nor the CSM appeared to have reports of problems in patients that were attributable to the use of antihistamines and grapefruit juice,^{7,10} although in 1997 the CSM had one report of a probable interaction with terfenadine.¹¹ Nevertheless because of the risk of serious cardiotoxicity (however small) it would be prudent for all patients taking terfenadine to avoid grapefruit juice. At least one manufacturer of terfenadine contraindicates grapefruit juice.¹²

The evidence from healthy subjects suggests that astemizole does not interact, but it is possible that individuals predisposed to cardiac conduction disorders are at risk.

Further study is required to determine the clinical relevance, if any, of the reductions in fexofenadine bioavailability in the presence of grapefruit juice, orange juice, and apple juice. Consider this interaction as the cause if fexofenadine seems less effective than expected.

Desloratadine appears to be a safe alternative.

Antihistamines + H₂-receptor antagonists

No pharmacokinetic interaction appears to occur when cimetidine is given with cetirizine, desloratadine, ebastine or terfenadine, or when ranitidine is given with terfenadine or chlorphenamine. However, an isolated case report describes torsade de pointes in one patient taking terfenadine with cimetidine. Cimetidine moderately raises hydroxyzine levels and considerably raises loratadine levels, but this is not thought to be of clinical significance. The renal clearance of fexofenadine was reduced by cimetidine in one study although there was no change in plasma pharmacokinetics.

Clinical evidence

A. Non-sedating antihistamines

(a) Cetirizine

Cetirizine 10 mg was given to 8 patients with chronic urticaria before and after they took cimetidine 600 mg every 12 hours for 10 days. The pharmacokinetics of cetirizine were statistically unaltered and its effects remained unchanged.¹

(b) Desloratadine

In a parallel study in 18 healthy subjects, cimetidine 600 mg every 12 hours had little effect on the pharmacokinetics of desloratadine 5 mg daily. The desloratadine AUC increased by about 20% and the maximum level by about 10%,^{2,3} but there was no change in ECG parameters including the QTc interval.²

(c) Ebastine

In a study in 12 healthy subjects cimetidine had no significant effect on the conversion of single 20-mg doses of ebastine to its active metabolite carebastine, and there was no evidence of sedation or other adverse effects. In this study cimetidine was given as 2 g in divided doses the day before the ebastine dose and 400 mg four times daily both on the day of and the day after the ebastine dose.⁴

(d) Fexofenadine

Cimetidine 400 mg twice daily for 6 days did not cause any changes in the plasma pharmacokinetics of a single 120-mg dose of fexofenadine in 12 healthy subjects. However, the renal clearance of fexofenadine was decreased by 39%.⁵

(e) Loratadine

Loratadine 10 mg and cimetidine 300 mg every 6 hours were given alone and together to 24 healthy subjects for 10 days. The AUCs of loratadine and its metabolite were increased by 103% and 6% respectively, but the safety profile of the loratadine (clinical laboratory tests, vital signs and adverse events) were unchanged. Cardiac repolarisation and all other ECG measurements were unaltered, and no sedation or syncope were seen.⁶

(f) Terfenadine

Cimetidine 1.2 g daily for 5 days had no effect on the pharmacokinetics of a single 120-mg dose of terfenadine in 12 healthy subjects.⁷ Another study in two groups of 6 healthy subjects confirmed that cimetidine 600 mg every 12 hours or ranitidine 150 mg every 12 hours had no effect on the pharmacokinetics of terfenadine 60 mg every 12 hours. No adverse ECG changes were seen.⁸ However, an isolated case report describes a 63-year-old woman who had 8 episodes of syncope (later identified as being due to torsade de pointes) and a convulsion 2 days after starting terfenadine 60 mg twice daily and cimetidine 400 mg twice daily. She was also taking chlorphenamine and co-proxamol (paracetamol (acetaminophen) and dextropropoxyphene (propoxyphene)).⁹

B. Sedating antihistamines

(a) Chlorphenamine

A study in healthy subjects found that the pharmacokinetics of a single 4-mg dose of racemic chlorphenamine were unaffected by ranitidine 75 mg twice daily for 6 days.¹⁰

(b) Hydroxyzine

In one study, 8 patients with chronic urticaria were given hydroxyzine 25 mg before and after taking cimetidine 600 mg every 12 hours for 10 days. The cimetidine increased the AUC of hydroxyzine by 33% and also increased its suppression of the wheal and flare response (although this was not statistically significant).¹ A previous study in 7 patients found that cimetidine raised serum hydroxyzine levels.¹¹

Mechanism

Cimetidine is a non-specific cytochrome P450 isoenzyme inhibitor, but it would seem that in most cases, with the exception of loratadine, these enzyme inhibitory effects do not significantly affect the metabolism of antihistamines. More recent evidence has shown cimetidine can also affect drug transporter proteins, in particular it may inhibit organic cation transporters. However, it probably does not affect anion transporter proteins since it does not affect the plasma pharmacokinetics of fexofenadine, which is a substrate of these transporters.⁵

Importance and management

There would seem to be no good reason for avoiding the concurrent use of either cetirizine, ebastine, fexofenadine, hydroxyzine, or loratadine with cimetidine, or chlorphenamine with ranitidine, nor would any of the other H₂-receptor antagonists be expected to interact with any of these antihistamines.

The situation with terfenadine and cimetidine is not totally clear because of the isolated case report of toxicity cited here, but currently there is not enough evidence to advise against the use of these two drugs. The manufacturer of mizolastine recommends caution with concurrent cimetidine on the basis that cimetidine might increase mizolastine levels and prolong the QT interval.¹² This is a cautious approach since a link between mizolastine and cardiac arrhythmias has not been proven.

Antihistamines + Macrolides

Erythromycin causes terfenadine and astemizole to accumulate in a few individuals, which can prolong the QT interval and lead to life-threatening torsade de pointes arrhythmias. Cases of torsade de pointes have been reported for astemizole with erythromycin, and terfenadine with erythromycin or troleandomycin. Other macrolides are believed to interact similarly, with the exception of azithromycin and possibly dirithromycin. Erythromycin modestly raises mizolastine levels, although this had no effect on the QT interval. Nevertheless, the manufacturers of mizolastine contraindicate erythromycin. Erythromycin markedly raised ebastine levels, which caused a modest prolongation of the QT interval. The manufacturers of ebastine advise against the

concurrent use of erythromycin, clarithromycin and josamycin. Because there is no information for acrivastine, the manufacturer advises caution.

There is a case of torsade de pointes possibly due to spiramycin with the sedating antihistamine mequitazine. The situation with erythromycin and loratadine is unclear as one study found that the combination caused a very slight increase in QT interval. Both azithromycin and erythromycin raise fexofenadine levels, but this had no effect on the QT interval, or on adverse events. Azelastine, cetirizine, desloratadine, and intranasal levocabastine seem to be free of clinically relevant interactions with macrolides.

Clinical evidence

The effect of various macrolides on the plasma levels of the non-sedating antihistamines, and their cardiac effects from controlled studies are summarised in 'Table 15.4', (p.591). The subsections below include data from case reports and other studies.

(a) Astemizole

1. *Azithromycin*. The manufacturers of astemizole report that an *in vivo* study has shown that azithromycin had a negligible effect on the bioavailability of astemizole.¹

2. *Erythromycin*. An 87-year-old woman collapsed suddenly in her kitchen 4 days after starting to take astemizole 10 mg daily and erythromycin twice daily [dose unknown]. An ECG showed her to be having multiple episodes of torsade de pointes arrhythmias, the longest of which lasted 17 seconds. Her QTc was 720 milliseconds and she was mildly hypokalaemic. She was given a temporary pacemaker and when she was eventually discharged with a normal sinus rhythm, her QTc had fallen to 475 milliseconds.²

(b) Loratadine

A study of loratadine alone in 50 healthy subjects found that 40 mg of loratadine daily (four times the recommended dose) for 90 days caused no changes in the ECG measurements, no episodes of dizziness or syncope, and no arrhythmias,³ but see also 'Table 15.2', (p.583).

(c) Mequitazine

A 21-year-old woman with a congenital long QT syndrome had several syncopal attacks, one at least of which was caused by torsade de pointes. This was attributed to the concurrent use of mequitazine and spiramycin over a 2-day period. The problem resolved when the drugs were withdrawn.⁴

(d) Terfenadine

1. *Erythromycin*. A 18-year-old girl who was taking terfenadine 60 mg twice daily and erythromycin 250 mg every 6 hours, fainted while at school and, when later hospitalised, was seen to have repeated episodes of ventricular tachycardia and ventricular fibrillation requiring resuscitation. Later she was also noted to have torsade de pointes. Her QTc interval was found to be prolonged at 630 milliseconds. The drugs were withdrawn and 9 days later, after a period in intensive care, she was discharged symptom-free with a normal QTc interval.⁵

In contrast, a retrospective report found no documented cardiac adverse events in 92 patients who had received erythromycin and terfenadine.⁶

2. *Troleandomycin*. The manufacturers of terfenadine have on record a case of a woman, with a history of aortic valve disease, who had an episode of torsade de pointes arrhythmia while taking troleandomycin. She had taken more than the maximum recommended dose of terfenadine.⁷ Another woman taking terfenadine 60 mg three times daily developed torsade de pointes arrhythmia and a prolonged QTc interval when troleandomycin 500 mg three times daily was added. She recovered when both were stopped, but again developed a significantly prolonged QTc interval when both were restarted.⁸

Mechanism

Some macrolides (particularly erythromycin and clarithromycin) appear to reduce the metabolism of terfenadine and astemizole by inhibition of the cytochrome P450 isoenzyme CYP3A.^{9,10} High serum levels of astemizole and terfenadine cause a prolongation of the QT interval and may precipitate the development of torsade de pointes arrhythmia, see 'Table 15.2', (p.583). The risk of cardiac arrhythmias with other non-sedating antihistamines appears to be non-existent or very much lower (see 'Table

15.2', (p.583)), so any pharmacokinetic interactions do not result in clinically relevant cardiac toxicity. In fact, studies have shown that fexofenadine in overdose,^{11,12} and mizolastine at four times the recommended dose¹³ do not affect the QT interval. However, some questions remain about mizolastine and ebastine.

The increased levels of fexofenadine with erythromycin may be due to increased absorption and decreased biliary secretion,¹² via an effect on drug transporters.

Importance and management

The interactions of terfenadine with erythromycin, clarithromycin, and troleandomycin; and astemizole with erythromycin are established, clinically important and potentially hazardous. From the reports above it does seem that only a very few individuals develop a clinically important adverse interaction with these macrolides, but identifying them in advance is not often practical or possible. Because of the unpredictability and potential severity of this interaction, the FDA,⁶ the CSM¹⁴ in the UK and the manufacturers of terfenadine¹⁵ and astemizole¹ now contraindicate macrolides in anyone taking terfenadine or astemizole. The only exception to this is azithromycin with astemizole.¹ The manufacturer of terfenadine extends this contraindication to the concurrent use of topical macrolides.¹⁵

The manufacturers of mizolastine also contraindicate the concurrent use of the macrolides,¹⁶ despite any evidence of a significant interaction. Erythromycin markedly raises ebastine levels causing a modest increase in QT interval. The manufacturer of ebastine advises against concurrent use of the macrolides erythromycin, clarithromycin and josamycin.¹⁷ Erythromycin also raises loratadine levels, which caused a very slight increase in QTc interval in one study. However, no special precautions appear to have been recommended for the use of loratadine with macrolides. Because there are no data on acrivastine with erythromycin, the manufacturer advises caution.¹⁸

Fexofenadine levels are raised by both azithromycin and erythromycin but because this does not result in adverse cardiac effects concurrent use is considered safe. Azelastine, cetirizine (and therefore probably its isomer levocetirizine) desloratadine and levocabastine seem to be free from clinically significant pharmacokinetic interactions, and have no cardiac effects, and so may therefore provide suitable alternatives if a non-sedating antihistamine is needed in a patient taking macrolides.

The isolated case with mequitazine is unlikely to be of general importance, since this sedating antihistamine is not usually associated with causing ventricular arrhythmias.

Antihistamines + Nefazodone

Nefazodone inhibits the metabolism of terfenadine and thereby prolongs the QT interval. This combination should be avoided. There is also some evidence that the combination of nefazodone and loratadine increases the QT interval, although to a lesser extent than terfenadine. *In vitro* evidence suggests nefazodone will also inhibit the metabolism of astemizole.

Clinical evidence, mechanism, importance and management

(a) Astemizole

The manufacturers of nefazodone and astemizole say that an *in vitro* study suggests that nefazodone may increase astemizole levels, and so concur-

rent use is contraindicated.^{1,2} The advice to avoid the combination would seem prudent since raised levels of astemizole with other inhibitors of CYP3A4 such as the ‘macrolides’, (p.589), have been rarely associated with life-threatening torsade de pointes arrhythmias.

(b) Loratadine

A randomised, placebo-controlled study in healthy subjects found that when they were given nefazodone 300 mg twice daily with loratadine 20 mg once daily, the loratadine AUC was increased by 39%. Similarly, the QTc interval was increased by 21.6 milliseconds by the combination, which was about half the increase seen with terfenadine 60 mg twice daily given with the same dose of nefazodone. Neither nefazodone, loratadine nor terfenadine alone prolonged the QTc interval.³ The findings for loratadine in this study were unexpected, since this antihistamine was considered to have no clinically relevant effect on the QT interval (but see also ‘Table 15.2’, (p.583)). The use of the Bazett formula to calculate QTc has

been questioned,⁴ but this is the most commonly used formula, and any overestimation would also apply to terfenadine. This appears to be the only study to have directly compared loratadine with terfenadine, and although it shows that loratadine at twice the recommended dose has half the QT-prolonging effect of terfenadine (at the maximum recommended dose), it nevertheless raises questions about the cardiac safety of loratadine.^{4,5} Further study is needed.

(c) Terfenadine

In a randomised, placebo-controlled study, healthy subjects were given nefazodone 300 mg twice daily and terfenadine 60 mg twice daily, given alone and in combination. Nefazodone increased the AUC of terfenadine by about fivefold, which was associated with a mean increase in the QTc interval of 42.4 milliseconds. This was considered to result in a clinically significant, increase in the risk of torsade de pointes arrhythmias.³ Studies using human liver microsomes found that nefazodone is a moderately weak inhibitor of the CYP3A4-mediated *N*-dealkylation and *C*-hydroxylation of terfenadine.⁶ Nefazodone is contraindicated with terfenadine,^{1,7} and it has been suggested that this explains the lack of clinical reports.⁶

Antihistamines + Protease inhibitors

Nelfinavir markedly increases terfenadine levels, which is expected to increase the risk of QT prolongation and torsade de pointes arrhythmias. Other protease inhibitors are predicted to interact similarly with both terfenadine and astemizole, and concurrent use is contraindicated. Ritonavir modestly increases cetirizine levels, and *in vitro* data suggests that saquinavir will have a similar effect, but this is not considered to be clinically relevant. Based on *in vitro* data, ritonavir is predicted to markedly raise fexofenadine levels, but this may not be of any clinical relevance.

Clinical evidence, mechanism, importance and management

(a) Astemizole

Protease inhibitors are inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which astemizole is metabolised. On the basis of the interaction of astemizole with other CYP3A4 inhibitors, such as the ‘azoles’, (p.584), the concurrent use of astemizole with any protease inhibitor is contraindicated.¹ This seems a sensible precaution.

(b) Cetirizine

In a study in 16 healthy subjects the concurrent use of cetirizine 10 mg daily and **ritonavir** 600 mg twice daily for 4 days (after reaching steady-state **ritonavir** levels), increased the AUC of cetirizine by 42% with a slight 9% increase in maximum plasma levels. It was suggested that **ritonavir** may have decreased the renal excretion of cetirizine. The increase in cetirizine levels was not considered to be clinically relevant. **Ritonavir** pharmacokinetics were minimally affected by cetirizine.²

(c) Fexofenadine

An *in vitro* study showed that **ritonavir** markedly reduced the transport of fexofenadine, thought to be via inhibition of P-glycoprotein.³ This would be predicted to markedly increase the bioavailability of fexofenadine, as occurs with verapamil, see ‘Calcium-channel blockers + Antihistamines’, p.861. However, the similar marked increases in fexofenadine levels that occurred with ‘erythromycin’, (p.589) and ‘ketoconazole’, (p.584) did not increase adverse effects and were not associated with any prolongation of the QT interval. This suggests that a clinically relevant interaction between **ritonavir** and fexofenadine is not expected.

(d) Terfenadine

Nelfinavir 750 mg every 8 hours for 5 days raised the levels of a single 60-mg dose of terfenadine from less than 5 nanograms/mL to a range of 5

to 15 nanograms/mL. The pharmacokinetics of **nelfinavir** were unaffected.⁴ This rise in terfenadine levels is predicted to prolong the QT interval, and to increase the risk of torsade de pointes arrhythmias. In an *in vitro* study, **saquinavir** was a potent inhibitor of the metabolism of **terfenadine**.⁵ Note that **saquinavir** is the least potent CYP3A4 inhibitor of the protease inhibitors. On the basis of *in vitro* study, and what is known about interactions with other inhibitors of CYP3A4 such as the ‘azoles’, (p.584), all protease inhibitors are predicted to raise terfenadine levels and consequently concurrent use is contraindicated.⁶ Because of the seriousness of this reaction, and the fact that it is not possible to predict which individuals will be affected, this seems a sensible precaution.

Antihistamines + Quinolones

Studies in healthy subjects showed that there was a small additive effect on the QT interval when terfenadine was given with sparfloxacin.

Clinical evidence, mechanism, importance and management

In a single-dose, placebo-controlled study in 8 healthy subjects, **sparfloxacin** 400 mg increased the QT interval by 14 milliseconds, **terfenadine** 60 mg increased the QT interval by 7.5 milliseconds (not statistically significant), and the combination caused an additive increase of 24.7 milliseconds.¹

The effects of the combination in this study were shown to be purely additive.¹

In a placebo-controlled study 22 patients were given **sparfloxacin** 400 mg on day 1 and 200 mg on days 2 to 4 with **terfenadine** 60 mg twice a day for 7 doses. The increase in the QT interval when the two drugs were given together was additive, and no pharmacokinetic interaction was found.²

Since the effects of therapeutic doses of **terfenadine** on the QT interval are minimal, any additional effect with **sparfloxacin** would be small. Nevertheless, since torsade de pointes can cause sudden death, the combination of two drugs with the potential to prolong the QT interval is generally considered contraindicated (see ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257) and the manufacturer of **terfenadine** specifically contraindicates **sparfloxacin**.³ If an antihistamine is required in a patient taking **sparfloxacin**, one that has no effect on the QT interval should be used, for example, **cetirizine**, see ‘Table 15.2’, (p.583). Other quinolones that cause QT prolongation include **gatifloxacin** and **moxifloxacin**, see ‘Table 9.2’, (p.257), and it would also be prudent to avoid use of antihistamines that prolong the QT interval (e.g. **astemizole** and **terfenadine**) with these quinolones.

Antihistamines + SSRIs

Two isolated reports describe cardiotoxicity, which was attributed to the concurrent use of terfenadine and fluoxetine, although other evidence suggests that an interaction is unlikely. Terfenadine does not appear to interact with paroxetine or sertraline. Nonetheless, the manufacturers of both astemizole and terfenadine contraindicate the concurrent use of SSRIs. There does not

appear to be a significant interaction between desloratadine and fluoxetine. An interaction between fluoxetine and loratadine is theoretically possible, but the clinical significance of this is unclear.

Clinical evidence

A. Astemizole

The manufacturer of astemizole contraindicates the concurrent use of SSRIs because there is a risk that they will inhibit astemizole metabolism, leading to a rise in its serum levels, which could result in QT interval prolongation and the development of torsade de pointes arrhythmias.¹

B. Desloratadine

The concurrent use of desloratadine 5 mg daily and **fluoxetine** 20 mg daily for 7 days (after attainment of **fluoxetine** steady-state) had no clinically relevant effects on the pharmacokinetics of desloratadine or **fluoxetine** (changes in maximum levels and AUC were less than 15%). There was no change in ECG parameters including the QTc interval, and the combination did not increase the incidence of adverse effects.² This study was placebo-controlled and in healthy subjects who were of extensive metaboliser phenotype for CYP2D6.

C. Loratadine

Fluoxetine is an inhibitor of the cytochrome P450 isoenzymes CYP3A4 (weak inhibitor) and CYP2D6 (moderate inhibitor), by which loratadine is metabolised. Fluoxetine may therefore moderately raise loratadine levels. One study suggests that high-dose loratadine does not cause adverse cardiac adverse effects.³ However, more recent case reports and studies have cast some doubt over the cardiac safety of loratadine (see 'Table 15.2', (p.583)).

D. Terfenadine

(a) Fluoxetine

A 41-year-old man with no previous history of heart disease awoke one night short of breath, with a sensation of his heart missing beats and beating irregularly. He also experienced orthostatic hypotension on a number of occasions. However, a later ECG showed a normal sinus rhythm. He was taking daily doses of terfenadine 120 mg, fluoxetine 20 mg (started a month previously), ibuprofen 2.4 g, misoprostol 400 micrograms, *Midrin* (paracetamol (acetaminophen), dichloralphenazone, isometheptene mucate) and ranitidine 300 mg. This reaction was attributed to an interaction between fluoxetine and terfenadine. However, a few days after stopping the terfenadine, and 12 days after this episode, his cardiac rhythm as recorded by a 24-hour Holter monitor showed some minor abnormalities (intermittent sinus tachycardia, isolated premature beats), although nothing approaching the previous alarming episode.⁴ A woman taking several drugs (topical aciclovir, beclometasone, pseudoephedrine, ibuprofen) had a prolonged QTc interval of 550 milliseconds two weeks after starting terfenadine and fluoxetine, but she remained asymptomatic. Within a week of stopping the terfenadine her QTc interval had returned to normal.⁵

In contrast, 12 healthy subjects who were given a single 60-mg dose of terfenadine before and after taking fluoxetine 60 mg daily for 8 days showed no significant changes in the pharmacokinetics of terfenadine or its acid metabolite.⁶ Other *in vitro* studies with human liver microsomal enzymes confirmed that fluoxetine has only a very slight inhibitory effect on the metabolism of terfenadine, which was considered to be clinically irrelevant.⁷

(b) Paroxetine

A two-period crossover study in 11 healthy subjects given terfenadine 60 mg twice daily found that paroxetine 20 mg daily for 8 days had no effect on the AUC of terfenadine or the QTc interval. A small, clinically unimportant reduction in the levels of carboxyterfenadine was seen. It was concluded that there is no clinically relevant interaction between terfenadine and paroxetine.⁸ *In vitro* studies with human liver microsomal enzymes confirmed that paroxetine has only a very slight inhibitory effect on the metabolism of terfenadine, which is not considered to be clinically significant.⁷

(c) Sertraline

Although the CSM in the UK initially stated that terfenadine should not be used with sertraline, they subsequently reviewed the data and now consider that an interaction is unlikely.⁹

Mechanism

Not understood. An *in vitro* model study using human liver microsomal enzymes, which accurately predicted a large and potentially hazardous interaction between terfenadine and ketoconazole or itraconazole (now clinically proven—see 'Antihistamines + Azoles', p.584), found that six SSRIs (desmethylsertraline, fluoxetine, fluvoxamine, norfluoxetine, paroxetine, sertraline) at usual clinical doses were at least 20 times less potent than ketoconazole at inhibiting terfenadine metabolism.⁷ This suggests that all of these SSRIs are very unlikely to interact with terfenadine clinically, although the authors of the study warn that if high doses of SSRIs are used (particularly fluoxetine) some caution is appropriate.⁷ Astemizole is metabolised in part by the cytochrome P450 isoenzyme CYP2D6, which is inhibited to a variable extent by the SSRIs, and therefore interactions involving this isoenzyme are possible.

Importance and management

The interaction between the SSRIs and terfenadine is not adequately established, and there is little evidence regarding interactions between the SSRIs and astemizole, although it is possible that the contraindication with astemizole has contributed to minimal usage of the combination and therefore a lack of reported interactions. In addition to fluoxetine and paroxetine, the manufacturers of terfenadine list **fluvoxamine** and **citalopram** as drugs that are expected to increase terfenadine serum levels,¹⁰ but direct evidence of this seems to be lacking. Nonetheless, the manufacturer contraindicates the use of all these SSRIs with terfenadine.¹⁰ Due to the severity of the potential interaction, it would appear prudent to use caution if terfenadine is used with any SSRI (excepting perhaps sertraline), and consider an alternative antihistamine without cardiac effects (see 'Table 15.2', (p.583)), wherever possible. Desloratadine appears to be a non-interacting alternative.

The situation with loratadine is unclear, and currently all the evidence is theoretical.

Antihistamines + Terbinafine

Terbinafine does not interact with astemizole or terfenadine to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In a large scale post-marketing survey of 25,884 patients taking terbinafine, over 40% were taking at least one other drug. From amongst this group, an unknown number of patients were taking **astemizole** or **terfenadine**. No adverse interactions were reported.¹ A cross-over study in 26 healthy subjects given terbinafine 250 mg daily or placebo with **terfenadine** 60 mg twice daily for 7 days found that terbinafine reduced the trough levels of terfenadine acid metabolite by about 20% on the last day of concurrent use. Other **terfenadine** acid metabolite pharmacokinetic parameters were not affected. The AUC, and peak and trough plasma levels of terbinafine were increased by about 16%, 6.6%, and 22%, respectively, after 7 days of concurrent use. Although the incidence of ECG abnormalities was not significantly higher in any group, a 10% prolongation of the QT interval was found in those receiving **terfenadine** either alone or with

terbinafine. Concurrent use was well-tolerated and it was concluded that terbinafine could safely be given with **terfenadine**.²

Antihistamines; Ocular + Miscellaneous

No specific interaction studies have been performed with eye-drop formulations of the antihistamines azelastine, emedastine, epinastine, or olopatadine. However, interactions are not anticipated since very little drug is expected to reach the systemic circulation.

Clinical evidence, mechanism, importance and management

The UK manufacturer of **azelastine** eye drops notes that interaction studies with high oral doses of **azelastine** bear no relevance to the eye drops, as systemic levels are only in the picogram range after administration of eye drops.¹ Similarly, the manufacturer of **epinastine** eye drops notes that no drug interactions are anticipated since systemic **epinastine** levels are extremely low after ocular use. They note that **epinastine** is also excreted mostly unchanged.² The manufacturer of **olopatadine** eye drops notes that *in vitro* studies showed that it was not an inhibitor of the common cytochrome P450 isoenzymes.³ No drug interactions would be anticipated between these, or any other, antihistamine eye drops and systemically administered drugs.

The manufacturer of **emedastine** eye drops notes that an interval of 10 minutes should be allowed after the administration of the eye drops and other ophthalmically administered medicines,⁴ which is good practice for any ocular drugs.

Astemizole + Quinine

Quinine causes a marked but transient increase in plasma astemizole levels, and to avoid the possible risk of cardiac arrhythmias the manufacturers contraindicate this combination. Three case reports confirm that this is a clinically important interaction.

Clinical evidence

Astemizole 30 mg daily for 4 days followed by 10 mg daily for the next 20 days, was given to 12 healthy subjects. The steady-state pharmacokinetics of the astemizole were then examined after the subjects took quinine 20 mg every 4 hours for 12 hours (a total of 80 mg quinine), and after a single 430-mg dose of quinine. The smaller dose of quinine caused only a slight increase in the maximum plasma astemizole levels and AUC, but the larger single dose of quinine resulted in a transient threefold increase in both maximum plasma levels and AUC, especially of desmethylastemizole, the metabolite of astemizole.¹

A patient who had been taking astemizole 10 mg daily for 10 months with fluoxetine, alprazolam, isradipine, and diuretics with potassium sulphate 260 mg for leg cramp. The ECG showed recurrent episodes of torsade de pointes with a QT interval of greater than 680 milliseconds. The only electrolyte abnormality was slight hypomagnesaemia. Intravenous magnesium was given and the patient's QT interval shortened to 420 milliseconds over 3 days.² The manufacturers have on record two other case reports³ of cardiac arrhythmias possibly attributable to an interaction between astemizole and quinine.

Mechanism

Uncertain. One suggestion is that the interaction is not primarily due to inhibition of the metabolism of astemizole by the quinine, but rather to a

transient quinine-induced displacement of both astemizole and its metabolite from its tissue binding sites.¹ Note that the desmethyl metabolite of astemizole causes QTc prolongation.

Importance and management

Information is very limited, but on the basis of the evidence cited above the manufacturers of astemizole contraindicate the concurrent use of quinine in order to avoid the risk of cardiac arrhythmias.⁴ The case report that is cited here confirms that this is a potentially clinically hazardous drug combination.²

The larger single dose of 430 mg of quinine used in the study approached the dosage used for the treatment of malaria, whereas the smaller dose of 80 mg was equivalent to the amount contained in 2 litres of a quinine-containing soft drink.¹ There would therefore appear to be no reason for those on astemizole to avoid moderate quantities of these quinine-containing drinks. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Cinnarizine + Phenylpropranolamine

Phenylpropranolamine 50 mg counteracted the mild sedation caused by cinnarizine 25 or 50 mg, and improved the performance of some skills related to driving in 12 healthy subjects.¹

- Savolainen K, Mattila MJ, Mattila ME. Actions and interactions of cinnarizine and phenylpropranolamine on human psychomotor performance. *Curr Ther Res* (1992) 52, 160–8.

Fexofenadine + Antacids or Omeprazole

An aluminium/magnesium hydroxide-containing antacid modestly reduced fexofenadine levels, and it is recommended that dosing should be separated by 2 hours. Omeprazole does not appear to interact with fexofenadine.

Clinical evidence, mechanism, importance and management

(a) Antacids

The manufacturer¹ notes that when a single 120-mg dose of fexofenadine was given within 15 minutes of an aluminium/magnesium hydroxide antacid (*Maalox*), the fexofenadine AUC was decreased by 41% and the maximum level was decreased by 43%. Although the effect of these reductions on possible efficacy has not been assessed, the manufacturer recommends that it is advisable to leave 2 hours between the administration of fexofenadine and antacids containing aluminium and magnesium hydroxide.²

(b) Omeprazole

The manufacturer notes that no interaction has been seen between fexofenadine and omeprazole.²

- Telfast (Fexofenadine hydrochloride). Aventis Pharma Ltd. UK Summary of product characteristics, September 2004.

Fexofenadine + Rifampicin (Rifampin)

Rifampicin increases the oral clearance of fexofenadine, but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management

A single 60-mg dose of fexofenadine was given to 24 healthy subjects 2 days before and on the last day of a 6-day course of rifampicin 600 mg daily. The oral clearance of fexofenadine was increased 1.3- to 5.3-fold, with no effect on renal clearance or half-life. This was thought to be due to the effect of rifampicin on P-glycoprotein, which is involved in the up-

take of fexofenadine.¹ The clinical significance of this interaction is unclear, but until more is known it would seem prudent to monitor the efficacy of fexofenadine if it is given in combination with rifampicin.

Fexofenadine + St John's wort (*Hypericum perforatum*)

Pretreatment with St John's wort (*Hypericum perforatum*) had no clinically relevant effect on the plasma levels of single-dose fexofenadine in one study, but markedly reduced them in another.

Clinical evidence, mechanism, importance and management

A single 900-mg dose of St John's wort (*Hypericum perforatum*) increased the maximum plasma level of a single 60-mg dose of fexofenadine by 45% and increased the AUC by 31% in 12 healthy subjects. Conversely, St John's wort 300 mg three times daily for 14 days caused a slight 5 to 10% decrease in the maximum level and AUC of a single dose of fexofenadine 60 mg in the same subjects.¹ In contrast, in another study, 12 days of pretreatment with St John's wort increased the oral clearance of a single dose of fexofenadine by about 1.6-fold in healthy subjects.² In both these studies St John's wort was thought to be interacting via its effects on P-glycoprotein.

The findings from these two studies for multiple dose St John's wort suggest that either no clinically relevant decrease in fexofenadine levels occurs, or that a decrease occurs that is possibly clinically important. Further study is needed. If fexofenadine becomes less effective in a patient taking regular St John's wort, consider the St John's wort as a possible cause.

Terfenadine + Atorvastatin

Atorvastatin does not appear to alter the pharmacokinetics of terfenadine.

Clinical evidence, mechanism, importance and management

A group of healthy subjects were given a single 120-mg dose of terfenadine on day 8 of a 10-day course of atorvastatin 80 mg daily. It was found that the atorvastatin caused some small to moderate changes in the pharmacokinetics of the terfenadine and its metabolite fexofenadine (AUC increased by 35% and decreased by 2% respectively, maximum serum levels decreased by 8% and decreased by 16% respectively), none of which reached statistical significance. More importantly there were no changes in the QTc interval, which indicates that atorvastatin does not increase the cardiotoxicity of the terfenadine.¹ There would therefore appear to be no reason for avoiding concurrent use.

1. Stern RH, Smithers JA, Olson SC. Atorvastatin does not produce a clinically significant effect on the pharmacokinetics of terfenadine. *J Clin Pharmacol* (1998) 38, 753–7.

Terfenadine + Paracetamol (Acetaminophen)

An isolated report describes the development of torsade de pointes arrhythmia in an elderly man on very large doses of paracetamol (acetaminophen) and amitriptyline when he began to take terfenadine.

Clinical evidence, mechanism, importance and management

An 86-year-old man taking **amitriptyline** 25 mg at night, prednisone 3 mg daily and excessive amounts of paracetamol (up to 1 g every 2 hours

over a 6-month period) developed breathlessness and bradycardia shortly after starting to take terfenadine 60 mg twice daily. In hospital he became unconscious and was initially pulseless but recovered spontaneously. An ECG showed that he had AV block and a prolonged QT interval, which resulted in runs of self-limiting torsade de pointes arrhythmia.¹ The reasons for this reaction are not known, but a suggested explanation is that overdosage with paracetamol produced large amounts of a metabolite (*N*-acetyl-p-benzoquinoneimine). This metabolite could have inhibited the metabolism of the terfenadine by the cytochrome P450 isoenzyme CYP3A4, thereby resulting in terfenadine accumulation and the development of its cardiotoxic effects.¹ The **amitriptyline** may additionally have had some part to play because it can also (although rarely) cause torsade de pointes.

This is an isolated case and unlikely to be of general importance. There would seem to be little reason on the basis of this report for patients on terfenadine to avoid normal therapeutic doses of paracetamol (acetaminophen). There appear to be no other reports of this interaction.

1. Matisis PP, Easthope RN. Torsades de pointes ventricular tachycardia associated with terfenadine and paracetamol self medication. *N Z Med J* (1994) 107, 402–403.

Terfenadine + Venlafaxine

Venlafaxine does not appear to significantly alter the pharmacokinetics of terfenadine.

Clinical evidence, mechanism, importance and management

A study in 24 subjects given a single 120-mg oral dose of terfenadine before and after taking venlafaxine 75 mg every 12 hours for 9 days found that the pharmacokinetic profile of terfenadine was unchanged, although its acid metabolite concentrations were slightly decreased by about 25%.¹ This study was undertaken to confirm that venlafaxine lacks inhibitory activity on the cytochrome P450 isoenzyme CYP3A4, but at the same time it also indicates that venlafaxine does not raise the serum levels of terfenadine, which are associated with serious cardiotoxicity. There would therefore seem to be no reason for avoiding concurrent use.

1. Amchin J, Zarycranski W, Taylor K, Albano D, Klockowski PM. Effect of venlafaxine on the pharmacokinetics of terfenadine. *Psychopharmacol Bull* (1998) 34,383–9.

Terfenadine + Zileuton

In one study zileuton modestly increased terfenadine levels, without altering the QTc interval. Nevertheless, the combination is contraindicated.

Clinical evidence, mechanism, importance and management

Terfenadine 60 mg every 12 hours for 7 days was given to 15 healthy subjects with either zileuton 600 mg every 6 hours or a placebo. The mean AUC_{0–6} and the maximum plasma concentrations of terfenadine increased by 35% in the presence of zileuton, but the levels were still very low (less than 5 nanograms/mL). The maximum plasma concentration and AUC of carboxyterfenadine (a terfenadine metabolite) were increased by about 15% by zileuton. ECG measurements showed that the addition of zileuton did not increase the QTc interval nor cause any other significant changes.¹ The authors concluded that the interaction was unlikely to be of clinical significance. However, the manufacturers of terfenadine currently contraindicate zileuton, on the basis that any drug that inhibits terfenadine metabolism may result in accumulation of terfenadine and prolongation of the QT interval with the risk of life-threatening arrhythmias.² Because of the unpredictability of these interactions, this seems a sensible precaution.

16

Antimigraine drugs

The drugs dealt with in this section are the ergot derivatives and the triptans (or more properly the serotonin 5-HT₁ agonists), whose main use is in the treatment of migraine. 'Table 16.1', (below) lists some of the drugs commonly used in migraine. Drugs such as propranolol, which are more commonly used in other conditions, are discussed elsewhere in the publication.

(a) Ergot derivatives

The main problem with the use of the ergot derivatives is that of ergotism. Drug interactions may result in additive effects or cause raised levels of ergot derivatives, which may result in the symptoms of ergot poisoning. This may include severe circulatory problems e.g. the extremities may become numb, cold to the touch, tingle, and muscle pain may result. In extreme cases there may be no palpable pulse. Ultimately gangrene may develop, and amputation may be required. Chest pain can also occur, and in some cases myocardial infarction has been reported. Since ergotamine and dihydroergotamine are metabolised in the liver by CYP3A4, drugs which inhibit this isoenzyme, particularly potent inhibitors, such as the 'protease inhibitors', (p.600), should generally be avoided due to the risk of precipitating ergotism.

(b) Triptans

Although the triptans would be expected to share a number of pharmacodynamic drug interactions, due to their differing metabolic pathways they will not all necessarily share the same pharmacokinetic interactions. For example, sumatriptan, which is metabolised mainly by monoamine oxidase A, is unlikely to interact with macrolide antibacterials, which are inhibitors of the cytochrome P450 isoenzyme CYP3A4. However, eletriptan, which is metabolised by CYP3A4 and possibly CYP2D6 could potentially interact (see 'Triptans + Macrolides', p.604, for full details). Frovatriptan and zolmitriptan are substrates for CYP1A2, and are affected by CYP1A2 inhibitors such as fluvoxamine, but zolmitriptan also inhibits

CYP1A2 and may therefore be expected to have additional interactions. The picture with zolmitriptan becomes more complicated since it is also metabolised by monoamine oxidase A. Naratriptan appears unlikely to undergo significant pharmacokinetic interactions since half the dose is excreted unchanged and the rest metabolised by a variety of isoenzymes. A summary of the metabolic pathways of the triptans can be found in 'Table 16.2', (below).

Early in the development of triptans it was theorised that they might possibly add to the increased levels of serotonin caused by other serotonergic drugs, leading to excess serotonergic activity and increasing the risk of 'the serotonin syndrome', (p.9). Therefore sumatriptan was contraindicated in patients taking SSRIs, MAOIs, and lithium, but note, there is little evidence that this occurs in practice. However, there is also a pharmacokinetic interaction between some triptans and 'MAOIs', see (p.604) or 'SSRIs', (p.605).

Table 16.1 Antimigraine drugs

Group	Drugs
Antihistamines	Flunarizine, Pizotifen
Beta blockers	Atenolol, Metoprolol, Nadolol, Propranolol, Timolol
Ergot derivatives	Codergocrine, Ergotamine, Dihydroergotamine, Methysergide
Triptans (Serotonin (5-HT ₁) agonists)	Almotriptan, Eletriptan, Frovatriptan, Naratriptan, Rizatriptan, Sumatriptan, Zolmitriptan

Table 16.2 Interactions between drug metabolising enzymes and the triptans[†]

	MAO-A	CYP1A2	CYP2C9	CYP2C19	CYP2D6	CYP3A4

[†]Other isoenzymes have been implicated, but not at clinically relevant concentrations of the triptans

Ergot derivatives + Antidepressants

One isolated report describes three cases in which patients developed symptoms indicative of the serotonin syndrome when they took amitriptyline, paroxetine/imipramine, or sertraline with dihydroergotamine.

Clinical evidence

A woman taking **imipramine**, **paroxetine** and lithium, who had a 3-week continuous headache, was treated with 300 micrograms of **dihydroergotamine** intravenously. Within 5 minutes of a subsequent 500-microgram dose she developed dysarthria, dilated pupils, diaphoresis, diffuse weakness, and barely responded to commands. She was diffusely hyperreflexic and showed occasional myoclonic jerks. She recovered after 90 minutes.¹

A woman with a history of migraine headaches responded well to **amitriptyline**, metoclopramide, and **dihydroergotamine**. Six weeks after the **amitriptyline** was replaced by **sertraline**, she was again successfully treated for acute migraine with 10 mg of intravenous metoclopramide and 1 mg of intravenous **dihydroergotamine**. However, 2 hours later she developed nausea, emesis, agitation, weakness, diaphoresis, salivation, chills, and fever. All of the symptoms subsided after 24 hours.¹

A woman with a history of migraines (treated prophylactically with **amitriptyline** and propranolol) was admitted to hospital in status migrainosus. She was given 1 mg of **dihydroergotamine**, 10 mg of prochlorperazine and 10 mg of metoclopramide (all intravenously). Within 20 minutes she became diaphoretic, tachycardic, diffusely hyperreflexic, agitated, confused, and briefly lost consciousness twice. Diazepam 8 mg given intramuscularly calmed her agitation, and all the symptoms resolved after 6 hours. A year later she was given 6 mg of subcutaneous sumatriptan while taking **nortriptyline** daily with no ill effects.¹

Mechanism

Not understood. All of these patients appeared to have developed symptoms similar to those of the serotonin syndrome, which is thought to be due to hyperstimulation of 5-HT receptors in the brain. Dihydroergotamine is a 5-HT agonist while paroxetine and sertraline are both serotonin (5-HT) reuptake inhibitors, all of which might be expected to increase 5-HT concentrations in the CNS, and thereby increase receptor stimulation.

Importance and management

These appear to be isolated cases and not of general importance, nevertheless they illustrate the potential for the development of the serotonin syndrome in patients given multidrug regimens that affect 5-HT receptors. The syndrome is rare and it may (so it has been suggested¹) sometimes be an idiosyncratic reaction.

1. Mathew NT, Tietjen GE, Lucker C. Serotonin syndrome complicating migraine pharmacotherapy. *Cephalalgia* (1996) 16, 323–7.

Ergot derivatives + CYP3A4 inhibitors

The azole antifungals are predicted to raise the levels of ergot derivatives, which may lead to ergotism. Concurrent use is contraindicated. Methysergide is also contraindicated with cimetidine and NNRTIs such as delavirdine. Caution is also advised with other CYP3A4 inhibitors, including grapefruit juice and quinupristin/dalfopristin.

Clinical evidence, mechanism, importance and management

The ergot alkaloids are mainly metabolised by the cytochrome P450 isoenzyme CYP3A4. The manufacturers of ergotamine dihydroergotamine and methysergide therefore logically predict that their levels will be raised by CYP3A4 inhibitors and advise against their concurrent use. They specifically contraindicate 'macrolides', (p.599), and 'protease inhibitors', (p.600), which are potent CYP3A4 inhibitors^{1–3} and which have been shown to interact with these ergot derivatives in a number of cases. They also contraindicate the **azole antifungals** and the **NNRTIs (delavirdine, efavirenz)**.^{1,4} Although there appear to be no studies or case reports, given the way other potent CYP3A4 inhibitors interact, this seems pru-

dent. Note that, of the azoles, **ketconazole**, **itraconazole** are the most potent CYP3A4 inhibitors, and would therefore be expected to interact to the greatest extent. The US manufacturers of ergotamine and dihydroergotamine specifically contraindicate these azoles, but advise caution with **fluconazole** and **clotrimazole**, which are less potent CYP3A4 inhibitors.^{2,3} The manufacturers of ergotamine also advise caution with the use of less potent CYP3A4 inhibitors including **grapefruit juice**,² **quinupristin/dalfopristin** and **cimetidine**.¹ The manufacturers of dihydroergotamine³ and methysergide⁴ give a similar list.

Given the rarity of cases of an adverse effect with the potent CYP3A4 inhibitors any clinically significant interaction with these drugs would be expected to be extremely rare indeed, but concurrent use should be well monitored so any adverse effect can be identified swiftly and appropriate treatment given.

4. Deseril (Methysergide). Alliance Pharmaceuticals. UK Summary of product characteristics, December 2006.

Ergot derivatives + Glyceryl trinitrate (Nitroglycerin)

The ergot derivatives such as dihydroergotamine would be expected to oppose the anti-anginal effects of glyceryl trinitrate. Nevertheless, an animal study has not borne out this expectation.

Clinical evidence, mechanism, importance and management

There seem to be no clinical reports of adverse interactions between the ergot derivatives and glyceryl trinitrate, but since **ergot** causes vasoconstriction and can provoke angina it would be expected to oppose the effects of glyceryl trinitrate when used as a vasodilator for the treatment of angina.¹ Nevertheless, a study in *animals* suggests that **dihydroergotamine** will not worsen exercise-induced angina pectoris, and that the antianginal efficacy of glyceryl trinitrate will not be neutralised by pretreatment with **dihydroergotamine**.²

However, glyceryl trinitrate has also been shown to increase the bioavailability of **dihydroergotamine** (by up to 370% in one case) in subjects with orthostatic hypotension, which would increase its vasoconstrictor effects.¹ The clinical outcome of concurrent use is therefore uncertain. Note that ergot derivatives are generally regarded as contraindicated in those with ischaemic heart disease.

Ergot derivatives + Heparin

The use of dihydroergotamine with heparin has resulted in ergotism. In some cases, amputation of the affected limb was necessary. The rate of absorption and peak levels of subcutaneous dihydroergotamine are reduced by heparin.

Clinical evidence, mechanism, importance and management

There have been several reports of ergotism following the combined use of **dihydroergotamine** and heparin for thromboembolic prophylaxis. In a retrospective review of 61 092 Austrian patients attending trauma units who received **dihydroergotamine** and heparin prophylaxis, complications attributable to ergotism were seen in 142 patients. In 7 patients amputation was necessary and in a further 7 cases immediate opening of the vessel and catheter dilatation was successful.¹ Other published reports support this interaction,^{2,3} including a report of two patients who experienced fatal myocardial infarctions, attributed to coronary artery spasm as a complication of prophylaxis with **dihydroergotamine** and heparin.⁴

It has been found that the use of heparin results in a 25% increase in the AUC of subcutaneously administered **dihydroergotamine**. Giving the

two drugs at the same site reduced the rate of dihydroergotamine absorption by 63%, the time to peak levels by 110%, and the peak levels by 15%. **Dihydroergotamine** had no effect on the pharmacokinetics of heparin.⁵

Because of the risk of peripheral ischaemia, the combination of **dihydroergotamine** and heparin is no longer widely used for thromboembolic prophylaxis. If the combination is used, the patient must be closely observed for any sign of vascular spasm.

Ergot derivatives + Macrolides

Ergot toxicity can develop rapidly in patients taking ergotamine or dihydroergotamine if they are given erythromycin or troleandomycin. Three possible cases of toxicity have occurred with clarithromycin, and one case has been reported with each of josamycin and oleandomycin. Toxicity is predicted to occur with midecamycin. No cases of toxicity appear to have been described with spiramycin, and none would be expected. There is no direct information about azithromycin but it would not be expected to interact.

Clinical evidence

(a) Clarithromycin

A 59-year-old woman took **ergotamine tartrate** 2 mg for a typical migraine headache. After 2 hours her tongue became swollen, painful and bluish in colour. She showed some hypertension (BP 200/110 mmHg) and her fingers and toes were cold and cyanotic (blue). She had taken this dose of **ergotamine** many times previously without problems, but on this occasion she had been taking clarithromycin 500 mg twice daily for the last 5 days. This adverse reaction was diagnosed as ergotism. Other evidence suggests that this patient may possibly have been unusually sensitive to vascular occlusion.¹ The authors of this report briefly quote another case, originating from the manufacturers of clarithromycin, of a possible interaction with **dihydroergotamine**, although this was complicated by the concurrent use of other medications (not named) used in the management of AIDS.¹ A woman who had previously uneventfully taken **Cafergot (ergotamine tartrate)** 1 mg, caffeine 100 mg) for migraine developed ergotism (leg pain, cold and cyanosed limbs, and impalpable pulses) within 3 days of starting to take clarithromycin (dosage not stated). The authors postulated that **smoking** and the use of **oxymetazoline** (both of which have vasoconstrictor effects) may also have had some part to play.²

(b) Erythromycin

A woman who had regularly and uneventfully taken **Migral (ergotamine tartrate)** 2 mg, cyclizine hydrochloride 50 mg, caffeine 100 mg) on a number of previous occasions, took one tablet during a course of treatment with erythromycin 250 mg every 6 hours. Within 2 days she developed severe ischaemic pain in her arms and legs during exercise, with a burning sensation in her feet and hands. When admitted to hospital 10 days later, her extremities were cool and cyanosed. Her pulse could not be detected in the lower limbs.³

Eight other cases of acute ergotism have been reported^{4–11} in which patients were taking **ergotamine tartrate** or **dihydroergotamine** and erythromycin. The reaction has been reported to develop within a few hours,⁷ but it may take several days to occur.¹⁰ One case appeared to occur when the erythromycin was started 3 days after the last dose of **dihydroergotamine**.⁵

(c) Josamycin

An isolated report describes a 33-year-old woman who developed severe ischaemia of the legs within 3 days of starting to take josamycin 2 g daily and **ergotamine tartrate** 300 micrograms. Her legs and feet were cold, white and painful, and most of her peripheral pulses were impalpable.¹²

(d) Midecamycin diacetate (Miocamycin)

After 12 healthy subjects took midecamycin diacetate 800 mg twice daily for 8 days, the peak concentrations of a single 9-mg dose of **dihydroergotamine** were raised 3 to 40-fold.¹³

(e) Oleandomycin

A case of ergotism has been reported in a 45-year-old woman who had been taking **ergotamine** 4 mg daily for 5 years and recently also oleandomycin.¹⁴

(f) Troleandomycin

A 40-year-old woman who had been taking **dihydroergotamine**, 90 drops daily, for 3 years without problems, developed cramp in her legs within a few hours of starting to take troleandomycin 250 mg four times a day. Five days later she was admitted to hospital as an emergency, with severe ischaemia of her arms and legs. Her limbs were cold and all her peripheral pulses were impalpable.¹⁵

There are reports of several other patients who had taken normal doses of **ergotamine tartrate** or **dihydroergotamine** for months or years without problems, who then developed severe ergotism within hours or days of starting to take normal doses of troleandomycin.^{16–23} This resulted in a myocardial infarction in one patient.²⁴

Mechanism

Erythromycin and troleandomycin are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of ergot derivatives.²⁵ Clarithromycin and oleandomycin are also known to inhibit CYP3A4. As a result the ergot is poorly metabolised and accumulates in the body. This leads to increased vasoconstriction and ultimately ischaemia. **Spiramycin**, and josamycin normally do not inhibit CYP3A4 and are therefore not expected to interact,²⁵ although a case has been reported.¹²

Importance and management

The interactions of ergot derivatives with erythromycin and troleandomycin are well documented, well established, and clinically important, whereas information about clarithromycin appears to be confined to three possible cases and that relating to oleandomycin to one case. There are no adverse reports about midecamycin, but it is expected to interact similarly. The concurrent use of all of these macrolides and ergot derivatives should be avoided. Some of the cases cited were effectively treated with sodium nitroprusside or naftidrofuryl oxalate, with or without heparin.^{1,5,7–9,21} Spiramycin, and josamycin would not be expected to interact because they do not inhibit CYP3A4. However, there is one unexplained and unconfirmed report of an interaction with josamycin.¹²

It has been suggested that ergot alkaloids should be avoided with **azithromycin**, because clinically important interactions have been seen between these drugs and other macrolide antibacterials related to **azithromycin**,^{26,27} and the UK manufacturers of both ergotamine and **azithromycin** contraindicate the combination.^{28,29} However, there seems so far to be no direct evidence of any adverse interactions between ergot alkaloids and **azithromycin**, and the US manufacturers say that concurrent use can be undertaken with careful monitoring.³⁰

Ergot derivatives + Methysergide

The concurrent use of methysergide and other ergot derivatives can increase the risk of severe and persistent spasm of major arteries in some patients.

Clinical evidence

A man developed loss of temperature sensitivity over the right side of his face and arm, as well as vertigo, dysphagia and hoarseness 7 days after starting combined treatment with methysergide 2 mg three times daily and 500 micrograms of subcutaneous **ergotamine tartrate** at night. Continued use resulted in impaired pain, touch and temperature sensation over the right side of his face, shoulder and arm. Arteriography demonstrated left vertebral artery occlusion and right vertebral arterial spasm. These symptoms, apart from the loss of temperature sensitivity, resolved when the drugs were stopped.¹ Another man treated for cluster headaches with methysergide 2 mg, intramuscular **ergotamine tartrate** and pizotifen developed ischaemia of the right foot, with impalpable popliteal and pedal pulses. Arteriography showed that blood flow to the arteries of the right leg was reduced.¹

Another report describes prolonged myocardial ischaemia in a patient with cluster headaches when a single 2-mg dose of **ergotamine tartrate** was added to methysergide 2 mg three times daily. Sublingual glyceryl trinitrate relieved the pain,² (but see also 'Ergot derivatives + Glyceryl trinitrate (Nitroglycerin)', p.598)

A further case is reported of a woman who developed gangrene of both big toes following surgical treatment of bilateral hallux valgus (bone swellings). Before the time of operation, and for 20 days afterwards she took 6 tablets of *Bellergal* (total of **ergotamine tartrate** 1.8 mg, alkaloids of belladonna 0.6 mg, phenobarbital 120 mg daily) and methysergide maleate 6 mg daily. One toe was subsequently removed by amputation, the other recovered slowly following cessation of the **ergotamine** and methysergide.³

Mechanism

Cluster headaches are associated with abnormal dilatation of the carotid arteries, which can be constricted by ergot derivatives. In the cases cited it would seem that combined vasoconstrictor effects caused arterial spasm elsewhere in the body, resulting in serious tissue ischaemia. Parenteral ergotamine increases the risk of arterial spasm.

Importance and management

Direct information seems to be limited to these cases. Cardiovascular complications can occur with ergot derivatives given alone, but these cases suggest that their concurrent use may unpredictably increase the risk in some patients. Clearly they should be used together with great caution, or avoided.

Ergot derivatives + Protease inhibitors

A patient receiving indinavir rapidly developed ergotism after taking normal doses of ergotamine. At least ten other patients taking ritonavir and ergotamine have had the same interaction. A patient taking nelfinavir developed peripheral arterial vasoconstriction after also taking ergotamine. Other ergot derivatives are predicted to interact similarly.

Clinical evidence

(a) Indinavir

An HIV-positive man who had been taking lamivudine, stavudine, co-trimoxazole and indinavir (2.4 g daily) for more than a year was given *Gyn-ergene caféiné* (**ergotamine tartrate** 1 mg with caffeine 100 mg) for migraine. He took two doses on two consecutive days, and 5 days later presented in hospital with numbness and cyanosis of the toes of his left foot. The next day he complained of intermittent claudication of his left leg, and 6 days later was admitted to hospital because of worsening symptoms and night cramps. Examination showed a typical picture of ergotism, with vasospasm and reduced blood flow in the popliteal, tibial and femoral arteries. He was treated with heparin and buflomedil, and recovered after 3 days.¹

See (c) ritonavir below for details regarding a fatality involving indinavir, ritonavir and ergotamine.

(b) Nelfinavir

A 40-year-old HIV-positive woman twice took **ergotamine** 2 mg for a migraine while also taking nelfinavir, zidovudine and lamivudine. On the first occasion she developed pain and cyanosis in her toes, and on the second occasion she developed cyanosis and oedema in her hands and feet, causing pain so severe that she was unable to walk. On both occasions peripheral arterial pulses were not palpable. Although she recovered spontaneously on both occasions, the authors caution concurrent use due to the extremely severe potential effects.²

(c) Ritonavir

A 63-year-old man with AIDS, who had taken **ergotamine tartrate** 1 to 2 mg daily for migraine headaches over the last 5 years, had his treatment with zidovudine, zalcitabine and co-trimoxazole changed to zidovudine, didanosine and ritonavir (600 mg every 12 hours). Within 10 days he developed paraesthesias, coldness, cyanosis and skin paleness of both arms, and when admitted to hospital his axillary, brachial, radial and ulnar pulses were found to be absent. An arterial doppler test showed the absence of blood flow in both his radial and ulnar arteries and he was diagnosed as having ergotism. The **ergotamine** and ritonavir were stopped, and he recovered when treated with prostaglandin E1 and calcium nadroparin.³

Another man, aged 31 years, taking ritonavir 400 mg twice daily (and also taking pizotifen, nelfinavir, stavudine, lamivudine, co-trimoxazole and venlafaxine) developed severe burning and numbness in both feet, and paraesthesias in his hands after taking 4 tablets of **ergotamine** 1 mg and caffeine 100 mg, over 10 days. He was diagnosed as having ergotism. The drugs were stopped and he was treated effectively with intravenous alprostadil and heparin.⁴

A case report describes irreversible coma in a 34-year-old woman who was taking ritonavir 600 mg twice daily, lamivudine and stavudine. She presented with dizziness, loss of vision, headache, vomiting, diarrhoea and a feeling of cold in her left foot after having taken three tablets of **ergotamine** 1 mg in the preceding 4 days. Peripheral pulses were absent in her extremities. After an initial period of recovery she again experienced a loss of consciousness, with signs of stenosis and vasospasm with cere-

bral hypoperfusion. Despite treatment with alprostadil, and discontinuation of ritonavir her condition deteriorated, and 2 years after the initial presentation, she remained in coma vigil (a state of altered consciousness).⁵

A fatality has been reported in a 49-year-old man taking ritonavir 200 mg twice daily and indinavir 800 mg twice daily in addition to stavudine and lamivudine. After taking three tablets of *Cafergot* (ergotamine tartrate 1 mg and caffeine 100 mg) his headache worsened, he developed progressive lower extremity weakness, severe peripheral vasoconstriction, labile hypertension and livedo reticularis (skin discolouration due to underlying capillary changes). He lapsed into coma and on day 5 was declared "brain dead".⁶

At least 6 other cases of ergotism have been reported in patients taking ritonavir after taking ergot derivatives,⁷⁻¹² and one required surgical amputation of the toes.⁸ The ergotism developed in three of the patients within a few hours to 24 hours of taking a single 1- or 2-mg dose of **ergotamine tartrate**,^{7,9,11} and in the others within about 4 to 15 days.^{8,10,12} One was taking a combination drug (**ergotamine tartrate** 300 micrograms, belladonna extract 200 micrograms and phenobarbital 20 mg) twice daily for gastric discomfort,⁸ another took up to 2 mg of **ergotamine** daily,¹⁰ and a third received 10 mg of ergotamine rectally over 4 consecutive days.¹²

Mechanism

Protease inhibitors reduce the metabolism of ergotamine by inhibiting the cytochrome P450 isoenzyme CYP3A4 to varying degrees. Therefore ergotamine levels are increased, which may result in toxicity. Ergotamine poisoning causes arterial spasm, which reduces and even shuts down the flow of blood in arteries.

Importance and management

Information appears to be limited to these reports, but what happened is consistent with the way other drugs that are potent inhibitors of CYP3A4 can interact with ergot derivatives (see 'Ergot derivatives + Macrolides', p.599). This interaction would appear to be established, and is clearly clinically important. It would now be prudent for any patient taking indinavir or ritonavir, and probably nelfinavir, to avoid the concurrent use of ergotamine or any other ergot derivative, such as **dihydroergotamine** or **methysergide**. Information about possible interactions between ergot derivatives and other protease inhibitors seems to be lacking. Even so to be on the safe side the manufacturers of most of the other protease inhibitors contraindicate concurrent use with ergot derivatives.

Ergot derivatives + Tetracyclines

Five patients taking ergotamine or dihydroergotamine developed ergotism when they also took doxycycline or tetracycline.

Clinical evidence

A woman who had previously taken **ergotamine tartrate** successfully and uneventfully for 16 years was given **doxycycline** and **dihydroergotamine** 30 drops three times a day. Five days later her hands and feet be-

came cold and reddened, and she was diagnosed as having a mild form of ergotism.¹

Other cases of ergotism, some of them more severe, have been described in two patients taking **ergotamine tartrate** and **doxycycline**,^{2,3} and in 3 patients taking **tetracycline**-containing preparations.^{2,4,5}

Mechanism

Unknown. One suggestion is that these antibacterials may inhibit the activity of the liver enzymes concerned with the metabolism and clearance of ergotamine, thereby prolonging its stay in the body and enhancing its activity.¹ One of the patients had a history of alcoholism² and two of them were in their eighties,⁵ so impaired liver function may have played a part.

Importance and management

Information is very limited indeed. The incidence and general importance of this interaction is uncertain, but it would clearly be prudent to be on the alert for signs of ergotism in any patient given ergot derivatives and a tetracycline. However, note that one of the manufacturers of ergotamine⁶ actually recommends that the concurrent use of 'tetracycline' should be avoided. Impairment of liver function may possibly be a contributory factor in this interaction.

Flunarizine + Antiepileptics

Limited evidence suggests that phenytoin and carbamazepine can reduce serum flunarizine levels. Flunarizine does not appear to alter phenytoin or carbamazepine levels.

Clinical evidence, mechanism, importance and management

A study found that flunarizine levels were lower in patients receiving multiple antiepileptics than in those receiving only one antiepileptic (statistically significant only for flunarizine 10 mg). The antiepileptics taken were **carbamazepine**, **phenytoin**, and **sodium valproate**. Flunarizine did not affect the serum levels of these antiepileptics.¹ Similarly, in another study involving 12 patients, four of whom were taking **phenytoin**, four **carbamazepine** and four both **phenytoin** and **carbamazepine**, there was no difference in the pharmacokinetics of a single 30-mg dose of flunarizine or of multiple-dose flunarizine between the three groups. However, the apparent clearance values of flunarizine were several fold greater in these patients than previously observed in healthy volunteers. There were no differences identified in the mean steady-state levels of the antiepileptics before and during flunarizine therapy.²

Although not conclusive, these data suggest that enzyme-inducing antiepileptics increase the metabolism of flunarizine. There would seem to be no reason for avoiding concurrent use, but the outcome should be monitored.

Triptans + Azoles

Ketoconazole and fluconazole increase the AUC of eletriptan by about sixfold and twofold, respectively. Almotriptan is less affected, and ketoconazole only raises its AUC by about 60%. Itraconazole is predicted to interact in the same way as ketoconazole.

Clinical evidence

(a) Almotriptan

In a randomised, open label, crossover study, 16 healthy subjects were given **ketoconazole** 400 mg daily on days 1 to 3, with a single 12.5-mg dose of almotriptan on day 2. Ketoconazole increased the AUC and maximum plasma levels of almotriptan by 57% and 61%, respectively. The renal clearance of almotriptan was also reduced by approximately 16%.¹

(b) Eletriptan

A pharmacokinetic study by the manufacturers of eletriptan found that **ketoconazole** 400 mg increased the maximum serum levels of eletriptan 2.7-fold, the AUC 5.9-fold and prolonged its half-life from 4.8 to 8.3 hours. **Fluconazole** caused a lesser 1.4-fold increase in the maximum serum levels of eletriptan, and a twofold increase in its AUC.²

Mechanism

Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which eletriptan is metabolised. Fluconazole is a less potent inhibitor of CYP3A4, and therefore has a more modest effect. Almotriptan is also metabolised by CYP3A4, but as this is not the only route of metabolism, and therefore inhibition of CYP3A4 by ketoconazole has a less dramatic effect on its levels.

Importance and management

Although studies are limited these interactions are established. In the study with almotriptan and ketoconazole adverse events were not significantly altered, and so no almotriptan dosage adjustment is considered necessary when using this combination.¹ Ketoconazole dramatically raises eletriptan levels, and therefore the manufacturers advise that concurrent use should be avoided.

Itraconazole, which is also a potent inhibitor of CYP3A4, has been predicted to interact in the same way as ketoconazole.²⁻⁴ In addition, the US manufacturers recommend that eletriptan should not be given within 72 hours of itraconazole and ketoconazole.² Fluconazole is a less potent inhibitor of CYP3A4 and therefore may be used with caution. Other triptans would be expected to have little or no interaction with the azoles as they are not predominantly metabolised by CYP3A4 (see 'Table 16.2', (p.597)).

Triptans + Beta blockers

No clinically important interaction occurs between most triptans and propranolol, but the plasma levels of rizatriptan are almost doubled by propranolol.

Clinical evidence, mechanism, importance and management

(a) Almotriptan

Twelve healthy subjects were given **propranolol** 80 mg twice daily for 7 days followed by a single 12.5-mg dose of almotriptan. Although some small changes were noted in the pharmacokinetics of almotriptan, these were not considered to be clinically significant and concurrent use of the combination was well tolerated.¹

(b) Eletriptan

In an interaction study, 12 healthy subjects were given a single 80-mg dose of eletriptan following pre-treatment with **propranolol** 80 mg twice daily for 7 days. It was found that the eletriptan AUC was increased 1.3-fold and the half-life increased from 4.9 to 5.2 hours. However, these changes were not considered to be clinically significant. No significant blood pressure changes or any adverse events were seen, when compared with taking eletriptan alone.²

The manufacturers say that in clinical trials where eletriptan was taken with beta blockers, no evidence of an interaction was seen.³

(c) Frovatriptan

A single 2.5-mg oral dose of frovatriptan was given to 12 healthy subjects after they had received pre-treatment with **propranolol** 80 mg twice daily for 7 days. The AUC and maximum levels of frovatriptan were increased by 25% and 23%, respectively. However, no changes occurred in the ECGs and vital signs of the subjects, and so the pharmacokinetic interaction was not thought to be of clinical significance.⁴

(d) Naratriptan

The manufacturers of naratriptan report that there is no evidence of interactions with **beta blockers** (none specifically named)⁵ so there would appear to be no problems with the concurrent use of **propranolol** with any other beta blocker.

(e) Rizatriptan

A series of double-blind, placebo-controlled studies were conducted in a total of 51 patients who were given a single 10-mg dose of rizatriptan after 7 days of pre-treatment with **propranolol** 60 or 120 mg twice daily, **nadolol** 80 mg daily, **metoprolol** 100 mg daily, or placebo.⁶ **Nadolol** and **metoprolol** had no effect on the pharmacokinetics of rizatriptan. However, **propranolol** raised the AUC and the maximum plasma concentration of rizatriptan by 1.67 and 1.75-fold, respectively. Adjusting the dose of **propranolol** and separating the administration by 2 hours had little effect on this interaction.⁶ *In vitro* studies have shown that **propranolol** markedly inhibits the metabolism of rizatriptan, whereas **atenolol**, **nadolol** and **timolol** do not affect the metabolism of rizatriptan.⁶ The manufacturers recommend that a 5-mg dose of rizatriptan (rather than the more usual 10 mg) should be used in the presence of **propranolol**, with a maximum of two⁷ or three doses in 24 hours.⁸ In the UK, they also state that administration should be separated by at least 2 hours,⁷ although the rationale for this is less clear given the findings of the above study.⁶ No reduction in the rizatriptan dosage would seem to be needed in the presence of **nadolol**, **metoprolol**, **atenolol** or **timolol**.

(f) Sumatriptan

In a study in 10 healthy subjects, **propranolol** 80 mg twice daily for 7 days did not alter the pharmacokinetics of a single 300-mg dose of sumatriptan given on day 7. There was no significant effect on pulse rate or blood pressure.⁹

(g) Zolmitriptan

In a double-blind, randomised, crossover study, 12 healthy subjects were given **propranolol** 160 mg or a placebo daily for 7 days, with a single 10-mg oral dose of zolmitriptan on day 7. The **propranolol** increased the maximum serum levels and the AUC of the zolmitriptan by 56% and 37%, respectively, and reduced the extent of its conversion to its active metabolite, probably due to inhibition of, or competition for metabolism by, cytochrome P450 isoenzymes. However, it was concluded that no clinically important changes in the therapeutic effects of zolmitriptan are likely, nor are any adjustments in its dosage needed.¹⁰

Triptans + Ergot derivatives

Simultaneous use of the ergot derivatives is contraindicated with all the triptans because of the theoretical risk of additive vasoconstriction, although this has been demonstrated only in one study with sumatriptan, and there is one isolated case of myocardial in-

farction in a woman taking sumatriptan and methysergide. No important additive effect has been seen in pharmacodynamic studies with almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan or zolmitriptan. Some of the manufacturers of the triptans give recommendations for the number of hours that should be allowed between administration of triptans and ergot derivatives.

Clinical evidence

(a) Almotriptan

The manufacturers of almotriptan say that no additive vasospastic effects were seen in a clinical study in 12 healthy subjects given almotriptan and ergotamine.¹ However, they do note that such effects are theoretically possible.

(b) Eletriptan

The manufacturers report that when oral ergotamine with caffeine was given 1 hour and 2 hours after eletriptan, minor additive increases in blood pressure were seen.²

(c) Frovatriptan

In a randomised, crossover study, 12 healthy subjects were given a single 5-mg dose of oral frovatriptan, a single 2-mg sublingual dose of ergotamine, or both drugs together. The ergotamine reduced the maximum levels and AUC of frovatriptan by about 25%. However, the frovatriptan had no effect on ergotamine pharmacokinetics, and no clinically significant changes in the haemodynamics or the ECGs of the subjects were noted.³

(d) Naratriptan

A study in 12 healthy subjects found that 1 mg of intramuscular dihydroergotamine reduced the AUC and the maximum serum levels of a single 2.5-mg dose of naratriptan by 15% and 20%, respectively, but this was considered to be clinically irrelevant. Concurrent use was well tolerated and no clinically significant blood pressure, heart rate or ECG effects were seen.⁴

(e) Rizatriptan

Additive vasospastic effects were not observed in a pharmacodynamic study in 16 healthy subjects given oral rizatriptan 10 mg and intravenous ergotamine 250 micrograms.^{5,6}

(f) Sumatriptan

A study in 38 migraine sufferers found that 1 mg of intravenous dihydroergotamine alone caused maximum increases in blood pressure of 13/9 mmHg, while 2 or 4 mg of subcutaneous sumatriptan alone caused a smaller rise in blood pressure of 7/6 mmHg. When given together the blood pressure rises were no greater than with dihydroergotamine alone.⁷ A clinical study of subcutaneous sumatriptan in patients taking oral dihydroergotamine found that the adverse event profile of sumatriptan was not affected by concurrent use.⁸ However, another pharmacodynamic study found that subcutaneous sumatriptan and intravenous ergotamine had additive vasoconstrictive effects (as assessed by decreases in toe-arm systolic blood pressure gradients).⁹

Myocardial infarction has been reported in a 43-year-old woman after she took two 2-mg doses of methysergide 12 hours apart, followed by sumatriptan 6 mg subcutaneously. Severe chest pain and tightness with breathlessness began 15 minutes later, and results of various tests were consistent with 'coronary spasm on an area of atherosclerosis'.¹⁰

(g) Zolmitriptan

In a randomised, double-blind, placebo-controlled study, 12 healthy subjects were given 5 mg of oral dihydroergotamine or a placebo twice daily for 10 days, with oral zolmitriptan 10 mg (four times the usual dose) on day 10. No significant changes in blood pressure, ECGs, or zolmitriptan pharmacokinetics were seen. Concurrent use was well tolerated.¹¹ Another randomised, double-blind, placebo-controlled study in 12 healthy subjects looked at the effects of oral zolmitriptan 20 mg (eight times the usual dose) given with oral ergotamine 2 mg (contained in Cafegot tablets; ergotamine 1 mg with caffeine 100 mg). Using a very detailed and thorough range of techniques, no clinically relevant cardiovascular changes were found, even at this large dose of zolmitriptan, and concurrent use was generally well tolerated. No important changes in the zolmitriptan pharmacokinetics were seen.¹²

Mechanism

Vasoconstriction is a well known adverse effect of ergot derivatives, and coronary vasoconstriction may also occur rarely with the triptans. (Note that in 1992, soon after the marketing of sumatriptan, the CSM in the UK had received 34 reports of pain or tightness in the chest caused by sumatriptan, possibly due to coronary vasoconstriction.¹³) It is therefore theoretically possible that the drugs may have additive vasoconstrictive effects, although there is little evidence of this in practice.

Importance and management

Due to the theoretical risk of additive vasoconstriction, and possible significant coronary vasoconstriction (see sumatriptan above) ergot derivatives are generally contraindicated with the triptans (the exception being naratriptan,¹⁴ where concurrent use is not recommended). The UK manufacturers of sumatriptan say that ergotamine should not be given less than 6 hours after taking the triptan, and recommend that the triptan should not be taken less than 24 hours after taking ergotamine.¹⁵ The same recommendations are made by the UK manufacturers of almotriptan,¹ rizatriptan,⁵ and zolmitriptan,¹⁶ whereas the UK manufacturers of eletriptan,² and frovatriptan,¹⁷ recommend that ergot derivatives are not given for a minimum of 24 hours (not just 6 hours) after these triptans. In general, in the US, it is recommended that triptans should not be taken within 24 hours of any ergotamine or ergot-type medication.

Triptans + Flunarizine

Flunarizine did not alter the pharmacokinetics or pharmacodynamics of sumatriptan in one study. Flunarizine does not appear to interact with eletriptan.

Clinical evidence, mechanism, importance and management

(a) Eletriptan

The manufacturer notes that although no formal interaction studies have been carried out, there was no evidence of an interaction between eletriptan and flunarizine in clinical trials.¹

(b) Sumatriptan

A double-blind study found that flunarizine 10 mg daily for 8 days had no effect on the pharmacokinetics of a single dose of sumatriptan, and the

combination caused no significant changes in blood pressure, ECG or heart rate.²

Triptans + Macrolides

Erythromycin markedly raises the plasma levels of eletriptan. Clarithromycin, josamycin and troleandomycin are predicted to interact similarly. Almotriptan levels may be raised by erythromycin. Clarithromycin does not significantly alter the pharmacokinetics of sumatriptan.

Clinical evidence

(a) Eletriptan

A clinical pharmacokinetic study by the manufacturers of eletriptan¹ found that **erythromycin** 1 g increased the maximum serum levels of eletriptan 2-fold, the AUC 3.6-fold and prolonged its half-life from 4.6 to 7.1 hours.

(b) Sumatriptan

A study in which 24 healthy subjects were given sumatriptan 50 mg on the morning of the fourth day of a course of **clarithromycin** 500 mg twice daily, found that **clarithromycin** did not significantly affect the pharmacokinetics of sumatriptan.²

Mechanism

The macrolides are, to varying degrees, inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which eletriptan is metabolised. Therefore giving erythromycin raises eletriptan plasma levels. Sumatriptan is not metabolised by CYP3A4 and therefore does not interact.

Importance and management

Information is limited but an interaction between eletriptan and erythromycin appears to be established. Because of the elevated levels seen, the manufacturers advise against their concurrent use.^{1,3} Other drugs that are potent CYP3A4 inhibitors are predicted to raise serum eletriptan levels similarly. Such drugs include **clarithromycin**^{1,3}, **josamycin**,¹ and **troleandomycin**.³ In addition, the US manufacturers recommend that eletriptan should not be given within 72 hours of **clarithromycin** or **troleandomycin**.³

Other triptans would be expected to have little or no interaction with the azoles as they are not predominantly metabolised by CYP3A4 (see 'Table 16.2', (p.597)). The exception to this is **almotriptan**, which is metabolised in part by CYP3A4. The US manufacturers⁴ therefore predict that its levels may be raised by erythromycin. However, note that, based on its interaction with 'ketoconazole', (p.601), dosage adjustments would not be expected to be necessary.

Triptans + MAOIs

Moclobemide markedly inhibits the metabolism of rizatriptan, and approximately doubles the bioavailability of sumatriptan. The manufacturers contraindicate these triptans with moclobemide and non-selective MAOIs. Moclobemide modestly inhibited the metabolism of zolmitriptan but had no clinically significant effect on almotriptan or frovatriptan. Selegiline does not interact with sumatriptan or zolmitriptan, and would not be expected to interact with any of the other triptans. Non-selective MAOIs (e.g. phenelzine) are not expected to inter-

act with eletriptan, frovatriptan, or naratriptan. Nevertheless, the manufacturer of frovatriptan contraindicates the concurrent use of MAOIs, based on a theoretical increased risk of serotonin syndrome.

Clinical evidence, mechanism, importance and management

(a) Almotriptan

In a study in 12 healthy subjects, **moclobemide** 150 mg twice daily for 8 days increased the AUC of a single 12.5-mg dose of almotriptan given on day 8 by 37%, decreased its clearance by 27% and increased the half-life by 24%, which was not considered clinically significant.¹ These findings are consistent with the fact that less than half of a dose of almotriptan is metabolised by monoamine oxidase A,² and it would seem therefore that concurrent use need not be avoided. There appears to be no direct clinical information about the use of non-selective MAOIs but it seems unlikely that a clinically relevant interaction will occur.

(b) Eletriptan

The manufacturer of eletriptan notes that it is not a substrate for monoamine oxidase, and therefore no interaction with MAOIs is expected.^{3,4} Because of this, they have not undertaken a formal interaction study.³

(c) Frovatriptan

The manufacturer of frovatriptan notes that it is not a substrate for, or an inhibitor of, monoamine oxidase.^{5,6} Nevertheless, they say that a potential risk of serotonin syndrome or hypertension cannot be excluded when it is used with MAOIs, so concomitant use is not recommended⁵ (but see also 'Antimigraine drugs', (p.597)). A study in 9 healthy subjects given a single 2.5-mg oral dose of frovatriptan following pre-treatment with **moclobemide** 150 mg twice daily for 7 days did not find any pharmacokinetic changes, or any changes in the vital signs and ECGs of the subjects. Therefore no adverse interaction would be expected with concurrent use.⁷

(d) Naratriptan

The manufacturer of naratriptan notes that it does not inhibit monoamine oxidase. Therefore interactions with MAOIs are not anticipated.⁸

(e) Rizatriptan

In a double blind, randomised, crossover study, 12 healthy subjects were given **moclobemide** 150 mg or a placebo three times daily for 4 days, with a single 10-mg dose of rizatriptan on day 4. The **moclobemide** increased the AUCs of rizatriptan and its active (but minor) metabolite by 2.2- and 5.3-fold, respectively, and increased their maximum serum levels by 1.4- and 2.6-fold, respectively. MAO-A is the principal enzyme concerned with the metabolism of rizatriptan. **Moclobemide** inhibits this enzyme and therefore raises rizatriptan levels. Despite these rises, the concurrent use of these drugs was well tolerated and any adverse effects were mild and similar to those seen when rizatriptan was given with the placebo. However, because of the magnitude of the rises, the authors recommend avoiding the combination.⁹ The manufacturers of rizatriptan contraindicate its use both during, and 2 weeks after stopping an MAOI, the stated reasons being that similar or greater rises in serum levels may be expected with irreversible non-selective MAOIs than with moclobemide.^{10,11} In addition, the US manufacturers¹¹ note that no interaction would be expected with selective inhibitors of MAO-A (namely **selegiline** and **rasagiline**).

(f) Sumatriptan

Three groups of 14 subjects were given a placebo, **moclobemide** 150 mg three times daily, or **selegiline** 5 mg twice daily for 8 days, with subcutaneous sumatriptan 6 mg on day 8. No statistically significant differences in pulse rates or in blood pressures were seen between any of the groups following the injection of the sumatriptan. However, the sumatriptan AUC of the **moclobemide**-treated group was approximately doubled (129% increase), its clearance was reduced by 56% and its half-life increased by 52%. The pharmacokinetic changes seen in the **selegiline** group were not consistent. There were no differences in the adverse events experienced by any of the three groups.¹² An *in vitro* study of the metabolism of sumatriptan confirms that it is the MAO-A enzyme, not MAO-B, that is the major enzyme involved in the metabolism of sumatriptan.¹³

A comprehensive search of the literature and reports from proprietary manufacturers, identified published reports of 31 patients taking sumatriptan and MAOIs concurrently, but no adverse events were reported,¹⁴ and a patient taking **moclobemide** 300 mg three times daily had no adverse effects when given oral sumatriptan 100 mg on six occasions.¹⁵

However, a patient who had taken an overdose of **moclobemide**, together with sumatriptan, sertraline, and citalopram developed the serotonin syndrome.¹⁶

The interaction between moclobemide and sumatriptan appears to be established. The same interaction seems likely to occur with any RIMA or non-selective MAOI, but not with the selective MAO-B inhibitors like **selegiline**. However, the increased sumatriptan bioavailability appears not to be clinically important because, in the study cited, those subjects taking moclobemide did not experience any more adverse effects than those taking the selegiline or placebo. Despite this the UK manufacturers of sumatriptan quite clearly say that the concurrent use of sumatriptan and MAOIs is contraindicated both during and for 2 weeks after stopping an MAOI.¹⁷

(g) Zolmitriptan

In a series of three-period, crossover, randomised studies, 12 healthy subjects were given **selegiline** 10 mg daily or **moclobemide** 150 mg twice daily for 7 days, with a single 10-mg oral dose of zolmitriptan on day 7.¹⁸ It was found that the AUC of the zolmitriptan was increased by 26% by the **moclobemide**. A threefold increase in the AUC of the active metabolite also occurred.¹⁹ It is likely that moclobemide inhibited the metabolism of zolmitriptan via monoamine oxidase A. Despite these increases, because of the good tolerability profile of zolmitriptan, no dosage reductions are thought to be needed if given with **moclobemide**, but a maximum intake of 5 mg in 24 hours is recommended by the UK manufacturers.¹⁹ However, the US manufacturers contraindicate the use of zolmitriptan both during and for 2 weeks after the use of RIMAs.²⁰

Selegiline on the other hand had no effect on the pharmacokinetics of zolmitriptan or its metabolites, apart from a small (7%) reduction in its renal clearance.¹⁸ This finding was expected, since **selegiline** is specific for monoamine oxidase B (but note that this specificity is lost at higher doses). No special precautions would therefore seem to be necessary if **selegiline** is given with sumatriptan.

Triptans + Pizotifen

Pizotifen did not alter the pharmacokinetics or pharmacodynamics of sumatriptan or zolmitriptan, and did not alter the efficacy of acute sumatriptan for migraine. It seems unlikely that any of the other triptans will interact.

Clinical evidence

(a) Sumatriptan

Pizotifen 500 micrograms three times daily for 8 days in 14 healthy subjects was found to have no significant effect on the pharmacokinetics of sumatriptan. In addition, there were no significant changes in blood pressure or heart rate.¹ In a clinical study, the addition of pizotifen prophylaxis did not alter the efficacy of acute sumatriptan for migraine relief. In this study, the combination was associated with more weight gain than sumatriptan alone, an effect which was attributed solely to the pizotifen.²

(b) Zolmitriptan

In a double-blind, randomised study, 12 healthy subjects were given pizotifen 1.5 mg or a placebo once daily for 8 days, with oral zolmitriptan 10 mg on day 8. Pizotifen did not significantly alter the pharmacokinetics of zolmitriptan, and no clinically relevant changes in heart rates or ECGs or blood pressures were seen as a result of concurrent use.³

Mechanism, importance and management

Although the information is limited, it shows that no sumatriptan or zolmitriptan dosage adjustments are expected to be needed if used with pizotifen. On the basis of the information on sumatriptan and zolmitriptan it seems unlikely that any of the other triptans will interact.

Triptans + Protease inhibitors

The manufacturers state that the concurrent use of eletriptan and ritonavir, indinavir, or nelfinavir should be avoided, because these protease inhibitors are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of eletriptan. Concurrent use would therefore be expected to markedly increase levels of eletriptan.^{1,2} In addition, the US manufacturers recommend that eletriptan should not be given within 72 hours of ritonavir and nelfinavir.² This predicted interaction is based on the known interaction with ‘erythromycin’, (p.604) and ‘ketoconazole’, (p.601). Similar predictions are made by the manufacturers of almotriptan, and they advise caution with the use of ritonavir.³

2. Relpax (Eletriptan hydrobromide). Pfizer Inc. US Prescribing information, April 2007.
3. Axert (Almotriptan malate). Ortho-McNeil Pharmaceutical Inc. US Prescribing Information, May 2007.

Triptans + SSRIs and related antidepressants

The SSRIs normally appear not to interact with the triptans, but there are a few rare cases of dyskinesias when sumatriptan was given with an SSRI, and there is some evidence to suggest that the serotonin syndrome may occasionally develop. Venlafaxine and duloxetine are predicted to interact similarly. Fluvoxamine modestly inhibits the metabolism of frovatriptan, and may inhibit the metabolism of zolmitriptan.

Clinical evidence

(a) Almotriptan

Fluoxetine 60 mg daily was given to 14 healthy subjects for 8 days, with a single 12.5-mg dose of almotriptan on day 8. **Fluoxetine** raised the maximum plasma levels of almotriptan by about 18%. The combination was well tolerated and caused no ECG changes, so no dose alterations were considered necessary.¹

(b) *Eletriptan*

The manufacturer notes that although no formal interaction studies have been done, there was no evidence of an interaction between eletriptan and SSRIs in clinical trials, and that SSRIs appeared unlikely to alter the pharmacokinetics of eletriptan.²

(c) *Frovatriptan*

Fluvoxamine has been shown to increase the blood levels of frovatriptan by 27 to 49%.³ The manufacturer recommends caution with concurrent use of frovatriptan and **fluvoxamine** or other SSRIs.⁴

(d) *Naratriptan*

The UK manufacturer of naratriptan notes that there is no evidence of interactions with SSRIs.⁵

(e) *Rizatriptan*

A single 10-mg dose of rizatriptan was given to 12 healthy subjects after they took **paroxetine** 20 mg or a placebo daily for 14 days. The plasma levels of rizatriptan and its active metabolite were not altered by **paroxetine**, and no adverse effects were seen. Safety evaluations included blood pressure, heart rate, temperature and a visual analogue assessment of mood. There was no evidence of the serotonin syndrome.⁶

(f) *Sumatriptan*

A study in 11 healthy subjects found that **paroxetine** 20 mg daily for 16 days had no effect on the response to a 6-mg dose of subcutaneous sumatriptan, as measured by prolactin levels. The sumatriptan levels remained unaltered, its cardiovascular effects were unchanged and no clinically significant adverse effects occurred.⁷ Other studies report that the concurrent use of sumatriptan and SSRIs (**fluoxetine** 20 to 60 mg daily, **fluvoxamine** 200 mg daily, **paroxetine** 20 to 50 mg daily, **sertraline** 50 to 100 mg daily) was successful and uneventful.^{8,9} No adverse effects have been noted in 148 other patients.¹⁰ However, a case report describes a 65-year-old woman who had been taking **paroxetine** 20 mg [daily] for a number of years, who developed confusion, strange behaviour, sinus tachycardia, hypertension and hyperthermia shortly after starting sumatriptan. The serotonin syndrome was diagnosed, and she recovered completely on withdrawal of the two drugs.¹¹

Additionally, in Canada, post-marketing surveillance of the voluntary reports received by the manufacturers of **fluoxetine**, identified 2 cases that showed good evidence, and another 4 cases that showed some, but not strong evidence, of reactions consistent with the serotonin syndrome in patients also taking sumatriptan.¹² Other cases describe a decrease in the efficacy of sumatriptan with **fluoxetine**,¹³ dyskinesias and dystonias with sumatriptan and **paroxetine**,¹⁴ and twenty possible cases of the serotonin syndrome with sumatriptan and SSRIs.^{10,15}

The manufacturers of sumatriptan also say that they have rare post-marketing reports of weakness, hyperreflexia and incoordination following the use of sumatriptan and SSRIs.¹⁶

A prospective study of 12 339 individuals receiving sumatriptan by injection identified 14.5% of these (1784) who were also taking SSRIs (**fluoxetine** 8.3%, **sertraline** 5.5%, **paroxetine** 3.9%, other 0.4%) or **venlafaxine** 1.7%. Patients taking SSRIs were found to have a higher absolute frequency of adverse neurological effects compared with those not taking antidepressants (0.8% and 0.25%, respectively). However, the authors concluded that there was no evidence of an interaction since the adverse events occurred more than 24 hours after the administration of sumatriptan.¹⁷ One case of intractable migraine was reported in a patient taking an SSRI and sumatriptan. The authors report that this infers a lack of effect of the sumatriptan.¹⁷

(g) *Zolmitriptan*

A two-period crossover, double-blind study in 20 subjects given **fluoxetine** 20 mg or a placebo daily for 28 days, with zolmitriptan 10 mg on day 28, found that the pharmacokinetics of zolmitriptan were unaffected by **fluoxetine**.¹⁸ Only very slight changes were seen in the pharmacokinetics of its active metabolite.¹⁸ **Sertraline**, **paroxetine**, and **citalopram** are also not expected to alter the pharmacokinetics of zolmitriptan. However, **fluvoxamine**, a CYP1A2 inhibitor, is predicted to increase levels of zolmitriptan,¹⁹ based on the known interaction with cimetidine (see 'Triptans; Zolmitriptan + Cimetidine', p.608).

