Nimesulide		↓ GFR & diuresis										
Phenylbutazone							↑ systolic BP by 18 mmHg					
Piroxicam		Diuretic effect ↓, excretion of Na ⁺ ↓	N/S				↑ BP					
Sulindac	Na ⁺ ↓ 22%; urine flow rate ↓ 21%	Diuretic effect ↓ 76%				Enhanced hypotensive effects	N/S	N/S		Excretion of Na ⁺ & K ⁺ ↓		
Tenoxicam		N/S										
Tofenamic acid		Diuretic effect ↓ 34%										

Abbreviations: ARF = acute renal failure; CHF = congestive heart failure; GFR: glomerular filtration rate; N/S = non-significant

one month did not alter the antihypertensive effect of the combinations of hydrochlorothiazide 25 mg daily with fosinopril 10 to 40 mg daily¹⁴ or lisinopril 10 to 40 mg daily.⁸

(d) *Indometacin*

A controlled study in 7 patients with hypertension taking amiloride 5 to 10 mg with hydrochlorothiazide 50 to 100 mg, found that indometacin 100 mg daily for 3 weeks raised their blood pressure by 13/9 mmHg when lying and by 16/9 mmHg when standing. Body-weight increased by 1.1 kg.⁵ A later study in patients taking hydrochlorothiazide found a 6/3 mmHg blood pressure rise after they took indometacin for 2 weeks, but this had gone after 4 weeks.¹⁵ A blood pressure rise of only 5/1 mmHg was seen in another study in hypertensive patients taking hydrochlorothiazide with indometacin 100 mg daily.¹⁶ Indometacin also attenuated the hypotensive effect of hydrochlorothiazide (given with amiloride) in another study.⁶

In other studies indometacin had no effect on blood pressure in healthy subjects,¹⁷ no effect on the sodium excretion caused by hydrochlorothiazide,¹⁸ and did not affect the pharmacokinetics of hydrochlorothiazide.^{17,18}

(e) *Kebuzone*

A mean systolic blood pressure rise of 18 mmHg (from 171 to 189 mmHg) occurred in 15 patients taking hydrochlorothiazide 50 mg daily, when they were given kebuzone 750 mg daily. This rise represents about a 35% reduction in the antihypertensive effect of hydrochlorothiazide.¹⁹

(f) *Naproxen*

One study found that naproxen had no clinically relevant interaction with hydrochlorothiazide alone,¹⁵ while another found that naproxen attenuated the antihypertensive efficacy of hydrochlorothiazide taken with timolol, but how much of the attenuation is due to an interaction with the diuretic is unclear.²⁰

(g) *Phenylbutazone*

A mean systolic blood pressure rise of 18 mmHg (from 171 to 189 mmHg) occurred in 15 patients taking hydrochlorothiazide 50 mg daily, when they were given phenylbutazone 750 mg daily. This rise represents about a 35% reduction in the antihypertensive effect of hydrochlorothiazide.¹⁹

(h) *Piroxicam*

One study found that piroxicam attenuated the antihypertensive efficacy of hydrochlorothiazide taken with timolol, but how much of the attenuation is due to an interaction with the diuretic is unclear.²⁰

(i) *Sulindac*

Sulindac does not appear to reduce either the hypotensive or diuretic effects of hydrochlorothiazide, and may even slightly enhance the antihypertensive effects.^{6,7,15,16,20,21} Another study found that sulindac did not alter the antihypertensive efficacy of hydrochlorothiazide/amiloride given with beta blockers.²² Similarly, sulindac 200 mg twice daily for one month did not alter the antihypertensive effect of the combinations of hydrochlorothiazide 25 mg daily with fosinopril 10 to 40 mg daily,¹⁴ or lisinopril 10 to 40 mg daily.⁸

D. *Metolazone*

(a) *Indometacin*

Indometacin was found to reduce the urinary sodium excretion due to metolazone by 34% in 6 healthy subjects.²³ The excretion of total potassium fell by 30%.

(b) *Sulindac*

Sulindac was found to reduce the urinary sodium excretion due to metolazone by 19% in 6 healthy subjects.²³ The excretion of total potassium fell by 16%.

E. *Unspecified*

In a randomised study, **ibuprofen** 400 mg every 8 hours caused a significant increase in blood pressure (mean increase of about 5 to 7 mmHg) in 12 hypertensive patients taking thiazides with beta blockers or centrally acting antihypertensives.²⁴

Mechanism

Not understood. NSAIDs can cause salt and water retention, which antagonises the effects of diuretics. Prostaglandins have a role to play in renal

function and drugs such as the NSAIDs, which inhibit prostaglandin synthesis, would therefore be expected to have some effect on the actions of diuretics, whose venodilatory effects also depend on the activity of the prostaglandins. A study in *rats* suggested that indometacin may oppose the effects of the thiazides by reducing chloride delivery to the site of thiazide action in the distal tubule.²⁵

Importance and management

Overall, the evidence suggests that some patients taking thiazide diuretics can have a rise in blood pressure when given NSAIDs, but this may not always be clinically relevant. Some consider that the use of NSAIDs should be kept to a minimum in patients taking antihypertensives.²⁶ The effects may be greater in the elderly and in those with blood pressures that are relatively high, as well as in those with high salt intake.²⁶ However, others consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.²⁷ While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inadequate control of blood pressure, other reasons may be more likely than any effect of concurrent NSAIDs.²⁷ There is insufficient data at present to clearly differentiate between NSAIDs, although there is some evidence that the effects of indometacin are greatest and sulindac least. Further study is needed. A retrospective analysis of records of patients taking diuretics (thiazides, loop and/or potassium-sparing) with NSAIDs found a twofold increase in the risk of hospitalisation for congestive heart failure on concurrent use. The most common NSAIDs taken by this cohort of patients were diclofenac, ibuprofen, indometacin and naproxen.²⁸ The European Society of Cardiology (ESC) Task Force and the joint American College of Cardiology/American Heart Association both recommend avoiding NSAID use, if possible, in patients with congestive heart failure.^{29,30}

Thiazide diuretics + Propantheline

Propantheline can slightly increase the absorption of hydrochlorothiazide.

Clinical evidence, mechanism, importance and management

In 6 healthy fasting subjects the absorption of hydrochlorothiazide 75 mg was delayed and increased (AUC increased by 23% and urinary recovery increased by 36%) by propantheline 60 mg. It is suggested that this occurs because propantheline causes a slower delivery of the hydrochlorothiazide to its areas of absorption.¹ This small increase is unlikely to be clinically important.

Gastrointestinal drugs

The various gastrointestinal drug groups covered in this section are listed in 'Table 27.1', (see below). 'Drug absorption interactions', (p.3) discusses how absorption interactions occur and contains more detailed information on some of the mechanisms of interaction covered in this section.

Metabolism of proton pump inhibitors

The main metabolic pathway for esomeprazole, lansoprazole, omeprazole, pantoprazole, and to a lesser extent rabeprazole, is through the cytochrome P450 isoenzyme CYP2C19. This isoenzyme is subject to genetic polymorphism,¹ (see 'Genetic factors', (p.4), for a further explanation of polymorphism). The poor metaboliser phenotype for CYP2C19 is found in approximately 1 to 6% of Caucasians, 1 to 7.5% of Blacks and 12 to 23% of Oriental and Indian Asians.²

Therefore most patients will be extensive CYP2C19 metabolisers, and their major route for the metabolism of these PPIs will be through this isoenzyme. As a consequence, the levels of PPIs in these patients are likely to be affected by drugs that inhibit or induce CYP2C19, such as 'fluvoxamine', (p.973).² Patients of the extensive metaboliser phenotype have also been shown in some studies to have a poorer clinical outcome, when compared with poor metabolisers e.g. in the eradication of *H. pylori*, as they tend to have lower therapeutic levels of PPIs.²⁻⁴

Poor metabolisers, who lack CYP2C19 metabolising capacity, use alternative pathways to metabolise PPIs, and this is mainly CYP3A4. Because poor metabolisers are more dependent on CYP3A4 for metabolism of the PPIs the levels of PPIs may be raised in these patients when they are given CYP3A4 inhibitors, such as 'clarithromycin', (p.971), and 'ketoconazole', (p.218).

Omeprazole and esomeprazole are also inhibitors of CYP2C19, and therefore they may increase the levels of drugs that are metabolised by CYP2C19, such as diazepam. Other CYP2C19 substrates are listed in 'Table 1.3', (p.6).^{1,2} Particular care may be required when giving drugs that

are CYP2C19 inhibitors to patients in those ethnic groups who have a higher percentage of poor CYP2C19 metabolisers, such as Indian Asians.^{1,2}

Table 27.1 Gastrointestinal drugs covered in this section

Group	Drugs
5-aminosalicylates	Balsalazide, Mesalazine, Olsalazine, Sulfasalazine
Antidiarrhoeals	Loperamide
Antimuscarinics	Pirenzepine
Bismuth compounds	Bismuth bismucate, Bismuth salicylate, Bismuth subnitrate, Tripotassium dicitratobismuthate
H ₂ -receptor antagonists	Cimetidine, Famotidine, Nizatidine, Ranitidine, Roxatidine
Mucosal protectants	Carbenoxolone, Liquorice, Sucralfate
Prokinetic drugs	Cisapride
Proton pump inhibitors	Esomeprazole, Lansoprazole, Omeprazole, Pantoprazole, Rabeprazole

Antacids + Milk

Hypercalcaemia, alkalosis and renal insufficiency (milk-alkali syndrome) can develop in patients taking antacids with calcium-containing substances, including dairy products.

Clinical evidence

A man presented with nausea, vomiting, constipation, polyuria and polydipsia, which was diagnosed as milk-alkali syndrome, due to daily treatment with 6 tablets of *Caved-S* and 3.5 pints of milk, for dyspepsia related to a peptic ulcer.¹ This dose of *Caved-S* meant he was taking 600 mg of **aluminium hydroxide**, 1200 mg of **magnesium carbonate**, 600 mg of **sodium bicarbonate** and 2280 mg of **deglycyrrhizinised liquorice** daily.¹ Another case report describes a 42-year-old man who presented with confusion, agitation, involuntary movements of his limbs, severe dehydration, and metabolic and respiratory alkalosis. He had taken large amounts of a **calcium/magnesium carbonate**-containing antacid preparation (*Rennies*) and had also consumed at least 3 litres of dairy products a day for upper abdominal complaints. Milk-alkali syndrome was diagnosed and he was successfully treated with isotonic saline and potassium.² A pregnant woman developed vomiting, drowsiness, abdominal pain and acute pancreatitis after excessive antacid use. She had been taking up to 10 tablets of *Rennies* antacid (**calcium/magnesium carbonate**), containing about 3 g of elemental calcium with up to 3 glasses of milk a day.³ In a study in 125 patients with non end-stage renal disease, milk-alkali syndrome was found to be the cause of hypercalcaemia in 11 (8.8%) of the patients, 9 of who had severe hypercalcaemia (serum calcium greater than 3.5 mmol/L).⁴ Several other cases have been reported in recent years involving excessive use of non-prescription **calcium carbonate**.⁵⁻⁷ one of which was in a pregnant woman.⁶

Mechanism

High intake and absorption of calcium can suppress the parathyroid hormone, which leads to bicarbonate retention by the kidneys, leading to metabolic and respiratory alkalosis. The alkalosis also causes reduced excretion of calcium by the kidneys. Hypermagnesaemia may also have a part to play.

Importance and management

The milk-alkali syndrome was a common adverse effect of antacid use when it was the primary treatment of peptic ulcer disease, but has become very uncommon with the advent of H₂-blockers and proton pump inhibitors. However, the above cases illustrate that while taking antacids, even well within the recommended dosage range, as in the first case, it is still possible to develop a serious and potentially life-threatening reaction if the intake of calcium is high. This should be borne in mind in patients who take both prescribed or non-prescription medications containing calcium, such as antacids or supplements for the prophylaxis of osteoporosis, and also consume large quantities of dairy products in their diet. Chronic milk-alkali syndrome can lead to the formation of calcification and kidney damage, which may be irreversible. The quantity of calcium ingested does not appear to be directly correlated to either the development or severity of milk-alkali syndrome, which has been reported with an intake of between 4 g to 60 g of calcium carbonate.³ However, a safe maximum calcium intake of 1.2 to 1.5 g of elemental calcium (3 to 3.75 g of calcium carbonate) has been suggested.³

Bismuth compounds + H₂-receptor antagonists

Ranitidine possibly causes an increase in the absorption of bismuth from tripotassium dicitratobismuthate, but not bismuth salicylate or bismuth subnitrate. Any increase is considered unlikely to be clinically relevant with recommended short courses for *H. pylori* eradication. Other H₂-receptor antagonists would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

The AUC of a single 240-mg dose of **tripotassium dicitratobismuthate** (**TDB**, *De Nol* tabs), was increased fourfold in 12 healthy subjects given two 300-mg doses of ranitidine (one the night before and one 2 hours before the bismuth compound). The maximum serum levels were approximately doubled. The same regimen of ranitidine had no significant effect on the absorption of bismuth from **bismuth salicylate** (*Pepto-Bismol*) or **bismuth subnitrate** (*Roter tablets*).¹

The authors suggest that the reduction in gastric acidity maintains TDB in its colloidal form, which is more likely to be absorbed, and that this may result in increased bismuth toxicity.¹ Other H₂-receptor antagonists, and other drugs that reduce gastric acidity would be expected to interact similarly (see also 'Bismuth compounds + Proton pump inhibitors', p.961).