Mechanism

Not understood. SSRIs increase the levels of 5-HT (serotonin) at post-synaptic receptors. In theory the triptans (5-HT₁ agonists) might possibly add

to the effects of these increased levels of serotonin, but in practice it is questionable whether this is normally clinically relevant (see also 'Antimigraine drugs', (p.597)). Fluvoxamine probably inhibits the metabolism of frovatriptan⁴ by cytochrome P450 isoenzyme CYP1A2, and is predicted to interact with zolmitriptan¹⁹ by the same mechanism.

Importance and management

The weight of evidence suggests that the concurrent use of the triptans and SSRIs is normally uneventful, but adverse reactions do occur occasionally. The authors of some of the references above concluded that their findings do not imply that concurrent use should be avoided, but that caution and close monitoring should be used.^{10,12} Many of the US manufacturers of the triptans generally advise that patients receiving a triptan and an SSRI or an SNRI (i.e. duloxetine or venlafaxine) should be monitored for any signs of weakness, hyperreflexia, and incoordination. However, see also 'Antimigraine drugs', (p.597). Since fluvoxamine is predicted to have a pharmacokinetic interaction with zolmitriptan the manufacturers recommend a maximum dosage of 5 mg in 24 hours in the presence of fluvoxamine.¹⁹

Triptans + St John's wort (*Hypericum perforatum*)

The CSM in the UK noted that pharmacodynamic (potentiation) interactions have been identified between triptans and St John's wort (*Hypericum perforatum*) leading to an increased risk of adverse effects. They suggest that patients taking triptans should not take St John's wort preparations.¹

1. Committee on Safety of Medicines/Medicines Control Agency. Reminder: St John's Wort (*Hypericum perforatum*) interactions. *Current Problems* (2000) 26, 6–7.

Triptans + Tobacco

The clearance of naratriptan and possibly frovatriptan is modestly increased by smoking. However, this is unlikely to be clinically relevant. There was no evidence of an interaction between smoking and sumatriptan.

Clinical evidence

(a) Frovatriptan

In a retrospective analysis of pharmacokinetic data from phase I studies, there was a trend for a lower frovatriptan AUC and maximum plasma level in smokers when compared with non-smokers. The clearance tended to be higher but the half-life did not differ.¹

(b) Naratriptan

The manufacturer notes that smoking increased the clearance of naratriptan by 30%.²

(c) Sumatriptan

A prospective study of 12 339 individuals receiving sumatriptan by injection identified 18.3% of these (2262) who were current smokers. There was no evidence of an interaction between sumatriptan and tobacco smoking.³

Mechanism

Tobacco smoke is known to induce the cytochrome P450 isoenzyme CYP1A2, which metabolises both naratriptan and frovatriptan to some extent. **Zolmitriptan** is also a substrate of CYP1A2, but the effect of smoking does not appear to have been studied.

Importance and management

Although data are limited, the possible small changes in the pharmacokinetics of frovatriptan and naratriptan with smoking are unlikely to be clinically relevant. It should be noted that smoking is a recognised risk factor for cardiovascular disease. Patients with such risk factors should only use the triptans after careful evaluation.

Triptans + Verapamil

Verapamil inhibits the metabolism of eletriptan (AUC increased 2.7-fold) and almotriptan (AUC increased by 20%) but neither of these changes are considered to be clinically significant.

Clinical evidence, mechanism, importance and management

(a) Almotriptan

In a crossover study, 12 healthy subjects were given a single 12.5-mg dose of almotriptan, either alone or following a week of treatment with sustained-release verapamil 120 mg twice daily. The AUC and maximum plasma level of almotriptan were raised by about 20% and 24%, respectively, by verapamil. However, the only effect this caused was a slight increase in systolic BP (8 mmHg) 2 hours after the dose. It was suggested that verapamil may inhibit the metabolism of almotriptan via the cytochrome P450 isoenzyme CYP3A4. The authors suggest that changes of this magnitude do not warrant dosage adjustments.¹

(b) Eletriptan

In a clinical study with verapamil 480 mg, the maximum plasma levels and AUC of eletriptan were markedly increased by 2.2-fold and 2.7-fold, respectively.^{2,3} However, the UK manufacturers state that these increases were not clinically significant as there were no associated increases in blood pressure or adverse events compared to eletriptan alone.²

Triptans; Sumatriptan + Butorphanol

Sumatriptan given by injection appears not to interact with butorphanol nasal spray, but if both drugs are given sequentially by

nasal spray a modest reduction in butorphanol absorption may occur.

Clinical evidence, mechanism, importance and management

No pharmacokinetic interactions or change in adverse effects were found to occur between single 1-mg doses of butorphanol tartrate nasal spray and a 6-mg subcutaneous dose of sumatriptan succinate in 24 healthy subjects. It was concluded that concurrent use during acute migraine attacks need not be avoided.¹

In another study, 19 healthy subjects were given a 1-mg dose of butorphanol nasal spray either 1 or 30 minutes following a 20-mg dose of sumatriptan nasal spray. When butorphanol was given 1 minute after sumatriptan the AUC and maximum plasma levels of butorphanol were reduced by about 29% and 38%, respectively. When butorphanol was given 30 minutes after sumatriptan no significant pharmacokinetic interaction was noted. It was suggested that sumatriptan may cause a transient vasoconstriction of nasal blood vessels, leading to reduced butorphanol absorption. It would therefore seem wise to separate administration to ensure the full effects of butorphanol are achieved.²

Triptans; Sumatriptan + Loxapine

An isolated report describes a woman taking loxapine who developed a severe dystonic reaction when she was given sumatriptan.

Clinical evidence, mechanism, importance and management

A woman was taking loxapine 10 mg twice daily for psychotic target symptoms, benztropine for the prophylaxis of extrapyramidal effects, carbamazepine for mood stabilisation, and *Fiorcet* (paracetamol (acetaminophen), caffeine, and butalbital) for migraine headaches. Two days after the loxapine dosage was raised to 35 mg daily she was given a single 6-mg subcutaneous dose of sumatriptan for a migraine headache. Within 15 minutes she developed torticollis, which was treated with intramuscular benztropine and intravenous diphenhydramine.

The authors of the report suggest that this reaction was possibly caused by the additive dystonic effects of the loxapine and sumatriptan, despite the presence of the benztropine. Dystonia is not an uncommon extrapyramidal reaction associated with antipsychotics, and neck stiffness and dystonia are recognised adverse effects of sumatriptan, but of low incidence.¹ This seems to be the first and only report of this apparent interaction, and therefore its general significance is unclear.

1. Garcia G, Kaufman MB, Colucci RD. Dystonic reaction associated with sumatriptan. *Ann Pharmacother* (1994) 28, 1199.

Triptans; Sumatriptan + Naproxen

A study in 12 healthy subjects found that a single 500-mg dose of naproxen had no significant effect on the pharmacokinetics of a single 100-mg oral dose of sumatriptan.¹

1. Srinivasu P, Rambhau D, Rao BR, Rao YM. Lack of pharmacokinetic interaction between sumatriptan and naproxen. *J Clin Pharmacol* (2000) 40, 99–104.

Triptans; Sumatriptan + Topiramate

Topiramate does not significantly affect the pharmacokinetics of oral or subcutaneous sumatriptan.

Clinical evidence, mechanism, importance and management

In a study 24 healthy subjects were given topiramate 50 mg every 12 hours increased to 100 mg every 12 hours for a total of 7 days, with a single 100-mg oral dose of sumatriptan on day 7. It was found that topiramate reduced the AUC of sumatriptan by 10%, but this was not considered

to be clinically relevant. Topiramate had no effect on the AUC of sumatriptan given as a 6 mg subcutaneous dose. The clearance of topiramate appeared to be reduced, when data from this study was compared with that from historical controls, but the magnitude of the effect was not stated.¹ The clinical significance of this effect is unclear.

1. Bialer M, Doose DR, Murthy B, Curtin C, Wang S-S, Twyman RE, Schwabe S. Pharmacokinetic interactions of topiramate. *Clin Pharmacokinet.* (2004) 43, 763–80.

Triptans; Zolmitriptan + Cimetidine

Cimetidine raises the plasma levels of zolmitriptan.

Clinical evidence, mechanism, importance and management

The manufacturer of zolmitriptan notes that the half-life of zolmitriptan was increased by 44% and the AUC by 48% when it was given after the use of cimetidine. They suggest that this may be because of the inhibitory effect of cimetidine on the cytochrome P450 isoenzyme CYP1A2, an enzyme involved in the metabolism of zolmitriptan. The UK manufacturer recommends a zolmitriptan dose reduction to a maximum of 5 mg in 24 hours in patients taking cimetidine.¹ The US manufacturer makes no recommendation on dose.²

1. Zomig (Zolmitriptan). AstraZeneca UK Ltd. UK Summary of product characteristics, September 2006.
2. Zomig (Zolmitriptan). AstraZeneca Pharmaceuticals LP. US Prescribing information, January 2007.

Triptans; Zolmitriptan + Metoclopramide

Metoclopramide does not affect the pharmacokinetics of zolmitriptan.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 15 healthy subjects were given single 10-mg doses of zolmitriptan alone or with metoclopramide 10 mg. Metoclopramide had no effect on the pharmacokinetics of zolmitriptan, so there would appear to be no reason for avoiding concurrent use of these two drugs.¹

1. Seaber EJ, Ridout G, Layton G, Posner J, Peck RW. The novel anti-migraine zolmitriptan (Zomig 311C90) has no clinically significant interactions with paracetamol or metoclopramide. *Eur J Clin Pharmacol* (1997) 53, 229–34.

Triptans; Zolmitriptan + Paracetamol (Acetaminophen)

Paracetamol causes a slight increase in zolmitriptan levels and zolmitriptan causes a slight reduction in the rate and extent of pa-

racetamol absorption, but this does not appear to be clinically relevant.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 15 healthy subjects were given single 10-mg doses of zolmitriptan, alone or with 1 g paracetamol. The paracetamol increased the zolmitriptan maximum plasma levels and AUC by 11%, while reducing its renal clearance by 9%. The paracetamol maximum plasma levels and AUC were reduced by 31% and 11%, and absorption was delayed (time to achieve maximum levels 3 versus 0.75 hours). The presence of oral metoclopramide 10 mg did not affect the interaction between zolmitriptan and paracetamol.¹ It was suggested that zolmitriptan might have some inhibitory effect on gastric emptying thereby slowing the absorption of paracetamol. The authors considered that the small changes in pharmacokinetics seen were of no clinical relevance.¹

1. Seaber EJ, Ridout G, Layton G, Posner J, Peck RW. The novel anti-migraine compound zolmitriptan (Zomig 311C90) has no clinically significant interactions with paracetamol or metoclopramide. *Eur J Clin Pharmacol* (1997) 53, 229–34.

Triptans; Zolmitriptan + Quinolones

The UK manufacturer recommends a dose reduction of zolmitriptan to a maximum of 5 mg in 24 hours in patients taking quinolone antibacterials such as ciprofloxacin. This is because these antibacterials are predicted to increase levels of zolmitriptan by inhibiting the cytochrome P450 isoenzyme CYP1A2, an enzyme involved in the metabolism of zolmitriptan.¹ This is based on the known interaction with ‘cimetidine’, (above). However, the US manufacturer makes no comment on this theoretical interaction.²

1. Zomig (Zolmitriptan). AstraZeneca UK Ltd. UK Summary of product characteristics, September 2006.
2. Zomig (Zolmitriptan). AstraZeneca Pharmaceuticals LP. US Prescribing information, January 2007.

Triptans; Zolmitriptan + Xylometazoline

In a clinical study in 18 healthy subjects, there was no change in the rate or extent of absorption of intranasal zolmitriptan 5 mg given 30 minutes after xylometazoline nasal spray.¹ This suggests that nasal vasoconstriction does not affect absorption of intranasal zolmitriptan.

1. Nairn K, Kemp JV, Dane AL, Roberts DW, Dixon R. Evaluation of the effect of xylometazoline on the absorption of zolmitriptan nasal spray. *Clin Drug Invest* (2002) 22, 703–7.

17

Antineoplastics

The antineoplastic drugs (also called cytotoxics or sometimes cytostatics) are used in the treatment of malignant disease alone or in conjunction with radiotherapy, surgery or immunosuppressants. They also find application in the treatment of a number of autoimmune disorders such as rheumatoid arthritis and psoriasis, and a few are used with other immunosuppressant drugs (ciclosporin, corticosteroids) to prevent transplant rejection. These other drugs are dealt with under the section on 'immunosuppressants', (p.1009).

Of all the drugs discussed in this publication, the antineoplastic drugs are amongst the most toxic and have a low therapeutic index. This means that quite small increases in their levels can lead to the development of serious and life-threatening toxicity. A list of the antineoplastic drugs that are fea-

ured in this section appears in 'Table 17.1', (below), grouped by their primary mechanism of action. This table also includes a number of hormone antagonists that are used in the treatment of cancer.

Unlike most of the other interaction monographs in this publication, some of the information on the antineoplastic drugs is derived from *animal* experiments and *in vitro* studies, so that confirmation of their clinical relevance is still needed. The reason for including these data is that the antineoplastic drugs as a group do not lend themselves readily to the kind of clinical studies that can be undertaken with many other drugs, and there would seem to be justification in this instance for including indirect evidence of this kind. The aim is not to make definite predictions, but to warn users of the interaction possibilities.

Table 17.1 Antineoplastics used in the treatment of cancer

Action	Drugs
Alkylating agents, and drugs that appear to have an alkylating action	
Nitrosoureas	Carmustine, Lomustine, Streptozocin
Platinum derivatives	Carboplatin, Cisplatin, Oxaliplatin
Others	Altretamine, Busulfan, Chlorambucil, Chloromethine (Mechlorethamine), Cyclophosphamide, Dacarbazine, Estramustine, Ifosfamide, Melphalan, Temozolomide, Thiotepea
Antimetabolites	
Folate antagonists	Methotrexate, Pemetrexed, Raltitrexed
Podophylotoxin derivatives	Etoposide, Teniposide
Purine analogues	Azathioprine, Cladribine, Fludarabine, Mercaptopurine, Tioguanine
Pyrimidine analogues	Capecitabine, Carmofur, Cytarabine, Fluorouracil, Gemcitabine, Tegafur
Mitotic inhibitors	
Vinca alkaloids	Vinblastine, Vincristine, Vindesine, Vinorelbine
Taxanes	Docetaxel, Paclitaxel
Topoisomerase inhibitors	Irinotecan, Topotecan, 9-Aminocamptothecin
Cytotoxic antibiotics	
Anthracyclines	Aclarubicin, Daunorubicin, Doxorubicin, Epirubicin, Idarubicin, Mitoxantrone
Others	Bleomycin, Dactinomycin, Mitomycin, Plicamycin
Anti-androgens	
	Bicalutamide, Flutamide, Nilutamide
Anti-oestrogens	
Oestrogen-receptor antagonists	Fulvestrant, Tamoxifen, Toremifene
Aromatase inhibitors	Aminoglutethimide, Anastrozole, Exemestane, Formestane, Letrozole
Miscellaneous	
	Amsacrine, Asparaginase (Colaspase, Crisantaspase, Pegaspargase), Bexarotene, Erlotinib, Hydroxycarbamide, Imatinib, Mitotane, Pentostatin, Procarbazine, Sorafenib, Thalidomide, Trastuzumab, Tretinoin

Altretamine (Hexamethylmelamine) + Antidepressants

Severe orthostatic hypotension has been described in patients given altretamine with either phenelzine, amitriptyline or imipramine.

Clinical evidence, mechanism, importance and management

Four patients experienced very severe orthostatic hypotension (described by the authors as potentially life-threatening) when they were given altretamine 150 to 250 mg/m² with either phenelzine 60 mg daily, amitriptyline 50 mg daily or imipramine 50 to 150 mg daily.¹ They experienced incapacitating dizziness, severe lightheadedness, and/or fainting within a few days of taking both drugs concurrently. Standing blood pressures as low as 50/30 and 60/40 mmHg were recorded. The reasons are not known. One of the patients had no problems when imipramine was replaced by nortriptyline 50 mg daily. One other patient who had also taken altretamine with antidepressants reported dizziness, while another noted non-specific discomfort. The incidence of this interaction is unknown, but it is clear that the concurrent use of altretamine and tricyclics or MAOIs should be closely monitored.

1. Bruckner HW, Schleifer SJ. Orthostatic hypotension as a complication of hexamethylmelamine antidepressant interaction. *Cancer Treat Rep* (1983) 67, 516.

Altretamine (Hexamethylmelamine) + Pyridoxine (Vitamin B₆)

Pyridoxine reduced the neurotoxicity associated with altretamine, but also reduced its effectiveness.

Clinical evidence, mechanism, importance and management

In a large randomised study in women with advanced ovarian cancer the neurotoxicity associated with altretamine and cisplatin chemotherapy was reduced by pyridoxine, but the response duration was also reduced.¹ In this study, cisplatin was given on day 1 (37.5 or 75 mg/m²) and altretamine 200 mg/m² daily was given on days 8 to 21, and half the patients also received pyridoxine 100 mg three times daily on days 1 to 21. It is unclear how pyridoxine reduced the activity of this regimen, but the use of pyridoxine (vitamin B₆) should probably be avoided in patients receiving altretamine.

1. Wiernik PH, Yeap B, Vogel SE, Kaplan BH, Comis RL, Falkson G, Davis TE, Fazzini E, Chevart B, Horton J. Hexamethylmelamine and low or moderate dose cisplatin with or without pyridoxine for treatment of advanced ovarian carcinoma: a study of the Eastern Cooperative Oncology Group. *Cancer Invest* (1992) 10, 1–9.

9-Aminocamptothecin + Antiepileptics

Enzyme-inducing antiepileptics can lower the serum levels of 9-aminocamptothecin.

Clinical evidence, mechanism, importance and management

A study in 59 patients with glioblastoma multiforme or recurrent high grade astrocytomas found that the steady-state plasma levels of 9-aminocamptothecin were reduced to about one-third in 29 of the patients also taking antiepileptics (carbamazepine, phenobarbital, phenytoin, sodium valproate). The incidence of myelosuppression was greater in those not taking antiepileptics.¹ A further study also found that the clearance of 9-aminocamptothecin was increased by carbamazepine and phenytoin.² The reason for the reduced 9-aminocamptothecin levels is not known, but it seems likely that it was due to the enzyme-inducing activity of carbamazepine, phenobarbital and phenytoin. These results suggest that higher than usual doses of 9-aminocamptothecin are possibly needed in the presence of enzyme-inducing antiepileptics. Related topoisomerase in-

hibitors are similarly affected, see 'Irinotecan + Antiepileptics', p.638, and 'Topotecan + Phenytoin', p.667.

2. Minami H, Lad TE, Nicholas MK, Vokes EE, Ratain MJ. Pharmacokinetics and pharmacodynamics of 9-aminocamptothecin infused over 72 hours in phase II studies. *Clin Cancer Res* (1999) 5, 1325–30.

Aminoglutethimide + Danazol

Danazol may reduce the efficacy of aminoglutethimide.

Clinical evidence, mechanism, importance and management

In a randomised clinical study, giving danazol with aminoglutethimide in women with breast cancer, reduced the response rate compared with aminoglutethimide alone. It was found that danazol suppresses sex hormone binding globulin leading to increased free oestradiol, which counteracts the oestradiol suppressive effect of aminoglutethimide.¹ Danazol should probably not be combined with anti-oestrogenic treatments.

1. Dowsett M, Murray RML, Pitt P, Jeffcoate SL. Antagonism of aminoglutethimide and danazol in the suppression of serum free oestradiol in breast cancer patients. *Eur J Cancer Clin Oncol* (1985) 21, 1063–8.

Aminoglutethimide + Diuretics

A single case report describes hyponatraemia, which occurred after a patient had taken aminoglutethimide and bendroflumethiazide for 10 months.

Clinical evidence, mechanism, importance and management

A woman who, for several years, had been taking bendroflumethiazide 10 mg daily and potassium chloride 578 mg for hypertension and mild cardiac decompensation, was given aminoglutethimide 1 g daily, and hydrocortisone 60 mg daily, for breast cancer. After 10 months of treatment she was hospitalised with severe hyponatraemia, which resolved on withdrawal of all the drugs. No significant change in electrolytes occurred over 3 months when the aminoglutethimide and hydrocortisone were used alone, but serum sodium fell again when the diuretic was restarted. The serum sodium levels were subsequently maintained by the addition of fludrocortisone 100 micrograms daily.¹ The hyponatraemia was thought to be caused by the combined inhibitory effect of the aminoglutethimide on aldosterone production (which normally retains sodium in the body) and the sodium loss caused by the diuretic. Plasma electrolytes should be monitored when aminoglutethimide is used, and this would seem particularly important if it is given with any diuretic.

1. Bork E, Hansen M. Severe hyponatremia following simultaneous administration of aminoglutethimide and diuretics. *Cancer Treat Rep* (1986) 70, 689–90.

5-Aminolevulinic acid + St John's wort (*Hypericum perforatum*)

An isolated case report describes a severe phototoxic reaction attributed to a synergistic effect of 5-aminolevulinic acid and St John's wort.

Clinical evidence, mechanism, importance and management

A 47-year-old woman experienced a phototoxic reaction on skin areas exposed to light 6 hours after receiving 5-aminolevulinic acid 40 mg/kg. She developed a burning erythematous rash and severe swelling of the face, neck and hands. Treatment with oral corticosteroids resulted in complete resolution after skin desquamation. She was also taking St John's wort (*Hyperiforce*), and it was suggested that there was a synergistic photosensitivity reaction between the two drugs. *In vitro* studies confirmed this.¹ This appears to be the only report of such an effect, but bear it in mind in the event of an unexpected adverse reaction to 5-aminolevulinic acid.

Anastrozole + Miscellaneous

Anastrozole does not appear to interact with aspirin, cimetidine, digoxin, oral antidiabetics or quinapril. It also appears to have no effect on cytochrome P450 enzymes, so it is unlikely to interact with drugs that are affected by enzyme inducers or inhibitors.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 10 elderly women with breast cancer were given anastrozole 1 mg daily for 10 weeks and 5 of them who also had hypertension were additionally given **quinapril**, after week 4, for 28 days. **Quinapril** did not affect plasma anastrozole levels and dose modification is not required during concurrent use.¹ A clinical study with **cimetidine** has shown that it does not affect the pharmacokinetics of anastrozole,² which suggests that anastrozole is unlikely to be affected by other drugs that inhibit cytochrome P450. Another clinical study showed that anastrozole does not affect the pharmacokinetics of **antipyrine (phenazone)**,³ so that it is unlikely to interact with those drugs which are known to be affected by enzyme inducers and inhibitors.

The UK manufacturers also say that in clinical studies there was no evidence of any interactions between anastrozole and commonly used drugs;⁴ **aspirin, digoxin, and oral antidiabetics** were specifically mentioned in the early product information.⁵

Anthracyclines + Calcium-channel blockers

Verapamil can increase the efficacy of doxorubicin in tissue culture systems and increase doxorubicin levels in patients. D-verapamil can alter the pharmacokinetics of epirubicin and possibly increase its bone marrow depressant effects.

Clinical evidence, mechanism, importance and management

(a) Doxorubicin

The efficacy of doxorubicin can be increased by **verapamil** and **nifedipine** in doxorubicin-resistant tissue culture systems,¹ while **nifedipine** has only minimal activity. A study in five patients with small cell lung cancer given doxorubicin, vincristine, etoposide and cyclophosphamide showed that when they were given **verapamil** 240 to 480 mg daily the AUC of doxorubicin was doubled, its peak serum levels were raised and its clearance was reduced. No increased toxicity was seen in this study.² However, although another study found no increase in non-cardiac toxicities, **verapamil** caused an unacceptable degree of cardiac toxicity.³ Be alert for this possibility if both drugs are used.

(b) Epirubicin

When used to reduce multidrug resistance in patients with advanced colorectal cancer receiving epirubicin, the **D-isomer of verapamil** appears to increase the bone marrow depressant toxicity of epirubicin.⁴ Another study found that **D-verapamil** halved the AUC and half-life of epirubicin, and increased its clearance,⁵ while yet another did not find these changes but found that the production of the metabolites of epirubicin was increased.⁶ These changes should be taken into account if both drugs are used. More study is needed to evaluate the possible advantages and disadvantages of giving these drugs together.

Anthracyclines + Ciclosporin

High-dose ciclosporin increases the serum levels and the myelotoxicity of doxorubicin. An isolated report describes severe neurotoxicity and coma in a patient who had taken ciclosporin and was then subsequently given doxorubicin. Ciclosporin can also increase daunorubicin, epirubicin, idarubicin and mitoxantrone serum levels.

Clinical evidence

(a) Daunorubicin

In a randomised study in patients treated with daunorubicin, ciclosporin significantly reduced the frequency of resistance to induction therapy (31% versus 47%) and increased relapse-free and overall survival. Ciclosporin recipients had higher steady-state serum levels of daunorubicin and its active metabolite daunorubicinol.¹

(b) Doxorubicin

Eight patients with small cell lung cancer were given an initial course of doxorubicin (25 to 70 mg/m² over 1 hour) and a subsequent ciclosporin-modulated doxorubicin course (ciclosporin 6 mg/kg bolus, then 16 mg/kg daily for 2 days) for multidrug resistant tumour modulation. All of the patients were also given cyclophosphamide and vincristine. Ciclosporin increased the AUC of doxorubicin by 48%, and that of its active metabolite doxorubicinol by 443%. The myelotoxicity was increased by concurrent use: the leucocyte count fell by 84% after doxorubicin and by 91% after doxorubicin with ciclosporin, and the platelet counts fell by 36% and 73%, respectively. The patients showed significant weight loss and severe myalgias.²

Three preliminary phase I studies^{3–5} are consistent with this report. In these studies, ciclosporin was found to increase the doxorubicin AUC by 40 to 73%, and the doxorubicinol AUC by 250 to 285%. However, no evidence of increased cardiotoxicity was found in a study of 23 patients given ciclosporin and doxorubicin.⁶

A cardiac transplant patient was given ciclosporin 2 mg/kg daily for 22 months. The ciclosporin was stopped and he was given doxorubicin 60 mg, vincristine 2 mg, cyclophosphamide 600 mg and prednisone 80 mg to treat Burkitt's lymphoma stage IVB. Eight hours later he developed disturbances of consciousness which lead to stage I coma, from which he spontaneously recovered 12 hours later. A week later a similar course of chemotherapy was started, and 10 to 15 minutes later he lost consciousness and generalised tonic clonic seizures progressively developed. He died 8 days later without recovering consciousness.⁷

(c) Epirubicin

Preliminary evidence suggests that ciclosporin can markedly increase the AUC of epirubicin (up to about fourfold) and increase the bone marrow suppression.⁵ Ciclosporin did not increase the cardiotoxicity of epirubicin in 20 patients in one study.⁶

(d) Idarubicin

The concurrent use of ciclosporin and idarubicin increased the AUC of idarubicin and its active metabolite idarubicinol by 77% and 181%, respectively, in 9 patients, when compared with 11 patients receiving idarubicin alone.⁸ Unacceptable toxicity occurred when idarubicin 9 or 12 mg/m² daily was combined with ciclosporin 16 mg/kg daily, when compared with idarubicin 12 mg/m² alone: 3 of 7 patients treated with the combination died. Increases in the AUC of idarubicin and idarubicinol produced by ciclosporin have also been reported elsewhere.⁹

(e) Mitoxantrone

The pharmacokinetics of mitoxantrone 10 mg/m² daily were compared with mitoxantrone 6 mg/m² (a 40% reduction in dose) with high-dose ciclosporin in children. The ciclosporin recipients had a 42% reduction in mitoxantrone clearance, a 12% increase in mitoxantrone AUC, and similar toxicity.¹⁰

Mechanism

Uncertain. One reason may be that the ciclosporin affects the P-glycoprotein of the biliary tract so that the clearance of these anthracyclines in the bile is reduced. An additional reason may be that ciclosporin inhibits the metabolism of metabolites, such as doxorubicinol, so that they accumulate.² The increased levels of both would explain the increases in toxicity. It is not clear why such severe neurotoxicity was seen in one patient.

Importance and management

An established and clinically important interaction. Ciclosporin alters the pharmacokinetics of the anthracyclines resulting in increased serum levels. This pharmacokinetic interaction has complicated study into the value of using ciclosporin to modulate multidrug resistance in tumours and thereby improve the response to chemotherapy. In the case of anthracyclines and 'etoposide', (p.630), any benefit could just be attributed to dose intensification. Consequently, some have suggested reducing the dose of the anthracycline.¹⁰ The use of high-dose ciclosporin for multidrug resistant tumour modulation remains experimental and should only be used in clinical studies. Concurrent use should be very well monitored. More study is needed to find out the possible effects of low-dose ciclosporin.

Anthracyclines + Taxanes

Toxicity associated with combinations of paclitaxel with doxorubicin or epirubicin depends on the order of administration. Some modest pharmacokinetic changes may occur when paclitaxel and epirubicin are given together. The combination of doxorubicin and paclitaxel is more cardiotoxic than doxorubicin alone: paclitaxel increases doxorubicin levels but doxorubicin does not alter paclitaxel levels. Docetaxel may modestly affect the pharmacokinetics of epirubicin and doxorubicin.

Clinical evidence

(a) Doxorubicin

Early studies in patients with breast cancer found a higher frequency of toxicity (particularly mucositis) when paclitaxel was given before doxorubicin (given as 24-hour and 48-hour infusions, respectively).¹ A subsequent study with similar effects revealed that doxorubicin clearance was reduced by one-third if paclitaxel was given first.² In another study the peak plasma levels of doxorubicin were increased when it was given by bolus injection 15 minutes after a 3-hour infusion of paclitaxel. The effect was non-linear and dependent on the dose of paclitaxel.³ The same authors had already shown that this regimen produced a higher than expected incidence of cardiac toxicity.⁴ Subsequent studies^{5,6} have shown this schedule to result in unacceptable cardiotoxicity when the total cumulative doxorubicin dose exceeds 340 to 380 mg/m². However, when paclit-

axel and doxorubicin were given together as a 3-hour infusion the levels of doxorubicin were lower than when it was given before paclitaxel,³ and in another study the pharmacokinetics of each drug were found to be unchanged when they were given simultaneously as a 72-hour infusion.⁷

In 10 patients the AUC of intravenous pegylated liposomal doxorubicin (*Caelyx*) 30 to 35 mg/m² was increased by a mean of 80% when it was given with intravenous paclitaxel 70 or 175 mg/m². Peak plasma levels of doxorubicin were also increased and clearance was reduced by 71%. In 9 other patients given *Caelyx* with docetaxel 30 or 60 mg/m², the AUC of doxorubicin was increased by 12% and clearance reduced by only 16%.⁸

In a study, 627 patients with breast cancer were given either doxorubicin 50 mg/m² with docetaxel 75 mg/m², or doxorubicin 60 mg/m² with cyclophosphamide 600 mg/m² postoperatively for 4 courses to assess disease-free survival at 5 years. The study was terminated prematurely because of the high risk of life-threatening complications in those given doxorubicin with docetaxel (2 deaths associated with drug toxicity and one case of perforated peritonitis in patients with febrile neutropenia). The incidence of febrile neutropenia was 40.8% and 7.1% in the doxorubicin-docetaxel and doxorubicin-cyclophosphamide groups, respectively.⁹

A woman with recurrence of breast cancer developed pseudomembranous colitis (non-*Clostridium difficile*) and cholestatic jaundice 6 days after completing her first cycle of treatment with doxorubicin and docetaxel and again 4 days after the second cycle about one month later.¹⁰

(b) Epirubicin

The pharmacokinetics of epirubicin were compared in 4 patients with breast cancer given intravenous epirubicin 90 mg/m² alone and 16 patients given the same dose followed immediately either by paclitaxel 175 mg/m² as a 3-hour infusion or docetaxel 70 mg/m² as a 1-hour infusion. No effect on epirubicin levels was detected, but the concentrations of epirubicin metabolites (epirubicinol and deoxydoxorubicinone) were increased by both paclitaxel and docetaxel.¹¹ In a subsequent study 21 patients were given the same regimen of epirubicin followed immediately by paclitaxel and 18 patients were given the drugs in the reverse order. Non-haematological toxicity was unaffected by the order of administration but when paclitaxel was given first the neutrophil and platelet nadir was lower and neutrophil recovery was slower. The AUC for epirubicin was also higher when paclitaxel was given first but the pharmacokinetics of paclitaxel were unaffected.¹² In one study, 21 women with breast cancer were given intravenous epirubicin 90 mg/m² followed 15 minutes later by a 3-hour intravenous infusion of paclitaxel 175 mg/m² (6 patients), 200 mg/m² (9 patients), or 225 mg/m² (6 patients). Six women were given paclitaxel 200 mg/m² 30 hours after epirubicin. A significant increase in the AUC of epirubicin occurred with paclitaxel 200 mg/m² (23%) and 225 mg/m² (34%) and increases in the AUC of the metabolite of epirubicin (epirubicinol) occurred at all dose levels of paclitaxel compared with those found when epirubicin was given 30 hours before paclitaxel.¹³ In another study, exposure to epirubicin metabolites, but not epirubicin itself, was increased when it was given 15 minutes before a 3-hour infusion of paclitaxel, when compared to a regimen using a 24-hour interval between the two drugs. In addition, the neutrophil nadir was lower, and clearance of paclitaxel was 30% slower with the former regimen, but cardiac toxicity was uncommon.¹⁴

Conversely, a study of the combination of docetaxel and epirubicin did not find that the sequence of drug administration affected the pharmacokinetics of epirubicin, nor was there any difference in toxicity.¹⁵ In another study, 16 patients with breast cancer had a transient but significant increase in epirubicin plasma levels during the subsequent infusion (after an interval of 1 hour) of docetaxel 75 mg/m², which was not seen if the docetaxel was given within 10 minutes of epirubicin.¹⁶

Mechanism

Studies in mice have found that the taxanes docetaxel and paclitaxel, and the vehicle used for paclitaxel *Cremophor*, may all modify the distribution and metabolism of doxorubicin increasing its levels in the heart, liver and kidneys. This may contribute to the cardiac toxicity seen during use with paclitaxel.¹⁷ Similarly, *in vitro* studies in human myocardium showed that paclitaxel and docetaxel increased the conversion of doxorubicin to doxorubicinol, the metabolite that is thought to be responsible for cardiotoxicity.¹⁸ An *in vitro* study on the effect of paclitaxel and *Cremophor* on epirubicin metabolism in human blood found that paclitaxel slightly decreased production of epirubicinol. A marked inhibition of epirubicinol production occurred in the presence of *Cremophor*, but because of the low

volume of distribution of *Cremophor* this is not likely to be of clinical significance.¹³ In addition, *in vitro* studies have shown that the taxanes may reduce the biliary excretion of doxorubicin and epirubicin by inhibiting P-glycoprotein,³ and inhibition of epirubicinol excretion via competition for P-glycoprotein by paclitaxel and *Cremophor* may be significant.¹³

The case of pseudomembranous colitis and cholestatic jaundice in one patient was attributed to the combination of docetaxel and doxorubicin, but the patient was also receiving long-term treatment with erythromycin and omeprazole which may have contributed to the interaction by inhibiting docetaxel metabolism by the cytochrome P450 isoenzyme CYP3A.¹⁰

Importance and management

The effect of paclitaxel on doxorubicin appears to be established. It has been noted that when paclitaxel or docetaxel are given with pegylated doxorubicin, exposure to doxorubicin is increased by at least 50% and less than 20%, respectively and that this should be taken into account during concurrent use.⁸ Various strategies have been suggested to reduce the cardiotoxicity of the combination of doxorubicin and taxanes. These include giving doxorubicin at least 24 hours before paclitaxel; reducing the cumulative dose of doxorubicin; or adding the cytoprotective drug dexrazoxane.¹⁹ Epirubicin is considered less cardiotoxic than doxorubicin, and may be an alternative in some situations. However, it still appears preferable to give the anthracycline before the taxane. Docetaxel appears to have little clinically relevant effect on epirubicin, but this requires confirmation. Further study is needed on the optimum scheduling of anthracyclines and taxanes to maximise efficacy and minimise toxicity.

Anthracyclines; Aclarubicin + Other antineoplastics

The bone marrow depressant effects of aclarubicin can be particularly severe in patients who have previously been treated with nitrosoureas or mitomycin. Aclarubicin appears not to interact with cyclophosphamide, cytarabine, enocitabine (behenoyl cytarabine), fluorouracil, mercaptopurine, tioguanine or vincristine.

Clinical evidence, mechanism, importance and management

Myelosuppression is among the adverse effects of aclarubicin. The concurrent use of other drugs with similar myelosuppressant actions may be expected to have additive effects. Previous treatment with **nitrosoureas** (not specifically named) or **mitomycin** has been shown to increase the severity of the myelosuppression.^{1,2}

Anthracyclines; Doxorubicin + Barbiturates

The effects of doxorubicin may be reduced by the barbiturates.

Clinical evidence, mechanism, importance and management

A comparative study in patients given doxorubicin found that those also taking barbiturates had a plasma clearance that was 50% higher than those who were not (318 mL/minute compared with 202 mL/minute).¹ This clinical study is in agreement with previous studies in *mice*.² A possible explanation is that the barbiturate increases the metabolism of the doxorubicin. It seems possible that the dosage of doxorubicin will need to be increased in barbiturate-treated patients to achieve maximal therapeutic effects.

- Reich SD, Bachur NR. Alterations in adriamycin efficacy by phenobarbital. *Cancer* (1976) 36, 3803–6.

Anthracyclines; Doxorubicin + Tamoxifen

Tamoxifen appears to have no significant effect on the pharmacokinetics of doxorubicin.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in patients with non-Hodgkin's lymphoma receiving CHOP (cyclophosphamide, vincristine, prednisone and doxorubicin 37.5 to 50 mg/m²) found that the addition of tamoxifen 480 mg daily for 5 days had no significant effect on the AUC or total clearance of doxorubicin.¹ For the possible additive thromboembolic effect of doxorubicin and tamoxifen, see 'Antineoplastics + Tamoxifen', p.616.

- El-Yazigi A, Berry J, Ezzat A, Wahab FA. Effect of tamoxifen on the pharmacokinetics of doxorubicin in patients with non-Hodgkin's lymphoma. *Ther Drug Monit* (1997) 19, 632–6.

Anthracyclines; Epirubicin + Cimetidine

Cimetidine can increase epirubicin serum levels.

Clinical evidence, mechanism, importance and management

In a study in 8 patients, cimetidine 400 mg twice daily increased the AUC of epirubicin by 50%. At the same time the AUCs of two metabolites of epirubicin, epirubicinol and 7-deoxydoxorubicinol aglycone, increased by 41% and 357%, respectively. Liver blood flow also increased by 17%.¹ The mechanism is unknown. More study of this interaction is needed but be aware of the possibility of cimetidine increasing the exposure to epirubicin; monitor the patient closely and adjust epirubicin dosage if needed. Cimetidine is available without a prescription in some countries so that patients may unwittingly increase the toxicity of epirubicin. Cimetidine has also increased the levels or toxicity of some other antineoplastics, see 'Nitrosoureas + Cimetidine', p.655, 'Cyclophosphamide + H₂-receptor antagonists', p.626 and 'Fluorouracil + H₂-receptor antagonists', p.633.

1. Murray LS, Jodrell DI, Morrison JG, Cook A, Kerr DJ, Whiting B, Kaye SB, Cassidy J. The effect of cimetidine on the pharmacokinetics of epirubicin in patients with advanced breast cancer: preliminary evidence of a potentially common drug interaction. *Clin Oncol* (1998) 10, 35–8.

Antineoplastics + Aprepitant

Aprepitant had no effect on the pharmacokinetics of a single dose of docetaxel. The activation of cyclophosphamide and thiotepa was slightly lower in patients receiving aprepitant, but this was not clinically relevant. However, because of the possibility of increased toxicity the manufacturer recommends caution with antineoplastics principally metabolised by the cytochrome P450 isoenzyme CYP3A4, particularly irinotecan, and also etoposide, vinorelbine, paclitaxel, ifosfamide, imatinib, vinblastine and vincristine, although there appears to be some limited evidence of safe concurrent use.

Clinical evidence

(a) Cyclophosphamide

The rate of auto-induction of cyclophosphamide was 23% lower and exposure to the active metabolite 4-hydroxycyclophosphamide was 5% lower in 6 patients receiving aprepitant with a 4-day course of high-dose CTC (cyclophosphamide, thiotepa, carboplatin) when compared with 49 patients receiving high-dose CTC without aprepitant.¹

(b) Docetaxel

Aprepitant 125 mg given one hour before docetaxel on day one, then 80 mg daily on days 2 and 3 had no effect on the pharmacokinetics of a single 60- to 100-mg/m² infusion of docetaxel in 10 cancer patients, and did not alter the toxicity profile. Each subject acted as their own control.²

(c) Thiotepa

The formation clearance of thiotepa was 33% lower and exposure to the active metabolite TEPA (triethylenephosphamide) was 20% lower in 6 patients receiving aprepitant with a 4-day course of high-dose CTC (cyclophosphamide, thiotepa, carboplatin) when compared with 49 patients receiving high-dose CTC without aprepitant.¹

Mechanism

In the short-term, aprepitant is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, and might therefore reduce the activation of antineoplastics activated by this isoenzyme (cyclophosphamide, thiotepa), or increase the toxicity of antineoplastics metabolised by this enzyme (docetaxel, irinotecan).

Importance and management

The UK manufacturer of aprepitant recommends caution when it is used with antineoplastics that are metabolised by CYP3A4, particularly **irinotecan**, because of the possibility of increased toxicity with this drug.³ They also mention that **etoposide**, **vinorelbine**, **docetaxel**, **paclitaxel**,^{3,4} **ifosfamide**, **imatinib**, **vinblastine** and **vincristine**,⁴ were given without dosage adjustment for potential interactions, but as this was not a formal interaction study they recommend caution. However, with intravenous docetaxel, it appears that no important changes in pharmacokinetics occur, and therefore dosage adjustments are unlikely to be needed for this drug,

and possibly also other intravenous antineoplastics metabolised by CYP3A4.² Similarly, the minor reductions in the activation of cyclophosphamide and thiotepa were considered small compared to total variability, and therefore unlikely to be clinically important.

Antineoplastics + Colony-stimulating factors

Because of the increased risk of myelosuppression, colony-stimulating factors such as filgrastim, lenograstim, and molgramostim should not be given at the same time as myelosuppressive cytotoxic antineoplastics.

Clinical evidence, mechanism, importance and management

Colony-stimulating factors such as filgrastim, lenograstim, and molgramostim promote the growth of myeloid cell lines. Since rapidly dividing myeloid cells have increased sensitivity to cytotoxic chemotherapy the manufacturers have advised that these drugs should not be used from 24 hours before until 24 hours after cytotoxic chemotherapy.^{1–3} In support of this, the manufacturer of filgrastim notes that preliminary evidence confirmed that the severity of neutropenia could be exacerbated when patients were treated concurrently with **fluorouracil** and filgrastim.²

Note also that there is some evidence that colony-stimulating factors may potentiate the pulmonary toxicity of 'bleomycin', (p.618) and 'cyclophosphamide', (p.625).

Antineoplastics + 5-HT₃-receptor antagonists

Some evidence suggests ondansetron may modestly affect the pharmacokinetics of cyclophosphamide and cisplatin but it does not appear to affect those of carmustine. Ondansetron did not affect the *in vitro* activity of epirubicin, bleomycin, cisplatin or estramustine. Cisplatin and fluorouracil do not affect the pharmacokinetics of ondansetron. In *in vitro* studies granisetron potentiated the cytotoxic effects of epirubicin, had an additive effect on bleomycin and estramustine activity and appeared not to affect the metabolism of docetaxel and paclitaxel.

Clinical evidence, mechanism, importance and management

(a) Granisetron

In an *in vitro* study, granisetron significantly potentiated the cytotoxic effects of **epirubicin** on fibroblasts, and the effect of granisetron on the cytotoxic effects of **bleomycin** and **estramustine** in lung cancer cells appeared to be additive. The clinical relevance of the effects of granisetron on **epirubicin** is not known.¹ Another *in vitro* study found that granisetron did not affect the metabolism of **docetaxel** or **paclitaxel**.²

(b) Ondansetron

The pharmacokinetics of high-dose **cyclophosphamide**, **cisplatin** and **carmustine** in 23 patients given ondansetron, lorazepam and diphenhydramine as antiemetics were compared with those in 129 patients who received prochlorperazine instead of ondansetron. It was found that the AUCs of **cyclophosphamide** and **cisplatin**, but not that of **carmustine**, were significantly lower (by 15% and 19%, respectively) in the ondansetron group.³ Similarly, in another study, the pharmacokinetics of antineoplastics were analysed in 54 patients with breast cancer who were receiving high-dose **cyclophosphamide**, **cisplatin** and **carmustine** with lorazepam and ondansetron with or without prochlorperazine and com-

pared with 75 matched control patients whose had been given prochlorperazine and lorazepam. In those given ondansetron the median AUC of **cyclophosphamide** was 17% lower, the **cisplatin** AUC was about 10% higher and the **carmustine** AUC was unchanged.⁴ In contrast, a study in 10 patients who received intravenous **cyclophosphamide** 600 mg/m² and **epirubicin** 90 mg/m² and either oral ondansetron 16 mg or placebo found that the pharmacokinetic parameters of **cyclophosphamide** or its metabolite were not significantly altered by ondansetron although there was considerable variation between subjects. It was concluded that ondansetron can be safely given with **cyclophosphamide**.⁵ No significant changes in the pharmacokinetics of ondansetron occurred in 20 cancer patients taking **cisplatin** 20 to 40 mg/m² and/or **fluorouracil** 1 g/m² for 5 days but the clearance was lower than in healthy subjects.⁶

An *in vitro* study found that ondansetron did not affect the cytotoxic effects of **bleomycin**, **epirubicin**, **estramustine** or **cisplatin** in fibroblasts and lung cancer cells.¹

Information seems to be limited to these studies, and the interaction is not established. The clinical relevance of these possible modest changes in AUC of cyclophosphamide (0 to 17% reduction) and cisplatin (19% reduction or 10% increase) remain to be determined.

Antineoplastics + Megestrol

There is some *in vitro* evidence to suggest that megestrol acetate may antagonise the antitumour activity of cisplatin. In one clinical study megestrol reduced the response rates to etoposide with cisplatin but in another had no effect on response rates to alternating cycles of cyclophosphamide, doxorubicin and vincristine, and etoposide with cisplatin.

Clinical evidence

A study in 243 patients with advanced small-cell lung cancer (SCLC) treated with **etoposide** and **cisplatin** found that those who also received megestrol acetate 800 mg daily had increased non-fluid body-weight and significantly less nausea and vomiting. Although the 1-year survival rate was similar in both groups those who received megestrol had a significantly worse response rate to **cisplatin** (68% compared with 80%) and a higher incidence of thromboembolic events. However the megestrol recipients did have poorer quality of life (a prognostic factor) at the beginning of the study and this may have influenced the findings.¹ In a similar study, megestrol acetate had no effect on response rates, symptom profile or overall survival in patients with SCLC receiving chemotherapy (alternating cycles of **cyclophosphamide**, **doxorubicin** and **vincristine**, and **etoposide** with **cisplatin** for a maximum of 6 cycles). In this study, megestrol acetate was given at a dose of 160 mg three times daily for 8 days starting 3 days before each cycle of chemotherapy.²

Mechanism

An *in vitro* study found that megestrol may antagonise the antineoplastic activity of cisplatin by up-regulating cellular detoxification mechanisms.³

Importance and management

The authors of the first study suggest that megestrol acetate should not be used routinely at the time of chemotherapy.¹ Be aware that the use of meg-

estrol may antagonise the antitumour activity of cisplatin. More study is needed.

Antineoplastics + Propofol

There are two isolated reports of severe pain occurring when patients who had previously received intravenous chemotherapy were given intravenous propofol via hand veins.

Clinical evidence, mechanism, importance and management

Although pain on injection of propofol is well known one group of workers noted that on a number of occasions patients previously treated with intravenous chemotherapy had marked pain, both at the site of injection and up the arm, when given propofol via hand veins.¹ This would seem to link with a report of a 15-year-old girl with acute lymphoblastic leukaemia who had been treated with several injections of **cyclophosphamide**, **methotrexate** and **vincristine** during the previous 6 months, and who was cannulated in her hand and given an infusion of *Plasmalyte B*. An injection of 60 micrograms of fentanyl via this cannula was painful and 20 mg of lidocaine helped, but 20 mg of propofol caused extreme pain. A further 20 mg of lidocaine was given and the propofol administration was stopped, but the pain continued. The whole hand became blue and congested, and blood began to move backwards up the drip tubing. The venous congestion gradually subsided over the next 15 minutes.² The authors recommended that propofol should be avoided in patients who have recently had intravenous chemotherapy.² The general applicability of these reports remains to be determined. The use of propofol alone may cause pain and it should be noted that the manufacturers of propofol recommend that local pain associated with propofol during the induction phase can be minimised by the use of the larger veins on the forearm and antecubital fossa.³

Antineoplastics + Protease inhibitors

Use of protease inhibitor-based regimens has been found to be associated with a higher incidence of infections and neutropenia in patients receiving cyclophosphamide, doxorubicin and etoposide (CDE) than use of a NNRTI-based regimen.

Clinical evidence, mechanism, importance and management

A study to compare the incidence of neutropenia and infection resulting from protease inhibitor or NNRTI-based antiretroviral regimen given with **cyclophosphamide**, **doxorubicin** and **etoposide** (CDE) chemotherapy for AIDS-related non-Hodgkin's lymphoma was carried out in 46 patients with AIDS-related non-Hodgkin's lymphoma. Eleven patients were taking protease inhibitor-based antiretroviral treatment. There was a higher incidence of infections requiring hospitalisation in the group taking a protease inhibitor than in the NNRTI-based treatment group (48% compared with 25%). There was a similar difference in the incidence of grade 4 neutropenia (54% compared with 38%) and day 10 and day 14 neutrophil counts were significantly lower in patients receiving protease inhibitors, resulting in delays in giving chemotherapy in 16% of cycles (compared with 9% when no protease inhibitor was given). Overall, however, there was no difference in response rate, disease-free survival or overall survival

between the two groups. The authors suggested that the increase in myelosuppression may be caused by the protease inhibitors reducing the metabolism of CDE via inhibition of cytochrome P450 enzymes, or inhibition of P-glycoprotein.¹ Inhibitors of CYP3A4 may increase toxicity with etoposide, see 'Etoposide + CYP3A4 inhibitors', p.631.

Antineoplastics + Semaxanib

The combination of semaxanib, cisplatin and gemcitabine has caused an unexpectedly high incidence of thromboembolic events.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of semaxanib (SU5416), **cisplatin** and **gemcitabine** were unaltered when they were given together in a phase I study but investigation of the combination was terminated after 8 of the 19 patients had thromboembolic events (transient ischaemic attacks, cerebrovascular accidents, deep vein thromboses). **Gemcitabine** 1250 mg/m² was given on day 1, immediately followed by **cisplatin** 80 mg/m², then semaxanib 85 mg/m² (escalated to 145 mg/m² in some patients). **Gemcitabine** then semaxanib were given on day 8, and semaxanib alone on days 4, 11, 15, and 18. The cycle was repeated every 3 weeks.¹ The incidence of thromboembolic events in this study (42%) was much higher than that seen with **cisplatin** and **gemcitabine** (0%) or semaxanib alone (2.2%), and was thought to be a result of the drug combination.¹ **Cisplatin** in particular, due to its effects on platelets and its vasoconstrictive effects, may be the drug interacting with the semaxanib.² Preliminary results of other studies of semaxanib with: **irinotecan**; **fluorouracil** and folinic acid; **irinotecan**, **fluorouracil** and folinic acid; or **paclitaxel** and **carboplatin** did not report this complication.^{3–6} The authors of the first study¹ caution against further clinical trials of antineoplastics with angiogenesis inhibitors such as semaxanib until the exact cause of the thromboembolic events has been elucidated.

Antineoplastics + Tamoxifen

Antineoplastics and tamoxifen are associated with an increased risk of thrombosis and there is the possibility that their combined use may further increase this risk.

Clinical evidence, mechanism, importance and management

A retrospective analysis of data from various Eastern Cooperative Oncology Group studies, suggested that venous thromboembolic complications were more common in women given tamoxifen with adjuvant chemotherapy (CMF; **cyclophosphamide**, **methotrexate**, **fluorouracil**) than women given CMF alone (3.8% versus 0% in one study).¹ In another study of patients given tamoxifen 30 mg daily for 2 years the incidence of thromboembolic events was 2.6% compared with 13.6% in those also given 8 cycles of CMF. The authors of this study considered the rate of thromboembolic events with the combination to be higher than that usually seen with CMF, and suggested that this occurred as a result of an interaction between tamoxifen and CMF.² In contrast, in another study, in the first

12 weeks of therapy, thrombosis occurred in 5 of 103 patients given tamoxifen with chemotherapy (**cyclophosphamide**, **methotrexate**, **fluorouracil**, **vincristine**, prednisone, **doxorubicin**) compared with 4 of 102 given the same chemotherapy alone, suggesting that tamoxifen made no significant contribution to the rate of thromboembolic events.³

Tamoxifen alone is known to carry a small risk of thromboembolic events when used for primary prevention of breast cancer.⁴ Antineoplastic chemotherapy also increases the risk of thrombosis,³ and cancer *per se* increases the risk, as does surgery for cancer.⁵

To what extent, if any, tamoxifen further increases the risk of thrombosis with antineoplastic therapy is unclear from the above studies. However, some authors recommend that serious consideration be given to the use of prophylactic anticoagulants if adjuvant CMF is given with tamoxifen in women with breast cancer,² and the UK manufacturers endorse this.⁶ This may be prudent with antineoplastic chemotherapy in any case.

Antineoplastics + Vaccines

The immune response of the body is suppressed by cytotoxic antineoplastics. The effectiveness of vaccines may be poor and generalised infection may occur in patients immunised with live vaccines.

Clinical evidence, mechanism, importance and management

Since cytotoxic antineoplastics are immunosuppressant, they reduce the response of the body to immunisation. A study¹ in 53 patients with Hodgkin's disease showed that chemotherapy reduced the antibody response to a **pneumococcal vaccine** by 60% when measured 3 weeks after immunisation. The patients were taking **chlormethine** (mechlorethamine), **vincristine**, prednisone and **procarbazine**. A few of them had also been given **bleomycin**, **vinblastine** or **cyclophosphamide**. Subtotal radiotherapy reduced the response by a further 15%. The response to **influenza immunisation** in children with various malignancies was also markedly suppressed by chemotherapy. The regimen included prednisone and the cytotoxic drugs **mercaptopurine**, **methotrexate**, and **vincristine**. Some of them were also given **dactinomycin** and **cyclophosphamide**.² In another study only 9 out of 17 children with leukaemia or other malignant diseases and taking **methotrexate**, **cyclophosphamide**, **mercaptopurine** and prednisone developed a significant response to immunisation with **inactivated measles vaccine**.³ Furthermore, immunisation with **live vaccines** may result in a potentially life-threatening infection. For example, a woman taking **methotrexate** 15 mg once a month for psoriasis developed a generalised vaccinal infection after vaccination against **smallpox**.⁴ Studies in *animals* given **smallpox vaccine** confirmed that they were more susceptible to infection if they had been given **methotrexate**, **mercaptopurine** or **cyclophosphamide**.⁵

Extreme care should therefore be exercised when using live vaccines for immunisation of patients who are receiving cytotoxics or other immunosuppressant drugs (see also 'Corticosteroids + Vaccines; Live', p.1061, and 'Immunosuppressants + Vaccines', p.1064).

Bexarotene + Miscellaneous

Gemfibrozil raises bexarotene plasma levels. The manufacturers warn that, theoretically, inhibitors of CYP3A4 (azoles, grapefruit juice, protease inhibitors and some macrolides) may possibly raise bexarotene levels, whereas CYP3A4 inducers (phenytoin, phenobarbital, rifampicin (rifampin)) may possibly reduce them. They also suggest that the efficacy of oral contraceptives may be reduced, and increased blood glucose-lowering effects may occur with insulin or oral antidiabetic drugs. No interaction seems to occur between bexarotene and atorvastatin or levothyroxine.

Clinical evidence, mechanism, importance and management

(a) Effects of enzyme inducers and inhibitors

Because it is known that bexarotene is metabolised by the cytochrome P450 isoenzyme CYP3A4, the manufacturers point out that there is a theoretical risk that drugs that inhibit CYP3A4 might increase bexarotene levels. They list **clarithromycin, erythromycin, itraconazole, ketoconazole, protease inhibitors and grapefruit juice** as possible interacting drugs because of their known inhibitory effects on CYP3A4. They also list a number of known CYP3A4 inducers, namely **dexamethasone, phenytoin, phenobarbital and rifampicin (rifampin)**, because they may theoretically increase the metabolism of bexarotene and reduce its levels.^{1,2}

The manufacturers also say that because bexarotene can induce liver enzymes, it may theoretically increase the metabolism of other substances metabolised by CYP3A4 such as **tamoxifen** and the steroids in oral or other systemic **contraceptives**, thereby reducing both their serum levels and their efficacy. For this reason they advise the use of additional non-hormonal contraception (e.g. a barrier method) to avoid the risk of contraceptive failure. They point out that this is particularly important because if failure were to occur, the foetus might be exposed to the teratogenic effects of bexarotene.^{1,2}

(b) Other possible drug interactions

A population analysis of patients with cutaneous T-cell lymphoma found that the concurrent use of **gemfibrozil** substantially increased the plasma levels of bexarotene. The reasons for this effect are unknown, although inhibition of CYP3A4 by **gemfibrozil** may be partially responsible.³ The US manufacturers state concurrent use is not recommended,² but note that fibrates are not generally recognised as inhibitors of this isoenzyme, see 'Lipid regulating drugs', (p.1086). Under similar conditions, they say that bexarotene levels were not affected by **atorvastatin** or **levothyroxine**. Changes in thyroid function caused by bexarotene have been successfully treated with **thyroid hormone supplements**.¹⁻³

The manufacturers recommend that because bexarotene is related to **vitamin A**, any **vitamin A supplements** should be limited to 15 000 units or less daily to avoid potentially additive toxic effects. They also say that although no cases of hypoglycaemia have been seen, because of the known mode of action of bexarotene it should be used with caution if given with **insulin** or drugs that enhance insulin secretion (e.g. **sulfonylureas**) or insulin sensitisers (e.g. **thiazolidinediones**).^{1,2} For a list of these drugs see 'Table 13.1', (p.469).

Bicalutamide + Phenazone (Antipyrine)

The results of an interaction study between bicalutamide and phenazone suggest that bicalutamide is unlikely to interact with other drugs through enzyme induction.

Clinical evidence, mechanism, importance and management

The pharmacokinetics and metabolism of phenazone (largely used as an investigational marker drug of enzyme induction or inhibition) were studied in two groups of patients with prostate cancer before and after they took either bicalutamide 50 mg daily (7 patients) or 150 mg daily (11 patients) for 12 weeks. Small changes in the phenazone pharmacokinetics were found (half-life reduced by 16.3% with the 50 mg bicalutamide dos-

age, AUC reduced by 18.6% with the 150 mg bicalutamide dosage). Nevertheless it was considered that bicalutamide does not significantly induce the liver enzymes responsible for the metabolism of phenazone and is therefore unlikely to interact with any other drugs by causing enzyme induction.¹

Bleomycin + Cisplatin

Cisplatin can increase the pulmonary toxicity of bleomycin by reducing its renal excretion. Digital ischaemia and arterial thrombosis have also been described in patients receiving both drugs.

Clinical evidence

Thirty patients with carcinoma of the cervix and 15 patients with germ cell tumours were given combination chemotherapy including bleomycin and cisplatin. Cisplatin was given by infusion on day 1, followed by bleomycin given intramuscularly every 12 hours for 4 days or by continuous infusion over 72 hours. Nine of the patients with normal renal function and no previous pulmonary disease developed serious pulmonary toxicity and 6 died from respiratory failure.¹

In a study of 18 patients given cisplatin and bleomycin for the treatment of disseminated testicular non-seminoma, 2 patients developed pneumonitis, and it was found that the cisplatin-induced reduction in renal function was paralleled by an increase in bleomycin-induced pulmonary toxicity.² Similar results were found in a much larger study of 54 patients by the same group.³ A study in 2 children showed that the total plasma clearance of bleomycin was halved (from 39 to 18 mL/minute/m²) when they were also given cisplatin in cumulative doses exceeding 300 mg/m². The renal clearance in one of the children fell from 30 to 8.2 mL/minute/m² although there was no evidence of severe bleomycin toxicity in either child.⁴ Two cases of fatal bleomycin toxicity have been described in patients with cisplatin-induced renal impairment.^{5,6}

A case report describes arterial thrombosis associated with pathological vascular changes in the arteries of a man treated with cisplatin, bleomycin and etoposide.⁷ Another man developed fatal thrombotic microangiopathy (characterised by microangiopathic haemolytic anaemia, thrombocytopenia, renal impairment), which was attributed to the use of bleomycin and cisplatin.⁸

In an earlier study, digital ischaemia occurred in 41% of patients treated with cisplatin, bleomycin and vinblastine compared with 21% of patients treated with only cisplatin and vinblastine.⁹

Mechanism

Renal excretion accounts for almost half of the total body clearance of bleomycin. Cisplatin is nephrotoxic and reduces the glomerular filtration rate so that the clearance of bleomycin is reduced. The accumulating bleomycin apparently causes the pulmonary toxicity.

Importance and management

Pulmonary toxicity with bleomycin is an established reaction with a potentially serious, sometimes fatal, outcome. Concurrent use should be very closely monitored and renal function checked. One of the problems is that levels of creatinine may not accurately indicate the extent of renal damage both during and after cisplatin treatment. The renal toxicity of cisplatin may also develop rapidly. Other toxic effects on the vascular system can also occur.

Bleomycin + Colony-stimulating factors

The concurrent use of granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor has been linked with an increased occurrence of bleomycin-induced pulmonary toxicity.

Clinical evidence, mechanism, importance and management

Pulmonary toxicity that developed at low cumulative bleomycin doses (70 to 130 units/m²) in at least 3 of 5 patients given standard ABVD treatment (doxorubicin, bleomycin, vinblastine, and dacarbazine) was attributed by the author of the report to the synergistic action of concurrent treatment with **G-CSF** (granulocyte colony-stimulating factor).¹ In another report 8 out of 40 patients with malignant non-Hodgkin's lymphoma given **G-CSF** developed drug-induced pneumonia. Three of these patients were treated with chemotherapy regimens including bleomycin (MA-COB-B, COP-BLAM III), and all 3 died of respiratory failure. None of 35 other patients, similarly treated but without **G-CSF**, developed pneumonia.² Non-infectious interstitial pneumonitis developed in a patient given doxorubicin, cyclophosphamide, bleomycin, vinblastine, methotrexate and prednisone with **GM-CSF** (granulocyte-macrophage colony-stimulating factor).³ Five further reports have identified a total of 23 other patients who developed bleomycin-pulmonary toxicity probably potentiated by **G-CSF** or **GM-CSF**, including at least 7 fatalities.^{4–8}

In contrast, analysis of two placebo-controlled studies of the use of adjuvant **G-CSF** (**filgrastim** or **lenograstim**) with combination chemotherapy including bleomycin found no evidence of an increase in pulmonary complications. Overall 7 of 139 patients treated with placebo and 9 of 139 treated with the **G-CSF** had pulmonary complications possibly related to bleomycin.^{9,10} Similarly, another retrospective analysis found that 34% of patients treated with bleomycin and **G-CSF** developed pulmonary toxicity, compared with 33% of those treated with bleomycin alone.¹¹

These interactions are not firmly established, but good pulmonary function monitoring appears to be advisable when colony-stimulating factors are used with antineoplastics causing pulmonary toxicity, such as bleomycin. If interstitial pneumonia occurs, the drugs should be discontinued and high-dose corticosteroids started immediately.⁷ More study is needed.

Bleomycin + Oxygen

Serious and potentially fatal pulmonary toxicity can develop in patients treated with bleomycin who are exposed to conventional oxygen concentrations during anaesthesia.

Clinical evidence

Five patients treated with bleomycin, exposed to oxygen concentrations of 35 to 42% during and immediately following anaesthesia, developed a severe respiratory distress syndrome and died. Bleomycin-induced pneumonitis and lung fibrosis were diagnosed at post-mortem. Another group of 12 matched patients who underwent the same procedures but with lower oxygen concentrations (22 to 25%) had an uneventful postoperative course.¹

Another comparative study² similarly demonstrated that adult respiratory distress syndrome (ARDS) in patients receiving bleomycin was reduced by a technique allowing the use of lower oxygen concentrations of 22 to 30%. Bleomycin-induced pulmonary toxicity, apparently related to oxygen concentrations, has also been described in other case reports.^{3–7} Studies in *animals* have also confirmed that the severity of bleomycin-induced pulmonary toxicity is increased by oxygen.^{8–10} However, in two other series of patients treated with bleomycin and undergoing surgery there was no obvious increase in pulmonary complications despite the use of usual concentrations of oxygen.^{11,12}

Mechanism

Not understood. One suggestion is that bleomycin-injured lung tissue is less able to scavenge free oxygen radicals, which may be present, and damage occurs as a result.³

Importance and management

An established, well-documented, serious and potentially fatal interaction. It is advised that any patient receiving bleomycin and undergoing general anaesthesia should have their inspired oxygen concentrations limited to less than 30%, and the fluid replacement should be carefully monitored to minimise the crystalloid load. This is clearly very effective because one author has treated 700 patients following these guidelines without a single case of pulmonary failure.¹³ It has also been suggested that reduced oxygen levels should be continued during the recovery period and at any time during hospitalisation.³ If an oxygen concentration equal to or greater than 30% has to be used, the short-term use of prophylactic corticosteroids should be considered. Intravenous corticosteroids should be given at once if bleomycin toxicity is suspected.³

Busulfan + Azoles

Itraconazole, but not fluconazole, modestly reduces the clearance of busulfan. There is some limited evidence to suggest that the use of busulfan with ketoconazole may increase the risk of hepatic veno-occlusive disease.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of busulfan in 26 bone marrow transplant patients, who had received busulfan without concurrent antifungal therapy, were compared with those in 13 similar patients given busulfan with **itraconazole** and in 13 given busulfan with **fluconazole**. The busulfan clearance was decreased by 20% by **itraconazole** (probably because **itraconazole** inhibits the metabolism of busulfan by the liver) but busulfan clearance

was not affected by the **fluconazole**.¹ The expected rise in serum busulfan levels is only likely to be moderate, but until more information is available it would be prudent to monitor for any signs of increased busulfan toxicity if **itraconazole** is used, but no special precautions seem to be needed with **fluconazole**. Concurrent **ketoconazole** has been identified as a possible risk factor for hepatic veno-occlusive disease after high-dose busulfan.² Further study is needed to confirm or refute this.

Busulfan + Benzodiazepines

Diazepam and lorazepam do not appear to alter the pharmacokinetics of busulfan.

Clinical evidence, mechanism, importance and management

In a study in patients receiving high-dose busulfan, no pharmacokinetic changes were seen in 8 patients given **diazepam**, apart from a steady decline in steady-state serum levels in just one.¹ Similarly, in another study, **lorazepam** did not alter the absorption and clearance of high-dose busulfan in children undergoing stem-cell transplantation.² Benzodiazepines may therefore be a suitable alternative to 'phenytoin', (below) for seizure prophylaxis during high-dose busulfan treatment.²

1. Hassan M, Öberg G, Björkholm M, Wallin I, Lindgren M. Influence of prophylactic anticonvulsant therapy on high-dose busulphan kinetics. *Cancer Chemother Pharmacol* (1993) 33, 181–6.
2. Chan KW, Mullen CA, Worth LL, Choroszky M, Koontz S, Tran H, Slopis J. Lorazepam for seizure prophylaxis during high-dose busulfan administration. *Bone Marrow Transplant* (2002) 29, 963–5.

Busulfan + Ketobemidone

Ketobemidone may increase plasma levels of busulfan.

Clinical evidence, mechanism, importance and management

A patient with acute myeloid leukaemia started treatment with a 4-day course of busulfan 1 mg/kg four times daily followed by cyclophosphamide for 2 days before bone marrow transplantation. At the time he was also receiving ketobemidone 1 g daily for a rectal fissure. Busulfan plasma levels after the first dose were elevated (AUC increased by about one-third). Later, when the dose of ketobemidone was reduced and morphine substituted, busulfan levels decreased.¹ The authors suggest that ketobemidone should not be used with high-dose busulfan unless monitoring is possible: dose adjustments may be required to prevent busulfan toxicity. An alternative analgesic should be considered.

1. Hassan M, Svensson J-O, Nilsson C, Hentschke P, AL-Shurbaji A, Aschan J, Ljungman P, Ringdén O. Ketobemidone may alter busulfan pharmacokinetics during high-dose therapy. *Ther Drug Monit* (2000) 22, 383–5.

Busulfan + Phenytoin

Phenytoin modestly increases the clearance of busulfan and lowers its serum levels. Subtherapeutic levels of phenytoin may occur in the presence of busulfan.

Clinical evidence

Seven patients given high-dose busulfan (1 mg/kg four times daily for 4 days) before bone marrow transplantation had a 19% increase in clearance, a 16% lower AUC and a shorter half-life (reduced from 3.94 to 3.03 hours) when they were given phenytoin 2.5 to 5 mg/kg daily. A continuous decline in the steady-state plasma levels of busulfan was also seen in 4 of the patients.¹

In a study in 51 patients given busulfan and prophylactic phenytoin 300 mg daily for 5 days, 3 patients developed convulsions and plasma levels analysed in 2 of them were found to be subtherapeutic.²

Mechanism

It seems likely that the phenytoin (a well recognised enzyme inducer) increases the metabolism of the busulfan by the liver, thereby decreasing its levels. In an *animal* study, phenytoin was found to reduce the myelo-suppressive effects of busulfan.³

Importance and management

The authors of one study suggest that antiepileptics with fewer enzyme-inducing properties than phenytoin should be used as prophylaxis if busulfan is given for bone marrow transplant pretreatment.¹ One UK manufacturer recommends prophylaxis with a benzodiazepine rather than phenytoin if high-dose busulfan is given.⁴ 'Clobazam'. (p.619), has been suggested as a possible alternative to phenytoin.⁵

The UK manufacturer of parenteral busulfan found no evidence that phenytoin increased its clearance.⁶ However, the US manufacturer of parenteral busulfan gives a dose assuming that phenytoin will also be given, and notes that if other antiepileptics are used instead, the busulfan plasma levels may be increased and monitoring is recommended.⁷

To overcome the problem of reduced phenytoin levels, the authors recommended a loading dose of phenytoin 18 mg/kg on the day before the first dose of busulfan, then 300 mg daily until 48 hours after the last busulfan dose. A further loading dose was given if the phenytoin level was subtherapeutic 48 hours after the initial dose (required in 35% of patients).²

Busulfan + Tioguanine

There is evidence that the long-term use of busulfan with tioguanine increases the risk of nodular regenerative hyperplasia of the liver, portal hypertension and oesophageal varices.

Clinical evidence, mechanism, importance and management

Five patients receiving continuous busulfan 2 mg and tioguanine 80 mg five days weekly for chronic myeloid leukaemia (CML) developed oesophageal varices and abnormal liver function tests. Three of them had gastrointestinal haemorrhages and one died. Liver biopsy of 4 of the patients showed nodular regenerative hyperplasia, which was the cause of portal hypertension and varices.¹ A later analysis of the Medical Research Council study comparing busulfan with busulfan and tioguanine in 675 patients with CML, revealed a total of 18 cases of portal hypertension and oesophageal varices (including 4 described in the first report¹), all 18 of which occurred in patients receiving both drugs. In addition, there was no survival advantage with the combination.² The risk of portal hypertension may be related to long-term use of tioguanine, or to its combination with busulfan. This drug combination should not be routinely used for long-term maintenance therapy of CML.²

Cetuximab + Irinotecan

No pharmacokinetic interaction occurs between cetuximab and irinotecan.

Clinical evidence, mechanism, importance and management

Cetuximab is used with irinotecan in the treatment of metastatic colorectal cancer. In a study 14 patients with advanced EGFR (epidermal growth factor responsive) positive adenocarcinoma were given either irinotecan 350 mg/m² every 3 weeks and cetuximab 400 mg/m² at week 2 then 250 mg/m² each week or cetuximab each week starting at week 1 and irinotecan starting at week 4. There was at least a 1 hour period between the end of the cetuximab infusion and the start of the irinotecan infusion. No evidence was found of a pharmacokinetic interaction between cetuximab and irinotecan, nor was there any significant increase in serious toxicities for the combination, when compared with treatment with either drug alone.¹

1. Delbaldo C, Pierga J-Y, Dieras V, Faivre S, Laurence V, Vedovato J-C, Bonnaay M, Mueser M, Nolting A, Kovar A, Raymond E. *Eur J Cancer* (2005) 41, 1739–45.

Chlorambucil + Prednisone

An isolated report describes seizures in a patient, which were possibly caused by the use of chlorambucil with prednisone.

Clinical evidence, mechanism, importance and management

A patient with non-Hodgkin's lymphoma experienced a syncopal episode with generalised tonic-clonic seizures 8 days after completing an initial 5-day course of treatment with chlorambucil 12 mg daily and prednisone 50 mg daily. The seizures were controlled with intravenous clonazepam. Four weeks later, on the third day of a second course, she again had generalised tonic-clonic seizures, which resolved spontaneously.

Chlorambucil-induced seizures have occurred in children with nephrotic syndrome. Cases in adults usually involve high-dose chlorambucil or are in patients with a history of seizures. The seizures in this patient may have been due to the additive effects of both drugs in reducing the seizure threshold.¹

Note that chlorambucil and prednisone or prednisolone have been widely used together.

1. Jourdan E, Topart D, Pinzani V, Jourdan J. Chlorambucil/prednisone-induced seizures in a patient with non-Hodgkin's lymphoma. *Am J Hematol* (2001) 67, 147.

Cisplatin + Aminoglycosides

The renal toxicity of cisplatin is potentiated by aminoglycoside antibacterials such as gentamicin and tobramycin. Extra care is required in patients treated with cisplatin requiring these antibacterials. In one retrospective analysis in patients taking cisplatin, hearing loss was not associated with the concurrent use of ototoxic drugs, including tobramycin.

Clinical evidence

(a) Hypomagnesaemia

Both cisplatin and the aminoglycosides can cause excessive loss of magnesium, and it has been suggested that combined use increases this loss.¹

(b) Nephrotoxicity

Early after the introduction of cisplatin it became apparent that aminoglycosides could increase the nephrotoxicity of this drug. In one report, 4 patients treated with cisplatin, in dosages ranging from low to very high (eight doses of 0.5 mg/kg, one or two doses of 3 mg/kg or a single-dose of 5 mg/kg), and who were subsequently given **gentamicin** and cefalotin developed acute and fatal renal failure. Autopsy revealed extensive renal tubular necrosis.²

Two similar cases of severe renal toxicity, attributed to the use of **gentamicin** and cefalotin in patients who had previously been given cisplatin, are described elsewhere.^{3,4} Another patient treated with cisplatin and **gentamicin** developed acute renal failure.⁵ A further 3 patients treated with cisplatin then **gentamicin** or **tobramycin** had greater decreases in creatinine levels than 12 others receiving cisplatin alone.⁵ A retrospective comparative study confirmed that the incidence of abnormal renal function was higher in patients who had received cisplatin and an aminoglycoside than in patients who had received cisplatin alone (12 of 17 versus 19 of 50 patients, respectively), but the renal impairment was described as usually

mild and not clinically significant.⁶ Similarly, a brief report stated that aminoglycoside use was associated with a greater decline in renal function in children receiving high-dose cisplatin.⁷ Conversely, in another study aminoglycosides were not found to be a significant factor in the development of renal impairment after the use of high-dose cisplatin-based therapy, and use of appropriate supportive care (hydration and mannitol diuresis) probably played a part in this.⁸

There is also evidence from a study in children to show that previous treatment with cisplatin is a risk factor for the delayed elimination of aminoglycosides (**gentamicin**, **amikacin**, **tobramycin**).⁹

(c) Ototoxicity

In one small retrospective analysis of cancer patients, the risk of developing hearing loss after low-dose, slow-infusion cisplatin did not correlate significantly with the concurrent use of other ototoxic drugs, such as furosemide or **tobramycin**.¹⁰ Enhanced renal toxicity and ototoxicity have been reported in *guinea pigs* given cisplatin and **kanamycin** for 2 weeks.¹¹ In another *animal* study **gentamicin** was given for 14 days. A single dose of cisplatin given early in the course enhanced the ototoxic effects of **gentamicin** but no increase in ototoxicity occurred when cisplatin was given at the end of the **gentamicin** course.¹²

Mechanism

Cisplatin is nephrotoxic and it would appear that its damaging effects on the kidney are additive with the nephrotoxic effects of the aminoglycoside antibacterials. Both gentamicin and cisplatin may cause ototoxicity.¹³ Previous exposure to cisplatin caused a significant decrease in gentamicin clearance in *rats*.¹⁴

Importance and management

An established and potentially serious interaction. However, aminoglycosides remain an important group of antibacterials for the empirical treatment of febrile neutropenia in patients receiving chemotherapy,^{15,16} including cisplatin-based regimens. However, in selecting an initial antibacterial regimen, it has been suggested that concurrent use of some drugs, including cisplatin and aminoglycosides, should be avoided if possible because of additive renal toxicity.¹⁷ Good supportive care is required (e.g. pre and post-treatment hydration with mannitol diuresis), and renal function should be well monitored. Audiometric tests should be carried out when cisplatin is used, particularly when other ototoxic drugs are also given.

Cisplatin + Diuretics

A single report describes the development of renal failure in a patient treated with furosemide and other antihypertensives during cisplatin therapy. However, note that furosemide can be used to promote diuresis during cisplatin therapy to reduce the risk of nephrotoxicity. Although animal studies show that the damaging effects of cisplatin on the ear can be markedly increased by the concurrent use of etacrynic acid or furosemide a retrospective analysis in patients did not find this effect.

Clinical evidence, mechanism, importance and management

(a) Nephrotoxicity

Three hours after receiving intravenous cisplatin 70 mg/m² a patient experienced severe nausea and vomiting and his blood pressure rose from 150/90 to 248/140 mmHg. This was managed with furosemide 40 mg intravenously, hydralazine 10 mg intramuscularly, diazoxide 300 mg intravenously and propranolol 20 mg orally twice daily for 2 days. Nine days later the patient showed evidence of renal impairment (creatinine raised from about 88 micromol/L to 283 micromol/L), which resolved within 3 weeks. The patient was subsequently similarly treated on two occasions with cisplatin and again developed hypertension, but no treatment was given and there was no evidence of renal impairment.¹ The reasons for the renal impairment are not known, but a study in rats² indicate that kidney damage may possibly be related to the concentrations of cisplatin, and that furosemide can increase cisplatin levels in the kidney. However, another study in patients found that there was no difference in the toxicity or pharmacokinetics of cisplatin when furosemide was used to induce diuresis, compared with mannitol.³ Two other studies have also found that furosemide does not alter cisplatin pharmacokinetics.^{4,5} Another study showed that sodium chloride solution with or without furosemide was associated with less cisplatin nephrotoxicity than sodium chloride solution with mannitol.⁶

Information seems to be limited to the case cited and its general clinical importance is uncertain. Although mannitol is by far the more usual drug used to induce diuresis during the use of cisplatin in order to reduce the risk of nephrotoxicity, furosemide may also be used for this indication.⁷

(b) Ototoxicity

Both cisplatin and loop diuretics such as etacrynic acid and furosemide given alone can be ototoxic in man. A study⁸ in guinea pigs showed that when cisplatin 7 mg/kg or etacrynic acid 50 mg/kg were given alone their ototoxic effects were reversible, but when given together the damaging effects on the ear were profound, prolonged and possibly permanent. Similarly, while cisplatin-induced ototoxicity was potentiated by furosemide in guinea pigs in one study⁹ in another this was only seen when a very high dose of furosemide was used.¹⁰ In one small retrospective analysis of cancer patients, the risk of developing hearing loss after low-dose slow-infusion cisplatin did not correlate significantly with concurrent use of other ototoxic drugs, such as furosemide.¹¹ Audiometric tests should be carried out when cisplatin is used, and this is of particular importance when other ototoxic drugs are also given.

Cisplatin + H₂-receptor antagonists

Cimetidine and ranitidine probably do not have a clinically relevant effect on the renal clearance of cisplatin.

Clinical evidence, mechanism, importance and management

Some animal studies have shown that organic cations such as cimetidine and ranitidine may compete with the renal tubular transport of cisplatin and thus could be useful in reducing cisplatin nephrotoxicity.^{1,2} However, in a study of 10 children receiving cisplatin, ranitidine had no effect on the total body disposition or renal clearance of cisplatin. This finding and further studies in dogs showed that cisplatin may not share transport systems with organic cations to a clinically relevant extent.³ Although information is limited, it appears that there is no interaction between cisplatin and cimetidine or ranitidine. Note that cimetidine has increased the levels or toxicity of some other antineoplastics, see 'Nitrosoureas + Cimetidine', p.655, 'Cyclophosphamide + H₂-receptor antagonists', p.626, 'Anthracyclines; Epirubicin + Cimetidine', p.613, and 'Fluorouracil + H₂-receptor antagonists', p.633.

Cisplatin + Probenecid

The available clinical data suggest that the nephrotoxicity of cisplatin is reduced by probenecid, but uncertainty remains.

Clinical evidence, mechanism, importance and management

In a randomised study in cancer patients, probenecid 2 to 4 g daily reduced the fractional clearance of free platinum after a single 60- to 100-mg/m² dose of cisplatin given as a 24-hour infusion, and no cases of renal impairment were seen.¹ Similarly, in a further phase I dose-escalation study no renal impairment was seen in patients given cisplatin at doses from 100 to 160 mg/m² when they were also given probenecid 1 g every 6 hours for 12 doses (beginning 24 hours before the cisplatin infusion, and continuing for 24 hours after).² It was concluded that probenecid may protect against cisplatin-induced renal toxicity. An earlier study in rats had also suggested that giving probenecid before cisplatin reduced nephrotoxicity, as assessed by blood urea levels and serum creatinine.³ Subsequently, a study in dogs has found that probenecid decreases the renal clearance of free cisplatin,⁴ and another in mice found that probenecid reduces the renal tubular damage seen with cisplatin alone.⁵

Conversely, some researchers have suggested that the combination of probenecid and cisplatin is potentially more toxic than cisplatin alone. They found that probenecid increased the fractional clearance of free platinum from cisplatin in rats, and that pretreatment with probenecid increased nephrotoxicity, as assessed by blood urea levels.⁶ Other authors similarly reported that probenecid increased cisplatin clearance in rats.⁷

It is unclear why some animal studies show that probenecid increases cisplatin-induced nephrotoxicity whereas others show a decrease. Although the available clinical data suggest that there is a decrease, some uncertainty remains. The combination should be used with caution.

Cyclophosphamide + Allopurinol

There is some evidence to suggest that the incidence of serious bone marrow depression caused by cyclophosphamide can be increased by allopurinol, but this was not confirmed in a controlled study. Allopurinol may prolong the half-life of cyclophosphamide and increase the levels of its cytotoxic metabolites.

Clinical evidence

A retrospective epidemiological survey of patients in four hospitals who, over a 4-year period, had been treated with cyclophosphamide, found that the incidence of serious bone marrow depression was 57.7% in 26 patients who had also received allopurinol, and 18.8% in 32 patients who had not.¹ A pharmacokinetic study in 9 patients with malignant disease and 2 healthy subjects showed that while taking allopurinol 600 mg daily the concentration of the cytotoxic metabolites of cyclophosphamide increased by an average of 37.5% (range 1.5 to 110%).² Another pharmacokinetic study reported that the half-life of cyclophosphamide was more than two-fold longer in 3 children also receiving allopurinol 300 mg/m², when compared with that in children not given allopurinol.³ However, another study found that although allopurinol pre-treatment increased the half-life of cyclophosphamide, the plasma alkylating activity and urinary metabolite and cyclophosphamide excretion were unchanged.⁴ Moreover, a randomised controlled study,⁵ designed as a follow-up to the survey cited above,¹ failed to confirm that allopurinol increased the toxicity of cyclophosphamide in 81 patients with Hodgkin's or non-Hodgkin's lymphoma. In this study, there was no difference in nadirs for white blood cells and platelets during 3 cycles of cyclophosphamide-containing chemotherapy in 44 patients receiving allopurinol and in 37 patients not receiving allopurinol.

Mechanism

Not understood. Cyclophosphamide itself is inactive, but it is converted by the liver into cytotoxic metabolites.⁴ Allopurinol or its metabolite oxypurinol may inhibit their renal excretion, or may alter hepatic metabolism.^{2,3}

Importance and management

This interaction is not established with any certainty. The authors of the randomised study consider that, if necessary, allopurinol can be used safely to prevent hyperuricaemia with the chemotherapy regimens used for lymphomas.⁵ However, the other data introduce a note of caution. Be alert for increased cyclophosphamide toxicity if allopurinol is given.

Cyclophosphamide + Amiodarone

Early-onset pulmonary toxicity occurred in one patient taking amiodarone after high-dose cyclophosphamide was given. Fatal pulmonary toxicity occurred in another patient taking amiodarone after a single dose of cyclophosphamide.

Clinical evidence

A patient with dendritic cell carcinoma who had been taking amiodarone for 18 months, and who had received 6 cycles of chemotherapy including cyclophosphamide over the previous 12 months, was admitted to hospital with progressive shortness of breath 18 days after being given a single 4000-mg/m² dose of cyclophosphamide. He was found to have interstitial

pneumonitis and a lung biopsy indicated drug-induced pulmonary toxicity. The patient's condition improved rapidly over the following 10 days with discontinuation of amiodarone and treatment with prednisolone 60 mg daily. Over the previous year he had also received vincristine, etoposide and prednisone, cisplatin, cytarabine and dexamethasone as part of his chemotherapy.¹ A patient with non-Hodgkin's lymphoma who had been taking amiodarone 300 mg twice daily for 4 years, developed acute respiratory distress 2 days after being given a single dose of cyclophosphamide. This was eventually fatal. Autopsy revealed lung damage consistent with the effects of amiodarone and cyclophosphamide, with the cyclophosphamide the major cause. Other drugs used as part of the chemotherapy regimen were rituximab, doxorubicin, vincristine and prednisone.²

Mechanism

Pulmonary toxicity may occur in about 10% of patients given amiodarone.^{3,4} Pulmonary toxicity due to cyclophosphamide may occur between 1 to 6 months after exposure or occur as a more insidious form after about 6 months. The early onset of symptoms in the patients described above suggests accelerated mechanisms of pulmonary toxicity. Both cyclophosphamide and amiodarone pulmonary toxicity appear to be enhanced by oxygen and the combination of cyclophosphamide with amiodarone may enhance oxidative stress and therefore pulmonary toxicity.