However, the manufacturers of TDB say that the toxic range of bismuth is arbitrary and a small increase in absorption is not clinically relevant, except perhaps in patients with renal failure, in whom this bismuth compound should be avoided in any case.² Note that a complex of ranitidine with bismuth and citrate (**ranitidine bismuth citrate**) is available in many countries and is a recommended constituent in one of the triple therapy regimens for *H. pylori* eradication. As with all bismuth compounds, it is recommended that this is used only for limited periods: a maximum of 16 weeks (two 8-week courses or four 4-week courses) in a 12-month period.³

- Yamanouchi Pharma Ltd. Personal communication, November 1994.
- Pylorid Tablets (Ranitidine bismuth citrate). GlaxoSmithKline UK. UK Summary of product characteristics, December 2005.

Bismuth compounds + Proton pump inhibitors

Omeprazole markedly increases the absorption and bioavailability of bismuth from tripotassium dicitratobismuthate and bismuth biskalcitrate. Other proton pump inhibitors are expected to interact similarly. However, this is probably unlikely to be clinically relevant.

Clinical evidence

Thirty-four healthy subjects were randomised to receive a triple therapy capsule *Helizide* (containing **bismuth biskalcitrate** 140 mg, metronidazole 125 mg, and tetracycline 125 mg) at a dose of three capsules four times daily with or without omeprazole 20 mg twice daily for 6 days. Omeprazole increased the maximum serum levels and AUC of bismuth by about threefold. However, the maximum serum level achieved was 25.5 micrograms/L, which was still well below 50 micrograms/L, a level reported to be highly unlikely to cause toxicity.¹ The authors also state that in clinical trials of *Helizide* with omeprazole for 10 days in several hundred patients,² no patient showed signs of encephalopathy, a notable toxic adverse effect of bismuth.¹

In an earlier single-dose study in 6 healthy subjects, a single 240-mg dose of **tripotassium dicitratobismuthate** was taken 1 hour after the last dose of a 1-week course of omeprazole 40 mg daily. Omeprazole increased the AUC of bismuth fourfold, and increased the maximum serum levels from 36.7 to 86.7 micrograms/L, which the authors pointed out approaches the considered "toxic range" for bismuth (100 micrograms/L and above).

Mechanism

The solubility and absorption of some bismuth compounds are known to be increased by decreased acidity of the stomach,¹ see also 'Bismuth compounds + H₂-receptor antagonists', p.961).

Importance and management

The authors of the single-dose study recommended that the dosage of tripotassium dicitratobismuthate should be halved when given with omeprazole because of the possibility of systemic bismuth toxicity.³ However, an increased risk of toxicity has not been seen in subsequent studies using bismuth biscalcitrates for up to 10 days.^{1,2} The manufacturers of tripotassium dicitratobismuthate say that the toxic range of bismuth is arbitrary and the small increase in absorption is not clinically relevant, except perhaps in patients with renal failure, in whom this bismuth compound should be avoided in any case.⁴ No clinically significant effect would be expected if combined treatment is limited to the recommended 2-week regimen for resistant *Helicobacter pylori* infection. As this interaction is due to changes in gastric pH other **proton pump inhibitors** would be expected to interact similarly.

- Yamanouchi Pharma Ltd. Personal communication, November 1994.

Carbenoxolone + Antacids

There is some evidence that antacids may possibly reduce the bioavailability of carbenoxolone liquid.

Clinical evidence, mechanism, importance and management

The bioavailability of carbenoxolone, in a liquid formulation, when given with **aluminium/magnesium hydroxide** antacids, was found to be approximately half that of carbenoxolone in granular and capsule formulations.¹ The extent to which antacids might reduce the ulcer-healing effects of carbenoxolone liquid seems not to have been assessed, but the possibility of a reduction should be borne in mind.

- Crema F, Parini J, Visconti M, Perucca E. Effetto degli antiacidi sulla biodisponibilità del carbenoxolone. *Farmaco (Prati)* (1987) 42, 357–64.

Carbenoxolone + Antihypertensives

Carbenoxolone causes fluid retention and raises blood pressure in some patients. This may be expected to oppose the effects of antihypertensive drugs. The potassium-depleting effects of carbenoxolone and diuretics such as the thiazides or loop diuretics can be additive. Spironolactone or amiloride can oppose the ulcer-healing effects of carbenoxolone.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives (unnamed)

Carbenoxolone can raise blood pressure. Five out of 10 patients taking carbenoxolone 300 mg daily, and 2 out of 10 patients taking carbenoxolone 150 mg daily, had a rise in diastolic blood pressure of 20 mmHg or more.¹ Other reports^{2–8} confirm that fluid retention and hypertension occur in those taking carbenoxolone, with the reported incidence of hypertension varying from as low as 4%⁸ to as high as 50%,⁷ and fluid retention occurring in 0%² to 46% of patients.⁷ The reason for the blood pressure

rise is that carbenoxolone has mineralocorticoid-like activity and therefore causes sodium and water retention. There appear to be few direct reports of adverse interactions between antihypertensives and carbenoxolone. Patients taking carbenoxolone should have regular checks on their weight and blood pressure, and carbenoxolone should be used with caution, if at all, in those with cardiac disease such as hypertension or congestive heart failure (see also Diuretics, below).

(b) Diuretics

Thiazide diuretics have been used to control the oedema and hypertension caused by carbenoxolone, but **spironolactone**³ (an aldosterone antagonist) and **amiloride**⁹ are best avoided because they oppose its ulcer-healing effects. If **thiazides** or other potassium-depleting diuretics (see 'Table 26.1', (p.944)) are used it should be remembered that the potassium-losing effects of the carbenoxolone and the diuretic will be additive, so that a potassium supplement may be needed to prevent hypokalaemia. For example, rhabdomyolysis and acute tubular necrosis associated with severe hypokalaemia occurred in a patient given carbenoxolone and **chlortalidone**, without a potassium supplement.¹⁰ Laryngospasm and stridor have been reported in a patient secondary to hypokalaemia and alkalosis caused by long-term use of **furosemide** and a carbenoxolone-containing antacid (*Pyrogastrone*).¹¹ Possible alternatives to carbenoxolone are the **H₂-receptor antagonists**, or the **proton pump inhibitors**, which do not appear to interact with antihypertensives.

Carbenoxolone + Phenytoin

A single 100-mg dose of phenytoin had no significant effect on the half-life of a single 100-mg dose of carbenoxolone in 4 healthy subjects.¹ This limited evidence would seem to suggest that there is no reason for avoiding concurrent use.

- Thornton PC, Papouchado M, Reed PI. Carbenoxolone interactions in man - preliminary report. *Scand J Gastroenterol* (1980) 15 (Suppl 65), 35–9.

Carbenoxolone + Sulphonylureas

Chlorpropamide appears to reduce the serum levels of carbenoxolone. Tolbutamide does not appear to have any significant effect on the pharmacokinetics of carbenoxolone.

Clinical evidence, mechanism, importance and management

A single 500-mg dose of **tolbutamide** had no significant effect on the half-life of a single 100-mg dose of carbenoxolone in 4 healthy subjects, whereas a single 250-mg dose of **chlorpropamide** delayed the absorption of carbenoxolone and reduced its plasma levels in 6 patients taking

carbenoxolone 100 mg three times daily.¹ The clinical importance of this latter interaction is uncertain.

1. Thornton PC, Papouchado M, Reed PI. Carbenoxolone interactions in man - preliminary report. *Scand J Gastroenterol* (1980) 15 (Suppl 65), 35-9.

Cimetidine + Dimeticone

The pharmacokinetics of a 200-mg dose of cimetidine were not significantly changed by dimeticone 2.25 g in 11 healthy subjects.¹ For the effect of antacids containing dimeticone, see 'H₂-receptor antagonists + Antacids', p.966.

1. Boismare F, Flipo JL, Moore N, Chanteclair G. Etude de l'effet du diméticone sur la biodisponibilité de la cimétidine. *Thérapie* (1987) 42, 9-11.

Cimetidine + Phenobarbital

Phenobarbital modestly reduces the AUC of cimetidine, although this is probably not clinically relevant.

Clinical evidence, mechanism, importance and management

Phenobarbital 100 mg daily for 3 weeks reduced the AUC of a single 400-mg oral dose of cimetidine in 8 healthy subjects by 15%, and the time during which the plasma concentrations of the cimetidine exceeded 0.5 micrograms/mL (regarded as therapeutically desirable) was reduced by 11%.¹

Phenobarbital apparently stimulates the enzymes in the gut wall so that the metabolism of the cimetidine is increased. Thus the amount of cimetidine absorbed and released into the circulation is reduced.

Direct information is very limited, but the effect of phenobarbital on cimetidine is small and unlikely to be clinically important. No special precautions seem to be necessary.

1. Somogyi A, Thielscher S, Gugler R. Influence of phenobarbital treatment on cimetidine kinetics. *Eur J Clin Pharmacol* (1981) 19, 343-7.

Cimetidine + Rifampicin (Rifampin)

Antituberculous treatment with rifampicin, isoniazid and ethambutol has been shown to increase the non-renal clearance of cimetidine by about 50%. This is probably due to enzyme induction caused by rifampicin. However, the total clearance is unchanged and so this interaction would appear to be of little clinical importance.¹

1. Keller E, Schollmeyer P, Brandenstein U, Hoppe-Seyler G. Increased nonrenal clearance of cimetidine during antituberculous therapy. *Int J Clin Pharmacol Ther Toxicol* (1984) 22, 307-11.

Cisapride + Miscellaneous

Ketoconazole, erythromycin, and clarithromycin can cause a marked rise in serum cisapride levels, increasing the risk of serious and life-threatening ventricular arrhythmias including torsade de pointes. Nefazodone and protease inhibitors are also predicted to have this effect. Although there do not appear to be any specific reports, cisapride should not be used with other drugs that prolong the QT interval (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257). No clinically relevant interactions with cisapride are apparent when it is given with antacids, cimetidine, esomeprazole, fluoxetine or pantoprazole, but two isolated reports attribute cardiotoxicity to the concurrent use of cisapride and ranitidine or diltiazem. Cisapride increases the rate of absorption of bromperidol, ciclosporin, diazepam, disopyramide, and nifedipine, but appears to have no important effect on digoxin, morphine,

paracetamol (acetaminophen) or propranolol. The effects of anticoagulants may be altered by cisapride.

Clinical evidence, mechanism, importance and management

In many countries cisapride has been withdrawn from the market, or is only available for restricted use because of its potential to cause torsade de pointes arrhythmias, especially when cisapride serum levels are elevated.¹ This can lead to cardiac arrest and sudden death. The interactions of cisapride and their importance and management are summarised in 'Table 27.2', (p.964).

Enteral feeds + Aluminium compounds and/or Sucralfate

Aluminium-containing antacids and sucralfate can interact with high-protein liquid enteral feeds to produce an obstructive plug.

Clinical evidence

(a) Aluminium-containing antacids

Three patients, who were being fed with a liquid high-protein nutrient (*Fresubin liquid*) through an enteral tube, developed an obstructing protein-aluminium-complex oesophageal plug when intermittently given an aluminium/magnesium hydroxide antacid (*Alucol-Gel*).¹ Another report also describes blockage of a nasogastric tube in a patient treated with aluminium hydroxide (*Aludrox*) and *Nutrison*.²

(b) Sucralfate alone or with aluminium-containing antacids

A number of reports describe the development of hard putty-like or creamy precipitations and encrustations that have blocked the oesophagus or stomach of patients given **sucralfate** with enteral feeds (*Ensure Plus*,³ *Fresubin plus F⁴* or *Osmolite*⁵). Another patient developed this precipitate when treated with *Isocal* and **sucralfate** with aluminium/magnesium hydroxide.⁶ Similarly, a patient receiving *Pulmocare* nasogastric feed, sucralfate and aluminium hydroxide gel also developed an oesophageal bezoar, which was analysed and found to contain components of both the drugs and the enteral feed.⁷

Data from the French Pharmacovigilance system database found 16 adults and 5 newborn babies who developed bezoars while taking sucralfate, and identified nasogastric feeding as a risk factor.⁸

Mechanism

It seems that a bezoar (a relatively insoluble complex) forms between the protein in the enteral feeds, and the aluminium from the antacids or sucralfate (sucralfate is about 18% aluminium). It thickens when the pH falls.³

Importance and management

An established and clinically important interaction that can result in the blockage of enteral or nasogastric tubes. The authors of one report say that high molecular protein solutions should not be mixed with antacids or followed by antacids, and if an antacid is needed, it should be given some time after the nutrients and the tube should be vigorously flushed beforehand.¹ The authors of another report say that they feed for 18 hours daily and then give the sucralfate overnight without problems.² The manufacturers recommend separating the administration of sucralfate suspension and enteral feeds given by nasogastric tube by one hour.⁹

Table 27.2 Summary of the interactions of cisapride			
<i>Interacting drugs</i>	<i>Reported effects</i>	<i>Action</i>	<i>Refs</i>
Alcohol	Cisapride increases gastric emptying and can modestly increase serum alcohol levels. A modest 22% increase in the AUC of cisapride seen in one study.	Unlikely to be significant, however the sedative effects might be accelerated. Unknown significance; monitor patient for sedation.	1-5
Antacids Aluminium oxide and magnesium hydroxide	No effect on cisapride absorption seen.	None.	6
Antiepileptics e.g. Phenytoin	Increase in gastrointestinal motility caused by cisapride may affect the rate and/or extent of absorption, which may be important for some drugs with a narrow therapeutic index, such as some antiepileptics. However, no available case reports to suggest this is a problem, and one case reporting no interaction.	Uncertain. Monitor antiepileptic drug levels as usual practice. Advise the patient to report any increase in adverse effects.	1, 7
Antimuscarinics e.g. Disopyramide	Cisapride increases gastric emptying but anticholinergics slow gastric emptying. Disopyramide absorption and serum levels were increased in one study.	The clinical outcome is uncertain but caution is warranted if increased levels of the other drug likely to be significant e.g. Disopyramide is contraindicated as it can prolong the QT interval.	8
Bromperidol	Increased psychotic symptoms and bromperidol levels occurred in one case report.	Significance uncertain, but probably small.	9
Ciclosporin	An increase in AUC and serum levels of ciclosporin has been reported.	Monitor ciclosporin levels more frequently.	10
CYP3A4 inhibitors: Macrolides e.g. Clarithromycin, Erythromycin Azole antifungals e.g. Ketoconazole Protease inhibitors Nefazodone Diltiazem Cimetidine See also Table 1.4, p. 6	Increased levels of cisapride result in an increase in the risk of QT prolongation and life-threatening ventricular arrhythmias e.g. <i>torsade de pointes</i> .	Avoid.	1, 11-20
Diazepam	Accelerated absorption of diazepam reported. Transient increase in sedation possible.	Monitor the patient and advise that sedation may occur more quickly.	1, 21
Digoxin	Small reduction in the AUC and serum levels of digoxin seen in one study.	Unlikely to be clinically significant.	22
Diltiazem	A case of syncope and prolonged QT interval reported – see also CYP3A4 inhibitors above.	See CYP3A4 inhibitors above.	23
Drugs that prolong the QT interval	Increased risk of QT prolongation and life-threatening ventricular arrhythmias.	Avoid. Should not be used with other drugs that prolong the QT interval.	1, 15
Esomeprazole	An increase in AUC and elimination half-life of cisapride reported, but no increase in serum levels. No QT-prolonging effects seen.	Unlikely to be clinically significant.	1, 24
Fluoxetine	No effect on the QT interval seen.	None.	25
Grapefruit juice	Significant increases in cisapride levels seen but high inter-subject variability occurred. No QT interval changes were seen.	May be of more significance in patients taking higher doses of cisapride or also taking other interacting drugs. Avoid concurrent use if possible.	26-28
H₂-receptor antagonists: Cimetidine, ranitidine	Increase in cisapride levels and reduction in cimetidine and ranitidine bioavailability seen.	Unlikely to be clinically significant. For cimetidine, see also CYP3A4 inhibitors, above.	1, 29-32
Morphine	An increase in peak morphine serum levels was seen but with no increase in the adverse effects of morphine.	Uncertain but be aware in case of increased morphine adverse effects.	33
Nifedipine	An increase in nifedipine levels with increased nifedipine effects seen, probably due to increased absorption.	Monitor patient and adjust the nifedipine dose accordingly.	34
Pantoprazole	Small reduction in cisapride levels and no QT interval effects seen.	None.	35
Paracetamol	No significant effect on the pharmacokinetics of paracetamol was found in one study but another small study found that the metabolism of paracetamol was reduced.	Unlikely to be clinically significant.	36, 37
Propranolol	No change in levels or effect of propranolol.	None.	38

Continued

Table 27.2 Summary of the interactions of cisapride (continued)

Interacting drugs	Reported effects	Action	Refs
Red wine	Minor changes in cisapride levels seen in one single-dose study.	Significance is unclear.	28
Simvastatin	Slightly increased cisapride levels and reduced simvastatin levels.	Unlikely to be generally significant although it may be prudent to check that simvastatin remains effective.	39
Warfarin and related anticoagulants	Warfarin: A small but insignificant increase in INR was seen in healthy subjects, but one case report describes large rise in INR. Acenocoumarol: Increased anticoagulant effect reported, which resolved when cisapride stopped. Phenprocoumon: No significant change in anticoagulant effects.	It seems prudent to monitor patients taking anticoagulants who are given cisapride until their INR is stable.	1, 40-43

H₂-receptor antagonists + Antacids

The absorption of cimetidine, famotidine, nizatidine, and ranitidine may possibly be reduced to some extent by antacids, but it seems doubtful if this significantly reduces their effects. Separating the dosages by 1 to 2 hours minimises any interaction. Roxatidine absorption appears not to be affected by antacids. Cimetidine appears not to interfere with the effectiveness of *Gaviscon* (sodium alginate compound).

Clinical evidence

(a) Cimetidine

When 12 healthy subjects were given oral cimetidine 300 mg four times daily for 5 doses, with and without 30 mL of *Mylanta II* (aluminium/magnesium hydroxide mixture), the absorption of cimetidine was unaffected.¹ No interaction was found in other single-dose studies using aluminium phosphate^{2,3} or aluminium/magnesium hydroxide^{4,5} antacids.

In contrast, a number of other single-dose studies indicated that antacids reduce the absorption of cimetidine. The AUCs of 200- to 800-mg doses of cimetidine were reduced by an average of 19 to 34% by 10 to 45 mL doses of a variety of aluminium/magnesium-containing antacids.^{6–10} When the antacids were given 1 to 3 hours after cimetidine 'marginal' or insignificant reductions occurred in the AUCs.^{7,11,12}

Gaviscon (sodium alginate/antacid) is an anti-reflux preparation that needs a small amount of gastric acid to be present in order for the alginic acid 'raft' to form. A study in 12 healthy subjects designed to find out if an H₂-receptor antagonist would alter the effectiveness of *Liquid Gaviscon* found that cimetidine 400 mg four times daily for 7 days caused some slight changes in gastric emptying, but the distribution of the *Gaviscon* in the fundus of the stomach was not altered.¹³

(b) Famotidine

Mylanta II (aluminium/magnesium hydroxide mixture) 30 mL reduced the AUC and peak serum levels of famotidine by about a third when taken simultaneously, but no significant interaction occurred when the antacid was taken 2 hours after famotidine.¹⁴ Another study found that the peak serum levels of famotidine were reduced by about 25% by *Mylanta II* in 17 healthy subjects.¹⁵

In contrast, *Mylanta Double Strength* (aluminium/magnesium hydroxide with simeticone) was found to reduce the absorption of famotidine by 19%, a difference that was considered unimportant.¹⁰ Two chewable tablets of *Mylanta II* were found to have no effect on the pharmacokinetics or pharmacodynamics of famotidine 10 or 20 mg in 18 healthy subjects.¹⁶

(c) Nizatidine

Mylanta Double Strength (aluminium/magnesium hydroxide with simeticone) reduced the absorption of nizatidine by 12%, which was considered clinically insignificant.¹⁰ In a study in 11 healthy subjects a single 30-mL dose of *Gelusil* (aluminium/magnesium hydroxide with simeticone) reduced the mean AUC and maximum serum levels of nizatidine (given simultaneously) by 13 and 17%, respectively.¹⁷ Another study found that the pharmacokinetics of nizatidine were not affected by an aluminium/magnesium hydroxide antacid (*Maalox*) although a non-significant reduction in the AUC of 8% and an increase in the time to peak effect of nizatidine were seen.¹⁸

(d) Ranitidine

Mylanta II (aluminium/magnesium hydroxide mixture) 30 mL reduced the ranitidine peak serum levels and AUC after a single 150-mg dose by about one-third in 6 healthy subjects.¹⁹ *Mylanta Double Strength* (aluminium/magnesium hydroxide with simeticone) reduced the absorption of ranitidine by 26%, which was not thought to be clinically significant.¹⁰

Reductions of up to 59% were found in another study.⁹ Yet another study showed that aluminium phosphate reduced the bioavailability of ranitidine by 30%.²⁰ In contrast, another study found no significant changes in the pharmacokinetics of ranitidine given with an aluminium/magnesium hydroxide antacid (*Maalox*).¹⁸

(e) Roxatidine

In an open-label crossover study, 24 healthy subjects were given roxatidine 150 mg with 10 mL of *Maalox* (aluminium/magnesium hydroxide) four times daily. The pharmacokinetics of roxatidine were unchanged, apart from a clinically insignificant lengthening of the half-life.²¹

Mechanism

Not fully understood. Changes in gastric pH caused by the antacid, and retarded gastric motility have been suggested as potential mechanisms. An *in vitro* study showed no absorption interaction occurred between cimetidine and antacids.⁵

Importance and management

A modest reduction in the bioavailability of cimetidine, famotidine, nizatidine and ranitidine can occur with some antacids although this appears to be more likely when larger doses of antacids are used. None of these interactions are well established and evidence that the effects of the H₂-receptor antagonists are reduced seems to be lacking. If the antacids are given 1 to 2 hours before or after the H₂-receptor antagonist (if fasting), or 1 hour after (if the H₂-receptor antagonist is taken with food), no reduction in absorption should occur.^{7,14,15,22} Preliminary evidence suggests that roxatidine is unaffected. Given the evidence available it seems unlikely that a clinically significant interaction will occur between any H₂-receptor antagonist and standard doses of an antacid. The action of *Gaviscon* (sodium alginate) does not appear to be compromised by cimetidine.¹³

H₂-receptor antagonists + Probenecid

Probenecid markedly decreases the renal clearance of famotidine and modestly reduces the renal clearance of cimetidine. However, these effects are not expected to result in adverse clinical effects.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study 6 healthy subjects were given probenecid 500 mg every 6 hours for 13 doses, with a single 300-mg intravenous dose of cimetidine 3 hours after the last probenecid dose. Probenecid reduced the renal clearance of cimetidine by 22%, without affecting overall clearance.¹ Probenecid 1.5 g increased the AUC of a single 20-mg dose of famotidine in 8 healthy subjects by 81%, and reduced the renal tubular clearance by 89%.² It has been suggested that probenecid inhibits the renal secretion of cimetidine and famotidine, thereby reducing their loss from the body. This is consistent with the way that probenecid affects some other drugs. The effects of famotidine would be expected to be increased, but dose-related toxicity arising from this interaction seems unlikely. The effects of cimetidine are unlikely to be significantly altered. There would therefore seem to be no reason for avoiding concurrent use. Other H₂-receptor antagonists are also renally excreted and therefore they may behave similarly.

H₂-receptor antagonists + Sucralfate

Most *in vitro* and human studies have found that sucralfate does not affect the absorption of either cimetidine,^{1–3} ranitidine,⁴ or roxatidine,⁵ but two studies found 22 to 29% reductions in ranitidine bioavailability due to concurrent use of sucralfate.^{6,7} There is no clear reason for avoiding concurrent use.