Importance and management

Although information seems to be limited to the two case reports cited, the potential for both cyclophosphamide and amiodarone to cause pulmonary toxicity is established. Be alert to the possibility of enhanced pulmonary toxicity if these drugs are given together.

Cyclophosphamide + Azathioprine

A report describes liver damage in four patients given cyclophosphamide and who had previously taken azathioprine. However, another study found that liver function improved when cyclophosphamide was substituted for azathioprine in 29 patients.

Clinical evidence, mechanism, importance and management

Four patients (two with systemic lupus erythematosus, one with Sjogren's syndrome, and one with Wegener's granulomatosis) developed liver injury when given cyclophosphamide and 3 of them had liver cell necrosis. All had previously been treated with azathioprine and 2 of them had received cyclophosphamide previously without apparent liver damage. It was suggested that azathioprine and cyclophosphamide may have interacted.¹ However, in a retrospective study of cardiac transplant recipients, substitution of cyclophosphamide for azathioprine was associated with improvement in liver function tests in 29 patients with suspected azathioprine-induced liver impairment.²

Cyclophosphamide or Ifosfamide + Azoles

Fluconazole and itraconazole inhibit the metabolism of cyclophosphamide. There is some evidence that, compared with fluconazole, itraconazole might increase cyclophosphamide toxicity. Ketoconazole inhibits the metabolism of ifosfamide. This did not improve the ratio of active to inactive-toxic metabolites, and the possibility remains that ifosfamide efficacy could be reduced.

Clinical evidence, mechanism, importance and management

(a) Cyclophosphamide

Twenty-two children with established cyclophosphamide metabolism profiles and who were not receiving other treatment known to affect drug metabolism were included in a retrospective case series investigation. The clearance of cyclophosphamide was reduced by 43% in 9 children who were given oral or intravenous **fluconazole** 5 mg/kg daily compared to the remaining 13 children who did not receive **fluconazole**.¹ A study in patients given either intravenous or oral **fluconazole** 400 mg daily or **itraconazole** (either 200 mg daily intravenously or 2.5 mg/kg three times daily orally) for prophylaxis after allogeneic stem cell transplantation found that those given **itraconazole** developed higher bilirubin and creatinine levels in the first 20 days after transplantation than those given **fluconazole**. Highest values were in patients who received **itraconazole** with cyclophosphamide. In this study, analysis of cyclophosphamide pharmacokinetics in 9 **itraconazole** recipients and 140 **fluconazole** recipients revealed that **itraconazole** recipients had a 20% greater clearance of cyclophosphamide, leading to greater exposure to the active metabolite of cyclophosphamide, 4-hydroxycyclophosphamide (HCY), and its metabolites.²

Cyclophosphamide is oxidised to HCY by the cytochrome P450 isoenzymes CYP2B6, CYP3A4, CYP2C9, and CYP2A6 and then HCY undergoes further metabolism to produce several toxic metabolites. It is also metabolised by CYP3A4 to an inactive metabolite, deschloroethylcyclophosphamide (DCCP). **Itraconazole** is a more potent inhibitor of CYP3A4 than **fluconazole**, but unlike **itraconazole**, **fluconazole** can also inhibit CYP2C9. It has been suggested that inhibition of CYP2C9 by **fluconazole** may decrease the formation of HCY and result in increased levels of DCCP and fewer toxic metabolites.² Further study is required to determine whether the inhibition of active metabolite formation by **fluconazole** reduces the therapeutic effect of cyclophosphamide.¹ Until more is known it may be prudent to encourage caution when azoles are used in patients receiving cyclophosphamide, other than therapies established in randomised clinical studies, being alert for unexpected toxicity or reduced efficacy.

(b) Ifosfamide

Eight patients undergoing chemotherapy were also given (for the first or second cycle of treatment) **ketoconazole** 200 mg twice daily for 4 days starting one day before treatment with ifosfamide. Concurrent treatment with **ketoconazole** modestly decreased the clearance of ifosfamide by 11%, increased its AUC by 14%, and increased urinary elimination by 26%. The fraction of ifosfamide metabolised to the inactive-neurotoxic, dechloroethylated metabolite was not affected, whereas the fraction metabolised to the active, hydroxylated metabolite was modestly decreased.³

Ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, an enzyme that is involved in the production of active and inactive-toxic metabolites of ifosfamide (see also 'Cyclophosphamide or Ifosfamide + Barbiturates', below). In the clinical study cited, **ketoconazole** modestly decreased the proportion of ifosfamide undergoing activation. It was suggested that concurrent use should be avoided, as it might result in decreased ifosfamide efficacy,³ although this remains to be shown.

Cyclophosphamide or Ifosfamide + Barbiturates

Evidence suggests that neither the toxicity nor the therapeutic effects of cyclophosphamide and ifosfamide are significantly altered by the concurrent use of barbiturates. However, an isolated report describes a girl taking phenobarbital who developed encephalopathy when given ifosfamide.

Clinical evidence

(a) Cyclophosphamide

In 4 patients **phenobarbital** 180 mg daily in divided doses for 10 days increased the mean plasma levels of cyclophosphamide total metabolites by

50% and increased their rate of urinary excretion.¹ Similarly, another study in 11 patients given cyclophosphamide reported that the peak level of normustard-like substances was 1.5 times higher after pretreatment with **phenobarbital**.² Similar changes in cyclophosphamide pharmacokinetics have been described in *animal* studies, and these have generally also shown that **phenobarbital** has no effect on the antitumour activity of cyclophosphamide³ although some have shown a reduction in its effects.⁴

Cyclophosphamide was reported to inhibit the clearance and increase the effects of **pentobarbital** in a study in *rats*.⁵ Another study found auto-induction of cyclophosphamide clearance in a patient taking **phenobarbital** with subsequent chemotherapy courses similar to that in patients not taking **phenobarbital**.⁶

(b) Ifosfamide

A 15-year-old girl who had been taking **phenobarbital** for epilepsy since infancy developed confusion and gradually became unconscious 6 hours after being given a first dose of ifosfamide for metastatic rhabdomyosarcoma. Her chemotherapy regimen was ifosfamide 3 g/m², mesna 3.6 g/m², vincristine 2 mg and dactinomycin. An EEG revealed signs of severe diffuse encephalopathy. She remained unconscious for 24 hours but was asymptomatic after 48 hours.⁷ In a pharmacokinetic study, **phenobarbital** 60 mg daily for 3 days had no effect on the pharmacokinetics of high-dose ifosfamide (4 g/m² over 1 hour each day for 3 days). The AUC for ifosfamide decreased from day one to day 3 irrespective of **phenobarbital** administration.⁸

Mechanism

Cyclophosphamide and ifosfamide are prodrugs that undergo hepatic metabolism, and it seems that they are able to induce their own metabolism. Cyclophosphamide appears to be hydroxylated by the cytochrome P450 subfamilies CYP2B and CYP2C, in particular, to form active metabolites, whereas ifosfamide appears to be principally hydroxylated by CYP3A. Both drugs also undergo dechloroethylation to produce inactive but neurotoxic metabolites, which can cause encephalopathy. For cyclophosphamide, this seems to be primarily catalysed by CYP3A, whereas for ifosfamide both CYP3A and CYP2B appear to be involved. Ifosfamide has a higher incidence of encephalopathy than cyclophosphamide.⁹ Phenobarbital and other barbiturates are inducers of both CYP2B and CYP3A. Therefore it is unlikely that barbiturates will generally alter the balance between dechloroethylation and hydroxylation for cyclophosphamide,³ although there is some evidence from *animal* studies they may do so for ifosfamide.¹⁰

Importance and management

The relationship between the case of encephalopathy and the use of ifosfamide with phenobarbital is not established, but it serves to emphasise the need for particular caution and good monitoring if concurrent use is undertaken. More study is needed. Although barbiturates can cause an increase in the rate of metabolism of cyclophosphamide, this does not appear to alter the AUC and the efficacy of this drug.

Cyclophosphamide or Ifosfamide + Benzodiazepines

Animal studies suggest that the benzodiazepines may possibly increase the metabolic activation and the toxicity of high doses of cyclophosphamide and ifosfamide. However, diazepam did not alter the pharmacokinetics of high-dose cyclophosphamide in a clinical study. Note also that lorazepam is widely used for chemotherapy-induced nausea and vomiting.

Clinical evidence, mechanism, importance and management

Studies in *mice* found that pretreatment with benzodiazepines (**chlordiazepoxide, diazepam, oxazepam**) increased the levels of the active metabolites and the lethality of high-dose cyclophosphamide¹ and similarly increased the levels of active metabolites and enhanced the toxicity of high-dose ifosfamide.² However, a clinical study found that the prophylactic use of **diazepam** 5 mg daily as an antiepileptic had no effect on the pharmacokinetics of very high-dose cyclophosphamide (60 mg/kg intravenously over 2 hours for 2 days) or its neurotoxic (dechloroethylated) metabolites in 3 patients receiving cyclophosphamide and busulfan before bone marrow transplantation.³ In the *animal* studies, it was suggested that benzodiazepines may induce the liver enzymes concerned with the metabolism of cyclophosphamide and ifosfamide to its active cytotoxic products. There are very limited data on this potential interaction. The widespread use of the benzodiazepine **lorazepam** in antiemetic regimens for chemotherapy-induced nausea and vomiting suggest that a significant increase in toxicity or alteration in efficacy of cyclophosphamide and ifosfamide does not occur clinically, but there do not appear to be any studies directly addressing this question.

Cyclophosphamide + Busulfan

The levels of cyclophosphamide may be increased, and those of its active metabolite decreased, if it is given within 24 hours of busulfan treatment.

Clinical evidence, mechanism, importance and management

In one study, the ratio of the AUC of cyclophosphamide and that of its active metabolite hydroxycyclophosphamide was higher in patients also receiving phenytoin and busulfan than in those receiving irradiation (suggesting reduced cyclophosphamide activation), but variability between patients was high.¹ In a similar study, 23 bone marrow transplant patients were pretreated with busulfan 4 mg/kg/day for 4 days, followed by cyclophosphamide 60 mg/kg/day for 2 days. The interval between the last dose of busulfan and starting cyclophosphamide was 24 to 50 hours in 12 patients [group A] and 7 to 15 hours in the remaining 11 [group B]. Nine others pretreated with cyclophosphamide and total body irradiation acted as the controls. In group A the AUCs of cyclophosphamide and hydroxycyclophosphamide were similar to those in the controls but in group B the AUC of cyclophosphamide was more than doubled and the AUC of hydroxycyclophosphamide significantly lower (representing a reduced ratio of hydroxycyclophosphamide to cyclophosphamide). In addition group B had greater toxicity.² Busulfan may directly inhibit the hepatic activation of cyclophosphamide or may act indirectly by depleting glutathione. Phenytoin induces the metabolism of cyclophosphamide (see 'Cyclophosphamide or Ifosfamide + Phenytoin', p.627).

It seems therefore that if the cyclophosphamide is given at least 24 hours after the last busulfan dose, its serum levels will not be greatly affected, whereas if the interval is short, activation may be decreased and toxicity increased. Further study is required to determine the optimum timing to

achieve maximum efficacy and minimum drug toxicity while taking into account other concurrent medication such as phenytoin.

Cyclophosphamide + Chloramphenicol

Some limited evidence suggests that chloramphenicol may reduce the production of the active metabolites of cyclophosphamide. Whether this reduces its therapeutic efficacy remains to be determined.

Clinical evidence, mechanism, importance and management

Cyclophosphamide itself is inactive, but after administration it is metabolised to active alkylating metabolites. A study in *animals*¹ found that pretreatment with chloramphenicol reduced the effects of cyclophosphamide and reduced the production of its active metabolites. Although another *animal* study also found a reduction in lethality of cyclophosphamide with chloramphenicol, the immunosuppressive effect of cyclophosphamide was unchanged.² A study in 4 patients found that chloramphenicol 1 g twice daily for 12 days prolonged the mean serum half-life of a single intravenous dose of cyclophosphamide from 7.5 to 11.5 hours, but did not significantly affect the AUC of the metabolites.³

Chloramphenicol is an inhibitor of the cytochrome P450 isoenzyme subfamily CYP2B, which is partially responsible for the activation of cyclophosphamide. It therefore seems possible that a reduction in the activity of cyclophosphamide may occur, but the extent to which this affects treatment with cyclophosphamide is uncertain. Concurrent use need not be avoided, but be alert for evidence of a reduced response. More study is needed.

Cyclophosphamide or Ifosfamide + Cisplatin

The renal toxicity of ifosfamide may be greater when used with cisplatin or in those who have had prior treatment with cisplatin. Ifosfamide may increase the hearing loss due to cisplatin.

Clinical evidence

(a) Nephrotoxicity

A comparative study in 36 children with malignant solid tumours taking a range of drugs including some known to be potentially nephrotoxic (high dose methotrexate, aminoglycosides, cyclophosphamide), indicated that previous treatment with cisplatin increased their susceptibility to ifosfamide toxicity (neurotoxicity, severe leucopenia or acute tubular damage).¹ Similarly, in another study the cumulative cisplatin dose given before high-dose ICE (ifosfamide, carboplatin, and etoposide) was found to be a strong risk factor for the development of nephrotoxicity.² The nephrotoxicity may not be reversible; 3 cases requiring long-term haemodialysis have been described.³

Other studies also suggested that the concurrent use of ifosfamide with cisplatin appeared to increase nephrotoxicity; one showed an increase in depletion of phosphate reabsorption,⁴ whereas the other showed increased microglobulin excretion.⁵

(b) Ototoxicity

A retrospective comparative study found that when ifosfamide was added to cisplatin, the hearing loss caused by cisplatin was exacerbated.⁶

Mechanism

Both cisplatin and ifosfamide are commonly associated with nephrotoxicity. It is thought that concurrent or possibly previous treatment with cisplatin damages the kidney tubules so that the clearance of the ifosfamide metabolites is reduced and their toxic effects are thereby increased. Damaged kidney tubules may also be less capable of converting mesna to its active kidney-protecting form. The increase in the hearing loss is not understood.

Importance and management

These interactions appear to be established. The authors of the paper cited¹ point out that the majority of patients who develop toxicity have persistently high urinary NAG concentrations (*N*-acetyl- β -D-glucosaminidase, an enzyme released by renal tubular cells), even though serum creatinine levels remain within the acceptable range for ifosfamide treatment. They suggest that evidence of subclinical tubular damage should be sought for by monitoring the excretion of urinary NAG. Note that cisplatin and ifosfamide are widely used in combination, and the related drug **cyclophosphamide** is also routinely used with cisplatin. Amifostine may be useful in reducing the nephrotoxicity of this combination.⁷ The authors who reported on hearing loss advised that serial audiograms should be done in patients treated with both drugs.⁶

Cyclophosphamide + Colony-stimulating factors

Granulocyte colony-stimulating factor (G-CSF) used with cyclophosphamide has been associated with an increased occurrence of pulmonary toxicity.

Clinical evidence, mechanism, importance and management

A 1-year-old boy with a neuroblastoma Evans stage III died of respiratory failure following treatment with **filgrastim** (a **G-CSF**) and normal doses of cyclophosphamide and doxorubicin. The authors of the report suggest that the pulmonary toxicity of the cyclophosphamide (normally only seen with high cumulative doses) is potentiated by **filgrastim**.¹ Six of 53 patients treated with CHOP (cyclophosphamide, doxorubicin, vincristine and prednisolone) and **G-CSF** developed pulmonary toxicity, which was considered a much higher incidence than usually seen with CHOP alone. The development of toxicity correlated with the mean peak leucocyte count.² Another 10 cases of interstitial pneumonitis have occurred with cyclophosphamide-based regimens (not including bleomycin or methotrexate) and **G-CSF**.^{3,4} There is some evidence that the pulmonary toxicity of bleomycin might possibly also be increased by colony-stimulating factors (see 'Bleomycin + Colony-stimulating factors', p.618). These interactions are not firmly established, but good pulmonary function monitoring appears to be advisable when colony-stimulating factors are used with antineoplastics causing pulmonary toxicity. If interstitial pneumonitis occurs, the drugs should be discontinued and high-dose corticosteroids started immediately.² More study is needed.

Cyclophosphamide or Ifosfamide + Corticosteroids

There is limited and conflicting evidence on the effect of prednisone and prednisolone on the metabolic activation of cyclophosphamide. Synergistic increases in enzyme induction may occur if cyclophosphamide is given with dexamethasone. Dexamethasone does not appear to alter ifosfamide metabolism.

Clinical evidence

(a) Dexamethasone

In an *in vitro* study it was noted that the combination of cyclophosphamide with dexamethasone resulted in a greater induction of the cytochrome P450 isoenzyme CYP3A4 than with cyclophosphamide alone; the extent of induction being dependent on baseline CYP3A4 activity.¹ In *rats*,² dexamethasone pretreatment caused a fourfold increase in the AUC of the inactive, neurotoxic, dechloroethylated metabolite of cyclophosphamide, and caused a 60% decrease in the AUC of the active, hydroxylated metabolite. In an earlier study in patients receiving high-dose cyclophosphamide and dexamethasone for 2 days, total clearance of both cyclophosphamide and dexamethasone were higher on the second than the first day, with higher concentrations of cyclophosphamide metabolites.³

In *rats*, dexamethasone pretreatment had no net impact on the fraction of ifosfamide undergoing activation.⁴ Similarly, in a clinical study, ifosfamide metabolism was no different when patients were given dexamethasone 4 mg every 8 hours with ifosfamide for 3 days than when they received ifosfamide alone.⁵

(b) Prednisone or Prednisolone

In an early study, single doses of prednisone were shown to inhibit the metabolic activation of cyclophosphamide,^{6,7} whereas another study briefly mentioned that massive single doses of prednisolone given just before cyclophosphamide did not inhibit cyclophosphamide metabolism.⁸ Longer-term prednisone treatment (50 mg daily for 1 to 2 weeks) increased the rate of activation of cyclophosphamide in the first study.^{6,7} Conversely, another study in 7 patients with systemic vasculitis given prednisone 1 mg/kg daily and cyclophosphamide 600 mg/m² intravenously every 3 weeks for 6 cycles found that, by the last cycle, the AUC of cyclophosphamide had significantly increased while that of its active metabolites had significantly decreased.⁹

Mechanism

Cyclophosphamide and ifosfamide are prodrugs that undergo hepatic metabolism to active and inactive-neurotoxic metabolites, and it appears they induce their own metabolism (see also 'Cyclophosphamide or Ifosfamide + Barbiturates', p.623). Corticosteroids are inducers of the cytochrome P450 isoenzymes CYP3A4. For cyclophosphamide, the CYP3A subfamily is thought to be principally involved in production of inactive-neurotoxic metabolites, whereas, for ifosfamide, CYP3A catalyses both the production of active and inactive-neurotoxic metabolites. On this basis, corticosteroids might be expected to decrease the efficacy and increase the neurotoxicity of cyclophosphamide (although this does not take account of auto-induction), whereas for ifosfamide they would not be expected to alter the balance between efficacy and toxicity.

Importance and management

The documentation is very limited. It appears that dexamethasone does not have any appreciable effect on the metabolism of ifosfamide. The information on cyclophosphamide is conflicting, and the clinical importance of any changes remains to be established. However, it should be noted that

prednisone and prednisolone have a long established use as part of chemotherapy regimens including cyclophosphamide and are also often combined in various autoimmune diseases, and dexamethasone is widely used as an antiemetic with cancer chemotherapy.

Cyclophosphamide + H₂-receptor antagonists

Ranitidine, and probably famotidine, appear not to increase the bone marrow toxicity of cyclophosphamide. Animal studies suggest that cimetidine might.

Clinical evidence, mechanism, importance and management

A study in 7 cancer patients found that although oral **ranitidine** 300 mg daily significantly prolonged the half-life and increased the AUC of intravenous cyclophosphamide 600 mg/m², it did not significantly affect the AUCs of the two major alkylating metabolites of cyclophosphamide, nor did it affect its bone marrow toxicity (leucopenia, granulocytopenia). The authors of the study conclude that **ranitidine** can safely be given with cyclophosphamide.¹ The same authors previously reported that **cimetidine**, when given with cyclophosphamide, increased the AUC of total alkylating metabolites of cyclophosphamide, and resulted in greater toxicity to normal bone marrow, but increased survival in leukaemia-bearing mice.^{2,3} Other studies in mice have shown that **cimetidine**, but not **famotidine**, increases the toxicity of cyclophosphamide to normal bone marrow cells.⁴

Cimetidine inhibits the cytochrome P450 isoenzyme CYP2C9, which has a minor role in the activation of cyclophosphamide (see 'Cyclophosphamide or Ifosfamide + Barbiturates', p.623). These results suggest that no special precautions are likely to be needed when **ranitidine** or **famotidine** are given with cyclophosphamide. The relevance of the findings with **cimetidine** is uncertain. **Cimetidine** has also increased the levels or toxicity of some other antineoplastics, see 'Nitrosoureas + Cimetidine', p.655, 'Anthracyclines; Epirubicin + Cimetidine', p.613, and 'Fluorouracil + H₂-receptor antagonists', p.633.

Cyclophosphamide + Indometacin

A single case report describes acute water intoxication when a patient taking indometacin was given low-dose intravenous cyclophosphamide.

Clinical evidence, mechanism, importance and management

A patient with multiple myeloma taking indometacin 50 mg every 8 hours, developed acute water intoxication and salt retention after being

given a single bolus intravenous injection of cyclophosphamide 500 mg (less than 10 mg/kg). The reasons are not understood, but it is suggested that it was due to the additive or synergistic effects of the two drugs, since water intoxication had not been noted before with this low-dose of cyclophosphamide.¹ There do not appear to be any further reports or studies on this potential interaction but water intoxication has subsequently been reported with low-dose intravenous cyclophosphamide alone.² The evidence does not justify any special precautions when both drugs are used.

- McCarron MO, Wright GD, Roberts SD. Water intoxication after low dose cyclophosphamide. *BMJ* (1995) 311, 292.

Cyclophosphamide + Metronidazole

A case report describes encephalopathy in a girl treated with cyclophosphamide and metronidazole.

Clinical evidence, mechanism, importance and management

After the fourth dose of pulse intravenous cyclophosphamide, a 9-year-old girl developed pancytopenia and gastrointestinal bleeding. She was then given metronidazole for presumptive *Clostridium difficile* colitis. Within 6 hours she developed encephalopathy with seizures and visual hallucinations, requiring antipsychotic therapy. Metronidazole is thought to cause disulfiram-like reactions by inhibiting aldehyde dehydrogenase (see 'Alcohol + Antibacterials; Metronidazole', p.44), and it was suggested that inhibition of this enzyme may cause toxic metabolites of cyclophosphamide to accumulate (see also 'Cyclophosphamide or Ifosfamide + Barbiturates', p.623).¹ This appears to be the only report of this potential interaction, and its general relevance is unclear. Further study is required.

Cyclophosphamide + Pentostatin

Acute and fatal cardiovascular collapse developed in two patients when pentostatin was added to high-dose cyclophosphamide treatment. Some recent studies have found the combination to be effective and safe in patients with chronic lymphocytic leukaemia.

Clinical evidence, mechanism, importance and management

A clinical study that was started to find out if pentostatin would improve the immunosuppressive effects of cyclophosphamide, carmustine and etoposide in bone marrow transplant patients was stopped when acute and fatal cardiovascular collapse developed in the first 2 patients. Both patients had been given cyclophosphamide 800 mg/m² and etoposide 200 mg/m², both every 12 hours for 8 doses, and carmustine 112 mg/m² daily for 4 doses. On day 3 pentostatin 4 mg/m², given over 4 hours, was added. Within 8 to 18 hours after completion of chemotherapy both patients developed confusion, hypothermia, hypotension, respiratory distress, pulmonary oedema, and eventually fatal ventricular fibrillation within 45 to 120 minutes of the first symptoms. A later study in rats similarly found that pentostatin markedly increased the acute toxicity of cyclophosphamide. The reasons for this cardiotoxicity are not understood. Neither of the 2 patients had previously shown any evidence of cardiac abnormalities.¹

However, in a more recent study in patients with previously treated chronic lymphocytic leukaemia (CLL), pentostatin 4 mg/m² with cyclophosphamide 600 mg/m² was found to be safe and effective.² Another study found that pentostatin 4 mg/m² and cyclophosphamide 600 mg/m² with or without rituximab 375 mg/m² was safe and effective for patients with Waldenström's macroglobinaemia.³ Other studies in patients with previously treated or untreated CLL found that cyclophosphamide 600 mg/m² with pentostatin 4 or 2 mg/m² and rituximab 375 mg/m² was effective and was either well-tolerated or had only modest toxicity.^{4,5}

Cyclophosphamide or Ifosfamide + Phenytoin

Phenytoin increases the metabolism of cyclophosphamide and ifosfamide, but the clinical relevance of this is uncertain. Both unchanged and increased efficacy has been suggested.

Clinical evidence

A child taking phenytoin and also given ifosfamide and etoposide had a neurotoxic reaction. The plasma levels of the dechloroethylated metabolites of ifosfamide were subsequently found to be markedly altered compared with those previously seen in 14 other children receiving the same chemotherapy but not taking phenytoin. The child recovered uneventfully after 3 days, and achieved clinical remission (she had not responded to first-line chemotherapy).¹ In a subsequent study, the use of prophylactic phenytoin increased the formation of *S*-dechloroethylated cyclophosphamide in 3 patients receiving cyclophosphamide and busulfan.² In yet another study, the ratio of the AUC of active hydroxycyclophosphamide to cyclophosphamide was higher in patients receiving phenytoin and busulfan than in those receiving irradiation.³ It is likely that phenytoin was responsible for this effect since busulfan alone decreases cyclophosphamide metabolism (see 'Cyclophosphamide + Busulfan', p.624). In an earlier study, in patients receiving enzyme-inducing drugs (2 of whom received phenytoin), the peak plasma levels of the alkylating metabolites of cyclophosphamide were raised, but declined rapidly, so that overall exposure was not different from those not taking these drugs.⁴ Another study reported that a patient taking phenytoin had a high clearance rate for cyclophosphamide during her first chemotherapy course, and that auto-induction of cyclophosphamide clearance was not apparent during her second course.⁵

Mechanism

The alteration in the pattern of ifosfamide metabolites suggested that phenytoin had induced the activity of the cytochrome P450 isoenzyme CYP2B6, and to a lesser extent CYP3A4.¹ The pattern of the increase in cyclophosphamide clearance is also consistent with induction of CYP2B and CYP3A.² See also 'Cyclophosphamide or Ifosfamide + Barbiturates', p.623.

Importance and management

The alteration in the metabolism of cyclophosphamide and ifosfamide caused by phenytoin is not surprising, but the clinical importance of any changes remains to be established. The authors of the study from the 1970s concluded that phenytoin was unlikely to have much effect on the antitumour and toxic effects of cyclophosphamide.⁴ Conversely, the authors of the more recent studies suggest that phenytoin may increase the therapeutic efficacy of cyclophosphamide and ifosfamide.^{1,2} Further study is needed.

Note that reduced phenytoin levels and seizures have been reported in a patient receiving chemotherapy including cyclophosphamide, see 'Table 14.1', (p.519).

Cyclophosphamide or Ifosfamide + Rifampicin (Rifampin)

Rifampicin induced the metabolism of cyclophosphamide and ifosfamide. For ifosfamide, this did not improve the ratio of active to inactive-toxic metabolites, and the possibility remains that efficacy could be reduced.

Clinical evidence, mechanism, importance and management

In a clinical study, rifampicin increased the clearance of ifosfamide by about 100%. In this study, patients were given rifampicin 300 mg twice daily for 3 days before ifosfamide and for 3 days concurrently for one cycle, then for another cycle they were given the ifosfamide alone. The fraction of ifosfamide metabolised to the inactive-neurotoxic, dechloroethylated metabolite was increased, but elimination of this metabolite was also increased resulting in reduced exposure. The fraction metabolised to the active, hydroxylated metabolite, and its exposure, were not altered appreciably.¹

An *in vitro* study in human liver cells showed that rifampicin was a potent inducer of the activation (hydroxylation) of cyclophosphamide and ifosfamide.²

Rifampicin is an inducer of the cytochrome P450 isoenzymes CYP3A4 and CYP2B6, which are involved in the metabolism of cyclophosphamide and ifosfamide (see also 'Cyclophosphamide or Ifosfamide + Barbiturates', p.623). In the clinical study cited,¹ rifampicin did not have a positive effect on the proportion of ifosfamide undergoing activation. In addition, since rifampicin increased metabolism overall, there is the possibility of decreased efficacy,¹ although this remains to be shown.

Cyclophosphamide + Sulfonamides

Some very limited evidence suggests that sulfaphenazole may modestly inhibit the metabolism of cyclophosphamide to its active metabolite, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

A study in 7 patients given a 50-mg dose of cyclophosphamide with **sulfaphenazole** 1 g twice daily for 9 to 14 days showed that the half-life of cyclophosphamide was unchanged in 3 patients, longer in 2 and shorter in the remaining 2 patients.¹ **Sulfaphenazole** and **sulfamethoxazole** are inhibitors of the cytochrome P450 isoenzyme CYP2C9, which shows genetic polymorphism (i.e. some people produce very little, while others produce larger quantities). This enzyme has a minor role in the metabolism (and therefore activation) of cyclophosphamide, and the extent of its involvement varies between patients. For example, an *in vitro* study showed that **sulfaphenazole** inhibited cyclophosphamide activation by 17 to 27% in one human liver sample, but insignificant inhibition occurred in two others.² Thus, sulfonamides such as **sulfaphenazole** and **sulfamethoxazole** may moderately inhibit the activation of cyclophosphamide in some patients, but the clinical relevance of this is uncertain. Note that **cotrimoxazole** is sometimes used for prophylaxis of infection in patients receiving chemotherapy. One study showed that this use did not increase the myelotoxicity of CAE (cyclophosphamide, doxorubicin, and etoposide).³

Cyclophosphamide or Ifosfamide + Taxanes

The clearance of ifosfamide is higher when it is given after docetaxel. This results in less toxicity, but the effect on efficacy is unknown. Ifosfamide did not alter the pharmacokinetics of docetaxel. The sequence of ifosfamide followed by paclitaxel was antagonistic *in vitro*.

Clinical evidence, mechanism, importance and management

(a) Docetaxel

The AUCs of ifosfamide and its metabolites were lower when ifosfamide was given immediately after docetaxel than when it was given 24 hours before docetaxel, due to increased clearance. Docetaxel pharmacokinetics were unaltered by ifosfamide.¹ This supports the evidence that the maximum tolerated dose is greater when ifosfamide is given after docetaxel.² The mechanism is unknown, but it has been suggested³ that docetaxel may competitively inhibit the activation of ifosfamide by the cytochrome P450 isoenzyme CYP3A4. These results show that the toxicity, and possibly efficacy, of the combination are schedule dependent. More study is needed. Cyclophosphamide does not appear to alter docetaxel pharmacokinetics. For full details see also 'Taxanes + Cyclophosphamide', p.661.

(b) Paclitaxel

In vitro studies in human liver microsomes found that additive or synergistic cytotoxicity occurred when activated ifosfamide (hydroxyifosfamide) and paclitaxel were given together or when paclitaxel was given first followed by hydroxyifosfamide. In contrast pronounced antagonism was seen when hydroxyifosfamide was given before paclitaxel.⁴ The mechanism is unknown. These results suggest that the scheduling of this combination may be important for efficacy. More study is needed. There is some evidence that toxicity associated with combinations of paclitaxel and cyclophosphamide is sequence-dependent. For full details see also 'Taxanes + Cyclophosphamide', p.661.

Cyclophosphamide + Thiotepa

Pretreatment with thiotepa may inhibit the metabolism of cyclophosphamide to its active metabolite and decrease both its efficacy and toxicity. Cyclophosphamide appears not to affect the metabolism of thiotepa.

Clinical evidence, mechanism, importance and management

(a) Effect on cyclophosphamide

The proportion of cyclophosphamide excreted unchanged in the urine (i.e. never metabolically activated) was found to be higher when cyclophosphamide was given as a 96-hour infusion with thiotepa and novobiocin than when it was given alone. The authors suggested that the possibility that thiotepa inhibited the metabolism of cyclophosphamide should be investigated.¹ Later, other authors observed that the concentration of the active metabolite of cyclophosphamide, 4-hydroxycyclophosphamide, decreased sharply after thiotepa was given to 20 patients.² In a study to investigate this effect further, 3 patients were given high-dose cyclophosphamide 1000 or 1500 mg/m² as a 1-hour infusion, followed by carboplatin and thiotepa for 4 days. The order of infusion was reversed on one treatment day in each of 4 courses. Giving thiotepa 1 hour before cy-

clophosphamide resulted in decreases in the peak plasma levels and AUC of 4-hydroxycyclophosphamide of 62% and 26%, respectively, when compared with thiotepa given 1 hour after cyclophosphamide.² In human microsomes, thiotepa was found to inhibit the conversion of cyclophosphamide to hydroxycyclophosphamide.² These results suggest that thiotepa can decrease both the efficacy and toxicity of cyclophosphamide, and that the order of administration may be of critical importance. The authors question the practice of giving cyclophosphamide and thiotepa simultaneously.²

(b) Effect on thiotepa

In an *in vitro* study using human microsomes, cyclophosphamide had no effect on the metabolism of thiotepa to TEPA (triethylenephosphamide) by cytochrome P450 at therapeutic concentrations.^{2,3}

Erlotinib + Miscellaneous

The metabolism of erlotinib is markedly affected by other drugs that are potent inhibitors (e.g. ketoconazole) or inducers (e.g. rifampicin) of the cytochrome P450 isoenzyme CYP3A4. Alternatives to these drugs should be used where possible; if not, alteration of the dose of erlotinib is required. The concurrent use of temozolomide may either reduce or increase erlotinib levels, depending on the dose of erlotinib. Smoking increases the metabolism of erlotinib.

Clinical evidence, mechanism, importance and management

(a) Antiepileptics, enzyme-inducing

As part of a study in 33 patients with glioma, the pharmacokinetics of erlotinib 100 mg daily increasing to 500 mg daily was compared between patients taking enzyme-inducing antiepileptics and those not. There was a 33 to 71% lower exposure to erlotinib when it was given with an enzyme-inducing antiepileptic drug, thought to be due to increased activity of the cytochrome P450 enzymes. Antiepileptic drugs taken were **carbamazepine, oxcarbazepine, phenytoin, fosphenytoin, phenobarbital and primidone**. Patients taking these drugs tolerated a higher dose of erlotinib, and for further studies in this disease it was recommended that the dose of erlotinib should be at least 500 mg daily in those taking enzyme-inducing antiepileptics and 200 mg daily in those patients not taking these drugs.¹ However, note that the manufacturer of erlotinib recommends using alternatives to these enzyme-inducing antiepileptics if possible, see *CYP3A4 inducers*, below.

(b) CYP3A4 Inhibitors

The AUC of erlotinib has been found to be increased by 66% when given with **ketoconazole** 200 mg twice daily for 5 days. The manufacturers advise caution with concurrent use, and recommend that the dose of erlotinib should be reduced if severe adverse reactions occur when given with strong CYP3A4 inhibitors. They specifically name **atazanavir, clarithromycin, erythromycin, grapefruit and grapefruit juice, indinavir, itraconazole, ketoconazole, nefazodone, nelfinavir, ritonavir, saquinavir, telithromycin, troleandomycin and voriconazole**.^{2,3}

(c) CYP3A4 inducers

Pretreatment with **rifampicin** 600 mg once daily for 7 days reduced the AUC of erlotinib by about 66%.³ In another study, the AUC of a single 450-mg dose of erlotinib, taken after 11 days treatment with **rifampicin** was about 57% of that of erlotinib 150 mg taken without rifampicin.^{2,3} The manufacturers advise that alternative treatments with no cytochrome P450 enzyme-inducing activity should be considered. If this is not possible, the starting dose of erlotinib should be adjusted to 300 mg (UK) with close monitoring, and, if tolerated, further increased after 2 weeks, in 50 mg increments, to 450 mg.³ They also advise caution with other CYP3A4 inducers, and specifically name **barbiturates, carbamazepine, phenobarbital, phenytoin, rifabutin, rifapentine, and St John's wort**.

and recommend the use of alternative non-inducing drugs when possible.^{2,3} For enzyme-inducing antiepileptics, see also (a) above.

(d) *Drugs that affect gastrointestinal pH*

Drugs, such as **antacids**, **H₂-receptor antagonists** or **proton pump inhibitors**, that increase the pH of the gastrointestinal tract may reduce the solubility of erlotinib, which the manufacturers^{2,3} state has a decreased solubility above pH 5. The manufacturers therefore recommend caution with concurrent use of these drugs during treatment with erlotinib as they cannot exclude that these drugs will reduce erlotinib efficacy.²

(e) *Gemcitabine*

There was no change in the pharmacokinetics of gemcitabine or erlotinib on concurrent use in a phase 1 study.²

(f) *Temozolomide*

As part of a phase 1 study, 16 patients with glioma were given erlotinib 100 mg daily increasing to 250 mg daily alone, and 14 were given erlotinib and temozolomide 150 mg/m² increasing to 200 mg/m² for 5 days in each 28 day cycle. At the lowest dose of erlotinib, the group also taking temozolomide had a 49% lower maximum plasma level of erlotinib, and almost 50% lower AUC of both erlotinib and its metabolite OSI-420. As the dose of erlotinib increased to 250 mg daily, this difference was reversed with temozolomide group showing a 45% higher AUC of erlotinib. The reason for these paradoxical findings is unclear, and their clinical relevance is uncertain.¹

(g) *Tobacco*

Twelve cigarette smokers and 14 non-smokers were given oral erlotinib 150 mg on day 1 and 300 mg on day 15 of a study. The subjects who smoked had lower maximum plasma levels of erlotinib; 35% lower after the 150 mg dose and 20% lower after the 300 mg dose. The AUC was also reduced by 65% and 57%, respectively. Cigarette smoking induces CYP1A1 and 1A2, which are involved in the metabolism of erlotinib. Consideration should therefore be given to the smoking status of a patient when planning treatment with erlotinib.⁴ The manufacturer says that these decreases are likely to be clinically important, and that patients should be encouraged to stop smoking.^{2,3}

(h) *Warfarin*

Raised INRs and infrequent bleeding have been reported in patients taking warfarin with erlotinib. Patients taking these drugs, and other coumarins, should be closely monitored for INR changes.^{2,3}

Estramustine + Clodronate

Clodronate markedly increases the serum levels of estramustine.

Clinical evidence, mechanism, importance and management

Estramustine bioavailability in 12 patients was increased by about 80% when clodronate 800 mg four times daily was given with estramustine 280 mg twice daily for 5 days. The serum levels and AUC of clodronate were not changed by estramustine.¹ Documentation appears to be limited to this study. However, the efficacy and toxicity of estramustine should be monitored if clodronate is also given. The effects of other bisphosphonates do not appear to have been studied.

Estramustine + Food and Calcium compounds

The absorption of estramustine is reduced by milk, foods, and drugs containing calcium.

Clinical evidence

A randomised three-way crossover study in 6 patients with prostate cancer showed that the absorption of single-doses of estramustine disodium (equivalent to 140 mg of estramustine) was reduced by 59% when taken with 200 mL of **milk**, and by 33% when taken with a standardised **break-fast** (2 pieces of white bread with margarine, ham, tomato, marmalade and water). Peak serum estramustine levels were reduced by 68% and 43%, respectively.¹

Mechanism

In vitro studies suggest that estramustine combines with calcium ions in milk and food to form a poorly-soluble complex that is not as well absorbed as the parent compound.¹

Importance and management

An established interaction although the information is limited. The manufacturers recommend that estramustine should be taken not less than 1 hour before or 2 hours after meals, and that it should not be taken with milk, milk products, calcium-rich foods,^{2,3} or drugs (such as **calcium-containing antacids**).³

Etoposide + Antiepileptics

Etoposide clearance appears to be increased by phenobarbital, phenytoin, and probably carbamazepine, and this may result in reduced efficacy.

Clinical evidence, mechanism, importance and management

The clearance of etoposide was found to be highly variable in children given etoposide 320 to 500 mg/m² over 6 hours on alternate days for a total of 3 doses. However, it was 77% higher in 7 children taking antiepileptics (**phenobarbital**, **phenytoin** or both) than in 22 others not taking antiepileptics.¹ In a retrospective survey, long-term antiepileptic use (**phenytoin**, **phenobarbital**, **carbamazepine**, or a combination) was associated with worse event-free survival, and greater haematological and/or CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leukaemia. The authors considered that the increased clearance of etoposide induced by the antiepileptics was a likely factor in these findings.² Be alert for the possible need to give larger doses of etoposide if these antiepileptics are used. More study is needed.

Etoposide + Atovaquone

The concurrent use of atovaquone with etoposide may modestly increase exposure to etoposide catechol. The clinical relevance of this is unclear.

Clinical evidence, mechanism, importance and management

A study in 9 children with acute lymphoblastic leukaemia or non-Hodgkin's lymphoma found that the AUC of etoposide and its metabolite etoposide catechol were slightly increased, by 8.6% and 28.4%, respectively, following atovaquone 45 mg/kg daily, when compared with co-trimoxazole 150/750 mg/m² daily. The mechanism by which this occurs is unclear, but atovaquone may affect the metabolism of etoposide by the cytochrome P450 isoenzyme CYP3A4 or its transport by P-glycoprotein.¹ The authors considered that an interaction with co-trimoxazole was unlikely, so used it as a control, however, ideally this requires confirma-

tion. The relevance of the minor changes seen is unclear. The authors note that the risk of etoposide-related secondary acute myeloid leukaemia has been linked to minor changes in therapy, therefore, they advise caution if atovaquone is given with etoposide, particularly if it is used with other substrates of CYP3A4 or P-glycoprotein.¹ They also say it may be possible to avoid the interaction by separating the administration by 1 to 2 days,¹ but this requires confirmation.

1. van de Poll MEC, Relling MV, Schuetz EG, Harrison PL, Hughes W, Flynn PM. The effect of atovaquone on etoposide pharmacokinetics in children with acute lymphoblastic leukemia. *Cancer Chemother Pharmacol* (2001) 47, 467–72.

Etoposide + Ciclosporin

High-dose ciclosporin markedly raises etoposide serum levels and increases the suppression of white blood cell production. Severe toxicity has been reported in one patient.

Clinical evidence

In a comparative study, 16 patients with multidrug resistant advanced cancer were given 20 paired courses of etoposide, alone or with ciclosporin. Ciclosporin levels were measured at the end of a 2-hour infusion: ciclosporin levels of greater than 2000 nanograms/mL were defined as high-dose and those less than 2000 nanograms/mL as low-dose. High and low-dose ciclosporin, respectively, increased the etoposide AUC by 80% and 50%, decreased the total clearance by 38% and 28%, increased its half-life by 108% and 40%, reduced the leucocyte count nadir by 64% and 37% and altered the volume of distribution at steady state by 46% and 1.4%.¹ The patients were given 150 to 200 mg/m² of etoposide daily as a 2-hour intravenous infusion for 3 consecutive days and ciclosporin in doses ranging from 5 to 21 mg/kg daily as a 3-day continuous infusion.¹ In another study, 18 children with recurrent or refractory tumours who had previously received etoposide were given high-dose ciclosporin (either a continuous infusion of 15 mg/kg per 24 hours for 60 hours (13 patients) or 30 mg/kg over 3 hours on 3 consecutive days (5 patients) and etoposide 150 mg/m² over 1 hour for 3 days, starting 1 hour after the beginning of the ciclosporin infusion. The AUC and half-life of etoposide were increased by 89% and 78%, respectively, and the clearance was decreased by 48%.² In a further study in children, the pharmacokinetics of etoposide 100 mg/m² daily were compared with etoposide 60 mg/m² (a 40% reduction in dose) with high-dose ciclosporin. Despite the dose reduction, recipients of ciclosporin had a 71% reduction in etoposide clearance and a 47% increase in the etoposide AUC, although toxicity was similar.³

The leukaemic cells in the bone marrow of a patient with acute T-lymphocyte leukaemia were totally cleared when ciclosporin 8.3 mg/kg orally twice daily was given with etoposide 100 to 300 mg daily for 2 to 5 days, but the adverse effects were severe (mental confusion, renal and hepatic toxicity). The patient died from respiratory failure precipitated by a chest infection.⁴

A patient with chronic myeloid leukaemia who had responded poorly to treatment with etoposide, mitoxantrone and cytarabine for blast crisis, returned to the chronic phase when given etoposide with ciclosporin.⁵ An *in vitro* study by the same authors showed that etoposide was partially toxic to blast cells but that its effect on blast cells was increased sixfold when it was given with ciclosporin.⁵

Mechanism

It is suggested that the ciclosporin decreases the metabolism of the etoposide by inhibiting its metabolism by cytochrome P450 isoenzymes⁶ and inhibiting P-glycoprotein mediated efflux from the hepatocyte, as well as inhibiting some unknown non-renal clearance mechanism.¹ The total effect is to cause the retention of etoposide in the body, thereby increasing its effects.

Importance and management

An established interaction. Ciclosporin alters the pharmacokinetics of etoposide resulting in increased serum levels. This pharmacokinetic interaction has complicated the study of the value of using ciclosporin to modulate multidrug resistance in tumours to improve the response to chemotherapy. In the case of 'anthracyclines', (p.611) and etoposide, any benefit could just be attributed to dose intensification. Consequently,

some,^{1–3} including one manufacturer,⁷ have suggested reducing the dose of etoposide by 40% or 50% in the presence of ciclosporin.^{1–3} In one study, a continuous infusion of ciclosporin was better tolerated than an intermittent regimen, but it was associated with similar hepatic and renal impairment as the short schedule (transient hyperbilirubinaemia, and elevated creatinine or urea).² The use of high-dose ciclosporin for multidrug resistant tumour modulation remains experimental and should only be undertaken in clinical studies. Concurrent use should be very well monitored. More study is needed to find out the possible effects of low-dose ciclosporin.

Etoposide + Cisplatin or Carboplatin

The clearance of etoposide may be modestly reduced by carboplatin and cisplatin, but this is probably unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Carboplatin

In one study in 4 patients, the pharmacokinetics of etoposide were unchanged when carboplatin was also given.¹ However, in another study of 14 young patients receiving etoposide and carboplatin the clearance of etoposide was lower than in previous reports in adults and children. They had been given an escalating dosage regimen starting with etoposide 960 mg/m², and increasing to 1200, and 1500 mg/m², given in three divided doses on alternate days, with carboplatin 400 to 700 mg/m² given on the other days, followed by autologous marrow rescue. The authors point out that the dose and the timing of carboplatin may be important determinants for any interaction.² In yet another study,³ carboplatin did not affect the pharmacokinetics of etoposide during the first cycle of chemotherapy (etoposide was given on days 1, 2 and 3, and carboplatin on day 2, and the AUC of etoposide was compared for days 1 and 2). However, during a second cycle of chemotherapy, the etoposide AUC was 8% higher on day 2 than day 1. These changes were considered unlikely to be clinically important.³

(b) Cisplatin

A study in 17 children with neuroblastoma found that when intravenous cisplatin 90 mg/m² was given immediately before etoposide, the clearance of etoposide 780 mg/m² fell by 20% and the serum levels rose. But after a cumulative dose of cisplatin of 360 mg/m² it had no effect on the clearance of etoposide.⁴ In another study, cisplatin did not affect the pharmacokinetics of etoposide during the first cycle of chemotherapy (etoposide was given on days 1, 2 and 3, and cisplatin on day 2, and the AUC of etoposide was compared for days 1 and 2). However, during a second cycle of chemotherapy, the etoposide AUC was 28% higher on day 3 than day 1. These changes were considered unlikely to be clinically important.³

Etoposide + CYP3A4 inhibitors

***In vitro* studies show that some CYP3A4 inhibitors may possibly increase the effects and toxicity of etoposide. In one clinical study, etoposide clearance was increased by prednisone.**

Clinical evidence, mechanism, importance and management

In vitro studies using human liver microsomes show that **ketoconazole, prednisolone, troleandomycin, verapamil and vincristine** can inhibit the metabolism (3'-demethylation) of etoposide by the cytochrome P450 isoenzyme CYP3A4. The implications of this are that concurrent use with these drugs might increase both the efficacy and the toxicity of etoposide.¹

However in a study, 102 children with acute lymphoblastic leukaemia were given **prednisone** 40 mg/m² daily for 28 days with etoposide 300 mg/m² on day 29. Forty-eight of them with high risk disease were given continuation therapy and received etoposide 300 mg/m² at week 54, two weeks or more after the last **prednisone** dose. Etoposide clearance was 62% higher on day 29 than at week 54 and the AUC for the catechol metabolite was significantly lower (27%) on day 29 compared with week 54.²

There seems to be little clinical confirmation that the potential interactions with the drugs listed above, other than corticosteroids (which found the opposite of the predicted effect) have clinical relevance, but good monitoring would be a prudent precaution. See also 'Antineoplastics + Protease inhibitors', p.615.

Etoposide + Food

In 8 patients with extensive small cell lung carcinoma the pharmacokinetics of a 100-mg oral dose of etoposide were unaffected when it was taken with a full breakfast, when compared with the fasting state.¹ However, the manufacturer recommends that etoposide should be taken on an empty stomach.²

2. Vepesid Capsules (Etoposide). Bristol-Myers Pharmaceuticals. UK Summary of product characteristics, July 2005.

Etoposide + Other antineoplastics

Doxorubicin and cyclophosphamide have no clinically relevant effects on the pharmacokinetics of oral or intravenous etoposide. Methotrexate and procarbazine do not affect the pharmacokinetics of oral etoposide.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 7 patients with small-cell lung cancer (SCLC) treated with **cyclophosphamide** 800 mg/m², **doxorubicin** 40 mg/m² and etoposide 100 mg/m² (all given intravenously) found that the protein binding, metabolism and renal clearance of etoposide were unaffected by the other antineoplastics.¹ Similarly, another study found only modest changes in the pharmacokinetics of intravenous etoposide when it was given with **cyclophosphamide** and **doxorubicin**, compared with use alone, and these changes were considered unlikely to be clinically relevant. Specifically, the AUC of etoposide was 9% higher and the clearance was 10% lower on day 1 of the CAE cycle (**cyclophosphamide**, **doxorubicin**, and etoposide) compared with days 2 and 3 (etoposide alone).² This is a commonly used regimen, and these data suggest there is no pharmacokinetic interaction.

Similarly, no changes in etoposide pharmacokinetics were seen when oral etoposide 100 mg was given immediately after oral **cyclophosphamide** 100 mg/m² and **methotrexate** 12.5 mg/m² in 8 patients with SCLC. In addition, no changes were seen when the same dose of oral etoposide

was given 15 minutes after intravenous **doxorubicin** 35 mg/m² and oral **procarbazine** 60 mg/m².³ Oral etoposide pharmacokinetics appear not to be affected by these antineoplastics.

For the lack of effect of platinum derivatives, see 'Etoposide + Cisplatin or Carboplatin', p.630.

Etoposide + St John's wort (*Hypericum perforatum*)

***In vitro* studies suggest that hypericin, a component of St John's wort may antagonise the effects of etoposide. It may also stimulate the hepatic metabolism of etoposide by the cytochrome P450 isoenzyme CYP3A4. Information is very limited but it seems that it would be prudent to avoid St John's wort in patients taking etoposide or related drugs.¹ More study is needed.**

Exemestane + CYP3A4 inducers and inhibitors

Ketoconazole appears not to interact with exemestane, whereas rifampicin reduces exemestane levels.

Clinical evidence, mechanism, importance and management

The manufacturers say that *in vitro* evidence shows that while exemestane is metabolised by both the cytochrome P450 isoenzyme CYP3A4 and aldo-ketoreductases, a clinical study found that **ketoconazole** (a specific inhibitor of CYP3A4) had no significant effects on the pharmacokinetics of exemestane. The manufacturers therefore suggest that interactions with CYP3A4 enzyme inhibitors are unlikely.^{1,2}

However, in an interaction study the potent enzyme inducer **rifampicin** reduced the AUC and maximum plasma levels of exemestane by 54% and 41%, respectively.

The manufacturers therefore caution the use of exemestane with CYP3A4 inducers such as **carbamazepine, phenobarbital, phenytoin** and **St John's wort**.^{1,2} The clinical relevance of these potential interactions is unknown, but it would seem prudent to monitor the outcome of concurrent use to ensure exemestane efficacy.

2. Aromasin (Exemestane). Pharmacia & Upjohn Company. US Prescribing information, February 2007.

Fludarabine + Dipyridamole

Because fludarabine phosphate is an analogue of adenine, the UK manufacturers warn that drugs that are adenosine uptake inhibitors, such as dipyridamole, may prevent the uptake of fludarabine into cells and reduce its efficacy.^{1,2} Dipyridamole should probably therefore be avoided in patients receiving fludarabine.

1. Schering Health Care Ltd. Personal communication, February 1995.
2. Fludara Tablets (Fludarabine phosphate). Schering Health Care Ltd. UK Summary of product characteristics, September 2005.

Fludarabine + Pentostatin

When fludarabine phosphate and pentostatin were used in the treatment of chronic lymphoid leukaemia, 4 out of 6 patients de-

veloped pulmonary toxicity consistent with interstitial pneumonitis, and 3 of them died.¹ Pentostatin should therefore not be used concurrently with fludarabine.^{2,3}

Fluorouracil + Allopurinol

Allopurinol has been studied as a modulator of the effects of fluorouracil, but has not gained an established clinical use in this setting.

Clinical evidence, mechanism, importance and management

Some early studies showed that allopurinol 300 mg two to four times daily allowed the usual maximum tolerated dose of fluorouracil to be increased by up to twofold.¹⁻³ The hope was that allopurinol would prove useful to decrease the toxicity and/or improve the activity of fluorouracil. However, most studies have shown no increase in response rates in colorectal cancer with allopurinol,^{4,5} even when the fluorouracil dose was escalated,^{2,4} and some have also shown no reduction in toxicity.⁵⁻⁷ These are by no means all the studies, and are just cited as examples. Allopurinol mouthwash has also been investigated to reduce the incidence of stomatitis with fluorouracil. Some controlled studies have shown a benefit,⁸ whereas others have not.⁹ Allopurinol clearly modulates some of the effects of fluorouracil; however, this has not been shown to be obviously beneficial or harmful in the clinical setting.

Fluorouracil + Aminoglycosides; Oral

Neomycin can delay the gastrointestinal absorption of fluorouracil, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

Some preliminary information from a study in 12 patients treated for metastatic adenocarcinoma found that with the use of oral neomycin 500 mg four times daily for a week delayed the absorption of fluorouracil, but the effects were generally too small to reduce the therapeutic response, except possibly in one patient.¹ It seems probable that this interaction occurs because neomycin can induce a malabsorption syndrome. If neomycin, and most probably paromomycin or kanamycin are used in patients receiving fluorouracil, the possibility of this interaction should be borne in mind.

Fluorouracil + Cisplatin or Oxaliplatin

Giving low-dose cisplatin with a fluorouracil infusion markedly increased toxicity in one study. Cardiotoxicity may possibly be

increased if higher doses of cisplatin are given with fluorouracil. Oxaliplatin appears to moderately raise fluorouracil levels, without increasing its toxicity.

Clinical evidence, mechanism, importance and management

(a) Cisplatin

Giving low-dose cisplatin 20 mg/m² once a week with continuous ambulatory fluorouracil infusions of 300 mg/m² daily considerably increased the toxicity (nausea, vomiting, anorexia, diarrhoea, stomatitis, myelosuppression) in 18 patients with advanced cancers. More than half developed multiple toxicities, and severe toxicity occurred in two-thirds. Leucopenia occurred in 28% given both drugs whereas it was virtually nonexistent with fluorouracil alone. Toxicity requiring treatment interruption or dose reduction was seen in 55% of patients receiving fluorouracil alone, and this rose to 94% in the presence of cisplatin.¹ In another study, signs of cardiotoxicity (chest pain, ST-T wave changes, arrhythmias) were seen in 12 of 80 patients given fluorouracil with cisplatin for carcinoma of the head, neck, oesophagus and stomach.² Studies in humans and *rats* have shown that there is prolonged elevation of filterable platinum levels associated with concurrent use of cisplatin and fluorouracil.³

The combination of a platinum derivative and fluorouracil is widely used, but the optimum schedule to improve activity and reduce toxicity is not firmly established. In one study of bolus cisplatin and continuous infusion fluorouracil, modifying the dose of fluorouracil based on AUC reduced toxicity while still maintaining response rates.⁴ In another study, cisplatin pharmacokinetics were said to be optimum when it was given as a continuous infusion with a continuous infusion of fluorouracil.⁵ Further study is needed.

(b) Oxaliplatin

In one study, 28 patients with advanced or metastatic colorectal cancer were given fluorouracil alone, or immediately following an 85 mg/m² dose of oxaliplatin given over 2 hours. Oxaliplatin did not significantly affect the pharmacokinetics of fluorouracil (either 2 cycles of a 400 mg/m² bolus followed by a 46-hour infusion of 2400 mg/m² given to 10 patients, with pharmacokinetic sampling over 46 hours, or a single cycle of a 400 mg/m² bolus followed by 600 mg/m² over 22 hours given to 18 patients, with pharmacokinetic sampling over 22 hours).⁶ However, in another study 29 patients with advanced colorectal cancer were given fluorouracil in a dose adjusted to give levels of between 2.5 and 3 mg/L (dose range 750 to 3500 mg/m² per week) either alone, or immediately following a 2-hour infusion of oxaliplatin 130 mg/m². In this study pharmacokinetic samples were taken on days 1, 8 and 15. Oxaliplatin raised the plasma levels of fluorouracil by about one-third, with the effect appearing to last for 15 days, however, fluorouracil toxicity was not increased.⁷

The combination of fluorouracil and oxaliplatin is widely used, but one of the studies cited here suggest that the schedules could still be adjusted to optimise efficacy and minimise toxicity.⁷

Fluorouracil + Dipyridamole

One study suggested that intravenous dipyridamole may reduce the steady-state plasma levels of fluorouracil, whereas others found that oral dipyridamole caused no important changes in fluorouracil pharmacokinetics.

Clinical evidence, mechanism, importance and management

Numerous preclinical studies found that dipyridamole enhanced the activity of fluorouracil, leading to its investigation as a biomodulator.¹ However, unexpectedly, in one phase I study of the combination, the use of dipyridamole was associated with lower steady state plasma level of fluorouracil, suggesting an approximately 30% increase in total body clearance or volume of distribution of fluorouracil.² In this study, 47 patients with advanced cancer were given fluorouracil in escalating doses ranging from 185 mg/m² daily to 3600 mg/m² daily with or without dipyridamole as a continuous infusion of 7.7 mg/kg per day for 72 hours.² In contrast, in a later randomised study, oral dipyridamole 75 mg three times daily for 5 days did not significantly alter the pharmacokinetics of fluorouracil, except for prolonging the half-life and slightly increasing the dose-intensity: over 5 cycles the average dose of fluorouracil was 479 mg/m² alone, compared with 533 mg/m² in the presence of dipyridamole. In this study, oral dipyridamole did not improve the antineoplastic activity of fluorouracil and folic acid.³ Similarly, another clinical study found that oral dipyridamole did not significantly alter the pharmacokinetics of fluorouracil.⁴ Thus, despite the promise of preclinical studies, the benefits of combining dipyridamole with fluorouracil have not been realised clinically.

Fluorouracil + Folic acid

Two patients developed severe fluorouracil toxicity while taking multivitamin preparations containing folic acid.

Clinical evidence

A woman who underwent surgery for carcinoma of the rectum was, a month later, given intravenous fluorouracil 500 mg/m² daily for 5 days. At the end of this chemotherapy she was admitted to hospital with anorexia, severe mouth ulceration, bloody diarrhoea and vaginal bleeding, which was interpreted as fluorouracil toxicity. Her concurrent medication included folic acid 5 mg daily (in *Multi-B forte*) along with loperamide, sulfasalazine, vitamins B₁₂ and K, and HRT. A month later, when she was again given fluorouracil, but without the folic acid, her treatment was well tolerated and without toxicity. A man similarly treated with fluorouracil for colonic cancer was admitted to hospital 2 days later with severe mouth ulceration and bloody diarrhoea. He too was found to be taking a multivitamin preparation, containing folic acid 500 micrograms (amount taken daily not known). Subsequent courses of fluorouracil at the same dosage but without the folic acid were well tolerated.¹ For a report of fatal toxicity associated with the concurrent use of folic acid and capecitabine, see 'Fluorouracil prodrugs; Capecitabine + Folinates', p.635.

Mechanism

It would seem that folic acid increases fluorouracil inhibition of thymidine formation which is important for DNA synthesis, and thereby increases fluorouracil toxicity.

Importance and management

Direct information seem to be limited to these two cases and a case of fatal toxicity associated with concurrent folic acid and capecitabine, a prodrug of fluorouracil (see 'Fluorouracil prodrugs; Capecitabine + Folinates', p.635) but the interaction would appear to be established. What happened is consistent with the way **folic acid**, another source of folate, is used therapeutically to increase the potency of fluorouracil. Patients treated with fluorouracil should therefore not be given folic acid, and should be told to avoid multivitamin preparations containing folic acid to prevent the development of severe fluorouracil adverse effects.

Fluorouracil + Gemcitabine

Pharmacokinetic analysis has shown that gemcitabine enhances systemic exposure to fluorouracil in patients with pancreatic carcinoma given folic acid, fluorouracil, and gemcitabine.^{1,2} In addition, *in vitro*, gemcitabine increases the accumulation of fluorouracil and its cytotoxicity.¹ Further study is needed.

Fluorouracil + H₂-receptor antagonists

Some data indicate that 4 weeks, but not 1 week, of treatment with cimetidine can markedly increase plasma fluorouracil levels. The combination may have increased activity in colorectal cancer.

Clinical evidence, mechanism, importance and management

A study in 6 patients with carcinoma given fluorouracil (15 mg/kg daily for 5 days, repeated every 4 weeks) found that **cimetidine** 1 g daily for 4 weeks increased the peak plasma fluorouracil levels by 74% and the AUC by 72% when fluorouracil was given orally. When fluorouracil was given intravenously the AUC was increased by 27% and the total body clearance was reduced by 28% by **cimetidine**. In this small group, no increased toxicity was noted. The pharmacokinetics of fluorouracil were unaltered when **cimetidine** was given for only one week.¹ **Cimetidine** had similar effects in *animal* studies but **ranitidine** had no effect on fluorouracil metabolism.² It is suggested that **cimetidine** reduces the hepatic metabolism of fluorouracil.^{1,2} At least three clinical studies have shown some treatment benefits from giving fluorouracil with long-term **cimetidine** in colorectal cancer.^{3–5} However, this benefit has been attributed to immunomodulation³ or inhibition of adhesion,⁴ rather than any pharmacokinetic interaction. Whatever the mechanism, it appears that **cimetidine** can increase the activity of fluorouracil. Concurrent treatment should be undertaken with care. **Cimetidine** can be obtained without a prescription in some countries so that patients may unwittingly increase the toxicity of fluorouracil. **Ranitidine** does not appear to interact.

Fluorouracil + Interferon alfa

Interferon alfa has increased plasma fluorouracil levels in some, but not other, studies.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study 26 patients with colorectal cancer were given a 5-day continuous infusion of fluorouracil 750 mg/m² daily repeated in week 4 followed by a bolus intravenous injection of 750 mg/m² once a week with or without subcutaneous interferon alfa-2a (*Roferon*) 9 million units three times a week. There was considerable within-patient variation but no significant differences in steady-state plasma levels were found between the two groups.¹ Similarly, others have also reported that interferon alfa does not significantly alter fluorouracil pharmacokinetics,^{2,3} however, other studies^{4–8} have found a significant increase in peak fluorouracil levels and/or AUC when interferon alfa is given. Despite

promising early pre-clinical and clinical data indicating that interferon may improve the response to fluorouracil, this has not yet been demonstrated in randomised studies.⁹ A study in 27 patients with metastatic melanoma treated with fluorouracil 1000 mg/m² every 28 days and interferon alfa 2a in doses of up to 9 million units daily for 70 days and then 3 million units three times a week for up to a year, found that the response rate was similar to that obtained in other studies using interferon alone. The most frequent adverse effects were related to the interferon, and no patients were withdrawn from the study due to toxicity.¹⁰

Fluorouracil + Metronidazole

The toxicity, but not the efficacy of fluorouracil, is increased by metronidazole.

Clinical evidence

A marked increase in fluorouracil toxicity was noted in 27 patients with metastatic colorectal cancer when they were given intravenous metronidazole 750 mg/m² one hour before receiving intravenous fluorouracil 600 mg/m² 5 days per week, every 4 weeks. Granulocytopenia occurred in 74% of patients, nausea and vomiting in 48%, anaemia in 41%, stomatitis and oral ulceration in 34%, and thrombocytopenia in 19%.¹ A pharmacokinetic study in 10 patients found that metronidazole reduced the clearance of fluorouracil by 27% over the 5-day period and increased the AUC by 34%. *In vitro* studies with human colon cancer cells failed to show any increased efficacy.¹

Studies using another nitroimidazole, misonidazole, in patients with colorectal cancer also found an increased incidence and severity of gastrointestinal toxicity with concurrent use,^{2,3} a slightly increased incidence of leucopenia² and a reduction in the clearance of fluorouracil.³

Mechanism

Metronidazole reduces the clearance of fluorouracil, thereby increasing its toxic effects.

Importance and management

Information is limited but the interaction between fluorouracil and metronidazole appears to be established. It was hoped that metronidazole or misonidazole (no longer in clinical use) might increase the efficacy of fluorouracil. However, the studies above show that the toxicity of fluorouracil is increased without an obvious increase in its therapeutic efficacy. Care should be taken if metronidazole is required for its antimicrobial effects in a patient receiving fluorouracil. Whether other nitroimidazoles (e.g. tinidazole) behave similarly appears not to have been studied.

- McDermott BJ, Van den Berg HW, Martin WMC, Murphy RF. Pharmacokinetic rationale for the interaction of 5-fluorouracil and misonidazole in humans. *Br J Cancer* (1983) 48, 705–10.

Fluorouracil + Miscellaneous

A retrospective analysis of studies in a total of 250 patients given fluorouracil for the treatment of gastrointestinal cancer found that chlorprothixene, cinnarizine, prochlorperazine, sodium pentobarbital, thiethylperazine, trimethobenzamide (in antiemetic doses) did not significantly increase toxicity or decrease therapeutic effects, when compared with a placebo.¹

- Moertel CG, Reitemeier RJ, Hahn RG. Effect of concomitant drug treatment on toxic and therapeutic activity of 5-fluorouracil (5-FU; NSC-19893). *Cancer Chemother Rep* (1972) 56, 245–7.

Fluorouracil prodrugs + Sorivudine

Marked and rapidly fatal toxicity, attributed to fluorouracil toxicity, has been seen in patients given tegafur or other fluorouracil prodrugs with sorivudine. Fluorouracil is expected to interact similarly.

Clinical evidence

In 1993, the Japanese Ministry of Health reported that 15 Japanese patients with cancer and a viral disease died several days after being given a fluorouracil prodrug (e.g. tegafur) and sorivudine. Before death most of them developed severe toxicity including severe anorexia, marked damage to the bone marrow with decreases in white cell and platelet counts, and marked atrophy of the intestinal membrane, with diarrhoea and loss of blood. Eight other patients given both drugs developed symptoms of severe toxicity.^{1,2}

Mechanism

Sorivudine appears to be converted in the gut into a metabolite (BVU or bromovinyluracil) that is a potent inhibitor of dihydropyrimidine dehydrogenase (DPD), an enzyme involved in the metabolism of fluorouracil (which is derived from tegafur and other fluorouracil prodrugs).^{1,3} There is some evidence that DPD activity is genetically determined, and that there are poor fluorouracil metabolisers with low DPD activity, who would be expected to be more susceptible to this interaction.⁴

Importance and management

Information appears to be limited to these reports but the interaction appears to be established and of clinical importance. The concurrent use of inhibitors of DPD (such as sorivudine and brivudine) and oral fluorouracil prodrugs such as capecitabine⁵ and tegafur is contraindicated. Note that sorivudine was withdrawn from the market following confirmation of this interaction.

- Xeloda (Capecitabine). Roche Products Ltd. UK Summary of product characteristics, March 2007.

Fluorouracil prodrugs; Capecitabine + Allopurinol

The activity of capecitabine is predicted to be decreased by allopurinol.

Clinical evidence, mechanism, importance and management

Capecitabine is a prodrug, which is activated by several enzymatic steps to produce active fluorouracil within the body. Because allopurinol is reported to modulate fluorouracil, with possible decreased efficacy (see

'Fluorouracil + Allopurinol', p.632), the UK manufacturers of capecitabine say that allopurinol should be avoided.¹

1. Xeloda (Capecitabine). Roche Products Ltd. UK Summary of product characteristics, March 2007.

Fluorouracil prodrugs; Capecitabine + Antacids

The absorption of capecitabine was not affected by an aluminium/magnesium hydroxide antacid.

Clinical evidence, mechanism, importance and management

A study in 12 patients found that 20 mL of an aluminium/magnesium hydroxide antacid (*Maalox*) caused a small increase in the plasma levels of a single 1250-mg/m² oral dose of capecitabine and one metabolite (5'-DFCR) but it had no effect on the other 3 major metabolites (5'DFUR, 5-FU and FBAL).¹ There would therefore seem to be no reason for taking special precautions if capecitabine and an antacid of this type are used concurrently.

1. Reigner B, Clive S, Cassidy J, Jodrell D, Schulz R, Goggin T, Banken L, Roos B, Utoh M, Mulligan T, Weidekamm E. Influence of the antacid Maalox on the pharmacokinetics of capecitabine in cancer patients. *Cancer Chemother Pharmacol* (1999) 43, 309–15.

Fluorouracil prodrugs; Capecitabine + Folinates

A patient died after treatment with capecitabine possibly because the concurrent use of folic acid enhanced capecitabine toxicity. The maximum tolerated dose of capecitabine is decreased by folic acid.

Clinical evidence, mechanism, importance and management

(a) Folic acid

A 51-year-old woman with metastatic breast cancer started treatment with capecitabine 2500 mg/m² daily for 14 days every 21 days. Treatment was stopped after 8 days because she developed diarrhoea, vomiting and hand-foot syndrome. She improved with parenteral hydration and symptomatic treatment, but 3 weeks later still had diarrhoea, leg oedema and hand-foot syndrome. She was found to have been taking folic acid 15 mg daily for several weeks before starting capecitabine and had continued to take it during and after capecitabine treatment. The patient's condition improved when the folic acid was stopped, but she then developed diarrhoea and fever followed by necrotic colitis and she died from septic shock and vascular collapse. It is possible that the concurrent use of folic acid enhanced the toxicity of capecitabine.¹

(b) Folinic acid

Studies in patients with refractory advanced cancer have shown that folic acid 30 mg twice daily does not have a major effect on the pharmacokinetics of capecitabine.² However, the pharmacodynamics of capecitabine were affected as determined by the more frequent occurrence of dose-limiting gastrointestinal disorders or hand-foot syndrome.² The UK manufacturers say that the maximum tolerated capecitabine dose when used alone in the intermittent regimen is 3000 mg/m², but it is reduced to 2000 mg/m² if folic acid 30 mg twice daily is also given.³

3. Xeloda (Capecitabine). Roche Products Ltd. UK Summary of product characteristics, March 2007.

Fluorouracil prodrugs; Capecitabine + Interferon alfa

The maximum tolerated dose of capecitabine is decreased by interferon alfa.

Clinical evidence, mechanism, importance and management

The UK manufacturers¹ say that the maximum tolerated capecitabine dose when used alone is 3000 mg/m², but when combined with interferon alfa-2a (3 million units/m² daily) the maximum tolerated dose is 2000 mg/m². Capecitabine is a prodrug of fluorouracil, which is thought to be modulated by interferon alfa. See also 'Fluorouracil + Interferon alfa', p.633.

1. Xeloda (Capecitabine). Roche Products Ltd. UK Summary of product characteristics, March 2007.

Fluorouracil prodrugs; Capecitabine + Taxanes

There are no clinically significant pharmacokinetic interactions between capecitabine and paclitaxel, and probably not between capecitabine and docetaxel.

Clinical evidence, mechanism, importance and management

A study in patients with advanced solid tumours found that the use of capecitabine with **docetaxel**, resulted in an almost twofold decrease in the maximum plasma concentration and AUC of fluorouracil. The authors suggest that more study is needed to assess the significance of this finding. Other pharmacokinetic parameters of capecitabine were not affected by **docetaxel**, and the pharmacokinetics of **docetaxel** were not significantly affected by capecitabine or its metabolites.¹

Other studies in similar patients also found that capecitabine did not alter the pharmacokinetics of **docetaxel**² and that the concurrent use of **paclitaxel** and capecitabine did not significantly alter the pharmacokinetics of either drug.³

1. Pronk LC, Vasey P, Sparreboom A, Reigner B, Planting AST, Gordon RJ, Osterwalder B, Verweij J. A phase I and pharmacokinetic study of the combination of capecitabine and docetaxel in patients with advanced solid tumours. *Br J Cancer* (2000) 83, 22–9.

Phase I and pharmacokinetic study of the oral fluoropyrimidine capecitabine in combination with paclitaxel in patients with advanced solid malignancies. *J Clin Oncol* (1999) 17, 1915–25.

Fulvestrant + Miscellaneous

The pharmacokinetics of intravenous fulvestrant were not affected by rifampicin, an inducer of the cytochrome P450 isoenzyme CYP3A4, or ketoconazole, an inhibitor of CYP3A4. In addition, intramuscular fulvestrant did not affect the pharmacokinetics of midazolam, a substrate of CYP3A4. It is therefore unlikely that fulvestrant will be affected by drug interactions involving this isoenzyme.¹

1. Robertson JFR, Harrison M. Fulvestrant: pharmacokinetics and pharmacology. *Br J Cancer* (2004) 90 (Suppl. 1), S7–S10.

Gemcitabine + Anthracyclines

The concurrent use of gemcitabine and doxorubicin or epirubicin does not appear to affect the pharmacokinetics of either drug. An *in vitro* study found that the efficacy of the combination of gemcitabine and epirubicin may be schedule-dependent.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of gemcitabine and **doxorubicin** did not differ when they were given on the same day, when compared with when they were given alone in patients with breast cancer.¹ Similarly, gemcitabine pharmacokinetics were unchanged by the concurrent use of **epirubicin** and paclitaxel in patients with breast cancer,² and gemcitabine did not alter the interaction between **epirubicin** and paclitaxel (see 'Anthracyclines + Taxanes', p.612).

An *in vitro* study using human bladder cancer cells found that both gemcitabine and **epirubicin** alone exerted a cytotoxic effect but the efficacy of the combination of **epirubicin** and gemcitabine depended on the schedule

used. When the drugs were used concurrently or if gemcitabine was used before **epirubicin**, there was an antagonistic interaction. There was synergistic cytotoxic activity when **epirubicin** was used before gemcitabine. This schedule is being investigated in clinical studies.³

Gemcitabine + Platinum derivatives

The toxicity and pharmacokinetics of gemcitabine combined with platinum drugs such as cisplatin is dependent upon the order in which they are given.

Clinical evidence, mechanism, importance and management

(a) Carboplatin

Gemcitabine 1000 mg/m² on days 1, 8, and 15 has been given with carboplatin (maximum tolerated dose, giving an AUC of 5.2 mg/mL per minute) on day 1, in a monthly cycle. No difference was detected in toxicity or tolerated dose when the gemcitabine was given before or after the carboplatin.¹ However, subsequent authors reported that this same dose schedule, with carboplatin given immediately after the gemcitabine, caused unexpected and severe thrombocytopenia, and could not be recommended.²

(b) Cisplatin

When gemcitabine was given 4 hours before or after cisplatin there were no major differences in the plasma pharmacokinetics of gemcitabine, deaminated gemcitabine and platinum. Similarly, cisplatin given 24 hours before gemcitabine did not significantly change gemcitabine and deaminated gemcitabine levels, although there was a trend towards an increased AUC of gemcitabine triphosphate.³ Gemcitabine given 24 hours before cisplatin decreased the platinum AUC twofold,³ and caused the least leucopenia of the schedules.⁴ Anaemia, thrombocytopenia, nausea and vomiting, and fatigue were not sequence dependent.⁴ On the basis of these findings, the authors are further evaluating the schedule of cisplatin given 24 hours before gemcitabine.^{3,4} Note that the combination of cisplatin and gemcitabine is commonly used for the treatment of various cancers, usually with the drugs given concurrently or sequentially on the same day.⁵

(c) Oxaliplatin

The pharmacokinetics of gemcitabine 800 to 1500 mg/m² and its main metabolite did not appear to be affected by oxaliplatin 70 to 100 mg/m² when oxaliplatin was given immediately after gemcitabine once every two weeks.⁶

Gemcitabine + Taxanes

One study found that giving paclitaxel before gemcitabine increased the gemcitabine levels by 25%, but other studies did not find a pharmacokinetic interaction. Gemcitabine distribution may be altered by docetaxel, but docetaxel pharmacokinetics are not affected. The clinical response to the combination of gemcitabine and a taxane may depend on the sequence of administration.

abine and a taxane may depend on the sequence of administration.

Clinical evidence, mechanism, importance and management

(a) Docetaxel

In a study of gemcitabine and docetaxel, given on days 1 and 8 of a 21-day cycle, drug toxicity and pharmacokinetics were unaffected by the relative order of their administration.¹ However, in another study, it appeared that while docetaxel pharmacokinetics were unaffected, the distribution of gemcitabine was altered by docetaxel, although there was no clear relationship between this and toxicity.²

A response rate of 43% was reported in a study in which 35 patients with sarcomas were given gemcitabine 675 mg/m² over 90 minutes on day 1 and 8, followed by docetaxel 100 mg/m², given over 60 minutes, on day 8. The possible synergistic antitumour effect may have been secondary to both the prolonged gemcitabine infusion and the sequence of drug administration.³ More study is needed.

(b) Paclitaxel

A study in 18 patients with non-small-cell lung cancer found that when they were given gemcitabine 1000 mg/m² on days 1 and 8 and paclitaxel 150 to 200 mg/m² on day one as a 3-hour infusion immediately before the gemcitabine, the plasma levels of gemcitabine and the AUC of its deaminated metabolite were unchanged, as was the AUC of paclitaxel. However, paclitaxel increased gemcitabine triphosphate levels, potentially improving efficacy.⁴ In a study in 14 patients with non-small cell lung cancer, gemcitabine 800 mg/m² was administered on day 1 and 8 of a 21 day cycle and paclitaxel 110 mg/m² was given 3 hours before the second dose of gemcitabine on day 8. When paclitaxel was given first the clearance, volume of distribution and interpatient pharmacokinetic variability of gemcitabine were decreased. Plasma levels of gemcitabine were increased by 25%, but there was no correlation between these changes and toxicity, and the clinical significance of the interaction is uncertain.⁵ In another study, no pharmacokinetic interactions were detected between gemcitabine and paclitaxel given once weekly, although gemcitabine showed saturation kinetics at higher doses.^{6,7} Another study in patients with advanced breast cancer given gemcitabine, epirubicin and paclitaxel also found no pharmacokinetic interaction between gemcitabine and paclitaxel.⁸

The high overall response rate of 71% in a phase II study⁹ in patients with advanced breast cancer treated with gemcitabine and paclitaxel, prompted an *in vitro* study¹⁰ which found that administration of paclitaxel followed by gemcitabine resulted in synergistic cytotoxic activity, whereas gemcitabine followed by paclitaxel had antagonistic activity. Phase III studies are being carried out to further evaluate the effects of order of administration of these drugs in patients with metastatic breast cancer.¹¹

Imatinib + CYP3A4 inducers

Rifampicin (rifampin) and St John's wort (*Hypericum perforatum*) lower serum imatinib levels; other CYP3A4 inducers (such as carbamazepine, phenobarbital and phenytoin) are predicted to do the same.

Clinical evidence

(a) Rifampicin (Rifampin)

A study reported that pretreatment with rifampicin 600 mg daily for 11 days decreased the maximum serum levels and AUC of a 400 mg dose of imatinib by 54% and 74%, respectively.¹

(b) St John's wort (*Hypericum perforatum*)

In a study in 12 healthy subjects, the pharmacokinetics of a single dose of imatinib was determined before and on day 12 of two weeks of treatment with St John's wort (*Hypericum perforatum*) extract (Kira [LI 160], Lichtwer Pharma) 300 mg three times daily. The AUC and maximum plasma level of imatinib was decreased by 30% and 15%, respectively. Imatinib clearance was increased by 43% and its half-life was decreased from 12.8 to 9 hours.² Similar results were found in another study.³

Mechanism

Rifampicin is a known potent inducer of many cytochrome P450 isoenzymes, including CYP3A4, by which imatinib is metabolised. Therefore rifampicin increases imatinib metabolism and decreases its levels. St John's wort induces intestinal CYP3A4 and it therefore also reduces imatinib levels.

Importance and management

Subtherapeutic levels of imatinib may occur if rifampicin is given. The manufacturers therefore reasonably recommend caution, and suggest that concurrent use with potent enzyme-inducing drugs should be avoided.^{4,5} St John's wort has smaller effects, but they may be sufficient to impair the effects of imatinib, and it has therefore been suggested that concurrent use should also be avoided.²

No specific studies have been carried out with imatinib and other CYP3A4-inducing drugs, but the manufacturers suggest that **carbamazepine, dexamethasone, phenobarbital, and phenytoin**, may also reduce imatinib serum levels, and they have a possible case on file with phenytoin.⁶ The manufacturers therefore reasonably recommend caution, and suggest that concurrent use with these drugs should be avoided.^{4,5} However, if this is not possible it would be prudent to monitor the outcome of concurrent use, and increase the imatinib dose as necessary.

Imatinib + CYP3A4 inhibitors

Ketoconazole raises serum imatinib levels; other cytochrome P450 isoenzyme CYP3A4 inhibitors (such as other azoles and macrolides) are predicted to do the same.

Clinical evidence

(a) Ketoconazole

An open-label, randomised, crossover study in 14 healthy subjects found that the maximum serum levels and AUC of imatinib rose by 26% and 40%, respectively, when they were given a single 400-mg dose of ketoconazole with a single 200-mg dose of imatinib.¹

(b) Voriconazole

A patient with chronic myeloid leukaemia developed a pustular eruption while taking imatinib 400 mg daily, increased to 800 mg daily 12 weeks after starting to take voriconazole for pulmonary aspergillosis. His imatinib plasma levels were approximately twice the predicted levels while taking both drugs. His condition improved within 3 weeks of stopping both voriconazole and imatinib, and did not recur with voriconazole treatment alone.²

Mechanism

Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of imatinib. Therefore ketoconazole reduces the metabolism and clearance of imatinib and its serum levels rise accordingly. Adverse skin reactions occur frequently with imatinib and may be associated with high doses of imatinib and/or increased levels due to an interaction with CYP3A4 inhibitors, such as voriconazole.²

Importance and management

The manufacturers therefore advise caution with ketoconazole and with other CYP3A4 inhibitors (examples listed are **clarithromycin, erythromycin and itraconazole**),^{3,4} but it is not entirely clear what action should be taken because information about excessive serum levels is very limited. The authors of one report suggest monitoring plasma levels of imatinib to identify patients at risk of severe toxicity.²

Imatinib + Miscellaneous

Imatinib increases serum tacrolimus levels and is therefore predicted to increase ciclosporin levels. Imatinib may also increase the levels of some benzodiazepines (e.g. midazolam), some calcium-channel blockers (e.g. nifedipine), oestrogens, paracetamol, pimozide, and warfarin. In one case lansoprazole was suspected to have raised imatinib levels.

Clinical evidence, mechanism, importance and management

(a) Calcium-channel blockers

The manufacturers suggest that the levels of the dihydropyridine calcium-channel blockers may be increased by imatinib.^{1,2} This suggestion is supported by the case of a patient taking **nifedipine** who developed nausea, vomiting and abdominal pain 8 weeks after starting to take imatinib 400 mg [daily]. Ultrasound showed a thickened gallbladder wall, dilatation of the principal bile ducts and a gallstone. He had not previously had any gall bladder disease. Imatinib was stopped until the abdominal pain was resolved and then restarted at half the initial dose. It was suggested that imatinib may inhibit the metabolism of **nifedipine**, leading to an increase in its effects on lipids, leading to an increase in biliary secretion and gallstone development.³ This needs confirmation.

(b) Ciclosporin or Tacrolimus

One study in patients with leukaemia who had undergone stem cell transplantation found that the levels of tacrolimus were increased by 25 to 33% within 72 hours of starting imatinib. An empiric tacrolimus dose reduction of 25% at the start of imatinib treatment was found to prevent further serum level fluctuations.⁴ The manufacturers suggest that ciclosporin levels may also be increased by imatinib, via its effects on the cytochrome P450 isoenzyme CYP3A4.^{1,2}

(c) Lansoprazole

A patient with a recurrence of a gastrointestinal stromal tumour was given imatinib 400 mg daily without adverse effect. However, after 2 months, lansoprazole 15 mg daily was also given for dyspepsia and the patient developed bilateral eyelid oedema with hyperaemic conjunctivae and labial oedema. Both drugs were stopped, but on reintroduction the symptoms re-

appeared and she developed Stevens-Johnson syndrome. Both drugs were again stopped and she recovered after treatment with methylprednisolone and desloratadine for one month. Two months later, she took a single dose of lansoprazole on the day before treatment with imatinib 300 mg daily (with prednisone and desloratadine) was started. One day later she developed eyelid and labial oedema and a generalised rash. She recovered after imatinib was stopped. Although the adverse effects could be attributed to either imatinib or lansoprazole alone, it was possible that the effects may have been the result of an interaction in which levels of imatinib were increased by lansoprazole, which is a weak inhibitor of CYP3A4.⁵ This needs confirmation.

(d) Oestrogens

A patient taking a low-dose oestrogen contraceptive developed nausea and abdominal pain after taking imatinib 400 mg daily for 4 months. Ultrasound showed multiple gallstones and increased gallbladder wall thickness.³ Imatinib is reported to increase plasma oestrogen levels by inhibiting its metabolism by the cytochrome P450 isoenzyme CYP3A4, possibly leading to increased cholesterol excretion, reduced bile salt excretion and gallstone development. This needs confirmation.

(e) Paracetamol (Acetaminophen)

During clinical studies one patient regularly taking paracetamol for fever, died of acute liver failure 11 days after starting to take imatinib.⁶ The manufacturers report that imatinib inhibits paracetamol O-glucuronidation *in vitro*. Although this potential interaction has not been studied in humans, the manufacturers recommend caution during concurrent use, especially with high doses of paracetamol.^{1,2}

(f) Warfarin

The manufacturers say that because warfarin is metabolised by CYP2C9, patients needing anticoagulation should be given low-molecular-weight or standard heparin instead. This recommendation is based on an observation in one patient⁷ and *in vitro* studies^{1,2} that show that imatinib can inhibit CYP2C9. There seems to be no other evidence that a clinically relevant interaction is likely to occur.

(g) Other drugs

The manufacturers of imatinib predict that it may raise the levels of **pimozide** with potentially serious consequences [arrhythmias] because of CYP3A4 inhibition. They also suggest that imatinib may raise the levels of the **triazolo-benzodiazepines** (e.g. **triazolam**, **midazolam**).^{1,2} This could lead to increased and prolonged sedation.