H₂-receptor antagonists + Tobacco or Nicotine

Smoking may reduce the plasma levels of cimetidine and ranitidine, but does not appear to affect famotidine. Cimetidine, and to a lesser extent ranitidine, reduce the clearance of nicotine from the body in non-smokers, but there is some evidence to suggest that cimetidine has no effect on nicotine clearance in smokers.

Clinical evidence

(a) Nicotine

Cimetidine 600 mg twice daily for one day, given before intravenous nicotine (1 microgram/kg per minute given intravenously for 30 minutes), reduced the nicotine clearance in 6 healthy non-smokers by 27 to 30%.

Ranitidine (300 mg twice daily taken for one day) reduced the clearance of nicotine by about 7 to 10%.¹ See also tobacco smoking, below.

(b) Tobacco

In one study, tobacco smokers were given single oral doses of either ranitidine 150 mg or cimetidine 200 mg on two separate days. On one of the days they were allowed to smoke as normal and on the other they were not allowed to smoke. Peak levels for both drugs occurred sooner and were higher on the smoking day than on the non-smoking day. However, the plasma levels of the H₂-receptor antagonists after peak levels were achieved were lower. No effect was seen when intravenous cimetidine or ranitidine were given.²

A study in heavy smokers (more than 20 cigarettes per day for at least 1 year) given cimetidine 400 mg three times daily for 2 weeks found no reduction in the clearance of nicotine or in the number of cigarettes smoked, when compared with placebo.³

There was no difference in the pharmacokinetics and gastric acid-lowering effect of famotidine between 12 healthy smokers and 8 non-smokers.⁴

Mechanism, importance and management

The authors of one of the above studies³ noted that tobacco smoking induces nicotine metabolism and that this may have been a factor in the lack of effect of cimetidine on nicotine clearance compared with their previous study in non-smokers.¹ On balance cimetidine and other H₂-receptor antagonists probably have little effect on nicotine replacement therapy or tobacco smoking.

The healing of duodenal ulcers in patients taking H₂-receptor antagonists such as cimetidine,^{5,6} famotidine,⁷ nizatidine⁸ and ranitidine^{6,7} is slower and ulcer recurrence is more common in smokers than in non-smokers. It is quite possible that this is due to smoking being a risk factor for the occurrence of duodenal ulcers^{5,7–9} rather than a significant interaction between smoking and H₂-receptor antagonists.

Loperamide + Colestyramine

An isolated report, supported by an *in vitro* study, indicates that the effects of loperamide can be reduced by colestyramine.

Clinical evidence, mechanism, importance and management

A man who had undergone extensive surgery to the gut, with the creation of an ileostomy, needed treatment for excessive fluid loss. His fluid loss was observed to be “substantially less” when he took loperamide 2 mg every 6 hours alone, than when he took loperamide in combination with colestyramine 2 g every 4 hours.¹ The probable reason is that the colestyramine binds to the loperamide in the gut, thereby reducing its activity. An *in vitro* study using 50 mL of simulated gastric fluid found that 64% of a 5.5-mg dose of loperamide was bound by 4 g of colestyramine.¹ Direct information is limited to this report, but what occurred is consistent with the way colestyramine interacts with other drugs. It has been suggested that the two drugs should be separated as much as possible to prevent mixing in the gut, or that the loperamide dosage should be increased.¹ It is a standard recommendation that other drugs should be given 1 hour before or 4 to 6 hours after colestyramine.

- Ti TY, Giles HG, Sellers EM. Probable interaction of loperamide and colestyramine. *Can Med Assoc J* (1978) 119, 607–8.

Loperamide + Co-trimoxazole

Co-trimoxazole increases the plasma levels of loperamide.

Clinical evidence, mechanism, importance and management

Co-trimoxazole 960 mg twice daily was given to healthy subjects for 24 hours before and then 48 hours after they took a single 4-mg dose of loperamide (12 subjects) or loperamide oxide (a prodrug of loperamide, 10 subjects). The co-trimoxazole increased the loperamide AUC by 89% and doubled its maximum plasma levels. The loperamide oxide AUC was raised by 54% and its maximum plasma levels were raised by 41%. It is thought that co-trimoxazole inhibits the metabolism of loperamide, possibly by reducing its first pass metabolism.¹ However, despite these rises, because loperamide has a very wide margin of safety, it is thought unlikely that any dosage changes are needed.

1. Kamali F, Huang ML. Increased systemic availability of loperamide after oral administration of loperamide and loperamide oxide with cotrimoxazole. *Br J Clin Pharmacol* (1996) 41, 125–8.

Loperamide + Protease inhibitors

Ritonavir increases the plasma levels of loperamide. Tipranavir, alone and combined with ritonavir, reduces the bioavailability and plasma levels of loperamide and its metabolites. No central opioid adverse effects are seen when loperamide is given with ritonavir alone, tipranavir alone, or tipranavir/ritonavir.

Clinical evidence

In a double-blind, placebo-controlled study, 12 healthy subjects were given a single 600-mg dose of **ritonavir** with either loperamide 16 mg or placebo. The loperamide AUC and maximum plasma level were increased threefold and 17%, respectively, by ritonavir, but no additional CNS adverse effects were seen.¹ Another study in 20 healthy subjects looked at the pharmacokinetics and pharmacodynamics of a single 16-mg dose of loperamide taken with either **tipranavir** 750 mg twice daily, **ritonavir** 200 mg twice daily or both drugs together. (Note that this dose of tipranavir is higher than the usual ritonavir-boosted dose of 500 mg twice daily.) **Tipranavir** alone reduced the maximum concentration and AUC of loperamide by 58% and 63%, respectively, whereas **ritonavir** increased these parameters by 83% and 121%, respectively. The combination of **tipranavir/ritonavir**, as is usual clinical practice, resulted in a net reduction in the maximum concentration and AUC of loperamide by 61% and 51%, respectively, similar to the effect seen with **tipranavir** alone. The maximum concentration and AUC of the metabolites of loperamide were also reduced. There were no clinically significant loperamide adverse effects on respiration or pupil contractility with either ritonavir alone, tipranavir alone, or the combination.²

Mechanism

Loperamide is primarily metabolised by cytochrome P450 isoenzyme CYP3A4, and is thought to lack CNS effects because it is a substrate for P-glycoprotein, which transports drugs out of the cells at the blood-brain barrier, thereby restricting CNS penetration.² The increase in loperamide levels with ritonavir alone is thought to be due to ritonavir inhibiting CYP3A4. The lack of an increase in loperamide CNS effects suggests that ritonavir alone does not inhibit P-glycoprotein.^{1,2} The reduction in loperamide levels with tipranavir alone or tipranavir/ritonavir is not thought to be via effects on CYP3A4, but is due to induction of gastrointestinal P-glycoprotein by tipranavir, resulting in decreased systemic bioavailability of loperamide.²

Importance and management

Despite the increases seen in loperamide plasma levels seen in both studies with ritonavir alone, a lack of central opioid effects with loperamide (such as pupillary constriction, respiratory depression and also analgesic effects) was demonstrated. This suggests that the combination of loperamide with

ritonavir is potentially safe to use as an antidiarrhoeal for protease inhibitor-induced diarrhoea.¹

The clinical relevance of the decrease in loperamide bioavailability with tipranavir alone or tipranavir/ritonavir is unknown.

Mesalazine (Mesalamine) + Ispaghula, Lactitol, or Lactulose

On theoretical grounds, formulations designed to release mesalazine in response to the higher pH in the colon should not be given with lactulose, lactitol or other preparations that lower the colonic pH. However, neither ispaghula or lactulose appear to affect the bioavailability of mesalazine.

Clinical evidence, mechanism, importance and management

Asacol is a preparation of mesalazine coated with an acrylic based resin (*Eudragit S*) that disintegrates above pH 7 and thereby releases the mesalazine into the terminal ileum and colon. Since the disintegration depends upon this alkaline pH, the UK manufacturers of *Asacol* say that the concurrent use of preparations that lower the pH in the lower part of the gut should be avoided.¹ *Salofalk* is another preparation of mesalazine with a pH-dependent enteric coating.

The pH in the colon can be lowered by lactulose and lactitol, which are metabolised by gut bacteria to a number of acids (e.g. acetic, butyric, propionic, and lactic acid).² In healthy subjects, lactulose 30 to 80 g daily has been found to cause slight falls in colonic pH;^{2,3} from about 6 to 5 in the right colon and from 7 to 6.7 in the left colon. Lactitol 40 to 180 g daily can cause similar falls in pH.² Ispaghula can also lower colonic pH (from 6.5 to 5.8 in the right colon, and from 7.3 to 6.6 in the left colon).⁴ However, a study in patients given mesalazine found that despite this colonic acidification by ispaghula husk (*Fybogel*), the release of mesalazine appeared not to be affected, as 24-hour faecal and urinary excretion of mesalazine metabolites were unchanged.⁵ Similarly, another study in 14 healthy subjects given delayed-release mesalazine (*Asacol*) 400 mg three times daily found that lactulose (15 mL increased to 30 mL twice daily) did not affect urinary or faecal excretion of mesalazine and its metabolites.⁶

Thus, although on theoretical grounds ispaghula husk and lactulose might be expected to reduce the effects of mesalazine, no interaction of clinical importance seems to occur, and there have been no reports as yet that a clinically important interaction occurs with either ispaghula husk, lactulose or lactitol. Also note that this interaction is not mentioned by the US manufacturers of *Asacol*.⁷

Mesalazine (Mesalamine) + Proton pump inhibitors

Omeprazole does not affect the release of mesalazine from a delayed-release preparation (*Asacol*).

Clinical evidence, mechanism, importance and management

Asacol is a preparation of mesalazine coated with an acrylic based resin (*Eudragit S*) that disintegrates above pH 7 and thereby releases the mesalazine into the terminal ileum and colon. The release is rapid at pH values of 7 and above, but it can also occur between pH 6 and 7. Since the proton pump inhibitors can raise the pH in the stomach to 6 and above, the potential exists for the premature release of mesalazine from *Asacol*. However, a study in 6 healthy subjects given *Asacol* 400 mg three times daily for 3 weeks found that when they were also given omeprazole 20 mg daily during the second week, and omeprazole 40 mg daily during the third week, the steady-state pharmacokinetics of the mesalazine remained unchanged.¹ Had mesalazine been released earlier, the absorption characteristics would have changed. There would therefore appear to be no reason for avoiding the concurrent use of *Asacol* and omeprazole in doses of up to 40 mg daily. On the basis of this study, it seems likely that other proton pump inhibitors will behave similarly at equivalent doses.

1. Hussain FN, Ajjan RA, Moustafa M, Weir NW, Riley SA. Mesalazine release from a pH dependent formulation: effects of omeprazole and lactulose co-administration. *Br J Clin Pharmacol* (1998) 46, 173–5.

Omeprazole + Artemisinin

Artemisinin modestly increases the metabolism of omeprazole, but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects found that the AUC of a single 20-mg dose of omeprazole was reduced by 35% by artemisinin 250 mg twice daily for 7 days. The pharmacokinetics of the omeprazole metabolites were unchanged, but the ratio of hydroxyomeprazole/omeprazole increased 2.2-fold in those of an extensive CYP2C19 metabolisers phenotype (see 'metabolism of proton pump inhibitors', (p.960)). This suggests that artemisinin affects the pharmacokinetics of omeprazole by inducing the cytochrome P450 isoenzyme CYP2C19, an enzyme involved in its metabolism, although other isoenzymes may also be involved. A single 250-mg dose of artemisinin had no effect on the pharmacokinetics of omeprazole, which supports the proposed mechanism of enzyme induction.¹ A subsequent study in 8 healthy subjects who were of the extensive CYP2C19 metaboliser phenotype similarly found that artemisinin 500 mg daily for 7 days decreased the AUC of both the *S* and *R*-enantiomers of a single 20-mg dose of omeprazole to the same extent, and increased the oral clearance of both enantiomers by about threefold.² The clinical significance of this interaction is unclear.

Omeprazole + Disulfiram

An isolated case describes a catatonic reaction in a patient given omeprazole and disulfiram.

Clinical evidence, mechanism, importance and management

A patient who had been taking omeprazole 40 mg daily for 7 months was also given disulfiram 500 mg daily. Six days later he gradually developed confusion, which progressed to a catatonic state with muscle rigidity and trismus (spasm of the muscles used to chew food) after 15 days. Both drugs were withdrawn and he gradually recovered. Some months later while taking disulfiram 250 mg daily, he again developed confusion, disorientation and nightmares within 72 hours of starting to take omeprazole 40 mg each morning. Again he recovered when both drugs were stopped.¹

The reason for this reaction is not understood, but the authors of the report suggest that the omeprazole may have allowed the accumulation of one of the metabolites of disulfiram, carbon disulphide, which could have been responsible for the toxic effects.¹

This is the first and only report of a possible interaction between omeprazole and disulfiram. Other patients given both drugs are said not to have shown adverse effects.² The general importance of this adverse interaction is therefore uncertain, but it seems likely to be small.

2. Astra Pharmaceuticals. Personal communication, 1991.

Pirenzepine + Antacids

***Mylanta* reduces the bioavailability of pirenzepine by about 30%. Another antacid, *Trigastril*, modestly increases the bioavailability of pirenzepine, but these changes are probably of little clinical importance.**

Clinical evidence, mechanism, importance and management

The AUC of a single 50-mg dose of pirenzepine was reduced by about 30% in 20 healthy subjects by 30 mL of *Mylanta* (aluminium/magnesium hydroxide and simeticone). The antacid reduced the peak plasma levels of pirenzepine by about 45%.¹ Another study in 10 healthy subjects found that the AUC of a single 50-mg dose of pirenzepine was increased by almost 25% by 10 mL of an antacid (*Trigastril*, aluminium/magnesium hydroxide, calcium carbonate).² In practical terms these modest changes in bioavailability are probably too small to matter.

1. Matzek KM, MacGregor TR, Keirns JJ, Vinocur M. Effect of food and antacids on the oral absorption of pirenzepine in man. *Int J Pharmaceutics* (1986) 28, 151–5.
2. Vergin H, Herrlinger C, Gugler R. Effect of an aluminium-hydroxide containing antacid on the oral bioavailability of pirenzepine. *Arzneimittelforschung* (1989) 39, 520–3.

Pirenzepine + Cimetidine

The pharmacokinetics of pirenzepine and cimetidine are not affected by the presence of the other drug, but pirenzepine increases the cimetidine-induced reduction in gastric acid secretion, which is an apparently advantageous interaction.¹

1. Jamali F, Mahachai V, Reilly PA, Thomson ABR. Lack of pharmacokinetic interaction between cimetidine and pirenzepine. *Clin Pharmacol Ther* (1985) 38, 325–30.

Pirenzepine + Food

Food reduces the bioavailability of pirenzepine by about 30%, but this is probably of little clinical importance.

Clinical evidence, mechanism, importance and management

The AUC of a single 50-mg dose of pirenzepine was reduced by about 30% in 20 healthy subjects when pirenzepine was taken half-an-hour before food, or with food. Peak plasma levels were reduced by about 30% and 45%, respectively. The time to achieve peak levels was also reduced.¹ In practical terms this modest change in bioavailability is probably too small to matter. The authors of this report suggest taking it with food because compliance is better if associated with a convenient daily ritual.¹

1. Matzek KM, MacGregor TR, Keirns JJ, Vinocur M. Effect of food and antacids on the oral absorption of pirenzepine in man. *Int J Pharmaceutics* (1986) 28, 151–5.

Proton pump inhibitors + Antacids

***Maalox* does not appear to alter the pharmacokinetics of omeprazole, pantoprazole or rabeprazole. Antacids may cause a slight reduction in the bioavailability of lansoprazole. This is probably not clinically relevant but can be accommodated by separating their administration by one hour. There is no interaction between sodium alginate and omeprazole.**

Clinical evidence, mechanism, importance and management

(a) Lansoprazole

In a study in 12 healthy subjects a single 30-mL dose of *Maalox* (**aluminium/magnesium hydroxide**) slightly reduced the AUC of a 30-mg dose of lansoprazole by 13% (not statistically significant), and reduced the maximum plasma level by 27%. However, no changes were seen when the lansoprazole was given 1 hour after the antacid.¹ Note that in this study, the bioavailability of lansoprazole was highly variable between subjects (the AUC varied by a factor of 6), and the effect of 'food', (below), was greater than the effect of the antacid. In another study, **magaldrate** had no effect on the AUC of lansoprazole, and slightly reduced the maximum level (by 28%), but this change was not considered clinically relevant.² Nevertheless, the manufacturer recommends that antacids should not be taken within one hour of lansoprazole,³ but this seems to be an overcautious recommendation.

(b) Omeprazole

Two single-dose studies have shown that *Maalox* suspension (**aluminium/magnesium hydroxide**) did not affect the absorption or disposition of omeprazole from an enteric-coated formulation.^{4,5} Similar findings were reported for *Maalox* suspension in another single-dose study. In contrast, this study found that *Maalox granules* modestly reduced the AUC of omeprazole enteric-coated tablets by 26% and reduced its plasma levels.⁶

A randomised, crossover study in healthy subjects given omeprazole capsules 20 mg daily for 3 days, with two *Gaviscon* tablets (aluminium hydroxide, **magnesium trisilicate** and **sodium alginate**) on day 3, found that omeprazole did not significantly affect the alginate raft formation or the length of time the raft stayed in the stomach.⁷ In another study in healthy subjects, concurrent use of *Gaviscon Advance* (**sodium alginate**) 10 mL four times daily and omeprazole (*Losec MUPS*) 20 mg daily for 3 days did not affect the pharmacokinetics of omeprazole, although it was noted that *Gaviscon Advance*, unlike *Gaviscon*, does not contain any antacid.⁸ No special precautions appear to be necessary if omeprazole is given with these antacids.

(c) Pantoprazole

Pantoprazole 40 mg daily was given to 24 healthy subjects with and without 10 mL of *Maalox* (**aluminium/magnesium hydroxide**). The AUC, maximum serum levels, and the half-life of the pantoprazole were unchanged by the antacid.⁹ No special precautions would seem to be necessary if pantoprazole is given with *Maalox*.

(d) Rabeprazole

In a single-dose study, 12 healthy subjects were, on separate occasions, given 20 mg of rabeprazole with, without, and 1-hour after a dose of **aluminium/magnesium hydroxide** antacid (*Maalox*).¹⁰ The antacid had no effect on the pharmacokinetics of rabeprazole, so no special precautions would seem necessary on concurrent use.

Foods such as apple sauce, apple or orange juice, and yoghurt do not seem to significantly affect the bioavailability of the contents of lansoprazole or omeprazole capsules, and apple sauce did not alter the bioavailability of the contents of esomeprazole capsules.

Clinical evidence, mechanism, importance and management

(a) Esomeprazole

In a crossover study in fasting healthy subjects, the bioavailability of the contents of an esomeprazole capsule mixed with one tablespoonful of **apple sauce** were similar to those of an intact esomeprazole capsule taken with water. Apple sauce was chosen because it is acidic and would therefore be unlikely to affect the enteric coat of the esomeprazole granules from the capsule.¹ An *in vitro* study found that esomeprazole enteric-coated granules from an opened capsule were stable when mixed with 100 mL tap water, yogurt, orange juice or apple juice.² The authors suggest that it is likely that esomeprazole could be mixed with these **juices** or other **soft acidic foods** in patients who cannot swallow a capsule.^{1,2} Nevertheless, for patients unable to swallow, the UK manufacturers recommend dispersing esomeprazole *tablets* in non-carbonated water only to avoid dissolving the enteric coating. They also note that food delays and decreases the absorption of esomeprazole *tablets*, but that this has little effect on the efficacy to reduce gastric acidity.³ The US manufacturers say that because the AUC of esomeprazole can be reduced by 43 to 54% by food, esomeprazole *capsules* and *oral suspension* should be taken at least one hour before meals.⁴

(b) Lansoprazole

A study found that food (a **standard meal**) reduced lansoprazole bioavailability by 27%.⁵ Another study found a 50% reduction in lansoprazole bioavailability with food (a **standard breakfast**).⁶ The authors of both these studies therefore recommended that lansoprazole should not be given with food.^{5,6} The maximum serum levels and AUC of lansoprazole are reduced by 50 to 70% when it is given 30 minutes after food. No significant effect was found when lansoprazole was given before meals.⁷ The manufacturers recommend that, to achieve optimal efficacy, lansoprazole should be given in the morning at least 30 minutes before food.^{7,8} However, in a crossover study in fasting healthy patients the bioavailability of the contents of a lansoprazole 30 mg capsule mixed with either **orange juice**, **tomato juice**, or one tablespoonful of **strained pear** was comparable to that of an intact capsule given with water.⁹ This study suggests that, for patients who are unable to swallow or who have difficulty swallowing, mixing the capsule contents with these specific juices or soft foods is acceptable. The US manufacturers also say that the intact contents of the *delayed-release capsules* may be mixed in with a small volume (60 mL) of **apple sauce**, **Ensure pudding**, **cottage cheese**, or **yoghurt**. However, the *soluble tablets* may only be dispersed in **water**, and, if given via a nasogastric tube, the tube should be flushed with water before and after administration. The *suspension* may only be mixed with **water** and must not be given through a nasogastric tube.⁷

(c) Omeprazole

In a study in healthy subjects, giving omeprazole with **breakfast** delayed its absorption, but did not affect the total amount absorbed.¹⁰ Similarly, in another study in healthy subjects, a **standardised breakfast** did not affect the bioavailability or maximum concentration of omeprazole enteric-coated tablets, when compared to the fasting state, or when taken immediately before a meal, although an increase in time to maximum concentration was seen.¹¹ Omeprazole may therefore be taken without regard to the timing of meals. For patients unable to swallow, the manufacturers recommend mixing the intact contents of the opened capsule with **non-carbonated water**, **apple**, **orange** or **pineapple juice**, **yoghurt**¹² or **apple sauce**.^{12,13}

(d) Pantoprazole

The manufacturers state that food has no effect on the bioavailability of pantoprazole. The US manufacturers recommend that the tablet is swallowed whole with water with or without food,¹⁴ whereas the UK manufacturers recommend taking it before a meal.¹⁵

(e) Rabeprazole

A high-fat meal may delay the absorption of rabeprazole but does not alter the AUC and maximum serum levels¹⁶ and so rabeprazole may be taken with or without food.^{16,17} The UK manufacturers note that, although food

Proton pump inhibitors + Food or Drinks

Food modestly reduces the bioavailability of lansoprazole and esomeprazole, but not omeprazole, pantoprazole, or rabeprazole.

has no effect on the activity of rabeprazole, for once daily regimens they recommend taking it in the morning, before breakfast, to aid compliance.¹⁷

Proton pump inhibitors + Grapefruit juice

Grapefruit juice has little effect on the AUC of lansoprazole or omeprazole, but modestly reduces the formation of the sulphone metabolites, which is unlikely to be clinically relevant.

Clinical evidence

(a) Lansoprazole

In a randomised, crossover study 21 subjects were given a single 60-mg dose of lansoprazole with either 200 mL of water or freshly-squeezed grapefruit juice. The AUC of lansoprazole was slightly increased by 18%, and the formation of the sulphone metabolite was reduced by the grapefruit juice. Metabolism to the hydroxyl metabolite was not significantly affected.¹

(b) Omeprazole

In a single-dose study in 12 healthy subjects, grapefruit juice 300 mL had no significant effect on the AUC or half-life of omeprazole 20 mg: the results were similar in both CYP2C19 metaboliser phenotypes, as indicated by plasma levels of hydroxyomeprazole. However, there was a 20% reduction in AUC of omeprazole sulphone.²

Mechanism

From the studies above^{1,2} it appears that grapefruit juice may have a minor inhibitory effect on the metabolism of omeprazole and lansoprazole by the cytochrome P450 isoenzyme CYP3A4 (which results in the sulphone metabolites). This was suggested to be due to intestinal inhibition of CYP3A4. Grapefruit juice does not affect the metabolism (hydroxylation) of the proton pump inhibitors by CYP2C19.

Importance and management

The small changes in lansoprazole and omeprazole pharmacokinetics are not clinically relevant, so it appears that they may be taken with grapefruit juice. See also 'Proton pump inhibitors + Food or Drinks', p.970, for the

finding that other fruit juices had no effect on lansoprazole or omeprazole bioavailability.

- Uno T, Yasui-Furukori N, Takahata T, Sugawara K, Tateishi T. Lack of significant effect of grapefruit juice on the pharmacokinetics of lansoprazole and its metabolites in subjects with different CYP2C19 genotypes. *J Clin Pharmacol* (2005) 45, 690–4.

Proton pump inhibitors + Herbal medicines

Both *Ginkgo biloba* and St John's wort induce the metabolism of omeprazole, and this might result in reduced efficacy. Other proton pump inhibitors are likely to be similarly affected.