Irinotecan + Antiepileptics

In patients with malignant gliomas, enzyme-inducing antiepileptics (carbamazepine, phenobarbital, phenytoin) and, to a lesser extent, non-enzyme inducing antiepileptics (gabapentin, valproate) increased the clearance of irinotecan. The clearance of the active metabolite of irinotecan was also increased by phenytoin. A number of case reports support these suggestions.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine

In a preliminary report of studies in patients with malignant glioma, the clearance of irinotecan was increased almost twofold in the presence of

carbamazepine. Peak plasma levels and AUC of irinotecan and SN-38 were significantly decreased.¹

(b) Phenobarbital

Preclinical data from *rats*² indicate that phenobarbital may lead to a reduction in the AUC of both irinotecan and its active metabolite SN-38. This is thought to be because phenobarbital induces the enzymes responsible for glucuronidation of SN-38. In a preliminary report of studies in patients with malignant glioma, clearance of irinotecan was increased by about 1.7-fold in the presence of phenobarbital. The AUC and peak plasma levels of irinotecan and SN-38 were significantly decreased.¹ In a phase I study in patients given ciclosporin and irinotecan, giving phenobarbital 90 mg daily for 2 weeks before irinotecan allowed a dose escalation of irinotecan from 75 mg/m² to 144 mg/m². Phenobarbital increased irinotecan clearance by 27% and reduced the AUC of SN-38 by 75%, when compared to irinotecan pharmacokinetics in patients given irinotecan with ciclosporin. Further clinical studies are needed to assess the effects of phenobarbital (with ciclosporin; see also, 'Irinotecan + Ciclosporin', p.639) on the antitumour response and toxicity of irinotecan.³

(c) Phenytoin

A 14-year-old girl with glioblastoma was given irinotecan 20 to 60 mg/m² daily for 5 days on 2 consecutive weeks every 21 days for 2 cycles. During the first cycle she also received phenytoin 300 mg and dexamethasone 6 mg daily. Irinotecan clearance was increased 2.5-fold compared with that in other patients receiving irinotecan alone, and there was decreased exposure to the active metabolite of irinotecan, SN-38. The effect on clearance decreased slowly over 8 days after stopping phenytoin.⁴ Another patient taking phenytoin and irinotecan was found to have much lower AUCs for irinotecan and SN-38 compared with data from patients not taking phenytoin.⁵ Similarly, a third patient had a threefold increase in irinotecan clearance and about a 60% reduction in the AUCs of irinotecan and SN-38 after starting phenytoin.⁶ In a comparative study, the AUC of the lactone forms of irinotecan and SN-38 were 27% and 51% lower, respectively, in 10 children taking enzyme-inducing antiepileptics (7 receiving phenytoin) than in 21 children not taking these antiepileptics.⁷ A preliminary report of studies in patients with malignant glioma, clearance of irinotecan was increased by about twofold in the presence of phenytoin. Peak plasma levels and AUC of irinotecan and SN-38 were significantly decreased.¹

It is thought that phenytoin increases the metabolism of irinotecan to an inactive metabolite by inducing the cytochrome P450 isoenzyme CYP3A, leading to decreased exposure to the active metabolite.⁵

The information is limited but serves to emphasise the need for caution and monitoring if irinotecan is given with phenytoin, which may reduce the availability of its active metabolite. Note that phenytoin has also been shown to increase the clearance of a related topoisomerase inhibitor, topotecan (see 'Topotecan + Phenytoin', p.667) and 9-aminocamptothecin (see '9-Aminocamptothecin + Antiepileptics', p.610).

(d) Non-enzyme-inducing antiepileptics

Preclinical data from *rats*² suggests that **sodium valproate** increases the AUC of the active metabolite of irinotecan, SN-38. This is because **valproate** inhibits its subsequent glucuronidation. The clinical relevance of this remains to be determined. A preliminary report of studies in patients with malignant gliomas found that in patients also taking non-enzyme-inducing antiepileptics (**gabapentin**, **lamotrigine**, **levetiracetam**, **tiagabine**, **topiramate**, **valproate**, or **zonisamide**) there was a small but statistically significant increase (about 1.4-fold) in irinotecan clearance.¹

Irinotecan + Cannabis

The pharmacokinetics of irinotecan are not altered by a herbal tea containing cannabis.

Clinical evidence, mechanism, importance and management

In a crossover study 24 patients were given intravenous **irinotecan** 600 mg before and 12 days after starting a 15-day course of 200 mL daily of a herbal tea containing cannabis 1 g/L. This was prepared from medicinal-grade cannabis (*Cannabis sativa* L. Flos, variety Bedrocan®) containing the cannabinoids Δ^9 -tetrahydrocannabinol 18% and cannabidiol 0.8%. The clearance and the AUC of **irinotecan** and its metabolites, SN-38 and SN-38G, were not significantly altered by the presence of cannabis. No dosage adjustments are likely to be needed if **irinotecan** is given with cannabis.¹

- Engels FK, de Jong FA, Sparreboom A, Mathot RA, Loos WJ, Kitzen JJEM, de Bruijn P, Verweij J, Mathijssen RHJ. Medicinal cannabis does not influence the clinical pharmacokinetics of irinotecan and docetaxel. *Oncologist* (2007) 12, 291–300.

Irinotecan + Cyclosporin

Cyclosporin reduces the clearance of irinotecan and increases exposure to its active metabolite, SN-38.

Clinical evidence, mechanism, importance and management

In a phase I study in patients with refractory solid tumours or lymphomas, cyclosporin 5 to 10 mg/kg was given as a 6-hour infusion beginning 3 hours before administration of irinotecan (initial dose 25 mg/m² increased to 72 mg/m² weekly). Cyclosporin increased the AUC of SN-38 (the active metabolite of irinotecan) by 23 to 630% and reduced irinotecan clearance by 39 to 64%, when compared with historical controls. The effects of cyclosporin on irinotecan may be due to inhibition of irinotecan- and SN-38-related biliary transporters,¹ and this suggestion is supported by a study in *rats*.² Further clinical studies are needed to assess the effects of cyclosporin on the antitumour response and toxicity of irinotecan.

Irinotecan + Fluorouracil

While some studies suggest that giving fluorouracil after irinotecan reduces the conversion of irinotecan to its active metabolite, others do not.

Clinical evidence, mechanism, importance and management

A study in 33 patients with metastatic colorectal cancer found that the toxicity and pharmacokinetics of irinotecan given with fluorouracil depended upon the order of administration of the two drugs.¹ When irinotecan was given before fluorouracil, the AUC of the major active metabolite of irinotecan, SN-38, was about 40% lower, and toxicity was lower. In this study, patients were randomised to receive a 60-minute infusion of irinotecan (150 mg/m² starting dose, escalated by 50 mg/m² increments) immediately before or after a 48-hour infusion of fluorouracil 3500 mg/m² modulated by folic acid in cycle 1, then given in the reverse sequence in cycle 2. Similarly, in a study using historical controls, the AUC of SN-38 was about 28% lower and the AUC of irinotecan about 35% higher when irinotecan was given over 90 minutes immediately before a 7-day fluorouracil infusion, compared with irinotecan alone.² Similar findings were reported in a study in *rats*.³ In contrast, another study found that fluorouracil did not substantially affect the metabolism of irinotecan to SN-38. The AUC of irinotecan and SN-38 did not differ between irinotecan alone, irinotecan immediately followed by folic acid and fluorouracil, and iri-

notecan immediately after folic acid and fluorouracil. In this study, irinotecan 100 to 150 mg/m² was given as a 90-minute infusion, and fluorouracil 210 to 500 mg/m² by rapid intravenous injection.⁴ Similarly, preliminary reports from another research group found that the clearance of irinotecan did not differ when it was given one day before or one day after 5 daily bolus doses of fluorouracil.^{5,6}

From these data it is unclear whether or not fluorouracil alters the pharmacokinetics of irinotecan. A key difference between the main studies is the use of bolus⁴ or continuous infusion¹ fluorouracil. The combination is in established clinical usage, where the recommendation is to give irinotecan before fluorouracil and folic acid.^{7,8} This combination has been shown to be more effective than fluorouracil and folic acid alone.^{7,8} Whether this is the optimal schedule remains to be determined.

Irinotecan + Ketoconazole

Ketoconazole, and therefore probably itraconazole, decreases irinotecan levels and increases the levels of its active metabolite.

Clinical evidence, mechanism, importance and management

A study found that ketoconazole decreased the AUC of irinotecan by 87% and increased the AUC of the active metabolite, SN-38, by 109%. This probably occurred because ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 by which irinotecan is metabolised. The manufacturers of irinotecan recommend that the concurrent use of ketoconazole should be avoided.^{1,2} The US manufacturers recommend stopping ketoconazole at least one week before starting irinotecan and contraindicate concurrent use.² It is likely that other azoles that are strong inhibitors of CYP3A4, such as **itraconazole**, may also affect the metabolism of irinotecan.

- Campto (Irinotecan hydrochloride trihydrate). Pfizer Ltd. UK Summary of product characteristics, January 2007.
- Camptosar (Irinotecan hydrochloride). Pfizer Inc. US Prescribing information, June 2006.

Irinotecan + Milk thistle

Milk thistle does not affect the pharmacokinetics of irinotecan.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study was undertaken in 6 patients who were being treated with intravenous irinotecan 125 mg/m² once weekly for 4 weeks, followed by a 2 week rest period. Four days before the second dose of irinotecan, a 14-day course of 200 mg milk thistle seed extract (containing silymarin 80%) three times daily was started. The pharmacokinetics of irinotecan and its metabolites did not differ between week 1 (no milk thistle), week 2 (4 days of milk thistle) or week 3 (12 days of milk thistle).¹ No dosage alterations would therefore be expected to be needed if milk thistle (standardised with silymarin 80%) is given with irinotecan.

- van Erp NPH, Baker SD, Zhao M, Rudek MA, Guchelaar H-J, Nortier JWR, Sparreboom A, Gelderblom H. Effect of milk thistle (*Silybum marianum*) on the pharmacokinetics of irinotecan. *Clin Cancer Res* (2005) 11, 7800–6.

Irinotecan + Miscellaneous

Preclinical data suggest that vinorelbine and physostigmine may decrease the formation of the active metabolite of irinotecan, SN-38.

Clinical evidence, mechanism, importance and management

In studies in human liver microsomes, **nifedipine**, **clonazepam**, **methylprednisolone**, **omeprazole**, and **vinorelbine** had significant effects on the metabolism of irinotecan. However, only the effect of **vinorelbine** occurred at a concentration considered clinically relevant.¹ Similarly, of various potential carboxylesterase inhibitors, only **physostigmine** was considered sufficiently potent to possibly inhibit irinotecan activation.² Further study is needed to assess the clinical relevance of these findings.

Irinotecan + Oxaliplatin

An isolated report suggests that the cholinergic toxicity associated with irinotecan may be enhanced by oxaliplatin.

Clinical evidence, mechanism, importance and management

One of 15 patients given a 1-hour infusion of irinotecan 80 mg/m² following an 2-hour infusion of oxaliplatin 85 mg/m² experienced hypersalivation and abdominal pain, which was treated successfully with atropine. In this patient, symptoms did not recur during subsequent treatment with irinotecan alone, nor when drugs were separated by one day, but rechallenge with the original combined regimen produced cholinergic toxicity.¹ The combination of irinotecan with oxaliplatin did not alter the pharmacokinetics of either drug in one study² therefore it was suggested that the observed effects in the patient may have been due to a pharmacodynamic interaction.³ It has been suggested that the cholinergic effects of irinotecan, which is a potent inhibitor of acetylcholinesterase,⁴ may be enhanced by oxaliplatin, which may like other alkylating drugs also inhibit acetylcholinesterase.³ The clinical relevance of this report is unknown. The combination of irinotecan and oxaliplatin has been extensively evaluated in clinical studies, and this appears to be the only report of this problem. However, it has been noted that the prophylactic use of atropine with irinotecan could mask any increased cholinergic toxicity.^{3,5} Further study is needed.

Irinotecan + Rifampicin (Rifampin)

A single case report found that rifampicin reduced the formation of two active metabolites of irinotecan. The clinical significance of this finding is unclear.

Clinical evidence, mechanism, importance and management

A case report describes a 54-year-old man with small cell lung cancer and *Mycobacterium* infection who was uneventfully treated with rifampicin 450 mg daily, isoniazid, streptomycin and pyrazinamide. After 2 weeks of antimycobacterial treatment he was given irinotecan, 75 mg/m² on days 1 and 8, and cisplatin 60 mg/m² on day 1 for 4 cycles, for one of which ri-

fampicin treatment was interrupted for a 4-day period. There was no difference in the pharmacokinetic profile of irinotecan with or without concurrent rifampicin, but the AUC of two active metabolites of irinotecan were reduced by 20% and 58%.¹

Further study is required to assess the significance of this finding. Also note that the effects of rifampicin can persist for some time after it is stopped and therefore a 4-day period may not have been sufficient for any effect to become apparent.

1. Yonemori K, Takeda Y, Toyota E, Kobayashi N, Kudo K. Potential interactions between irinotecan and rifampin in a patient with small-cell lung cancer. *Int J Clin Oncol* (2004) 9, 206–9.

Irinotecan + Selenium

Selenium at a dose of 2.2 mg daily does not appear to alter the pharmacokinetics of irinotecan, nor does it attenuate the toxicity of irinotecan.

Clinical evidence, mechanism, importance and management

In a study in 13 patients with metastatic or unresectable solid tumours **selenomethionine**, at a dose of elemental selenium 2.2 mg daily, was given with irinotecan weekly, in escalating doses from 125 mg/m² to 160 mg/m² for 4 weeks of a 6-week cycle. Irinotecan doses above the previously recommended maximum tolerated dose were still considered intolerable, with 3 of 4 patients receiving a dose of 160 mg/m² developing dose-limiting diarrhoea. There were no significant alterations in the pharmacokinetics of irinotecan or its metabolites, SN-38 and SN-38G. It was suggested that higher doses of selenomethionine should be investigated to see if they protect against irinotecan toxicity.¹

1. Fakhri MG, Pendyala L, Smith PF, Creaven PJ, Reid ME, Badmaev V, Azrak RG, Prey JD, Lawrence D, Rustum YM. A phase I and pharmacokinetic study of fixed-dose selenomethionine and irinotecan in solid tumors. *Clin Cancer Res* (2006) 12, 1237–44.

Irinotecan + Sorafenib

Sorafenib might increase levels of irinotecan and its major metabolite.

Clinical evidence, mechanism, importance and management

A study in 3 groups of 6 patients given sorafenib in doses of 200 mg, 400 mg or 800 mg daily, and irinotecan 125 mg/m² as an intravenous infusion found that the pharmacokinetics of irinotecan and its major active metabolite, SN-38, were not affected by sorafenib. In addition, sorafenib pharmacokinetics were not affected by irinotecan.¹

In contrast, the manufacturers note that when sorafenib was given with irinotecan there was a 26 to 42% increase in the AUC of irinotecan, and a 67 to 120% increase in the AUC of SN-38. They suggest that this occurs because sorafenib inhibits glucuronidation of SN-38. The clinical significance of this finding is unknown, but they recommend caution on concurrent use.^{2,3}

Irinotecan + St John's wort (*Hypericum perforatum*)

St John's wort increases the metabolism of irinotecan, which may decrease its activity.

Clinical evidence

In a randomised, crossover study St John's wort decreased the plasma levels of the active metabolite of irinotecan, SN-38, by 42%. Myelosuppression was also reduced; with irinotecan alone the leucocyte and neutrophil counts decreased by 56% and 63%, respectively, but in the presence of St

John's wort the decreases were only 8.6% and 4.3%, respectively. In this study, irinotecan was given as a single 350-mg/m² intravenous dose every 3 weeks, and during one cycle a St John's wort preparation was given three times daily, beginning 14 days before and stopping 4 days after the irinotecan.¹

Mechanism

St John's wort induces the cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein, which are both involved in the metabolism of irinotecan. The evidence suggests that St John's wort increases the metabolism of irinotecan to an unknown inactive metabolite, rather than the active SN-38, thereby reducing its effects.¹

Importance and management

The evidence appears to be limited to this study. Irinotecan has a narrow therapeutic range, and the lower levels of SN-38 suggest that its activity will be reduced in the presence of St John's wort. It would therefore seem sensible to warn patients who are about to receive irinotecan to avoid St John's wort. It seems likely that **topotecan**, a related drug that is also a substrate for CYP3A4, will be similarly affected, but evidence for this is currently lacking.

Irinotecan + Thalidomide

Thalidomide slightly increases irinotecan levels, but the clinical significance of this is uncertain.

Clinical evidence, mechanism, importance and management

Patients with solid tumours treated with irinotecan 350 mg/m² on day 1 of a 3 week cycle were also given thalidomide 400 mg daily from days 1 to 14 of the first cycle. Thalidomide slightly increased the AUC of irinotecan by 21% (not significant) and its SN-38-glucuronide metabolite by 28%, but decreased the AUC of the SN-38 metabolite by 26%. There was no difference in the toxicities seen when irinotecan was given with or without thalidomide.¹ Further study is required in larger groups of patients to establish if these changes in irinotecan pharmacokinetics are clinically relevant.

Irinotecan in combination with thalidomide in patients with advanced solid tumors: a clinical study with pharmacodynamic and pharmacokinetic evaluation. *Cancer Chemother Pharmacol* (2006) 58, 585–93.

Irinotecan + Tobacco

Retrospective data suggests that tobacco smoking might increase the clearance of irinotecan and reduce its toxicity, and presumably therefore, its efficacy.

Clinical evidence

In a retrospective analysis, the pharmacokinetics of irinotecan were compared between 49 patients who were smokers and 141 who were non-smokers, and who had received intravenous irinotecan 175 to 350 mg/m² (or a fixed dose of 600 mg) once every 3 weeks. Clearance of irinotecan was 18% faster in the group of patients who smoked, and these patients also showed more extensive conversion of the active metabolite SN-38 to the inactive glucuronide (SN-38G). Smokers experienced significantly less haematological toxicity than non-smokers (grade 3 to 4 neutropenia 6% versus 38%), possibly as a result of the increased rate of clearance.¹

Mechanism

Irinotecan is metabolised by the cytochrome P450 CYP3A isoenzymes, which, although not the most commonly implicated isoenzyme in interactions involving tobacco smoking, may be induced by some of the components of tobacco smoke, resulting in increased clearance of irinotecan. In addition, smoking might induce glucuronyltransferases (which are responsible for glucuronidation).¹

Importance and management

The findings of this retrospective analysis suggest that smoking might reduce the efficacy of irinotecan. However, the evidence is insufficient to make recommendations regarding smoking cessation or an increased irinotecan dose.¹ Further study is required.

Published ahead of print at <http://jco.ascopubs.org/cgi/reprint/JCO.2006.09.6115v1>.

Letrozole + Cimetidine

The pharmacokinetics of a single 2.5-mg dose of letrozole were unchanged by cimetidine 400 mg every 12 hours in 17 healthy subjects.¹

1. Morgan JM, Palmisano M, Spencer S, Hirschhorn W, Piraino AJ, Rackley RJ, Choi L. Pharmacokinetic effect of cimetidine on a single 2.5-mg dose of letrozole in healthy subjects. *J Clin Pharmacol* (1996) 36, 852.

Letrozole + Miscellaneous

The UK manufacturers report that in interaction clinical studies there was no evidence of clinically relevant interactions between letrozole and other commonly prescribed drugs, namely benzodiazepines such as diazepam, barbiturates, diclofenac, furosemide, ibuprofen, omeprazole, and paracetamol (acetaminophen).¹

Melphalan + Cimetidine

Cimetidine modestly reduces the bioavailability of melphalan.

Clinical evidence, mechanism, importance and management

A study in 8 patients with multiple myeloma or monoclonal gammopathy showed that pretreatment with cimetidine 1 g daily for 6 days reduced the bioavailability of a 10-mg oral dose of melphalan by 30%. The melphalan half-life was reduced from 1.94 to 1.57 hours. The interindividual variability in melphalan pharmacokinetics was high.¹ Note that, because of the variability in melphalan absorption, the dose of oral melphalan is usually cautiously increased until myelosuppression is seen, to ensure therapeutic levels. Therefore, this modest interaction with cimetidine is unlikely to have many clinical consequences.

1. Sviland L, Robinson A, Proctor SJ, Bateman DN. Interaction of cimetidine with oral melphalan. *Cancer Chemother Pharmacol* (1987) 20, 173–5.

Melphalan + Food

The absorption of oral melphalan can be reduced by food.

Clinical evidence, mechanism, importance and management

A study in 10 patients with multiple myeloma showed that the half-life of oral melphalan 5 mg/m² was unaffected when it was taken with a standardised **breakfast**, but the AUC was reduced by 39%. In one patient, no melphalan was detectable in the plasma when it was given with food. In 8 of the patients who had also been given intravenous melphalan at the same dose, the bioavailability of oral melphalan was calculated to be 85% (range 26% to 96%) when fasting and 58% (7% to 99%) when given with food. The authors recommend that melphalan should not be taken with food.¹ The manufacturer notes that absorption after oral administration is highly variable, and that the dosage should be adjusted based on frequent monitoring of blood counts. They make no specific recommendations about intake in relation to food.^{2,3}

Melphalan + Interferon alfa

Interferon alfa modestly decreases the AUC of melphalan, but melphalan cytotoxicity is possibly increased because of the interferon-induced fever.

Clinical evidence, mechanism, importance and management

In 10 myeloma patients the AUC of melphalan 250 microgram/kg was reduced by 13% when it was given 5 hours after the administration of human interferon alfa (7×10^6 units/m²), possibly due to the fever caused by the interferon.¹ The clinical importance of this is uncertain but the authors of the report suggest that despite this small reduction in the AUC, the cytotoxicity of the melphalan is increased by the fever. The use of interferon alfa with melphalan and prednisone in multiple myeloma has been associated with more adverse effects.²⁻⁴

Methotrexate + Amiodarone

An isolated case report tentatively attributes the development of methotrexate toxicity with the concurrent use of amiodarone.

Clinical evidence, mechanism, importance and management

An elderly woman, whose psoriasis was effectively controlled for 2 years with methotrexate, developed ulceration of the psoriatic plaques within 2 weeks of starting treatment with amiodarone. The reason is not understood. A modest increase in her dosage of furosemide is a suggested contributory factor because it might have interfered with the excretion of the methotrexate.¹

Methotrexate + Amphotericin B

Amphotericin B may delay the clearance of methotrexate.

Clinical evidence, mechanism, importance and management

Two children had delayed clearance of pulse methotrexate (1 g/m² over 24 hours) while they were receiving amphotericin B. Methotrexate levels were about 300 to 500% higher 48 hours after methotrexate when they were receiving amphotericin B, compared with methotrexate alone.¹ In a study, methotrexate clearance in 18 children given high-dose methotrexate (1 g/m² intravenously) was significantly correlated with the glomerular filtration rate (GFR). Concurrent amphotericin B in 6 of the children significantly decreased the GFR.² A history of heavy amphotericin B treatment (greater than 30 mg/kg) correlated with decreased methotrexate clearance in 24 children with relapsed leukaemia.³ Amphotericin B may cause renal impairment, which can result in delayed methotrexate clearance. The adverse effects of methotrexate should be carefully monitored (e.g. patient reported symptoms, LFTs, blood counts) in patients taking amphotericin B or those previously extensively treated with the drug. In patients taking large doses of methotrexate (e.g. not the weekly doses giv-

en for conditions such as rheumatoid arthritis) the monitoring of methotrexate levels is recommended.

Methotrexate + Antibacterials; Aminoglycosides, oral

There is evidence that the gastrointestinal absorption of methotrexate can be reduced by paromomycin, neomycin and possibly other oral aminoglycosides, but increased by kanamycin.

Clinical evidence

A study in 10 patients with small cell bronchogenic carcinoma taking methotrexate found that when they were also given a range of oral anti-infectives (paromomycin, vancomycin, polymyxin B, nystatin) the urinary recovery of methotrexate was reduced by over one-third (from 69% to 44%).¹ The paromomycin was believed to have been responsible. In another study the concurrent use of neomycin 500 mg four times a day for 3 days reduced the methotrexate AUC and the 72-hour cumulative excretion by 50%.² In contrast, the same report suggests that kanamycin can increase the absorption of methotrexate, but no details are given.

Mechanism

Oral aminoglycosides reduce the activity of the gut flora, which metabolise methotrexate so that more is available for absorption. However, paromomycin³ and neomycin, in common with other oral aminoglycosides, can cause a malabsorption syndrome, which reduces drug absorption and presumably negates any effect altering the gut flora has. Kanamycin may possibly be different because it causes less malabsorption.

Importance and management

The documentation of these interactions is sparse, but it would seem prudent to be on the alert for a reduction in the response to methotrexate if patients are given oral aminoglycosides such as paromomycin or neomycin. An increased response may possibly occur with kanamycin. No interaction would be expected if aminoglycosides are given parenterally.

Methotrexate + Antibacterials; Cefotiam

Pancytopenia and pseudomembranous colitis occurred when a patient treated with low-dose methotrexate and loxoprofen was given cefotiam.

Clinical evidence, mechanism, importance and management

An elderly woman who had been treated with low-dose methotrexate 5 mg weekly and loxoprofen for one month developed acute pyelonephritis. Intravenous cefotiam was started, and on day 7 she developed severe watery diarrhoea. Analysis showed pancytopenia and *Clostridium difficile* infection. Methotrexate and cefotiam were stopped, and vancomycin started, and the patient recovered.¹ It was suggested that the combination of the antineoplastic drug and antibacterial increased the risk of *Clostridium difficile* diarrhoea. In addition, the NSAID (see 'Methotrexate + NSAIDs', p.649) and renal impairment from the pyelonephritis could have contributed to the methotrexate toxicity.¹ This appears to be an isolated case, and any interaction with cefotiam is not established.

Methotrexate + Antibacterials; Ciprofloxacin

A report describes two patients who developed methotrexate toxicity when they were given ciprofloxacin.

Clinical evidence

When 2 patients with osteosarcoma, treated with high-dose methotrexate 12 g/m² per course, were given ciprofloxacin 500 mg twice daily, either during or 2 days before the start of the methotrexate course, methotrexate elimination was delayed, resulting in raised serum levels, severe cutaneous toxicity and renal impairment. The first patient also had hepatic injury and haematological toxicity. Following increased folic acid rescue, methotrexate levels normalised after several days. In earlier courses without ciprofloxacin in the first patient and subsequent courses without ciprofloxacin in the second patient, methotrexate elimination was normal.¹ This preliminary report¹ has subsequently been published in full.^{2,3}

Mechanism

Not fully understood. Ciprofloxacin may displace methotrexate from its plasma-protein binding sites resulting in a rise in levels of unbound methotrexate. Ciprofloxacin may also cause a decrease in renal clearance of methotrexate.

Importance and management

Information appears to be limited to one report, but it would seem prudent to monitor for raised methotrexate levels if concurrent use is necessary. More study is needed.

Methotrexate + Antibacterials; Co-trimoxazole or Trimethoprim

Eleven cases of severe bone marrow depression have been reported, three of them fatal, caused by the concurrent use of low-dose methotrexate and treatment doses of trimethoprim or co-trimoxazole (sulfamethoxazole and trimethoprim). Pancytopenia has also been reported in a few patients given treatment doses of co-trimoxazole shortly after stopping methotrexate.

Clinical evidence

A 61-year-old patient with rheumatoid arthritis, taking methotrexate 7.5 mg weekly, developed generalised bone marrow hypoplasia over 2 months after a 10-day course of treatment with co-trimoxazole for a urinary tract infection. She had taken a total of 775 mg of methotrexate when the hypoplasia appeared.¹ Eleven other cases of severe bone marrow depression, three of them fatal,^{2,3} have been described in patients taking low-dose weekly methotrexate with given co-trimoxazole^{2,4–8} or trimethoprim.^{3,6,9,10} Life-threatening complications (no details given) are said to have occurred in two other patients taking low-dose methotrexate with unnamed sulfonamides.¹¹ A 10-year (1981 to 1991) regional survey in Ottawa identified co-trimoxazole as one of four factors associated with serious pancytopenia in patients taking low-dose methotrexate. The other factors were elevated BUN or creatinine levels, increased mean corpuscular volumes and increasing age.¹²

Three cases of severe pancytopenia, one of them fatal, have been reported in patients given treatment dose co-trimoxazole for pneumocystis pneumonia shortly after stopping low-dose methotrexate therapy.^{13–15} A fatal case of severe agranulocytosis and toxic epidermal necrolysis occurred in a patient receiving co-trimoxazole for prophylaxis of pneumocystis pneumonia after high-dose methotrexate therapy.¹⁶

Mechanism

Not fully understood. Both drugs can suppress the activity of dihydrofolate reductase and it seems possible that they can act additively to pro-

duce folate deficiency, which could lead to some of the bone marrow changes seen. There may also be a pharmacokinetic mechanism. An early study found that the concurrent use of co-trimoxazole had no effect on the pharmacokinetics of methotrexate in children;¹⁷ however, another study reported that co-trimoxazole caused an increase in 'free' methotrexate from about 37% to 52% while the renal clearance was more than halved.¹⁸ This was calculated to increase the exposure to methotrexate by 66%.¹⁸ Another sulfonamide, **sulfafurazole** (sulfisoxazole),¹⁹ has been found to cause a small reduction in the clearance of methotrexate by the kidneys.

Importance and management

Information seems to be limited to the reports cited but the interactions between methotrexate and co-trimoxazole or trimethoprim are established. Low-dose co-trimoxazole is commonly given to patients taking methotrexate as prophylaxis of pneumocystis pneumonia without problem. This type of patient should be having regular blood monitoring as a matter of course. However, the situation with higher doses of either drug is potentially more hazardous. Some have recommended avoiding the combination. If both drugs must be used, the haematological picture should be very closely monitored because the outcome can be life-threatening.

Methotrexate + Antibacterials; Penicillins

Reduced clearance and acute methotrexate toxicity has been attributed to the concurrent use of various penicillins (amoxicillin, benzylpenicillin, carbenicillin, dicloxacillin, flucloxacillin, mezlocillin, oxacillin, penicillin, phenoxymethylpenicillin, piperacillin, ticarcillin) in a small number of case reports.

Clinical evidence

Reduced methotrexate clearance and acute methotrexate toxicity has been attributed to the concurrent use of various penicillins in a number of patients. See 'Table 17.2', (p.644) for details.

A survey of the Wyeth/Lederle safety database in 1996 identified two additional unpublished cases of methotrexate toxicity (aplastic anaemia, thrombocytopenia, pneumonitis) in patients who had recently started penicillins.¹

Table 17.2 Reports of reduced methotrexate clearance during penicillin use

Methotrexate	Penicillin (dose)	Indication (number of patients)	Outcome	Refs
High-dose regimen (with folinic acid rescue)				
Intravenous infusion 8 g/m ² over 6 hours	Amoxicillin (1 g every 6 hours orally)	Osteogenic sarcoma (1)	56% reduction in methotrexate clearance; prolonged and marked enhancement of methotrexate plasma levels; acute and subacute methotrexate toxicity	1
Intravenous infusion 6 g/m ² (10.8 g) over one hour, then 1.2 g/m ² per hour for 23 hours	Carbenicillin (30 g daily)	Acute lymphoblastic leukaemia (1)	Elevated plasma methotrexate levels and decreased methotrexate clearance	2
Intravenous bolus 15 to 60 mg/m ² , then 15 to 60 mg/m ² intravenous infusion over 36 hours	Dicloxacillin (not stated) (Indometacin also given)	Oesophageal cancer (1)	93% reduction in methotrexate clearance; prolonged folinic acid rescue necessary	3
Intravenous infusion 12 g/m ² over 4 hours	Mezlocillin (330 mg/kg daily)	Osteogenic sarcoma (1)	Reduced methotrexate clearance; increased gastrointestinal toxicity	4
Intravenous infusion 15 g over 6 hours	Oxacillin (1 g every 8 hours starting 6 hours after methotrexate infusion)	Osteogenic sarcoma (1)	Plasma methotrexate levels 53-fold higher than in previous cycles without oxacillin; fatal acute toxicity (renal failure and aplastic anaemia)	5
Intravenous bolus 15 to 60 mg/m ² , then 15 to 60 mg/m ² intravenous infusion over 36 hours	Penicillin [sic] (not stated)	Breast cancer (1)	36% reduction in methotrexate clearance; prolonged folinic acid rescue necessary	3
Intravenous bolus 15 to 60 mg/m ² , then 15 to 60 mg/m ² intravenous infusion over 36 hours	Piperacillin (not stated)	Chronic Myeloid Leukaemia (1)	67% reduction in methotrexate clearance; prolonged folinic acid rescue necessary	3
Intravenous infusion 3 g/m ² over 6 hours	Piperacillin (1 g every 6 hours intravenously)	Non-Hodgkin's lymphoma (1)	Reduced methotrexate clearance	6
Intravenous bolus 15 to 60 mg/m ² , then 15 to 60 mg/m ² intravenous infusion over 36 hours	Ticarcillin (not stated)	Acute Myeloid Leukaemia (1)	60% reduction in methotrexate clearance; prolonged folinic acid rescue necessary	3
Low-dose regimen				
7.5 mg weekly	Amoxicillin 500 mg orally three times daily for 7 days; from day 17, intravenous flucloxacillin 2 g every 4 hours, plus intravenous benzylpenicillin 2 million units every 4 hours	Rheumatoid arthritis	Neutropenia and thrombocytopenia probably as a result of reduced methotrexate clearance; folinic acid given, but patient died	7
7.5 mg weekly orally	Co-amoxiclav (amoxicillin + clavulanic acid)	Psoriasis (1)	Neutropenia and thrombocytopenia, probably as a result of reduced methotrexate clearance	7
5 mg weekly orally	Flucloxacillin (4 g four times daily, intravenously then orally)	Rheumatoid arthritis (1)	Suspected methotrexate-induced pneumonitis	8
5 to 15 mg weekly orally	Flucloxacillin (500 mg four times daily orally)	Rheumatoid arthritis (10, and 10 not given flucloxacillin)	No significant effect on methotrexate pharmacokinetics	8
2.5 mg three times each week orally	Flucloxacillin (1 g every 6 hours intravenously) plus piperacillin (2 g every 6 hours intravenously)	Psoriasis (1)	Neutropenia and thrombocytopenia, probably as a result of reduced methotrexate clearance; folinic acid given, but patient died	7
5 mg twice weekly orally	Piperacillin (intravenous; dose not stated)	Psoriasis (1)	Neutropenia and thrombocytopenia, probably as a result of reduced methotrexate clearance; folinic acid given, but patient died	7
Other regimen				
Intravenous 50 mg weekly	Phenoxymethylpenicillin 250 mg on alternate days	Dermatomyositis (also treated with prednisone; and prostatic cancer treated with diethylstilbestrol (stilboestrol); also treated with furosemide)	Methotrexate toxicity within week of starting phenoxymethylpenicillin; treated with folinic acid and fluid replacement (and nafcillin and tobramycin)	9

Mechanism

It is thought that weak acids such as the penicillins can possibly successfully compete with methotrexate in the kidney tubules for excretion so that the methotrexate is retained, thereby increasing its effects and its toxicity.² However, this was not demonstrated in a study with flucloxacillin,³ and the mechanism has been disputed.⁴

Importance and management

Information seems to be limited to the reports given here, which would seem to indicate that serious interactions between methotrexate and penicillins are uncommon. It is not known why only a few patients have been affected and what other factors may have contributed, but the problem does not seem to be confined to patients receiving high-dose methotrexate. There is not enough evidence to forbid concurrent use (although some do advise against it²), but close monitoring is obviously advisable. One published recommendation is to carry out twice-weekly platelet and white cell counts for 2 weeks initially, with the measurement of methotrexate levels if toxicity is suspected. Folinic acid (leucovorin) rescue should be available.⁶ For the general guidelines given by the CSM in the UK on the use of methotrexate see *Importance and management* in 'Methotrexate + NSAIDs', p.649.

Methotrexate + Antibacterials; Pristinamycin

An isolated report describes severe methotrexate toxicity when a patient was also given pristinamycin.

Clinical evidence

A 13-year-old boy with acute lymphoblastic leukaemia had a relapse and began a series of regimens with high-dose methotrexate in combination with other drugs, including dexamethasone, mercaptopurine, vincristine, cytarabine and asparaginase, tioguanine and ifosfamide. During a late cycle when he was also taking pristinamycin 2 g daily for a staphylococcal infection, the clearance of methotrexate was markedly decreased (half-life prolonged from 6 to 203 hours). He developed severe methotrexate toxicity (oral mucositis, anusitis, balanitis, neutropenia and thrombocytopenia) and was given folinic acid rescue and haemodialysis.¹

Mechanism

Not understood, but on the basis of experimental evidence the authors of the report excluded the possibilities of kidney impairment or reduction by the pristinamycin of liver metabolism.¹

Importance and management

This appears to be the first and only report of an interaction between methotrexate and pristinamycin. Its general importance is unknown but the authors strongly advise the avoidance of pristinamycin in patients taking methotrexate.¹

Methotrexate + Antibacterials; Tetracyclines

Two case reports describe the development of methotrexate toxicity in patients also given tetracycline or doxycycline.

Clinical evidence, mechanism, importance and management

A man being successfully and uneventfully treated for psoriasis with methotrexate 25 mg weekly was also given **tetracycline** 500 mg four times daily for a mycoplasmal infection. Within 5 days he developed recurrent fever, ulcerative stomatitis and diarrhoea. His white cell count fell to 1000 and his platelet count to 30 000 (units not stated, previous counts not given), all signs of methotrexate toxicity. The problem resolved when the methotrexate was withdrawn, but the psoriasis returned.¹ A 17-year-old girl with osteosarcoma of the femur was given **doxycycline** 100 mg every 12 hours for an abscess in her left eye at the same time as her eleventh cycle of high-dose methotrexate with folinic acid rescue. Elevated plasma methotrexate levels were observed and she developed haematological toxicity and severe vomiting, requiring antiemetics, continued folinic acid, a prolonged stay in hospital and postponement of her next dose of methotrexate. **Doxycycline** had not been taken during the first 10 cycles of methotrexate and the pharmacokinetic changes and symptoms seen in the eleventh cycle were attributed to the concurrent use of **doxycycline**.² This interaction has also been observed in *mice*,³ but not *rabbits*.⁴ Displacement of the methotrexate from its binding sites may be part of the explanation. There appears to be the only two clinical reports of this interaction on record. Concurrent use need not be avoided, but it should be well monitored.

Methotrexate + Antibacterials; Vancomycin

Delayed excretion and toxicity was seen when high-dose methotrexate was given to two patients recently treated with vancomycin. No significant interaction was found in eight other patients.

Clinical evidence, mechanism, importance and management

Two patients treated with a chemotherapy regimen containing high-dose methotrexate, cisplatin, doxorubicin and ifosfamide had delayed methotrexate excretion and methotrexate toxicity during a cycle soon after they had received vancomycin. Methotrexate levels took 170 to 231 hours to fall to 200 micromol/mL, and toxicity (mucositis) occurred. Subclinical

renal impairment was found, which subsequently improved. In previous and subsequent cycles, where vancomycin was not given, serum methotrexate levels in both patients fell to 200 micromol/mL within 48 to 96 hours.¹ It was suggested that vancomycin caused subclinical nephrotoxicity, which resulted in delayed excretion of methotrexate, which is primarily renally excreted.¹

However, in another report of 8 patients who had received high-dose methotrexate following the use of vancomycin (all but one within 10 days) for previous neutropenia, there was no significant interaction in the absence of overt renal impairment. It was suggested that the difference in outcome may be due to slightly lower methotrexate doses and the fact that the drug regimen in the 8 patients did not include ifosfamide, which particularly in combination with cisplatin may cause cumulative renal tubular damage.²

Vancomycin is commonly used in oncology patients with febrile neutropenia, and this appears to be the first report of this interaction. The authors of this report¹ suggest that it would be prudent to measure glomerular filtration rate with an EDTA renal scan before giving high-dose methotrexate to patients recently treated with vancomycin, to allow modification of the methotrexate dose if necessary.¹ However, the authors of the second report disagree and suggest such monitoring cannot be supported by their findings.² Further study is needed.

Methotrexate + Antiepileptics

Enzyme-inducing antiepileptics appear to increase the clearance of methotrexate given as a 24-hour infusion, and their use is associated with lower efficacy of combination therapy for B-lineage leukaemia.

Clinical evidence, mechanism, importance and management

In a retrospective survey, long-term antiepileptic use (**phenytoin, phenobarbital, carbamazepine**, or a combination) was associated with worse event-free survival, and greater haematological relapse and CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leukaemia. Faster clearance of high-dose methotrexate given as a 24-hour infusion was found in those receiving these enzyme-inducing antiepileptics, but clearance of short 4 to 6-hour methotrexate infusions did not appear to be affected, neither was weekly low-dose methotrexate.¹ Further study is needed.

Note that reduced phenytoin and carbamazepine levels, but unaltered phenobarbital levels, have been reported in various case reports of patients receiving chemotherapy including methotrexate, see 'Table 14.1', (p.519).

Methotrexate + Ascorbic acid (Vitamin C)

A study in a single patient showed that the urinary excretion of methotrexate was not significantly changed by the concurrent use of large amounts of vitamin C.

Clinical evidence, mechanism, importance and management

Vitamin C 1 g three times daily was found to have no effect on the urinary excretion of methotrexate 45 mg given intravenously to a woman with breast cancer, despite the urine becoming more acidic at pH 5.9 (compare 'Methotrexate + Urinary alkalinisers', p.654). She was also receiving oral cyclophosphamide, propranolol, amitriptyline, perphenazine and prochlorperazine.¹ No special precautions appear to be necessary.

Methotrexate + Caffeine

Although caffeine may theoretically reduce the efficacy of methotrexate, the clinical significance of a high caffeine intake is unclear.

Clinical evidence

A study in 39 patients who had recently started treatment with methotrexate 7.5 mg weekly found that patients with a self reported high caffeine intake (more than 180 mg caffeine per day, 13 patients) had less relief in their symptoms of rheumatoid arthritis, such as swollen joints and joint pain, and smaller reductions from baseline in their erythrocyte sedimentation rate (ESR), a marker for inflammation, than patients with a low caffeine intake (less than 120 mg caffeine per day, 13 patients).¹ A survey of 91 patients taking methotrexate 5 to 15 mg weekly for rheumatoid arthritis found that those who were regular coffee drinkers (more than 7 cups a week) had a higher rate of methotrexate discontinuation (due to treatment failure in 80% of cases).²

In contrast, an analysis of data in 264 patients taking long-term methotrexate for rheumatoid arthritis found that the consumption of caffeinated beverages did not appear to affect the efficacy of methotrexate for rheumatoid arthritis in either low, moderate or high consumers of caffeinated drinks. The average dose of methotrexate was 16 mg weekly and the average intake of caffeine from caffeinated drinks was 212 mg daily. No difference in inflammatory markers or worsening of rheumatoid arthritis was found between the low-caffeine intake group and the high-caffeine intake group.³ A survey in 64 patients taking methotrexate (mean dose of 13 mg weekly) for psoriasis and psoriatic arthritis found no effect on the efficacy or dosage requirements of methotrexate between low caffeine intake (less than 120 mg daily) and high caffeine intake (more than 180 mg daily).⁴

Mechanism

It is not known exactly how methotrexate produces its effects in rheumatoid arthritis, but one theory is that it possibly increases levels of adenosine by blocking a step in purine biosynthesis, leading to accumulation of adenosine, which results in anti-inflammatory effects.¹ It also inhibits the enzyme 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase, raising levels of AICAR, which in turn increases adenosine levels. It may also contribute to the phosphorylation of adenosine nucleotides creating an accumulation of adenosine in tissues.^{1,3} Caffeine is an adenosine receptor antagonist and therefore could reverse the effects of methotrexate.

Importance and management

There is limited information available regarding a potential interaction between caffeine consumption and methotrexate. The data collection results and patient survey seem to indicate that caffeine intake is not an issue, even with a high intake, although one study and another survey did find a reduced efficacy in those with a higher caffeine intake. However, these results, particularly the surveys, were limited by a number of factors, including subjective reporting of caffeine consumption, lack of caffeine blood levels, and uncontrolled ingestion of both drugs. One UK manufacturer of intravenous methotrexate (licensed for rheumatoid arthritis) recommends avoiding the excessive consumption of caffeine and theophylline-containing drinks.⁵ There do not appear to be any case reports or studies indicating treatment failure with a high caffeine intake in patients receiving chemotherapy with high-dose methotrexate. More study is needed but bear in mind that a high caffeine intake may be a factor in a reduced benefit from methotrexate given for psoriasis or rheumatoid arthritis.

Methotrexate + Chloroquine or Hydroxychloroquine

Chloroquine caused a moderate reduction in the AUC of methotrexate in one study. Conversely, hydroxychloroquine caused a minor increase in the AUC of methotrexate in another study.

Clinical evidence, mechanism, importance and management

Eleven patients with rheumatoid arthritis taking methotrexate 15 mg weekly were studied after they took a single dose of methotrexate alone and after they took methotrexate with chloroquine 250 mg. The chloroquine reduced the maximum plasma levels of methotrexate by 20% and its AUC by 28%. It is suggested that this occurs because the absorption of the methotrexate from the gut is reduced in some way.¹ These reductions are only modest, but they may reduce both the toxicity and the efficacy of the methotrexate: the clinical importance of this interaction awaits assessment.

In contrast, in a randomised crossover study in 10 healthy subjects, hydroxychloroquine 200 mg *increased* the AUC of methotrexate 15 mg by 52%, while still slightly decreasing the maximum methotrexate level (by 17%).² The authors considered that the increased AUC could explain the increased efficacy of the combination in rheumatoid arthritis, while the decreased maximum level could explain the reduction in acute liver toxicity.² Further study is needed.

Methotrexate + Cisplatin

The risk of methotrexate toxicity appears to be markedly increased by the previous use of cisplatin. Methotrexate may inhibit the clearance of cisplatin.

Clinical evidence, mechanism, importance and management

Six out of 106 patients developed clinical signs of methotrexate toxicity and died 6 to 13 days after receiving standard doses of methotrexate (20 to 50 mg/m²) in the absence of signs of renal impairment, and despite having previously been given methotrexate without serious toxicity. On this occasion all had previously been given cisplatin. Four of the patients were regarded as good-risk (i.e. methotrexate toxicity was not considered likely as they did not have renal or hepatic impairment, and their general condition was good).¹ A study in children and adolescents suggested that those who had received a cumulative dose of cisplatin greater than 360 mg/m² had delayed methotrexate clearance and a greater risk of methotrexate toxicity.² Similarly, a further report by the same authors, in 14 patients receiving high-dose methotrexate,³ indicated that prior treatment with one course of cisplatin sharply increased the serum levels of methotrexate, particularly if the cumulative cisplatin dose exceeded 400 mg/m².

The picture is not totally clear but it seems possible that the previous use of cisplatin causes kidney damage that may not necessarily be detectable with the usual creatinine clearance tests. The effect is to cause a marked reduction in the clearance of the methotrexate. The serum methotrexate levels of such patients should be closely monitored so that any delay in its clearance is detected early and folinic acid rescue therapy can be given.² This appears to prevent serious toxicity.^{1–3}

There is also a report that suggests that methotrexate inhibits the renal clearance of cisplatin. The renal clearance of platinum in 4 of 5 patients with non-small-cell lung cancer given cisplatin 50 mg/m² and methotrexate 40 mg/m² was reduced in the first 6 hours after administration (50% lower in the first 3 hours). Apart from a transient increase in serum urea nitrogen and creatinine in one patient, there was no sign of nephrotoxicity with concurrent use.⁴

Methotrexate + Colestyramine

The serum methotrexate levels of three patients given methotrexate by infusion were markedly reduced by colestyramine.

Clinical evidence

An 11-year-old girl with osteosarcoma who developed colitis when treated with high-dose intravenous methotrexate, was subsequently given colestyramine 2 g every 6 hours from 6 to 48 hours after the methotrexate. Serum methotrexate levels at 24 hours were approximately halved. A marked fall in serum methotrexate levels was seen in another patient similarly treated.¹ Colestyramine similarly reduced methotrexate levels in cases of toxicity in another two patients.^{2,3}

Mechanism

Methotrexate undergoes enterohepatic recirculation, that is to say it is excreted into the gut in the bile and re-absorbed further along the gut. If colestyramine is given orally, it can bind strongly to the methotrexate in the gut, thereby preventing its reabsorption and, as a result, the serum levels fall.^{1,4}

Importance and management

The documentation seems to be limited. In the cases cited^{1–3} the colestyramine was deliberately used to reduce serum methotrexate levels. However, in some circumstances it might represent an unwanted interaction. Since methotrexate is excreted into the gut in the bile, separating the oral dosages of the colestyramine and methotrexate may not necessarily prevent their coming into contact and interacting together. Monitor concurrent use.

Methotrexate + Corticosteroids

Methotrexate clearance may be modestly reduced by the long-term use of prednisolone, but methotrexate does not alter prednisolone pharmacokinetics. Limited evidence suggests methotrexate may alter prednisone levels. Dexamethasone may increase the acute hepatotoxicity of high-dose methotrexate.

Clinical evidence, mechanism, importance and management

There is some evidence that **prednisolone** may reduce the clearance of methotrexate: patients taking long-term **prednisolone** 15 mg daily had a 20% lower clearance of intramuscular methotrexate 10 mg and a 30% higher AUC than patients given **prednisolone** 15 mg daily for just 4 days before the methotrexate, or those not given corticosteroids.¹ In another study, methotrexate had no effect on **prednisolone** pharmacokinetics in 7 patients, or **methylprednisolone** pharmacokinetics in one patient.² Preliminary findings of another study suggested that methotrexate may increase plasma methylprednisone levels in response to a dose of **prednisone**; in 2 of 4 patients given methotrexate, plasma methylprednisone levels remained stable despite a decrease in the **prednisone** dose.³ These findings require confirmation. Their clinical relevance is uncertain.

Dexamethasone may increase the acute hepatotoxicity of high-dose methotrexate. A retrospective comparison in children with brain tumours given methotrexate alone (24 patients), or with **dexamethasone** (33 patients), found that no serious brain oedema occurred in either of the groups

and there were no differences in bone marrow toxicity or mucositis, but liver enzymes were significantly higher in the **dexamethasone** group indicating liver toxicity. AST levels were 76 units/L compared with 19 units/L, and ALT levels were 140 units/L compared with 39 units/L. This effect was not due to differences in serum methotrexate levels.⁴ The authors recommend that **dexamethasone** should not be included in high-dose methotrexate protocols for children with brain tumours when they are not glucocorticoid dependent.⁴

Methotrexate + Diuretics

Some very limited evidence suggests that triamterene may possibly increase the bone marrow suppressive effects of methotrexate. It seems doubtful if thiazides interact adversely.

Clinical evidence, mechanism, importance and management

A 57 year-old woman who had been treated for several years with daily doses of diclofenac 150 mg, atenolol 50 mg and **triamterene** with **hydrochlorothiazide** 50/25 mg, for rheumatoid arthritis and hypertension, additionally started treatment with methotrexate 5 mg weekly. After 2 months she was admitted to hospital with pancytopenia, extensive mucosal ulceration and renal impairment. The authors point out that **triamterene** is structurally similar to folate and has anti-folate activity, which may therefore have been additive with the effects of methotrexate,¹ but the diclofenac may also have contributed (see 'Methotrexate + NSAIDs', p.649). In 1998, the manufacturer noted there were two other reports of pancytopenia in patients taking methotrexate and **triamterene**, but again the patients were also taking NSAIDs.²

A study in 9 patients found that neither **furosemide** nor **hydroflumethiazide** had any effect on the clearance of methotrexate in the urine.³ However, a study in women with breast cancer, treated with methotrexate, **cyclophosphamide** and **fluorouracil** found that the concurrent use of a **thiazide diuretic** appeared to increase the myelosuppressant effects, but it is not clear which of the antineoplastics might have been affected.⁴

Methotrexate + Fluorouracil

Two patients taking low-dose methotrexate had a toxic skin reaction when they started to use a cream containing fluorouracil. The activity of systemic treatment with methotrexate and fluorouracil are said to be dependent on the order in which the two drugs are given, but this does not appear to be important in the commonly used CMF regimen.

Clinical evidence, mechanism, importance and management

(a) Topical fluorouracil

Two patients with rheumatoid arthritis treated with low-dose methotrexate 7.5 to 12.5 mg weekly for 6 to 14 months were given 2% fluorouracil cream for actinic keratosis. Within 2 to 3 days both patients developed erythema, blister formation and necrosis. The cream was stopped and the lesions healed over the next 2 to 3 weeks.¹ It would seem that concurrent use should be avoided.

(b) Systemic fluorouracil

In vitro and *animal* data indicate that methotrexate and fluorouracil can be mutually antagonistic under certain conditions.^{2–4} Other studies indicate that the sequence (methotrexate first)^{5,6} is important for additive or synergistic activity. However, the combination of cyclophosphamide, methotrexate and fluorouracil (CMF) has been the most commonly used adjuvant therapy in breast cancer, and the sequence of administration is said not to be important.⁷

Methotrexate + Folinates

Folic acid or folinic acid are sometimes added to low-dose methotrexate treatment for rheumatoid arthritis or psoriasis to reduce adverse effects. Folinic acid is frequently used as an antidote to high-dose methotrexate in cancer therapy. Patients taking methotrexate should avoid the inadvertent use of folates in multivitamin preparations.

Clinical evidence, mechanism, importance and management

Methotrexate acts as a folic acid antagonist by reversibly binding to the enzyme dihydrofolate reductase so blocking the conversion of folic acid to tetrahydrofolate. Therefore folic acid and folinic acid (a derivative of tetrahydrofolate) would be expected to interfere with both the toxic and therapeutic effects of methotrexate.

Folic acid or folinic acid are commonly used to reduce the adverse effects of low-dose methotrexate used for rheumatoid arthritis and psoriasis, although the optimum doses and schedules to maximise tolerability and efficacy remain to be determined.

Similarly, folinic acid is used in conjunction with high-dose methotrexate for various cancers to minimise toxicity, when it is typically started 24 hours after methotrexate administration (folinic acid or 'leucovorin' rescue). In this setting, the antidote effect is clearly influenced by the dose of folinate in relation to the dose of methotrexate, and the timing of folinate administration in relation to methotrexate administration.

Patients taking methotrexate for any indication should avoid the inadvertent or unsupervised use of folates, which are commonly found in multivitamin preparations.

Methotrexate + Food

The absorption of low-dose oral methotrexate appears not to be significantly affected by food.

Clinical evidence, mechanism, importance and management

In 10 children with lymphoblastic leukaemia the peak serum levels of a 15-mg/m² oral dose of methotrexate (measured at 1.5 hours) were reduced by about 40% when the methotrexate was taken with a **milky meal** (milk, cornflakes, sugar, white bread and butter). The AUC_{0–4} was reduced by about 25%. A smaller reduction in methotrexate absorption was seen when it was taken after a **'citrus meal'** (orange juice, fresh orange, white bread, butter and jam).¹ However, a 4-hour study is too short to assess the extent of the total absorption. Another study in 16 other children given methotrexate 8 to 22.7 mg/m² found that the peak levels and AUC were not significantly affected if methotrexate was given before a meal.² Yet another study in 12 healthy subjects found that a **high fat-content breakfast** delayed the absorption of methotrexate 7.5 mg orally by about 30 minutes

but the extent of the absorption was unchanged.³ It would therefore appear that methotrexate may be taken without regard to meals.

Methotrexate + Miscellaneous

Animal studies suggested that the toxicity of methotrexate might be increased by the use of chloramphenicol, aminosalicic acid, sodium salicylate, sulfamethoxypyridazine, tetracycline or tolbutamide, but confirmation of this in man has only been seen with the salicylates, sulphonamides and possibly tetracycline.

Clinical evidence, mechanism, importance and management

Some lists, reviews and books on interactions say that **chloramphenicol**, aminosalicic acid, sodium salicylate, **sulfamethoxypyridazine**, tetracycline or **tolbutamide** interact with methotrexate, apparently based largely on the preliminary findings of a study in which male *mice* were treated for 5 days with each of 4 doses of methotrexate (1.53 to 12.25 mg/kg intravenously) and immediately afterwards with non-toxic intraperitoneal doses of the drugs listed. These drugs were said to decrease the lethal dose and/or decrease the survival time of the *mice*.¹ That is to say, the toxicity of the methotrexate was increased. The reasons are not understood, but it is suggested that displacement of the methotrexate from its plasma protein binding sites could result in a rise in the levels of unbound and active methotrexate, and in the case of sodium salicylate to a decrease in renal clearance.

These *animal* studies were done in 1968. Since then the clinical importance of the interaction with salicylates has been confirmed (see 'Methotrexate + NSAIDs', p.649); there are a few cases involving 'sulfonamides', (p.643)); and there are two isolated case report of an interaction with 'tetracyclines', (p.645), but there appears to be no direct clinical evidence of interactions between methotrexate and **chloramphenicol** or **tolbutamide**. The results of *animal* experiments cannot be applied directly and uncritically to man and it now seems probable that some of these suggested or alleged interactions are more theoretical than real.

1. Dixon RL. The interaction between various drugs and methotrexate. *Toxicol Appl Pharmacol* (1968) 12, 308.

Methotrexate + Nitrous oxide

Methotrexate-induced stomatitis and other toxic effects may be increased by the use of nitrous oxide.

Clinical evidence, mechanism, importance and management

A study in which intravenous methotrexate, cyclophosphamide and fluorouracil (CMF) were used within 36 hours of mastectomy suggested that stomatitis may be caused by a toxic interaction between methotrexate and nitrous oxide used during anaesthesia. Stomatitis was much more common in those receiving CMF within 6 hours of surgery.^{1–3} A possible reason is that the effects of methotrexate on tetrahydrofolate metabolism are increased by nitrous oxide, and this has been confirmed in *animals*.⁴ It was found that the incidence of stomatitis, severe leucopenia, thrombocytopenia, and of severe systemic and local infections could be reduced by giving calcium folinate (leucovorin) and intravenous hydration.^{2,3} Alternatively, the use of nitrous oxide shortly before methotrexate administration should be avoided.⁴

4. Ermens AAM, Schoester M, Spijkers LJM, Lindemans J, Abels J. Toxicity of methotrexate in rats preexposed to nitrous oxide. *Cancer Res* (1989) 49, 6337–41.

Methotrexate + NSAIDs

Increased methotrexate toxicity, sometimes life-threatening, has been seen in a few patients also taking NSAIDs whereas other patients have been treated uneventfully. The pharmacokinetics of methotrexate can also be changed by some NSAIDs (aspirin, choline magnesium trisalicylate, etodolac, etoricoxib, ibuprofen, metamizole sodium, naproxen, rofecoxib, sodium salicylate, tolmetin). The development of toxicity may be dose related and the risk appears to be lowest in those taking low-dose methotrexate for psoriasis or rheumatoid arthritis who have normal renal function.

Clinical evidence

(a) Aminophenazone

Megaloblastic pancytopenia occurred in a woman with rheumatoid arthritis who took methotrexate 15 mg weekly with aminophenazone 1 to 1.5 g daily.¹

(b) Aspirin and other salicylates

A study in 15 patients with rheumatoid arthritis given a single 10-mg bolus dose of methotrexate, either with or without aspirin 975 mg four times daily, found that the methotrexate clearance was reduced by aspirin (systemic clearance about 16%, renal clearance of unbound methotrexate about 30%). Also the unbound fraction of methotrexate was higher during aspirin use. Despite these changes no acute toxicity was seen.² Another study found that aspirin did not affect the pharmacokinetics of methotrexate.³ Yet another study found that, although aspirin did not alter the pharmacokinetics of methotrexate, it did increase the AUC of the metabolite 7-hydroxymethotrexate.⁴

A study in 4 patients found that the renal clearance of methotrexate was reduced by 35% by an infusion of **sodium salicylate** (2 g initially, then 33 mg/minute).⁵ A further study found that **choline magnesium trisalicylate** reduced methotrexate clearance by 24 to 41%, and increased the unbound fraction by 28%, when compared with paracetamol (acetaminophen).⁶

Lethal pancytopenia in 2 patients given methotrexate and aspirin prompted a retrospective survey of the records of other patients given intra-arterial infusions of methotrexate 50 mg daily for 10 days, for epidermoid carcinoma of the oral cavity. Six out of 7 who developed rapid and serious pancytopenia were found to have taken aspirin or other salicylates.⁷ There are other case reports^{8,9} of methotrexate toxicity in patients taking salicylates but whether a causal relationship exists is uncertain. It has been suggested that pneumonitis in patients receiving low-dose methotrexate may have resulted from the concurrent use of aspirin 4 to 5 g daily.¹⁰

See also the report about the comparative use of aspirin and other NSAIDs in section (w), below, on NSAIDs in general.

(c) Azapropazone

A woman who had been taking methotrexate 25 mg weekly for 4 years for psoriasis had acute toxicity (oral and genital ulceration, bone marrow failure) shortly after starting to take azapropazone (reducing from a dose of 2.4 g on the first day, 1.8 g on the second day to 1.2 g daily for a week). She was also taking aspirin 300 mg daily.^{11,12}

(d) Bromfenac

In a short-term study, 10 patients taking methotrexate weekly were given bromfenac 50 mg three times daily for 6 days. No significant changes were seen in either the pharmacokinetics of bromfenac or methotrexate. However, the AUC of the major metabolite of methotrexate, 7-hydroxymethotrexate, was increased by 30% and its renal clearance was reduced by 16%. Eight of the patients had mild to moderate adverse effects and one patient had to withdraw because of moderate hypertension. No patient had any clinically important abnormal laboratory test results.¹³ Note that systemic bromfenac has been withdrawn from the market because of reports of hepatic failure.

(e) Celecoxib

Fourteen female patients with rheumatoid arthritis taking methotrexate 5 to 20 mg weekly for at least 3 months were also given celecoxib 200 mg or a placebo twice daily for a week. It was found that the maximum serum levels of the methotrexate, its AUC, renal clearance, and other pharmacok-

inetic parameters were unchanged by the celecoxib.¹⁴ The authors note that, in clinical studies, celecoxib was taken in combination with low-dose methotrexate for up to 12 weeks by over 450 patients, and the incidence of adverse effects was similar to that in patients taking methotrexate with placebo.¹⁴

(f) *Diclofenac*

A study found that diclofenac 100 mg daily did not affect the pharmacokinetics of methotrexate;³ however, 5 patients taking low-dose methotrexate 7.5 to 12.5 mg weekly for psoriasis or rheumatoid arthritis developed serious/fatal neutropenias. These cases probably involved other drug interactions, but diclofenac may have been an additional factor in two of them.¹⁵ Other cases involving diclofenac are mentioned in the sections on *indometacin* (k) and *ketoprofen* (l).

(g) *Etodolac*

A pharmacokinetic study in patients with rheumatoid arthritis found that etodolac 600 mg daily did not affect the AUC of methotrexate, but the duration of exposure was lengthened (mean residence time increased from 8.5 to 11.4 hours). No clinical toxicity was seen.¹⁶

(h) *Etoricoxib*

A study in patients taking methotrexate 7.5 to 20 mg weekly for rheumatoid arthritis found that the addition of etoricoxib 60, 90 or 120 mg daily had no effect on the methotrexate AUC or on its renal clearance. However, another similar study found that etoricoxib 120 mg daily increased the methotrexate AUC by 28% and reduced its clearance by 13%.¹⁷

(i) *Flurbiprofen*

A study in 6 patients taking low doses of methotrexate 10 to 25 mg weekly found no important changes in methotrexate levels when they were given flurbiprofen 100 mg three times daily.¹⁸ In another study of 10 patients with rheumatoid arthritis taking methotrexate 7.5 to 17.5 mg weekly and flurbiprofen 3 mg/kg daily, methotrexate oral and renal clearance were similarly unaffected by flurbiprofen.¹⁹

In contrast to these pharmacokinetic studies, a case report describes an elderly woman who had been taking methotrexate 2.5 mg three times a week for 3 years for rheumatoid arthritis, who developed haematemesis, neutropenia and thrombocytopenia (diagnosed as methotrexate toxicity) within 1 to 2 weeks of starting to take flurbiprofen 100 mg daily.²⁰

(j) *Ibuprofen*

A study in 7 patients found that the clearance of oral methotrexate 7.5 to 15 mg was halved by ibuprofen 40 mg/kg per day, when compared with paracetamol (acetaminophen).²¹ In a related study the clearance of methotrexate was reduced by 40% by ibuprofen.⁶ Another study in 6 patients with rheumatoid arthritis taking methotrexate 10 to 25 mg weekly found that ibuprofen 800 mg three times daily had no effect on the pharmacokinetics of methotrexate.¹⁸ Similar findings have been reported by other workers.³ A patient taking methotrexate who was given ibuprofen required prolonged folinic acid rescue because the clearance of methotrexate had fallen by two-thirds.²² Another patient receiving high-dose methotrexate (7.5 g/m²) had severe methotrexate-induced nephrotoxicity and delayed excretion of methotrexate while taking ibuprofen 400 mg every 4 hours.²³ A report attributes pancytopenia and resulting pneumocystis pneumonia in a 16-year-old patient taking methotrexate 5 to 10 mg weekly to the concurrent use of ibuprofen 600 mg twice daily (and also 1 mg prednisolone daily).²⁴

(k) *Indometacin*

The AUC of child taking methotrexate 7.5 mg/m² weekly for 9 months was increased by 140% when indometacin and **aspirin** were also given.²⁵ Another study found that indometacin did not affect the pharmacokinetics of methotrexate.³

Two patients given sequential intermediate-dose methotrexate and fluorouracil who were also taking indometacin 75 to 100 mg daily died from acute drug toxicity, which the authors of the report attributed to indometacin-associated renal failure.²⁶ Another case of acute renal failure has been described,²⁷ but there were no cases of toxicity in 4 other patients taking methotrexate with either paracetamol (acetaminophen) or indometacin.⁹ An elderly woman taking indometacin 50 mg daily rectally and **diclofenac** 100 mg daily intravenously died after being given single 10-mg intramuscular dose of methotrexate.²⁸

(l) *Ketoprofen*

In a study in 10 patients with rheumatoid arthritis taking methotrexate 7.5 to 17.5 mg weekly and ketoprofen 3 mg/kg daily, the methotrexate

oral and renal clearance and the fraction of methotrexate unbound were unaffected by ketoprofen.¹⁹ Similarly, in another study in 18 patients with rheumatoid arthritis who were given intravenous methotrexate 15 mg weekly, ketoprofen had no significant effect on the AUC, half-life, or clearance of methotrexate and its major metabolite, 7-hydroxymethotrexate.²⁹ However, a retrospective study of 118 cycles of *high-dose* methotrexate treatment (800 to 8300 mg/m²; mean 3200 mg/m²) in 36 patients found that 4 out of the 9 patients who developed severe methotrexate toxicity had also taken ketoprofen 150 to 200 mg daily for 2 to 15 days. Three of them died. A marked and prolonged rise in serum methotrexate levels was observed. Another patient who had methotrexate toxicity had also been given **diclofenac** 150 mg (in one day).³⁰ The authors of this report state that ketoprofen should not be given at the same time as high-dose methotrexate, but it may be safe to give it 12 to 24 hours after the methotrexate because 50% of the methotrexate is excreted by the kidneys within 6 to 12 hours. This was tried in two patients without adverse effects.³⁰

(m) *Lumiracoxib*

In a double-blind, placebo-controlled study in patients with rheumatoid arthritis given low-dose methotrexate 7.5 to 15 mg weekly, lumiracoxib 400 mg daily for 7 days had no significant effects on the pharmacokinetics of methotrexate.³¹

(n) *Meloxicam*

Thirteen patients with rheumatoid arthritis were given intravenous methotrexate 15 mg before and after taking meloxicam 15 mg daily for a week. The pharmacokinetics of the methotrexate were unaffected by the meloxicam and no increase in toxicity was seen.³²

(o) *Metamizole sodium (Dipyrone)*

A study in a patient with osteosarcoma found that metamizole sodium 4 g daily more than doubled the methotrexate AUC during the first cycle of high-dose methotrexate treatment.³³

(p) *Naproxen*

Naproxen had no significant effect on the AUC, half-life, or clearance of methotrexate and its major metabolite 7-hydroxymethotrexate in 18 patients with rheumatoid arthritis given intravenous methotrexate 15 mg weekly.²⁹ Other studies have found that naproxen did not affect the pharmacokinetics of methotrexate.³ In a study in 27 patients with rheumatoid arthritis who had taken oral methotrexate 7.5 to 15 mg weekly for at least 3 months, the concurrent use of naproxen 600 mg twice daily with lansoprazole did not affect the pharmacokinetics of methotrexate or 7-hydroxymethotrexate.³⁴ Another study in patients with rheumatoid arthritis with normal renal function found that no toxicity was caused when naproxen 500 mg twice daily was given with methotrexate 15 mg given orally or intravenously, nor was the methotrexate clearance altered.³⁵

In contrast, a study found that the clearance of methotrexate was decreased by 22% by naproxen.^{6,21} In addition, two children taking methotrexate for 1 and 2 years had increases in the AUC of methotrexate of 22% and 71% when given naproxen with **aspirin** or **indometacin**, respectively.²⁵ A further study in 9 children taking methotrexate 0.22 to 1.02 mg/kg per week found that the clearance was increased in 4 children by more than 30% when they were given naproxen 14.6 to 18.8 mg/kg daily. There was also a 30% or more change in the pharmacokinetics of naproxen in 6 of the patients, but as both increases and decreases in clearance occurred, the significance of these findings are uncertain.³⁶ A woman died of gross methotrexate toxicity apparently exacerbated by the concurrent use of naproxen,³⁷ and a report attributes pneumonitis in a patient taking methotrexate 7.5 to 10 mg weekly to the concurrent use of naproxen (initially 1 g then 500 mg) daily.³⁸

(q) *Parecoxib*

Studies in patients with rheumatoid arthritis found that oral valdecoxib 40 mg twice daily had no clinically significant effect on the plasma levels of methotrexate given weekly by the intramuscular route [dose not stated].³⁹ Even so the manufacturers suggest that careful monitoring should be considered, probably because of the problems seen with other NSAIDs. Note that valdecoxib is the main metabolite of parecoxib.

(r) *Phenylbutazone*

Two patients taking methotrexate for psoriasis developed methotrexate toxicity and skin ulceration shortly after starting to take phenylbutazone 200 to 600 mg daily. One of them died from septicemia following bone marrow depression.⁴⁰

(s) Piroxicam

No effect on the pharmacokinetics of either free or bound methotrexate was seen in 20 patients with rheumatoid arthritis taking methotrexate 10 mg weekly when they were given piroxicam 20 mg daily for at least 15 days.⁴¹ In another study in 10 patients with rheumatoid arthritis taking methotrexate 7.5 to 17.5 mg weekly, methotrexate oral and renal clearance were similarly unaffected by piroxicam 20 mg daily.¹⁹

(t) Rofecoxib

Rofecoxib 12.5 to 50 mg once daily had no effect on the AUC and renal clearance of methotrexate or 7-hydroxymethotrexate in 19 patients taking methotrexate 7.5 to 20 mg once weekly.⁴² However, the authors note that in previous evaluations (data on file), higher than therapeutic doses of rofecoxib (75 mg and 250 mg) were associated with a 23% and 40% increase in the AUC of methotrexate, and an 11% and 40% decrease in its renal clearance, respectively.⁴²

(u) Sulindac

Sulindac (mean dose 400 mg daily) had no effect on the pharmacokinetics of a single 10-mg/m² intravenous dose of methotrexate, but it slightly increased the AUC of the 7-hydroxymethotrexate metabolite.⁴

(v) Tolmetin

Three children taking methotrexate for between 6 months and 1 year had increases in the AUC of methotrexate of 42% when given tolmetin, and of 18% and 25% when given tolmetin with aspirin.²⁵

(w) NSAIDs in general

In a study of 34 patients with rheumatoid arthritis taking methotrexate 5 or 10 mg/m² (to nearest 2.5 mg) weekly, 12 patients also took aspirin (average 4.5 g daily) and 22 took other NSAIDs. Twenty-one of the 34 also took prednisone. Toxicity, sometimes serious (5 patients withdrawn), was common, but no clinical differences between aspirin or other NSAIDs with respect to this toxicity was seen during 12 months of concurrent use.⁴³

A preliminary report of a study in 87 patients receiving long-term treatment with methotrexate (mean weekly dose 8.19 mg), most of whom were also taking unspecified NSAIDs, found that the majority (72%) experienced no untoward effects and in the rest adverse effects were only relatively mild.⁴⁴ The concurrent use of methotrexate and NSAIDs in more than 450 patients with psoriatic arthritis or rheumatoid arthritis was said to be without clinical interaction problems.⁴⁵

A literature review of interactions between methotrexate and NSAIDs found that low-dose methotrexate pharmacokinetics were unaltered by NSAIDs, with the exception of salicylates.⁴⁶

In a review of the records of 315 patients with rheumatoid arthritis taking low-dose methotrexate, 13 patients had low platelet counts. The thrombocytopenia was believed to have resulted from an interaction with an NSAID or in some patients a multiple drug interaction. If multiple drug interactions were not involved, the authors found that if the NSAID was given on a separate day, or dosages spaced according to the NSAID half-life, therapy could be re-introduced avoiding the problems of thrombocytopenia.⁴⁷

Mechanism

Methotrexate is largely cleared unchanged from the body by renal excretion. The NSAIDs as a group inhibit the synthesis of the prostaglandins (PGE₂) resulting in a fall in renal perfusion, which could lead to a rise in serum methotrexate levels, accompanied by increased toxicity. In addition, salicylates competitively inhibit the tubular secretion of methotrexate, which would further reduce its clearance.⁵ NSAIDs can also cause renal impairment, which would allow the methotrexate to accumulate. The pyrazolone derivatives and related drugs (e.g. azapropazone, metamizole sodium, phenylbutazone, aminophenazone), in particular, can cause bone marrow depression, which could be additive with that of methotrexate. Protein binding displacement of methotrexate or its metabolite (7-hydroxymethotrexate) have also been suggested as possible additional mechanisms.^{48,49} There is also some evidence that 7-hydroxymethotrexate is cleared more slowly in the presence of NSAIDs.⁴

Importance and management

The evidence presented here clearly shows that a few patients taking methotrexate have developed very serious toxicity, apparently due to the concurrent use of NSAIDs whereas many other patients have experienced no

problems at all. There is also other evidence that the pharmacokinetics of the methotrexate are changed (in particular reduced clearance) by some NSAIDs (aspirin, choline magnesium trisalicylate, etodolac, ibuprofen, metamizole sodium, rofecoxib (at higher than therapeutic doses), sodium salicylate, tolmetin), which might be expected to increase its toxicity.

The consensus of opinion seems to be that the risks are greatest with high-dose methotrexate (150 mg or more daily to treat neoplastic diseases) and in patients with impaired renal function, but less in those given low doses (5 to 25 mg weekly) for psoriasis or rheumatoid arthritis and with normal kidney function. The manufacturers of methotrexate and the CSM do not advise the avoidance of NSAIDs (except azapropazone and non-prescription aspirin and ibuprofen), even though their use is a recognised additional risk factor for toxicity. Instead their advice is that the methotrexate dosage should be well monitored, which implies that the precautions for methotrexate use should be stepped up. The advice of the CSM in the UK is that any patient given methotrexate alone should have a full blood count, renal and liver function tests before starting treatment. These should be repeated weekly until therapy is stabilised, and thereafter every 2 to 3 months. Patients should be told to report any sign or symptom suggestive of infection, particularly sore throat (which might possibly indicate that white cell counts have fallen) or dyspnoea or cough (suggestive of pulmonary toxicity).⁵⁰ Aminophenazone or metamizole sodium can cause agranulocytosis on their own (and they consequently have limited use) so their use with methotrexate should also be avoided.

Some of the NSAIDs cited here have not been reported to interact (celecoxib, lumiracoxib, meloxicam, piroxicam), and information about some other NSAIDs seems to be lacking, but the same general precautions indicated above should be followed with all NSAIDs just to be on the safe side.

Methotrexate + Paracetamol (Acetaminophen)

Paracetamol appears not to interact with methotrexate.

Clinical evidence, mechanism, importance and management

A study in patients with rheumatoid arthritis found that the clearance of oral methotrexate 7.5 to 15 mg was unaffected by the concurrent use of paracetamol.¹ In a study of patients with psoriasis taking methotrexate in doses up to 25 mg weekly, no cases of toxicity occurred in 4 patients also taking paracetamol or indometacin.² In one study, methotrexate clearance was reduced by NSAIDs but not by paracetamol, which was included in the study as a control.³

Methotrexate + Probenecid

Probenecid markedly increases serum methotrexate levels (three to fourfold).

Clinical evidence

The concurrent use of oral or intravenous probenecid 500 mg to 1 g and methotrexate 200 mg/m² as an intravenous bolus resulted in serum methotrexate levels in 4 patients that were more than four times higher than in

4 others who had not been given probenecid (400 micrograms/L compared with 90 micrograms/L, measured 24-hours post-dose).¹

A three to fourfold increase in serum methotrexate levels at 24 hours was also seen in 4 patients given probenecid.² Pretreatment with probenecid (500 mg every 6 hours for 5 doses) doubled the serum methotrexate levels of another 4 patients.³ Severe and life-threatening pancytopenia occurred when a woman taking low-dose methotrexate 7.5 mg weekly for rheumatoid arthritis was given probenecid. She also had renal impairment, hyponatremia and was taking salsalate (a salicylic acid derivative).⁴

Mechanism

Probenecid inhibits the renal excretion of methotrexate in both *monkeys* and *rats*^{5,6} and this probably also happens in man. Changes in the protein binding of methotrexate may also have some part to play.⁷ The increased methotrexate levels increase the risk of serious bone marrow depression.

Importance and management

An established and clinically important interaction. A marked increase in both the therapeutic and toxic effects of methotrexate can occur, apparently even with low doses if other risk factors are present.⁴ Anticipate the need to reduce the dosage of the methotrexate and monitor the effects well if probenecid is used concurrently, or avoid the combination.

Methotrexate + Proton pump inhibitors

The excretion of methotrexate is reported to have been reduced in twelve patients given omeprazole and three patients given lansoprazole. However, similar elevations in methotrexate levels in another patient were independent of omeprazole use. One patient had myalgia and elevated 7-hydroxymethotrexate levels when given methotrexate with pantoprazole.

Clinical evidence

(a) Lansoprazole

In a study in 76 patients with solid tumours treated with high-dose methotrexate infusions (300 mg/m² to 12 g/m² over 1 to 24 hours), the clearance of methotrexate and its metabolite 7-hydroxymethotrexate was significantly decreased and plasma levels significantly increased in the 3 patients who were also given lansoprazole 30 mg daily.¹

(b) Omeprazole

In a study in 76 patients with solid tumours treated with high-dose methotrexate infusions (300 mg/m² to 12 g/m² over 1 to 24 hours), the clearance of methotrexate and its metabolite 7-hydroxymethotrexate was significantly decreased and the plasma levels significantly increased in the 10 patients who had also been given omeprazole 20 to 40 mg daily.¹ A man with Hodgkin's disease developed osteosarcoma and was treated with cyclophosphamide, bleomycin, dactinomycin and methotrexate, followed by folinic acid rescue. He was also taking senna, levothyroxine, omeprazole, baclofen, aciclovir, ferrous sulfate and docusate sodium. During the first cycle of treatment his serum methotrexate levels remained elevated for several days, and suspicion fell on the omeprazole, which was stopped. The patient's serum methotrexate levels then fell rapidly, and during the following three cycles the methotrexate pharmacokinetics were normal.² An 11-year-old boy with osteoblastic osteosarcoma was given high-dose methotrexate 15 g as a 4-hour infusion. He was also given omeprazole 20 mg twice daily (for about one week prior to methotrexate), megestrol acetate, sucralfate and folinic acid rescue. Methotrexate elimination was delayed and so further folinic acid was given. When later cycles of methotrexate were given, with ranitidine instead of omeprazole, the

elimination of methotrexate was normal. The elimination half-life of the initial phase after the first dose given with omeprazole was 65% longer, when compared with that of the second dose without omeprazole.³

In contrast to these findings, a case is reported in which a man with chondroblastic osteosarcoma, who had been taking omeprazole, was treated with high-dose methotrexate 20 g over 6 hours with hydration, urinary alkalisation and, after 24 hours, folinic acid rescue. The folinic acid dose was adjusted in response to elevated methotrexate levels and omeprazole was stopped. A second dose of methotrexate 2 weeks later, this time without omeprazole, resulted in similar elevated methotrexate levels. Thus the elevated methotrexate levels in this patient could not be attributed to co-administered omeprazole.⁴

(c) Pantoprazole

Severe generalised myalgia occurred in a man taking pantoprazole 20 mg daily after he received intramuscular methotrexate 15 mg weekly. The symptoms subsided and eventually disappeared when the pantoprazole was replaced with ranitidine. The symptoms reappeared in response to rechallenge with pantoprazole, and the AUC of 7-hydroxymethotrexate was found to be increased by about 70%, although the AUC of methotrexate was unchanged.⁵

Mechanism

Proton pump inhibitors may affect renal, and possibly hepatic, clearance of methotrexate by inhibition of methotrexate transporter proteins.^{1,6} It has been suggested that omeprazole may inhibit the activity of a hydrogen-ion dependent mechanism in the kidney, on which methotrexate depends for its excretion, so that its loss is diminished.² It has also been suggested that the situation with lansoprazole may be similar, but that pantoprazole may differ since at about the pH found in the renal tubules (pH 5), pantoprazole is more slowly activated than omeprazole.³ However, a case of an interaction with pantoprazole has also been reported.⁵

Importance and management

Information seems to be limited to these few reports and with the exception of one case report, they all found that proton pump inhibitors reduced the clearance of methotrexate. Any changes in methotrexate kinetics are important in terms of the potential for increased toxicity. Further study is required. The authors of one study in which the levels of methotrexate and its active metabolite were increased during the concurrent use of omeprazole or lansoprazole advise against concurrent use.¹ Further, the authors of one report recommend that if omeprazole is necessary for a patient about to receive methotrexate, then omeprazole should be discontinued 4 to 5 days before methotrexate administration.³ The situation with other proton pump inhibitors may be similar. Ranitidine was found to be a suitable alternative in two of the cases.^{3,5} Note that the risks would appear to be most significant with high-dose methotrexate, but the case report involving a 15 mg weekly dose of methotrexate introduces a note of caution in all patients.

Methotrexate + Retinoids

Although the concurrent use of methotrexate with etretinate can be successful, the incidence of severe liver toxicity appears to be considerably increased. The serum levels of methotrexate may be increased by etretinate.

Clinical evidence

A man was given a 48-hour infusion of methotrexate 10 mg every week, for chronic discoid psoriasis but when he was also given etretinate 30 mg

daily his serum methotrexate levels almost doubled. Concentrations at 12 and 24 hours during the infusion were 0.11 mmol/L, compared with 0.07 and 0.05 mmol/L before the etretinate.¹ A later study² in psoriatic patients found that those receiving etretinate had 38% higher maximum plasma levels of methotrexate, but no difference in clearance or elimination half-life (i.e. no methotrexate accumulation).

Severe toxic hepatitis has been reported in a number of cases when both etretinate and methotrexate were given.^{3–5} It may take several months to develop.³ In one clinic, signs of liver toxicity were seen in 2 out of 10 patients given both drugs, but there was no evidence of liver toxicity in 531 patients given methotrexate alone or in 110 patients given etretinate alone.³

Mechanism

Not understood. The increased incidence of toxic hepatitis may possibly be related to the increased maximum methotrexate plasma levels.

Importance and management

Although methotrexate and etretinate have been used together with success for psoriasis,^{6–8} the risk of severe drug-induced hepatitis seems to be very considerably increased. One author says that he has decided not to use this combination in future.³ Concurrent use should clearly be undertaken with great care. Etretinate has been largely superseded by acitretin (a metabolite of etretinate, which has a shorter half-life) but some consider that the combination of methotrexate and acitretin should also be avoided.⁹

Methotrexate + Sulfasalazine

The pharmacokinetics of methotrexate are unaffected by sulfasalazine. Clinical studies in patients with rheumatoid arthritis suggest that the combination of methotrexate and sulfasalazine may not improve therapeutic efficacy and may result in folate-deficiency anaemias.

Clinical evidence, mechanism, importance and management

A study in 15 patients with rheumatoid arthritis found that when sulfasalazine 2 g was given with methotrexate 7.5 mg weekly, the pharmacokinetics of the methotrexate remained unchanged. Similarly, methotrexate did not alter the trough levels of sulfasalazine.¹ Although this study suggests there is no reason to avoid the concurrent use of sulfasalazine and methotrexate, clinical studies in patients with rheumatoid arthritis have found that concurrent use does not significantly increase therapeutic efficacy and seems to increase the development of folate-deficiency anaemias.² The results of an *in vitro* study suggest this may be because sulfasalazine is a potent inhibitor of the reduced folate carrier- (RFC-) mediated cellular uptake of methotrexate and folinate.³ An alternative explanation is that both sulfasalazine and methotrexate promote enhanced adenosine release which may suppress inflammation and the combination of two drugs with the same mechanism of action may not improve the therapeutic response of either.⁴

Methotrexate + Tacrolimus

No adverse interaction appears to occur between methotrexate and tacrolimus.

Clinical evidence, mechanism, importance and management

A study in 3 bone marrow transplant patients taking tacrolimus 30 micrograms/kg per day found that low-dose methotrexate (15 mg/m² on day 1, and 10 mg/m² on days 3, 6 and 11) did not significantly affect clinical care and no interaction of clinical significance was seen.¹ A further study in 40 patients given methotrexate (15 mg/m² on day 1 followed by 10 mg/m² on days 3, 6 and 11 after a transplant) with 30 micrograms/kg of intravenous tacrolimus daily, similarly found no evidence of an adverse interaction.²

Methotrexate + Theophylline

Methotrexate causes a modest reduction in the theophylline clearance. Theophylline may reduce methotrexate-induced neurotoxicity, but there is the possibility that it may also reduce methotrexate efficacy.

Clinical evidence

(a) Effects on theophylline

The apparent clearance of theophylline (given as oral aminophylline, choline theophyllinate or theophylline) was reduced by 19% in 8 patients with severe, steroid-dependent asthma after 6 weeks of treatment with intramuscular methotrexate 15 mg weekly. Three patients complained of nausea and the theophylline dosage was reduced in one of them as the theophylline level was more than 20 micrograms/mL.¹

(b) Effects on methotrexate

Four of 6 patients aged 3 to 16 years with acute lymphoblastic leukaemia and high-dose methotrexate-induced neurotoxicity had a complete resolution of their symptoms when they were given a 2.5-mg/kg aminophylline infusion over 1 hour. The other 2 had some improvement in symptoms. One patient also had symptom relief with rapid-release theophylline.² Similar results were reported for another child who developed neurotoxicity after receiving high-dose methotrexate. In this case, aminophylline was reported not to alter methotrexate levels.³ A patient with methotrexate-induced leukoencephalopathy recovered after being given a combination of intravenous folinic acid with intravenous aminophylline 145 mg daily for 7 days.⁴

Mechanism

It is not known why theophylline clearance is altered. Methotrexate neurotoxicity may be linked with increased levels of adenosine. Theophylline is a competitive antagonist for adenosine receptors at serum concentrations within the therapeutic range used in respiratory disease.²

Importance and management

The clinical importance of the small reduction in theophylline clearance is uncertain, although it may be worth bearing this in mind in patients maintained at the higher end of the therapeutic levels for theophylline, as they may be more likely to develop toxicity. Aminophylline may reduce methotrexate-induced neurotoxicity, and, although there is some evidence that theophylline does not alter the cytotoxic effects of methotrexate, this requires confirmation.² One UK manufacturer of methotrexate (licensed for

rheumatoid arthritis) recommends avoiding excessive consumption of caffeine and theophylline-containing drinks, however this recommendation appears to be based on studies and surveys which looked at the effects of caffeine intake in patients taking low-dose, weekly methotrexate for rheumatoid arthritis or psoriasis,^{5,6} see 'Methotrexate + Caffeine', p.646.