Clinical evidence and mechanism

(a) *Ginkgo biloba*

In one study, 18 healthy Chinese subjects were given a single 40-mg dose of omeprazole before and after a 12-day course of a standardised extract of *Ginkgo biloba* 140 mg twice daily. The subjects were divided into three groups: homozygous extensive CYP2C19 metabolisers (6 subjects), heterozygous extensive CYP2C19 metabolisers (5) and poor CYP2C19 metabolisers (7). The AUC of omeprazole was modestly decreased by 42%, 27% and 40%, respectively, and levels of the inactive metabolite, hydroxyomeprazole, were increased by 38%, 100%, and 232%, in the three groups, respectively. Renal clearance of hydroxyomeprazole was also reduced by *Ginkgo biloba*. It was concluded that *Ginkgo biloba* increases the metabolism (hydroxylation) of omeprazole by inducing the cytochrome P450 isoenzyme CYP2C19.¹

(b) *St John's wort* (*Hypericum perforatum*)

In a crossover study 12 healthy subjects (6 of the extensive CYP2C19 metaboliser phenotype and 6 of the poor CYP2C19 metaboliser phenotype) were given *St John's wort* 300 mg three times daily or placebo for 14 days, followed by a single 20-mg dose of omeprazole on day 15. *St John's wort* modestly decreased the AUC of omeprazole in all subjects (by 49% in extensive metabolisers and 41% in poor metabolisers), and also increased the levels of hydroxyomeprazole by 35% in those who were extensive metabolisers. It also markedly increased the levels of the inactive CYP3A4 sulfone metabolite of omeprazole in both extensive and poor metabolisers (by 148% and 132%, respectively).² It was concluded that *St John's wort* increases the metabolism of omeprazole by inducing both CYP2C19 and CYP3A4.

Importance and management

These appear to be the only studies examining the effects of *Ginkgo biloba* and *St John's wort* on proton pump inhibitors. However, the reduction in the AUCs of omeprazole seen (about 40%) suggest that there is a possibility that omeprazole will be less effective in patients taking these herbal medicines. As all PPIs are metabolised by CYP2C19 to varying extents, it is likely that the effects of *Ginkgo biloba* and *St John's wort* seen in these studies will be similar with other PPIs. There is insufficient evidence to suggest that these herbs should be avoided in patients taking PPIs. However, the potential reduction in the efficacy of the PPI should be borne in mind, particular where the consequences may be serious, such as in patients with healing ulcers.

Proton pump inhibitors + Macrolides

Clarithromycin approximately doubles the serum levels of esomeprazole, lansoprazole and omeprazole, but has no effect on pantoprazole. A small rise in the serum levels of clarithromycin might also occur, which may be therapeutically useful. Some very limited evidence indicates that erythromycin raises serum omeprazole

levels, without significantly altering its effects. **Lansoprazole and omeprazole do not appear to affect the pharmacokinetics of roxithromycin.**

Clinical evidence

(a) Clarithromycin

When 11 healthy subjects taking **omeprazole** 40 mg daily were also given clarithromycin 500 mg every 8 hours for 5 days, the maximum serum levels of **omeprazole** rose by 30% and its AUC₀₋₂₄ rose by 89%, but the effect of **omeprazole** on gastric pH was unchanged. The maximum serum clarithromycin levels rose by 11% and the AUC₀₋₈ was increased by 15%.¹ In a similar study, approximately twofold increases in the AUC of **omeprazole** were reported.² In another study in 8 subjects (all extensive metabolisers of CYP2C19), clarithromycin 500 mg twice daily for 7 days caused a similar twofold increase in the AUC of **omeprazole** 20 mg twice daily but did not affect the AUC of **pantoprazole** 40 mg twice daily. The levels of clarithromycin itself were not affected.³

The AUC of a single 60-mg dose of **lansoprazole** was raised 1.55-fold to 1.8-fold by clarithromycin 500 mg twice daily for 6 days in both extensive and poor metabolisers of CYP2C19.⁴ In another study in healthy subjects, the AUC of lansoprazole 30 mg twice daily was increased by just 25% by clarithromycin 500 mg twice daily and amoxicillin 1 g twice daily for 4 days. The AUC of the hydroxyl metabolite of clarithromycin was also increased by about 25%.⁵

In a study in 18 healthy subjects the AUC, maximum serum levels and half-life of **esomeprazole** 40 mg once daily were increased by 70%, 18% and 35%, respectively, when taken with clarithromycin 500 mg twice daily and amoxicillin 1 g twice daily for 7 days. When the study was repeated in 19 healthy subjects with **esomeprazole** 20 mg the AUC, maximum serum levels and half-life of **esomeprazole** were increased by 127%, 39% and 50%, respectively. All subjects were of the CYP2C19 extensive metaboliser phenotype. Similar increases in **esomeprazole** levels (e.g. AUC doubled) were seen in a further 6 subjects who were of the CYP2C19 poor metaboliser phenotype. In these studies, **esomeprazole** did not alter clarithromycin levels.⁶

See also 'Proton pump inhibitors + Penicillins', below, for information on case reports of glossitis, stomatitis and a black tongue with lansoprazole and antibacterial regimens including clarithromycin.

(b) Erythromycin

A study was undertaken in a patient to confirm the *in vitro* findings that erythromycin inhibits the metabolism of **omeprazole**. After taking 500 mg of erythromycin base and 20 mg of **omeprazole** daily for 8 weeks, it was found that the AUC of **omeprazole** was increased almost fourfold, and the metabolite of **omeprazole** was undetectable. These raised **omeprazole** levels might have been expected to increase its effectiveness, but in this patient the time during which gastric pH was less than 4 decreased by 22%.⁷

(c) Roxithromycin

A study of roxithromycin 300 mg twice daily with **omeprazole** 20 mg twice daily or with **lansoprazole** 30 mg twice daily, for 6 days found that neither PPI significantly affected the pharmacokinetics of roxithromycin.⁸

Mechanism

Clarithromycin appears to inhibit the metabolism of **esomeprazole**, **lansoprazole**⁴ and **omeprazole**^{1,2} by the cytochrome P450 isoenzyme CYP3A4, one of the enzymes involved in their metabolism. Pantoprazole is metabolised by CYP2C19 only and was therefore not affected by the inhibition of CYP3A4. See 'Gastrointestinal drugs', (p.960) for an overview of the metabolism of PPIs and the role of CYP2C19 polymorphism. Erythromycin interacts similarly, whereas roxithromycin has only weak effects on CYP3A4.

Importance and management

The pharmacokinetic interactions between clarithromycin and **omeprazole**, **esomeprazole** and **lansoprazole** are established. However, none of the changes reported represents an adverse interaction, but they may help to explain why concurrent use is valuable in the eradication of *Helicobacter pylori*. Erythromycin is likely to interact similarly, whereas roxithromycin does not. Pantoprazole is not affected by macrolides.

Proton pump inhibitors + Metronidazole

Omeprazole has no clinically significant effect on the pharmacokinetics of oral or intravenous metronidazole.

Clinical evidence, mechanism, importance and management

The plasma pharmacokinetics of a single oral dose of metronidazole were unaffected by 5 days pre-treatment with **omeprazole** 20 mg twice daily in 14 healthy subjects.¹ Similar results were found in another study with oral and intravenous metronidazole, but when the gastric juice was further studied it was found that the transfer of metronidazole into the gastric juice following an intravenous dose dropped from 15.5 to 2.6% in the presence of **omeprazole**.² The significance of these findings is unclear, but the clinical relevance seems small.

See also 'Proton pump inhibitors + Penicillins', below, for case reports of glossitis, stomatitis and a black tongue with lansoprazole and antibacterial regimens including metronidazole.

- David FL, Da Silva CMF, Mendes FD, Ferraz JGP, Muscara MN, Moreno H, De Nucci G, Pedrazzoli J. Acid suppression by omeprazole does not affect orally administered metronidazole bioavailability and metabolism in healthy male volunteers. *Aliment Pharmacol Ther* (1998) 12, 349–54.
- Jessa MJ, Goddard AF, Barrett DA, Shaw PN, Spiller RC. The effect of omeprazole on the pharmacokinetics of metronidazole and hydroxymetronidazole in human plasma, saliva and gastric juice. *Br J Clin Pharmacol* (1997) 44, 245–53.

Proton pump inhibitors + Penicillins

Esomeprazole, lansoprazole and omeprazole do not alter the pharmacokinetics of amoxicillin, and omeprazole does not alter bacampicillin bioavailability. Isolated reports describe glossitis, stomatitis and/or black tongue in a small number of patients when treated with lansoprazole and antibacterials, which included amoxicillin, clarithromycin and metronidazole.

Clinical evidence and mechanism

(a) Pharmacokinetic interactions

A study in 12 healthy subjects found no significant changes in the pharmacokinetics of **amoxicillin** 1 g twice daily when it was given with **lansoprazole** 30 mg twice daily and clarithromycin 500 mg twice daily for 4 days.¹ Other randomised, crossover studies in a total of 36 healthy subjects also found no changes in the bioavailability or half-life of **amoxicillin** 1 g twice daily when it was given with clarithromycin 500 mg twice daily and either **esomeprazole** 20 mg twice daily or 40 mg once daily for 7 days.²

In other studies **omeprazole** caused a few small changes in the pharmacokinetics of **bacampicillin** and **amoxicillin**, but their bioavailabilities were not reduced,³⁻⁵ and the use of **amoxicillin** with **omeprazole** had a synergistic effect on *Helicobacter pylori* eradication.⁴ Similarly, in another study, **omeprazole** 40 mg twice daily for 5 days did not affect the pharmacokinetics of amoxicillin 750 mg twice daily for 5 days, although the mean serum concentration of omeprazole was 12% lower and intragastric pH was slightly lower with the combination than with omeprazole alone. This was felt to be partly due to suppression of *H. pylori*.⁶

(b) Stomatitis and similar adverse effects

Six cases of glossitis, stomatitis and/or black tongue were reported to the Sicilian Regional Pharmacovigilance Centre in patients on **lansoprazole**, when combined with antibacterials used to treat *H. pylori* infections. All 6 patients had been given daily doses of **lansoprazole** 60 mg with clarithromycin 1 g and either metronidazole 1 g (3 patients) or **amoxicillin** 2 g (3 patients) for one week, after which the antibacterials were stopped. The **lansoprazole** continued at 30 mg for periods of up to 3 weeks. The glossitis (1 patient), black tongue (3 patients) and stomatitis (2 patients) developed between days 2 and 19 of the courses of treatment.⁷ In one small randomised study, nine cases of glossitis occurred when **lansoprazole** was given with **amoxicillin** but none occurred with **lansoprazole** alone.⁸

Importance and management

The incidence of glossitis, stomatitis and black tongue reported with lansoprazole and antibacterials appears to be rare and no new cases appear to have been published since these reports, whereas these drug combinations are commonly used for the eradication of *H. pylori*. Just why these drugs cause these adverse effects, and whether they are due to just one drug or to an interaction is not understood. Note that the CSM in the UK have received reports of stomatitis, glossitis and a black, hairy tongue or discoloration with each of the reported drugs individually. The CSM in the UK have received reports of 4 cases of stomatitis, one case of glossitis and one case of a black hairy tongue with sole use of lansoprazole, but these are rare effects.⁹

The pharmacokinetics of amoxicillin do not appear to be affected by concurrent use of esomeprazole, lansoprazole and omeprazole, and omeprazole was not affected by amoxicillin.

Proton pump inhibitors + SSRIs

Fluvoxamine markedly inhibits the metabolism of the proton pump inhibitors lansoprazole, omeprazole and rabeprazole in those of the CYP2C19 extensive metaboliser phenotype, producing levels comparable to those in poor metabolisers. However, these increases are probably of little clinical relevance. Theoretically escitalopram may have the same effect. Omeprazole may increase escitalopram levels.