Methotrexate + Urinary alkalinisers

Alkalinisation increases the solubility of methotrexate in the urine and also increases its excretion.

Clinical evidence, mechanism, importance and management

Methotrexate is much more soluble in alkaline than in acid fluids, therefore urinary alkalinisers such as **sodium bicarbonate** and **acetazolamide** (and ample fluids) are often given to patients receiving high-dose methotrexate to prevent the precipitation of methotrexate in the renal tubules, which would cause damage. However alkalinisation also increases the loss of methotrexate in the urine because at high pH values more of the drug exists in the ionised form, which is not readily reabsorbed by the tubules. This increased loss was clearly shown in about 70 patients in whom alkalinisation of the urine (to pH greater than 7) with **sodium bicarbonate** and hydration reduced the serum methotrexate levels at 48 hours by 73% and at 72 hours by 76%.¹ In this instance the interaction was being exploited therapeutically to avoid toxicity. This interaction has also been shown by others.² The possible consequences should be recognised if concurrent use is undertaken.

For the effects of acidic urine on methotrexate excretion see 'Methotrexate + Ascorbic acid (Vitamin C)', p.646.

Mitomycin + Doxorubicin

An increased incidence of cardiotoxicity has been seen in patients treated with mitomycin who were previously or simultaneously given doxorubicin.

Clinical evidence, mechanism, importance and management

Fourteen out of 91 (15.3%) patients with advanced breast cancer who had previously failed to respond to doxorubicin developed congestive heart failure when later treated with a combination of intravenous mitomycin 20 mg/m² every 4 to 6 weeks and megestrol acetate 160 mg daily. None of them had any pre-existing heart disease. This compares with only 3 out of 89 (3.5%) of another group of patients who had received doxorubicin but no mitomycin. The maximum cumulative dose of doxorubicin was 450 mg/m² and all of the patients had also been given cyclophosphamide. Some of them also received other drugs during the doxorubicin phase of treatment. These included fluorouracil, methotrexate, tegafur and vincristine. The heart failure developed slowly (mean time of 8.5 months) compared with those in the control group (1.5 months).¹

Other studies have also suggested that the combination of mitomycin and doxorubicin may increase cardiotoxicity.^{2,3} In a randomised study, 2 of 39 patients treated with doxorubicin 45 mg/m² once every 3 weeks and mitomycin 10 mg/m² once every 6 weeks developed cardiomyopathy, compared with none of 42 patients treated with doxorubicin 75 mg/m² once every 3 weeks alone.⁴

The reasons for this apparent synergistic cardiotoxicity are not understood, but it may be related to free radical generation. This interaction is not established with certainty. The authors of one report suggest that its in-

cidence is probably less than 10%, and that it does not occur until a cumulative mitomycin dose of 30 mg/m² or more.³ It may be prudent to monitor patients treated with mitomycin closely if they have previously received anthracycline drugs.¹ Note that the combination (FAM, fluorouracil, doxorubicin and mitomycin) has been widely used for gastric cancer.

Mitomycin + Fluorouracil

Serious and potentially life-threatening intravascular haemolysis and renal failure may develop rarely after the long-term use of mitomycin and fluorouracil.

Clinical evidence, mechanism, importance and management

Two patients developed chronic haemolysis and progressive renal impairment after long-term treatment with mitomycin and fluorouracil following partial or total gastrectomy for gastric cancer. The haemolysis was exacerbated by blood transfusions. The authors of the report¹ say that these two cases are “. . . the extreme of a syndrome we are finding increasingly in our pretransfusion patients, after 6 months or more of maintenance therapy.” A similar syndrome occurred in 2 other patients, one with gastric carcinoma and one without, when treated with these two drugs.^{2,3} This severe and potentially fatal syndrome has also been seen with mitomycin alone.^{4,5} Its incidence is not known, but note that a regimen of fluorouracil, doxorubicin and mitomycin (FAM) has been widely used in gastric cancer and there are only a few reports of this syndrome. The authors of one report suggest that the drugs should be stopped at the first sign of intravascular haemolysis, persistent proteinuria and rising urea levels (two consecutive values above 8 mmol/L).¹ The syndrome has also occurred when tamoxifen was given to patients who had been treated with mitomycin, see ‘Mitomycin + Tamoxifen’, below.

Mitomycin + Furosemide

A study in 5 patients with advanced solid tumours treated with mitomycin C 10 mg/m² showed that furosemide given as a 40 mg intravenous bolus either 120 or 200 minutes after the mitomycin had no effect on its pharmacokinetics.¹

1. Verweij J, Kerpel-Fronius S, Stuurman M, de Vries J, Pinedo HM. Absence of interaction between furosemide and mitomycin C. *Cancer Chemother Pharmacol* (1987) 19, 84–6.

Mitomycin + Tamoxifen

Haemolytic anaemia, thrombocytopenia and renal impairment, leading to potentially fatal haemolytic uraemic syndrome, has occurred in a few patients given tamoxifen with, or shortly after, mitomycin.

Clinical evidence, mechanism, importance and management

After a woman with metastatic breast cancer who had previously been treated with mitomycin, mitoxantrone and methotrexate, developed rapid-

ly fatal acute renal failure 21 days after starting tamoxifen, a retrospective survey was undertaken of other patients who had also received all of these drugs.¹ Nine out of 94 (9.6%) patients developed anaemia, thrombocytopenia and renal impairment, compared with none in another group of 45 patients not given tamoxifen. One of the 9 died from renal failure. The doses used were mitomycin 7 mg/m² intravenously every 42 days for four courses; mitoxantrone 7 mg/m² and methotrexate 35 mg/m² intravenously every 21 days for eight courses; tamoxifen 20 mg orally daily.¹ A few other reports describe cases of haemolytic uraemic syndrome in patients given mitomycin and tamoxifen.^{2–4}

The authors of the first study suggested that this haemolytic uraemic syndrome was due to a combination of subclinical endothelial damage induced by mitomycin C, and a thrombotic effect on platelets caused by tamoxifen.¹ They advise the avoidance of tamoxifen with or shortly after mitomycin C unless concurrent use can be carefully monitored. Erythropoietin may be useful in managing the syndrome.⁴ This syndrome has also occurred rarely with mitomycin alone, or when combined with fluorouracil, see ‘Mitomycin + Fluorouracil’, above.

Mitotane + Spironolactone

In an isolated report, the effects of mitotane appeared to be inhibited by spironolactone in a patient with Cushing's disease.

Clinical evidence, mechanism, importance and management

A woman with Cushing's disease taking chlorpropamide, digoxin and furosemide was given spironolactone 50 mg four times daily to control hypokalaemia. She was also given mitotane 3 g daily for 5 months to control the elevated cortisol levels, but this had no effect.¹ When an interaction was suspected (on the basis of *animal* studies¹) it was decided to withdraw the spironolactone, whereupon severe nausea and profuse diarrhoea developed within 24 to 48 hours, suggesting mitotane toxicity. This subsided, and then redeveloped when the mitotane was stopped, and then restarted a week later. The mechanism of this apparent interaction is not understood. It would seem that mitotane can become ineffective in the management of Cushing's syndrome in the presence of spironolactone.

1. Wortsman J, Soler NG. Mitotane. Spironolactone antagonism in Cushing's syndrome. *JAMA* (1977) 238, 2527.

Nitrosoureas + Cimetidine

The bone marrow depressant effects of carmustine and lomustine are possibly increased by cimetidine.

Clinical evidence

Nine patients treated with **carmustine** 80 mg/m² daily for 3 days, cimetidine 300 mg four times daily for 1 to 4 weeks, steroids, and cranial irradiation over 6 weeks, demonstrated marked leucopenia during the first cycle. Bone marrow aspirates confirmed the marked decrease in granulocytic elements in 2 patients. In comparison, 31 patients treated similarly, but without cimetidine, had no significant white cell depression.^{1,2}

Neutropenia was found in a man taking regular cimetidine, phenytoin, phenobarbital, and dexamethasone, 53 days after he was given **lomustine** 120 mg, and 16 days after he was given **lomustine** 160 mg. The cimetidine was discontinued and the neutropenia rapidly reversed within 14 days. The neutrophil nadir from the **lomustine** 160 mg dose occurred after a further 16 to 19 days and was much less severe.³

Mechanism

Studies in *animals* suggest that cimetidine impairs the clearance of carmustine.⁴ Cimetidine has also increased the levels or toxicity of some oth-

er antineoplastics, see 'Cyclophosphamide + H₂-receptor antagonists', p.626, 'Anthracyclines; Epirubicin + Cimetidine', p.613, and 'Fluorouracil + H₂-receptor antagonists', p.633.

Importance and management

Information appears to be limited to the reports cited, but it seems to be an established reaction. Patients given both drugs should be closely monitored for changes in blood cell counts. Because of its immunomodulatory effects, cimetidine has been used as an adjunct to carmustine in the treatment of malignant melanoma, but this did not improve outcomes.⁵

Nitrosoureas; Lomustine + Theophylline

A single case report describes thrombocytopenia and bleeding attributed to the concurrent use of lomustine and theophylline.

Clinical evidence, mechanism, importance and management

An asthmatic woman taking theophylline and treated for medulloblastoma with lomustine, prednisone and vincristine, developed severe nose bleeding and thrombocytopenia 3 weeks after the third cycle of chemotherapy.¹ This was attributed to the concurrent use of lomustine and theophylline. The suggested explanation for this effect is that theophylline inhibited the activity of phosphodiesterase within the platelets, thereby increasing cyclic AMP levels and disrupting normal platelet function, which seems to be supported by an experimental study,² while lomustine causes thrombocytopenia. What is known is far too limited to act as more than a warning of the possibility of increased thrombocytopenia during the concurrent use of theophylline and lomustine.

- DeWys WD, Bathina S. Synergistic anti-tumour effect of cyclic AMP elevation (induced by theophylline) and cytotoxic drug treatment. *Proc Am Assoc Cancer Res* (1978) 19, 104.

Pemetrexed + Miscellaneous

Aspirin and ibuprofen had little effect on pemetrexed clearance in patients with normal renal function, but they, and other short-acting NSAIDs, should be withheld in patients with mild to moderate renal function. NSAIDs with longer half-lives such as piroxicam should be withheld in all patients. Caution is recommended if pemetrexed is given with nephrotoxic drugs such as the aminoglycosides, loop diuretics, and ciclosporin, and drugs that are secreted by the renal tubules, such as probenecid and penicillin.

Clinical evidence, mechanism, importance and management

(a) Cisplatin

The US manufacturers state that there is no pharmacokinetic interaction between pemetrexed and cisplatin,¹ but there is the possibility that cisplatin-induced nephrotoxicity could decrease pemetrexed clearance and increase its toxicity.^{1,2} However, it should be noted that the use of pemetrexed with cisplatin is indicated for mesothelioma.^{1,2}

(b) Folic acid and vitamin B₁₂

Oral folic acid and intramuscular vitamin B₁₂ has been reported to not alter the pharmacokinetics of pemetrexed¹ and because these vitamins were found to decrease pemetrexed toxicity, it is recommended that all patients receiving pemetrexed should receive folic acid and B₁₂ supplements.^{1,2}

(c) Nephrotoxic drugs

The manufacturers consider that the concurrent use of nephrotoxic drugs could potentially decrease the clearance of pemetrexed and therefore increase its toxicity.^{1,2} In the UK, the manufacturer specifically mentions **aminoglycosides, loop diuretics, platinum compounds** (see also (a) cisplatin above) and **ciclosporin**, and recommends caution with combined use, and, if necessary, close monitoring of creatinine clearance.²

(d) NSAIDs and Aspirin

In a study in 27 patients with advanced cancer, aspirin 325 mg every 6 hours for 9 doses, starting 2 days before and with the last dose 1 hour before an infusion of pemetrexed 500 mg/m², did not alter the pharmacokinetics of pemetrexed.³ In a similar study **ibuprofen** 400 mg four times daily caused a slight 16% decrease in the clearance of pemetrexed, and increased its AUC by 20%.³ The effects of higher doses of aspirin or **ibuprofen** are not known, but they could be greater. Because of this, in patients with normal renal function, the manufacturer recommends caution when pemetrexed is used with high doses of NSAIDs (e.g. **ibuprofen** greater than 1.6 g daily) or high-dose aspirin (greater than 1.3 g daily).² Moreover, in patients with mild to moderate renal impairment, the manufacturer recommends that NSAIDs and higher dose aspirin be avoided for 2 days before, the day of, and for 2 days after pemetrexed use.^{1,2}

Because of the lack of data on pemetrexed clearance with NSAIDs with longer half-lives [e.g. **piroxicam**], the manufacturer recommends that all patients taking these NSAIDs stop them for 5 days before pemetrexed, on the day, and for at least 2 days afterwards.^{1,2}

(e) Probenecid and other drugs secreted by the renal tubules

It is possible that drugs that are secreted by the renal tubules (e.g. probenecid, **penicillin**) could decrease the clearance of pemetrexed, which is also secreted by this mechanism. For this reason, the manufacturer recommends caution with combined use, and, if necessary, close monitoring of creatinine clearance.²

Procarbazine + Antiepileptics

The use of enzyme-inducing antiepileptics seems to increase the risk of procarbazine hypersensitivity reactions.

Clinical evidence, mechanism, importance and management

A study of the records of 83 patients with primary brain tumours who were treated with procarbazine between 1981 and 1996 showed that 20 of them had procarbazine hypersensitivity reactions. Of these 20, 95% had also taken antiepileptics compared with 71% of those not developing hypersensitivity. In addition, there was a significant dose-response association between the development of hypersensitivity reactions and the serum levels of the antiepileptics used (**phenytoin, phenobarbital, or carbamazepine**, with or without valproate).¹ It was suggested that the enzyme-inducing antiepileptics may increase the metabolism of procarbazine to metabolites causing hypersensitivity. This may also explain why the incidence of procarbazine-induced hypersensitivity is higher in patients with brain tumours, who commonly receive seizure-prophylaxis therapy.¹

- Lehmann DF, Hurteau TE, Newman N, Coyle TE. Anticonvulsant usage is associated with an increased risk of procarbazine hypersensitivity reactions in patients with brain tumours. *Clin Pharmacol Ther* (1997) 62, 225–9.

Procarbazine + Chlormethine (Mechlorethamine)

A report on two patients suggests that the use of high doses of procarbazine with chlormethine may result in neurological toxicity.

Clinical evidence, mechanism, importance and management

Two patients with acute myelogenous leukaemia admitted to hospital for marrow transplantation and who were given *high doses* of procarbazine 12.5 and 15 mg/kg and chlormethine 0.75 and 1 mg/kg on the same day became lethargic, somnolent and disorientated for about a week. Two other patients who received the same drugs on different days had no neurological complications. In addition, only one of 45 patients treated with high-dose procarbazine alone had similar persistent lethargy. Although no interaction has been proved, the authors suggest that the chlormethine may have enhanced the neurotoxic effects of the procarbazine, and advise that it would be prudent to avoid high-doses of these drugs on the same day.¹ Note that lower doses of the combination have been widely used in the MOPP regimen (mechlorethamine, vincristine, procarbazine, and prednisone) without problems.

1. Weiss GB, Weiden PL, Thomas ED. Central nervous system disturbances after combined administration of procarbazine and mechlorethamine. *Cancer Treat Rep* (1977) 61, 1713–14.

Procarbazine + Miscellaneous

The effects of drugs that can cause CNS depression or lower blood pressure may possibly be increased by the presence of procarbazine.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives

In one early clinical study, 4 of 48 patients developed postural hypotension when treated with procarbazine. In addition, another patient with hypertension (180/110 mmHg) had a progressive fall in blood pressure (to 110/80 mmHg) while being treated with procarbazine.¹ Additive hypotensive effects may therefore be expected if procarbazine is given to patients taking antihypertensives.

(b) CNS depressants

Procarbazine can cause CNS depression ranging from mild drowsiness to profound stupor. In early clinical studies, the incidence was variously reported as 8%, 14%, and 31% (when combined with prochlorperazine, see also (c) below).^{1–3} Additive CNS depression may therefore be expected if other drugs possessing CNS-depressant activity are given with procarbazine.

(c) Prochlorperazine

An isolated report describes an acute dystonic reaction (difficulty in speaking or moving, intermittent contractions of muscles on the left side of the neck) in a patient taking procarbazine with prochlorperazine.⁴ Prochlorperazine was thought to have contributed to the sedative effects of procarbazine in one early clinical study.³

Procarbazine + Sympathomimetics

Despite warnings, it seems doubtful that the weak MAO-inhibitory properties of procarbazine can under normal circumstances cause a hypertensive reaction with tyramine or other sympathomimetics.

Clinical evidence, mechanism, importance and management

The manufacturers say that procarbazine is a weak inhibitor of MAO and therefore predict that interactions with certain foods and drugs may occur in rare cases.¹ This is apparently based on the results of *animal* experiments, which show that the monoamine oxidase inhibitory properties of procarbazine are weaker than pheniprazine.² There seem to be no formal reports of hypertensive reactions in patients taking procarbazine who have

eaten tyramine-containing foods (e.g. cheese) or after using indirectly-acting sympathomimetic amines (e.g. **phenylpropanolamine**, **amfetamines**, etc.). The only account traced is purely anecdotal and unconfirmed: “. . . I recall one patient who described vividly reactions to wine and chicken livers which had occurred while he was taking MOPP chemotherapy (mechlorethamine, vincristine, procarbazine, and prednisone) several years earlier. Since he had not been forewarned, the reactions had been a frightening experience.”³ A practical way to deal with this interaction problem has been suggested by a practitioner in an Oncology unit:³ patients taking procarbazine should ideally be given a list of the potentially interacting foodstuffs (see ‘MAOIs or RIMAs + Tyramine-rich foods’, p.1153), with a warning about the nature of the possible reaction but also with the advice that it very rarely occurs. The foods may continue to be eaten, but patients should start with small quantities to ensure that they still agree with them. Those taking MOPP should also be told that any reaction is most likely to occur during the second week of a 14-day course of treatment with procarbazine, and during the week after it has been stopped.

3. Maxwell MB. Reexamining the dietary restrictions with procarbazine (an MAOI). *Cancer Nurs* (1980) 3, 451–7.

Raltitrexed + Miscellaneous

On theoretical grounds the manufacturers say that folic acid and folic acid may possibly interfere with the action of raltitrexed. Warfarin and NSAIDs do not appear to interact with raltitrexed.

Clinical evidence, mechanism, importance and management

(a) Folinates

The antimetabolite, raltitrexed, is a folate analogue and is a potent and specific inhibitor of the enzyme thymidylate synthase. Inhibition of this enzyme ultimately interferes with the synthesis of deoxyribonucleic acid (DNA) leading to cell death. The intracellular polyglutamation of raltitrexed leads to the formation within cells of even more potent inhibitors of thymidylate synthase. Folate (methylene tetrahydrofolate) is a co-factor required by thymidylate synthase and therefore theoretically folic acid or folic acid may interfere with the action of raltitrexed. Clinical interaction studies have not yet been undertaken to confirm these predicted interactions.¹

(b) Warfarin, NSAIDs

The manufacturers say that no specific clinical interaction studies have been conducted but a review of the clinical study database did not reveal any evidence of interactions between raltitrexed and warfarin, NSAIDs or other drugs.¹

1. Tomudex (Raltitrexed). AstraZeneca UK Ltd. UK Summary of product characteristics, October 2001.

Sorafenib + Miscellaneous

Sorafenib levels may be reduced by inhibitors of CYP3A4. Antacids may reduce the absorption of sorafenib. Sorafenib may increase docetaxel and doxorubicin levels. Isolated cases of raised INRs and bleeding have been reported in patients taking warfarin with sorafenib.

Clinical evidence, mechanism, importance and management

(a) Cytochrome P450 inducers

A 5 day course of **rifampicin (rifampin)** reduced the AUC of a single dose of sorafenib by an average of 37%. Other inducers of the cytochrome P450 isoenzyme CYP3A4, such as **St John's wort**, **carbamazepine**, **phenytoin**, **phenobarbital** and **dexamethasone**, may also reduce sorafenib levels.¹

(b) Docetaxel

Sorafenib 200 mg or 400 mg twice daily on days 2 to 19 of a 21-day cycle increased the AUC and maximum concentration of docetaxel 75 or

100 mg/m² every 21 days were increased by 36 to 80%, and 16 to 32%, respectively.¹ The manufacturer therefore recommends caution with concurrent use of these drugs.¹

(c) *Doxorubicin*

A 21% increase in the AUC of doxorubicin occurred when it was given with sorafenib. The manufacturers therefore recommend caution with concurrent use of these drugs.^{1,2}

(d) *Drugs that affect gastrointestinal pH*

Drugs, such as **antacids**, **H₂-receptor antagonists** or **proton pump inhibitors**, that raise the pH of the gastrointestinal tract may reduce the solubility of sorafenib, although this has not been specifically studied. The manufacturers therefore recommend avoiding chronic treatment with these drugs during treatment with sorafenib as they cannot exclude the possibility that these drugs will reduce sorafenib efficacy.¹

(e) *Warfarin*

A study in patients given sorafenib and taking warfarin found that the INR did not differ between those patients taking sorafenib and those not taking sorafenib, despite previous *in vitro* evidence that sorafenib inhibits the cytochrome P450 isoenzyme CYP2C9, the main isoenzyme involved in the metabolism of warfarin.

However, raised INRs and infrequent bleeding have been reported in patients taking warfarin with sorafenib. The manufacturers therefore advise close monitoring of the INR patients taking these drugs together.^{1,2}

2. Nexavar (Sorafenib tosylate). Bayer Pharmaceuticals Corp. US Prescribing information, February 2007.

Streptozocin + Phenytoin

A single case report indicates that phenytoin can reduce or abolish the effects of streptozocin.

Clinical evidence, mechanism, importance and management

A patient with an organic hypoglycaemic syndrome, due to a metastatic apud cell carcinoma of the pancreas, who was taking streptozocin 2 g daily with phenytoin 400 mg daily for 4 days, failed to show the expected response until the phenytoin was withdrawn.¹ It would seem that the phenytoin inhibited the effects of the streptozocin by some mechanism as yet unknown. Although this is an isolated case report its authors recommend that concurrent use should be avoided.

1. Koranyi L, Gero L. Influence of diphenylhydantoin on the effect of streptozotocin. *BMJ* (1979) 1, 127.

Tamoxifen + Aromatase inhibitors

Aminoglutethimide, but not anastrozole, exemestane, or letrozole, markedly increases tamoxifen clearance and reduces its serum levels. Tamoxifen modestly reduces anastrozole and letrozole levels, but it does not alter aminoglutethimide levels, or exemestane levels and effects.

Clinical evidence

(a) *Effect on tamoxifen*

In 6 menopausal women with breast cancer **aminoglutethimide** 250 mg four times daily for 6 weeks markedly reduced the serum levels of tamoxifen 20 to 80 mg daily and most of its metabolites. The clearance of the tamoxifen was increased by 3.2-fold and the tamoxifen AUC was reduced by 73% (range 56 to 80%).¹ Conversely, the concurrent use of **anastrozole** 1 mg daily for 28 days did not affect the pharmacokinetics of tamoxifen in a double-blind, placebo-controlled study in 34 women with breast cancer who had been taking tamoxifen 20 mg daily for at least 10 weeks.² Similarly, **letrozole** 2.5 mg daily had no effect on the pharmacokinetics of tamoxifen in 18 women taking tamoxifen 20 mg daily.³ Further, a study in 32 women clinically disease-free following primary treatment for breast cancer and who had been taking tamoxifen 20 mg daily for at least 4 months found that **exemestane** 25 mg daily for 8 weeks

had no effect on the pharmacokinetics of tamoxifen or the formation of tamoxifen metabolites and the combination was well-tolerated.⁴

(b) *Effect on aromatase inhibitors*

Tamoxifen 20 to 80 mg daily did not alter the pharmacokinetics of **aminoglutethimide** 250 mg four times daily.¹ In a pilot study, 18 postmenopausal women with breast cancer were given **exemestane** 25 mg daily for 14 days, then **exemestane** and tamoxifen 20 mg daily for 4 weeks. Tamoxifen did not affect the pharmacokinetics (plasma levels) or pharmacodynamics (estrone, estrone sulfate and estradiol suppression) of **exemestane** and the combination was well-tolerated.⁵ In 12 women **letrozole** levels were reduced by 38% (range 0 to 70%) 6 weeks after tamoxifen 20 mg daily was added to **letrozole** 2.5 mg daily. This reduction persisted after 4 to 8 months; however, the estradiol suppressant effects of **letrozole** did not appear to be affected.⁶ Similarly, although the estradiol suppressant effects of **anastrozole** 1 mg daily did not appear to be affected by tamoxifen 20 mg daily in two studies,^{2,7} in one of these studies, **anastrozole** levels were decreased by 27% by tamoxifen.⁷

Mechanism

It is likely that aminoglutethimide, an enzyme inducer, increases the metabolism of the tamoxifen by the liver, thereby increasing its loss from the body. It is not known how tamoxifen reduces anastrozole and letrozole levels, although it may also be via enzyme induction.⁶

Importance and mechanism

Theoretically, the combination of an oestrogen antagonist such as tamoxifen and an aromatase inhibitor should provide additional benefit in the treatment of hormone-dependent cancers, however, no clinical studies have yet found this to be so. The pharmacokinetic interactions described above may partly explain this. It may be preferable to use these drugs sequentially rather than concurrently.⁶

Tamoxifen and other anti-oestrogens + Herbal medicines

Indirect evidence hints at the possibility that some herbal medicines that possess oestrogenic activity may oppose the actions of anti-oestrogens, such as tamoxifen, used in the treatment of breast cancer.

Clinical evidence, mechanism, importance and management

A letter in the Medical Journal of Australia¹ draws attention to fact that some women with breast cancer receiving chemotherapy or hormone antagonists who develop menopausal symptoms have found relief from hot flushes by taking a Chinese herb '**dong quai**' (or '**danggui**' root), which has been identified as *Angelica sinensis*. A possible explanation is that this and some other herbs (**vitex berry** (*Agnus castus*), **hops flower** (**lupulus**), **ginseng root**, **black cohosh** (**cimicifuga**)) have significant oestrogen-binding activity and physiological oestrogenic actions.² The concern expressed in the letter is that the oestrogenic activity of these herbs might directly stimulate breast cancer growth and oppose the actions of competitive oestrogen receptor antagonists such as tamoxifen. Consider also, 'Tamoxifen and other anti-oestrogens + HRT', p.659.

Although this is largely speculative at the moment, the writer of the letter suggests that such herbal medicines are undesirable in patients with breast cancer. In addition to tamoxifen, there are now a number of other drugs used for breast cancer that in one way or another reduce the stimulation of oestrogen receptors (**anastrozole**, **exemestane**, **letrozole**, **toremifene**). More study is needed.

Tamoxifen and other anti-oestrogens + HRT

Contrary to expectations HRT may not increase the risk of recurrent breast cancer in women taking tamoxifen. HRT is reported to oppose the lipid-lowering effects of tamoxifen.

Clinical evidence, mechanism, importance and management

(a) Anti-oestrogenic effects

In a cohort study of the use of HRT in the management of menopausal symptoms in women treated for breast cancer, the use of continuous combined HRT (an oestrogen plus a progestogen) was not associated with an increased risk of breast cancer recurrence in women taking tamoxifen.¹ This is of interest since HRT might be expected to oppose the effects of anti-oestrogens such as tamoxifen in the treatment and prevention of breast cancer. For this reason, HRT and other oestrogens are often considered to be contraindicated in women taking anti-oestrogens such as **anastrozole**,² **exemestane**,^{3,4} **letrozole**, tamoxifen and **toremifene** (see also 'Tamoxifen and other anti-oestrogens + Herbal medicines', p.658). The cohort study described¹ suggests that there need not be a complete restriction on their concurrent use, but ideally randomised prospective studies are required to confirm this.

(b) Cardiovascular effects

A large-scale comparative study was undertaken over a 12-month period in groups of women taking tamoxifen alone, HRT alone, or tamoxifen with transdermal HRT to see whether the cardiovascular risk factors (low-density lipoprotein cholesterol, high-density lipoprotein-cholesterol levels, platelet counts) were changed by concurrent use. It was found that the decrease in total and LDL-cholesterol levels due to the tamoxifen was unchanged in current HRT users, but reduced by two-thirds in women taking tamoxifen who then started HRT.⁵ It would therefore seem important to check the outcome of concurrent use. More study is needed.

Tamoxifen + Medroxyprogesterone acetate

Medroxyprogesterone affects the metabolism of tamoxifen but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

In 20 women with breast cancer taking tamoxifen 20 mg twice daily, the addition of medroxyprogesterone acetate 500 mg twice daily only slightly reduced the tamoxifen serum levels over a 6-month period, but considerably reduced the levels of the desmethyl metabolite of tamoxifen, presumably because of some effect on the metabolism of the tamoxifen by the liver.¹ The clinical importance of this interaction awaits assessment.

1. Reid AD, Horobin JM, Newman EL, Preece PE. Tamoxifen metabolism is altered by simultaneous administration of medroxyprogesterone acetate in breast cancer patients. *Breast Cancer Res Treat* (1992) 22, 153–6.

Tamoxifen + Rifampicin (Rifampin)

Rifampicin increased the metabolism of tamoxifen.

Clinical evidence, mechanism, importance and management

In 10 healthy *men* rifampicin 600 mg daily for 5 days reduced the AUC of a single 80-mg dose of tamoxifen by 86%, reduced the peak plasma levels by 55%, and reduced the half-life by 44%. Similarly, the AUC of *N*-demethyltamoxifen was reduced by 62%.¹

It is likely that rifampicin induces the metabolism of tamoxifen by the cytochrome P450 isoenzyme CYP3A4, thereby reducing its levels. These findings suggest that the efficacy of tamoxifen may be reduced by rifampicin. However, there is some *in vitro* evidence that suggests that tamoxifen and rifampicin have additive antineoplastic effects in pancreatic carcinoma cell lines.² Also, tamoxifen induces its own metabolism on long-term use.³ Thus, further study is needed to assess the clinical impact of the long-term combined use of these drugs.

Tamoxifen + SSRIs

Paroxetine reduces the metabolism of tamoxifen to one of its active metabolites. The clinical relevance of this is unknown, although one small case-control study found that inhibitors of CYP2D6 such as the SSRIs did not increase the recurrence of breast cancer in tamoxifen users.

Clinical evidence

Twelve women taking tamoxifen 20 mg daily were also given **paroxetine** 10 mg daily for 4 weeks, and plasma levels of tamoxifen and its metabolites were measured.¹ Before **paroxetine**, the plasma levels of the 4-hydroxy-*N*-desmethyl-tamoxifen metabolite (endoxifen) were about 12 times higher than those of the 4-hydroxy-tamoxifen metabolite. **Paroxetine** reduced endoxifen levels by 56%, but those of *N*-desmethyl-tamoxifen, and 4-hydroxy-tamoxifen were unchanged. The reduction in endoxifen levels was greatest in those who were extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6 (see 'Genetic factors', (p.4)). In a further study by the same research group, 80 women starting tamoxifen 20 mg daily had plasma levels of tamoxifen measured after 1 and 4 months of therapy.² These were then correlated with CYP2D6 metaboliser phenotype and the concurrent use of CYP2D6 inhibitors (taken by 24 women). In women who were CYP2D6 extensive metabolisers, use of CYP2D6 inhibitors was associated with a 58% lower endoxifen level, which was substantially lower in those taking **paroxetine**, but only slightly reduced by venlafaxine, and intermediate in those taking **sertraline**.²

However, a case-control study of 28 women taking tamoxifen with recurrences of oestrogen receptor positive breast cancer found that there was no difference in the number of women taking CYP2D6 inhibitors (**fluoxetine**, **paroxetine**, **sertraline**) between cases and controls (women taking tamoxifen with no recurrence). Similarly, there was no differences for CYP2C9 inhibitors (including **paroxetine** and **sertraline**).³

Mechanism

Endoxifen and 4-hydroxy-tamoxifen are more active anti-oestrogens than tamoxifen.¹ Tamoxifen is metabolised to 4-hydroxy-tamoxifen and *N*-desmethyl-tamoxifen principally by CYP3A,¹ although others have found that other isoenzymes are involved,⁴ and to endoxifen by CYP2D6.¹ Of the SSRIs, paroxetine is the most potent inhibitor of CYP2D6. However, tamoxifen resistance may be more to do with altered oestrogen receptor sensitivity than reduced levels of tamoxifen metabolites.³ Further it has been suggested that the plasma levels of tamoxifen and metabolites found in one study¹ would be sufficient to block oestrogen binding to oestrogen receptors so that a decrease in endoxifen levels would not substantially affect anti-oestrogen activity.⁵

Importance and management

Although information is limited, it is established that potent inhibitors of CYP2D6 such as paroxetine can alter the metabolism of tamoxifen to its active metabolites. However, the effect this has on the clinical efficacy of tamoxifen remains to be established. The one small case-control study suggests the effect is not great. At present, there is insufficient evidence to recommend caution when giving SSRIs with tamoxifen, but further study is clearly needed. Any interaction would apply equally to other CYP2D6 inhibitors, see 'Table 1.3', (p.6) for a list.

Taxanes + Amifostine

Amifostine had no effect on docetaxel and paclitaxel pharmacokinetics, except in one study which found that amifostine extended paclitaxel plasma circulation time. Amifostine appears not to reduce the toxicity of these taxanes.

Clinical evidence, mechanism, importance and management

In a randomised study, amifostine did not alter the response to, or the pharmacokinetics of, **paclitaxel**, neither did it protect against **paclitaxel**-related neurotoxicity or myelotoxicity.¹ Another study in 8 patients has confirmed that amifostine (750 mg/m² as a 15-minute infusion 30 minutes beforehand) had no effect on the pharmacokinetics of **paclitaxel** 135 to 200 mg/m². Six of the patients were also taking epirubicin and cisplatin.² Although the preliminary findings of an earlier study had suggested that pre-treatment with amifostine reduced the AUC of **paclitaxel** by 29%,³ the full report of this study concluded that amifostine had no clinically relevant effect on **paclitaxel** pharmacokinetics.⁴ In a study in which patients were given amifostine 500 mg as an infusion over 15 minutes just before low-dose **paclitaxel** 80 mg/m² as a one-hour infusion, amifostine reduced maximum plasma levels by about 20%. However, the AUC of paclitaxel was not affected, but the paclitaxel plasma circulation time was prolonged.⁵

Amifostine had no effect on the pharmacokinetics of **docetaxel**, nor did it reduce **docetaxel**-induced myelotoxicity.⁶

The finding in two of these studies^{1,6} that the toxicity of taxanes was not reduced by amifostine does not support earlier *in vitro* data where amifostine protected normal tissue from **paclitaxel** toxicity.⁷

Most studies show no beneficial or adverse consequences from giving amifostine with the taxanes. Further study is needed to evaluate the possible effects of amifostine on taxane plasma circulation time.

Taxanes + Ciclosporin

Ciclosporin increases the levels of docetaxel and paclitaxel after oral administration.

Clinical evidence, mechanism, importance and management

(a) Docetaxel

One study has demonstrated that the bioavailability of *oral* docetaxel may be increased from 8% to 90% by ciclosporin due to inhibition of both P-glycoprotein transport and the metabolism of docetaxel by the cytochrome P450 isoenzyme CYP3A4.¹ In another study, the AUC of ciclosporin was increased by about 1.5-fold when it was given with *oral* docetaxel, probably because of competitive inhibition of CYP3A4-mediated ciclosporin metabolism.²

(b) Paclitaxel

Oral paclitaxel has poor bioavailability because of a high affinity for P-glycoprotein in the gastrointestinal tract. Studies in *mice* have shown that the combination of ciclosporin with oral paclitaxel produced a tenfold increase in systemic exposure to paclitaxel. Plasma levels of paclitaxel were below therapeutic concentrations in 5 patients when they were given an oral dose (intravenous formulation) of paclitaxel 60 mg/m² followed by intravenous doses of 175 mg/m² for subsequent courses. However, therapeutic levels above 100 micromol/mL (a ninefold increase) were achieved in 9 patients who received the same regimen with ciclosporin 15 mg/kg. The combination was well-tolerated, but further study is required to determine whether paclitaxel treatment via the oral route is as active as that by the intravenous route.³

Taxanes + Cisplatin or Carboplatin

The toxicity of paclitaxel given with cisplatin appears to be dependent on the order of administration, with more severe myelosuppression occurring if cisplatin is given first. There does not appear to be any sequence dependent interaction for the combination of docetaxel with carboplatin or docetaxel with cisplatin. Paclitaxel may reduce the thrombocytopenia associated with carboplatin. The combination of carboplatin with paclitaxel appears to be more neurotoxic than carboplatin with docetaxel.

Clinical evidence, mechanism, importance and management

(a) Carboplatin

Several clinical studies have found that the severity of thrombocytopenia with the combination of **paclitaxel** and carboplatin was less than that expected with carboplatin alone.^{1–5} This does not appear to be due to any changes in carboplatin pharmacokinetics. In one study, patients were given carboplatin as a 30-minute infusion, either alone or immediately following **paclitaxel** 175 mg/m² as a 3-hour infusion, and it was found that the pharmacokinetics of carboplatin were not significantly affected by **paclitaxel**.⁶ Similarly, a pharmacokinetic interaction was not noted when **paclitaxel** and carboplatin were given in either order in another study.¹ Other studies found the AUC of carboplatin to be similar to that predicted, despite the presence of paclitaxel.^{2,5} Although one study found the AUC of carboplatin to be about 12% lower in the presence of **paclitaxel**,⁴ the same researchers also found that the AUC associated with a 50% decrease in platelet count increased by 68% (i.e. more carboplatin is needed to cause the same degree of thrombocytopenia), which suggests a pharmacodynamic basis for the attenuated toxicity of the combination.⁷ Other researchers also reported that the AUC of carboplatin causing a 50% reduction in platelets was about 6.3 mg/mL per minute when given with **paclitaxel** compared with historical data of 4 mg/mL per minute when given alone.⁸ Although thrombocytopenia may be lower than expected, myelosuppression (in the form of neutropenia) is a dose-limiting toxicity

of the combination of carboplatin and **paclitaxel**.¹⁻⁴ In one study, patients given **paclitaxel** with carboplatin experienced significantly greater neurotoxicity than those given **docetaxel** with carboplatin, but the regimens were similar in efficacy.⁹ Further, there appear to be no pharmacokinetic interactions between carboplatin and **docetaxel**.^{10,11}

(b) Cisplatin

Early studies of the combination of cisplatin and **paclitaxel** showed that the degree of myelosuppression was sequence dependent. When cisplatin was given first, a greater degree of myelosuppression was seen.¹² Pharmacokinetic studies suggest that sequence-dependent differences in myelosuppression may be due to a 25% reduction in **paclitaxel** clearance when cisplatin is given first.¹² For this reason, the manufacturers recommend that **paclitaxel** is given before cisplatin.^{13,14} There is also some evidence that **myelosuppression** is greater for the combination when **paclitaxel** is given over 24 hours as opposed to 3 hours.¹³ When **paclitaxel** is given with cisplatin, **neurotoxicity** (peripheral neuropathy) is common,¹³ and there is some evidence that this is more severe if the **paclitaxel** is given over 3 hours as opposed to over 24 hours.¹⁵ In one study,¹⁶ neurotoxicity was unexpectedly severe when **paclitaxel** alone was used in patients who had relapsed after treatment with cisplatin; however, this was not the case in another similar study.¹⁷

In contrast to **paclitaxel**, early studies did not reveal any obvious sequence dependent toxicity for the combination of **docetaxel** and cisplatin.¹⁸ In addition, cisplatin did not cause any significant changes in **docetaxel** pharmacokinetics.^{18,19}

Taxanes + Cyclophosphamide

There is some evidence to suggest that the toxicity associated with combinations of paclitaxel and cyclophosphamide is dependent on the order of administration. Results from one study indicate that docetaxel pharmacokinetics are unaltered by cyclophosphamide.

Clinical evidence, mechanism, importance and management

(a) Docetaxel

The pharmacokinetics of docetaxel were not altered by pretreatment with an intravenous bolus dose of cyclophosphamide in a phase I study.¹ For a report that the pharmacokinetics of docetaxel are not affected by **ifosfamide**, see 'Cyclophosphamide or Ifosfamide + Taxanes', p.628.

(b) Paclitaxel

A study in patients given paclitaxel as a 24-hour infusion and cyclophosphamide as an infusion over 1 hour found that neutropenia and thrombocytopenia were more severe when paclitaxel preceded cyclophosphamide.² Similarly, in another study, concurrent use of a continuous 72-hour infusion of paclitaxel and a daily bolus of cyclophosphamide had acceptable toxicity. However, when the cyclophosphamide was given as a single intravenous dose after the end of the 72-hour paclitaxel infusion, severe haematological and gastrointestinal toxicity occurred.³ Whether the clinical efficacy of this combination is also altered by the schedule and sequence has not been determined. See also 'Cyclophosphamide or Ifosfamide + Taxanes', p.628.

Taxanes + Protease inhibitors

Life-threatening haematological toxicities have been reported in a few patients taking protease inhibitors when given paclitaxel or docetaxel. Nelfinavir and ritonavir appear to inhibit the clearance of paclitaxel and are predicted to inhibit the metabolism of docetaxel by CYP3A4.

Clinical evidence

(a) Docetaxel

A HIV-positive 64-year-old woman taking **nelfinavir** was given trastuzumab and docetaxel 36 mg/m² for breast cancer. Three days later she was hospitalised with early, severe myelosuppression, which was attributed to an interaction between the nelfinavir and docetaxel, and she died from sepsis.¹

(b) Paclitaxel

A 39-year-old woman taking **lopinavir** was given **carboplatin** and **paclitaxel** 175 mg/m² for adenocarcinoma. Five days later she was hospitalised with early, severe myelosuppression, which was attributed to an interaction between lopinavir and paclitaxel, and she later died.¹ In another report, an HIV-positive patient who was taking **lopinavir/ritonavir**, delavirdine and didanosine was also given paclitaxel 100 mg/m² to treat Kaposi's sarcoma. Within 3 days he developed myalgia and arthralgia, and 8 days after treatment developed fever, tachycardia and a productive cough. He was treated with antibacterials and G-CSF, but later died. Findings at post mortem included severe oesophageal mucositis, *Streptococcus viridans* pneumonia and a massive saddle embolism (an embolism that sits across two vessels).² A second patient taking **indinavir**, **ritonavir**, lamivudine and stavudine developed severe leucopenia and thrombocytopenia

within 7 days of being given paclitaxel 100 mg/m² for Kaposi's sarcoma, and again after a second course of paclitaxel. Further courses of paclitaxel were tolerated by giving a reduced dose of 60 mg/m² together with G-CSF.²

The UK manufacturer of paclitaxel briefly mentions that studies in patients with Kaposi's sarcoma, who were taking multiple concomitant medications, suggest that the systemic clearance of paclitaxel was significantly lower in the presence of **nelfinavir** and **ritonavir**, but not with **indinavir**.³

Mechanism

Paclitaxel is metabolised by the cytochrome P450 enzymes CYP2C8 and CYP3A4. Docetaxel is metabolised by CYP3A4. Protease inhibitors such as ritonavir and indinavir are known to inhibit CYP3A4, which might result in increased taxane levels and toxicity.

Importance and management

Evidence is limited, nevertheless the UK manufacturers advise that paclitaxel should be given to patients also receiving protease inhibitors with caution.³ The manufacturers of docetaxel also advise that it should be used with caution with drugs that inhibit CYP3A4, see 'Taxanes; Docetaxel + Miscellaneous', below, which would include the protease inhibitors.

Taxanes; Docetaxel + Cannabis

The pharmacokinetics of docetaxel are not altered by a herbal tea containing cannabis.

Clinical evidence, mechanism, importance and management

In a crossover study 24 patients were given **docetaxel** 180 mg before and on day 12 of a 15-day course of 200 mL daily of a herbal tea containing cannabis 1 g/L. This was prepared from medicinal-grade cannabis (*Cannabis sativa* L. Flos, variety Bedrocan[®]) containing the cannabinoids Δ⁹-tetrahydrocannabinol 18% and cannabidiol 0.8%. The clearance and the AUC of **docetaxel** were not significantly altered by the cannabis. No dosage adjustments are likely to be needed if **docetaxel** is given with cannabis.¹

Taxanes; Docetaxel + Miscellaneous

Based on *in vitro* studies, the manufacturers suggest that CYP3A inhibitors (such as ketoconazole and erythromycin) will raise docetaxel levels, whereas CYP3A inducers (such as rifampicin (rifampin) and the barbiturates) will reduce docetaxel levels. This has been seen for ketoconazole.

Clinical evidence, mechanism, importance and management

The manufacturers^{1,2} say that no formal clinical drug interaction studies have been carried out with docetaxel, but because it is known from *in vitro* studies that the metabolism of docetaxel is mainly mediated by the cytochrome P450 isoenzyme CYP3A family,³ they say that drugs that are inhibitors of CYP3A might possibly increase its serum levels and increase its toxicity. Caution is advised. The drugs named include **erythromycin**, **ketoconazole**, **terfenadine**, **troleandomycin** and **nifedipine**,^{1,2} although note that some of these drugs (such as **terfenadine** and **nifedipine**) are more usually considered to be competitive inhibitors of CYP3A4 (that is, they share the same metabolic pathway) rather than actually inhibiting the isoenzyme. This prediction is supported by a study in 7 patients, in which **ketoconazole** 200 mg daily for 3 days reduced the clearance of docetaxel 10 mg/m² by 49%, which could increase the risk of neutropenia.⁴

An *in vitro* study found that **hyperforin**, a constituent of **St John's wort** induced docetaxel metabolism in a dose-dependent manner by 2.6 to 7-fold when compared to controls. In the same study, **rifampicin (rifampin)** increased docetaxel metabolism by 6.8 to 32-fold when compared to controls.⁵

Microsomes prepared from patients treated with **pentobarbital** and/or **phenobarbital** are reported to have stimulated docetaxel metabolism strikingly whereas those prepared from a patient taking **prednisone** did not.⁶ In a study in patients with metastatic prostatic cancer, **prednisone** did not significantly affect the pharmacokinetics of docetaxel.¹

None of these drugs, with the exception of **ketoconazole**, **pentobarbital**, **phenobarbital** and **prednisone**, appear to have been studied in patients, so that the clinical importance of these predicted interactions awaits formal clinical evaluation.

Taxanes; Paclitaxel + Antiepileptics

Enzyme-inducing antiepileptics (phenytoin, carbamazepine, and phenobarbital) increase the clearance of paclitaxel and increase its maximum tolerated dose.

Clinical evidence, mechanism, importance and management

In a study in patients with glioblastoma multiforme the maximum tolerated dose (MTD) of paclitaxel was 43% higher in patients receiving antiepileptics (**phenytoin**, **carbamazepine**, and **phenobarbital**) than in those not receiving them.¹ Another study in patients with recurrent malignant gliomas reported the same finding: a 50% increase in MTD coupled with a 104% increase in plasma clearance of paclitaxel in those taking antiepileptics. In addition, this study reported that the dose-limiting toxicity differed: central neurotoxicity in those taking antiepileptics and myelosuppression and/or gastrointestinal toxicity in those not.²

It is probable that enzyme-inducing antiepileptics increase the metabolism of paclitaxel, and therefore it is likely that patients taking these antiepileptics will require an increase in paclitaxel dose. Further study is needed. Note that barbiturates are predicted to increase the metabolism of docetaxel, see 'Taxanes; Docetaxel + Miscellaneous', above.

Taxanes; Paclitaxel + Ketoconazole

Ketoconazole does not appear to affect the pharmacokinetics of paclitaxel.

Clinical evidence, mechanism, importance and management

Women with ovarian cancer were treated with 3-hour infusions of paclitaxel 175 mg/m² once every 21 days. It was found that when single oral doses of ketoconazole were given 3 hours before or 3 hours after the paclitaxel, the serum levels of the paclitaxel and its principal metabolite (6- α -hydroxypaclitaxel) remained unchanged. These findings confirmed those of *in vitro* studies. The conclusion was reached that these two drugs can therefore be given together safely without any dosage adjustments.^{1,2}

2. Taxol (Paclitaxel). Bristol-Myers Squibb Pharmaceuticals Ltd. UK Summary of product characteristics, August 2005.

Taxanes; Paclitaxel + Miscellaneous

In vitro studies with human liver tissue suggest that no metabolic interactions are likely to occur between paclitaxel and cimetidine, dexamethasone or diphenhydramine. *Cremophor* may inhibit the intracellular uptake and metabolism of paclitaxel.

Clinical evidence, mechanism, importance and management

(a) *Cimetidine, Dexamethasone, Diphenhydramine*

On the basis of an *in vitro* study using human liver slices and human liver microsomes it has been concluded that the metabolism of paclitaxel is unlikely to be altered by cimetidine, dexamethasone or diphenhydramine, all of which are frequently given to prevent the hypersensitivity reactions associated with paclitaxel or its vehicle, *Cremophor* (see b, below).¹ The UK manufacturers say that paclitaxel clearance in patients is not affected by cimetidine premedication,² although some authors³ have advised caution when using cimetidine with docetaxel or paclitaxel since cimetidine is known to affect the cytochrome P450 isoenzyme CYP3A4, which is responsible, in part, for the metabolism of these taxanes.

(b) *Cremophor*

In vitro, *Cremophor* was found to inhibit the metabolism of paclitaxel in human liver microsomes,¹ which might be expected to increase its toxicity. The concentration used in the *in vitro* study may be achieved clinically in patients given paclitaxel with *Cremophor* as the vehicle.⁴ This may be worth bearing in mind if other drugs formulated with *Cremophor* are given with paclitaxel.

(c) *Methotrexate*

An *in vitro* study in human bladder cancer cells found that the antineoplastic effect of paclitaxel in combination with methotrexate was dependent on the order of exposure to the two drugs.⁵

Temozolomide + Miscellaneous

Valproic acid may reduce the clearance of temozolomide. Carbamazepine, H₂-receptor antagonists, dexamethasone, phenobarbital, phenytoin, prochlorperazine and ondansetron did not affect the clearance. Food, but not ranitidine slightly reduced extent of absorption of temozolomide.

Clinical evidence, mechanism, importance and management

The manufacturer notes that concurrent use of **carbamazepine, dexamethasone, H₂-receptor antagonists, ondansetron, phenobarbital, phenytoin or prochlorperazine** did not affect the clearance of temozolomide, based on an analysis of population pharmacokinetics from phase II studies.^{1,2} However, **valproic acid** modestly reduced the clearance of temozolomide.^{1,2}

Ranitidine 150 mg twice daily had no effect on the absorption or plasma pharmacokinetics of temozolomide, or that of its active metabolite in a study in 12 patients given temozolomide 150 mg/m² daily.³ The manufacturer notes that **food** slightly reduces the temozolomide AUC by 9% and maximum plasma concentration by 33%. They recommend that it should be given without **food**.^{1,2}

Teniposide + Antiepileptics

Carbamazepine, phenytoin and phenobarbital markedly increase the clearance of teniposide. A reduction in its effects has been noted in B-lineage leukaemia.

Clinical evidence, mechanism, importance and management

The clearance of teniposide was increased two to threefold (from 13 to 32 mL/minute per m¹) in 6 children with acute lymphocytic leukaemia when they also took **phenytoin** or **phenobarbital**.² Another patient had a twofold increase in teniposide clearance when **carbamazepine** was given.² In a retrospective survey, long-term antiepileptic use (**phenytoin, phenobarbital, carbamazepine**, or a combination) was associated with worse event-free survival, and greater haematological relapse and CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leukaemia. In this study, faster clearance of teniposide was found in those receiving antiepileptics.¹

These effects probably occur because these antiepileptics are potent liver enzyme inducers, which may increase the metabolism of teniposide by the liver and thereby reduce its levels. The authors of these reports therefore conclude that an increased dosage of teniposide will be needed in the presence of these antiepileptics to achieve systemic exposure to the drug comparable to that achievable in their absence.² It may be preferable to use alternative antiepileptics (that are not enzyme inducers) in patients requiring teniposide.¹ More study is needed.

Thalidomide + Doxorubicin

The concurrent use of thalidomide and doxorubicin is associated with an increased risk of deep-vein thrombosis in patients with multiple myeloma.

Clinical evidence, mechanism, importance and management

In a study in 100 patients with newly diagnosed multiple myeloma given induction chemotherapy (dexamethasone, vincristine, doxorubicin, cyclophosphamide, etoposide and cisplatin) with or without thalidomide, deep vein thrombosis developed in 14 of the 50 patients (28%) given thalidomide compared with 2 of 50 patients (4%) not given thalidomide.¹ Deep vein thrombosis has been reported to occur in 10% of patients treated for multiple myeloma but is reported to occur in about 2% in patients with multiple myeloma treated with thalidomide alone.¹

In a further study by the same authors, 232 patients with multiple myeloma were treated with DT-PACE (dexamethasone, thalidomide, cisplatin, doxorubicin, cyclophosphamide, etoposide) if they had preceding standard dose therapy but no prior autotransplantation, or with DCEP-T (dexamethasone, cyclophosphamide, etoposide, cisplatin, thalidomide) for relapse after transplantation. Deep-vein thrombosis developed in 31 of 192 patients (16%) treated with the doxorubicin-containing regimen (DT-PACE) and only 1 of 40 (2.5%) treated with DCEP-T (no doxorubicin).²

In patients with multiple myeloma, the risk of deep-vein thrombosis appears to be increased when thalidomide is given with combination chemotherapy containing doxorubicin. It has been suggested that, until more information is available, the concurrent use of thalidomide and doxorubicin should probably be limited to patients in monitored investigational studies.²

Thalidomide + Epoetins

A higher than expected incidence of thromboembolic events occurred in patients with myelodysplastic syndrome treated with thalidomide and darbepoetin-alfa, but not in patients with multiple myeloma given thalidomide with epoetin.

Clinical evidence, mechanism, importance and management

A phase II study to investigate the efficacy and tolerability of the concurrent use of thalidomide 100 mg daily and **darbepoetin-alfa** 2.25 micrograms/kg per week subcutaneously in patients with myelodysplastic syndrome was discontinued because of an unexpectedly high incidence of thromboembolic events. Of the first 7 patients enrolled in the study, two developed deep vein thrombosis and one died of pulmonary embolism. The authors recommended careful monitoring and possibly thromboprophylaxis (heparin or warfarin) in patients with myelodysplastic syndrome given both thalidomide and epoetin.¹

In contrast to these findings, in a study in patients with multiple myeloma treated with thalidomide, thromboses were reported in 4 of 49 patients (8.1%) also treated with epoetin and in 14 of 150 patients not treated with epoetin (9.3%). These results suggest that epoetin does not increase the risk of thrombosis in patients with multiple myeloma receiving thalidomide.²

The differences in findings have not been explained, but may be due to differences in both the disease states and the actions of darbepoetin alfa and epoetin in different regimens.

2. Galli M, Elice F, Crippa C, Comotti B, Rodeghiero F, Barbui T. Recombinant human erythropoietin and the risk of thrombosis in patients receiving thalidomide for multiple myeloma. *Haematologica* (2004) 89, 1141–2.

Thalidomide + Interferons

Severe bone marrow depression is reported in a patient given thalidomide with peginterferon alfa.

Clinical evidence, mechanism, importance and management

A patient with multiple myeloma in remission after an autologous stem cell transplantation was given thalidomide 200 mg daily. Five weeks after also being given **peginterferon alfa-2b** severe reversible bone marrow hypoplasia developed. **Peginterferon** was probably responsible for the bone marrow depression. However, thalidomide may also cause bone marrow depression and it was suggested that the severe suppression in this patient may have been due to the combined effects of the **peginterferon** and thalidomide.¹

1. Gómez-Rangel JD, Ruiz-Delgado GJ, Ruiz-Argüelles GJ. Pegylated-interferon induced severe bone marrow hypoplasia in a patient with multiple myeloma receiving thalidomide. *Am J Hematol* (2003) 74, 290–1.

Thalidomide + Miscellaneous

Rifampicin and phenobarbital did not appear to alter thalidomide clearance in one study. Thalidomide increases the effect of other CNS depressants, and its CNS depressant activity is reduced by CNS stimulants. Thalidomide does not alter the pharmacokinetics of oral contraceptive steroids.

Clinical evidence, mechanism, importance and management

(a) CNS depressants

Animal studies have shown an increase in CNS depressant activity when thalidomide was given with **alcohol**, **barbiturates**, **chlorpromazine** and **reserpine**.¹

(b) CNS stimulants

The depressant effect of thalidomide is reduced by the concurrent use of CNS stimulants such as **metamfetamine** and **methylphenidate**.¹

(c) Cytochrome P450 isoenzyme inducers

There was no clear relationship between thalidomide clearance and the concurrent use of enzyme inducers such as **rifampicin (rifampin)**, or **phenobarbital** in a study in patients with glioma.² For the possible additive CNS depressant effect with barbiturates, see *CNS depressants*, above.

(d) Hormonal contraceptives

Thalidomide 200 mg daily for 3 weeks did not alter the pharmacokinetics of single doses of **ethinylestradiol/norethisterone** in two studies in healthy women.^{3,4} Thalidomide is not therefore expected to alter the clinical efficacy of oral contraceptives. Note that, because thalidomide is an established human teratogen, it is very important that women taking it do not become pregnant. In the USA, it is standard practice to recommend that two forms of contraception should be used, of which hormonal contraceptives can be one.⁵ This is because, even though hormonal methods of contraception are highly effective, they do, on rare occasions, fail.

5. Thalomid (Thalidomide). Calgene Corp. US Prescribing information, February 2007.

Thalidomide + Zoledronic acid

The pharmacokinetics of zoledronic acid are not affected by thalidomide.

Clinical evidence, mechanism, importance and management

In a study intravenous zoledronic acid 4 mg every 4 weeks with alternate day prednisolone was given with or without thalidomide 200 mg daily for up to 1 year. The zoledronic acid pharmacokinetics were not affected by thalidomide and based on renal function no clinically adverse interaction occurred during concurrent use. The subjects in this study were patients with multiple myeloma with no disease progression 6 weeks after autologous stem-cell transplantation and conditioning with melphalan.¹

1. Spencer A, Roberts A, Bailey M, Schran H, Lynch K. No evidence for an adverse interaction between zoledronic acid and thalidomide: preliminary safety analysis from the Australasian Leukaemia and Lymphoma Group (ALLG) MM6 Myeloma Trial. *Blood* (2003) 102, 383–4.

Thiopurines + Allopurinol

The haematological effects of azathioprine and mercaptopurine are markedly increased by allopurinol.

Clinical evidence

(a) Azathioprine

A patient taking allopurinol 300 mg daily for gout was also given azathioprine 100 mg daily to treat autoimmune haemolytic anaemia. Within 10 weeks his platelet count fell from 236 to 45 x 10⁹/L, his white cell count fell from 9.4 to 0.8 x 10⁹/L and his haemoglobin concentration fell from 11.5 to 5.3 g/dL.¹

A number of other reports similarly describe reversible bone marrow toxicity associated with anaemia, pancytopenia, leucocytopenia and thrombocytopenia in patients given azathioprine with allopurinol,^{1–9} and in one case a fatality occurred as a result of neutropenia and septicemia.⁸ In a retrospective analysis of 24 patients who had received both azathioprine and allopurinol, 11 developed leucopenia, 7 developed moderate anaemia, and 5 developed thrombocytopenia. Only 14 of the patients had received a greater than two-thirds reduction in their azathioprine dose when allopurinol was started, but despite this, some of these patients still developed haematological toxicity.¹⁰

(b) Mercaptopurine

In early studies, allopurinol 200 to 300 mg reduced the effective dose of mercaptopurine by approximately fourfold in 7 patients with chronic granulocytic leukaemia or variants.¹¹

Profound pancytopenia developed in the first 3 of 13 children given maintenance treatment with mercaptopurine 2.5 mg/kg daily and allopurinol 10 mg/kg daily, but when the mercaptopurine dosage was halved, toxicity was manageable in the remaining 9 children.¹² Severe leucopenia and thrombocytopenia occurred in another patient given allopurinol with standard dose mercaptopurine.¹³

A pharmacokinetic study found that allopurinol caused a fivefold increase in the AUC and in peak plasma mercaptopurine levels when the mercaptopurine was given *orally*. The bioavailability increased from 12% to 59%.¹⁴ This did not occur when the mercaptopurine was given *intravenously*.^{14,15}

Mechanism

Azathioprine is firstly metabolised in the liver to mercaptopurine and then enzymatically oxidised in the liver and intestinal wall by xanthine oxidase to an inactive compound (6-thiouric acid), which is excreted. Allopurinol inhibits first-pass metabolism by xanthine oxidase so that mercaptopurine accumulates, blood levels rise and its toxic effects develop (leucopenia, thrombocytopenia, etc.).

Importance and management

A well documented, well established, clinically important and potentially life-threatening interaction. The dosages of azathioprine and mercaptopurine should be reduced by about two-thirds or three-quarters when given orally to reduce the development of toxicity. Despite taking these precautions toxicity may still be seen¹⁰ and very close haematological monitoring is advisable if concurrent use is necessary. On the basis of two studies^{14,15} it would seem that this precaution might not be necessary if mercaptopurine is given intravenously, but note that parenteral mercaptopurine is not routinely available.

Thiopurines + 5-Aminosalicylates

The haematological toxicity of azathioprine and mercaptopurine may be increased by mesalazine, olsalazine or sulfasalazine. Balsalazide may be less likely to interact but this requires confirmation.

Clinical evidence

(a) Balsalazide

The frequency of clinically important neutropenia did not increase significantly in 10 patients with Crohn's disease receiving **azathioprine** or **mercaptopurine** when they were given balsalazide 6.75 g daily for

8 weeks, but significant increases in whole blood 6-thioguanine nucleotide concentrations were seen.¹

(b) Mesalazine

A 13-year old boy with severe ulcerative pancolitis and cholangitis was treated with prednisone 60 mg daily, ursodeoxycholic acid 15 mg/kg daily and mesalazine 25 mg/kg daily. When **azathioprine** 2 mg/kg daily was added in an attempt to reduce the prednisone dosage, he developed marked and prolonged **azathioprine** toxicity (severe pancytopenia), which was attributed to an interaction resulting from abnormally high, persistent levels of an **azathioprine** metabolite.² In another study, there was a trend towards an increased rate of clinically important neutropenia in 10 patients with Crohn's disease receiving **azathioprine** or **mercaptopurine** when they were given mesalazine 4 g daily for 8 weeks. One patient was withdrawn from the study after 6 weeks because of leucopenia. Significant increases in whole blood 6-thioguanine nucleotide concentrations were also seen.¹

(c) Olsalazine

A case report describes a patient with Crohn's disease who had two separate episodes of bone marrow suppression while receiving **mercaptopurine** 50 to 75 mg daily and olsalazine 1 to 1.75 g daily. It was found necessary to reduce the **mercaptopurine** dosage on the first occasion and to withdraw both drugs on the second.³

(d) Sulfasalazine

A decrease in leucocyte counts was seen in 4 patients taking **azathioprine** (2.1 to 3.3 mg/kg daily) after the addition of sulfasalazine. This lasted several months in one patient, and was transitory in two. The fourth patient developed agranulocytosis after 4 days, which required treatment discontinuation. When the drugs were later resumed at a lower dose, no reduction in leucocyte counts occurred.⁴ Another report describes 38 patients taking **azathioprine** (mean dose 92.8 mg) and sulfasalazine (mean dose 2.1 g) for rheumatoid or psoriatic arthritis. Some patients did well, but in general the combination was poorly tolerated, and only 45% continued treatment after 6 months. Reasons for withdrawal included rash (3 patients), gastrointestinal upset (7), leucopenia (1) and nephrotic syndrome (1).⁵ In another study, there was a trend towards an increased rate of clinically important neutropenia in 12 patients with Crohn's disease receiving **azathioprine** or **mercaptopurine** when they were given sulfasalazine 4 g daily for 8 weeks. One patient withdrew from the study after 6 weeks because of leucopenia. Significant increases in whole blood 6-thioguanine nucleotide concentrations were also found.¹

Mechanism

The metabolism of azathioprine and mercaptopurine depends on *S*-methylation by thiopurine methyltransferase (TPMT) and oxidation by xanthine oxidase. An *in vitro* study using recombinant TPMT found that both sulfasalazine and its metabolites inhibit the activity of TPMT.⁶ Therefore if these drugs are used together, the clearance of azathioprine and mercaptopurine may be reduced by the sulfasalazine, resulting in an increase in their toxicity (there is only a small margin between their therapeutic and toxic levels). About 11% of patients may be at particular risk because of genetic polymorphism whereby they have TPMT enzyme activity that is only half that of the rest of the population.^{1,6} *In vitro* studies confirmed that mesalazine,⁷ olsalazine and its metabolite olsalazine-*O*-sulfate^{3,7} and balsalazide⁷ are inhibitors of recombinant TPMT. In patients, increased levels of 6-thioguanine nucleotide are probably due to inhibition of TPMT.¹ It is suggested that the reported *in vitro* concentration (IC₅₀) of balsalazide required to halve the TPMT activity is about 1000 times higher than peak plasma levels after therapeutic doses and therefore an interaction is unlikely. Mesalazine and olsalazine peak levels may also be less than the IC₅₀ concentrations, but peak plasma levels of sulfasalazine are close to IC₅₀ concentrations.⁸

Importance and management

These reports underline the importance of taking particular care if azathioprine or mercaptopurine are used with balsalazide, mesalazine, olsalazine, or sulfasalazine. Balsalazide may be less likely to interact, but this requires confirmation.¹ Some have postulated that the interaction may actually benefit patients, as increased whole blood 6-thioguanine nucleotide

or mild leucopenia is associated with a greater chance of remission in those taking azathioprine or mercaptopurine.^{1,9} Extra monitoring of white blood cell counts is required when starting therapy with the combination.⁹ More study is needed.

Thiopurines; Azathioprine + Co-trimoxazole or Trimethoprim

There is some evidence that the risk of haematological toxicity may be increased in renal transplant patients taking azathioprine if they are given co-trimoxazole or trimethoprim, particularly if they are given for extended periods. However, other evidence suggests that the drugs may be used together safely, and the combination is commonly used in practice.

Clinical evidence

The observation that haematological toxicity often seemed to occur in renal transplant patients given azathioprine and co-trimoxazole, prompted a retrospective survey of the records of 40 patients. It was found that there was no difference in the incidence of thrombocytopenia and neutropenia in those given azathioprine, either alone, or with co-trimoxazole, (trimethoprim 160 to 320 mg and sulfamethoxazole 800 mg to 1.6 g daily) for a short time (6 to 16 days), but a significant increase occurred in the incidence and duration of thrombocytopenia and neutropenia if both drugs were given together for 22 days or more.¹

Another report describes a marked fall in white cell counts in renal transplant recipients during concurrent treatment with either co-trimoxazole (described as frequent) or trimethoprim (3 cases).² In one case the fall occurred within 5 days and was managed by temporarily withdrawing the azathioprine and reducing the trimethoprim dosage from 300 to 100 mg daily.²

Conversely, in an early study, there was no difference in the incidence of leucopenia when renal transplant recipients were given co-trimoxazole or other antibacterials.³ Similarly, in 252 renal transplant patients given continuous prophylaxis with co-trimoxazole or **sulfafurazole** for 12 to 25 months, toxicity was minimal: leucopenia occurred only occasionally and was reversed by temporarily withholding azathioprine. This was needed in a similar number of patients with each antibacterial.⁴ In another placebo-controlled study in cardiac transplant recipients taking triple therapy including azathioprine, co-trimoxazole prophylaxis for 4 months did not alter total white blood cell counts: leucopenia did not occur and no change in azathioprine dose was required.⁵

Mechanism

Not understood. It seems possible that the bone marrow depressant effects of all three drugs may be additive. In addition, in some patients impaired renal function may allow co-trimoxazole levels to become elevated, and haemodialysis may deplete folate levels, which could exacerbate the anti-folate effects of the co-trimoxazole. Trimethoprim has been shown to inhibit renal tubular creatinine secretion.⁶

Importance and management

Information appears to be limited and the interaction is not established. Although there is some evidence of increased risk of haematological toxicity in renal transplant patients taking azathioprine if they are treated with co-trimoxazole or trimethoprim, this has not been shown in all studies. Two of the early studies suggested that the incidence of leucopenia with co-trimoxazole was related to the time after transplantation, and it improved if the dose of azathioprine was decreased or temporarily suspended.^{3,7} Prophylaxis with co-trimoxazole post-transplant is commonly used in some centres.

Thiopurines; Mercaptopurine + Doxorubicin

One study postulated that the hepatotoxicity of intravenous mercaptopurine can be increased by doxorubicin.

Clinical evidence, mechanism, importance and management

One report describes 11 patients who developed liver damage after being given *intravenous* mercaptopurine 500 mg/m² daily for 5 days, with doxorubicin 50 mg/m² on the first day. The frequency and severity of liver damage was greater than the authors had previously seen with mercaptopurine alone. They postulated that doxorubicin potentiated the hepatotoxicity of mercaptopurine.¹ Mercaptopurine is no longer commonly used *intravenously*, and the dose given in this study is much higher than that currently used *orally*. The general applicability of this study is therefore unknown.

1. Minow RA, Stern MH, Casey JH, Rodriguez V, Luna MA. Clinico-pathological correlation of liver damage in patients treated with 6-mercaptopurine and adriamycin. *Cancer* (1976) 38, 1524–8.

Thiopurines; Mercaptopurine + Food

Food may reduce and delay the absorption of mercaptopurine.

Clinical evidence

A study in 17 children with acute lymphoblastic leukaemia showed that the absorption of mercaptopurine 5 mg/m² was reduced if it was given 15 minutes after a standard **breakfast** of 250 mL of milk and 50 g of biscuits, when compared with fasting. The AUC was reduced by 26%, the maximum plasma levels by 36%, and the time to maximum plasma levels delayed from 1.2 to 2.3 hours.¹ Some individuals showed more marked effects than others; 11 subjects had a decrease in absorption, whereas 6 subjects had no change or a small increase.¹ Similarly, in another study in 7 children, peak plasma mercaptopurine levels were lower and were delayed when it was given with a **standard breakfast** compared with those after an overnight fast.² However, in a third study in 10 children, mercaptopurine levels varied widely between individuals and there was no clear effect of food. The peak plasma levels were increased only 11% (range 67% decrease to 81% increase), and the AUC was increased by a mean of 3% (range 53% decrease to 86% increase) when given in the fasting state compared with after food.³

Mechanism

Not understood. Delayed gastric emptying is a suggested reason.¹

Importance and management

The documentation is limited, and the interaction is not established. Mercaptopurine levels vary widely, and it is not established whether food is a clear factor in this variation. Some have suggested that mercaptopurine should be taken before food to optimise its absorption,² whereas others do not consider the evidence sufficient to make a recommendation.³

Thiopurines; Mercaptopurine + Methotrexate

Methotrexate can increase the bioavailability of mercaptopurine, but the contribution this makes to their synergistic action in leukaemia is unclear. One report suggests the combination may not be synergistic.

Clinical evidence, mechanism, importance and management

In 14 children receiving maintenance therapy for leukaemia oral low-dose methotrexate 20 mg/m² increased the AUC and peak plasma levels of mercaptopurine 75 mg/m² by 31% and 26%, respectively.¹ In another study, 10 children with acute lymphoblastic leukaemia in remission were treated with mercaptopurine 25 mg/m² daily and intravenous infusions of high-dose methotrexate 2 or 5 g/m² once every other week for consolidation therapy. It was found that methotrexate 2 or 5 g/m² increased the AUC of mercaptopurine by 69% and 93%, respectively, and raised the maximum serum levels of mercaptopurine by 108% and 121%, respectively.² The reasons for this pharmacokinetic interaction are not understood, although it is thought that methotrexate is a xanthine oxidase inhibitor, which may therefore inhibit the metabolism of mercaptopurine.^{1,2}

The combination of methotrexate and mercaptopurine has an established place in the therapy of leukaemia and has been found to be synergistic. These pharmacokinetic findings may be part of the explanation for this, although biochemical mechanisms may be more important.³ The risk of relapse of leukaemia did not appear to be related to the pharmacokinetics of methotrexate or mercaptopurine, which showed considerable inter and inpatient variability, in one study in children.⁴

In contrast, one report suggests that, in certain circumstances at least, the combination of mercaptopurine and methotrexate may not be synergistic. In a study, children with newly diagnosed acute lymphoblastic leukaemia were given intravenous mercaptopurine 1 g/m² over 6 hours, either alone, or after low-dose oral methotrexate (6 doses of 30 mg/m²) or high-dose intravenous methotrexate (1 g/m² over 24 hours). Methotrexate increased the plasma levels of mercaptopurine, but, unexpectedly, it was also found that thioguanine nucleotide levels in bone marrow leukaemic lymphoblasts were 13-fold lower during methotrexate use. It is not known whether methotrexate would reduce thiopurine metabolite levels in leukaemic lymphoblasts when mercaptopurine is given as continuation therapy where the leukaemic burden is less substantial than in newly diagnosed cases. In addition, the changes in leukocyte counts over 3 days suggested mercaptopurine alone had little effect, and although methotrexate caused a reduction in intracellular thiopurine metabolite levels, it produced a greater decrease in leukocytes than mercaptopurine alone. It was concluded that in this particular study, the antileukaemic effect was primarily due to methotrexate.⁵

Topotecan + Amifostine

In 10 women with ovarian cancer amifostine (given daily, before topotecan, for 5 days) did not significantly affect the pharmacokinetics of topotecan.¹

1. Zackrisson A-L, Malmström H, Peterson C. No evidence that amifostine influences the plasma pharmacokinetics of topotecan in ovarian cancer patients. *Eur J Clin Pharmacol* (2002) 58, 103–8.

Topotecan + Phenytoin

Phenytoin may possibly increase topotecan clearance.

Clinical evidence, mechanism, importance and management

A 5-year-old child with medulloblastoma received a course of topotecan, firstly with phenytoin and then without. Phenytoin increased the total topotecan clearance by 47%.¹ This suggests that an increased topotecan dosage may possibly be needed in the presence of phenytoin in other patients. For a similar effect of antiepileptics on related topoisomerase inhibitors, see 'Irinotecan + Antiepileptics', p.638 and '9-Aminocamptothecin + Antiepileptics', p.610.

1. Zamboni WC, Gajjar AJ, Heideman RL, Beijnen JH, Rosing H, Houghton PJ, Stewart CF. Phenytoin alters the disposition of topotecan and *N*-desmethyl topotecan in a patient with medulloblastoma. *Clin Cancer Res* (1998) 4, 783–9.

Topotecan + Probenecid

In mice, probenecid markedly inhibited the renal tubular secretion of topotecan, which led to an increase in topotecan systemic exposure.¹

1. Zamboni WC, Houghton PJ, Johnson RK, Hulstein JL, Crom WR, Cheshire PJ, Hanna SK, Richmond LB, Luo X, Stewart CL. Probenecid alters topotecan systemic and renal disposition by inhibiting renal tubular secretion. *J Pharmacol Exp Ther* (1998) 284, 89–94.

Topotecan + Ranitidine

Ranitidine does not alter the pharmacokinetics of topotecan.

Clinical evidence, mechanism, importance and management

In 18 patients with solid tumours, the pharmacokinetics of topotecan (given in initial doses of 2.3 mg/m² daily for 5 days and repeated every 3 weeks) and its active metabolite, topotecan lactone, were not affected by the previous use of ranitidine 150 mg twice daily for 4 days.¹ No special precautions would seem necessary if ranitidine or other drugs that increase gastric pH are given with oral topotecan.

1. Akhtar S, Beckman RA, Mould DR, Doyle E, Fields SZ, Wright J. Pretreatment with ranitidine does not reduce the bioavailability of orally administered topotecan. *Cancer Chemother Pharmacol* (2000) 46, 204–10.

Toremifene + Antiepileptics

Carbamazepine, phenobarbital and possibly phenytoin can reduce the serum levels of toremifene.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study of toremifene in two groups of 10 patients (a control group and a group of patients taking antiepileptics) found that the AUC of a single 120-mg dose of toremifene and its half-life was approximately halved in the antiepileptic group. The antiepileptics used were **carbamazepine** alone (3 patients) or with clonazepam (3 patients), or **phenobarbital** alone (3 patients) or with **phenytoin** (1 patient). This interaction is thought to occur because these antiepileptics induce the liver enzymes (almost certainly the cytochrome P450 isoenzyme CYP3A4) by which toremifene is metabolised, resulting in increased toremifene clear-

ance.¹ The UK manufacturers of toremifene have therefore reasonably suggested that the toremifene dosage may need to be doubled in the presence of these antiepileptics.²

1. Anttila M, Laakso S, Nyländén P, Sotaniemi EA. Pharmacokinetics of the novel antiestrogenic agent toremifene in subjects with altered liver and kidney function. *Clin Pharmacol Ther* (1995) 57, 628–35.
2. Fareston (Toremifene citrate). Orion Pharma UK Ltd. UK Summary of product characteristics, February 2006.

Toremifene + Miscellaneous

Based on theoretical considerations, the manufacturers advise care when toremifene is given with thiazides and with CYP3A inhibitors such as erythromycin, ketoconazole, and troleandomycin.

Clinical evidence, mechanism, importance and management

The manufacturers of toremifene note that it is mainly metabolised by the cytochrome P450 isoenzymes CYP3A4, CYP3A5, and CYP3A6 so it is suggested that drugs that can inhibit these enzymes (such as **erythromycin, troleandomycin, ketoconazole**) may possibly increase its effects.^{1,2}

Hypercalcaemia is a recognised adverse effect of toremifene, and it is suggested that drugs such as the **thiazides**, which decrease renal calcium excretion, may increase the risk of hypercalcaemia.^{1,2} These warnings are based on indirect evidence and theoretical considerations so that their clinical importance awaits confirmation.

1. Fareston (Toremifene citrate). Orion Pharma UK Ltd. UK Summary of product characteristics, February 2006.
2. Fareston (Toremifene citrate). GTx, Inc. US Prescribing information, December 2004.

Toremifene + Rifampicin (Rifampin)

Rifampicin increases the metabolism of toremifene, and might be expected to reduce its efficacy.

Clinical evidence, mechanism, importance and management

A study in 9 healthy men found that rifampicin 600 mg daily for 5 days reduced the AUC, peak plasma levels, and half-life of a single 120-mg dose of toremifene by 87%, 55%, and 44%, respectively. Similarly, the AUC of *N*-demethyltoremifene was reduced by 80%.¹ Rifampicin may therefore reduce the efficacy of toremifene.¹

Tretinoin + Antifibrinolytics

In acute promyelocytic leukaemia the combination of tretinoin and antifibrinolytics such as tranexamic acid and aprotinin has been associated with fatal thrombotic complications.

Clinical evidence, mechanism, importance and management

In an analysis of 31 patients with acute promyelocytic leukaemia (APL) treated over a 7-year period, **tranexamic acid** 1 to 2 g daily for 6 days was given for prophylaxis of haemorrhage to 15 of 24 patients receiving tretinoin and chemotherapy, 4 of 4 receiving tretinoin only and 2 of 3 receiving chemotherapy only. Seven of the patients treated with tretinoin died during the study period and 4 of them, who had received only the combination of tretinoin and **tranexamic acid**, died within 42 days (early deaths). Three of the early deaths were attributed to thrombotic complications.¹ Another earlier report describes a similar fatal case of thromboembolism in a patient treated with tretinoin and **tranexamic acid**,² and another in a patient treated with tretinoin and **aprotinin**.³ A further report describes acute renal cortex necrosis as a result of arterial thrombosis in a patient treated with tretinoin and **tranexamic acid**.⁴ Tretinoin alone causes a pro-coagulant tendency in APL, and this may be exacerbated by use of antifibrinolytics. Although antifibrinolytics and chemotherapy may be safely used concurrently in APL, the combination of tretinoin and antifibrinolytics can cause fatal thrombotic complications and should be used with cau-

tion. The use of blood, platelets and plasma rather than **tranexamic acid** for prophylaxis of haemorrhage has been advocated for APL patients.¹

Tretinoin + Azoles

The metabolism of tretinoin can be inhibited by fluconazole, and a case report describes tretinoin toxicity as a result of this interaction. Ketoconazole may interact similarly.

Clinical evidence, mechanism, importance and management

A 4-year-old boy with acute promyelocytic leukaemia was given induction chemotherapy consisting of cytarabine, daunorubicin and tretinoin 45 mg/m² daily in two divided doses. Febrile neutropenia was treated with meropenem and amphotericin B for periods up to day 20. On day 20 he started antifungal prophylaxis with **fluconazole** 100 mg daily. The next day he complained of headache and a week later he had headache, vomiting and papilloedema. His CT scan was normal. Pseudotumor cerebri was diagnosed and symptoms of increased intracranial pressure resolved within a day of stopping tretinoin. Restarting tretinoin on day 30 at 75% of the previous dose resulted in headache and vomiting, and the treatment was continued from day 35 with an even lower dose (30%), which caused headache but only one episode of vomiting. **Fluconazole** was stopped on day 41 and within 24 hours the patient had improved clinically with the headache and vomiting fully resolved. He was then able to tolerate the full dose of tretinoin without adverse effects.¹

Fluconazole inhibits the cytochrome P450 isoenzymes CYP3A4 and CYP2C9, which are amongst those involved in the oxidative metabolism of tretinoin, and it was suggested that this resulted in increased plasma levels of tretinoin.¹ Another study has also shown that **fluconazole** may inhibit the ADPH-dependent cytochrome P450-mediated metabolism of tretinoin.² **Ketoconazole** may similarly affect the pharmacokinetics of tretinoin.³

Although it has been suggested that drugs such as **fluconazole** may be useful in overcoming clinical resistance to tretinoin,² it has also been suggested that the concurrent use of tretinoin with drugs that affect its metabolism should be avoided if possible, or patients should be carefully monitored.¹

Vinca alkaloids + Azoles

Itraconazole can increase the toxicity of vincristine and vinblastine; posaconazole and voriconazole may interact similarly. There is a theoretical possibility that itraconazole and ketoconazole may increase the toxicity of vinorelbine.

Clinical evidence, mechanism, importance and management

Four out of 14 patients with ALL given induction chemotherapy with weekly injections of **vincristine** (with prednisone, daunorubicin and asparaginase) and antifungal prophylaxis with **itraconazole** 400 mg daily, developed severe and early **vincristine**-induced neurotoxicity (paraesthesia and muscle weakness of the hands and feet, paralytic ileus, mild laryngeal nerve paralysis). The degree and early onset of these neurotoxic reactions were unusual, and were all reversible except for mild paraesthesia in one patient. The complications were more serious than in a previous

series of 460 patients given **vincristine** without **itraconazole** (29% compared to 6%).¹ Five children with ALL developed severe **vincristine** toxicity attributed to the concurrent use of **itraconazole**. They were also receiving 'nifedipine', (p.671), which is known to reduce the clearance of **vincristine**, and which may have made things worse.² Severe **vincristine** neurotoxicity developed in four other children³⁻⁵ and two adults⁶ with ALL when they were given **itraconazole**. Another study similarly indicates that greater **vincristine** toxicity may occur in patients given **itraconazole**.⁷

The reasons for this interaction are not understood, but among the suggestions are that the **itraconazole** inhibits the metabolism of **vincristine** by the cytochrome P450 enzyme system, so that it is cleared from the body less quickly.¹ Another possible explanation is that **itraconazole** inhibits P-glycoprotein,¹ and increased **vincristine** neurotoxicity may be the result of the inhibition of this pump in endothelial cells of the blood-brain barrier.⁷

The authors of one report¹ suggest that **itraconazole** should be avoided in patients taking **vincristine**, and the manufacturers of **vincristine** also issue a warning about the increased risks of concurrent use.⁸

Acute neurotoxicity and myelotoxicity occurred in a boy with Hodgkin's lymphoma treated with **vinblastine**, doxorubicin and methotrexate when he was also given **itraconazole**. The toxicity did not occur when he was given the same chemotherapy without itraconazole.⁹

Some UK¹⁰ and US¹¹ manufacturers advise caution if **vinorelbine**, which is metabolised by CYP3A4, is given with inhibitors of this isoenzyme such as **itraconazole** and **ketoconazole** because of the theoretical risk of increased neurotoxicity. The manufacturers of **vindesine** note that concurrent administration with CYP3A inhibitors may result in early onset or increased severity of vindesine side-effects.¹²

The manufacturers of **posaconazole** advise avoidance of concurrent use with vinca alkaloids (**vincristine** and **vinblastine** are named), but if they are given, then dose adjustments of the vinca alkaloids should be considered.¹³

The manufacturers of **voriconazole** advise caution if it is given to patients treated with the vinca alkaloids (**vincristine** and **vinblastine** are named) because of the risk of neurotoxicity.^{14,15} The US manufacturer recommends that dose adjustments of the vinca alkaloids should be considered.¹⁵

Vinca alkaloids + Macrolides

Erythromycin increased the toxicity of vinblastine in three patients. Clarithromycin possibly does not interact with vinca alkaloids.

Clinical evidence

Three patients with renal cell carcinoma given ciclosporin 10 or 13 mg/kg daily and **erythromycin** 1 g daily for 3 days developed severe toxicity when given **vinblastine** 7 to 10 mg/m² on the third day. Ciclosporin was used as a modifier of multidrug resistance and **erythromycin** was given to achieve higher ciclosporin levels at a lower dose (see 'Ciclosporin + An-

tibacterials; Macrolides', p.1016). To rule out increased ciclosporin toxicity, one patient was given **erythromycin** without ciclosporin but he still developed **vinblastine** toxicity (severe neutropenia, constipation, myositis, severe myalgia) typical of much higher doses of **vinblastine**. Of the other 2 patients, only negligible toxicity developed in one when he was later given **vinblastine** alone, and the other had received ciclosporin and **vinblastine** on two previous occasions without problems.¹ Other authors report that they have used **clarithromycin** with standard doses of vinca alkaloids in at least 6 patients without any evidence of increased toxicity.²

Mechanism

Uncertain, but erythromycin inhibits the cytochrome P450 isoenzyme CYP3A4, which is concerned with the metabolism of vinblastine.³ This would be expected to reduce the metabolism of vinblastine resulting in an increase in its toxicity.

Importance and management

Information seems to be limited to this report. On the basis of their findings the authors suggest that erythromycin should be avoided at the time of vinblastine infusion.¹ Use with clarithromycin may be safe.² The UK manufacturers of **vincristine** and **vindesine** have warned that caution should be exercised in patients taking any drugs known to inhibit the CYP3A subfamily because of the risk of an earlier onset and/or increased severity of adverse effects.^{4,5} One manufacturer of vinblastine states that erythromycin may increase vinblastine toxicity.⁶ Note that itraconazole, another CYP3A4 inhibitor, is known to increase the toxicity of vincristine, see 'Vinca alkaloids + Azoles', p.668.

Vinca alkaloids + Mitomycin

A syndrome of acute pulmonary toxicity, characterised by severe shortness of breath, can occur when vinblastine, vindesine or vinorelbine is given with mitomycin. Fatalities have occurred.