Clinical evidence*(a) Escitalopram*

Omeprazole 30 mg daily caused a 50% increase in the plasma levels of escitalopram. This is only a moderate increase, but the manufacturer suggests that caution is warranted and a dose adjustment of the escitalopram may be needed.¹

(b) Fluvoxamine

Several studies in healthy subjects have investigated the effects of fluvoxamine (a CYP2C19 inhibitor) on the metabolism of PPIs. In these studies, fluvoxamine 25 mg twice daily for 6 days had significant effects on the pharmacokinetics of three different PPIs in patients who were of the ex-

tensive CYP2C19 metaboliser phenotype (the most common phenotype) as follows:

- **Lansoprazole:** Fluvoxamine increased the AUC and elimination half-life of a single 40-mg dose of lansoprazole by 3.8-fold and 3-fold, respectively.²
- **Omeprazole:** Fluvoxamine increased the AUC, half-life and maximum plasma concentration of a single 40-mg dose of omeprazole by 6-fold, 2.6-fold and 3.7-fold, respectively.³
- **Rabeprazole:** Fluvoxamine increased the AUC, elimination half-life and maximum plasma concentration of a single 20-mg dose of rabeprazole by 2.8-fold, 2.4-fold and 2-fold, respectively.⁴

However, these pharmacokinetic changes essentially had the effect of turning the extensive metabolisers into poor metabolisers.^{2–4} In contrast, in patients who were of the CYP2C19 poor metabolisers phenotype, fluvoxamine did not have any significant effect on the pharmacokinetics of either of these three PPIs.^{2–4}

In an earlier study in 12 healthy subjects (7 extensive metabolisers and 5 poor metabolisers of CYP2C19) given fluvoxamine 10 to 50 mg daily for 7 days, with a single 20-mg dose of omeprazole on day 7, the AUC of omeprazole was increased by nearly threefold by fluvoxamine 10 to 20 mg and by over fourfold by fluvoxamine 25 to 50 mg (all subjects combined).⁵

Mechanism

All proton pump inhibitors are primarily metabolised by the cytochrome P450 isoenzyme CYP2C19, which is subject to genetic polymorphism, see 'Gastrointestinal drugs', (p.960). As fluvoxamine inhibits CYP2C19, it can increase the levels of PPIs in patients who are extensive CYP2C19 metabolisers, but does not significantly affect the metabolism of PPIs in patients who are poor metabolisers.

Importance and management

An established interaction. The increased levels of these PPIs seen in extensive metabolisers taking fluvoxamine are similar to those seen in poor metabolisers not taking fluvoxamine, and are unlikely to lead to an increase in adverse effects because of the wide therapeutic margin of PPIs.

Some studies have shown that CYP2C19 genotype is a factor in the success of PPI-based eradication regimens, as poor metabolisers of CYP2C19 appear to have higher *H. pylori* eradication rates with these regimens than extensive metabolisers.^{6,7} Therefore, treatment of *H. pylori* is likely to be more successful in patients who are extensive metabolisers and are also taking an inhibitor of CYP2C19 such as fluvoxamine (see 'Table 1.3', (p.6)). However, the addition of fluvoxamine to improve PPI-based eradication regimens is not clinically appropriate because of the risk of fluvoxamine adverse effects.

Sulfasalazine + Antibacterials

Ampicillin and rifampicin markedly reduce the colonic release of 5-aminosalicylate (the active drug) from sulfasalazine. Metronidazole appears not to interact adversely with sulfasalazine.

Clinical evidence*(a) Ampicillin*

In a study in 5 healthy subjects the conversion and release of the active metabolite of sulfasalazine, 5-aminosalicylic acid was reduced by one third when a single 2-g dose of sulfasalazine was given after a 5-day course of ampicillin 250 mg four times daily.¹

(b) Metronidazole

A study in 10 patients (7 with Crohn's disease and 5 with ulcerative colitis) taking long-term sulfasalazine 2 to 4 g daily found that no statistically significant changes in serum sulphapyridine levels occurred while they were also taking metronidazole 400 mg twice daily for 8 to 14 days.²

(c) Rifampicin (Rifampin)

A crossover trial in 11 patients with Crohn's disease receiving long-term treatment with sulfasalazine found that rifampicin 10 mg/kg daily and ethambutol 15 mg/kg daily reduced the plasma levels of both 5-aminosalicylic acid and sulphapyridine by about 60%.³ A similar study in patients taking sulfasalazine 1.5 g to 4 g daily found that the plasma sulphapyridine levels were reduced by 57% when patients were taking rifampicin 10 mg/kg and ethambutol 15 mg/kg daily, when compared with placebo. They also noted an increase in the erythrocyte sedimentation rate (ESR) during antibacterial treatment.⁴

Mechanism

The azo link of sulfasalazine is split by anaerobic bacteria in the colon to release sulphapyridine and 5-aminosalicylic acid, the latter being the active metabolite that acts locally in the treatment of inflammatory bowel disease. Antibacterials that decimate the gut flora can apparently reduce this conversion and this is reflected in lower plasma levels. Rifampicin also possibly increases the metabolism of the sulphapyridine.

Importance and management

Information is limited, but the interaction appears to be established. However, the extent to which these antibacterials actually reduce the effectiveness of sulfasalazine in the treatment of Crohn's disease or ulcerative colitis seems not to have been assessed, but be alert for evidence of a reduced effect if ampicillin, rifampicin or any other oral antibacterial is given. **Neomycin**, which also affects the activity of the gut microflora, has been seen to interact similarly in *animal* studies,⁵ but limited evidence suggests metronidazole does not interact.

Sulfasalazine + Cimetidine

Cimetidine does not interact with sulfasalazine.

Clinical evidence, mechanism, importance and management

In a study, 5 patients with rheumatoid arthritis were given sulfasalazine alone, and another 9 patients were given cimetidine 400 mg three times daily for 18 weeks as well as their usual sulfasalazine. On comparing the two groups, it was found that cimetidine did not affect the plasma or urinary levels of sulfasalazine and there were no changes in blood cell counts

or haemoglobin levels. It was concluded that no clinically important interaction occurs between these two drugs.¹

- Pirmohamed M, Coleman MD, Galvani D, Bucknall RC, Breckenridge AM, Park BK. Lack of interaction between sulphasalazine and cimetidine in patients with rheumatoid arthritis. *Br J Rheumatol* (1993) 32, 222–6.

Sulfasalazine + Colestyramine

Animal studies show that colestyramine can bind with sulfasalazine in the gut, thereby reducing its activity, but it is not known if this also occurs in clinical use.

Clinical evidence, mechanism, importance and management

A study in *rats* found that colestyramine binds with sulfasalazine so that the azo-bond is protected against attack by the bacteria within the gut. As a result the active 5-aminosalicylic acid is not released and the faecal excretion of intact sulfasalazine increases 30-fold.¹ It seems possible that this interaction could also occur in humans, but confirmation of this is lacking. Separating the drug dosages to prevent their admixture in the gut has proved effective with other drugs that bind with colestyramine. Standard advice is to avoid other drugs for one hour before, and 4 to 6 hours after colestyramine.

- Pieniaszek HJ, Bates TR. Cholestyramine-induced inhibition of salicylazosulphapyridine (sulfasalazine) metabolism by rat intestinal microflora. *J Pharmacol Exp Ther* (1976) 198, 240–5.

Sulfasalazine + Iron compounds

Sulfasalazine and iron appear to bind together in the gut, but whether this reduces the therapeutic response to either drug is uncertain.

Clinical evidence, mechanism, importance and management

Ferrous iron 400 mg reduced the peak serum levels of a single 50-mg/kg dose of sulfasalazine by 40% in 5 healthy subjects. The reasons are not known, but it seems likely that the sulfasalazine chelates with the **iron** in the gut and thereby interferes with its absorption.¹ The extent to which this suggested chelation affects the ability of the intestinal bacteria to split the sulfasalazine and release its locally active metabolite 5-aminosalicylic acid seems not to have been studied. Therefore the effect of this interaction on the clinical response to sulfasalazine is unclear.

- Das KM, Eastwood MA. Effect of iron and calcium on salicylazosulphapyridine metabolism. *Scott Med J* (1973) 18, 45–50.

Sulfasalazine + Zileuton

No pharmacokinetic interaction appears to occur between sulfasalazine and zileuton.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, placebo-controlled study, 14 healthy subjects were given sulfasalazine 1 g every 12 hours for 8 days, with zileuton 800 mg or a placebo every 12 hours on days 3 to 8. It was found that the pharmacokinetics of the sulfasalazine and its metabolites (sulphapyridine and *N*-acetyl sulphapyridine) were not significantly changed. The study did not directly look at the pharmacokinetics of the zileuton but the parameters measured were similar to those seen in a previous study.¹ There would seem to be no reason for special precautions if both drugs are used.

- Awni WM, Braeckman RA, Locke CS, Dubé LM, Granneman GR. The influence of multiple oral doses of zileuton on the steady-state pharmacokinetics of sulfasalazine and its metabolites, sulphapyridine and *N*-acetylsulphapyridine. *Clin Pharmacokinetics* (1995) 29 (Suppl 2), 98–104.

Hormonal contraceptives and Sex hormones

The oral contraceptives are of two main types: the **combined hormonal contraceptives** containing both an oestrogen and a progestogen (monophasic, biphasic, triphasic, or sequential), available as tablets or a patch, and the **progestogen-only contraceptives**, which are available as tablets (sometimes called 'mini' pills), parenteral preparations (implants, depot injections) and intrauterine devices.

The oestrogen most commonly used in combined hormonal contraceptives is ethinylestradiol, in a usual daily dose of 20 to 50 micrograms, although higher doses of ethinylestradiol may be used with liver enzyme-inducing drugs such as rifampicin. Mestranol (a pro-drug of ethinylestradiol) is used only rarely (daily dose 50 micrograms). The progestogens used in both combined and progestogen-only oral contraceptives are commonly those derived from 19-nortestosterone and can be subdivided into first generation (e.g. etynodiol diacetate, lynestrenol, norethisterone), second generation (levonorgestrel, norgestrel) and third generation (e.g. desogestrel, drospirenone, gestodene, norgestimate). Note that drospirenone is an analogue of spironolactone and has antiandrogenic and antimineralocorticoid effects. A patch containing ethinylestradiol and norelgestromin is also available. The progestogens used in parenteral progestogen-only contraceptives are either 19-nortestosterone derivatives (e.g. etonogestrel, norethisterone) or derived from progesterone (e.g. medroxyprogesterone acetate). Those in intra-uterine devices are 19-nortestosterone derivatives (e.g. levonorgestrel).

Combined oral preparations are most usually taken for 21 days, followed by a period of 7 days during which withdrawal bleeding occurs. Some of them include 7 inert tablets to be taken at this time so that the daily routine of taking a tablet is not broken. The combined patch is applied weekly for 3 weeks followed by a patch-free week. The oestrogenic and progestogenic components of these contraceptives act together to consistently suppress ovulation.

The progestogen-only oral contraceptives are taken continuously; the implants, injections or intra-uterine devices slowly release the progestogen over an extended period of time. They do not inhibit ovulation reliably in all cycles and probably act mainly by increasing the viscosity of the cervical mucus so that the movement of the sperm is retarded. They may also cause changes in the endometrium, which inhibit successful implantation.

Interactions

(a) Combined hormonal contraceptives

Almost all of the interactions of the hormonal contraceptives described in this publication involve the combined hormonal contraceptives. Most of the clinically important interactions with the combined hormonal contraceptives involve increased metabolism. The major route for hepatic metabolism of ethinylestradiol is hydroxylation by the cytochrome P450 isoenzyme CYP3A4, and progestogens are also substrates for this enzyme. Thus, inducers of this enzyme can increase the clearance of the contraceptive steroids and possibly increase breakthrough bleeding and decrease contraceptive efficacy (see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985). The drugs that have been shown to induce the metabolism of hormonal contraceptives are listed in 'Table 28.1', (see below). Conversely, inhibitors of CYP3A4 may

increase the incidence of adverse effects such as nausea, breast tenderness, headaches, and potentially more serious complications such as thromboembolic events, although the latter has yet to be demonstrated.

Some of the conjugated metabolites of ethinylestradiol undergo enterohepatic recirculation, and certain antibacterials are postulated to reduce this by inhibiting gut flora, thereby possibly decreasing contraceptive efficacy, although this is unproven (see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981). Low-dose combined oral contraceptives may be more susceptible to drug interactions than standard-dose or high-dose preparations, but evidence to support this is scant. When considering any pharmacokinetic interactions, it should be noted that there is a large interindividual variation in plasma levels of ethinylestradiol and progestogens.

Table 28.1 Enzyme-inducing drugs shown to reduce the efficacy and/or increase the metabolism of hormonal contraceptives

Group	Drugs
Antibacterials	Rifabutin, Rifampicin (Rifampin)
Antiepileptics	Barbiturates (e.g. phenobarbital, primidone), Carbamazepine, Phenytoin, Topiramate
Antifungals	Griseofulvin
Antivirals	Nevirapine, Protease inhibitors (e.g. nelfinavir, ritonavir)
Other drugs	Aprepitant, Modafinil, St John's wort (<i>Hypericum perforatum</i>)

(b) Progestogen-only contraceptives

There is very little direct information about interactions with the progestogen-only contraceptives (oral, parenteral, and intrauterine). It is unwise to uncritically assume that interactions known to occur with the combined oral contraceptives also occur with these. However, it seems probable that an increased risk of failure with the oral and parenteral progestogen-only contraceptives is likely with drugs that cause enzyme induction (listed in 'Table 28.1', (see above)), which results in an increased clearance of the progestogen, with an accompanying loss of efficacy. The progestogen-releasing intrauterine system is thought to have a primarily local effect, and may not be affected by enzyme-inducers (see 'Progestogen-only contraceptives + Enzyme inducers', p.1007). However, much more study is needed to clarify the situation.