Clinical evidence, mechanism, importance and management

There are now numerous reports describing acute lung disease in patients given mitomycin with vinca alkaloids, which appears to be different to the chronic pulmonary fibrosis seen with mitomycin alone. Sudden onset of acute shortness of breath has been described shortly after administration of the vinca alkaloid as part of a vinca alkaloid and mitomycin-containing regimen. Chest radiographs have shown diffuse lung damage characterised by interstitial infiltrates and pulmonary oedema. The acute syndrome has usually improved over 24 hours, although some patients have chronic respiratory impairment (60% in one case series¹). Fatalities have occurred.²⁻⁴ The syndrome has been reported with mitomycin and **vinblastine**,¹⁻⁹ **vindesine**^{1,8,10-12} and **vinorelbine**.¹²⁻¹⁵ The incidence is reported to be about 3 to 6%.^{1,7,12}

The potential hazards of combining these drugs should be recognised, and in view of the unpredictability of the reaction, close observation of patients receiving this combination is recommended.^{1,3} If the reaction occurs, supportive measures such as supplemental oxygen and mechanical ventilation may be needed. Corticosteroids are also often used in an attempt to treat the acute symptoms, and to possibly decrease the risk of chronic respiratory impairment.¹ In patients who have developed acute pulmonary toxicity, the use of both mitomycin and vinca alkaloids should subsequently be avoided.¹

Vinca alkaloids; Vinblastine + Bleomycin

The combination of vinblastine and bleomycin with or without cisplatin commonly causes Raynaud's phenomenon. Rarely, it also appears to cause serious life-threatening cardiovascular toxicity.

Clinical evidence, mechanism, importance and management

Five patients (aged 23 to 58) treated for germ cell tumours died from unexpected acute life-threatening vascular events (myocardial infarction, rectal infarction, cerebrovascular accident) after treatment with VBP (vinblastine, bleomycin, cisplatin). A survey of the literature by the authors of this paper revealed 14 other cases of both acute and long-term cardiovascular problems (myocardial infarction, coronary heart disease, cerebrovascular accident) in patients given VBP.¹

Raynaud's phenomenon is common, occurring in one-third to half of those treated with vinblastine and bleomycin or VBP,^{2,3} and there is evidence that blood vessels are pathologically altered.² Cisplatin may contribute to the effect.³ Analysis of late vascular toxicity after chemotherapy for testicular cancer revealed that the use of VBP carried a higher risk of Raynaud's phenomenon than bleomycin with etoposide and cisplatin (BEP).⁴

The use of the VBP (PVB) regimen has largely been replaced by the BEP (PEB) regimen, because of its reduced toxicity.

Vinca alkaloids; Vinblastine + Protease inhibitors

Severe neutropenia has been seen in two patients given vinblastine and antiretroviral regimens including lopinavir/ritonavir.

Clinical evidence, mechanism, importance and management

A 55-year-old HIV-positive man who was taking zidovudine, lamivudine, abacavir, nevirapine and ritonavir-boosted lopinavir experienced unexpected severe gastrointestinal and haematological toxicities and moderate renal failure after the second and third intravenous injections of vinblastine 10 mg given to treat multicentric Castleman's disease (MCD). Subsequently, the antiretrovirals were stopped and the patient did not experience these toxicities when vinblastine was given alone. When the MCD was un-

der control, the antiretrovirals were then restarted, and the vinblastine dose reduced to 3 mg every three weeks without problems.¹ A second HIV-positive patient who was taking a lopinavir/ritonavir based antiretroviral regimen developed life-threatening neutropenia when given ABVD chemotherapy, consisting of doxorubicin, bleomycin, vinblastine and dacarbazine for Hodgkin's lymphoma. Further vinblastine treatment was successfully given by interrupting the protease inhibitors around the time the chemotherapy was given.²

It was suggested that the metabolism of vinblastine by the cytochrome P450 isoenzyme CYP3A was inhibited by ritonavir, resulting in increased toxicity.

These appear to be the only cases so far of a possible interaction. Nevertheless, it would now be prudent to carefully monitor any patient taking a ritonavir-based antiretroviral regimen who receives vinblastine. Further study is needed.

Vinca alkaloids; Vincristine + Antiepileptics

Carbamazepine and phenytoin appear to reduce the plasma levels of vincristine, and may reduce its efficacy. A number of case reports have described reduced phenytoin levels in patients receiving chemotherapy including vinca alkaloids.

Clinical evidence, mechanism, importance and management

The systemic clearance of vincristine 2 mg was 63% higher and the AUC was 43% lower in 9 patients receiving carbamazepine or phenytoin than in 6 patients not taking antiepileptics. In this study, patients were being treated with procarbazine, lomustine and vincristine for brain tumours.¹ In a retrospective survey, long-term antiepileptic use (phenytoin, phenobarbital, carbamazepine, or a combination) was associated with worse event-free survival, and greater haematological relapse and CNS relapse in children receiving chemotherapy for B-lineage acute lymphoblastic leukaemia. The authors considered that the increased clearance of vincristine induced by the antiepileptics was a likely factor in these findings.²

These enzyme-inducing antiepileptics increase the metabolism of vincristine by the cytochrome P450 isoenzyme CYP3A4. However, *in vitro* studies have shown that phenytoin may potentiate the antineoplastic (antimitotic) effects of the vinca alkaloids.^{3,4} Thus, further study is required to determine the overall effect of phenytoin on the efficacy and toxicity of vincristine and other vinca alkaloids. Carbamazepine would be expected to reduce the efficacy of vincristine.

Note that a number of case reports have described reduced phenytoin levels in patients receiving chemotherapy including vinca alkaloids, see 'Table 14.1', (p.519).

Vinca alkaloids; Vincristine + Asparaginase

An isolated case report suggests that vincristine neurotoxicity may possibly have been increased by subsequent asparaginase therapy.^{1,2} The UK manufacturer recommends that vincristine should be given 12 to 24 hours before asparaginase.³ Regimens including both drugs are commonly used in treating leukaemia.

- Vincristine sulphate. Mayne Pharma plc. UK Summary of product characteristics, April 2004.

Vinca alkaloids; Vincristine + Isoniazid

Some limited evidence suggests that vincristine neurotoxicity may possibly be increased by isoniazid.

Clinical evidence, mechanism, importance and management

An 85-year-old woman with Hodgkin's disease was given COPP/ABVD, alternating every 28 days. She started COPP (cyclophosphamide and 2 mg vincristine on day 1, with procarbazine and prednisone days 1 to 14) and was also given isoniazid 300 mg daily as prophylaxis of tuberculosis. Five days after the start of this treatment she experienced tingling in her fingers and weakness in her legs, which was interpreted by the authors of this report as being vincristine toxicity brought about by the concurrent use of isoniazid (paraesthesia of the feet and/or hands being a recognised early manifestation of vincristine toxicity). Their reasoning was that such a small dosage of vincristine dosage on its own was unlikely to cause severe neurotoxicity of this kind, but it is not clear why isoniazid should apparently interact like this. The authors suggest that the age of this patient and her diabetes (well controlled) may have contributed to this increase in vincristine neurotoxicity.¹

This report is consistent with another much earlier report of two patients who also developed peripheral neurotoxicity when they were given vincristine after starting to take isoniazid and pyridoxine, the cumulative doses of vincristine being 11 mg and 11.2 mg, respectively,^{2,3} and of a case of severe neurotoxicity with an overdose of isoniazid and high-dose vincristine.⁴

These reports appear to be the only ones implicating isoniazid in an increase in vincristine toxicity, but they serve to emphasise the importance of very close neurological supervision in anyone given both drugs.

Vinca alkaloids; Vincristine + Nifedipine

Nifedipine reduces the clearance of vincristine.

Clinical evidence, mechanism, importance and management

In a study in 12 patients nifedipine reduced the clearance of a single 2-mg intravenous dose of vincristine by 68%, and increased the AUC threefold, when compared with 14 patients receiving vincristine alone. Nifedipine was given at a dose of 10 mg three times daily for 3 days before and 7 days after vincristine was given. However, no important adverse effects were noted in either group of patients, suggesting that these pharmacokinetic changes did not markedly increase vincristine toxicity.¹ Further study is needed. Note that increased vincristine-related neurotoxicity has been seen in a child taking nifedipine and itraconazole (see 'Vinca alkaloids + Azoles', p.668).

Antiparkinsonian and related drugs

The drugs in this section are considered together because their major therapeutic application is in the treatment of Parkinson's disease, although some of the related antimuscarinic (anticholinergic) drugs included here are also used for other conditions. Parkinson's disease is named after Dr James Parkinson who originally described the four main signs of the disease, namely rigidity, tremor, dystonias and dyskinesias (movement disorders). Similar symptoms may also be displayed as the unwanted adverse effects of therapy with certain drugs.

The basic cause of the disease lies in the basal ganglia of the brain, particularly the striatum and the substantia nigra, where the normal balance between dopaminergic nerve fibres (those that use dopamine as the chemical transmitter) and cholinergic nerve fibres (those that use acetylcholine as the transmitter) is lost, because the dopaminergic fibres degenerate. As a result the cholinergic fibres end up in relative excess. Much of the treatment of Parkinson's disease is based on an attempt to redress the balance, and there are several groups of drugs that can be used to this end. These are listed in 'Table 18.1', (below), and discussed below.

Levodopa

Levodopa can pass the blood-brain barrier (unlike dopamine), where it is converted into dopamine, and thus acts by 'topping up' the CNS dopaminergic system. Levodopa is most usually given with **carbidopa** or **benserazide** (dopa-decarboxylase inhibitors), which prevent the 'wasteful' peripheral metabolism of levodopa. This allows lower doses of levodopa to be given, which results in fewer adverse effects.

Amantadine (and memantine)

These drugs may augment dopaminergic activity in the brain.

Dopamine agonists

Bromocriptine, cabergoline, pergolide, ropinirole and similar drugs act as dopamine agonists and so also have the effect of increasing dopaminergic activity in the brain.

Entacapone and tolcapone

The catechol-*O*-methyltransferase (COMT) inhibitors work by inhibiting the peripheral metabolism of levodopa by COMT. Note that this enzyme is the major metabolising enzyme for levodopa when a decarboxylase inhibitor (e.g. benserazide) is being used.

Rasagiline and selegiline

The selective irreversible MAO-B inhibitors enhance dopamine activity by preventing dopamine degradation. These drugs sometimes interact like older non-selective MAOIs, and the reader is cross-referred to the information under MAOIs when appropriate. Selegiline undergoes rapid first-pass metabolism to produce amphetamine metabolites. A buccal tablet has been developed, which markedly reduces this first-pass metabolism, and is consequently given as a smaller dose.

Antimuscarinics

Benzhexol, orphenadrine, procyclidine and other antimuscarinic (anticholinergic) drugs work by correcting the relative cholinergic excess.

The interactions that affect the antimuscarinic effects of these drugs are discussed in this section. However, the antimuscarinics also affect the actions of other drugs (such as the centrally-acting anticholinesterases) and these are therefore discussed elsewhere in the publication.

Table 18.1 Antiparkinsonian drugs

Group	Drugs
Dopaminergic drugs	
Amino-acid precursor of dopamine	Levodopa
Levodopa combined with a peripheral dopa-decarboxylase inhibitor	Co-beneldopa (levodopa + benserazide) Co-careldopa (levodopa + carbidopa)
COMT-inhibitors	Entacapone, Tolcapone
Dopamine agonists	
Ergot derivatives	Bromocriptine, Cabergoline, Lisuride, Pergolide
Non-ergot dopamine agonists	Piribedil, Pramipexole, Quinagolide, Ropinirole, Rotigotine
Other dopamine agonists	Apomorphine
MAO-B inhibitors	Rasagiline, Selegiline
Other	Amantadine
Other	
Peripheral dopa-decarboxylase inhibitors	Benserazide, Carbidopa
Antimuscarinics	Benzatropine, Biperiden, Bornaprine, Dextemide, Metixene, Orphenadrine, Procyclidine, Profenamine, Trihexyphenidyl, Trospatepine

Amantadine + Co-trimoxazole

An interaction between amantadine and co-trimoxazole is thought to have caused acute confusion in an elderly man and amantadine toxicity in a patient with end-stage renal disease. However, in both cases other factors could have been responsible for the adverse reactions.

Clinical evidence, mechanism, importance and management

An 84-year-old man with parkinsonism, COPD and chronic atrial fibrillation, had been taking amantadine 100 mg twice daily and digoxin 125 micrograms daily for at least 2 years. Within 72 hours of starting co-trimoxazole twice daily for bronchitis he became mentally confused, incoherent and combative. He also showed cogwheel rigidity and a resting tremor. Within 24 hours of stopping the amantadine and co-trimoxazole, the patient's mental status returned to normal.¹ The reasons for this reaction are not understood, but on the basis of *animal* studies, the authors suggest that the **trimethoprim** component of the co-trimoxazole may have competed with the amantadine for renal secretion. This resulted in an accumulation of amantadine and led to the adverse effects seen.¹ This interaction is more likely in the elderly because ageing results in a decrease in the clearance of these and many other drugs. However, it should be noted that both drugs can cause some mental confusion, and also that mental confusion is not an uncommon symptom of infection in the elderly. Another case of amantadine toxicity has been reported in a 27-year-old woman with end-stage renal disease who was also taking co-trimoxazole. As in the other case the authors suggest that the **trimethoprim** component of the co-trimoxazole may have competed with the amantadine for renal secretion. However, they also note that amantadine toxicity occurred 5 days after the amantadine dose was increased, and during an episode of acute renal failure, which could both account for the toxicity.²

These seem to be the only reports of a possible interaction, so the general importance of this interaction remains uncertain.

- Michalski LS, Hantsch CE, Hou SH. Amantadine toxicity in a renal transplant patient. Abstracts of the 2003 North American Congress of Clinical Toxicology Annual Meeting, 93.

Amantadine + Diuretics

A patient has been described who developed amantadine toxicity when given hydrochlorothiazide-triamterene.

Clinical evidence

Amantadine toxicity (ataxia, agitation, hallucinations) developed in a patient within a week of starting to take two tablets of *Dyazide* (**hydrochlorothiazide** with **triamterene**) daily. The symptoms rapidly disappeared when all the drugs were withdrawn. In a later study this patient showed about a 50% rise in amantadine plasma levels (from 156 to 243 nanograms/mL) after taking the diuretic for 7 days.¹

Mechanism

Uncertain. Amantadine is largely excreted unchanged in the urine and it seems probable that these diuretics reduce the renal clearance.¹

Importance and management

Published information about an adverse interaction appears to be limited. There seems to be little reason for avoiding concurrent use, but bear this case in mind in the event of an unexpected response to treatment.

- Wilson TW, Rajput AH. Amantadine–Dyazide interaction. *Can Med Assoc J* (1983) 129, 974–5.

Amantadine + MAOIs or MAO-B inhibitors

An isolated report describes a rise in blood pressure in a patient on amantadine within 72 hours of taking phenelzine. One manu-

facturer suggests that the use of selegiline with amantadine may increase adverse effects.

Clinical evidence, mechanism, importance and management

(a) Older non-selective MAOIs

A 49-year-old woman was taking amantadine 200 mg daily, haloperidol 5 mg daily and flurazepam 30 mg at night was given **phenelzine** 15 mg twice daily for depression. Within 72 hours her blood pressure rose from 140/90 to 160/110 mmHg. The **phenelzine** was withdrawn, and 24 hours later, the amantadine and haloperidol were withdrawn. The blood pressure remained elevated for a further 72 hours.¹ In contrast, a woman is reported to have been successfully and uneventfully treated with amantadine 200 mg daily for Parkinson's disease and **phenelzine** 45 mg daily for depression.²

The first case appears to be the only reported interaction with amantadine. Its general importance is uncertain, but bear it in mind in case of an unusual response to treatment.

(b) Selective MAO-B inhibitors

One manufacturer of **selegiline** states that concurrent use of amantadine can increase the occurrence of adverse effects (e.g. dizziness, tremor, orthostatic hypotension).³

- Zelapar (Selegiline hydrochloride). Zeneus Pharma Ltd. UK summary of product characteristics, January 2006.

Amantadine + Phenylpropranolamine

The use of amantadine in a patient also taking phenylpropranolamine resulted in psychosis, and concurrent use in another patient resulted in intense and recurrent déjà vu experiences.

Clinical evidence, mechanism, importance and management

A case report describes the development of severe psychosis in a woman within 7 to 8 days of starting amantadine 100 mg [frequency unclear but possibly twice daily] and phenylpropranolamine 80 mg daily. The reasons are not known, but both drugs alone, and in high doses sometimes cause psychosis, and concurrent use may enhance this effect.¹ Another report describes intense and recurrent déjà vu experiences in a 39-year-old man taking amantadine 100 mg twice daily and phenylpropranolamine 25 mg twice daily during a viral infection. These experiences stopped the day he discontinued the drugs. He had previously taken phenylpropranolamine without this effect. The authors considered the déjà vu experiences to be related to increased dopamine activity caused by both drugs.²

Concurrent use need not be avoided, but remain aware of the potential for this interaction.

Amantadine + Quinidine or Quinine

In a single-dose study, quinidine and quinine modestly reduced the loss of amantadine in the urine in men, but not women. However, the absence of any clinical reports suggest that a significant interaction is unlikely.

Clinical evidence, mechanism, importance and management

Single-dose studies into the renal excretion of amantadine in healthy subjects found that quinine sulfate 200 mg and quinidine sulfate 200 mg reduced the renal clearance of oral amantadine 3 mg/kg by about 30%, but only in male subjects.¹ Whether long-term use of these drugs would therefore cause a clinically relevant rise in serum amantadine levels is uncertain. However, the absence of any clinical reports suggests it is unlikely.

Nevertheless, be aware that amantadine toxicity (e.g. headache, nausea, or dizziness) could possibly result from the concurrent use of quinine or quinidine.

1. Gaudry SE, Sitar DS, Smyth DD, McKenzie JK, Aoki FY. Gender and age as factors in the inhibition of renal clearance of amantadine by quinine and quinidine. *Clin Pharmacol Ther* (1993) 54, 23–7.

Amantadine + Tobacco

Amantadine clearance was not altered by tobacco smoking in one study.

Clinical evidence, mechanism, importance and management

The elimination of a single 3-mg/kg dose of amantadine was compared between heavy smokers (20 or more cigarettes daily) and non-smokers.

Although a higher apparent volume of distribution was noted in the heavy smokers, renal and plasma clearances were unchanged, suggesting that no interaction of note occurs.¹

Antimuscarinics + Antimuscarinics

Additive antimuscarinic effects, both peripheral and central, can develop if two or more drugs with antimuscarinic effects are used together. The outcome may be harmful.

Clinical evidence, mechanism, importance and management

The antimuscarinic (sometimes called anticholinergic) effects of some drugs are exploited therapeutically. These include antimuscarinic bronchodilators, gastrointestinal antispasmodics, mydriatics, urological antimuscarinics, and drugs such as **trihexyphenidyl** and **benztropine** (see 'Table 18.1', (p.672)), which are used for the control of parkinsonian symptoms. Other drugs, such as some antiemetics, sedating antihistamines, antipsychotics, and tricyclic antidepressants, (see 'Table 18.2', (below)), may also possess some antimuscarinic effects that are unwanted and troublesome, but usually not serious, unless they are worsened by the addition of another drug with similar properties.

The easily recognised and common peripheral antimuscarinic effects are blurred vision, dry mouth, constipation, difficulty in urination, reduced sweating and tachycardia. Central effects include confusion, disorientation, visual hallucinations, agitation, irritability, delirium, memory problems, belligerence and even aggressiveness. Problems are most likely to arise in patients with particular physical conditions such as glaucoma, prostatic hypertrophy or constipation, in whom antimuscarinic drugs should be used with caution, if at all. It has been pointed out that the antimuscarinic adverse effects can mimic the effects of normal ageing.

'Table 18.1', (p.672) and 'Table 18.2', (below) list many of the drugs with antimuscarinic effects, which may be expected to be additive if used together, but apart from some reports describing life-threatening reactions (see 'Antipsychotics + Antimuscarinics', p.708) there are very few reports describing this simple additive interaction, probably because the outcome is so obvious. Many of these interactions are therefore 'theoretical' but their probability is high.

Some drugs with only minimal antimuscarinic properties sometimes cause difficulties if given with other antimuscarinics. A patient taking **isopropamide iodide** developed urinary retention needing catheterisation, only when **trazodone** 75 mg daily was also taken, but not when either drug was taken alone.¹ **Trazodone** is usually regarded as having minimal antimuscarinic effects. Another case describes acute psychosis in an elderly woman taking **hyoscine** and **meclozine**, both of which have antimuscarinic effects.²

If the central antimuscarinic effects caused by the use of antimuscarinic drugs are not clearly recognised for what they are, there is the risk that antipsychotics may be prescribed to treat them. Many antipsychotics also have antimuscarinic adverse effects so that matters are simply made worse. If the patient then demonstrates dystonias, akathisia, tremor and rigidity, even more antimuscarinics may be added to control the extrapy-

ramidal effects, which merely adds to the continuing downward cycle of drug-induced problems.

In addition to the obvious and very well recognised drugs with antimuscarinic effects, a study of the 25 drugs most commonly prescribed for the elderly identified detectable antimuscarinic activity (using an antimuscarinic radioreceptor assay) in 14 of them, 9 of which (**codeine**, **digoxin**, **dipyridamole**, **isosorbide dinitrate**, **nifedipine**, **prednisolone**, **ranitidine**, **theophylline**, and **warfarin**) produced levels of antimuscarinic activity that have been shown to cause significant impairment in tests of memory and attention in the elderly.³ Thus the problem may not necessarily be confined to those drugs that have well recognised antimuscarinic properties.

Antimuscarinics + Areca (Betel nuts)

The control of the extrapyramidal (parkinsonian) adverse effects of fluphenazine and flupenthixol with procyclidine was lost in two patients when they began to chew areca.

Clinical evidence

An Indian patient receiving depot fluphenazine (50 mg every three weeks) for schizophrenia, and with mild parkinsonian tremor controlled with **procyclidine** 5 mg twice daily, developed marked rigidity, bradykinesia and jaw tremor when he began to chew areca. The symptoms were so severe he could barely speak. When he stopped chewing areca his stiffness and abnormal movements disappeared. Another patient receiving depot flupenthixol developed marked stiffness, tremor and akathisia, despite taking

Table 18.2 Drugs with antimuscarinic effects (main or adverse effects)

Group	Drugs
Antiarrhythmics	Disopyramide, Propafenone
Antiemetics	Cyclizine, Dimenhydrinate, Meclozine, Hyoscine (Scopolamine)
Antihistamines	Brompheniramine, Chlorphenamine, Cyproheptadine, Diphenhydramine, Hydroxyzine, Triprolidine
Antiparkinsonian drugs (Antimuscarinics)	see Table 18.1, p. 672
Antipsychotics	Chlorpromazine, Chlorprothixene, Clozapine, Loxapine, Perphenazine, Pimozide, Mesoridazine, Trifluoperazine, Thioridazine
Antispasmodics	Anisotropine, Atropine, Belladonna alkaloids, Dicycloverine (Dicyclomine), Flavoxate, Hyoscine (Scopolamine), Hyoscyamine, Isopropamide, Oxybutynin, Propanteline, Tolterodine
Antiulcer drugs	Clidinium, Hexocyclium, Isopropamide, Mepenzolate, Methanthelinium, Oxyphenyclimine, Pirenzepine, Tridihexethyl
Cycloplegic mydriatics	Atropine, Cyclopentolate, Homatropine, Hyoscine (Scopolamine), Tropicamide
Muscle relaxants	Baclofen, Cyclobenzaprine, Orphenadrine
Peripheral vasodilator	Papaverine
Tricyclic and related antidepressants	Amitriptyline, Amoxapine, Clomipramine, Desipramine, Doxepin, Imipramine, Maprotiline, Protriptyline, Nortriptyline, Trimipramine

After Barkin RL, Stein ZLG. *South Med J* (1989) 82, 1547, and others.

The categorization is not exclusive; some of these drugs are used for a range of effects. There are many other antimuscarinic drugs.

up to 20 mg of **procyclidine** daily, when he began to chew areca. The symptoms vanished within 4 days of stopping the areca.¹

Mechanism

Areca contains arecoline, an alkaloid with cholinergic activity, which could therefore oppose the antimuscarinic (anticholinergic) actions of procyclidine. As the procyclidine was being used to control the extrapyramidal adverse effects of the two antipsychotics, opposing its action allowed the adverse effects to re-emerge and worsen.

Importance and management

Direct information seems to be limited to this report but the interaction would seem to be established and clinically important. Patients taking antimuscarinic drugs for the control of drug-induced extrapyramidal (parkinsonian) adverse effects, or Parkinson's disease, should avoid areca. The authors of this report suggest that a dental inspection for the characteristic red stains of the areca may possibly provide a simple explanation for the sudden and otherwise mysterious deterioration in the symptoms of patients. Betel is traditionally chewed by those from the continent of Asia, and the East Indies. Symptoms seem to develop over a period of 2 weeks, and resolve fairly rapidly (within a week).

Antimuscarinics + SSRIs

Eight patients developed delirium when given fluoxetine, paroxetine or sertraline with benztropine, in the presence of an antipsychotic (usually perphenazine or haloperidol). Other patients taking the combination remained symptom free.

Clinical evidence, mechanism, importance and management

Five patients became confused and developed delirium when given an antipsychotic, an SSRI (4 taking **fluoxetine** and one taking **paroxetine**) and **benztropine**. No peripheral antimuscarinic toxicity was seen. The delirium developed within 2 days in two cases, but took several weeks to appear in another. The authors of the report attributed this to an interaction between the SSRIs and **benztropine**, speculating that the SSRIs may have inhibited the metabolism of the **benztropine** thereby increasing its toxicity. Alternatively they suggest a possible additive central antimuscarinic effect. They also very briefly mention two other patients who became delirious when given an unnamed antipsychotic and either **sertraline** or **paroxetine** with **benztropine**.¹ It is noteworthy that 4 of the first group of patients were given perphenazine and one haloperidol,¹ both of which have been involved in additive antimuscarinic interactions (see 'Antipsychotics + Antimuscarinics', p.708). Also note that adverse interactions have been reported with the use of 'antipsychotics and SSRIs', (p.712). Another case describes delirium in a 17-year-old boy, 8 days after **paroxetine** was added to his medication which included **benztropine** and haloperidol. Serum levels of **benztropine** were markedly increased.²

In contrast, another report describes 12 patients on **fluoxetine** and perphenazine who also received **benztropine** 1 mg daily without showing signs of delirium.^{3,4} The general clinical importance of this interaction is therefore very uncertain indeed, but it would now seem prudent to be alert for evidence of confusion and possible delirium in patients given SSRIs with **benztropine**, particularly if they are also taking other psychotropics that may have antimuscarinic actions. The authors of the first report say that they have not seen delirium with combinations of SSRIs (not named) and other antimuscarinic drugs such as **biperiden** and **diphenhydramine**.¹

Apomorphine + Antihypertensives

The hypotensive adverse effects of apomorphine may possibly be increased by nitrates, calcium-channel blockers and alpha blockers. There is some evidence that ACE inhibitors, beta blockers and diuretics do not increase the risk of hypotension. Nevertheless, caution is advised with all antihypertensives, and patients should be told about the symptoms of orthostatic hypotension and what to do should they occur.

Clinical evidence

(a) ACE inhibitors

A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 25 patients taking ACE inhibitors [not specifically named]. One patient experienced symptomatic hypotension.¹

(b) Alpha blockers

A single 5-mg sublingual dose of apomorphine caused a greater decrease in systolic blood pressure from supine to standing in 24 patients taking alpha blockers [not specifically named] when compared with placebo (decrease in systolic BP of 23 versus 13 mmHg at 40 minutes post dose). One patient experienced symptomatic hypotension.¹

(c) Beta blockers

A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 26 patients taking beta blockers [not specifically named]. One patient experienced syncope and one had symptomatic hypotension.¹

(d) Calcium-channel blockers

A single 5-mg sublingual dose of apomorphine caused a greater decrease in systolic blood pressure from supine to standing in 26 patients taking calcium-channel blockers [not specifically named] when compared with placebo (decreased in systolic BP of 17 versus 11 mmHg at 20 minutes post dose).¹

(e) Diuretics

A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 21 patients taking diuretics [not specifically named]. One patient experienced symptomatic hypotension.¹

(f) Nitrates

1. *Short-acting.* A single 5-mg sublingual dose of apomorphine produced no clinically relevant changes in heart rate or blood pressure in 20 patients taking short-acting nitrates. The apomorphine was given 30 minutes before the patient took their short-acting nitrate. Two patients experienced symptomatic hypotension after their sublingual glyceryl trinitrate.¹

2. *Long-acting.* A single 5-mg sublingual dose of apomorphine caused a greater decrease in systolic blood pressure from supine to standing in 20 patients taking long-acting nitrates when compared with placebo (decrease in systolic BP of 12 versus 6 mmHg at 50 minutes post dose). Two patients experienced symptomatic hypotension.¹

Mechanism

Apomorphine alone may cause postural hypotension, and this is potentially additive with the effects of vasoactive antihypertensives and nitrates.

Importance and management

A potentially clinically relevant interaction resulting in orthostatic hypotension may occur when sublingual apomorphine is given to patients on calcium channel blockers or alpha blockers. Similarly symptomatic hypotension on standing may be more common in patients taking nitrates. Note that the 5-mg dose used in the study was slightly higher than the recommended 2- to 3-mg sublingual dose commonly used for erectile dysfunction. All the patients who had symptomatic hypotension experienced a prodrome of symptoms such as nausea, dizziness, pallor, and/or sweating.¹ On the basis of this study the manufacturers suggest caution in patients on antihypertensives and particularly nitrates, which in practice means telling patients what may possibly happen and what to do if adverse effects occur (i.e. do not attempt to stand up, but lie down and raise their

legs until the symptoms resolve).² Note that the cardiovascular conditions contraindicating or cautioning either the use of sublingual apomorphine for erectile dysfunction or subcutaneous apomorphine in parkinsonism should be observed.^{2,3}

3. APO-go ampoules (Apomorphine hydrochloride). Britannia Pharmaceuticals Ltd. UK Summary of product characteristics, March 2007.

Apomorphine + COMT inhibitors

Entacapone had no effect on the pharmacokinetics or efficacy of apomorphine in a single-dose study. Similarly, tolcapone had no relevant effect on single-dose apomorphine.

Clinical evidence

(a) Entacapone

In a placebo-controlled crossover study in 24 patients with Parkinson's disease a single dose of entacapone 200 mg or 400 mg given 30 minutes before a subcutaneous injection of apomorphine had no effect on the pharmacokinetics of apomorphine. In addition, entacapone had no effect on measures of apomorphine efficacy (tapping test and incidence of dyskinesias).¹

(b) Tolcapone

Tolcapone 200 mg three times daily for 5 days then 200 mg one hour before sublingual apomorphine 40 mg caused a non-significant increase in the AUC of apomorphine of about 13% in 5 patients with Parkinson's disease.²

Mechanism

In vitro and *animal* data suggested that the enzyme catechol-*O*-methyl transferase (COMT) is involved in the metabolism of apomorphine³ and that COMT inhibitors might increase apomorphine bioavailability. However, the single dose studies above suggest that this metabolic pathway for apomorphine may not be important in humans.

Importance and management

The evidence from these single-dose studies suggest that there is no pharmacokinetic interaction between entacapone or tolcapone and apomorphine, and that the drugs can be used together without alteration of the apomorphine dose. However, further data are required from longer-term concurrent use to confirm this. Until more is known, increased monitoring during concurrent use of COMT inhibitors and apomorphine may be prudent, as is recommended by the manufacturers.⁴⁻⁶

6. Comtess (Entacapone). Orion Pharma (UK) Ltd. UK Summary of product characteristics, February 2007.

Apomorphine + Hormonal contraceptives

The sedative effects of apomorphine were decreased by a combined oral contraceptive in one study.

Clinical evidence, mechanism, importance and management

A study¹ in a group of 9 women found that the sedative effects of a single 5-micrograms/kg subcutaneous dose of apomorphine were decreased when they were taking a combined oral contraceptive (**ethinylestradiol**

30 micrograms, **levonorgestrel** 150 or 250 micrograms). The clinical importance of this is uncertain.

1. Chalmers JS, Fulli-Lemaire I, Cowen PJ. Effects of the contraceptive pill on sedative responses to clonidine and apomorphine in normal women. *Psychol Med* (1985) 15, 363–7.

Apomorphine + Miscellaneous

The hypotensive adverse effects of apomorphine may possibly be increased by alcohol. The concurrent use of other drugs used for erectile dysfunction or dopamine agonists or antagonists is not recommended. However, domperidone, and prochlorperazine are said not to interact when apomorphine is used for erectile dysfunction, and domperidone is the recommended antiemetic when apomorphine is used for Parkinson's disease. There is evidence that antidepressants, antiepileptics, and ondansetron do not interact adversely.

Clinical evidence, mechanism, importance and management

(a) Alcohol

The manufacturers say that interaction studies in subjects given apomorphine (for erectile dysfunction) found that alcohol increased the incidence and extent of hypotension (one of the adverse effects of apomorphine). They also point out that alcohol can diminish sexual performance.¹

(b) Antidepressants

The manufacturers say that no studies about interactions between apomorphine and antidepressants have been undertaken, but clinical experience in erectile dysfunction suggests that no interaction occurs.¹

(c) Antiemetics

The small doses of apomorphine used for erectile dysfunction (2 to 3 mg) do not normally cause vomiting, but nausea does occur in about 7% of patients and the manufacturers say that interaction studies and/or clinical experience show that **domperidone**, **ondansetron** or **prochlorperazine** may safely be given as antiemetics in this patient group.¹ Studies with other antiemetics have not been carried out, so at the moment concurrent use is not recommended.¹

Note that **prochlorperazine** should not be given if apomorphine is used for Parkinson's disease, as its dopamine antagonist actions can worsen the disease (see also 'Levodopa + Antiemetics', p.682). Because apomorphine is highly emetogenic at the doses required for the treatment of Parkinson's disease (1 to 4 mg/hour by subcutaneous infusion), patients with Parkinson's disease requiring apomorphine should be pretreated with **domperidone** 20 mg three times daily for at least 2 days.² Rare reports of extrapyramidal adverse effects have been reported with **ondansetron**,³ which may be of relevance in patients with Parkinson's Disease.

(d) Antiepileptics

The manufacturers say that no studies about interactions between apomorphine and antiepileptics have been undertaken, but clinical experience in erectile dysfunction suggests that no interaction occurs.¹

(e) Dopamine antagonists

The manufacturers say that apomorphine should not be given with centrally-acting dopamine antagonists¹ because potentially they may antagonise the effects of apomorphine. Such drugs would include some **antipsychotics**. Some manufacturers recommend that if neuroleptics are necessary in patients with Parkinson's disease receiving dopamine agonists, the dopamine agonist should be progressively reduced (and then stopped⁴), as sudden withdrawal may cause neuroleptic malignant syndrome.^{2,4}

The manufacturer of *APO-go* specifically notes that there is a potential interaction between **clozapine** and apomorphine, although they say that **clozapine** may also be used to reduce the symptoms of neuropsychiatric complications of Parkinson's disease.² See also prochlorperazine in (c) above, and 'Levodopa + Antipsychotics', p.683.

(f) Other dopamine agonists

The manufacturers say that apomorphine should not be given with other centrally-acting dopamine agonists.¹ See 'Table 18.1', (p.672) for a list of these drugs.

(g) Other drugs used for erectile dysfunction

The manufacturers say that no formal studies have been done with a combination of apomorphine and other drugs used for erectile dysfunction but

there seems to be no evidence of problems, nevertheless they do not recommend concurrent use.¹ Other drugs used for this condition include **alprostadil**, **moxisylyte**, **papaverine**, **phentolamine**, and the **phosphodiesterase inhibitors** such as **sildenafil**.

Bromocriptine and other dopamine agonists + Antiemetics

Domperidone and metoclopramide would be expected to reduce the prolactin-lowering effect of bromocriptine. Metoclopramide, but not domperidone, would be expected to reduce the effect of any dopamine agonist.

Clinical evidence, mechanism, importance and management

(a) Antiemetic effect

Dopamine agonists frequently cause nausea and vomiting on starting treatment. The manufacturers of **bromocriptine**,¹ **lisuride**,² and **pergolide**³ state that if necessary this may be reduced by taking a peripheral dopamine antagonist such as **domperidone**. **Metoclopramide** is not considered a suitable antiemetic for use in Parkinson's disease because it crosses the blood brain barrier and has central dopamine antagonist effects, and may therefore reduce the efficacy of dopamine agonists in this condition, see also 'Levodopa + Antiemetics', p.682. The manufacturers of **cabergoline**,⁴ **ropinirole**,⁵ and **rotigotine**⁶ advise against the use of metoclopramide for this reason.

(b) Prolactin-lowering effect

Both **domperidone** and **metoclopramide** are dopamine antagonists and can raise prolactin levels, sometimes causing galactorrhoea, gynaecomastia or mastalgia.^{7,8} They would therefore be expected to reduce the prolactin-lowering effect of **bromocriptine**.¹ However, an early study in 10 patients with Parkinson's disease given single doses of **bromocriptine** 12.5 to 100 mg found that pretreatment with a single 60-mg dose of **metoclopramide** had no consistent effect on plasma bromocriptine levels or on the clinical or hormonal response⁹ [although this does not seem to have been studied in a multiple dose study]. Nevertheless, it would be prudent to monitor the efficacy of **bromocriptine** if **domperidone** or **metoclopramide** are required.

Bromocriptine and other dopamine agonists + Antipsychotics

Some antipsychotics have dopamine antagonist actions, which would be expected to inhibit the efficacy of dopamine agonists such as bromocriptine. Careful monitoring is required if combined use is considered necessary.

Clinical evidence, mechanism, importance and management

Many antipsychotics have dopamine antagonist properties and can cause movement disorders (extrapyramidal effects). For this reason, these drugs

can reduce the efficacy of dopamine agonists used in Parkinson's disease, and exacerbate the disorder. This interaction is well established for levodopa: see 'Antipsychotics', (p.683), which discusses the relative tendency for various classical and atypical antipsychotics to cause this effect. It would equally well be anticipated for any dopamine agonist. Therefore, the manufacturers of **bromocriptine**,¹ **cabergoline**,² **lisuride**,³ **pergolide**,⁴ **pramipexole**,⁵ **ropinirole**⁶ and **rotigotine**⁷ all caution against concurrent use with dopamine antagonist antipsychotics. If an antipsychotic is required for psychosis in Parkinson's disease, the risk-benefit ratio should be carefully assessed, and an antipsychotic chosen that has a lower risk of extrapyramidal effects such as an atypical antipsychotic. Similarly, the prolactin-lowering effects of **bromocriptine**,¹ **cabergoline**⁸ and **quinagolide**⁹ are expected to be reduced by dopamine antagonist antipsychotics.

Dopamine agonists may also lessen some of the effects of antipsychotics: for a case of reduced efficacy see 'Antipsychotics + Bromocriptine', p.710.

Bromocriptine and other dopamine agonists + Ergot derivatives

Because cabergoline is an ergot derivative, the manufacturers have looked at what happens if other ergot derivatives are used concurrently, but have so far found no evidence of changes in the efficacy or safety of cabergoline. Nevertheless they do not recommend their concurrent use.¹ Similarly, the manufacturers of bromocriptine do not recommend concurrent use of other ergot derivatives.²

2. Parlodel (Bromocriptine). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, September 2006.

Bromocriptine and other dopamine agonists + Food

Food did not alter the pharmacokinetics of bromocriptine, cabergoline or lisuride. These dopamine agonists are usually taken with food to try and improve their tolerability.

Clinical evidence

(a) Bromocriptine

Taking a single dose of bromocriptine 7.5 mg after breakfast did not alter the bromocriptine AUC compared with the fasted state, although it slightly reduced the maximum plasma level in a study in 7 healthy subjects.¹

(b) Cabergoline

The pharmacokinetics of cabergoline did not change when a single dose of cabergoline 1 mg was taken after breakfast compared with the fasting state in a study in healthy subjects.²

(c) Lisuride

Thirty healthy subjects were given lisuride 200 micrograms orally while fasting or with food. It was found that food did not significantly modify either the pharmacokinetics or the pharmacodynamics of the lisuride.³

Mechanism

None.

Importance and management

Food had no effect on the pharmacokinetics of the ergot dopamine agonists studied, and as **rotigotine** is given transdermally, food is not expected to affect its pharmacokinetics.⁴ The manufacturers of bromocriptine, cabergoline and lisuride recommend that they are taken with food.⁵⁻⁷ They commonly cause nausea and vomiting, especially on starting therapy, and taking them with food may improve tolerability.^{6,7}

Bromocriptine + Griseofulvin

Evidence from a single patient, who was taking bromocriptine for acromegaly, suggests that its effects can be opposed by griseofulvin.

Clinical evidence, mechanism, importance and management

In a study of the effects of bromocriptine used for the treatment of acromegaly, one patient who initially had a good response to bromocriptine developed resistance to the drug. After a number of months it was found that this patient had subsequently been given griseofulvin 500 mg daily for the treatment of a fungal nail infection. When the griseofulvin was stopped, the bromocriptine was again effective.¹ The mechanism of this interaction and its general importance are unknown, but prescribers should be aware of it when treating patients with bromocriptine.

1. Schwinn G, Dirks H, McIntosh C, Köbberling J. Metabolic and clinical studies on patients with acromegaly treated with bromocriptine over 22 months. *Eur J Clin Invest* (1977) 7, 101–7.

Bromocriptine and other dopamine agonists + Macrolides

Erythromycin markedly increases bromocriptine plasma levels, and a case of toxicity has been reported. Bromocriptine toxicity also occurred in a patient given josamycin. Clarithromycin increases cabergoline levels, and erythromycin would be expected to interact similarly. Erythromycin had no effect on lisuride levels.

Clinical evidence*(a) Bromocriptine*

1. *Erythromycin*. Erythromycin estolate 250 mg four times daily for 4 days increased the peak plasma levels and the AUC of a single 5-mg oral dose of bromocriptine by about 360% and 268%, respectively in 5 healthy subjects.¹ Another report describes 2 women taking levodopa/carbidopa and bromocriptine for parkinsonism in whom the disease was better controlled when erythromycin was added. Bromocriptine plasma levels were found to be 40 to 50% higher while they were taking erythromycin.² An elderly woman taking levodopa and bromocriptine 15 mg developed psychotic symptoms when she took erythromycin, which were attributed to bromocriptine toxicity.³

2. *Josamycin*. An elderly man with Parkinson's disease, well-controlled for 10 months with daily levodopa/benserazide, bromocriptine 70 mg and domperidone, was additionally given josamycin 2 g daily for a respiratory infection. Shortly after the first dose he became drowsy with visual hallucinations, and began to show involuntary movements of his limbs, similar

to the dystonic and dyskinetic movements seen in choreoathetosis. These adverse effects (interpreted as bromocriptine toxicity) disappeared within a few days of withdrawing the josamycin.⁴

(b) Cabergoline

The concurrent use of cabergoline 1 mg daily and **clarithromycin** 400 mg daily increased the AUC of cabergoline by 163% and increased the maximum level by 176% in healthy subjects. Preliminary results from a study in patients with Parkinson's disease also showed that **clarithromycin** increased the bioavailability of cabergoline by about 2 to 4-fold.⁵

(c) Lisuride

Twelve healthy subjects were given lisuride 200 micrograms orally or 50 micrograms as a 30 minute intravenous infusion after taking **erythromycin** [dose unknown] twice daily for 4 days. Preliminary results showed that **erythromycin** did not significantly modify either the pharmacokinetics or the pharmacodynamics of the lisuride.⁶

Mechanism

The ergot dopamine agonists bromocriptine and cabergoline undergo extensive metabolism, most likely by the cytochrome P450 isoenzyme CYP3A4. Erythromycin and clarithromycin (and potentially other macrolides, with the exception of azithromycin) inhibit this metabolism, thus significantly elevating bromocriptine and cabergoline plasma levels.¹

Importance and management

Information seems to be limited to these reports, but the pharmacokinetic interaction would appear to be established. Concurrent use should be well monitored if any of these macrolides (clarithromycin, erythromycin, josamycin) is added to bromocriptine or cabergoline treatment. Note that azithromycin does not normally cause enzyme inhibition and so may not interact. Moderately increased levels may be therapeutically advantageous, but grossly elevated levels can be toxic. The authors of one report¹ suggest reducing the bromocriptine dose, while in another case the dose was reduced by 50% to avoid toxicity.³ Preliminary data suggest that dosage adjustments are not needed if lisuride is given with erythromycin.

Bromocriptine + Octreotide

Octreotide modestly increases the bioavailability of bromocriptine, whereas bromocriptine does not appear to alter octreotide pharmacokinetics.

Clinical evidence, mechanism, importance and management

The combined use of bromocriptine 5 mg twice daily and subcutaneous octreotide 200 micrograms twice daily increased the bioavailability of bromocriptine by about 40%, without altering its clearance or half-life. The pharmacokinetics of octreotide were unchanged.¹ This effect may contribute to the increased efficacy of combined treatment in acromegaly shown in some studies. Bear it in mind when considering combined therapy.

Bromocriptine + Proton pump inhibitors

A single case describes worsening mobility, which was attributed to an interaction between lansoprazole and bromocriptine. The

same patient later received bromocriptine and omeprazole without problems.

Clinical evidence, mechanism, importance and management

A 73-year-old man taking levodopa/benserazide and bromocriptine for Parkinson's disease was given **lansoprazole** 15 mg daily to treat reflux oesophagitis. Two days later, the patient exhibited akinesia (more motor difficulties and slowness in movements) associated with frequent falls. **Lansoprazole** was discontinued, with disappearance of the symptoms the day after. About 3 months later the patient was prescribed **omeprazole** 20 mg daily, which caused no aggravation of Parkinson's disease over the following 6 months.

The authors attribute this case to a possible interaction between **lansoprazole** and bromocriptine,¹ although any mechanism is unclear, especially as **omeprazole** was given without problems.

This single unexplained case seems unlikely to be of clinical significance.

1. Anglès A, Bagheri H, Saivin S, Montastruc JL. Interaction between lansoprazole and bromocriptine in a patient with Parkinson's disease. *Therapie* (2002) 57, 408–10.

Bromocriptine + Sympathomimetics

A healthy postpartum woman taking bromocriptine developed very severe headache and marked hypertension after also taking phenylpropranolamine. Similarly another woman developed seizures with cerebral vasospasm, and a third developed a severe headache, hypertension and severe cardiac dysfunction after also taking isometheptene. A further patient taking bromocriptine developed psychosis when pseudoephedrine was added.

Clinical evidence

Two healthy women who had given birth 3 to 4 days previously, developed severe headaches while taking bromocriptine 2.5 mg twice daily for milk suppression. After additionally taking three 65-mg doses of **isometheptene mucate**, the headache of one of them markedly worsened, and hypertension with life-threatening ventricular tachycardia and cardiac dysfunction developed. The other woman took two 75-mg doses of **phenylpropranolamine**, and developed grand mal seizures and cerebral vasospasm.¹

A 32-year-old woman took two 5-mg doses of bromocriptine for milk suppression without any adverse effects following the birth of a child. Within 2 hours of taking a third dose with **phenylpropranolamine** 50 mg she awoke with a very severe headache and was found to have a blood pressure of 240/140 mmHg. She was given 5 mg of intramuscular morphine and her blood pressure became normal within 24 hours. Another 5-mg dose of bromocriptine taken 48 hours after the original dose of **phenylpropranolamine** had the same effect, but the blood pressure rise was less severe (160/120 mmHg).²

A woman who had recently given birth and who had taken bromocriptine 2.5 mg twice daily for 9 days without problems became psychotic shortly after starting to take **pseudoephedrine** 60 mg four times daily.³

Mechanism

Not understood. Severe hypertension occasionally occurs with either bromocriptine or phenylpropranolamine given alone. Shortly after giving birth some individuals show increased vascular reactivity, and it could be that all of these factors conspired together to cause these adverse effects.² Psychosis occasionally occurs after giving birth or on bromocriptine alone, so that in the latter case the addition of pseudoephedrine may have been coincidental.³

Importance and management

Direct information seems to be limited to these four cases, but the severity of the reactions suggests that it might be prudent for postpartum patients to avoid sympathomimetics like these while taking bromocriptine. Note that bromocriptine is not recommended for the routine suppression of lactation postpartum.

2. Chan JCN, Critchley JAJH, Cockram CS. Postpartum hypertension, bromocriptine and phenylpropranolamine. *Drug Invest* (1994) 8, 254–6.
3. Reeves RR, Pinkofsky HB. Postpartum psychosis induced by bromocriptine and pseudoephedrine. *J Fam Pract* (1997) 45, 164–6.

Cabergoline + Itraconazole

Two patients taking cabergoline had improvements in their Parkinson's disease symptoms while taking itraconazole. In one case a 300% increase in cabergoline levels occurred, and the other patient reduced the dose of her medications without adversely affecting disease control.

Clinical evidence

A man with Parkinson's disease taking cabergoline 4 mg once daily and selegiline 5 mg twice daily was prescribed pulse itraconazole therapy (200 mg twice daily for one week out of four) for a fungal nail infection. At the end of the first week the patient reported improvements in his parkinsonism, which was confirmed by clinical investigation. The improvement gradually decreased during the weeks without itraconazole therapy, and re-emerged while taking the itraconazole. Analysis of cabergoline blood levels found a 300% increase in levels after he had taken itraconazole for a week.¹

Another similar patient taking cabergoline 2 mg twice daily, selegiline, entacapone, and levodopa/carbidopa, experienced symptoms of overdose (hyperkinesia of the extremities) 3 days after starting itraconazole 200 mg twice daily. She reduced the dose of her Parkinson's medication, and had marked improvement in her usual Parkinson's symptoms, which then gradually reduced after stopping the itraconazole. This was repeated following two additional periods of itraconazole therapy.¹

Mechanism

Cabergoline is an ergot derivative that is metabolised by the cytochrome P450 isoenzyme CYP3A4 (see also 'Bromocriptine and other dopamine agonists + Macrolides', p.678). Itraconazole is a potent inhibitor of this isoenzyme, and would therefore be expected to increase cabergoline levels.

Importance and management

Although evidence is limited, this interaction would be predicted on the basis of the known pharmacokinetics of cabergoline. It would be prudent to monitor toxicity and efficacy in any patient on cabergoline requiring itraconazole, or similar potent inhibitors of CYP3A4 (see 'Table 1.4', (p.6) for a list).

1. Christensen J, Dupont E, Østergaard K. Cabergoline plasma concentration is increased during concomitant treatment with itraconazole. *Mov Disord* (2002) 17, 1360–2.

COMT inhibitors + MAOIs

In a single dose study, there was no adverse effect on heart rate or blood pressure when entacapone was given with moclobemide (a RIMA), but caution is recommended until further clinical experience is gained. The COMT inhibitors may be used with the MAO-B inhibitors (such as selegiline). However, the manufacturers of entacapone and tolcapone contraindicate concurrent use of non-selective MAOIs or a combination of both a RIMA and a MAO-B inhibitor.

Clinical evidence

In a single-dose, placebo-controlled study, **moclobemide** 150 mg did not change the heart rate or blood pressure at rest or during exercise, when given **entacapone** 200 mg, compared with either drug alone or placebo. In addition, the plasma concentrations of endogenous noradrenaline (norepinephrine) and adrenaline (epinephrine) were not altered.¹

Mechanism

Monoamine oxidase and COMT are the two major enzyme systems involved in the metabolism of catecholamines. Therefore it is theoretically

possible that the combination of a COMT inhibitor and a non-selective MAOI would result in inhibition of the normal metabolism of catecholamines, with an increase in their effects (e.g. hypertension). Using an MAO-B inhibitor with a RIMA is similar to giving a non-selective MAOI and therefore using these two drugs with a COMT inhibitor would also be likely to inhibit the normal metabolism of catecholamines.

Importance and management

The results of the single-dose study of entacapone and the RIMA moclobemide suggest that no adverse haemodynamic interaction occurs. Nevertheless, this finding needs confirmation in a clinical setting. Until further information is available, caution would be advisable on combined use. The manufacturers of entacapone and **tolcapone** contraindicate or advise against the use of non-selective MAOIs (e.g. **phenelzine**, **tranylcypromine**)²⁻⁵ and combinations of both a RIMA (e.g. moclobemide) plus an MAO-B inhibitor (e.g. **selegiline**).^{2,4} However, they state that **selegiline** alone is compatible with the COMT inhibitors provided not more than 10 mg daily is used.^{2,4} At this dose, **selegiline** is likely to remain selective for MAO-B.

COMT inhibitors + Sympathomimetics; Directly-acting

Entacapone potentiated the increase in heart rate and arrhythmogenic effects of isoprenaline (isoproterenol) and epinephrine (adrenaline) in a study in healthy subjects. Therefore, the manufacturers of entacapone and tolcapone issue a caution about the concurrent use of adrenaline (epinephrine), isoprenaline (isoproterenol), and a number of other sympathomimetics.

Clinical evidence

The maximal increase in heart rate during an infusion of **adrenaline (epinephrine)** was about 80% greater (25 *versus* 14 bpm) after pretreatment with a single 400-mg dose of **entacapone** in a study in healthy subjects. Similarly, the maximal increase in heart rate during **isoprenaline (isoproterenol)** infusion was about 50% greater (40 *versus* 27 bpm) after pretreatment with the same dose of **entacapone**. Moreover, more subjects experienced palpitations when pretreated with **entacapone**, and this study was terminated early because of two cases of ventricular arrhythmias, one requiring treatment with propranolol. There was no change in blood pressure, nor any increase in plasma levels of the sympathomimetics.¹

Mechanism

Tolcapone and entacapone inhibit the enzyme catechol-*O*-methyl transferase (COMT), which is concerned with the metabolism of drugs such as adrenaline (epinephrine) and isoprenaline (isoproterenol). There is therefore a possibility of increased serum levels and related adverse effects of these drugs.

Importance and management

The evidence from this single-dose study confirms the theoretical prediction that COMT inhibitors might potentiate the effects of directly-acting sympathomimetics such as adrenaline (epinephrine). Because of this, the manufacturers of entacapone and tolcapone suggest caution if drugs known to be metabolised by COMT are given to patients on COMT inhibitors.²⁻⁵ Of the sympathomimetics, adrenaline (epinephrine), **dobutamine**, **dopamine**, isoprenaline (isoproterenol) and **noradrenaline (norepinephrine)**, are specifically named in one or more of the lists,²⁻⁵ and one manufacturer of entacapone also lists **bitolterol** and **isoetarine**

(**isoetarine**), and specifically includes the inhaled route of administration.⁵ See also 'COMT inhibitors + Sympathomimetics; Indirectly-acting', below.

2. Tasmar (Tolcapone). Valeant Pharmaceuticals Ltd. UK Summary of product characteristics, August 2006.
3. Tasmar (Tolcapone). Valeant Pharmaceuticals International. US Prescribing information, December 2006.
4. Comtess (Entacapone). Orion Pharma (UK) Ltd. UK Summary of product characteristics, February 2007.
5. Comtan (Entacapone). Novartis. US Prescribing information, March 2000.

COMT inhibitors + Sympathomimetics; Indirectly-acting

A single case report describes severe hypertension in a patient given entacapone and intravenous ephedrine. Tolcapone did not alter the effect of ephedrine in one study.

Clinical evidence

(a) Entacapone

A 76-year-old woman with Parkinson's disease taking levodopa/carbidopa and entacapone 200 mg five times daily, was given 3 mg of intravenous ephedrine during cataract surgery to correct a low blood pressure of 85/35 mmHg. Her blood pressure immediately rose to 225/125 mmHg. The patient needed several doses of hydralazine over the following 140 minutes before her blood pressure returned to normal.¹

(b) Tolcapone

The manufacturer notes that tolcapone did not alter the effect of ephedrine (route of administration not stated) on haemodynamic parameters or plasma catecholamine levels, either at rest or during exercise.^{2,3}

Mechanism

COMT inhibitors may inhibit the normal metabolism of ephedrine (and the catecholamines it releases at adrenergic nerve endings), which could result in a marked exaggeration of its normal effects.¹ See also 'COMT inhibitors + Sympathomimetics; Directly-acting', above.

Importance and management

The single case report with entacapone and intravenous ephedrine appears to be the only evidence that COMT inhibitors could potentiate the effect of indirectly-acting sympathomimetics such as ephedrine. The manufacturer of tolcapone states that ephedrine and tolcapone can be used concurrently.^{2,3} Nevertheless, some caution may be warranted with intravenous ephedrine.

1. Renfrew C, Dickson R, Schwab C. Severe hypertension following ephedrine administration in a patient receiving entacapone. *Anesthesiology* (2000) 93, 1562.
2. Tasmar (Tolcapone). Valeant Pharmaceuticals Ltd. UK Summary of product characteristics, August 2006.
3. Tasmar (Tolcapone). Valeant Pharmaceuticals International. US Prescribing information, December 2006.

COMT inhibitors + Tricyclic and related antidepressants

Entacapone and imipramine did not interact adversely in a single-dose study. Similarly, tolcapone and desipramine did not interact adversely. Nevertheless, the manufacturers of entacapone and tolcapone recommend caution if they are used with tricyclic antidepressants or other drugs that inhibit noradrenaline (norepinephrine) uptake, such as maprotiline or venlafaxine.

Clinical evidence

(a) Entacapone

In a single-dose crossover study 12 healthy women were given entacapone 200 mg with imipramine 75 mg, either drug alone, or placebo. Although both drugs can impair the inactivation of catecholamines the study found

no evidence that combined drug use had any relevant effect on haemodynamics or on free adrenaline (epinephrine) or noradrenaline (norepinephrine) plasma levels. The combination was well tolerated in all subjects.¹

(b) Tolcapone

In one study, healthy subjects were given **desipramine** 25 mg three times daily for 3 days then 50 mg three times daily for 10 days. For the last 5 days they were also given levodopa/carbidopa 100/25 mg three times daily and either a placebo or tolcapone 200 mg three times daily. The addition of tolcapone to combined treatment with levodopa/carbidopa and **desipramine** did not lead to any changes in haemodynamics or catecholamine levels, nor to any changes in **desipramine** pharmacokinetics.²

Mechanism

Both COMT inhibitors and drugs with noradrenaline re-uptake inhibitory activity can impair the inactivation of catecholamines, so in theory the effects of catecholamines may be increased by concurrent use. However, this did not appear to occur in the above studies.

Importance and management

In these pharmacological studies, no important interaction between entacapone and imipramine or between tolcapone and desipramine was detected. Nevertheless, the manufacturer of entacapone says there is limited clinical experience of the use of entacapone with tricyclic antidepressants, and they therefore recommend caution.³ Similarly, the manufacturers of tolcapone suggest that caution should be exercised with desipramine^{4,5} and any drugs that are potent noradrenaline (norepinephrine) uptake inhibitors such as **maprotiline** and **venlafaxine**.⁴

COMT inhibitors; Entacapone + Iron compounds

Entacapone formed chelates with iron *in vitro*. The manufacturer recommends that iron preparations and entacapone are given 2 to 3 hours apart.

Clinical evidence, mechanism, importance and management

An *in vitro* study¹ found that entacapone formed chelates with iron. Although the clinical relevance of this does not appear to have been assessed, the manufacturers recommend that entacapone and iron preparations should be taken at least 2 to 3 hours apart.²

Levodopa + Antacids

Antacids do not appear to interact significantly with immediate-release levodopa, but they may reduce the bioavailability of modified-release preparations of levodopa.

Clinical evidence

(a) Immediate-release preparations

One study found that 15 mL of an **aluminium/magnesium hydroxide** antacid, given 30 minutes before levodopa, to a patient with a prolonged gastric emptying time, caused a threefold increase in levodopa serum levels, which was associated with a marked improvement in symptoms.¹ Another patient was able to reduce his levodopa dose when taking antacids, without affecting symptom control.¹ A further study found that the maxi-

mum plasma concentration of levodopa was raised by 20% when 20 mL of an antacid was given before the levodopa.²

However, when 8 patients (only 3 with Parkinson's disease) were given *Mylanta* (containing **aluminium/magnesium hydroxide** and simeticone), 30 minutes before, and/or with levodopa, only occasional increases in bioavailability were seen. One of the 3 patients with Parkinson's disease who had shown improved bioavailability while on antacids had his levodopa dose lowered and continued to take *Mylanta*, but the parkinsonian symptoms worsened and the levodopa was increased back to the original dose.³ Another study, in 15 parkinsonian patients taking dopamine agonists (e.g. bromocriptine) and levodopa/carbidopa who were given six 30-mL doses of **aluminium hydroxide** daily, inferred that the antacid had no significant effect on levodopa bioavailability, because of the lack of clinical fluctuations in effect.⁴

(b) Sustained-release preparations

In a study using *Madopar HBS*, a sustained-release preparation of levodopa and benserazide, the concurrent use of an unnamed antacid reduced the levodopa bioavailability by about one-third in healthy subjects.⁵ The manufacturers of *Madopar CR* state that antacids reduce the bioavailability of levodopa from the controlled-release preparation in comparison with conventional *Madopar*.⁶

Mechanism

The small intestine is the major site of absorption for levodopa, and delayed gastric emptying appears to result in low plasma levodopa levels, probably because levodopa can be metabolised in the stomach. In theory, antacids may reduce gastric emptying time, and increase levodopa absorption.¹ It is not known why antacids reduced absorption from the slow-release preparation.⁵

Importance and management

The overall picture is that concurrent use need not be avoided with standard preparations, although some individuals may be affected so the outcome should be monitored. With modified-release preparations it would seem advisable to avoid concurrent administration (1 to 2 hours is usually enough in other similar cases of interactions with antacids). Again, the outcome should be monitored.

Levodopa + Anticholinesterases; Centrally acting

Reports describe cases of a worsening of Parkinson's disease in patients given donepezil or tacrine. Other centrally acting anticholinesterases may exacerbate or induce extrapyramidal symptoms, including worsening of Parkinson's disease. In contrast, one study found that donepezil did not affect the control of Parkinson's disease, and actually caused a non-significant increase in levodopa levels.

Clinical evidence

(a) Donepezil

Donepezil 5 mg daily for 15 days caused a modest 30% increase in the AUC₀₋₄ of levodopa in a placebo-controlled study in 23 patients with Parkinson's disease taking levodopa/carbidopa. There was no change in carbidopa pharmacokinetics, and the pharmacokinetics of donepezil did not differ between the patients with Parkinson's disease and a control group of healthy subjects. There was no obvious difference in adverse effects between patients with Parkinson's disease and the control subjects, and no evidence that donepezil significantly altered motor activity in those treat-

ed with levodopa/carbidopa.¹ This latter finding is in contrast to a report which found a worsening of Parkinson's disease, which responded to levodopa/carbidopa, in 3 of 9 patients who had taken donepezil for 24 weeks.²

(b) Tacrine

The mild parkinsonism of an elderly woman with Alzheimer's disease worsened, leading to severe tremor, stiffness and gait dysfunction within 2 weeks of doubling her tacrine dosage from 10 mg to 20 mg four times daily. This improved when levodopa/carbidopa was started, but the tremor returned when tacrine was increased to 30 mg four times daily. The symptoms disappeared when the tacrine dosage was reduced to 20 mg four times daily.³

Mechanism

Parkinsonism is due to an imbalance between two neurotransmitters, dopamine and acetylcholine, in the basal ganglia of the brain. Centrally acting anticholinesterases increase the amount of acetylcholine in the brain, which could lead to an exacerbation of parkinsonian symptoms. Levodopa improves the situation by increasing the levels of dopamine. It is not known why donepezil modestly increased the levels of levodopa.

Importance and management

Direct information seems to be limited, but the reports of worsening Parkinson's disease are consistent with the known pharmacology of these drugs and the biochemical pathology of Parkinson's disease. Be aware that if donepezil or tacrine is given to any patient with parkinsonism, whether taking levodopa or any other anti-parkinson drug, the disease may possibly worsen. The antiparkinson drug dosage may need increasing and/or the dosage of the anticholinesterase may need reducing. Other centrally acting anticholinesterases (**galantamine**, **rivastigmine**) may also worsen Parkinson's disease.

Levodopa + Antiemetics

Although metoclopramide can increase the rate of levodopa absorption, it may also antagonise its effects by aggravating symptoms of Parkinson's disease, so metoclopramide should generally be avoided in patients with Parkinson's disease. However, two studies found no evidence that metoclopramide altered the efficacy of levodopa. Phenothiazine antiemetics such as prochlorperazine are also generally considered to be contraindicated in Parkinson's disease. See also 'Levodopa + Antipsychotics', p.683. In one small study, promethazine did not affect the control of Parkinson's disease in patients taking levodopa. Domperidone is the antiemetic of choice to prevent and treat nausea and vomiting caused by levodopa. Other antiemetics that are generally considered useful include cyclizine and 5-HT₃ antagonists.

Clinical evidence, mechanism, importance and management

(a) Domperidone

Domperidone is a dopamine antagonist similar to metoclopramide.¹ However, since it acts on the dopamine receptors in the stomach wall, and unlike metoclopramide, it does not readily cross the blood-brain barrier, it does not appear to oppose the effects of levodopa within the brain, although some extrapyramidal symptoms have been observed. It may even slightly increase the bioavailability and effects of levodopa (by stimulating gastric emptying).² Domperidone can therefore be used to control the nausea and vomiting associated with levodopa treatment of Parkinson's disease.

(b) Metoclopramide

Metoclopramide is a dopamine antagonist that can cause extrapyramidal disturbances (parkinsonian symptoms), especially in children and young

adults, and possibly also in the elderly, where the effects may be misdiagnosed as Parkinson's disease.³ On the other hand, metoclopramide stimulates gastric emptying, which can result in an increase in the bioavailability of levodopa.^{4,5} The outcome of these two effects (possible antagonism resulting in aggravation of Parkinson's disease, or potentiation resulting in increased bioavailability) is uncertain, and it is generally considered that metoclopramide should be avoided in Parkinson's disease. However, in one open study, metoclopramide 30 to 60 mg daily in divided doses for a range of 4 to 16 weeks caused no change in mean total disability scores in 10 patients with Parkinson's disease taking levodopa.⁶ Similarly, in a controlled trial in 7 patients, the incidence and severity of levodopa-induced involuntary movements was unchanged and additional acute dyskinesias did not appear when metoclopramide was also given.⁶ Nevertheless, if alternative antiemetics are unsuitable for a patient with Parkinson's disease and consequently metoclopramide is given, it would seem prudent to monitor the outcome closely.

(c) Phenothiazine antiemetics

Phenothiazines block the dopamine receptors in the brain and can therefore upset the balance between cholinergic and dopaminergic components within the striatum and substantia nigra. As a consequence they may not only induce the development of extrapyramidal (parkinsonian) symptoms, but they can aggravate parkinsonism and antagonise the effects of levodopa used in its treatment. See 'Levodopa + Antipsychotics', p.683. Phenothiazines, used in smaller doses as antiemetics, such as **prochlorperazine**,^{7,8} can also behave in this way. For this reason drugs of this kind are generally regarded as contraindicated in patients with Parkinson's disease, and there are other more suitable alternatives, see (d) below. However, one small controlled study found that **promethazine** (a phenothiazine derivative with few extrapyramidal effects) did not change the total disability score or alter the incidence or severity of levodopa-induced involuntary movements in 4 patients with Parkinson's disease taking levodopa.⁶

(d) Non-interacting antiemetics

Antiemetics that are generally considered useful in patients with Parkinson's disease include **cyclizine** and 5-HT₃ antagonists such as **granisetron** and **ondansetron**,³ which do not affect dopamine, and **domperidone** as discussed above. However, note that rare cases of extrapyramidal adverse effects have been reported with **ondansetron**, which may be of relevance in patients with Parkinson's disease.⁹

Levodopa + Antimuscarinics

Antimuscarinics and other drugs with antimuscarinic effects, such as the tricyclics, may modestly reduce the rate, and possibly the extent, of absorption of levodopa. One case describes levodopa toxicity, which occurred after the withdrawal of an antimuscarinic.

Clinical evidence

A study¹ in 6 healthy subjects and 6 patients with Parkinson's disease found that **trihexyphenidyl** 2 mg twice daily for 3 days lowered the peak plasma levels of a 500-mg dose of levodopa by 42% in the healthy subjects and 17% in the patients, although the interaction was present in only about half of the subjects. The AUC was reduced in both groups by less than 20%.¹

A study in 6 patients with Parkinson's disease taking levodopa plus carbidopa or benserazide found that **orphenadrine** caused either a delay, a reduction, or an increase in levodopa absorption in 3 patients.² Another

study in 4 healthy subjects³ found that **imipramine** 25 mg four times daily for 3 days reduced the peak plasma concentration of a single 500-mg dose of levodopa by about 50%, but did not appear to alter the extent of absorption. See also 'Levodopa + Tricyclic antidepressants', p.690 for other non-antimuscarinic interactions of the tricyclics.

A patient who needed 7 g of levodopa daily while taking **homatropine** developed levodopa toxicity when the **homatropine** was withdrawn, and he was subsequently restabilised on only 4 g of levodopa daily.⁴

Mechanism

The small intestine is the major site of absorption for levodopa. Delayed gastric emptying, which can be caused by antimuscarinics, appears to result in lower plasma levodopa levels and thus lower brain levodopa levels. This is because the gastric mucosa has more time to metabolise the levodopa to dopamine and therefore less is available for absorption.⁵

Importance and management

Antimuscarinics are commonly given with levodopa, and they are of established benefit. However, limited evidence suggests they might sometimes reduce levodopa efficacy. Levodopa preparations are now more usually given in conjunction with a dopa decarboxylase inhibitor to minimise metabolism in the gastric mucosa. This would be expected to minimise the effects of any interaction. However, note that one of the above studies included a dopa-decarboxylase inhibitor, yet still found an effect on levodopa absorption. There is certainly no need to avoid concurrent use, but it would be prudent to be alert for any evidence of a reduced levodopa response if antimuscarinics are added, or for levodopa toxicity if they are withdrawn.

Levodopa + Antipsychotics

Phenothiazines, butyrophenones, diphenylbutylpiperidines and thioxanthenes can oppose the effects of levodopa because of their dopamine antagonist properties, causing deterioration of motor function in Parkinson's disease. The antipsychotic effects and extrapyramidal adverse effects of these drugs can be opposed by levodopa. Of the atypical antipsychotics, risperidone and olanzapine cause deterioration in motor function in Parkinson's disease. Ziprasidone may act similarly, and there have been reports with quetiapine. Clozapine does not have this effect.

Clinical evidence, mechanism, importance and management

(a) Classical antipsychotics

Phenothiazines (e.g. fluphenazine, perphenazine, prochlorperazine, and trifluoperazine), **butyrophenones** (e.g. haloperidol, droperidol) **diphenylbutylpiperidines** (e.g. pimozide) and **thioxanthenes** (e.g. flupentixol and zuclopenthixol) block the dopamine receptors in the brain and can therefore upset the balance between cholinergic and dopaminergic components within the striatum and substantia nigra. As a consequence they may not only induce the development of extrapyramidal (parkinsonian) symptoms, but they can aggravate parkinsonism and antagonise the effects of levodopa used in its treatment.^{1–5} For this reason drugs of this kind are generally regarded as contraindicated in patients being treated for Parkinson's disease, or only used with great caution in carefully controlled conditions. The extrapyramidal symptoms that frequently occur with the **phenothiazines** have in the past been treated without much success with levodopa. However, the levodopa may also antagonise the antipsychotic effects of the **phenothiazines**,⁶ and other dopamine-antagonist antipsychotics. Consider also 'Levodopa + Antiemetics', p.682.

(b) Atypical antipsychotics

Of the atypical antipsychotics, both **risperidone** and **olanzapine** have caused deterioration of motor function in patients with Parkinson's disease. There have also been reports of deterioration in motor function with **quetiapine**. There is far less experience with **ziprasidone**, but it may have a propensity to cause extrapyramidal adverse effects that is similar to **olanzapine**.

Low-dose **clozapine** appears to cause little deterioration in motor function, and may improve tremor. It therefore remains the preferred antipsychotic for patients with Parkinson's disease and levodopa-induced psychosis. Note that individual reports and studies of the use of these antipsychotics in patients with Parkinson's disease are numerous. The reader is referred to a recent review on the topic.⁷

Levodopa + Baclofen

Unpleasant adverse effects (hallucinations, confusion, headache, nausea) and worsening of the symptoms of parkinsonism have occurred in patients on levodopa who were given baclofen.

Clinical evidence

Twelve patients with parkinsonism on levodopa plus a dopa-decarboxylase inhibitor were additionally given baclofen. The eventual baclofen dosage was intended to be 90 mg daily, but the adverse effects were considerable (visual hallucinations, a toxic confusional state, headaches, nausea) so that only 2 patients reached this dosage, and 2 patients withdrew because they could not tolerate these adverse effects. The mean dosage for those who continued was 45 mg daily. Rigidity was aggravated by an average of 46% and functional capacity deteriorated by 21%.¹

A patient with Parkinson's disease taking levodopa/carbidopa, orphenadrine and diazepam became acutely confused, agitated, incontinent and hallucinated when given a third dose of baclofen (in all 15 mg). The baclofen was stopped, but on the following night she again hallucinated and became confused. The next day she was given two 2.5-mg doses of baclofen but she became anxious and hallucinated with paranoid ideas.²

Mechanism

Not understood. The toxicity seen appears to be an exaggeration of the known adverse effects of baclofen.

Importance and management

Information appears to be limited to these reports, but they suggest that baclofen should be used very cautiously in patients taking levodopa.

Levodopa + Benzodiazepines and related drugs

On rare occasions it seems that the therapeutic effects of levodopa can be reduced by chlordiazepoxide, diazepam or nitrazepam.

Clinical evidence

Various benzodiazepines [dose unstated] were given to 8 patients with Parkinson's disease in addition to their levodopa treatment. In 5 of the patients (3 taking **chlordiazepoxide**, 1 taking **nitrazepam**, 1 taking **oxazepam**) no interactions were seen. However, the other 3 patients (1 taking **diazepam**, 2 taking **nitrazepam**) experienced transient disturbances in the control of their Parkinson's disease, which lasted up to

3 weeks in the case of the patient taking **diazepam**.¹ Other cases of a reversible loss of control of Parkinson's disease have been seen in 3 patients taking **diazepam**² and 4 patients taking **chlordiazepoxide**.^{3,4} In one further case, a patient taking **chlordiazepoxide** experienced falls associated with a worsening of parkinsonian symptoms while taking **chlordiazepoxide**. She recovered 5 days after the **chlordiazepoxide** was withdrawn.⁵

In contrast, a case-control study of patients with Parkinson's disease taking levodopa therapy did not find a statistically significant increase in the required dose of antiparkinsonian drug treatment in the 180 days after starting a benzodiazepine.⁶

Mechanism

Not understood, although *animal* studies have shown that benzodiazepines can decrease the levels of dopamine in the striatum.⁶

Importance and management

Not established. Given the widespread use of benzodiazepines in patients taking levodopa,⁷ any major or common interaction would be expected to have come to light by now. It would therefore seem that this interaction is fairly rare, and on the basis of one of the reports cited above, possibly only transient. There is no need to avoid concurrent use, but bear these reports in mind in the case of an unexpected response to treatment.

Levodopa + Beta blockers

The concurrent use of levodopa and beta blockers normally appears to be favourable, but be aware that, as with all antihypertensives, additive hypotensive effects can occur.

Clinical evidence, mechanism, importance and management

Most of the effects of the combined use of levodopa and beta blockers seem to be favourable, although additive hypotension can be a problem. Dopamine derived from levodopa stimulates beta-receptors in the heart, which can cause arrhythmias.¹ These receptors are blocked by **propranolol** and other beta blockers. An enhancement of the effects of levodopa and a reduction in tremor has been described in 23 out of 25 patients taking **propranolol**,² but not in 9 patients taking **oxprenolol**,³ or in another placebo-controlled study in 18 patients taking **propranolol**.⁴ Early evidence showed that growth hormone levels were substantially raised by **propranolol**^{5,6} or **practolol** [now withdrawn due to fatal reactions] in conjunction with levodopa, but no clinical relevance for this has been demonstrated.

Levodopa + Bromocriptine and other dopamine agonists

The combined use of levodopa and dopamine agonists can increase efficacy and adverse effects in Parkinson's disease, therefore doses of both drugs should be slowly adjusted to optimise therapy. A study suggests that bromocriptine can moder-

ately alter levodopa levels whereas there was no pharmacokinetic interaction between levodopa and cabergoline, pramipexole or ropinirole. An isolated report describes the development of the serotonin syndrome when levodopa/carbidopa was added to treatment with bromocriptine.

Clinical evidence

(a) Bromocriptine

A study in 20 patients with Parkinson's disease taking levodopa/carbidopa found that overall there was no difference in plasma levodopa levels after bromocriptine was also taken, although some patients had either significant elevations or significant reductions in levels. However, the only adverse clinical change found was an increase in dyskinesias in the patients with elevated levodopa levels.¹ An earlier study found no pharmacokinetic interaction between levodopa/carbidopa and bromocriptine, but it should be noted that this was a single-dose study and may not reflect long-term concurrent use.²

A patient with parkinsonism, who had been taking bromocriptine 60 mg daily for nearly 3 years, was also given levodopa/carbidopa (25/250 mg daily increasing over a week to 75/750 mg) while the bromocriptine dose was reduced to 20 mg daily. On the seventh day he started shivering, and developed myoclonus of the trunk and limbs, hyperreflexia, patellar clonus, tremor, diaphoresis, anxiety, diarrhoea, tachycardia and had a temperature of 37.9°C with a blood pressure of 180/100 mmHg. The serotonin syndrome was suspected. The patient responded to treatment with the 5-HT antagonist methysergide.³

A case of pathological gambling was attributed to the combined use of bromocriptine and levodopa/carbidopa in a 54-year-old woman.⁴

(b) Cabergoline

Levodopa/carbidopa 25/250 mg daily did not cause a clinically significant change in the pharmacokinetics of cabergoline 2 mg daily when the combination was given to patients newly diagnosed with Parkinson's disease. Similarly, cabergoline (in increasing doses up to 4 mg once daily) for 8 weeks had no effect on the absorption, AUC or elimination half-life of levodopa in another group of patients with fluctuating Parkinson's disease who were taking levodopa/carbidopa.⁵

(c) Pergolide

The manufacturer notes that the use of pergolide in patients on levodopa may cause and/or exacerbate pre-existing states of dyskinesia, confusion, and hallucinations. Also, they say that stopping pergolide abruptly in patients on levodopa may precipitate the onset of hallucinations and confusion.⁶

(d) Pramipexole

Patients on a stable dose of levodopa/carbidopa were given increasing doses of pramipexole or placebo for 7 weeks. Pramipexole 1.5 mg daily and 4.5 mg daily had no effect on levodopa bioavailability.⁷ As pramipexole enhances the actions of levodopa the manufacturer suggests reducing the dose of levodopa as the dose of pramipexole is increased.⁸

(e) Ropinirole

In patients on a stable dose of levodopa with a dopa-decarboxylase inhibitor, ropinirole had no effect on the pharmacokinetics of levodopa, except for a small clinically irrelevant 16% increase in maximum level. Similarly, levodopa had no effect on the pharmacokinetics of ropinirole in another group of patients.⁹ As the dose of ropinirole is increased, the dose of levodopa may be reduced gradually, by around 20% in total.¹⁰

(f) Rotigotine

The manufacturer of rotigotine reports that levodopa and carbidopa had no effect on the pharmacokinetics of rotigotine and similarly, rotigotine had no effect on the pharmacokinetics of either levodopa or carbidopa. However, as with other dopamine agonists, rotigotine may cause and/or exacerbate dyskinesia in patients taking levodopa and may potentiate the dopaminergic adverse reactions of levodopa.¹¹

Mechanism

Additive dopaminergic effects would be expected. The serotonin syndrome is thought to occur because of increased stimulation of the 5-HT receptors in the brainstem and spinal cord. A syndrome resembling neuroleptic malignant syndrome (which has similar symptoms to the serotonin syndrome) can occur when a dopamine agonist like bromocriptine is

withdrawn abruptly. It is therefore possible that the effects of reducing the bromocriptine dose were additive with those of levodopa, which can displace serotonin from the nerve endings.³ Pathological gambling has been associated with the misuse of levodopa and dopamine agonists alone, but an association is not clearly established.

Importance and management

The combined use of levodopa and ergot dopamine agonists can increase efficacy in Parkinson's disease, but adverse effects such as hallucinations and dyskinesias may also be increased, and the dose of both drugs should be gradually adjusted to optimise therapy. If the decision is made to withdraw the dopamine agonist, this should be done slowly, over several days.

The serotonin syndrome described with levodopa and bromocriptine appears to be an isolated incident and not of general importance. Similarly, the case of gambling with levodopa/bromocriptine is probably not of general importance, except to say that use of dopaminergic drugs should be considered as a possible contributing factor in a patient with pathological gambling.

Levodopa + Clonidine

Limited evidence suggests that clonidine may oppose the effects of levodopa. Be aware that, as with all antihypertensives, additive hypotensive effects may occur.

Clinical evidence

A study in 2 patients taking levodopa with carbidopa found that concurrent treatment with clonidine (up to 1.5 mg daily for 10 to 24 days) caused a worsening of the parkinsonism (an exacerbation of rigidity and akinesia). The concurrent use of antimuscarinic drugs reduced the effects of this interaction.¹

Another report on 10 hypertensive and 3 normotensive patients with Parkinson's disease, 9 of them taking levodopa and 4 of them not, claimed that concurrent treatment with clonidine did not affect the control of the parkinsonism. However, 2 patients stopped taking the clonidine because of an increase in tremor and gait disturbance.²

Mechanism

Not understood. A suggestion is that clonidine opposes the antiparkinson effects by stimulating alpha-receptors in the brain. Another idea is that clonidine directly stimulates post-synaptic dopaminergic receptors.

Importance and management

Information seems to be limited to these reports. Be alert for a reduction in the control of the Parkinson's disease during concurrent use. The effects of this interaction appear to be reduced if antimuscarinic drugs are also be-

ing used.¹ Also note, that as with all antihypertensives, additive hypotensive effects may occur.

Levodopa + COMT inhibitors

Entacapone and tolcapone increase the AUC of levodopa given with benserazide or carbidopa. This may require a reduction in the levodopa dose to avoid symptoms of dopamine excess when first starting the COMT inhibitor. Tolcapone increases the levels of benserazide, but neither entacapone nor tolcapone alters carbidopa pharmacokinetics.

Clinical evidence

(a) Levodopa

Entacapone^{1,2} and **tolcapone**^{3,4} have been shown to increase the AUC and prolong the elimination half-life of levodopa (as levodopa/benserazide or levodopa/carbidopa) without altering the maximum levodopa level. COMT inhibitors can therefore improve the clinical condition of patients with Parkinson's disease, which is mainly seen as a decrease in "off" time.⁵ However, as levodopa levels are raised, there may be an accompanying increase in the adverse effects of levodopa (e.g. dyskinesias, nausea, vomiting, orthostatic hypotension, hallucinations).^{6–8}

(b) Benserazide or carbidopa

The effects of COMT inhibitors on the pharmacokinetics of dopa-decarboxylase inhibitors has also been studied. Neither **entacapone**² nor **tolcapone**⁹ altered the pharmacokinetics of carbidopa. However, **tolcapone** increased the serum levels of benserazide in patients with Parkinson's disease.¹⁰ The benserazide levels remained within the usual range in patients taking levodopa products containing benserazide 25 mg and **tolcapone** 200 mg three times daily. However, with a 50-mg dose of benserazide the AUC of benserazide was increased 4.8-fold with standard-release preparation and 2.3-fold with a controlled-release preparation.¹⁰

Mechanism

When levodopa is given with a dopa-decarboxylase inhibitor such as carbidopa or benserazide, COMT becomes the major enzyme for metabolising levodopa, so inhibiting COMT delays the breakdown of levodopa.

Importance and management

When starting a COMT inhibitor, all patients should be informed of the symptoms of excess levodopa, and what to do if they occur. The manufacturers of entacapone suggest that if entacapone is started, the daily dose of levodopa should be reduced by about 10 to 30% (within the first few days or weeks) to accommodate these potential adverse effects.^{7,11} This can be done by either extending the dosing intervals and/or by reducing the amount of levodopa per dose. Patients on levodopa/benserazide may require a greater dose reduction than those on levodopa/carbidopa because entacapone increases the bioavailability of standard levodopa/benserazide preparations by 5 to 10% more than standard levodopa/carbidopa.⁷ The manufacturers of tolcapone say that the average reduction in the daily dose of levodopa required on starting tolcapone was 30%, and that greater than 70% of patients on levodopa doses above 600 mg daily required such a reduction.^{8,12} The clinical significance of the increase in benserazide levels is unknown, but the manufacturers advise good monitoring for benserazide adverse effects.¹²

Levodopa + Dacarbazine

An isolated report describes a reduction in the effects of levodopa caused by dacarbazine.

Clinical evidence, mechanism, importance and management

A patient who had been treated surgically for melanoma, continued to have intermittent dacarbazine treatment (200 mg intravenously daily) for sporadic positive melanuria. He later developed Parkinson's disease, and was started on levodopa, which had no effect on his melanoma. However, each time he was treated with dacarbazine he complained that the effects of the levodopa/benserazide were reduced and his Schwab and England score (measures of activities of daily living) fell by as much as 25%. A subsequent double-blind study on the patient using a modified Columbia Score confirmed this.¹ The reasons are not understood, but since the serum dopamine levels remained unchanged it is suggested that competition between the two drugs at the blood-brain barrier may be the explanation.¹ Be alert for the need to modify levodopa treatment if dacarbazine is used concurrently. However, note also that the manufacturers contraindicate levodopa in those with a history of malignant melanoma because there is some suggestion that levodopa may activate this malignancy,² although some consider that this is unlikely from the available evidence.³

Levodopa + Food

The fluctuations in response to levodopa experienced by some patients may be due to the timing of meals and the type of diet, particularly the protein content, both of which can reduce the effects of levodopa. The effects of levodopa can be reduced by the amino acid methionine, and the blood levels of levodopa can be reduced by the amino acid tryptophan.

Clinical evidence

(a) Effects of meals

A study in patients with Parkinson's disease taking levodopa found that if taken with a meal, the mean absorption of levodopa from the gut and the peak plasma levels were reduced by 27 and 29% respectively, and the peak plasma level was delayed by 34 minutes.¹ Another study found that peak plasma levodopa levels were reduced if the levodopa was taken with food rather than when fasting.²

(b) Effects of protein

A study in healthy subjects found that a **low-protein meal** (protein 10.5 g) caused a small reduction in levodopa absorption when compared with the fasting state, but also found that a **high-protein meal** (protein 30.5 g) was no different to the fasting state.³ Other studies have found that a high daily

intake of protein reduces the effects of levodopa (with or without a dopa-decarboxylase inhibitor), compared with a lower intake of protein.^{4,6}

(c) Effects of specific amino acids

A study found that the clinical response to a constant intravenous infusion of levodopa in 4 patients was unchanged by **glycine** and **lysine** but was reduced by **phenylalanine**, **leucine** and **isoleucine**, although the plasma levodopa levels remained unchanged.¹

Fourteen patients treated with levodopa for Parkinson's disease were given a **low-methionine** diet (0.5 g daily) for a period of 8 days. Seven patients were given additional **methionine** (4.5 g daily), while the other 7 were given placebo. Five out of the 7 given **methionine** 4.5 g daily showed a definite worsening of the symptoms (gait, tremor, rigidity, etc.). The symptoms subsided when the **methionine** was withdrawn, although this took 7 to 10 days in one patient. Three out of the 7 given placebo (while on the low-methionine diet) showed some subjective improvement.⁷

The blood levels of levodopa were markedly reduced in normal healthy subjects when levodopa 500 mg was taken with 1 g of **tryptophan**.⁸ The clinical importance of this was not assessed.

Mechanism

(a) Meals that delay gastric emptying increase the potential for peripheral metabolism of levodopa in the gut, which reduces the amount available for absorption. In addition (b) some large neutral amino acids arising from the digestion of proteins can compete with levodopa for transport into the brain so that the therapeutic response may be reduced, whereas other amino acids (c) do not have this effect.^{1,3,5,9}

Importance and management

An established interaction, but unpredictable. Since the fluctuations in the response of patients to levodopa may be influenced by what is eaten and when, a change in the pattern of drug and food administration on a trial-and-error basis may be helpful. Note that the manufacturers of *Madopar* recommend taking with food or slowly increasing the dose in the early stages of treatment to control anorexia, nausea, vomiting, and diarrhoea.¹⁰ Multiple small doses of levodopa and distributing the intake of proteins may also diminish the effects of these interactions. Diets that conform to the recommended daily allowance of protein (said to be 800 mg/kg in this report) are reported to reduce this adverse drug-food interaction.⁵

The amino acid methionine is used therapeutically, and although information about its interaction with levodopa is very limited, it indicates that large doses of methionine should be avoided in patients being treated with levodopa.

Levodopa + Indinavir

An isolated report describes a man taking levodopa who developed severe dyskinesias when given indinavir.

Clinical evidence, mechanism, importance and management

A 66-year-old man with idiopathic Parkinson's disease and AIDS was free of dyskinesias when taking levodopa with a dopa-decarboxylase inhibitor, although he had unpredictable fluctuations. After 1 month of starting indinavir 2400 mg daily, lamivudine and zidovudine, he developed severe peak-dose dyskinesias, and the 'on' periods lasted all day, with no fluctu-

ations. The antivirals were stopped and the dyskinesias improved within 5 days. Each antiviral was then given separately for 2 weeks. Only indinavir induced dyskinesias, which started after 3 days of treatment.¹

The mechanism of this interaction is uncertain, but may be related to the inhibition of cytochrome P450 by protease inhibitors such as indinavir.¹

This appears to be the only report of this possible interaction. Bear in mind the possibility that the levodopa dose may need to be decreased if a protease inhibitor such as indinavir is required.

Levodopa + Iron compounds

Ferrous sulfate can reduce the bioavailability of levodopa and carbidopa, and may possibly reduce the control of Parkinson's disease.

Clinical evidence

A study in 9 patients with Parkinson's disease found that a single 325-mg dose of **ferrous sulfate** reduced the AUC of levodopa by 30% and reduced the AUC of carbidopa by more than 75%. There was a trend towards an increase in disability, suggesting a worsening of disease, but this did not reach statistical significance. Some, but not all of the patients had some deterioration in the control of their disease¹

In another study, 8 healthy subjects were given a single 250-mg dose of levodopa, with and without a single 325-mg dose of **ferrous sulfate**, and the plasma levodopa levels were measured for the following 6 hours. Peak plasma levodopa levels and the levodopa AUC were reduced by 55% and the AUC was reduced by 51%. Those subjects who had the highest peak levels and greatest absorption when given levodopa alone, showed the greatest reductions when additionally given **ferrous sulfate**.²

Mechanism

Ferrous iron rapidly oxidises to ferric iron at the pH values found in the gastrointestinal tract. Ferric iron binds strongly to carbidopa and levodopa to form chelation complexes that are poorly absorbed.²⁻⁴

Importance and management

Information appears to be limited to these single-dose and *in vitro* studies. The importance of this interaction in patients taking both drugs long-term awaits further study but the extent of the reductions in absorption (30 to 50%), and the hint of worsening control,¹ suggests that this interaction may be of clinical importance. Be alert for any evidence of this. Separating the administration of the iron and levodopa as much as possible is likely to prove effective, as this appears to be an absorption interaction. More study is needed.

Levodopa + Isoniazid

There is evidence that isoniazid can reduce the control of Parkinson's disease in patients taking levodopa. An isolated case report describes hypertension, tachycardia, flushing and tremor in a patient attributed to concurrent use of levodopa and isoniazid.

Clinical evidence

Following the observation that levodopa-induced dyskinesias were reduced by isoniazid in one patient, a further study was undertaken in 20 others taking levodopa plus a dopa-decarboxylase inhibitor. It was found that isoniazid (average dose 290 mg daily, range 100 to 800 mg daily) reduced the dyskinesias of 18 of the 20 patients. However, the reduction in dyskinesias was accompanied by an intolerable worsening of parkinsonism, shown by decreased mobility and greater 'off' periods. The reduction

in mobility was so severe that the isoniazid had to be stopped immediately in several cases and was discontinued after an average of 5.2 weeks in all the patients. Control of parkinsonism was then restored.¹ Another patient taking levodopa/carbidopa similarly had a deterioration in the control of parkinsonism within 1 to 2 weeks of starting isoniazid/rifampicin (*Rifinah*). When the antitubercular drugs were stopped, the patient's motor performance improved ('on' period lengthened by 75%), the levodopa AUC rose by 37%, its half-life doubled, and the maximum plasma levels fell by 33%.²

An isolated report describes a patient on levodopa who developed hypertension, agitation, tachycardia, flushing and severe non-parkinsonian tremor after starting to take isoniazid. He recovered when the isoniazid was stopped.³

Mechanism

Not understood. Metabolic studies in one patient suggest that isoniazid inhibits dopa-decarboxylase,² although other mechanisms have been proposed.^{1,2} The isolated case of hypertension and tachycardia is also not understood, but it has been suggested that it may have been due to a weak monoamine oxidase inhibitory effect of the isoniazid metabolites. See 'MAOIs or RIMAs + Levodopa', p.1136, for further explanation.

Importance and management

Information seems to be limited to the reports cited. If concurrent use is thought to be necessary, be alert for any evidence of a reduction in the control of the parkinsonism, and be aware that drug treatment may need to be modified. One of the reports suggests that it may take 15 to 20 days or more for the deterioration in parkinsonian symptoms to occur.¹ More study is needed. The isolated case seems not to be of general importance.

Levodopa + MAO-B inhibitors

No serious interaction occurs between levodopa and selegiline, although the dose of levodopa may need to be reduced when selegiline is added. Levodopa does not affect rasagiline clearance.

Clinical evidence

(a) Rasagiline

The manufacturer notes that levodopa had no effect on rasagiline clearance.¹

(b) Selegiline

The combination of levodopa and selegiline has been very extensively used. No serious hypertensive reactions of the kind seen with 'non-selective MAOIs and levodopa', (p.1136) seem to occur. No adverse pharmacokinetic interactions have been reported,^{2,3} and serious adverse interactions are said to be lacking.^{4,5} Many studies have reported beneficial effects of this combination,⁶⁻¹¹ but one has suggested that it may result in increased mortality.¹² Urinary retention has also been suggested as being associated with this drug combination.¹³ Selegiline potentiates the effects of levodopa, so the usual adverse effects (dyskinesias, nausea, agitation, confusion, hallucinations, headache, postural hypotension, cardiac arrhythmias, and vertigo) may be increased, particularly if the levodopa dose is too high.¹⁴

Mechanism

MAO-B inhibitors prevent the metabolism of dopamine, therefore additive dopaminergic effects occur with levodopa.

Importance and management

No adverse interactions occur if levodopa and selegiline are given concurrently. However, the manufacturers say that after adding selegiline a reduction in the dose of levodopa is usually required to avoid symptoms of

levodopa excess (about 10 to 30% is suggested).¹⁴⁻¹⁶ Reduction of the levodopa dose should be gradual, in steps of 10% every 3 to 4 days.¹⁵

Levodopa + Methylodopa

Methylodopa can increase the effects of levodopa and permit a reduction in the dosage in some patients taking levodopa alone, but it can also worsen dyskinesias in others. This interaction would not be expected to be significant in a patient taking levodopa with benserazide or carbidopa but this does not appear to have been studied. A small increase in the hypotensive actions of methylodopa may also occur.

Clinical evidence

(a) Effects on the response to levodopa

A double-blind crossover study in 10 patients with Parkinson's disease who had been taking levodopa alone for 12 to 40 months, found that the optimum daily dose of levodopa fell by 68% with methylodopa 1920 mg daily, and by 50% with methylodopa 800 mg daily.¹

Other reports in patients taking levodopa alone describe reductions in the levodopa dosage of up to 30%² and 70%³ during concurrent treatment with methylodopa. Another report states that the control of Parkinson's disease improved during the concurrent use of methylodopa in some patients taking levodopa alone, but the dyskinesias were worsened in others.⁴ Methylodopa on its own can cause a reversible parkinsonian-like syndrome.⁵⁻⁷

(b) Effects on the response to methylodopa

A study in 18 patients with Parkinson's disease taking levodopa alone found that combined use of levodopa and methylodopa lowered the blood pressure. The doses used did not affect the systolic blood pressure when given alone. Daily doses of 1 to 2.5 g of levodopa with methylodopa 500 mg caused a 12/6 mmHg fall in blood pressure. No change in the control of the Parkinson's disease was seen, but the study lasted only a few days.⁸

Mechanism

(a) Methylodopa inhibits the breakdown of levodopa outside the brain (by dopa decarboxylase) so that more is available to exert its therapeutic effects.

(b) The increased hypotension may simply be due to the additive effects of the two drugs.

Importance and management

Well documented. Concurrent use need not be avoided but the outcome should be well monitored. In patients on levodopa alone, the use of methylodopa may allow a reduction in the dosage of the levodopa (the reports cited¹⁻³ quote figures of between 30 and 70%) and may enhance the control of Parkinson's disease, but it should also be borne in mind that in some patients dyskinesias may be worsened. However, in the presence of carbidopa or benserazide the dopa decarboxylase effects of methylodopa would be expected to be less significant and so it seems unlikely that a dose reduction of levodopa would be required. The increased hypotensive effects seem to be small, but they too should be checked.

Levodopa + Mirtazapine

An isolated report describes the development of serious psychosis, which was attributed to an interaction between levodopa and mirtazapine.

Clinical evidence, mechanism, importance and management

A 44-year-old woman taking levodopa/carbidopa, pergolide, selegiline and memantine for Parkinson's disease, was started on mirtazapine in increasing doses rising from 15 to 60 mg daily over 24 days, for depression, labile mood, anxiety, social withdrawal and sleep disturbance. She initially improved, but then major depression and psychosis developed, and on day 26 she attempted self-strangulation. She recovered when the mirtazapine, memantine and selegiline were stopped and low-dose clozapine started. The authors concluded that the reaction was attributable to dopamine-induced psychosis triggered by the addition of mirtazapine to levodopa.¹

Levodopa + Papaverine

Case reports describe a deterioration in the control of parkinsonism in patients taking levodopa when given papaverine, but a controlled trial failed to confirm this interaction.

Clinical evidence

(a) Levodopa effects reduced

A woman with long-standing parkinsonism, well controlled on levodopa (with the later addition of carbidopa), began to show a steady worsening of her parkinsonism within a week of additionally starting papaverine 100 mg daily for cerebral vascular insufficiency. The deterioration continued until the papaverine was withdrawn. The normal response to levodopa returned within a week. Four other patients had a similar response.¹ Two other similar cases have been described in another report.²

(b) Levodopa effects unchanged

A double-blind crossover trial in 9 patients with parkinsonism taking levodopa (range 100 to 750 mg daily) plus a dopa-decarboxylase inhibitor did not find any changes in disease control when they also took papaverine hydrochloride 150 mg daily for 3 weeks. Two patients were also taking bromocriptine 40 mg daily and two trihexyphenidyl 15 mg daily.³

Mechanism

Not understood. One suggestion is that papaverine blocks the dopamine receptors in the striatum of the brain, thereby inhibiting the effects of the

levodopa.^{1,4} Another is that papaverine may have a reserpine-like action on the vesicles of adrenergic neurones^{1,5} (i.e. it can deplete dopamine stores).

Importance and management

Direct information seems to be limited to the reports cited. Concurrent use can apparently be uneventful. However, in the light of the reports of adverse interactions it would be prudent to monitor the outcome closely. Carefully controlled trials can provide a good picture of the general situation, but may not necessarily identify the occasional patient who may be affected by an interaction.

Levodopa + Penicillamine

Penicillamine can raise plasma levodopa levels in a few patients. This may improve the control of the parkinsonism but the adverse effects of levodopa may also be increased.

Clinical evidence, mechanism, importance and management

A patient with Parkinson's disease taking levodopa with a dopa-decarboxylase inhibitor [probably carbidopa] had a 60% increase in his levodopa plasma levels after taking penicillamine 600 mg daily. This resulted in improved control of symptoms but with an increase in dyskinesia. It was noted that this patient had slightly low serum copper and ceruloplasmin levels.¹ Another study also saw improvements in 2 patients with Parkinson's disease taking levodopa when they also took penicillamine, but levodopa levels were apparently not measured. Again it was noted that the patients had slightly low copper and ceruloplasmin levels. In another 4 similar patients the effects of penicillamine seemed absent in the presence of normal copper and ceruloplasmin levels.² The authors of this report² attribute the improvement in parkinsonism to the copper chelating properties of penicillamine. However, the authors of the other report¹ suggest that as the effect of penicillamine would not be this rapid, penicillamine must be affecting levodopa pharmacokinetics.

This limited evidence suggests that the concurrent use of levodopa and penicillamine need not be avoided, and in some patients parkinsonian symptoms may be improved. However, if both drugs are given, monitor the effects as an increase in the adverse effects of levodopa is also possible.

Levodopa + Phenylbutazone

A single case report describes antagonism of the effects of levodopa by phenylbutazone.

Clinical evidence, mechanism, importance and management

A patient (who was very sensitive to levodopa) found that he was only able to prevent the involuntary movements of his tongue, jaw, neck and limbs caused by levodopa, by taking frequent small doses (125 mg) of levodopa. He was able to suppress the levodopa adverse effects with phenylbutazone. However, the phenylbutazone also lessened the therapeutic effect of the levodopa.¹ The reason is not understood. This interaction has not been confirmed, and its general importance is not known.

Levodopa + Phenytoin

The therapeutic effects of levodopa can be reduced or abolished by phenytoin.

Clinical evidence, mechanism, importance and management

A study in 5 patients taking levodopa 630 to 4600 mg (four also taking carbidopa 150 to 225 mg daily) for Parkinson's disease, found that when they also took phenytoin in doses of up to 500 mg daily for 5 to 19 days the levodopa-induced dyskinesias were relieved, but the beneficial effects of the levodopa on parkinsonism were reduced or abolished. The patients became slow, rigidity re-emerged, and some of them became unable to get out of a chair. Within 2 weeks of stopping the phenytoin, their parkinsonism was again well controlled by the levodopa.¹ Despite many suggestions, the mechanism of this interaction is not understood. Information seems to be limited to this study, nevertheless it would seem prudent to monitor concurrent use for any evidence of reduced levodopa efficacy.

1. Mendez JS, Cotzias GC, Mena I, Papavasiliou PS. Diphenylhydantoin blocking of levodopa effects. *Arch Neurol* (1975) 32, 44–6.

Levodopa + Pyridoxine (Vitamin B₆)

The effects of levodopa are reduced or abolished by pyridoxine, but this interaction does not occur when levodopa is given with the dopa-decarboxylase inhibitors carbidopa or benserazide, as is usual clinical practice.

Clinical evidence

(a) Levodopa

A study in 25 patients taking levodopa alone found that if they were given high doses of pyridoxine (750 to 1000 mg daily), the effects of the levodopa were reduced within 24 hours, and were completely abolished within 3 to 4 days. Daily doses of pyridoxine 50 to 100 mg also reduced or abolished the effects of levodopa, and an increase in the signs and symptoms of parkinsonism occurred in 8 out of 10 patients taking only 5 to 10 mg of pyridoxine daily.¹

The antagonism of the effects of levodopa (given without a dopa-decarboxylase inhibitor) by pyridoxine has been described in numerous other reports.^{1–6}

(b) Levodopa/carbidopa

A study in 15 patients with Parkinson's disease taking long-term levodopa found that a single 250-mg oral dose of levodopa produced a peak dopa level of 600 nanograms/mL. When pyridoxine 50 mg was also given, the peak plasma levels of dopa fell by almost 70%. When the levodopa was given with carbidopa 50 mg the peak plasma dopa levels were 1300 nanograms/mL, and were not significantly affected by pyridoxine.⁶ The results from a subset of these patients have been reported elsewhere.⁷ The absence of an interaction in the presence of a dopa-decarboxylase inhibitor is confirmed in another report.⁸

Mechanism

The conversion of levodopa to dopamine within the body requires the presence of pyridoxal-5-phosphate (derived from pyridoxine) as a co-factor. When dietary amounts of pyridoxine are high, the peripheral metabolism of levodopa by dopa-decarboxylase is increased so that less is available for entry into the CNS, and its effects are reduced accordingly. Pyridoxine may also alter levodopa metabolism by Schiff-base formation. However, in the presence of dopa-decarboxylase inhibitors such as carbidopa or benserazide, this peripheral metabolism of levodopa is reduced and much larger amounts are available for entry into the CNS, even if quite small doses are given. So even in the presence of large amounts of pyridoxine, the peripheral metabolism remains unaffected and the serum levels of levodopa are virtually unaltered.

Importance and management

A clinically important, well documented and well established interaction, but principally of historical interest now since levodopa is rarely used alone. The problem of this interaction can be totally solved by using levo-

dopa with a dopa-decarboxylase inhibitor such as carbidopa or benserazide. In the rare cases that levodopa is used alone, pyridoxine in doses as low as 5 mg daily can reduce the effects of levodopa and should therefore be avoided. Warn patients about proprietary pyridoxine-containing preparations such as multivitamins and supplements. Some breakfast cereals are fortified with pyridoxine and other vitamins, but the amounts are usually too small to matter (e.g. a 30 g serving of Kellogg's Corn Flakes or Rice Krispies (UK products) contains only about 0.6 mg of pyridoxine). There is no good clinical evidence to suggest that a low-pyridoxine diet is desirable, and indeed it may be harmful since the normal dietary requirements are about 2 mg daily.

Levodopa + Rauwolfia alkaloids

The effects of levodopa are opposed by rauwolfia alkaloids such as reserpine.

Clinical evidence, mechanism, importance and management

Reserpine and other rauwolfia alkaloids deplete the brain of monoamines, including dopamine, thereby reducing their effects.¹ This can lead to parkinsonian-like symptoms, and may oppose the actions of administered levodopa. There are not only sound pharmacological reasons for believing this to be an interaction of clinical importance, but a reduction in the antiparkinsonian activity of levodopa has been observed in patients given **reserpine**.² The rauwolfia alkaloids should be avoided in patients with Parkinson's disease, whether or not they are taking levodopa.

2. Yahr MD. Personal communication, February 1977.

Levodopa + Spiramycin

The plasma levels of levodopa (given with carbidopa) are reduced by spiramycin, thereby reducing its therapeutic effects.

Clinical evidence

The observation of a patient with Parkinson's disease taking levodopa/carbidopa whose condition became less well-controlled when treated with spiramycin, prompted further study. Levodopa/carbidopa 250/25 mg was given to 7 healthy subjects after they had taken spiramycin 1 g twice daily for 3 days. The spiramycin reduced the AUC of levodopa by 57%, and maximum plasma levels fell from 2162 to 1680 nanograms/mL (not significant). The relative bioavailability of levodopa was only 43%. The plasma levels of the carbidopa were barely detectable.¹

Mechanism

Not fully established. In some way spiramycin markedly reduces the absorption of carbidopa, possibly by forming a non-absorbable complex in the gut or by accelerating its transit through the gut. As a result, not enough carbidopa is absorbed to inhibit the peripheral metabolism of the levodopa by dopa-decarboxylase, so that the effects of the levodopa are reduced.¹

Importance and management

Information is very limited, but the interaction appears to be established and of clinical importance. The management of this interaction is unclear, but since it appears to be due to an effect on absorption it would seem pru-

dent to try to separate the dosing of these two drugs by as much as possible, although this may be difficult with some levodopa regimens. Monitor the outcome of concurrent use on the control of Parkinson's disease. It is not known whether other macrolide antibacterials behave in a similar way, or whether spiramycin affects levodopa/benserazide preparations. More study is needed.

1. Brion N, Kollenbach K, Marion MH, Grégoire A, Advenier C, Pays M. Effect of a macrolide (spiramycin) on the pharmacokinetics of L-dopa and carbidopa in healthy volunteers. *Clin Neuropharmacol* (1992) 15, 229–35.

Levodopa + SSRIs

The use of an SSRI is often beneficial in parkinsonian patients taking levodopa to treat the depression associated with the disease. However, sometimes parkinsonian symptoms are worsened.

Clinical evidence

Four patients taking levodopa 375 to 990 mg daily, a dopa-decarboxylase inhibitor [drug and dose not stated] and amantadine [dose not stated], had a deterioration in the control of their parkinsonism when they were also given **fluoxetine** 20 mg daily for 8 to 11 weeks. The **fluoxetine** was withdrawn and their motor performance was restored. The antidepressant efficacy of **fluoxetine** was not found to be substantial in any of the 4 patients.¹ Another patient taking levodopa developed frequent hallucinations after the addition of **fluoxetine**. They resolved when the **fluoxetine** was withdrawn.² In a retrospective study of 23 parkinsonian patients who were given **fluoxetine** up to 40 mg daily, 20 patients had no change in the control of their parkinsonism but 3 others experienced a worsening in their Parkinson's disease signs.³ These are just a few of the reports on the onset or worsening of Parkinson's with SSRIs, and a number of reviews have been published about the extrapyramidal effects of SSRIs.^{4,5}

Mechanism

Not understood. Extrapyramidal effects are rare but recognised adverse effects of SSRIs.^{4,5}

Importance and management

Although the information is limited, it seems that in some cases parkinsonism can be worsened by SSRIs. Concurrent use is valuable and need not be avoided, but monitor the outcome and withdraw the SSRI if necessary.

Levodopa + Tricyclic antidepressants

The concurrent use of levodopa and the tricyclics is usually uneventful although two unexplained hypertensive crises have occurred when imipramine or amitriptyline was used with levodopa/carbidopa. See also 'Levodopa + Antimuscarinics', p.682 for interactions due to the antimuscarinic effects of tricyclic antidepressants.

Clinical evidence

A hypertensive crisis (blood pressure 210/110 mmHg) associated with agitation, tremor and generalised rigidity developed in a woman taking 6 tablets of levodopa/carbidopa 100/10 mg daily the day after she started to take **imipramine** 25 mg three times daily. The **imipramine** was stopped and she recovered over the following 24 hours. The same reaction occurred again when she was later accidentally given **amitriptyline** 25 mg three times daily.¹ A similar hypertensive reaction (a rise from 190/110 to 270/140 mmHg) occurred over 34 hours in another woman taking **amitriptyline** 20 mg at night when she was given levodopa/carbidopa 50/5 mg and metoclopramide 10 mg, both three times a day. This resolved when all three drugs were stopped.²

Mechanism

Not understood.

Importance and management

Information seems to be limited to these reports. Concurrent use is normally successful and uneventful.³⁻⁵ However, be alert for the possibility of a hypertensive reaction, which resolves if the tricyclic antidepressant is withdrawn. See also 'Levodopa + Antimuscarinics', p.682 for interactions due to the antimuscarinic adverse effects of tricyclic antidepressants.

MAO-B inhibitors + Antidepressants

A few cases of the serotonin syndrome and other serious CNS disturbances have been seen when selegiline was given with tricyclic antidepressants, fluoxetine or venlafaxine. One of the manufacturers of selegiline contraindicates its use with any antidepressant drug, while another advises avoiding SSRIs and venlafaxine, and using caution with tricyclics. See also 'MAO-B inhibitors + MAOIs or RIMAs', p.692 for information on selegiline and MAOIs. The manufacturer of rasagiline specifically recommends avoiding the concurrent use of fluoxetine or fluvoxamine and recommends caution on the concurrent use of any antidepressant.

Clinical evidence

A. SSRIs

(a) Citalopram

In a double-blind randomised study 18 healthy subjects were given citalopram 20 mg or a placebo daily for 10 days followed by 4 days with concurrent **selegiline** 10 mg daily. There was no evidence of changes in vital signs or in the frequency of adverse events, but the bioavailability of the **selegiline** was slightly reduced by about 30% in the presence of citalopram. The authors of this report concluded that no clinically relevant interaction occurred between **selegiline** and citalopram.¹

(b) Fluoxetine

A woman with Parkinson's disease taking **selegiline**, bromocriptine and levodopa/carbidopa was also given fluoxetine 20 mg. Several days later she developed episodes of shivering and sweating in the mid-afternoon, which lasted several hours. Her hands became blue, cold and mottled and her blood pressure was elevated (200/120 mmHg). These episodes disappeared when both fluoxetine and **selegiline** were stopped, and did not reappear when the fluoxetine alone was restarted.² A case of mild serotonin syndrome has been described in a woman taking levodopa and **selegiline** a few days after starting fluoxetine,³ and a possible case of the serotonin syndrome has been described in another patient taking **selegiline** and fluoxetine.⁴

Other patients have become hyperactive and apparently manic,² have developed ataxia,⁵ or developed a tonic-clonic seizure and headache, flushes, palpitations, and a blood pressure of 250/130 mmHg (a pseudophaeochromocytoma syndrome),⁶ all after the concurrent use of fluoxetine and **selegiline**. These reports contrast with a retrospective study of 23 patients with parkinsonism, who received both **selegiline** and fluoxetine without any serious adverse effects occurring, although worsening confusion was noted in 5 patients.⁷

(c) Fluvoxamine

The manufacturer of **selegiline** notes that serious reactions similar to those seen with fluoxetine have occurred in patients receiving **selegiline** and fluvoxamine.⁸

(d) Paroxetine

A retrospective study of patients with Parkinson's disease taking **selegiline** 5 to 10 mg daily (and other antiparkinsonian drugs such as levodopa/carbidopa, bromocriptine, amantadine, pergolide, and antimuscarinics) noted that the addition of paroxetine 10 to 40 mg daily caused no adverse effects and the patients appeared to obtain overall benefit, including some improvement in parkinsonian symptoms.⁹ However, the manufacturers of **selegiline** note that serious reactions similar to those seen with fluoxetine have occurred in patients receiving **selegiline** and paroxetine.^{8,10}

(e) Sertraline

A retrospective study of patients with Parkinson's disease taking **selegiline** 5 to 10 mg daily (and other antiparkinsonian drugs such as levodopa/carbidopa, bromocriptine, amantadine, pergolide, and antimuscarinics) noted that the addition of sertraline 25 to 100 mg daily caused no adverse effects and the patients appeared to obtain overall benefit, including some improvement in parkinsonian symptoms.⁹ However, the manufacturers of **selegiline** note that serious reactions similar to those seen with concurrent fluoxetine have occurred in patients receiving **selegiline** and sertraline.^{8,10}

B. Tetracyclic antidepressants

For a case report of a hypertensive crisis, which was attributed to the concurrent use of **maprotiline**, **selegiline** and ephedrine, see 'MAO-B inhibitors + Sympathomimetics; Indirectly-acting', p.693.

C. Tricyclic antidepressants

Between 1989 and 1994 the FDA in the USA received 16 reports of adverse interactions between **selegiline** and tricyclic antidepressants, which were attributed to the serotonin syndrome.¹¹

The manufacturers very briefly describe severe CNS toxicity in one patient given **selegiline** and **amitriptyline** (hyperpyrexia and death), and in another given **protriptyline** (tremor, agitation, restlessness, followed by unresponsiveness and death).^{8,10,12} They state that related adverse events including hypertension, syncope, asystole, diaphoresis, seizures, changes in behavioural and mental status, and muscular rigidity have also been reported in some patients receiving **selegiline** and various tricyclics.^{8,10} A further report describes the serotonin syndrome in a woman given **nortriptyline** and **selegiline** concurrently.¹³

However, these warnings need to be balanced by other reports indicating that these reactions are uncommon. One study based on the findings of 45 investigators treating 4,568 patients with **selegiline** and antidepressants [not specifically named but possibly including the tricyclics] found that only 11 patients (0.24%) experienced symptoms considered to represent the serotonin syndrome, and only 2 patients (0.04%) experienced symptoms considered to be serious.¹⁴ Another small retrospective study designed to evaluate the tolerability and efficacy of combining **selegiline** and tricyclic antidepressants [not specifically named] identified 28 patients who had taken both drugs.¹¹ In total, 17 patients definitely benefited and 6 patients possibly benefited from taking the combination. Another retrospective study of 25 occasions of combined tricyclic-**selegiline** use found no cases of the serotonin syndrome.⁴

D. Miscellaneous antidepressants

(a) Trazodone

A retrospective study of patients with Parkinson's disease taking **selegiline** 5 to 10 mg daily (and other anti-parkinson drugs such as levodopa/carbidopa, bromocriptine, amantadine, pergolide, and antimuscarinics) noted that the addition of trazodone 25 to 150 mg daily caused no adverse effects and the patients appeared to obtain overall benefit, including some improvement in parkinsonian symptoms.⁹

(b) Venlafaxine

A man developed the serotonin syndrome 15 days after stopping **selegiline** 50 mg [daily] and within 30 minutes of starting venlafaxine 37.5 mg.¹⁵

Mechanism

Not fully understood. In some cases the symptoms seen appear to be consistent with the serotonin syndrome, which is typified by CNS irritability, increased muscle tone, shivering, altered consciousness and myoclonus, and appears to be associated with the use of more than one serotonergic

drug, see 'The serotonin syndrome', (p.9). This syndrome has also occurred with non-selective MAOIs and 'SSRIs', (p.1142), 'tricyclics', (p.1149), and 'venlafaxine', (p.1156). Note that selegiline may have some non-selective MAOI activity.

Importance and management

The possibility of the serotonin syndrome or similar (signs and symptoms may include diaphoresis, flushing, ataxia, tremor, hyperthermia, hyper/hypotension, seizures, palpitation, dizziness and mental changes that include agitation, confusion and hallucinations progressing to delirium and coma)^{8,12} occurring with selegiline and SSRIs or venlafaxine would appear to be established, although the incidence is very rare. The manufacturers of selegiline recommend that these drug combinations should be avoided.^{8,10,12} In addition, selegiline should not be started for 5 weeks after stopping fluoxetine, 2 weeks after stopping sertraline, and one week after stopping other SSRIs, and SSRIs should not be started for 2 weeks after stopping selegiline.^{8,12}

Similarly, the manufacturers of **rasagiline** recommend avoiding combined use with fluoxetine and fluvoxamine. **Rasagiline** should not be started for 5 weeks after stopping fluoxetine or 2 weeks after starting fluvoxamine, and fluoxetine should not be started for 2 weeks after stopping **rasagiline**.¹⁶

If the decision is made to combine selegiline and any of the tricyclic antidepressants, the outcome should be well monitored, but the likelihood of problems seems to be small. Nevertheless, some manufacturers of selegiline advise avoiding the combination of tricyclic antidepressants and selegiline.^{10,12} Similarly, the manufacturers of **rasagiline** advise caution if it is given with antidepressants.¹⁶

Limited evidence suggests that trazodone is unlikely to interact with selegiline.⁹ However, interactions with other antidepressants are rare. Therefore if trazodone is given with either selegiline or **rasagiline** some caution would seem prudent.

MAO-B inhibitors + Dextromethorphan

The manufacturer of **rasagiline**¹ suggests that its use with **dextromethorphan** should be avoided. Similarly, some consider that patients taking selegiline should try to avoid **dextromethorphan**.² These warnings are based on the serious adverse reactions (the serotonin syndrome or similar) that have rarely occurred when **dextromethorphan** has been used with 'non-selective MAOIs or RIMAs', (p.1134). The likelihood of any interaction with MAO-B

inhibitors would appear to be very small, but because of the potential severity, some caution would appear to be prudent.

- Jacob JE, Wagner ML, Sage JI. Safety of selegiline with cold medications. *Ann Pharmacother* (2003) 37, 438–41.

MAO-B inhibitors + MAOIs or RIMAs

Marked orthostatic hypotension has been seen in two patients taking iproniazid or tranlycypromine/trifluoperazine when given selegiline. When the RIMA moclobemide is given with selegiline, restriction of dietary tyramine is necessary, and there may be an increased risk of hypotensive reactions. Some manufacturers of MAO-B inhibitors contraindicate the concurrent use of MAOIs or RIMAs.

Clinical evidence, mechanism, importance and management

(a) MAOIs

In a pilot study, one patient taking **iproniazid** 150 mg daily developed severe orthostatic hypotension on two occasions within an hour of taking **selegiline** 5 mg. Two other patients (one on **tranlycypromine**/trifluoperazine and one on **tranlycypromine**/trifluoperazine plus **isocarboxazid**) did not have this reaction to **selegiline** 5 mg twice daily. The authors mention another patient who similarly developed postural hypotension on two occasions within 2 hours of taking **selegiline** 5 mg. He had stopped taking **tranlycypromine**/trifluoperazine, 4 weeks previously.¹ The reasons are not understood. This evidence suggests that **selegiline** should be given with caution to patients taking, or who have recently stopped, non-selective MAOIs. One UK manufacturer of **selegiline**² and the manufacturer of **rasagiline**³ actually contraindicate the concurrent use of non-selective MAOIs. At least 14 days should elapse between stopping **rasagiline** and starting an MAOI.³

(b) RIMAs

A study in 24 healthy subjects, designed to assess the safety and tolerability of giving **moclobemide** 100 to 400 mg and **selegiline** 5 mg twice daily, sequentially or combined, found that the adverse effects were no greater under steady-state conditions than with either drug alone, but the sensitivity to tyramine was considerably increased. The mean tyramine sensitivity factor for **moclobemide** alone was 2 to 3, **selegiline** alone was 1.4, and **moclobemide** plus **selegiline** was 8 to 9 (and even 18 in one subject).^{4,5} The reason is, that when taken together, the **moclobemide** inhibits MAO-A while **selegiline** inhibits MAO-B, so that little or no MAO activity remains available to metabolise the tyramine. However, unexpectedly, the combined effect was more than additive.⁵ **Selegiline** had no effect on the pharmacokinetics of **moclobemide**.⁶ In a clinical trial using tyramine restriction, one of 5 **selegiline** recipients and one of 5 **selegiline/moclobemide** recipients reported symptomatic hypotension, and there was no increase in blood pressure in any patient.⁷

In practical terms this means that patients taking **moclobemide** with **selegiline** should be given the same dietary restrictions for tyramine-rich foods and drinks (see 'tyramine-rich drinks', (p.1151) and 'tyramine-rich foods', (p.1153)), that relate to the non-selective MAOIs such as phenelzine and tranlycypromine.⁵ However, because of the potential risks the manufacturer of **moclobemide**⁸ contraindicate this combination. On the basis of work done on the *pig* it is suggested that if **selegiline** is replaced by **moclobemide**, the dietary restrictions can be relaxed after a wash-out period of about 2 weeks. If switching from **moclobemide** to **selegiline**, a wash-out period of 1 to 2 days is sufficient.⁴

MAO-B inhibitors + Pethidine (Meperidine)

A case of fluctuating stupor and agitation, with muscle rigidity, sweating and a raised temperature has been reported when pethidine was used with selegiline. This case is similar to cases reported with the older non-selective MAOIs or RIMAs and pethidine. The manufacturers say that selegiline and rasagiline should not be used with pethidine.

Clinical evidence, mechanism, importance and management

A patient taking **selegiline** 5 mg twice daily, pergolide, levodopa/carbidopa, imipramine and desipramine was treated with pethidine beginning on postoperative day one for 4 days in doses of 75 to 150 mg daily. On the second day he became increasingly restless and irritable, progressing to delirium on the fourth day, with fluctuations between stupor and severe agitation associated with muscular rigidity, sweating and a raised temperature. The patient remained normotensive. Both pethidine and then **selegiline** were stopped, with full recovery.¹ This case is similar to various cases described with 'older nonselective MAOI inhibitors and pethidine', see (p.1140). US information states that other serious reactions including death have occurred with the combination of **selegiline** and pethidine.²

On the basis of this evidence the manufacturers of **selegiline**^{2,3} and **rasagiline**⁴ contraindicate concurrent use with **pethidine**, which is a prudent precaution. The manufacturers of **rasagiline** additionally say that pethidine should not be given until 14 days after stopping **rasagiline**,⁴ which makes sense since it is an irreversible inhibitor of MAO-B. One manufacturer of **selegiline** also cautions that **tramadol** may potentially interact with **selegiline**,⁵ which seems a possibility based on evidence of an interaction between 'tramadol and non-selective MAOIs', (p.1141). Another manufacturer of **selegiline** contraindicates concurrent use with all opioids,³ which is probably unnecessary, based on the evidence with non-selective MAOIs, see 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1140.

MAO-B inhibitors + Sympathomimetics; Indirectly-acting

An isolated report describes a hypertensive crisis, which was attributed to an interaction between selegiline, ephedrine, and maprotiline.

Clinical evidence

An isolated case report describes a man taking **selegiline** 10 mg daily, levodopa/carbidopa, lisuride, maprotiline 75 mg daily, and theophylline/**ephedrine** 180 mg/32 mg daily who developed hypertensive crises (blood pressure up to 300/150 mmHg), intense vasoconstriction, confusion, abdominal pain, sweating, and tachycardia (110 bpm) within 2 days of raising the dose of theophylline/**ephedrine** to 270 mg/48 mg daily. All of the drugs were stopped, and the patient was treated with intravenous nicardipine. He recovered uneventfully.¹

Mechanism

It is thought that this reaction occurred as a result of excess sympathomimetic amines: ephedrine is an indirectly-acting sympathomimetic that causes increased release of noradrenaline; selegiline has some MAO-A in-

hibitory activity and may therefore inhibit noradrenaline metabolism; and maprotiline inhibits reuptake of noradrenaline.¹ Compare also 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1147 and 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1149.

Importance and management

This appears to be the only report of a hypertensive reaction in a patient taking selegiline and ephedrine, and concurrent maprotiline was also implicated. In general, if selegiline is used at recommended doses it is selective for MAO-B and no restrictions are required in the use of indirectly-acting sympathomimetics such as ephedrine and **pseudoephedrine**. Nevertheless, this report suggests that, rarely, interactions are still possible, and some consider that patients taking selegiline should try to avoid **pseudoephedrine**.² The manufacturer of **rasagiline** also recommends against the concurrent use of sympathomimetics such as those present in decongestants or cold medications containing ephedrine or **pseudoephedrine**.³

MAO-B inhibitors + Tyramine-rich foods

No dietary restrictions are required with the doses of rasagiline and selegiline recommended for use in Parkinson's disease. An isolated report describes the cheese reaction in a patient taking selegiline 20 mg daily. Thus, at higher doses of selegiline, restriction of the amount of tyramine in the diet may be necessary.

Clinical evidence

(a) Rasagiline

The manufacturer notes that the results of four tyramine challenge studies, together with the results of home monitoring of blood pressure after meals (from 464 patients treated with rasagiline 0.5 or 1 mg daily or placebo without tyramine restrictions), and the lack of reported problems in clinical trials without tyramine restriction, indicate that no dietary restrictions are necessary with rasagiline.¹ No specific details were provided of any of the studies.

(b) Selegiline

1. *Oral selegiline*. The pressor response to oral tyramine was not altered by pretreatment with selegiline 10 mg daily in healthy volunteers and patients with Parkinson's disease.² However, another study³ found that selegiline 5 mg daily for at least 14 days reduced the dose of oral tyramine required to achieve the cardiovascular threshold (increase in systolic BP of greater than 30 mmHg, a diastolic BP greater than 100 mmHg or a fall in heart rate of greater than 20%) by a factor of 2.8. Nevertheless, this reduction was less than the RIMA moclobemide (4.3) and the MAOI phenelzine (10.3).³ In other studies, higher doses of selegiline (20 or 30 mg daily) increased the sensitivity to oral tyramine by 2- to 4.5-fold.^{4,5} A patient taking selegiline 20 mg daily was reported to have had a hypertensive reaction (severe headache and rise in blood pressure) after eating macaroni and **cheese**,⁶ but this appears to be the only published report of the 'cheese reaction' with selegiline.

2. *Buccal and transdermal selegiline*. The dose of tyramine required to elicit a pressor effect was not altered by pretreatment with buccal selegiline 1.25 mg in healthy subjects.⁷ Similarly, the pressor response to tyramine up to 200 mg was not significantly altered by pretreatment with a single 24-hour application of transdermal selegiline 7.8 mg/24 hour in healthy subjects.⁸

Mechanism

Rasagiline and selegiline specifically inhibit MAO-B, which leaves MAO-A still available to metabolise any tyramine in foodstuffs. However, at higher doses the selectivity of selegiline diminishes, and inhibition of the metabolism of tyramine is more likely. Nevertheless, the 2- to 4.5-fold increase in effect of tyramine seen with selegiline 5 to 30 mg daily is still

less than that seen with older non-selective MAOIs, see 'MAOIs or RIMAs + Tyramine-rich foods', p.1153.

Importance and management

The manufacturer states that no dietary tyramine restrictions are necessary with rasagiline.¹ Similarly, at the recommended doses of conventional or buccal selegiline used in Parkinson's disease the manufacturers say that no dietary restrictions are necessary,⁹⁻¹¹ and this is supported by the scarcity of any published reports of reactions. If higher doses of selegiline are used, patients should be advised to avoid large amounts of tyramine-rich foods. For a list of the possible tyramine-content of some foods, see 'Table 32.3', (p.1154).

MAO-B inhibitors; Rasagiline + CYP1A2 inhibitors

Ciprofloxacin increases the AUC of rasagiline. Other inhibitors of cytochrome P450 isoenzyme CYP1A2 are predicted to interact similarly.

Clinical evidence, mechanism, importance and management

The manufacturer notes that concurrent use of rasagiline and **ciprofloxacin** increased the AUC of rasagiline by 83%.¹ **Ciprofloxacin** inhibits the cytochrome P450 isoenzyme CYP1A2, which is the major enzyme responsible for the metabolism of rasagiline. The clinical relevance of this increase has not been assessed, but until more is known caution is warranted. This caution should be extended to other potent inhibitors of CYP1A2. For a list see 'Table 1.2', (p.4).

1. Azilect (Rasagiline mesilate). Teva Pharmaceuticals Ltd. UK Summary of product characteristics, April 2007.

MAO-B inhibitors; Selegiline + Cocaine

Cocaine and selegiline appear not to interact adversely.

Clinical evidence, mechanism, importance and management

In a study to establish the safety of using selegiline to prevent relapse in cocaine addiction, 5 otherwise healthy intravenous cocaine users were given 0, 20 and 40 mg intravenous doses of cocaine one hour apart following treatment with selegiline 10 mg or placebo orally. The cocaine increased the heart rate, blood pressure, pupil diameter and subjective indices of euphoria as expected. However, the presence of selegiline reduced pupillary diameter, but did not alter the pupil dilation or other effects normally caused by cocaine. It was concluded that concurrent use is safe and unlikely to increase the reinforcing effects of cocaine.¹ In another study, transdermal selegiline did not alter the pharmacokinetics of

intravenous cocaine in cocaine-dependent subjects. Some physiological effects (blood pressure and heart rate) and subjective effects of cocaine were attenuated by selegiline.²

MAO-B inhibitors; Selegiline + Dopamine agonists

No significant pharmacokinetic interaction occurs between selegiline and cabergoline, pramipexole or ropinirole.

Clinical evidence, mechanism, importance and management

(a) Cabergoline

No pharmacokinetic interaction was found to occur between cabergoline 1 mg daily and selegiline 10 mg daily after 22 days of concurrent use in a study in 6 subjects with Parkinson's disease.¹

(b) Pramipexole

The manufacturers of pramipexole say that no pharmacokinetic interaction occurs with selegiline.²

(c) Ropinirole

The manufacturers of ropinirole note that a population pharmacokinetic analysis showed a lack of effect of selegiline on ropinirole.³

1. Dostert P, Benedetti MS, Persiani S, La Croix R, Bosc M, Fiorentini F, Deffond D, Vernay D, Dordain G. Lack of pharmacokinetic interaction between the selective dopamine agonist cabergoline and the MAO-B inhibitor selegiline. *J Neural Transm* (1995) 45 (Suppl), 247-57.
2. Mirapexin (Pramipexole). Boehringer Ingelheim Ltd. UK Summary of product characteristics, August 2006.
3. SmithKline Beecham. Personal Communication, September 1996.

MAO-B inhibitors; Selegiline + Hormonal contraceptives or HRT

In a small study, the bioavailability of selegiline was markedly higher (mean of about 20-fold) in women taking combined oral contraceptives than in those not taking contraceptives. In a controlled study, the AUC of selegiline was modestly increased by HRT (60%) and the change was not considered clinically relevant.

Clinical evidence

(a) Combined oral contraceptives

The AUCs of single doses of selegiline 5 to 40 mg were 16 to 45-fold higher in 4 women taking combined oral contraceptives than in 4 women who were not taking contraceptives. Three subjects were taking ethinylestradiol/gestodene 30/75 micrograms, and one was taking a triphasic preparation of ethinylestradiol/levonorgestrel.¹

(b) HRT

The AUC of a single 10-mg dose of selegiline was increased by 60% (which was not statistically significant) following 10 days of HRT (containing estradiol valerate/levonorgestrel 2 mg/250 micrograms) in a cross-over study in 12 young healthy women. There was marked variability in selegiline levels with two women having a threefold increase in AUC, and 3 having a decrease. Other changes in pharmacokinetics of selegiline or its metabolites were small.²

Mechanism

It was suggested that the combined oral contraceptive inhibited the first pass metabolism of selegiline and so markedly increased its bioavailability.¹ However, this was not found for HRT containing a different estrogenic hormone.

Importance and management

Although data are limited, it appears that combined oral contraceptives may markedly increase the bioavailability of selegiline. One UK manufacturer advises caution with combined use,³ and the other suggests the combination should be avoided.⁴ Although short-term use of menopausal HRT also increased the AUC of selegiline, the changes were modest and were not considered clinically relevant. Nevertheless, the results perhaps need confirming with longer term combined use. One UK manufacturer of selegiline also advises the avoidance of concurrent HRT.⁴

2. Palovaara S, Anttila M, Nyman L, Laine K. Effect of concomitant hormone replacement therapy containing estradiol and levonorgestrel on the pharmacokinetics of selegiline. *Eur J Clin Pharmacol* (2002) 58: 259–63.
3. Eldepryl (Selegiline hydrochloride). Orion Pharma (UK) Ltd. UK Summary of product characteristics, July 2006.
4. Zelapar (Selegiline hydrochloride). Cephalon Ltd. UK Summary of product characteristics, November 2006.

MAO-B inhibitors; Selegiline + Itraconazole

The concurrent use of selegiline and itraconazole does not appear to alter the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

In a randomised placebo-controlled crossover study, 12 healthy subjects were given selegiline 10 mg after taking itraconazole 200 mg daily for 4 days. Itraconazole did not have any significant effects on the pharmacokinetics of selegiline, although the AUC of desmethylselegiline, a primary metabolite, was increased by 11%. The pharmacokinetics of itraconazole were also unaffected. There would appear to be no reason for avoiding concurrent use.¹

1. Kivistö KT, Wang J-S, Backman JT, Nyman L, Taavitsainen P, Anttila M, Neuvonen PJ. Selegiline pharmacokinetics are unaffected by the CYP3A4 inhibitor itraconazole. *Eur J Clin Pharmacol* (2001) 57, 37–42.

Memantine + Miscellaneous

Drugs that make the urine alkaline (e.g. sodium bicarbonate, carbonic anhydrase inhibitors) will reduce the elimination of memantine. Memantine should be used with caution with other NMDA antagonists, such as amantadine, ketamine and dextromethorphan, or concurrent use should be avoided, because of the theoretical increased risk of adverse effects. Memantine is predicted to interact with other drugs eliminated by the same renal secretion mechanism, but no important interaction was seen with glibenclamide, hydrochlorothiazide, metformin or triamterene.

Clinical evidence, mechanism, importance and management

(a) Antidiabetics

The use of memantine with a combined product containing **glibenclamide** and **metformin** did not result in any changes in the pharmacokinetics of either of the three drugs. Memantine did not reduce the glucose-lowering effects of either drug.¹

(b) Antispasmodic drugs

Memantine might modify the effects of antispasmodic drugs such as **dantrolene** or **baclofen** and dosage adjustment might be required.²

(c) Barbiturates and Antipsychotics

Memantine is predicted to reduce the effects of barbiturates and antipsychotics.²

(d) Dopaminergics

Memantine is predicted to enhance the effects of dopaminergic drugs.²

(e) Drugs that make the urine alkaline

The clearance of memantine was markedly reduced (by about 80%) when the urine was alkaline (pH 8).¹ This would be expected to lead to memantine accumulation and an increase in adverse effects. Drugs that could in-

teract via this mechanism include **sodium bicarbonate** and **carbonic anhydrase inhibitors** (such as acetazolamide).¹

(f) Interactions via cytochrome P450 isoenzymes

The results of *in vitro* studies indicate that memantine is not likely to cause interactions via induction or inhibition of the major cytochrome P450 isoenzymes involved in drug metabolism (CYP1A2, CYP2C9, CYP3A4).^{1,2} In addition, memantine is not metabolised by this enzyme system, and is therefore not expected to undergo interactions via this mechanism.¹

(g) Other drugs eliminated by renal tubular secretion

Memantine is predicted to interact with other drugs that use the same renal cationic transport system leading to increased levels of memantine and/or the other drug. The manufacturer lists **cimetidine**, **ranitidine**, **hydrochlorothiazide**, **metformin**, **procaïnamide**, **quinidine**, **quinine** and **triamterene** as possible examples.^{1,2} However, in an interaction study, the concurrent use of memantine and **hydrochlorothiazide/triamterene** did not result in any change in the steady-state AUC of memantine or **triamterene**, and the AUC of **hydrochlorothiazide** showed a modest *reduction* of about 20%.¹ This degree of change is unlikely to be clinically relevant. Therefore, whether any clinically important interactions occur via this mechanism remains to be established.

(h) Other NMDA-antagonists

Memantine is chemically related to **amantadine**, and the manufacturer advises that concurrent use should be avoided² or undertaken with caution¹ because of the increased risk of adverse CNS-related drug reactions such as psychosis.² Although there are no data, an increased risk is also predicted for **ketamine** and **dextromethorphan**, which are also NMDA antagonists. Avoidance of,² or caution with,¹ concurrent use is advised.

(i) Warfarin

The manufacturer of memantine notes that, although no causal relationship has been established, isolated cases of INR increases have been reported in patients treated with warfarin. They suggest close monitoring of anticoagulant effects.^{1,2}

2. Ebixa (Memantine). Lundbeck Ltd. UK Summary of product characteristics, November 2006.

Piribedil + Clonidine

Clonidine is reported to oppose the effects of piribedil.

Clinical evidence, mechanism, importance and management

A study in 5 patients taking piribedil found that concurrent treatment with clonidine (up to 1.5 mg daily for 10 to 24 days) caused a worsening of the parkinsonism (an exacerbation of rigidity and akinesia). The concurrent use of antimuscarinic drugs reduced the effects of this interaction.¹ The reason is uncertain.

1. Shoulson I, Chase TN. Clonidine and the anti-parkinsonian response to L-dopa or piribedil. *Neuropharmacology* (1976) 15, 25–7.

Pramipexole + Drugs altering its renal clearance

Cimetidine, and possibly amantadine modestly reduce the clearance of pramipexole from the body, and some caution is advised on concurrent use. Probenecid had a minor effect on pramipexole clearance, which is not clinically relevant.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that multiple doses of **cimetidine** reduced the total oral clearance of a single 250-microgram dose of pramipexole by about 35% and increased its half-life by 40%. A similar reduction in the renal clearance of pramipexole was noted. The authors suggest that **cimetidine** reduces the renal excretion of pramipexole by inhibiting the active renal organic cation transport system.¹ The manufacturers say that **cimetidine** and other drugs that are eliminated by this route such as **amantadine** may interact with pramipexole to reduce excretion of either or both drugs.² The clinical significance of these interactions is

uncertain, and as yet there appear to be no reports of any adverse interactions. Nevertheless, the manufacturers suggest a reduction of the pramipexole dose should be considered when **amantadine** or **cimetidine** are given with pramipexole.²

Multiple doses of **probenecid** given to 12 healthy subjects reduced the clearance of a single 250-microgram dose of pramipexole by 10.3%.¹ This change is not clinically relevant.

2. Mirapexin (Pramipexole). Boehringer Ingelheim Ltd. UK Summary of product characteristics, August 2006.

Ropinirole + CYP1A2 inhibitors

Ciprofloxacin increased the AUC of ropinirole by 84%, and other CYP1A2 inhibitors are predicted to interact similarly. Ropinirole dose adjustment may be required if potent CYP1A2 inhibitors are started or stopped.

Clinical evidence

Ciprofloxacin 500 mg twice daily increased the AUC of ropinirole 2 mg three times daily by 84% and increased the maximum plasma level by 60% in a study in 12 patients.¹

Mechanism

Ropinirole is principally metabolised by the cytochrome P450 isoenzyme CYP1A2, of which ciprofloxacin is a known inhibitor.

Importance and management

Although the clinical relevance of this pharmacokinetic interaction has not been assessed, it would seem possible that the effects of ropinirole may be increased. The manufacturers suggest that if therapy with a known potent inhibitor of CYP1A2 is stopped or started during therapy with ropinirole, adjustment of the ropinirole dose may be required.^{1,2} The UK manufacturer specifically mentions **cimetidine** and **fluvoxamine** in addition to ciprofloxacin.² For a full list of CYP1A2 inhibitors, see 'Table 1.2', (p.4).

2. Requip (Ropinirole hydrochloride). GlaxoSmithKline UK. UK Summary of product characteristics, March 2007.

Ropinirole + Miscellaneous

Estrogens (HRT) and tobacco smoking may reduce the clearance of ropinirole. Amantadine and trihexyphenidyl appear not to alter the pharmacokinetics of ropinirole.

Clinical evidence, mechanism, importance and management

(a) Amantadine

The manufacturer notes that population analysis revealed that amantadine did not have any relevant effects on ropinirole pharmacokinetics.^{1,2}

(b) Estrogens

Population pharmacokinetic analysis of clinical study data showed that estrogens (mainly ethinylestradiol²) used in HRT reduced ropinirole clearance by one-third.^{1,4} In another analysis it was found that women taking HRT received a slightly lower daily dose of ropinirole than those not on HRT, with no difference in adverse effects.⁴ Therefore, in women already receiving HRT, ropinirole treatment may be started using the usual dose titration.^{2,3} However, it is suggested that a reduction in the ropinirole dosage may be needed if HRT is started, and an increase if it is withdrawn.^{2,3}

(c) Tobacco

The manufacturer notes that 7 tobacco smokers were found to have a 38% lower ropinirole AUC and a 30% lower maximum level than 11 non-smokers in a study in patients with restless leg syndrome.² Tobacco induces the cytochrome P450 isoenzyme CYP1A2, by which ropinirole is extensively metabolised. Because the dose of ropinirole is titrated to effect, this interaction is unlikely to be clinically relevant, except perhaps if patients stop or start smoking while taking ropinirole.

(d) Trihexyphenidyl

The manufacturer notes that population analysis revealed that trihexyphenidyl did not have any relevant effects on ropinirole pharmacokinetics.¹

Antiplatelet drugs and Thrombolytics

Platelets usually circulate in the plasma in an inactive form, but following injury to blood vessels they become activated and adhere to the site of injury. Platelet aggregation then occurs, which contributes to the haemostatic plug. Platelet aggregation involves the binding of fibrinogen with a glycoprotein IIb/IIIa receptor on the platelet surface. The activated platelets secrete substances such as adenosine diphosphate (ADP) and thromboxane A₂ that result in additional platelet aggregation and also cause vasoconstriction. Finally a number of platelet derived factors stimulate production of thrombin and hence fibrin through the coagulation cascade (see 'The blood clotting process', (p.358)). Opposing this process is the fibrinolysis pathway, which is initiated during clot formation by a number of mediators such as tissue plasminogen activator (tPA) and urokinase. These proteins convert plasminogen to plasmin, which in turn degrades fibrin, the main component of the clot.

Antiplatelet drugs (see 'Table 19.1', (below)) reduce platelet aggregation and are used to prevent thromboembolic events. They act through a wide range of mechanisms including:

- prevention of thromboxane A₂ synthesis or inhibition of thromboxane receptors e.g. aspirin inhibits platelet cyclo-oxygenase, preventing synthesis of thromboxane A₂
- interference with adenosine diphosphate mediated platelet activation e.g. thienopyridines; inhibition of adenosine reuptake e.g. dipyridamole; interference with adenosine metabolism by inhibiting cyclic adenosine monophosphate (cAMP) phosphodiesterase e.g. cilostazol
- interference in the final step in platelet aggregation by stopping fibrinogen binding with the glycoprotein IIb/IIIa receptor on the platelet surface

Therefore some antiplatelet drugs can have beneficial additive effects with other antiplatelet drugs that act via different mechanisms. Furthermore, other drugs such as dextrans, heparin, some prostaglandins and sulfinpyrazone also have some antiplatelet activity.

Thrombolytics (see 'Table 19.1', (below)) are used in the treatment of thromboembolic disorders. Thrombolytics activate plasminogen to form

plasmin, which is a proteolytic enzyme that degrades fibrin and therefore produces clot dissolution.

This section is primarily concerned with those interactions where the activities of antiplatelet drugs or thrombolytics are changed by the presence of another drug. Note that the interactions of high-dose aspirin are covered under analgesics.

Table 19.1 Antiplatelet drugs and thrombolytics

Group	Drugs
Antiplatelet drugs	
Adenosine reuptake inhibitors/Phosphodiesterase inhibitors	Cilostazol, Dipyridamole
Cyclo-oxygenase inhibitors	Aspirin, Indobufen, Triflusal
Glycoprotein IIb/IIIa-receptor antagonists	Abciximab, Eptifibatide, Tirofiban
Thienopyridines (inhibitors of adenosine diphosphate mediated platelet aggregation)	Clopidogrel, Ticlopidine
Thromboxane receptor antagonists	Picotamide
Miscellaneous	Ditazole, Trapidil
Thrombolytics	
Thrombolytics	Alteplase, Anistreplase, Defibrotide, Reteplase, Streptokinase, Tenecteplase, Urokinase

Alteplase + Glycerol trinitrate (Nitroglycerin)

Glycerol trinitrate may reduce the thrombolytic efficacy of alteplase, but this is not thought to be clinically relevant.

Clinical evidence, mechanism, importance and management

In a randomised study, 60 patients with acute anterior myocardial infarction were given intravenous alteplase 100 mg over 3 hours, as well as heparin and aspirin. In addition, 27 of the patients were also given intravenous glycerol trinitrate 100 micrograms/minute for 8 hours. Patients receiving both alteplase and glycerol trinitrate had signs of reperfusion less often (56%) than the patients who received alteplase alone (76%). In the combined treatment group time to reperfusion was also longer (37.8 versus 19.6 minutes) and the incidence of coronary artery re-occlusion was higher (53% versus 24%). Giving alteplase with glycerol trinitrate produced plasma levels of tissue plasminogen activator (tPA) antigen that were about two-thirds lower than when alteplase was given alone.¹ Impaired thrombolysis has been found in another study² and also in an earlier study in dogs.³

It was postulated that glycerol trinitrate increased hepatic blood flow and therefore increased the metabolism of alteplase, which resulted in reduced plasma tPA levels.¹ However, an *in vitro* study found that glycerol trinitrate enhanced the degradation of alteplase, and therefore a mechanism other than increased hepatic blood flow seems likely to be involved.⁴ It has been suggested that this interaction may not be clinically important,⁵ and the current evidence is too sparse to warrant changing current practice.

Anagrelide + Miscellaneous

Anagrelide should not be used with other phosphodiesterase III inhibitors (e.g. milrinone) because of the potential for increased inotropic effects. Inhibitors of CYP1A2 (e.g. fluvoxamine) are predicted to increase anagrelide levels. Some caution might be required with concurrent aspirin and other platelet inhibitors. Whether anagrelide inhibits theophylline metabolism to a clinically relevant extent is not known. No pharmacokinetic interaction occurs with digoxin or warfarin.

Clinical evidence, mechanism, importance and management

(a) Aspirin

Based on *in vitro* data, anagrelide could have additive effects with drugs that inhibit platelet function, such as aspirin; although in clinical development no such effects were observed. Nevertheless, the manufacturer recommends that the risk/benefit ratio should be assessed before aspirin in used with anagrelide in patients with a high platelet count (greater than $1500 \times 10^9/L$) and/or a history of haemorrhage.¹

(b) CYP1A2 inhibitors and substrates

Anagrelide is principally metabolised by the cytochrome P450 isoenzyme CYP1A2. Drugs that are inhibitors of this isoenzyme are therefore predicted to reduce the clearance of anagrelide, and the manufacturer specifically names **fluvoxamine** and **omeprazole**.¹ Be aware that increased effects, both beneficial and adverse, might occur. However, note that **omeprazole** is only a weak CYP1A2 inhibitor, and would not be expected to have much effect on anagrelide. **Grapefruit juice** has also been predicted to interact via this mechanism,¹ but again, it has little clinically relevant effect on CYP1A2. For a list of CYP1A2 inhibitors, see 'Table 1.2', (p.4).

Anagrelide is a weak inhibitor of CYP1A2, therefore be aware that it might interact with CYP1A2 substrates, such as **theophylline**.¹

(c) Digoxin

The manufacturer briefly mentions that there was no pharmacokinetic interaction between digoxin and anagrelide.¹

(d) Food

Food delays the absorption of anagrelide, but does not alter the overall amount absorbed. The interaction is not clinically relevant.¹

(e) Hydroxycarbamide

In a preclinical study in *dogs*, there was no pharmacokinetic interaction between hydroxycarbamide and anagrelide, therefore no clinical pharmacokinetic interaction is expected.¹

(f) Other phosphodiesterase inhibitors

Anagrelide is a cyclic AMP phosphodiesterase III inhibitor, and consequently has positive inotropic effects. The manufacturer recommends against its concurrent use with other phosphodiesterase III inhibitors, because of the potential increased inotropic effects, and they specifically mention **amrinone**, **cilostazol**, **enoximone**, **milrinone**, and **olprinone**.¹

(g) Warfarin

The manufacturer briefly mentions that there was no pharmacokinetic interaction between warfarin and anagrelide.¹

Antiplatelet drugs + Aspirin

There is an increased risk of bleeding if clopidogrel is given with aspirin, but the use of low-dose aspirin and clopidogrel can be beneficial. Ticlopidine increases the antiaggregant effects of aspirin and there is an increased risk of bleeding on concurrent use. Cilostazol appears not to interact to a clinically relevant extent with low-dose aspirin, and the addition of dipyridamole to aspirin does not appear to increase the incidence of bleeding.

Clinical evidence, mechanism, importance and management

(a) Cilostazol

In a randomised, double-blind, placebo-controlled study involving 11 healthy subjects, cilostazol 100 mg twice daily given with aspirin 325 mg daily for 5 days increased the inhibition of ADP-induced platelet aggregation by 23 to 35% when compared with the use of cilostazol alone, but there were no statistically significant additive effects on arachidonic acid-induced platelet aggregation. In addition, no clinically relevant effects on prothrombin times, aPTT or bleeding times occurred when cilostazol was given with or without aspirin. However, there was a minor 22% increase in the AUC of cilostazol when it was given with aspirin.¹ The US manufacturers report that in 8 randomised, placebo-controlled trials, in a total of 201 patients receiving cilostazol and aspirin, the incidence of bleeding was no greater than that seen with aspirin and placebo. The most frequent doses and mean duration of aspirin therapy were 75 to 81 mg daily for 137 days (107 patients) and 325 mg daily for 54 days (85 patients).²

These studies suggest that no special precautions are needed if cilostazol is used concurrently with low-dose aspirin, although note that the UK manufacturer of cilostazol recommends that, when given with cilostazol, the daily dose of aspirin should not exceed 80 mg.³

(b) Clopidogrel

A variety of studies have investigated the beneficial effects of using the combination of aspirin with clopidogrel. Although these studies were primarily designed to assess the benefits of concurrent use they did also report on bleeding events. The key findings were:

- In patients with recent acute coronary syndrome (CURE): an increase in major bleeding events following the use of clopidogrel 75 mg daily with aspirin 75 to 325 mg daily compared with aspirin alone (3.7% versus 2.7%, respectively).⁴
- In patients with recent stroke or transient ischaemic attack (MATCH): an increase in life-threatening bleeding events following the use of clopidogrel 75 mg daily with aspirin 75 mg daily compared with aspirin alone (2.6% versus 1.3%, respectively).⁵
- In patients with clinically evident cardiovascular disease or multiple atherosclerotic risk factors (CHARISMA): an increase in the risk of moderate and severe bleeding following the use of clopidogrel 75 mg

daily with aspirin 75 to 162 mg daily compared with aspirin alone (moderate 2.1% and 1.3%, respectively, severe 1.7% and 1.3%, respectively).⁶

A study in 7 healthy subjects found that clopidogrel 75 mg and aspirin 150 mg daily for 2 days caused a significant 3.4-fold increase in bleeding time relative to baseline, and when the clopidogrel dose was increased to 300 mg there was a 5-fold increase in bleeding time.⁷ Spontaneous haemarthrosis of the knee has been associated with the concurrent use of aspirin and clopidogrel in one patient.⁸ A report describes two surgical cases, which were complicated by bleeding associated with the combination of aspirin and clopidogrel. In both cases the bleeding was delayed, in that it was not obvious until the end of surgery, causing unanticipated surgical re-exploration.⁹ Further reports describe increased perioperative bleeding in patients taking both aspirin and clopidogrel.^{10,11}

The manufacturer of clopidogrel warns that the concurrent use of clopidogrel and aspirin should be undertaken with caution because of the increased risk of bleeding, although the two drugs have been given together for up to one year. They recommend that, in patients taking clopidogrel, the dose of aspirin should not exceed 100 mg daily as higher doses are associated with higher bleeding risks.¹² For patients undergoing surgery, it has been suggested that, if possible, the combined use of clopidogrel and aspirin should be discontinued about 5 days before the surgery to minimise the risks of bleeding.^{4,10,13} The manufacturer says that if an antiplatelet effect is not necessary, clopidogrel should be discontinued 5 to 7 days prior to surgery,^{12,14} although note that this needs to be balanced against the possible adverse effects of stopping such treatment.

(c) Dipyridamole

A study in 10 healthy subjects found that dipyridamole 50 mg three times daily given with a single 180-mg dose of aspirin, or dipyridamole 75 mg three times daily given with aspirin 120 mg maximally inhibited platelet functions but did not prolong the bleeding time.¹⁵ The manufacturer of dipyridamole states that the addition of dipyridamole to aspirin does not increase the incidence of bleeding events.¹⁶

(d) Ticlopidine

Aspirin combined with ticlopidine appears to inhibit platelet aggregation more than either drug alone.^{17,18} The UK manufacturer of ticlopidine¹⁹ warns that combined use increases the risk of bleeding because there is an increase in platelet antiaggregant activity and aspirin also damages the gastro-duodenal lining, which can cause bleeding. They recommend that clinical monitoring is advisable.¹⁹

Antiplatelet drugs + Bupropion

Clopidogrel and ticlopidine appear to inhibit the metabolism of bupropion. Dosage adjustments may be necessary.

Clinical evidence

(a) Clopidogrel

A study in healthy subjects given clopidogrel 75 mg once daily for 4 days found that the AUC of a single 150-mg dose of bupropion was increased by 60% and the AUC of its active metabolite, hydroxybupropion was reduced by 52%.¹

(b) Ticlopidine

A study in healthy subjects given ticlopidine 250 mg twice daily for 4 days found that the AUC of a single 150-mg dose of bupropion was increased by 85% and the AUC of its active metabolite, hydroxybupropion was reduced by 84%.¹

Mechanism

The reduction in bupropion hydroxylation is due to inhibition of its cytochrome P450 isoenzyme CYP2B6-mediated metabolism by clopidogrel or ticlopidine.^{1,2}

Importance and management

Patients taking bupropion may require dose adjustments if they also take clopidogrel or ticlopidine.¹ Until more is known about this interaction it would seem prudent to monitor for increased bupropion adverse effects (lightheadedness, gastrointestinal effects) and efficacy.

- Turpeinen M, Tolonen A, Uusitalo J, Jalonen J, Pelkonen O, Laine K. Effect of clopidogrel and ticlopidine on cytochrome P450 2B6 activity as measured by bupropion hydroxylation. *Clin Pharmacol Ther* (2005) 77, 553–9.

Antiplatelet drugs + Herbal medicines

***Ginkgo biloba* has been associated with platelet, bleeding and clotting disorders and there are isolated reports of serious adverse reactions after its concurrent use with antiplatelet drugs such as aspirin, clopidogrel and ticlopidine. An animal study suggests that *Kangen-Karyu* may also enhance the antiplatelet and antithrombotic effects of ticlopidine.**

Clinical evidence

(a) *Ginkgo biloba*

A 70-year-old man developed spontaneous bleeding from the iris into the anterior chamber of his eye within a week of starting to take a *Ginkoba* tablet twice daily. He experienced recurrent episodes of blurred vision in one eye lasting about 15 minutes, during which he could see a red discoloration through his cornea. Each *Ginkoba* tablet contained 40 mg of concentrated (50:1) extract of *Ginkgo biloba*. He was also taking aspirin 325 mg daily, which he had taken uneventfully for 3 years since having coronary bypass surgery. He stopped taking the *Ginkoba* but continued with the aspirin, and 3 months later had experienced no recurrence of the bleeding.¹ In an analysis of supplement use, 23% of 123 patients were currently taking supplements, and 4 patients were found to be taking ginkgo and aspirin. However, no problems from this use were found on review of the patients' notes.²

A search of Health Canada's database of spontaneous adverse reactions for the period January 1999 to June 2003 found 21 reports of suspected adverse reactions associated with ginkgo. Most of these involved platelet, bleeding and clotting disorders. One report of a fatal gastrointestinal haemorrhage was associated with ticlopidine and ginkgo, both taken over

2 years along with other medications. Another report was of a stroke in a patient taking multiple drugs including **clopidogrel**, aspirin and a herbal product containing ginkgo.⁵

(b) *Kangen-Karyu*

Kangen-Karyu is a Chinese traditional herbal medicine used for 'blood stasis'. A study in *animals* suggested that *Kangen-Karyu* may augment the antiplatelet and antithrombotic effects of **ticlopidine** and that the dosage of ticlopidine should be reduced to prevent adverse effects such as thrombotic thrombocytopenic purpura or haemorrhage.⁴

Mechanism

The reason for the bleeding is not known, but *Ginkgo biloba* extract contains ginkgolide B, which is a potent inhibitor of platelet-activating factor, which is needed for arachidonate-independent platelet aggregation. On their own, *Ginkgo biloba* supplements have been associated with prolonged bleeding times,^{5,6} left and bilateral subdural haematomas,^{5,7} a right parietal haematoma,⁸ post-laparoscopic cholecystectomy bleeding,⁹ and subarachnoid haemorrhage.⁶ The authors of the first report¹ suggest that the use of aspirin, which is also an inhibitor of platelet aggregation, may have had an additional part to play in what happened.

Importance and management

The evidence from these reports is too slim to forbid patients taking aspirin, clopidogrel or ticlopidine and *Ginkgo biloba* concurrently, but some do recommend caution,¹⁰ which seems prudent. Medical professionals should be aware of the possibility of increased bleeding tendency with *Ginkgo biloba*, and report any suspected cases.⁸ Consider also 'NSAIDs + *Ginkgo biloba*', p.148. Similarly caution would seem prudent if *Kangen-karyu* is used with any antiplatelet drug.

Antiplatelet drugs + NSAIDs

The manufacturers of clopidogrel warn about possible gastrointestinal bleeding if it is used with naproxen or other NSAIDs. There is also an increased risk of bleeding if ticlopidine is given with NSAIDs.

Clinical evidence, mechanism, importance and management

(a) *Clopidogrel*

A double-blind, placebo-controlled study in 30 healthy subjects given **naproxen** 250 mg twice daily, found that the addition of clopidogrel 75 mg daily increased faecal blood loss compared with **naproxen** alone. Six subjects receiving both drugs had bleeding time prolongation factors above 5, which was greater than expected (clopidogrel alone prolongs bleeding by a factor of about 2) and one subject had subcutaneous haemorrhages of moderate intensity after taking clopidogrel with **naproxen**.¹ A report describes intracerebral haemorrhage in an 86-year-old woman after taking **celecoxib** 200 mg daily with clopidogrel 75 mg daily for 3 weeks. The authors comment that there may possibly have been a pharmacokinetic interaction between clopidogrel and **celecoxib** mediated via the cytochrome P450 isoenzyme CYP2C9, although the haemorrhage could have been secondary to other factors such as age or the individual drugs.²

Due to the lack of interaction studies with other NSAIDs, it is unclear whether there is an increased risk of gastrointestinal bleeding with all NSAIDs. The manufacturers advise caution if NSAIDs and clopidogrel are given together.^{3,4}

(b) *Ticlopidine*

The UK manufacturer of ticlopidine warns that concurrent use of NSAIDs increases the risk of bleeding because there is an increase in platelet antiaggregant activity and because NSAIDs damage the gastro-duodenal lining, which can cause bleeding. They recommend that if NSAIDs are necessary, close clinical monitoring is advisable.⁵

Cilostazol + Clopidogrel

In one study clopidogrel slightly increased levels of cilostazol, without altering platelet count, aPTT, or prothrombin time. However, the effect of concurrent use on bleeding time was not assessed.

Clinical evidence, mechanism, importance and management

The concurrent use of cilostazol 150 mg twice daily and clopidogrel 75 mg daily for 5 days increased the AUC of cilostazol by only 9%, but increased the AUC of the dehydro metabolite of cilostazol by 24% (this metabolite has 3 to 4 times the potency of cilostazol in inhibiting platelet aggregation). No changes in platelet count, prothrombin time or aPTT were seen. However, clopidogrel alone prolonged bleeding time, and it was not possible to determine whether there was an additive effect with cilostazol.¹

The UK manufacturer suggests caution if cilostazol is given with any drug that inhibits platelet aggregation, and say that consideration should be given to monitoring the bleeding time at intervals.¹

1. Pletal (Cilostazol). Otsuka Pharmaceuticals (UK) Ltd. UK Summary of product characteristics, May 2006.

Cilostazol + Food

Food increases the bioavailability of cilostazol, which may increase adverse effects.

Clinical evidence, mechanism, importance and management

A randomised, single-dose, crossover study in 15 healthy subjects found that giving cilostazol 100 mg within 10 minutes of a high fat meal caused an increase in the rate and extent of cilostazol absorption. The maximum plasma concentration of cilostazol was increased by about 95%, the AUC was increased by 25%, and the half-life decreased from 15.1 to 5.4 hours, when compared with the fasted state.¹ The manufacturer recommends that cilostazol should be taken 30 minutes before or 2 hours after food, because the increase in maximum plasma concentrations of cilostazol when taken with food may be associated with an increased incidence of adverse effects.^{2,3}

Cilostazol + Miscellaneous

Erythromycin, diltiazem and ketoconazole, all inhibitors of the cytochrome P450 isoenzyme CYP3A4, increase the plasma levels of cilostazol. Other inhibitors of CYP3A4 are predicted to interact similarly, but grapefruit juice does not appear to interact significantly. Cilostazol may increase the levels of lovastatin and other substrates of CYP3A4 (and possibly CYP2C19). Omeprazole, an inhibitor of CYP2C19, increases the bioavailabil-

ity of cilostazol and its active metabolite; other CYP2C19 inhibitors are predicted to interact similarly.

Quinidine, an inhibitor of CYP2D6, does not appear to affect the pharmacokinetics of cilostazol and it is therefore suggested that other CYP2D6 inhibitors or substrates will not interact. Cilostazol appears not to interact to a clinically relevant extent with tobacco smoke.

Clinical evidence, mechanism, importance and management

(a) CYP2C19 inhibitors

In a crossover study¹ in 20 healthy subjects **omeprazole** 40 mg daily for one week increased the AUC of a single 100-mg dose of cilostazol by a modest 26%. More importantly, the AUC of 3,4-dehydro-cilostazol (a metabolite with 4 to 7 times the activity of cilostazol) was increased by 69%.^{2,3} **Omeprazole** inhibits the cytochrome P450 isoenzyme CYP2C19, which is involved in the metabolism of cilostazol, and may possibly also affect the elimination of the active metabolite. For this reason the US manufacturers suggest that the dose of cilostazol should be halved when given with **omeprazole**,² while the UK manufacturers contraindicate concurrent use.³ Other CYP2C19 inhibitors such as **lansoprazole** may also interact, and therefore concurrent use is contraindicated by the UK manufacturers.³ The manufacturers also recommend caution with drugs that are substrates of CYP2C19.³

(b) CYP3A4 inhibitors

A study in 16 healthy subjects found that **erythromycin** 500 mg three times daily increased the maximum plasma level and the AUC of a single 100-mg oral dose of cilostazol by 47% and 73%, respectively. **Erythromycin** inhibits the cytochrome P450 isoenzyme CYP3A4, by which cilostazol is metabolised, thereby raising its plasma levels.⁴ Other macrolide antibacterials e.g. **clarithromycin** (but not **azithromycin**) would be expected to have a similar effect.²

Diltiazem is also a moderate inhibitor of CYP3A4. When **diltiazem** 180 mg daily was given with cilostazol 100 mg twice daily the AUC of cilostazol was increased by about 40%.^{2,3}

In a single-dose study, **ketconazole** 400 mg caused a greater than two-fold increase in the AUC of cilostazol.³ Other potent CYP3A4 inhibitors such as **itraconazole** are expected to interact similarly.²

In view of these effects the US manufacturers suggest halving the dose of cilostazol in the presence of CYP3A4 inhibitors such as **erythromycin**, **diltiazem**, **itraconazole**, and **ketconazole**.² However, the UK manufacturers contraindicate CYP3A4 inhibitors, and they specifically name **erythromycin**, **diltiazem**, **ketconazole**, **cimetidine**, and the **protease inhibitors**.³ Just why these recommendations differ is not clear. The US manufacturers suggest that other CYP3A4 inhibitors, such as **azole antifungals (fluconazole, miconazole)**, **SSRIs (fluoxetine, fluvoxamine, sertraline)** and **nefazodone**, may also interact.²

(c) Grapefruit juice

Grapefruit juice has been predicted to increase the levels of cilostazol by inhibiting CYP3A4.² However, the UK manufacturers note that 240 mL of grapefruit juice did not have a notable effect on the pharmacokinetics of a single 100-mg dose of cilostazol.³ No special precautions seem necessary on concurrent use.

(d) Lovastatin and other substrates of CYP3A4

In a study in 13 healthy subjects, a single 80-mg oral dose of lovastatin was given before, and then on the final day of a 7-day treatment period with cilostazol 100 mg twice daily. The AUCs of lovastatin and its beta-hydroxy acid metabolite were increased by about 60 and 70%, respectively by cilostazol, but the maximum plasma levels were unaffected.⁵ At the end of this study (day 9), 12 subjects were given lovastatin 80 mg with a larger 150-mg dose of cilostazol. It was found that the maximum level and the AUC of the lovastatin metabolite were increased by about twofold, suggesting that larger cilostazol doses may have a greater effect.⁵ Lovastatin is metabolised by the cytochrome P450 isoenzyme CYP3A4 and although cilostazol can inhibit this enzyme, *in vitro* studies indicate that this occurs only at concentrations several times greater than those found therapeutically. The increases in lovastatin levels described here are lower than those seen with potent CYP3A4 inhibitors (e.g. see 'Statins +

Azoles', p.1093) but the authors of the study still suggest that the dose of lovastatin may need to be reduced if cilostazol is also taken. Lovastatin decreased the absorption of cilostazol by about 15%, but this was not considered to be clinically relevant.⁵

The UK manufacturers advise caution when cilostazol is given with drugs that are substrates of CYP3A4, especially those with a narrow therapeutic index. They specifically mention **cisapride**, **midazolam**, **nifedipine** and **verapamil**.³ Further study is needed to establish these predicted interactions.

(e) Quinidine

A crossover study in 22 healthy subjects found that the pharmacokinetics of a single 100-mg dose of cilostazol were unaffected by pretreatment with two 200-mg doses of quinidine sulfate, one taken 25 hours previously and the other taken one hour previously. Quinidine inhibits the activity of the cytochrome P450 isoenzyme CYP2D6, and it appears that this enzyme does not play a significant role in the metabolism of cilostazol or its primary metabolites.⁶

(f) Tobacco smoking

The manufacturers report that population pharmacokinetic analysis suggests that tobacco smoking reduces the exposure to cilostazol by about 20%,² but this is unlikely to have much, if any, clinical relevance.

Clopidogrel + Miscellaneous

No adverse interactions appear to occur with clopidogrel and aluminium/magnesium hydroxide, atenolol, cimetidine, digoxin, food, insulin, nifedipine, oestrogens, phenobarbital, phenytoin or tolbutamide.

Clinical evidence, mechanism, importance and management

Two studies, one in 12 healthy subjects (average age 67 years) and the other in 12 healthy subjects (average age 23 years), found that the bioavailability of a single 75-mg dose of clopidogrel remained unchanged when it was taken with food or 1-hour after two 400-mg tablets of **aluminium/magnesium hydroxide**.¹ No clinically significant pharmacodynamic interactions were seen when clopidogrel was given with **atenolol**, **nifedipine** or a combination of **atenolol** and **nifedipine**,² and the activity of clopidogrel was not altered by the concurrent use of **cimetidine**,³ **oestrogen**³ or **phenobarbital**.³ Another study found that clopidogrel does not alter the plasma levels of **digoxin** and that the pharmacodynamics of clopidogrel do not appear to be affected by **digoxin**.⁴ One study found that the inhibition of platelet aggregation by clopidogrel was not reduced by **acetylcysteine**.⁵ Data from the CAPRIE study and other clinical studies showed that **ACE inhibitors**, **antidiabetics (insulin, tolbutamide named)**,³ **antiepileptics (phenytoin named)**,³ **beta blockers**, **calcium-channel blockers**, **coronary or peripheral vasodilators**, **diuretics** and **HRT** have been safely given with clopidogrel.⁶

No special precautions would therefore seem necessary when clopidogrel is given with any of these drugs.

Clopidogrel + Statins

Some evidence suggests that atorvastatin, and possibly other CYP3A4-metabolised statins (e.g. simvastatin) may interfere with the antiplatelet actions of clopidogrel, but the data is conflicting and there is currently insufficient evidence to warrant changing practice.

Clinical evidence

Some studies have shown that statins metabolised by CYP3A4 (most notably atorvastatin) can cause a reduction in the antiplatelet activity of clopidogrel, especially during the initial stages of treatment (following the loading dose of clopidogrel), whereas other, mainly retrospective, studies have found no clinical evidence of reduced efficacy. However, the studies are difficult to compare as some have measured platelet function using different techniques and other studies are based on clinical outcome using varying lengths of treatment and end points. Furthermore, up to 25% of patients may not respond at all to clopidogrel and this seems unrelated to treatment with a statin.¹

Dose may be an important factor as to whether or not a significant clinical interaction occurs. One study found that a high loading dose of clopidogrel (600 mg) was not affected by statins,² but there is increased risk of serious bleeding with this dose. Lower doses of statins (e.g. atorvastatin 10 mg daily)³ also appear to be less likely to interact, and one study found that the effect was dose-dependent.⁴

Some studies have found that **atorvastatin** attenuates the antiplatelet activity of clopidogrel in patients undergoing coronary artery stenting,^{4–6} or balloon angioplasty.⁶ However, other studies have found no evidence of an interaction.^{1–3,7–12} Furthermore, one of the studies reporting an interaction⁴ has been criticised for, among other things, being small, non-randomised, and using poorly defined study groups.¹

Simvastatin has also been found to reduce the effects of clopidogrel in patients undergoing coronary artery stenting or balloon angioplasty,⁶ although other studies have found no interaction.^{2,11} The situation with **pravastatin** is clearer, as several studies have reported a lack of an interaction,^{2–5,7,8,11,12} and there do not appear to be any studies suggesting that an interaction occurs. Similarly, studies including **cerivastatin**,⁷ **lovastatin**,^{2,7} **fluvastatin**,^{2,5,7,8,11} or **rosuvastatin**¹² suggest that they do not interact with clopidogrel. Furthermore, a prospective single centre cohort study in 1651 patients with acute coronary syndromes found that clopidogrel plus a statin was associated with lower 6-month mortality and morbidity compared with the use of clopidogrel alone. There was no significant difference in clinical benefit between a statin predominantly metabolised by the cytochrome P450 isoenzyme CYP3A4 (said to be **atorvastatin**, **cerivastatin**, **lovastatin**, **simvastatin**) or a statin not predominantly metabolised by CYP3A4 (**fluvastatin**, **pravastatin**, **rosuvastatin**).¹³ Similarly, a retrospective examination of data from the CREDO trial suggested that there was no difference in 1-year outcomes in patients given **atorvastatin** or **pravastatin**.⁸ Despite this, some commentators have suggested that there were actually differences at the 28-day endpoint¹⁴ and a trend towards differences in the 1-year outcome,¹⁵ and suggest that an interaction may therefore have occurred.

Mechanism

Clopidogrel is an inactive prodrug that is metabolised mainly in the liver. The cytochrome P450 isoenzyme CYP3A4 appears to be primarily responsible for the metabolism and activation of clopidogrel, although other isoenzymes are also involved. Several statins, including atorvastatin, are also metabolised by CYP3A4 and it has been suggested that these statins may competitively inhibit the activation of clopidogrel.^{4,16} However, it has been suggested that the expression and/or activity of CYP3A4 can vary widely between individuals and this, rather than an interaction, may conceivably lead to individual variation in metabolism.¹⁴ The effect of CYP3A4-metabolised statins on the antiplatelet effects of clopidogrel may

occur only in the loading phase of therapy (within the first 24 hours). It has been suggested that the lack of an interaction in maintenance treatment may be due an adaptation of platelet function or the metabolic capability of the liver or possibly due to upregulation of CYP3A4 in the liver.¹⁷

Importance and management

The picture is quite confused and by no means conclusive. Even though the statins metabolised by CYP3A4 appear to reduce the antiplatelet effect of clopidogrel, the overall clinical effect is unclear. The beneficial properties of statins may offset any attenuating effects on the antiplatelet action of clopidogrel.¹⁸ Nevertheless, it has been suggested that higher doses of atorvastatin, and perhaps simvastatin, should not be prescribed for patients taking clopidogrel, particularly patients recovering from acute coronary syndrome, stent implantation (particularly a drug-eluting stent), or brachytherapy; pravastatin or rosuvastatin may be preferred in these patients.¹⁵ However, other workers have said, given the marginal interference and high variability, until there is evidence to change clinical practice, there is no need to discontinue the statin use during clopidogrel treatment or to prefer hydrophilic statins in patients with clopidogrel comedication.^{1,19,20} Further prospective studies are needed to determine whether a clinically significant interaction exists. Until then, a change in practice does not seem justified.

Dipyridamole + Beta blockers

No adverse reactions normally occur in patients taking beta blockers who undergo dipyridamole–thallium-201 scintigraphy and echocardiography, but case reports suggest that very rarely bradycardia and asystole can occur.

Clinical evidence

A 71-year-old woman taking **nadolol** 120 mg daily and bendroflumethiazide, with a 3-week history of chest pain, was given a 300-mg dose of oral dipyridamole as part of a diagnostic dipyridamole-thallium imaging test for coronary artery disease. She was given thallium-201 intravenously, 50 minutes after the dipyridamole, but 3 minutes later, while exercising, she complained of chest pain and then had a cardiac arrest. She was given cardiopulmonary resuscitation and a normal cardiac rhythm was obtained after she was given intravenous aminophylline.¹

Adverse interactions occurred in another 2 patients taking beta blockers during diagnostic dipyridamole-thallium stress testing. One patient, who was taking **atenolol**, developed bradycardia then asystole, which was treated with aminophylline and atropine, and the other patient, who was taking **metoprolol**, developed bradycardia, which resolved after she was given aminophylline.²

These reports need to be set in a broad context. A very extensive study of high-dose dipyridamole echocardiography (10 451 tests in 9 122 patients) noted significant adverse effects in only 96 patients, with major adverse reactions occurring in just 7 patients. Three of the 7 developed asystole and two of these patients were taking unnamed beta blockers.³

Mechanism

Not established. One possible explanation is that both drugs have negative chronotropic effects on the heart.

Importance and management

The value and safety of dipyridamole perfusion scintigraphy and echocardiography have been very extensively studied in very large numbers of patients, and reports of bradycardia and asystole, attributed to an interaction between dipyridamole and beta blockers, are sparse. It would therefore appear to be a relatively rare interaction (if such it is).

Dipyridamole + Drugs that affect gastric pH

The effective disintegration, dissolution and eventual absorption of dipyridamole in tablet form depends upon having a low pH in the stomach. Drugs that raise the gastric pH significantly are expected to reduce the bioavailability of dipyridamole.

Clinical evidence, mechanism, importance and management

The solubility of dipyridamole depends very much on the pH. It is very soluble at low pH values and almost insoluble at neutral pH.¹ This indicates that dipyridamole needs a low pH in the stomach if solid formulations of the drug are to disintegrate and dissolve adequately. A study in 11 healthy elderly subjects (6 control subjects with a low fasting gastric pH and 5 achlorhydric subjects with fasting gastric pH greater than 5) found that elevated gastric pH reduced the absorption of a single 50-mg oral dose of dipyridamole. In addition, pretreatment with **famotidine** 40 mg increased the gastric pH to above 5 for at least 3 hours, which resulted in reduced dipyridamole absorption. The dipyridamole AUC was reduced by 37% (not statistically significant) and the maximum serum levels were significantly delayed and reduced.² In another study 20 healthy subjects were given **lansoprazole** 30 mg daily for 5 days and then either:

- a single dose of an extended release preparation of dipyridamole 200 mg with aspirin 25 mg (formulated with tartaric acid to improve bioavailability of dipyridamole if the gastric pH is elevated)
- or a conventional dipyridamole formulation (100 mg given with 81 mg of aspirin, followed 6 hours later by another dose of dipyridamole).

In the presence of **lansoprazole** (gastric pH greater than 4) the relative bioavailability of dipyridamole with conventional tablets was about 50% of that with the buffered extended release tablets.³

A consequential conclusion is that any drug that raises the stomach pH significantly would be likely to reduce the dissolution and absorption of dipyridamole. It would therefore be reasonable to expect that proton pump

inhibitors, H₂-receptor antagonists and possibly antacids, which can raise the gastric pH, would interact to reduce the bioavailability of dipyridamole. Further study is needed to find out whether this is a clinically relevant interaction or not.

Dipyridamole + Irbesartan

A study in 13 patients with coronary artery disease found that **irbesartan 150 mg daily reduced the extent and severity of perfusion defects after dipyridamole-induced stress.**¹

1. Altun GD, Altun A, Yildiz M, Firat MF, Hacimahmutoglu S, Berkarda S. Irbesartan has a masking effect on dipyridamole stress induced myocardial perfusion defects. *Nucl Med Commun* (2004) 25, 195–9.

Dipyridamole + Xanthines

Caffeine (in tea, coffee, cola, etc.) may interfere with dipyridamole-thallium-201 scintigraphy tests. Similarly, theophylline can also reduce some of the effects of dipyridamole.

Clinical evidence, mechanism, importance and management

Caffeine 4 mg/kg intravenously (roughly equivalent to 2 to 3 cups of coffee), given before dipyridamole-thallium-201 myocardial scintigraphy, caused a false-negative test result in a patient.¹ A further study in 8 healthy subjects confirmed that **caffeine** inhibits the haemodynamic response to an infusion of dipyridamole.² Similarly, oral **theophylline** markedly reduced the diagnostic accuracy of myocardial imaging using dipyridamole.³ In addition, intravenous **aminophylline** accelerated the myocardial washout rate of thallium-201 after a dipyridamole infusion.⁴

It appears that xanthine derivatives such as **caffeine** and **theophylline** might antagonise some of the haemodynamic effects of dipyridamole because they act as competitive antagonists of adenosine (an endogenous vasodilator involved in the action of dipyridamole).^{1,2} Due to these opposing effects, parenteral **aminophylline** has been used to treat adverse events associated with intravenous dipyridamole,^{5,6} and it is recommended that **aminophylline** should be made available before beginning dipyridamole echocardiography.^{6,7}

Patients should therefore abstain from **caffeine** (tea, coffee, chocolate, cocoa, cola, caffeine-containing analgesics etc.)^{1,2,7} and other xanthine derivatives such as **theophylline**³ for 24 hours^{2,6} before dipyridamole testing, and if during the test the haemodynamic response is low (e.g. no increase in heart rate) the presence of **caffeine** should be suspected.²

Glycoprotein IIb/IIIa antagonists + Drugs that affect coagulation

The risk of bleeding with glycoprotein IIb/IIIa antagonists may be increased by heparin and thrombolytics, but low-dose thrombolytic appears less likely to cause a problem.

Clinical evidence, mechanism, importance and management

(a) Abciximab

Although the manufacturers of abciximab recommend concurrent therapy with **heparin**, they also report that there is an increase in the incidence of bleeding.^{1,2} In one study in patients with acute coronary syndrome without early revascularisation, the concurrent use of **low-molecular-weight heparin** was considered to be one of the factors that increased the risk of bleeding events with abciximab.³

Limited experience of abciximab in patients who have received **thrombolytics** suggests an increase in the risk of bleeding.^{1,2} A retrospective analysis of 103 patients who presented with acute myocardial infarction and underwent angioplasty with adjunctive abciximab therapy, found that there was a significant increase in major bleeding complications when abciximab was used with full-dose **alteplase**. A major bleed occurred in 5 of 22 (23%) patients who underwent angioplasty within 15 hours of receiving thrombolytic therapy compared with 0 of 36 patients who underwent elective angioplasty more than 15 hours after fibrinolysis, and 1 of 45 (2%) without prior fibrinolysis.⁴ However, the combination of abciximab with low-dose **reteplase** appeared not to result in the haemorrhagic complications associated with full-dose fibrinolytic therapy,⁵ and no increase in bleeding complications were reported in studies using reduced-dose thrombolytic therapy with full-dose abciximab.^{5,6}

The manufacturer of abciximab recommends caution when it is used with other drugs that affect haemostasis, such as **heparin**, **warfarin**, **thrombolytics** and antiplatelet drugs other than aspirin, such as **dipyridamole** and **ticlopidine**.^{1,2}

(b) Eptifibatide

In an acute myocardial infarction study involving 181 patients, eptifibatide at the highest infusion rates studied (1.3 and 2 micrograms/kg per minute) appeared to increase the risk of bleeding when given with **streptokinase** 1.5 million units over 60 minutes. However, the manufacturers state that data on the use of eptifibatide in patients receiving thrombolytics are limited, and in a percutaneous coronary intervention study and an acute myocardial infarction study there was no consistent evidence that eptifibatide increased the risk of major or minor bleeding associated with **alteplase**.^{7,8}

The UK manufacturer of eptifibatide reports that concurrent use with **warfarin** and **dipyridamole** did not appear to increase the risk of major and minor bleeding, and the use of **heparin** is recommended, but they warn that if eptifibatide is given with **heparin**, there must be careful monitoring including the aPTT.

Caution must be employed when eptifibatide is used with other drugs that affect haemostasis, including **clopidogrel**, **ticlopidine**, **dipyridamole**, **oral anticoagulants** or **thrombolytics** and concurrent or planned use of another **glycoprotein IIb/IIIa inhibitor** is contraindicated.^{7,8}

Streptokinase + Aspirin

Patients with acute ischaemic stroke treated with streptokinase have an increased risk of early death due to cerebral haemorrhage if they are also given aspirin.

Clinical evidence, mechanism, importance and management

A post hoc analysis of 313 patients with acute ischaemic stroke given intravenous streptokinase 1.5 million units found that the addition of oral aspirin 300 mg daily for 10 days increased the risk of early death. The

combined regimen significantly increased early fatalities (from day 3 to 10) with 53 deaths occurring out of 156 patients (34%) compared with 30 of 157 (19%) who received streptokinase alone. Early death was mainly due to cerebral causes (42 versus 24) and associated with intracranial haemorrhage (25 versus 11).¹

If streptokinase is given to acute ischaemic stroke patients, it would seem sensible to avoid giving aspirin until thrombolysis is accomplished.¹

Streptokinase + Other thrombolytics

The thrombolytic effects of streptokinase or anistreplase are likely to be reduced or abolished if they are given some time after a dose of streptokinase because of persistently high levels of streptokinase antibodies. There is also an increased risk of hypersensitivity reactions. This may also be true for urokinase.

Clinical evidence

A study in 25 patients who had been given streptokinase for the treatment of acute myocardial infarction, found that 12 weeks later, 24 patients had enough anti-streptokinase antibodies in circulation to neutralise an entire 1.5 million unit dose of streptokinase. After 4 to 8 months, 18 out of 20 still had enough antibodies to neutralise half of a 1.5 million unit dose of streptokinase.¹ Further study has suggested that after streptokinase use, anti-streptokinase antibodies fall within 24 hours, but then increase gradually and are significantly raised by 4 days after treatment. The antibody titres reach a peak (approximately 200 times that of pretreatment levels) after 2 weeks and then subsequently decline, but remain above baseline values for at least one year.² Antibody titres may remain high enough to neutralise the effects of streptokinase for several years after a dose,^{3,4} and high titres persisting for up to 7.5 years have been reported.⁵ However, in contrast, another study found that the neutralising antibody titres had returned to control levels by 2 years.⁶ Increased titres of streptokinase antibodies have also been seen in patients receiving topical streptokinase for wound care,⁷ intrapleural streptokinase for pleural effusions,⁸ and following streptococcal infections.⁹ Apart from the reduced thrombolytic effect, repeated dosing¹⁰ or high pre-treatment anti-streptokinase antibody titres¹¹ may increase the risk of allergic reactions.

Anistreplase, like its parent drug streptokinase, has been shown to be neutralised by anti-streptokinase antibodies.^{12,13}

Of 6 patients given **urokinase** 1.5 million units infused over 30 minutes for recurrent myocardial infarction, rigors occurred in 4 patients and 2 of these also had bronchospasm; they had all previously received streptokinase.¹⁴

Mechanism

Streptokinase use causes the production of anti-streptokinase antibodies. These persist in the circulation so that the clot-dissolving effects of another dose of streptokinase given many months later may be ineffective, or less effective, because it becomes bound and neutralised by the antibodies. Many people already have a very low titre of antibodies resulting from previous streptococcal infections, yet this does not usually appear to influence thrombolysis.¹⁵

Importance and management

The interaction that results in neutralisation of the thrombolytics is established and clinically important. One author¹⁶ says that clinically, therapy is not repeated within a year as it would not work. Given that it has been suggested that the effects may be very persistent, it would seem prudent, if a second use is needed, to use a thrombolytic with less antigenic effects such as alteplase. The British National Formulary says that streptokinase should not be used again beyond 4 days of the first use of either streptokinase or anistreplase.¹⁷ In addition, the manufacturer recommends avoidance of streptokinase in patients who have had recent streptococcal infections that have produced high anti-streptokinase titres, such as acute rheumatic fever or acute glomerulonephritis.⁹

Little is known about the increased risk of hypersensitivity reactions.

Ticlopidine + Antacids or Food

Food causes a moderate increase, and Maalox causes a moderate decrease, in the absorption of ticlopidine.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects the extent of absorption of a single 250-mg dose of ticlopidine was increased by 20% and occurred more rapidly when ticlopidine was taken after food, when compared with the fasting state. In contrast, 30 mL of *Maalox* [aluminium/magnesium hydroxide] reduced the extent of ticlopidine absorption by about 20%.¹ These modest changes are unlikely to be of much clinical importance.

It is suggested that ticlopidine is taken with food, but this is to minimise gastric intolerance.¹

1. Shah J, Fratis A, Ellis D, Murakami S, Teitelbaum P. Effect of food and antacid on absorption of orally administered ticlopidine hydrochloride. *J Clin Pharmacol* (1990) 30, 733–6.

Ticlopidine + Miscellaneous

Ticlopidine-induced increases in bleeding times are opposed by methylprednisolone and prednisolone but its effects on platelet function are not affected. Ticlopidine decreases the clearance of phenazone (antipyrene), which suggests that it has mild enzyme-inhibiting effects. Beta blockers, calcium-channel blockers and diuretics are reported not to interact with ticlopidine.

Clinical evidence, mechanism, importance and management

(a) Corticosteroids

A study involving 14 healthy subjects found that a single 20-mg intravenous injection of **methylprednisolone** or oral **prednisolone** 15 mg twice daily for 7 days decreased the prolongation of bleeding times caused by ticlopidine 250 to 500 mg twice daily for 7 days. However, the antiplatelet effects of ticlopidine were not affected.¹ The clinical importance of this interaction is uncertain.

(b) Phenazone (Antipyrene)

A study in 10 healthy subjects found that ticlopidine 250 mg twice daily for 3 weeks decreased the clearance of phenazone (a marker of enzyme inhibition or induction). The AUC increased by 14% and the half-life increased by 27%, suggesting that ticlopidine has some mild enzyme-inhibiting effects.² This is consistent with the way ticlopidine appears to inhibit the metabolism of 'theophylline', (p.1177), but so far no other drugs seem to be affected to a clinically important extent.

(c) Non-interacting drugs

The manufacturers of ticlopidine report that in clinical studies in which ticlopidine was given with **beta blockers**, **calcium-channel blockers** and **diuretics** [none of the individual drugs named], no clinically significant adverse interactions were reported.^{3,4}

Antipsychotics, Anxiolytics and Hypnotics

The interactions where the effects of antipsychotic, anxiolytic and hypnotic drugs are affected are covered in this section but there are other monographs elsewhere in this publication where the effects of other drugs are altered by a benzodiazepine or antipsychotic.

(a) Antipsychotics

The antipsychotics are represented by chlorpromazine (and other phenothiazines), haloperidol (and other butyrophenones) and thioxanthenes, and the atypical, or newer, antipsychotic drugs, such as clozapine and risperidone. Their major use is in the treatment of psychoses such as schizophrenia and mania. These are listed in 'Table 20.1', (below). Some of the antipsychotics are also used as antiemetics, and for motor tics and hiccups.

The majority of interactions between the older antipsychotics are pharmacodynamic, relating to their effect on dopamine, whilst several of the newer atypical antipsychotics are metabolised to a significant extent by the cytochrome P450 isoenzymes. The concurrent use of other drugs which are inhibitors or inducers of these isoenzymes may result in large changes in plasma levels. In particular, tobacco smoking and caffeine can have an effect on the pharmacokinetics of some of these drugs, leading to adverse effects or lack of therapeutic effect following lifestyle changes.

(b) Benzodiazepines

The anxiolytics include the benzodiazepines and related drugs, cloral hydrate and other drugs used to treat psychoneuroses such as anxiety and tension, and are intended to induce calm without causing drowsiness and sleep. Some of the benzodiazepines and related drugs are also used as antiepileptics and hypnotics. 'Table 20.1', (below) contains a list of the benzodiazepines and related drugs. Many benzodiazepines undergo phase I metabolism by *N*-dealkylation and hydroxylation and many of the metabolites are active. They may then undergo phase II conjugation, mainly to form glucuronides before being excreted. For example, diazepam is metabolised to nordazepam (desmethyldiazepam), temazepam and oxazepam. The metabolism of diazepam in the liver is also mediated by cytochrome P450 isoenzymes, particularly CYP2C19, and diazepam is excreted mainly as free or conjugated metabolites.

The triazolo- and related benzodiazepines, such as alprazolam, midazolam and triazolam, are mainly metabolised by hydroxylation, mediated by CYP3A4, to active compounds, which then rapidly undergo glucuronide conjugation.

Therefore drugs that affect CYP2C19 may interact with benzodiazepines such as diazepam and those that affect CYP3A4 may interact with midazolam or triazolam.

Benzodiazepines such as lorazepam, oxazepam and temazepam, which are mainly conjugated without prior phase I metabolism, are unlikely to be involved in interactions with inhibitors or inducers of cytochrome P450. Benzodiazepines themselves do not significantly induce cytochrome P450 isoenzymes, so interactions involving enhanced metabolism of other drugs are not usual.

(c) Non-benzodiazepine hypnotics

Zaleplon, zolpidem and zopiclone are metabolised by several cytochrome CYP450 isoenzymes and it has been suggested that because of this, other drugs which affect a particular isoenzyme such as CYP3A4, may have less effect on their metabolism. However, their pharmacokinetics are affected by potent inducers such as rifampicin and by inhibitors such as the azole antifungals. **Buspirone** undergoes CYP3A4-mediated metabolism in the liver.

Table 20.1 Antipsychotics, anxiolytics, and hypnotics

Group	Drugs
Antipsychotics	
Atypical antipsychotics	Amisulpride, Aripiprazole, Clozapine, Olanzapine, Quetiapine, Risperidone, Sertindole, Ziprasidone, Zotepine
Phenothiazines	Butaperazine, Chlorpromazine, Fluphenazine, Levomepromazine, Mesoridazine, Pericyazine, Perphenazine, Prochlorperazine, Promazine, Thioridazine, Trifluoperazine
Butyrophenones	Benperidol, Bromperidol, Droperidol, Haloperidol
Thioxanthenes	Chlorprothixene, Flupentixol, Tiotixene, Zuclopentixol
Miscellaneous	Loxapine, Molindone, Pimozide, Sulpiride
Anxiolytics and hypnotics	
Benzodiazepines	Alprazolam, Bromazepam, Brotizolam, Chlordiazepoxide, Clobazam, Clonazepam, Clorazepate, Clotiazepam, Diazepam, Flunitrazepam, Flurazepam, Ketazolam, Loprazolam, Lorazepam, Lormetazepam, Medazepam, Midazolam, Nitrazepam, Oxazepam, Oxazolam, Quazepam, Temazepam, Triazolam
Miscellaneous	Buspirone, Clomethiazole, Cloral betaine, Cloral hydrate, Eszopiclone, Glutethimide, Hydroxyzine, Meprobamate, Promethazine, Triclofos, Zaleplon, Zolpidem, Zopiclone

Amisulpride + Lithium

Amisulpride does not appear to affect the pharmacokinetics of lithium. However, limited evidence suggests that lithium may increase the plasma levels of amisulpride.

Clinical evidence, mechanism, importance and management

In a study in 24 healthy subjects, lithium carbonate 500 mg twice daily was given for 7 days to obtain stable lithium serum levels, and then amisulpride 100 mg twice daily or placebo was added for a further 7 days. Amisulpride appeared to have no effect on lithium pharmacokinetics.¹ In a pharmacokinetic analysis of amisulpride levels in patients with schizophrenia or schizoaffective disorder, dose-corrected amisulpride plasma levels were 1.8-fold higher in 3 patients taking lithium than in 13 patients taking amisulpride alone.² Further study is needed to confirm this finding and establish its clinical significance.

1. Canal M, Legangneux E, van Lier JJ, van Vliet AA, Coulouvat C. Lack of effect of amisulpride on the pharmacokinetics and safety of lithium. *Int J Neuropsychopharmacol* (2003) 6, 103–9.
2. Bergemann N, Kopitz J, Kress KR, Frick A. Plasma amisulpride levels in schizophrenia or schizoaffective disorder. *Eur Neuropsychopharmacol* (2004) 14, 245–50.

Antipsychotics + Antacids or Sucralfate

Antacids containing aluminium/magnesium hydroxide or magnesium trisilicate can reduce the serum levels of chlorpromazine which would be expected to reduce the therapeutic response. Sucralfate and an aluminium/magnesium hydroxide antacid can reduce the absorption of sulpiride. *In vitro* studies suggest that this interaction may possibly also occur with other antacids and phenothiazines. There seem to be no clinical studies or reports confirming the anecdotal evidence of a possible reduction in the effects of haloperidol by antacids.

Clinical evidence

(a) Haloperidol

In 1982 a questioner in a letter asked whether haloperidol interacts with antacids because he had a patient responding well to treatment with haloperidol who had begun to deteriorate when *Amphojel* (aluminium hydroxide) was added. In a written answer it was stated¹ that there are no reports of this interaction but several clinicians had said that based on clinical impressions oral haloperidol and antacids should not be given together.

(b) Phenothiazines

A study in 10 patients taking chlorpromazine 600 mg to 1.2 g daily showed that 30 mL of *Aludrox* (aluminium/magnesium hydroxide gel) reduced their urinary excretion of chlorpromazine by 10 to 45%.²

A study was prompted by the observation of one psychiatric patient, taking chlorpromazine who relapsed within 3 days of starting to take an unnamed antacid. When 30 mL of *Gelusil* (aluminium hydroxide with magnesium trisilicate) was given with chlorpromazine suspension to 6 patients, the serum chlorpromazine levels measured 2 hours later were reduced by about 20% (from 168 to 132 nanograms/mL).³ *In vitro* studies have also found that other phenothiazines (trifluoperazine, fluphenazine, perphenazine, thioridazine) are adsorbed to a considerable extent onto a number of antacids (magnesium trisilicate, bismuth subnitrate, aluminium hydroxide with magnesium carbonate) but there do not appear to be any clinical studies of the possible clinical effects of these interactions.⁴

(c) Sulpiride

A study in 6 healthy subjects found that the bioavailability of a single 100-mg dose of sulpiride was reduced by 40% by sucralfate 1 g and by 32% by 30 mL of *Simeco* (aluminium/magnesium hydroxide and simeticone). When either the sucralfate or the antacid were taken 2 hours before sulpiride the reduction in bioavailability was only about 25%, and no change in bioavailability was seen in one subject when the sucralfate was given 2 hours after the sulpiride.⁵

Mechanism

Chlorpromazine and other phenothiazines become adsorbed onto these antacids,^{3,6} which would seem to account for the reduced bioavailability. It is possible that adsorption also occurs with sulpiride, but this has not been proven.

Importance and management

Clinical information seems to be limited to the reports cited. Reductions of up to 45% in serum antipsychotic levels would be expected to be clinically important, but so far only one case seems to have been reported.³ Separating the doses as much as possible (1 to 2 hours) to avoid admixture in the gut should minimise any effects. This may also prove of use in the interactions with haloperidol and sulpiride (although note; the haloperidol interaction is not confirmed). In the case of chlorpromazine an alternative would be to use calcium carbonate-glycine or magnesium hydroxide gel, which seem to affect its gastrointestinal absorption to a lesser extent.⁶ Other phenothiazines and antacids are known to interact *in vitro*,⁴ but the clinical importance of these interactions awaits further study.

6. Pinell OC, Fenimore DC, Davis CM, Moreira O, Fann WE. Drug-drug interaction of chlorpromazine and antacid. *Clin Pharmacol Ther* (1978) 23, 125.

Antipsychotics + Antiepileptics

Haloperidol plasma levels are roughly halved by carbamazepine, phenobarbital and phenytoin. Bromperidol, fluphenazine and tiotixene levels are also reduced by carbamazepine. The plasma levels of chlorpromazine and haloperidol do not appear to be affected by oxcarbazepine. Neurotoxicity has been seen with haloperidol and carbamazepine and haloperidol can raise serum carbamazepine levels. Valproate or valproic acid appear not to interact.

Clinical evidence

(a) Carbamazepine

For mention of carbamazepine toxicity and other adverse reactions following the concurrent use of antipsychotics, see 'Carbamazepine + Antipsychotics', p.524.

1. *Bromperidol*. When 13 schizophrenic patients taking bromperidol 12 or 24 mg daily were given carbamazepine 200 mg twice daily for 4 weeks, the plasma levels of bromperidol and reduced bromperidol (a metabolite) were decreased by 37% and 23%, respectively. Despite this fall in levels, the Clinical Global Impression scores (a measure of severity of illness) fell slightly.¹

2. *Chlorpromazine*. **Oxcarbazepine** was substituted for carbamazepine in 4 difficult to treat schizophrenic patients. All patients were also taking chlorpromazine, and in 3 cases other antipsychotic medication (lithium, zuclopenthixol or clozapine). After 3 weeks of taking the **oxcarbazepine** all the 4 patients had rises in their chlorpromazine levels, of 28%, 63%, 76%, and 90%, respectively. In one case this rise was associated with increased extrapyramidal adverse effects.²

3. *Fluphenazine*. A patient receiving intramuscular fluphenazine decanoate 37.5 mg weekly had a rise in serum levels from 0.6 to 1.17 nanograms/mL 6 weeks after stopping carbamazepine 800 mg daily. A moderate improvement in his schizophrenic condition occurred.³

4. *Haloperidol*. A study in 9 schizophrenics taking haloperidol (average dose 30 mg daily) found a 55% reduction in plasma haloperidol levels (a mean fall from 45.5 to 21.2 nanograms/mL) when they were given carbamazepine for 5 weeks (precise dose not stated). They also took trihexyphenidyl 10 mg daily and oxazepam 30 mg at night as necessary. Carbamazepine serum levels and the control of the disease remained unchanged.⁴

Other studies have similarly found 40 to 60% falls in plasma haloperidol levels in patients taking carbamazepine,⁵⁻⁷ with the occasional patient having undetectable levels.^{6,8} Decreases in plasma haloperidol levels of unspecified amounts have also been described.⁹⁻¹² A study in 9 patients taking haloperidol 6 mg twice daily who were then given carbamazepine, with the daily dose increased at fortnightly intervals from 100 to 300 and to 600 mg, found a dose-dependent reduction in haloperidol levels. Mean plasma haloperidol levels were reduced by 25%, 61%, and 82%, respectively.¹³ A few patients have had clinical worsening or increased adverse effects.⁶⁻⁸ Three patients had two to fivefold increases in plasma haloperidol levels and clinical improvement when carbamazepine 1.2 to 1.4 g daily was stopped, but extrapyramidal adverse effects developed within 1 to 30 days.¹⁴ Three cases of neurotoxicity (drowsiness, slurred speech, confusion) have also been described in patients taking haloperidol and carbamazepine.^{9,15,16}

A case report describes 3 schizophrenic patients taking haloperidol whose treatment was changed from carbamazepine to **oxcarbazepine**. After 2 weeks their plasma haloperidol levels had dramatically risen (from 6 to 18 nanomol/L, from 6 to 14 nanomol/L and from 17 to 27 nanomol/L). This was accompanied by severe extrapyramidal adverse effects, which necessitated dose reductions in 2 patients.²

A fall of 45% in haloperidol levels was noted in a study of 7 patients taking haloperidol and carbamazepine, and patients also experienced a worsening of clinical symptoms.¹⁷

A study in Japanese schizophrenic patients found that carbamazepine reduced the serum haloperidol levels by an unstated amount, while at the same time the serum carbamazepine levels were raised by about 30%, despite a 25% dose reduction.¹⁰ An associated study by the same group of workers found that concurrent use increased the incidence of QTc lengthening.¹⁸

5. **Tiotixene**. A retrospective study in 42 patients found that the mean clearance of tiotixene in those taking liver enzyme inducer drugs (carbamazepine, phenytoin, primidone) was threefold greater than in the control group. Of the group taking enzyme inducers, 5 patients had non-detectable serum tiotixene levels, and not surprisingly showed no clinical response.¹⁹

(b) Phenobarbital and/or Phenytoin

A study in epileptic patients, 2 taking phenobarbital, 3 taking phenytoin, and 4 taking both drugs, found that after taking **haloperidol** 10 mg three times daily for 6 weeks their serum **haloperidol** levels were about half of those in a control group who were not taking anticonvulsants (19.4 compared to 36.6 nanograms/mL). Antiepileptic levels remained unchanged.²⁰ A patient had a marked rise in serum **haloperidol** levels and clinical improvement when phenytoin 300 mg daily was stopped.¹⁴ A retrospective study found that phenobarbital reduced the **haloperidol** concentration/dose ratio, suggesting that phenobarbital may affect the metabolism of **haloperidol**.¹² See also **Tiotixene** above.

A case-control, retrospective review of patients taking **thioridazine** 100 to 200 mg daily with either phenytoin, phenobarbital or both drugs found a reduction in both phenobarbital (approximately 25%) and **thioridazine** levels when taken together. Inconsistent effects were seen on the pharmacokinetics of phenytoin, with a possible trend towards a reduction in phenytoin levels. These results, together with the seizure threshold-lowering effect of phenothiazines, highlights the need to carefully monitor antiepileptic drug levels if phenothiazines are added to, or removed from therapy.²¹ See 'Phenothiazines + Barbiturates', p.759, for the interaction of phenobarbital with chlorpromazine.

(c) Valproic acid or Valproate

A study in 6 patients given **haloperidol** 6 to 10 mg daily found no significant interaction with valproic acid.²² Similarly, **haloperidol** was not found to interact with valproate in two further studies,^{17,23} although in one of these studies an increase of 64% in **haloperidol** plasma levels was seen, which was considered not significant.¹⁷ For the interaction of valproic acid with chlorpromazine, see 'Valproate + Chlorpromazine', p.577.

Mechanism

Carbamazepine, phenobarbital and phenytoin are recognised enzyme inducers, therefore it seems highly likely that the reduced plasma bromperidol, chlorpromazine and haloperidol levels occur because their metabolism by the liver is markedly increased by these antiepileptics. Oxcarbazepine does not appear to interact, probably because it is not an enzyme inducer.

Importance and management

The interactions of haloperidol with carbamazepine, phenytoin and phenobarbital are moderately well documented and appear to be clinically important, but only a few patients have been reported to show clinical worsening. Although there are advantages in adding carbamazepine to haloperidol in treating some patients²⁴ be alert for the need to increase the haloperidol dosage if any of these antiepileptics is also given. The authors of one study with phenobarbital and phenytoin suggest a two to threefold increase in the haloperidol dosage may be needed.²⁰ Another study, in which intramuscular haloperidol was used, recommended shortening the interval between injections rather than raising the dosage, but it was not stated by how much.²⁵ Remember too that if the anticonvulsants are withdrawn it may be necessary to reduce the haloperidol dosage. Also be alert for the development of dystonic reactions and for a rise in serum carbamazepine levels. Similar precautions seem necessary with tiotixene, and may be needed with bromperidol and chlorpromazine, but this needs confirmation. Limited evidence suggest that no special precautions are necessary with oxcarbazepine, or if sodium valproate is used with haloperidol.

Antipsychotics + Antimuscarinics

Antipsychotics and antimuscarinics are very often given together advantageously and uneventfully, but occasionally serious and even life-threatening interactions occur. These include heat stroke in hot and humid conditions, severe constipation and adynamic ileus, and atropine-like psychoses. Antimuscarinics used to

counteract the extrapyramidal adverse effects of antipsychotics may also reduce or abolish their therapeutic effects.

Clinical evidence

The use of antipsychotics with antimuscarinics can result in a generalised, low grade, but not usually serious, additive increase in the antimuscarinic effects of these drugs (blurred vision, dry mouth, constipation, difficulty in urination, see 'Antimuscarinics + Antimuscarinics', p.674). However, sometimes serious intensification takes place. For the sake of clarity these have been subdivided here into (a) heat stroke, (b) constipation and adynamic ileus, (c) atropine-like psychoses, (d) antagonism of antipsychotic effects and (e) miscellaneous effects.

(a) Heat stroke in hot and humid conditions

Three patients were admitted to hospital in Philadelphia for drug-induced hyperpyrexia during a hot and humid period. In each case their skin and mucous membranes were dry and they were tachycardic (120 bpm). There was no evidence of infection.¹

Drug combinations implicated in reports of heat stroke, some of them fatal, include:¹⁻⁵

- chlorpromazine and benztropine
- chlorpromazine and trifluoperazine
- chlorpromazine, amitriptyline and benztropine
- chlorpromazine, chlorprothixene and benztropine
- chlorpromazine, fluphenazine, trihexyphenidyl and benztropine
- chlorpromazine, trifluoperazine and benztropine
- haloperidol and benztropine
- promazine and benztropine.

The danger of heat stroke in patients taking atropine or atropine-like compounds was recognised in the 1920s, and the warning has been repeated many times.^{6,7}

(b) Constipation and adynamic ileus

Paralytic ileus with faecal impaction (fatal in 6 cases) has been reported in a number of patients taking:

- chlorpromazine and amitriptyline,⁸ imipramine,⁹ nortriptyline,¹⁰ or trihexyphenidyl⁹
- haloperidol and benztropine¹¹
- levomepromazine and imipramine with benztropine⁹
- levomepromazine and trihexyphenidyl⁹
- mesoridazine and benztropine¹²
- thioridazine and imipramine with trihexyphenidyl⁹
- trifluoperazine and benztropine¹³ or trihexyphenidyl⁹
- trifluoperazine and benztropine with methylphenidate.¹⁴

Severe constipation also occurred in a woman given thioridazine, biperiden and doxepin.¹⁵

(c) Atropine-like psychoses

In a double-blind study 3 patients given a phenothiazine and benztropine for the parkinsonian adverse effects, developed an intermittent toxic confusional state (marked disturbance of short-term memory, impaired attention, disorientation, anxiety, visual and auditory hallucinations) with peripheral antimuscarinic signs.¹⁶ Similar reactions occurred in 3 elderly patients given imipramine or desipramine, with trihexyphenidyl,¹⁷ and in another man given chlorpromazine, benztropine and doxepin.¹⁵

(d) Antagonism of the antipsychotic effects

A study in psychiatric patients given chlorpromazine 300 to 800 mg daily found that when trihexyphenidyl 6 to 10 mg daily was added, the plasma chlorpromazine levels were reduced from a range of 100 to 300 nanograms/mL to less than 30 nanograms/mL. When the trihexyphenidyl was withdrawn the plasma chlorpromazine levels rose again and clinical improvement was seen.^{18,19}

Other studies confirm that trihexyphenidyl^{20,21} and orphenadrine²² reduce the plasma levels and effects of chlorpromazine. In contrast to these reports, another found that trihexyphenidyl increased chlorpromazine levels by 41% in 20 young schizophrenics, but no clinical change was seen. The levels dropped again over the first 4 weeks of treatment.²³ Some of the beneficial actions of haloperidol on social avoidance behaviour are lost during concurrent treatment with benztropine, but cognitive integrative function is unaffected.²⁴

A study to investigate any possible interaction between procyclidine 5 to 15 mg daily and chlorpromazine, fluphenazine or haloperidol found that the addition of procyclidine caused a transient fall in the serum

levels of chlorpromazine, whilst the fall in levels of fluphenazine and haloperidol was maintained for the 4 week treatment period with procyclidine. Two patients in the haloperidol group experienced a worsening of symptoms whilst taking procyclidine.²⁵

(e) Miscellaneous effects

A study in psychotic patients found that the addition of biperiden 2 mg three times daily or orphenadrine 50 mg three times daily for 3 weeks had no effect on the steady-state levels of perphenazine 24 to 48 mg daily.²⁶

An isolated report describes the development of a hypoglycaemic coma in a non-diabetic patient given chlorpromazine and orphenadrine.²⁷

Mechanism

Antimuscarinic (anticholinergic) drugs inhibit the parasympathetic nervous system, which innervates the sweat glands, so that when the ambient temperature rises the major body heat-losing mechanism can be partially or wholly lost.²⁸ Phenothiazines, thioxanthenes and butyrophenones may also have some antimuscarinic effects, but additionally they impair to a varying extent the hypothalamic thermoregulatory mechanisms that control the body's ability to keep a constant temperature when exposed to heat or cold. Thus, when the ambient temperature rises, the body temperature also rises. The tricyclics can similarly disrupt temperature control. Therefore in very hot and humid conditions, when the need to reduce the temperature is great, the additive effects of these drugs can make patients unable to control their temperature,⁴ which can be fatal.

Antimuscarinic drugs also reduce peristalsis, which in the extreme can result in total gut stasis. Additive effects can occur if two or more antimuscarinic drugs are taken.

The toxic psychoses described resemble the CNS effects of atropine or belladonna poisoning and appear to result from the additive effects of the drugs used.

The mechanism for antipsychotic antagonism is not understood. *Animal* studies suggest that the site of interaction is in the gut.¹⁹

Importance and management

Established and well-documented interactions. While these drugs have been widely used together with apparent advantage and without problems, prescribers should be aware that an unsuspected low-grade antimuscarinic toxicity can easily go undetected, particularly in the elderly because the symptoms can be so similar to the general complaints of this group. Also be aware of the serious problems that can sometimes develop, particularly if high doses are used.

- Warn patients to minimise outdoor exposure and/or exercise in hot and humid climates, particularly if they are taking high doses of antipsychotic/antimuscarinic drugs.
- Be alert for severe constipation and for the development of complete gut stasis, which can be fatal.
- Be aware that the symptoms of central antimuscarinic psychosis can be confused with the basic psychotic symptoms of the patient. Withdrawal of one or more of the drugs, or a dosage reduction and/or appropriate symptomatic treatment can be used to control these interactions.
- Ensure that the concurrent use of antimuscarinics to control the extrapyramidal adverse effects of neuroleptics is necessary^{29,30} and be aware that the therapeutic effects may possibly be reduced as a result.

Note that tricyclic antidepressants have antimuscarinic adverse effects and may therefore interact similarly. The tricyclics also have other interactions with antipsychotics, see 'Phenothiazines + Tricyclic antidepressants', p.760. Some antipsychotics and antimuscarinics prolong the QT interval. Consider also 'Antimuscarinics + Antimuscarinics', p.674.

Antipsychotics + Bromocriptine

The concurrent use of bromocriptine with antipsychotics can be successful. However, one report describes the re-emergence of schizophrenic symptoms in a patient when bromocriptine was added to treatment with molindone and imipramine. Another case reports a rise in prolactin levels and deterioration of vision when thioridazine was given with bromocriptine.

Clinical evidence, mechanism, importance and management

Single 2-mg doses of bromocriptine have been found to improve the psychopathology of chronic schizophrenia in patients taking antipsychotics¹ and a case report describes a reduction in psychopathology when bromocriptine 2.5 mg daily was given with haloperidol.²

A case of reduced prolactin levels has been reported in a man treated with fluphenazine and benztropine who took bromocriptine to treat a pituitary tumour. His prolactin level became undetectable, and his psychiatric status was unchanged, although no reduction in tumour size was seen with the bromocriptine.³ However, the prolactin levels of a patient with a prolactin-secreting pituitary adenoma fell from almost 8,000 nanograms/mL to 400 nanograms/mL when bromocriptine was started, but increased again to 1,000 nanograms/mL when he started to take thioridazine 25 mg twice daily. As the thioridazine dose was increased to 200 mg daily, his prolactin level increased further to 2,000 nanograms/mL and his visual fields deteriorated. Normal vision returned within 5 days of stopping the thioridazine, and his prolactin levels fell to below 500 nanograms/mL.⁴ A woman with schizoaffective schizophrenia, taking molindone 100 mg and imipramine 200 mg daily, relapsed within 5 days of starting treatment with bromocriptine 2.5 mg three times daily for amenorrhoea and galactorrhoea.⁵ Within 3 days of stopping the bromocriptine the symptoms of relapse (agitation, delusions, and auditory hallucinations) vanished. The reason suggested by the authors of the report is that the bromocriptine (a dopamine agonist) opposed the actions of the antipsychotic medication (dopamine antagonists) thereby allowing the schizophrenia to re-emerge. Limited evidence suggests that 'levodopa', (p.683), and other 'dopamine agonists', (p.677), also may antagonise the effects of antipsychotics, which adds weight to this theory.

Antipsychotics + Coffee or Tea

Tea and coffee can cause some drugs to precipitate out of solution *in vitro*, but so far there is no clinical evidence to show that this normally affects the bioavailability of the drugs nor that it has a detrimental effect on treatment.

Clinical evidence, mechanism, importance and management

A single report describes 2 patients whose schizophrenia was said to have been exacerbated by an increased consumption of tea and coffee.¹ Subsequent *in vitro* studies^{2–6} showed that a number of drugs (**chlorpromazine**, **promethazine**, **fluphenazine**, **orphenadrine**, **promazine**, **prochlorperazine**, **trifluoperazine**, **thioridazine**, **loxapine**, **haloperidol**, **droperidol**) form a precipitate with tea or coffee due to the formation of a drug-tannin complex, which was thought might possibly lower the absorption of these drugs in the gut. Studies with *rats* also showed that tea abolished the cataleptic effects of **chlorpromazine**, which did not appear to be related to the presence of caffeine.⁷ However, the drug-tannin complex gives up the drug into solution if it becomes acidified, as in the stomach.⁶ Moreover, a clinical study of this interaction showed that the plasma levels of **chlorpromazine**, **fluphenazine**, **trifluoperazine** and **haloperidol** in a group of 16 patients were unaffected by the consumption of tea or coffee.⁸ Their behaviour also remained unchanged.⁸ A study in 12 healthy subjects also concluded that there was no significant decrease in plasma levels of a single 5-mg dose of **fluphenazine** given with either tea, coffee, or water.⁹ So there appears to be little or no direct evidence that this physicochemical interaction is normally of any clinical importance.

Antipsychotics + Lithium

Chlorpromazine levels can be reduced to subtherapeutic concentrations by lithium. The development of severe extrapyramidal adverse effects or severe neurotoxicity has been seen in one or more patients given lithium with various antipsychotics. Sleepwalking has been described in some patients taking chlorpromazine-like drugs and lithium.

Clinical evidence

(a) Chlorpromazine

In a double-blind study in psychiatric patients it was found that chlorpromazine 400 to 800 mg daily, a dose that normally produced plasma levels of 100 to 300 nanograms/mL, only produced levels of 0 to 70 nanograms/mL when lithium carbonate was also given.¹

Other studies confirm that normal therapeutic levels of lithium carbonate reduce plasma chlorpromazine levels.^{2,3} The peak serum levels and AUC of chlorpromazine were reduced by 40% and 26%, respectively, in healthy subjects given lithium carbonate.²

A paranoid schizophrenic taking chlorpromazine 200 to 600 mg daily for 5 years with no extrapyramidal symptoms developed stiffness of his face, arms and legs, and parkinsonian tremor of both hands within one day of starting to take lithium 900 mg daily. His lithium blood level after 3 days was 0.5 mmol/L. He was later given lithium 1.8 g daily (blood level

1.17 mmol/L), chlorpromazine 200 mg daily and benztropine 2 mg daily, which improved his condition, but he still complained of stiffness and had a persistent hand tremor.⁴

A number of other reports describe the emergence of severe extrapyramidal adverse effects when chlorpromazine was given with lithium.⁵⁻⁷ Ventricular fibrillation, thought to be caused by chlorpromazine toxicity, occurred in a patient taking lithium when both drugs were suddenly withdrawn.⁸ Severe neurotoxicity has also been seen in a handful of other patients taking lithium and chlorpromazine.^{9,10}

(b) Haloperidol

A large-scale retrospective study of the literature over the period 1966 to 1996 using the Medline database identified 41 cases of neurotoxic adverse effects in 41 patients with low therapeutic concentrations of lithium. Of these patients, 10 were taking haloperidol.⁹

Another retrospective study using both Medline and the spontaneous reporting system of the FDA in the US, over the period 1969 to 1994, identified 237 cases of severe neurotoxicity involving lithium, of which 59 also involved the concurrent use of haloperidol.^{11,12}

Other reports describe encephalopathic syndromes (lethargy, fever, tremulousness, confusion, extrapyramidal and cerebellar dysfunction),¹³ neuromuscular symptoms, impaired consciousness and hyperthermia,¹⁴ delirium, severe extrapyramidal symptoms and organic brain damage in patients taking haloperidol with lithium.¹⁵⁻²⁶ In one study it was found that of the 13 patients who were taking haloperidol, 5 developed neurotoxic reactions, and they were receiving higher doses of haloperidol (average dose was 59 mg) than the 8 patients who did not develop such symptoms (average dose was 34.9 mg).²⁷ The sudden emergence of extrapyramidal or other adverse effects with lithium and haloperidol has also been described in other studies.^{9,15,28}

In contrast to the reports cited above, there are others describing successful and uneventful use.^{13,29-32} A retrospective search of Danish hospital records found that 425 patients had taken both drugs and none of them had developed serious adverse reactions.³³

A small rise in serum lithium levels occurs in the presence of haloperidol, but it is almost certainly of little or no clinical significance.³⁴

(c) Other antipsychotics

A large-scale retrospective study of the literature over the period 1966 to 1996 using the Medline database identified 41 cases of neurotoxic adverse effects in 41 patients with low, therapeutic concentrations of lithium. Of these patients, 51.2% were also taking at least one antipsychotic drug.⁹ Another retrospective study using both Medline and the spontaneous reporting system of the FDA in the US, over the period 1969 to 1994, identified 237 cases of severe neurotoxicity involving lithium, with 188 involving lithium with antipsychotics.^{11,12} The sudden emergence of extrapyramidal or other adverse effects has also been described in other studies. The antipsychotics implicated in this interaction with lithium are **amoxapine**,^{11,12} **bromperidol**,^{11,12} **chlorprothixene**,^{11,12} **clopenthixol**,⁹ **clozapine**,^{9,11,12} **flupentixol**,^{15,28,35} **fluphenazine**,^{9,11,12,15,28,36} **levomepromazine**,^{9,11,12} **loxapine**,^{11,12,37,38} **mesoridazine**,^{11,12} **molindone**,^{11,12} **perphenazine**,^{11,12,28} **pipotiazine**,³⁹ **prochlorperazine**,^{11,12} **sulpiride**,⁴⁰ **thioridazine**,^{9,11,12,28,41,42} **tiotixene**,^{9,11,12,16,28} **trifluoperazine**,^{11,12} and **zuclopenthixol**.⁹ Examples of some cases are cited in a little more detail below.

A study of 10 patients taking **fluphenazine**, **haloperidol** or **tiotixene** found that the addition of lithium worsened their extrapyramidal symptoms.⁴³ Neurotoxicity (tremor, rigidity, ataxia, tiredness, vomiting, confusion) attributed to an interaction between lithium and **fluphenazine** has been described in another patient. He previously took **haloperidol** and later took **chlorpromazine** with lithium, without problem.⁴⁴ Irreversible brain damage has been reported in a patient taking **fluphenazine decanoate** and lithium.⁴⁵ Severe neurotoxic complications (seizures, encephalopathy, delirium, abnormal EEGs) developed in 4 patients taking **thioridazine** 400 mg daily or more and lithium. Serum lithium levels remained below 1 mmol/L. Lithium and other phenothiazines had been taken by 3 of them for extended periods without problems, and the fourth subsequently took lithium and **fluphenazine** without problems.⁴⁶ In one study the concurrent use of lithium and **chlorpromazine**, **perphenazine**, or **thioridazine** was associated with sleep-walking episodes in 9% of patients.⁴⁷ **Somnolence**, confusion, delirium, creatinine phosphokinase elevation and fever occurred in a man taking lithium when **risperidone** was given.⁴⁸ A retrospective review of 39 patients with a diagnosis of neurotoxicity caused by treatment with lithium and an antipsychotic, found that

the onset of symptoms varied from 24 hours to 3 months after taking the two drugs together, with an average delay of 12.7 days.²⁸

A study in 8 patients found a fourfold increase in half life of **molindone** when given with lithium.⁴⁹

Mechanism

Not understood. One suggestion to account for the reduced serum levels of chlorpromazine, which is based on *animal* studies,^{50,51} is that chlorpromazine can be metabolised in the gut. Therefore, if lithium delays gastric emptying, more chlorpromazine will be metabolised before it reaches the circulation. Just why severe neurotoxicity and other adverse effects sometimes develop in patients taking lithium and antipsychotics is not understood. It is the subject of considerable discussion and debate.^{9,11,12,52,53}

Importance and management

Information about the reduction in chlorpromazine levels caused by lithium is limited, but it would seem to be an established interaction of clinical importance. Serum chlorpromazine levels below 30 nanograms/mL have been shown to be ineffective, whereas clinical improvement is usually associated with levels within the 150 to 300 nanogram/mL range.⁵⁴ Thus a fall in levels to below 70 nanograms/mL, as described in one study, would be expected to result in a reduced therapeutic response to chlorpromazine. Therefore the effects of concurrent use should be closely monitored and the chlorpromazine dosage increased if necessary.

The development of severe neurotoxic or severe extrapyramidal adverse effects with combinations of antipsychotics and lithium appears to be uncommon and unexplained but be alert for any evidence of toxicity if lithium is given with any of these drugs. One recommendation is that the onset of neurological manifestations, such as excessive drowsiness or movement disorders, warrants electroencephalography without delay and withdrawal of the drugs, especially as irreversible effects have been seen. A review⁵⁵ suggests that the concurrent use of haloperidol seems to be safe if lithium levels are below 1 mmol/L. It is not known whether this also applies to other antipsychotics.

At the moment there seems to be no way of identifying the apparently small number of patients who are particularly at risk, but possible likely factors include a previous history of extrapyramidal reactions with antipsychotics and the use of large doses of the antipsychotic.

For interactions of **atypical antipsychotics** with lithium see 'amisulpride', (p.707); 'aripiprazole', (p.714); 'clozapine', (p.748); 'olanzapine', (p.756); 'quetiapine', (p.763); and 'ziprasidone', (p.770).

Antipsychotics + Orlistat

No changes in the plasma levels of haloperidol or clozapine were seen when orlistat was also given.

Clinical evidence, mechanism, importance and management

In a study, 8 patients who had experienced weight gain as a result of treatment with **haloperidol** (2), **clozapine** (2), clomipramine (3), desipramine (1), or carbamazepine (2), and were given orlistat 120 mg three times daily for 8 weeks. There was no significant changes in the plasma levels of the antipsychotic drugs, and steatorrhea, which occurred in three patients, had no effect on their bioavailability.¹ Although an interaction appears to be unlikely, due to the small numbers involved in this study, it would be advisable to monitor patients for reduced absorption of antipsychotic drugs until more data is available.

1. Hilger E, Quiner S, Ginzl I, Walter H, Saria L, Barnas C. The effect of orlistat on plasma levels of psychotropic drugs in patients with long-term psychopharmacotherapy. *J Clin Psychopharmacol* (2002) 22, 68–70.

Antipsychotics + SSRIs

On the whole no significant adverse interactions appear to occur between the antipsychotics and the SSRIs. However, a number of case reports describe extrapyramidal adverse effects following the use of fluoxetine or paroxetine with an antipsychotic, and galactorrhea and amenorrhoea developed in one patient given loxapine and fluvoxamine. Fluoxetine and fluvoxamine appear to raise haloperidol levels, which may increase adverse effects. Thioridazine levels are expected to be increased with fluoxetine, fluvoxamine, or paroxetine treatment with a risk of QT interval prolongation.

Clinical evidence, mechanism, importance and management

(a) Chlorpromazine

A study in schizophrenic patients found that over a 12-week period the serum levels of chlorpromazine were not significantly altered by **citlopram** 40 mg daily.¹

(b) Cyamemazine

A study in patients taking cyamemazine found that **fluvoxamine** 150 mg daily had no effect on its serum levels, but the authors of the report also say that no firm conclusions should be drawn from this finding because the number of patients was too small.²

(c) Flupentixol

Parkinson-like symptoms developed in a patient taking amitriptyline and flupentixol when **fluoxetine** was given.³

(d) Fluphenazine

A severe dystonic reaction (painful jaw tightness and throat 'closing up') occurred in a man taking **fluoxetine** 40 mg daily when he took fluphenazine 2.5 mg on two consecutive nights.⁴

(e) Haloperidol

1. **Citalopram.** A study in schizophrenic patients found that over a 12-week period the serum levels of haloperidol were not significantly altered by citalopram 40 mg daily.¹

2. **Escitalopram.** Escitalopram is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, and may therefore inhibit haloperidol metabolism. The manufacturers say that consideration should be given to reducing the dose of haloperidol.⁵

3. **Fluoxetine.** A woman taking haloperidol 2 to 5 mg daily for 2 years with only occasional mild extrapyramidal symptoms began to experience severe extrapyramidal symptoms (tongue stiffness, parkinsonism, akathisia) shortly after starting to take fluoxetine 40 mg twice daily and was virtually incapacitated for 3 days. Both drugs were stopped and she recovered over a period of one week.⁶ Three other patients developed movement disorders after receiving both drugs,^{7–9}

In one case severe antimuscarinic adverse effects also occurred.⁸ A report describes 8 patients who had a 20% rise in plasma haloperidol levels when fluoxetine 20 mg daily was added. Although no overall increase in extrapyramidal effects was seen, one patient developed tremor, and another developed akathisia.¹⁰ Similarly 15 patients showed an increase of nearly 30% in haloperidol plasma levels after fluoxetine was given, and 5 of 17 patients had aggravated parkinsonian symptoms.¹¹ Another report describes a more than 100% rise in plasma haloperidol levels accompanied by clinical improvement in 7 patients given fluoxetine 20 to 40 mg with haloperidol.¹²

4. **Fluvoxamine.** A study in 12 schizophrenic patients found that haloperidol levels were increased by 20%, 39%, and 60% by fluvoxamine 25, 75, and 150 mg daily, respectively, which suggested the extent of the interaction was related to the dose of fluvoxamine.¹³ A study in 3 schizophrenic patients found that the addition of fluvoxamine caused their serum haloperidol levels to rise, and when the fluvoxamine was stopped the levels fell. This was not a formal pharmacokinetic study, but while taking fluvoxamine 150 to 200 mg daily the haloperidol serum levels of one patient rose from 17 to 38 nanograms/mL. The fluvoxamine was then stopped and 54 days later his serum haloperidol levels had fallen to 9 nanograms/mL. This patient became lethargic and showed worsening of all of the clinical and cognitive functions assessed while taking these drugs.¹⁴ It should be

noted that all three patients were also taking benztropine (see 'Antimuscarinics + SSRIs', p.675). Another limited study also observed that fluvoxamine caused a rise in the serum levels of haloperidol.²

5. *Paroxetine*. In one study the sedative effects and impairment of psychomotor performance caused by haloperidol 3 mg were not increased by paroxetine 30 mg.¹⁵

6. *Sertraline*. In a randomised, placebo-controlled study, 21 healthy subjects were given a single 2-mg dose of haloperidol on days 2 to 25. On days 9 to 25 the subjects were given sertraline, increased over 7 days to 200 mg daily. All subjects took psychomotor tests on days 1, 2 and 25 to assess the effect of haloperidol. Their cognitive function was impaired for 6 to 8 hours after taking the haloperidol, but this effect had disappeared after 23 hours. Overall, sertraline did not appear to worsen the cognitive impairment caused by haloperidol.¹⁶ Another study found similar pharmacodynamic results, and also found that the pharmacokinetics of haloperidol are unaffected by sertraline.¹⁷ In contrast, a study in 16 hospitalised patients who were taking haloperidol found that the addition of sertraline 50 mg daily for 2 weeks resulted in an increase in plasma haloperidol concentrations, and a reduction in the plasma concentrations of the metabolite, reduced haloperidol.¹⁸

(f) *Levomepromazine*

A study in patients taking levomepromazine found that **fluvoxamine** 150 mg daily did not affect its serum levels, but the authors of the report also say that no firm conclusions should be drawn from this finding because the number of patients was too small.² A further study in 15 patients also found that there was no significant change in the pharmacokinetics of **fluvoxamine** when given with levomepromazine in doses of 5 to 25 mg daily. Additionally, patients in this study found that the levomepromazine counteracted the insomnia caused by **fluvoxamine**.¹⁹

A study in three groups of 8 healthy subjects taking **citalopram** 40 mg daily for 10 days found that a single 50-mg oral dose of levomepromazine increased the initial steady-state levels of the primary metabolite of **citalopram** (desmethylcitalopram) by 10 to 20%, which was not considered to be clinically significant.²⁰

A study in schizophrenic patients found that over a 12-week period the serum levels of levomepromazine were not significantly altered by **citalopram** 40 mg daily.¹

(g) *Loxapine*

A 38-year-old woman developed amenorrhoea, followed shortly by galactorrhoea, about 6 weeks after starting to take fluvoxamine and loxapine. The galactorrhoea resolved within 3 weeks of stopping the **fluvoxamine**, and menstruation occurred one week later. Her prolactin levels were found to be 80 micrograms/L (normal 4 to 30 micrograms/L).²¹

(h) *Metopimazine*

A French regional pharmacovigilance centre reported 37 cases of extrapyramidal adverse effects linked to concurrent use of an SSRI and a neuroleptic. In 2 cases **metopimazine** was given.²²

(i) *Molindone*

An elderly woman taking molindone 10 mg twice daily developed severe and disabling extrapyramidal symptoms (severe bradykinesia, tremor, inability to feed herself, delirium) within about 2 weeks of starting **paroxetine** 10 mg daily. The symptoms resolved when molindone was stopped, and no problems occurred when **fluoxetine** alone was started.²³

(j) *Pericyazine*

A New Zealand study describes a patient who developed extrapyramidal symptoms when given pericyazine and **fluoxetine**.⁷

(k) *Perphenazine*

1. *Citalopram*. A study in schizophrenic patients found that over a 12-week period the serum levels of perphenazine were not significantly altered by citalopram 40 mg daily.¹

2. *Fluoxetine*. The combination of perphenazine and fluoxetine was found to be effective in the treatment of psychotic depression in 30 patients, and the adverse effects (which included dry mouth, blurred vision, constipation, tremor or rigidity, orthostasis and hypotension) were thought to be easier to tolerate than an antipsychotic with a tricyclic antidepressant.²⁴ However, one woman developed marked extrapyramidal symptoms within 2 weeks of starting perphenazine 4 mg twice daily and fluoxetine 20 mg daily.²⁵

3. *Paroxetine*. The effects of a single 100-microgram/kg oral dose of perphenazine on the performance of psychomotor tests were assessed after 4, 6, 8 and 10 hours in 5 subjects. The tests were then repeated after the subjects also took paroxetine 20 mg daily for 10 days. The scores for these tests were worsened by the perphenazine when compared with a placebo and further worsened by the presence of the paroxetine. In addition to over-sedation and impairment of the performance of psychomotor tests and memory, 2 of the subjects developed akathisia 10 hours after taking both drugs. The AUC of the perphenazine was increased sevenfold and the maximum plasma levels sixfold.²⁶

(l) *Pimozide*

See 'Pimozide + SSRIs', p.762.

(m) *Sulpiride*

Parkinson-like symptoms developed in a patient taking sulpiride and maprotiline when **fluoxetine** was also given.²⁷

(n) *Thioridazine*

A study in schizophrenic patients found that over a 12-week period the serum levels of thioridazine were not significantly altered by **citalopram** 40 mg daily.¹

A study in 10 schizophrenic patients found that when **fluvoxamine** 50 mg daily was added to established treatment with thioridazine 30 to 200 mg daily, thioridazine plasma levels were increased by 225%. There were no reported changes in either clinical status or adverse effects.²⁸

(o) *Tiotixene*

A study in 10 healthy subjects found that **paroxetine** 20 mg daily for 3 days did not significantly affect the pharmacokinetics of a single 20-mg dose of tiotixene.²⁹

(p) *Trifluoperazine*

A New Zealand study describes a patient who developed extrapyramidal symptoms when given trifluoperazine and **fluoxetine**.⁷

(q) *Zuclophenxol*

A study in schizophrenic patients found that over a 12-week period the serum levels of zuclophenxol were not significantly altered by **citalopram** 40 mg daily.¹

Mechanism

Movement disorders and raised antipsychotic serum levels seem most common with fluoxetine and paroxetine, possibly because they inhibit the metabolism of some antipsychotics by the cytochrome P450 isoenzyme CYP2D6.²⁶ However, the movement disorders may just be a result of the additive adverse effects of antipsychotics and SSRIs. Fluoxetine alone has been shown to occasionally cause movement disorders.^{7,30}

Galactorrhoea is a known adverse effect of loxapine, but just why fluvoxamine apparently increased this effect is not understood.²¹

Importance and management

On the whole significant interactions between the antipsychotics and SSRIs appear rare (although see thioridazine, below). The combination can be useful and so the isolated cases of extrapyramidal adverse effects should not prevent concurrent use. However, if extrapyramidal effects become troublesome bear this interaction in mind as a possible cause. The significance of the rise in haloperidol levels caused by fluoxetine and fluvoxamine is unclear, be aware that haloperidol adverse effects may be increased in some patients and consider reducing the haloperidol dose if problems occur. The rise in perphenazine levels caused by paroxetine seems to result in a greater number of more serious adverse effects and so consideration should be given to reducing the dose of perphenazine if paroxetine is started. Citalopram may be a suitable alternative as it does not appear to affect perphenazine levels.

Note that, although the studies with thioridazine did not appear to show any clinically significant interaction the US manufacturers of fluoxetine,³¹ fluvoxamine,³² and paroxetine,³³ contraindicate the concurrent use of thioridazine as they suggest that its metabolism (by CYP2D6) may be inhibited by these SSRIs, leading to raised levels and the risk of QT prolongation. The use of thioridazine is also contraindicated for 5 weeks after fluoxetine has been stopped.³¹ Similarly, it has been suggested that the

dose of thioridazine may need to be reduced when it is given with escitalopram.⁵

SSRI antidepressants may lower the seizure threshold, and therefore concomitant use with other drugs, which can also lower the seizure threshold, such as phenothiazines, should be undertaken with caution.

Antipsychotics + Tobacco or Cannabis

Smokers of tobacco or cannabis may possibly need larger doses of chlorpromazine, fluphenazine, haloperidol or tiotixene than non-smokers.

Clinical evidence

(a) Chlorpromazine

A comparative study found that the frequency of drowsiness in 403 patients taking chlorpromazine was 16% in non-smokers, 11% in light

smokers, and 3% in heavy smokers (more than 20 cigarettes daily).¹ Another report describes a patient taking chlorpromazine who experienced increased sedation and dizziness and higher plasma chlorpromazine levels when he gave up smoking.² A study in 31 patients found that the clearance of chlorpromazine was increased by 38% by tobacco smoking, by 50% by cannabis smoking, and by 107% when both tobacco and cannabis were smoked.³

(b) Fluphenazine

A retrospective study in 40 psychiatric inpatients found that the plasma fluphenazine levels of non-smokers were more than double those of smokers (1.83 nanograms/mL compared with 0.89 nanograms/mL) when they were given fluphenazine hydrochloride by mouth. The clearance of both oral and intramuscular fluphenazine was 1.67-fold and 2.33-fold greater, respectively, in the smokers than in the non-smokers.⁴ No behavioural differences were seen.⁴

(c) Haloperidol

Steady-state haloperidol levels were found to be lower in a group of 23 cigarette smokers than in another group of 27 non-smokers (16.83 nanograms/mL compared with 28.8 nanograms/mL) and the clearance was increased by 44%.⁵ Other studies have broadly confirmed these findings.^{6,7}

(d) Tiotixene

Tobacco smoking increased the clearance of tiotixene in patients taking enzyme inhibitors or no other drugs, but not in patients taking enzyme inducers. Those who smoked were found to need on average 45% more tiotixene than the non-smokers taking no other interacting drugs.⁸

Mechanism

Not established. The probable reason is that some of the components of tobacco smoke act as enzyme inducers, which increase the rate at which the liver metabolises these antipsychotics, thereby reducing their serum levels and clinical effects.

Importance and management

Established interactions but of uncertain clinical importance. Be alert for the need to increase the dosages of these antipsychotics in patients who smoke, and reduce the dosages if smoking is stopped.

Aripiprazole + Lithium

Lithium does not affect the pharmacokinetics of aripiprazole to a clinically significant extent.

Clinical evidence, mechanism, importance and management

Aripiprazole 30 mg daily was given to 7 healthy subjects for 5 weeks, with lithium carbonate slow-release tablets 1.2 to 1.8 g daily (to give a plasma level of 1 to 1.4 mmol/L) for weeks 3 to 5 of the study. The mean AUC and maximum plasma concentrations of aripiprazole were found to increase by 15% and 19%, respectively, but these changes were not considered to be clinically significant.¹

- Citrome L, Josiassen R, Bark N, Salazar DE, Mallikaarjun S. Pharmacokinetics of aripiprazole and concomitant lithium and valproate. *J Clin Pharmacol* (2005) 45, 89–93.

Aripiprazole + Miscellaneous

Aripiprazole plasma levels are increased by inhibitors, and decreased by inducers, of CYP3A4. Quinidine increases aripiprazole levels. The manufacturers advise caution with drugs that can prolong the QT interval. Food and famotidine do not have a clinically relevant effect on the pharmacokinetics of aripiprazole, and aripiprazole does not affect the pharmacokinetics of dextromethorphan, omeprazole, and warfarin.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers

The manufacturers report that **carbamazepine** reduced the mean maximum plasma concentration and AUC of aripiprazole 30 mg by 68% and 73%, respectively. They recommend that the dose of aripiprazole is doubled when taken with **carbamazepine**.^{1,2} Other potent inducers of CYP3A4, such as **efavirenz**, **nevirapine**, **phenytoin**, **phenobarbital**, **primidone**, **rifabutin**, **rifampicin** and **St John's wort** are expected to have similar effects and an increase in the dose of aripiprazole may also be necessary if these drugs are given.¹

(b) CYP3A4 inhibitors

Ketoconazole, an inhibitor of CYP3A4, increased the AUC and maximum plasma concentration of aripiprazole by 63% and 37%, respectively.^{1,2} Other potent inhibitors of CYP3A4, such as **itraconazole** and **protease inhibitors** would be expected to produce similar or greater increases in aripiprazole levels, and the manufacturers recommend that the dose of aripiprazole should be halved with these drugs. The dose of aripiprazole should also be increased again if the drug is stopped. Moderate inhibitors of CYP3A4, such as **diltiazem**, may produce more modest increases in aripiprazole levels,¹ and patients should be closely monitored for signs of aripiprazole toxicity, although an initial dose reduction of aripiprazole may not be required.

(c) Famotidine

Famotidine reduces the rate of absorption of aripiprazole but this effect is not clinically significant.¹

(d) Food

A study in 39 healthy subjects who received 15 mg aripiprazole either after fasting, or 5 minutes after a high-fat breakfast, found no significant changes in the pharmacokinetics of aripiprazole.³

(e) QT prolongation

The manufacturers report that in clinical studies the incidence of QT prolongation with aripiprazole was comparable to placebo. Nevertheless, they recommend caution when prescribing aripiprazole with other drugs that may prolong the QT interval or cause electrolyte disturbances, see 'drugs that prolong the QT interval', (p.257).

(f) Quinidine

Quinidine, an inhibitor of CYP2D6, has been found to increase the AUC of aripiprazole by 107%, although the maximum concentration was unchanged. It is recommended that the dose of aripiprazole is halved if given concomitantly with quinidine.^{1,2}

(g) Miscellaneous

Aripiprazole 10 to 30 mg daily had no significant effects on the metabolism of **dextromethorphan** (CYP2D6 and CYP3A4 substrate), **warfarin** (CYP2C9 substrate) and **omeprazole** (CYP2C19 substrate). Aripiprazole is not expected to affect CYP1A2-mediated metabolism. The manufacturers therefore conclude that aripiprazole is unlikely to have clinically significant interactions with drugs that are substrates for these isoenzymes.¹

Aripiprazole + SSRIs and related antidepressants

Fluoxetine and probably paroxetine may cause clinically significant increases in aripiprazole levels. The concurrent use of aripiprazole with SSRIs or venlafaxine has led to adverse effects such as the neuroleptic malignant syndrome and extrapyramidal symptoms.

Clinical evidence, mechanism, importance and management

A study analysing routing samples sent for aripiprazole monitoring noted that the plasma levels of aripiprazole were 44% higher in 5 patients taking inhibitors of the cytochrome P450 isoenzyme CYP2D6, which included 2 patients taking **fluoxetine**. However, note that they also included levomepromazine in this group, which is not known to be a potent CYP2D6 inhibitor, and may therefore have reduced the true increase seen with **fluoxetine**. Further, in 6 patients taking **escitalopram** or **citalopram** the plasma levels of aripiprazole were found to be 39% and 34% higher, respectively, when compared with patients taking aripiprazole alone.¹

The manufacturers suggest that potent inhibitors of CYP2D6, such as **fluoxetine** and **paroxetine** would be expected to increase aripiprazole levels, and they recommend that the dose of aripiprazole should be halved if these drugs are given.^{2,3} The UK manufacturer suggests that weaker inhibitors of this isoenzyme (they name **escitalopram**) would only be expected to cause modest increases in aripiprazole levels, and therefore no dosage adjustment would be expected to be required.²

Two case reports of extrapyramidal effects in association with aripiprazole treatment have been attributed to an interaction with antidepressants. In the first case the patient, who was taking **venlafaxine**, trazodone and clonazepam, developed parkinsonian symptoms a few days after starting to take aripiprazole 15 mg daily. Her symptoms resolved on stopping the aripiprazole. The second patient was taking **sertraline** 200 mg daily, and after starting to take aripiprazole 10 mg daily he developed akathisia. This did not respond to a reduction of aripiprazole dose, but gradually resolved when the aripiprazole was withdrawn.⁴ Neuroleptic malignant syndrome developed in a patient within 2 weeks of starting aripiprazole 30 mg daily and **fluoxetine** 20 mg daily. The patient had stopped taking the aripiprazole 2 days before admission, fluoxetine was stopped on admission, and he recovered within one week with symptomatic treatment. The authors suggested that **fluoxetine** may have increased the risk of this syndrome developing by raising aripiprazole levels.⁵

The concurrent use of aripiprazole and SSRIs can be useful, but it is important to remember to adjust the dose if **paroxetine** or **fluoxetine** are started or stopped, and be aware that, rarely, adverse effects such as extrapyramidal symptoms and the neuroleptic malignant syndrome may develop.

5. Duggal HS, Kithas J. Possible neuroleptic malignant syndrome with aripiprazole and fluoxetine. *Am J Psychiatry* (2005) 162, 397–8.

Aripiprazole + Valproate

Valproate causes a reduction in aripiprazole levels which is not considered to be clinically significant.

Clinical evidence, mechanism, importance and management

Aripiprazole 30 mg daily was given to 6 healthy subjects for 5 weeks, with **valproate semisodium (divalproex sodium)** daily in doses to achieve a serum valproate level of 50 to 125 mg/L, for weeks 3 to 5 of the study. The mean AUC and maximum plasma concentrations of aripiprazole were found to decrease by 24% and 26%, respectively, and the time to maximum aripiprazole levels was extended by 2 hours. Since aripiprazole and valproate share the same protein binding sites, it was considered likely that the valproate displaced bound aripiprazole leading to increased

oral clearance. The change in levels was not considered to be clinically significant.¹

1. Citrome L, Josiassen R, Bark N, Salazar DE, Mallikaarjun S. Pharmacokinetics of aripiprazole and concomitant lithium and valproate. *J Clin Pharmacol* (2005) 45, 89–93.

Barbiturates + Miscellaneous

Miconazole increases serum pentobarbital levels. The hypnotic effects of pentobarbital are reduced or abolished by the concurrent use of caffeine.

Clinical evidence, mechanism, importance and management

(a) Caffeine

In a placebo-controlled study caffeine 250 mg and pentobarbital 100 mg were given together and alone to 34 patients. It was found that the hypnotic effects of the pentobarbital given with caffeine were reduced, and indistinguishable from those of the placebo.¹ Caffeine stimulates the cerebral cortex and impairs sleep, whereas pentobarbital depresses the cortex and promotes sleep. These mutually opposing actions would seem to explain this interaction. This seems to be only direct study of this interaction, but it is well supported by common experience and the numerous studies of the properties of each of these compounds. Patients given barbiturate hypnotics should avoid caffeine-containing drinks (tea, coffee, cola drinks, etc.) or analgesics at or near bedtime if the hypnotic is to be effective.

(b) Miconazole

High-dose intravenous pentobarbital was given to 5 patients in intensive care to decrease intracranial pressure. When miconazole was also given, all patients had marked rises in plasma pentobarbital levels, and a 50 to 90% reduction in total plasma clearance. This is thought to occur because miconazole inhibits the liver enzymes concerned with the metabolism of the barbiturate, thereby reducing its clearance from the body.² It would be prudent to monitor the effects of concurrent use to ensure that plasma barbiturate levels do not rise too high. Note that miconazole oral gel can be absorbed in sufficient amounts to potentially interact. There seems to be no information about other barbiturates.

Benzodiazepines + Acetazolamide

Although acetazolamide can be used to treat acute mountain sickness at very high altitudes, a case report suggests that it may potentiate the respiratory depressant effects of benzodiazepines such as triazolam. Acetazolamide did not improve symptoms of sleep apnoea worsened by flurazepam.

Clinical evidence, mechanism, importance and management

A study in elderly subjects found that sleep apnoea worsened in 4 of 10 subjects given a single 30-mg dose of flurazepam at night. These 4 subjects were then pretreated with acetazolamide 500 mg twice daily for 3 days, as acetazolamide has been found to improve sleep apnoea. A further dose of flurazepam 30 mg was given on the fourth night.¹ Treatment with acetazolamide did not block the benzodiazepine-associated increase of sleep apnoea in these subjects, possibly because the acetazolamide treatment period was not long enough.¹

Acetazolamide is sometimes used by climbers at very high altitudes as a prophylactic against acute mountain sickness. Benzodiazepines are used in this situation to treat insomnia, which is common at high altitude. Benzodiazepines are believed to depress breathing because they reduce the normal respiratory response to hypoxia. This was demonstrated by a Japanese climber in the Himalayas who took acetazolamide 500 mg daily and triazolam 500 micrograms, and then needed to be reminded to hyperventilate in order to relieve his hypoxia while returning from a climb. The acetazolamide did not prevent, and may possibly have increased, the central ventilatory depression of the triazolam, possibly by increasing its delivery to the brain. The authors of the report advise against taking these

two drugs together at high altitudes,² thus confirming a previous warning about the risks of taking benzodiazepines at high altitude.³

1. Guilleminault C, Silvestri R, Mondini S, Coburn S. Aging and sleep apnea: action of benzodiazepine, acetazolamide, alcohol, and sleep deprivation in a healthy elderly group. *J Gerontol* (1984) 39, 655–61.

Benzodiazepines + Alosetron

Alosetron 1 mg twice daily for 2 days had no significant effect on the pharmacokinetics of a single 1-mg dose of alprazolam in 12 healthy subjects. No increase in adverse effects was noted with the combination.¹ No special precautions therefore seem necessary on concurrent use.

1. D'Souza DL, Levasseur LM, Nezamis J, Robbins DK, Simms L, Koch KM. Effect of alosetron on the pharmacokinetics of alprazolam. *J Clin Pharmacol* (2001) 41, 452–4.

Benzodiazepines + Amiodarone

An isolated report describes clonazepam toxicity, which was attributed to the concurrent use of amiodarone.

Clinical evidence, mechanism, importance and management

A 78-year-old man with congestive heart failure and coronary artery disease was taking furosemide, potassium, and calcium supplements, a multivitamin preparation, and amiodarone 200 mg daily for sustained ventricular tachycardia. Two months after clonazepam 500 micrograms at night was added to treat restless leg syndrome he developed slurred speech, confusion, difficulty in walking, dry mouth and urinary incontinence. This was interpreted as clonazepam toxicity. The problems cleared when the clonazepam was stopped. The authors of the report suggest that the amiodarone may have inhibited the oxidative metabolism of the clonazepam by the liver, thereby allowing it to accumulate. They also point out that this patient may have been more sensitive to these effects because of a degree of hypothyroidism caused by the amiodarone. Hypothyroidism is known to decrease the metabolism of drugs that undergo oxidative metabolism by the liver.¹

This is an unconfirmed and isolated case of doubtful general importance.

1. Witt DM, Ellsworth AJ, Levesee JH. Amiodarone-clonazepam interaction. *Ann Pharmacother* (1993) 27, 1463–4.

Benzodiazepines + Antacids

Although antacids can moderately change the rate of absorption of chlordiazepoxide, clorazepate and diazepam, no adverse interaction of clinical importance has been reported.

Clinical evidence

In a three-period study 10 healthy subjects were given clorazepate 7.5 mg at night, with either water, or with Maalox 30 mL, or with Maalox 30 mL three times daily before meals. The mean steady-state serum levels of the active metabolite of clorazepate, desmethylclorazepate, were not affected by Maalox, although they varied widely between individuals.¹ This is in line with another report,² but contrasts with a single-dose study, in which the peak plasma concentration of desmethylclorazepate was delayed and reduced by about one-third by the use of Maalox. The AUC₀₋₄₈ was reduced by about 10%.³

In another study the absorption of a single dose of chlordiazepoxide was delayed by Maalox, though the total amount of drug absorbed was not significantly affected.⁴ Similar results have been found with diazepam and aluminium hydroxide-containing antacids.⁵ Another study found that 40 mL of Aluminium Hydroxide Gel BP and 30 mL of sodium citrate (0.3 mmol/L) marginally hastened the sedative effect of diazepam 10 mg when used as an oral premedication before minor surgery. Magnesium Trisilicate Mixture BPC 30 mL tended to delay sedation.⁶

Mechanism

The delay in the absorption of chlordiazepoxide and diazepam is attributed to the effect of the antacid on gastric emptying. Clorazepate on the other hand is a prodrug, which needs acid conditions in the stomach for conversion by hydrolysis and decarboxylation to its active form. Antacids are presumed to inhibit this conversion by raising the pH of the stomach contents.⁷

Importance and management

Most of the reports describe single-dose studies, but what is known suggests that no adverse interaction of any clinical importance is likely if antacids are given with chlordiazepoxide, clorazepate or diazepam. Whether the delay in absorption has an undesirable effect in those who only take benzodiazepines during acute episodes of anxiety, and who need rapid relief is uncertain. Information about other benzodiazepines is lacking. However, no special precautions would seem to be necessary.

Benzodiazepines and related drugs + Antiepileptics; Carbamazepine

The use of benzodiazepines with carbamazepine is common, although some evidence suggests that the effects of the benzodiazepines are sometimes reduced. Levels of alprazolam were reduced by almost 50% and levels of midazolam were markedly reduced and its effects almost abolished by carbamazepine. Single-dose studies have shown that the sedative effects of zopiclone and carbamazepine are additive, however it has been predicted that when taken long-term carbamazepine will reduce the effects of zopiclone.

Clinical evidence

A. Benzodiazepines

(a) Alprazolam

A patient with atypical bipolar disorder and panic attacks, given alprazolam 7.5 mg daily, had a reduction of more than 50% in plasma alprazolam levels, from 43 to 19.3 nanograms/mL when given carbamazepine. This was accompanied by a deterioration in his clinical condition, which was managed with haloperidol.¹

(b) Clonazepam

A study found that carbamazepine reduces the plasma levels of clonazepam and increases the levels of norclonazepam (the principal metabolite).² Similarly, a reduction in steady-state clonazepam levels, with a rise in norclonazepam levels, is described in another study in 6 healthy subjects taking carbamazepine.³

A 66-year-old man taking carbamazepine and topiramate experienced fatigue, ataxia, impairment of gait and clumsiness while taking clobazam 10 mg daily. His symptoms resolved when the clobazam was stopped. When he was later given carbamazepine, topiramate, and clobazam 20 mg daily his carbamazepine level rose from 36.8 to 41.9 micromol/L. The carbamazepine level returned to 35.5 micromol/L 5 days after the clobazam was stopped.⁴ However, another study in 15 epileptic patients taking carbamazepine alone and another 7 patients taking carbamazepine with clobazam, found that carbamazepine levels were similar in both groups, but levels of carbamazepine metabolites, including the active carbamazepine-10,11-epoxide, were higher in those also taking clobazam. It

was suggested that clobazam increased the metabolism of carbamazepine by about 1.5-fold.⁵

(c) Clonazepam

Clonazepam, in slowly increasing doses up to a maximum of 4 to 6 mg/day given over a 6-week period, had no effect on carbamazepine serum levels. Some patients were also taking phenobarbital.⁶ A study in 7 healthy subjects found that carbamazepine 200 mg daily given over a 3-week period reduced the plasma levels of clonazepam 1 mg daily from a range of 4 to 7 nanograms/mL down to 2.5 to 4 nanograms/mL, and reduced the half-life by about one-third.⁷ A retrospective analysis of this interaction in 183 patients found that clonazepam clearance was increased by 22% and carbamazepine clearance was decreased by 20.5% by concurrent use.⁸

(d) Diazepam

A study found that the plasma clearance of a single 10-mg intravenous dose of diazepam was threefold greater, and the half-life shorter in a group of 9 epileptics when compared to 6 healthy subjects. Seven of the epileptics were taking carbamazepine.⁹

(e) Midazolam

The pharmacokinetics and pharmacodynamics of a single 15-mg oral dose of midazolam was studied in 6 epileptic patients taking either carbamazepine, phenytoin or both drugs together, and in 7 control subjects not taking either antiepileptic. The AUC of midazolam in the epileptics was reduced to 5.7%, and the peak serum levels to 7.4% of the value in the control subjects. The pharmacodynamic effects of the midazolam (subjective drowsiness, body sway with eyes closed and open, as well as more formal tests) were also reduced. Most of the epileptics did not notice any effects from taking midazolam, while the control subjects were clearly sedated for 2 to 4 hours, and also experienced amnesia after taking the midazolam.¹⁰

B. Non-benzodiazepine hypnotics

A crossover study in 12 healthy subjects given a single 7.5-mg dose of **zopiclone** and carbamazepine 600 mg found only minor changes in the plasma levels of both drugs. **Zopiclone** levels were higher and carbamazepine levels slightly lower. Psychomotor tests confirmed that both drugs had sedative effects, which were additive, and in a simulated driving test it was found that co-ordination was impaired and reaction times prolonged.¹¹ However, there do not appear to be any multiple-dose studies. Carbamazepine is a strong inducer of the cytochrome P450 isoenzyme CYP3A4 (by which **zopiclone** is metabolised) and it is therefore predicted that the effect of long-term carbamazepine treatment would be a reduction in **zopiclone** serum levels and hypnotic effects.¹²

Mechanism, importance and management

The midazolam and possibly alprazolam interactions with carbamazepine appear to be of greatest clinical significance. Alprazolam and midazolam are both metabolised by the cytochrome P450 isoenzyme CYP3A4, of which carbamazepine is a known inducer. Much larger doses of midazolam are likely to be needed in the presence of carbamazepine. An alternative sedative may be needed. **Triazolam** is predicted to interact like midazolam.¹⁰

Since norclobazam retains some of the activity of clobazam the effects of carbamazepine probably have little clinical significance, and the case of carbamazepine toxicity appears to be isolated and is therefore probably of limited importance. The pharmacokinetic changes seen with clonazepam seem likely to be too small to be clinically significant, but this needs confirmation.

The evidence for an interaction between zopiclone and carbamazepine is slim, and the effects of long-term use unclear. However, it would seem prudent to be alert for the need to increase the zopiclone dosage in patients taking carbamazepine. More study of this potential interaction is needed.

Benzodiazepines + Antiepileptics; Miscellaneous

The use of benzodiazepines with antiepileptics is common and possibly accompanied by some changes in serum levels, which are normally of limited clinical importance. However, isolated interactions have been reported between chlordiazepoxide or clobazam and phenobarbital; between clonazepam and lamotrigine or primidone; and between clorazepate and primidone.

Clinical evidence

(a) Felbamate

A retrospective study compared norclobazam level to dose ratios in patients taking clobazam and enzyme-inducing antiepileptics, without felbamate (group B, 28 patients) or with felbamate (group C, 16 patients). When compared with 22 patients (group A) receiving clobazam alone or with non-enzyme-inducing antiepileptics, the norclobazam level to dose ratio of group B was increased twofold and the norclobazam level to dose ratio of group C was increased fivefold,¹ suggesting that felbamate further increased the effect of enzyme-inducing antiepileptics on clobazam metabolism. However, in 18 healthy subjects, the pharmacokinetics of clonazepam 1 mg every 12 hours were not significantly altered by felbamate 1.2 g every 12 hours for 10 days.² No serious adverse reactions were reported.

(b) Lamotrigine

The plasma clonazepam levels in 4 of 8 patients fell by about 38% when they were also given lamotrigine.³

(c) Phenobarbital and Primidone

A single case report describes a man given phenobarbital and chlordiazepoxide who became drowsy, unsteady, and developed slurred speech, nystagmus, poor memory and hallucinations, all of which disappeared once the phenobarbital was withdrawn and the chlordiazepoxide dose reduced from 80 to 60 mg daily.⁴

Phenobarbital slightly reduces the levels of both clobazam and its active metabolite, norclobazam.⁵

Clonazepam, in slowly increasing doses up to a maximum of 4 to 6 mg daily, given over a 6-week period to patients taking phenobarbital with or without carbamazepine, had no effect on phenobarbital levels.⁶ A study in patients receiving various combinations of phenytoin, phenobarbital and primidone, found that their serum levels were not significantly altered by the addition of clonazepam 3 mg daily for 4 weeks, but the levels of clonazepam were reduced in the presence of the other antiepileptics, particularly phenobarbital and primidone. Depression was reported in one patient and personality changes with irritability and violent behaviour was reported in another.⁷ A study found that phenobarbital caused some small changes in the pharmacokinetics of a single dose of clonazepam but only the small increase in clearance was statistically significant.⁸ In contrast, an analysis of the serum levels of antiepileptics in children found that those taking clonazepam had markedly higher levels of primidone, and toxicity was seen.⁹

A report suggested that the concurrent use of primidone and clorazepate may have been responsible for the development of irritability, aggression and depression in 6 of 8 patients.¹⁰

Phenobarbital 100 mg daily for 8 days had no effect on the metabolism of diazepam in a group of healthy subjects.¹¹ Some modest additive CNS

depression may possibly be expected, but the authors of this report make no comment about this.

(d) Tiagabine

Studies in healthy subjects have excluded any pharmacodynamic interaction between tiagabine and triazolam.¹²

Mechanism

Uncertain. Changes in the drug metabolism in some cases or simple additive effects in others seem likely. It has been suggested that felbamate inhibits the clearance of norclobazam.¹

Importance and management

None of the interactions between the benzodiazepines and antiepileptics described here appear to be of major clinical importance, with the possible exception of the interaction between clobazam and felbamate. If both drugs are given be aware that additive sedative or other adverse effects may occur. This may also be possible in some rare cases with chlordiazepoxide or clobazam and phenobarbital; clonazepam and lamotrigine or primidone; and clorazepate and primidone.

Benzodiazepines + Antiepileptics; Phenytoin

Reports are inconsistent: benzodiazepines can cause serum phenytoin levels to increase (toxicity has been seen), decrease, or remain unaltered. In addition phenytoin may reduce clonazepam, diazepam, midazolam and oxazepam serum levels.

Clinical evidence

(a) Phenytoin levels increased

The observation that toxicity developed in patients taking phenytoin when they were given chlordiazepoxide or diazepam prompted a more detailed study. The serum phenytoin levels of 25 patients taking phenytoin 300 or 400 mg daily and chlordiazepoxide or diazepam were 80 to 90% higher than those of 99 subjects taking phenytoin without a benzodiazepine.¹

Further reports attribute increased phenytoin serum levels and phenytoin toxicity to chlordiazepoxide², clobazam,³ clonazepam,^{4–7} and diazepam.^{8–10}

(b) Phenytoin levels decreased

The serum phenytoin levels of 12 patients fell by about 30% over a 2-month period while they were taking clonazepam 1.5 to 12 mg daily. When data from another 12 patients were combined, the mean fall was only 18%.¹¹ Other studies describe similar findings with clonazepam^{5,12} and diazepam.^{13,14}

(c) Phenytoin levels unchanged

In one study alprazolam did not affect the serum phenytoin levels in healthy subjects.¹⁵ Clonazepam did not alter serum phenytoin levels in

one study,¹⁶ and another concluded that it produced no predictable change in phenytoin levels.⁵ A single-dose study in healthy subjects found no significant pharmacokinetic interaction between intravenous **diazepam** 10 mg and intravenous **fosphephenytoin** 1.125 g (or the phenytoin formed by the hydrolysis of fosphephenytoin).¹⁷

(d) Benzodiazepine levels reduced

A study in 5 patients given phenytoin 250 to 400 mg daily found that serum **clonazepam** levels were reduced by more than 50%,¹⁸ and another study found that phenytoin decreased the clearance of **clonazepam** by about 50%.¹⁹ In a further study phenytoin reduced the plasma levels of **clobazam** and increased the levels of norclobazam (the principal metabolite).²⁰ **Diazepam**²¹ and **oxazepam**²² may be similarly affected in epileptic patients given phenytoin.