(c) Emergency hormonal contraceptives

It is not known whether interacting drugs are likely to affect the emergency hormonal contraceptives, although it is common practice that women taking enzyme-inducing drugs (see 'Table 28.1', (see above)) are given an increased dosage to accommodate the increased rate of metabolism by the liver (see 'Emergency hormonal contraceptives + Enzyme inducers', p.977). The efficacy of progestogen-only emergency hormonal contracep-

tives is not affected by antibacterials that do not induce liver enzymes (see 'Emergency hormonal contraceptives + Antibacterials', p.977).

(d) *Hormone replacement therapy (HRT)*

The preparations used for HRT contain oestrogens, either alone or combined with progestogens. They differ from the hormonal contraceptives as the most commonly used oestrogens in HRT are natural oestrogens such as estradiol and conjugated oestrogens, and their dosages are generally lower than equivalent doses of ethinylestradiol used in combined hormonal contraceptives. There are only a few reports of interactions with HRT preparations, but generally they are expected to behave very much like the combined oral contraceptives.

(e) *Other preparations*

Cyproterone acetate combined with ethinylestradiol (co-cyprindiol) is intended for use in women with androgen-dependent skin conditions, but it also acts as an oral contraceptive and is therefore predicted to interact like conventional oestrogen-containing oral contraceptives (see 'Co-cyprindiol (Cyproterone/Ethinylestradiol) + Miscellaneous', p.977).

Co-cyprindiol (Cyproterone/Ethinylestradiol) + Miscellaneous

Co-cyprindiol is expected to interact with enzyme inducers in a similar manner to the combined oral contraceptives, and therefore the risk of contraceptive failure is increased. Like combined oral contraceptives, there may be rare cases of contraceptive failure with broad-spectrum antibacterials. There is some evidence that co-cyprindiol also interacts with minocycline to increase facial pigmentation.

Clinical evidence, mechanism, importance and management

Co-cyprindiol is a mixture of the anti-androgenic progestogen, cyproterone acetate 2 mg, with ethinylestradiol 35 micrograms. It is used for the treatment of acne and moderately severe hirsutism in women who may also wish to use it as an oral contraceptive, and its contraceptive efficacy is expected to be reduced by the same hepatic enzyme inducers (see 'Table 28.1', (p.975)) that interact with conventional combined oral contraceptives.¹ The precautions described in this section for the combined hormonal contraceptives with the various drugs listed in 'Table 28.1', (p.975), should therefore be followed, see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985.

Similarly, it is anticipated that the use of broad-spectrum antibacterials that do not induce liver enzymes may rarely reduce the contraceptive efficacy of co-cyprindiol and the Faculty of Family Planning and Reproductive Health Care (FFPRHC) guidance under 'Hormonal contraceptives + Antibacterials; Penicillins', p.981, should be followed. Usually these precautions (additional barrier methods) are considered unnecessary after 3 weeks of concurrent use. However, the manufacturer of co-cyprindiol says that when **tetracyclines** are being taken it is advisable to use additional non-hormonal methods of contraception (except the rhythm or temperature methods) since an extremely high degree of contraceptive protection must be provided with co-cyprindiol due to the theoretical risk of cyproterone causing feminization of a male foetus. However, they do also note that oral **tetracyclines** have not actually been shown to reduce the contraceptive efficacy of co-cyprindiol. In addition co-cyprindiol may also possibly interact with **minocycline** to accentuate facial pigmentation (see 'Tetracyclines; Minocycline + Ethinylestradiol', p.350).

The manufacturer also points out that **combined oral contraceptives** (and presumably the combined hormonal contraceptive patch) must not be taken with co-cyprindiol.¹ To do this would be analogous to doubling the ethinylestradiol dose with consequent increased risk of adverse effects. In addition, some of the progestogens in combined oral contraceptives have weak androgenic effects, which could oppose the benefits of cyproterone.

Drospirenone + Potassium-sparing drugs

Drospirenone has the potential to cause hyperkalaemia and may have additive effects with other potassium-sparing drugs.

Clinical evidence, mechanism, importance and management

Drospirenone is an analogue of spironolactone and has antimineralocorticoid and potassium-sparing effects, and therefore may increase the risk of hyperkalaemia if it is given to patients with conditions that predispose to hyperkalaemia (e.g. renal failure), and/or with potassium supplements or other drugs that may increase potassium levels such as ACE inhibitors, angiotensin II receptor antagonists, ciclosporin, heparin, NSAIDs (uncommon), potassium-sparing diuretics (such as amiloride, triamterene) and other aldosterone antagonists (such as spironolactone and eplerenone).¹⁻³ Note that the US manufacturer³ notes that hyperkalaemia did not occur in a study in which drospirenone was given to patients with mild to moderate renal impairment, or when drospirenone was given with potassium-sparing diuretics (although in 5 patients in the potassium-sparing diuretic group had a rise in potassium level of 0.33 mmol/L). Furthermore, in a study where drospirenone was given with enalapril 10 mg twice daily, no subject developed hyperkalaemia (defined as serum potassium greater

than 5.5 mmol/L). It is generally recommended that serum potassium is measured during the first cycle of treatment with drospirenone.

Emergency hormonal contraceptives + Antibacterials

There is a theoretical possibility that the emergency contraceptive efficacy of norgestrel/ethinylestradiol could be affected by antibacterials that do not induce liver enzymes, such as the penicillins and tetracyclines. The efficacy of levonorgestrel given for emergency contraception is not likely to be affected by these antibacterials.

Clinical evidence, mechanism, importance and management

(a) Combined oestrogen/progestogen

The manufacturer has stated that the efficacy of **norgestrel with ethinylestradiol (Schering PC4)** may be reduced by **ampicillin** and other antibacterials.¹ This is presumably an extrapolation from the rare cases of combined oral contraceptive failure seen with various other antibacterials that do not induce liver enzymes, which, it has been suggested, are due to reduced enterohepatic recycling of **ethinylestradiol** (see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981). However, it has been suggested that it is likely that sufficient hormone is absorbed initially for the emergency contraceptive to be effective² (it is taken as 2 doses within 12 hours of each other). Note that **rifampicin** and **rifabutin** are likely to reduce the efficacy of all forms of combined hormonal contraceptives, as they induce the metabolism of oestrogens and progestogens, see 'Hormonal contraceptives + Rifamycins', p.1001. The use of combined oestrogen/progestogen as an emergency contraceptive has been superseded by a progestogen-only preparation, as the latter is associated with a higher efficacy and less oestrogen-related adverse effects.

(b) Progestogen only

Levonorgestrel is metabolised to inactive substances before it is conjugated,³ and does not therefore undergo enterohepatic recycling of the active moiety.⁴ There is no reason to expect that its efficacy as an emergency contraceptive would be affected by antibacterials that alter gut flora and do not induce liver enzymes.⁴ No special precautions are necessary with these antibacterials. However, **rifampicin** and **rifabutin** are likely to reduce the efficacy of most forms of hormonal contraceptives, as they induce the metabolism of oestrogens and progestogens, see 'Hormonal contraceptives + Rifamycins', p.1001.

Emergency hormonal contraceptives + Enzyme inducers

The efficacy of both the progestogen-only and combined emergency hormonal contraceptive is likely to be reduced by enzyme inducers such as rifampicin and some antiepileptics.

Clinical evidence, mechanism, importance and management

The manufacturer has stated that some enzyme inducers (see 'Table 28.1', (p.975)) might reduce the efficacy of **norgestrel/ethinylestradiol (Schering PC4)**¹ [withdrawn from the UK market in 2001] and **levonorgestrel (Levonelle One Step)**² used as emergency contraceptives. Cases of failure of emergency contraceptives have been reported with '**St John's wort**', (p.1002). Various enzyme inducers have specifically been shown to decrease the levels of contraceptive steroids when used as components of

combined oral contraceptives (see individual monographs). This would also be expected when they are used as postcoital emergency contraceptives. However, it is difficult to envisage a study design that would show whether this reduced metabolism results in reduced efficacy of emergency contraception (e.g. indicators of ovulation do not necessarily indicate likely reduced efficacy).

The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit notes that there appears to be no good evidence on how to manage this interaction, but current clinical practice is to increase the contraceptive dose by approximately 50%.³ The British National Formulary recommends giving a dose of levonorgestrel 1.5 mg immediately followed by another 1.5-mg dose 12 hours later, although this is unlicensed.⁴ A copper IUD may also be used as an effective alternative.³ In the UK it is possible to buy emergency hormonal contraception without a prescription; however, it has been advised that patients taking enzyme inducers should not be supplied the emergency hormonal contraceptive but should be referred to a doctor or family planning service.^{3,5} Given the potential consequences of an unwanted pregnancy, these seem sensible precautions.

Gestrinone + Enzyme inducers

The manufacturer says that rifampicin and antiepileptics may reduce the effects of gestrinone.

Clinical evidence, mechanism, importance and management

The manufacturer suggests that **rifampicin** and **antiepileptics** (not named, but by implication those that are enzyme-inducers, see 'Table 28.1', (p.975)) can accelerate the metabolism of gestrinone thereby reducing its effects.¹ However, there appear to be no reports that this actually occurs.² Good monitoring is advisable if any of these drugs are given concurrently, with dosage adjustments if necessary.

Hormonal contraceptives + Antacids

Despite *in vitro* evidence that some antacids might reduce the availability of norethisterone acetate, evidence from healthy women indicates that no interaction occurs. This also appears to be true for ethinylestradiol and levonorgestrel.

Clinical evidence, mechanism, importance and management

An *in vitro* study found that a 1% suspension of **magnesium trisilicate** in water adsorbed about 80% of **mestranol** and 50% of **norethisterone**, but minimal amounts of **ethinylestradiol**.^{1,2} Similarly, another *in vitro* study reported reduced dissolution of **norethisterone acetate** from combined oral contraceptive tablets in the presence of **magnesium trisilicate**, **kaolin mixture**, and **aluminium hydroxide**.³ In contrast, a single dose study in 12 healthy women given a combined oral contraceptive (**ethinylestradiol** 30 micrograms and either **norethisterone acetate** 1 mg or **levonorgestrel** 150 micrograms) with **magnesium trisilicate** 500 mg and **aluminium hydroxide** 250 mg, showed that the AUC and peak levels of all three steroids were unchanged.⁴ This is in line with common experience. There do not appear to be any reports of contraceptive failure with antacids and **norethisterone acetate** or **mestranol**-containing combined oral contraceptives. No special precautions seem to be necessary.

Hormonal contraceptives + Anthelmintics

The use of praziquantel or metrifonate does not appear to alter the pharmacokinetics of combined oral contraceptives. The manufacturer of albendazole recommends that women should use effective methods of contraception because of a possible teratogenic risk.

Clinical evidence, mechanism, importance and management

(a) Albendazole

The manufacturer recommends that women taking albendazole should use effective methods of contraception during and for one month after stopping the drug.¹ This is because albendazole is teratogenic in some *animal* species.^{1,2}

(b) Metrifonate and Praziquantel

A study in 25 women with early active schistosomiasis (*S. haematobium* or *S. mansoni*) without signs of liver disease and 6 healthy women showed that neither the disease itself nor the concurrent use of antischistosomal drugs (a single 40-mg/kg dose of praziquantel, or metrifonate in three doses of 10 mg/kg at fortnightly intervals) had any effect on the plasma levels of steroids from a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 50/500 micrograms).³ Moreover, in another study there was no evidence that women with early active schistosomiasis without signs of liver disease were at any greater risk of hepatic impairment while using combined oral contraceptives.⁴ No special precautions would therefore appear necessary in women with early active schistosomiasis taking oral contraceptives and praziquantel or metrifonate. Note that oral contraceptives are considered contraindicated in schistosomiasis with liver involvement.

Hormonal contraceptives + Antibacterials; Cephalosporins

A few anecdotal cases of combined oral contraceptive failure have been reported with cefalexin, cefalexin with clindamycin, and unspecified cephalosporins. The interaction (if such it is) appears to be very rare indeed.

Clinical evidence

Two pregnancies were attributed to the use of cephalosporins (unspecified) and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (61 cases were attributed to other antibacterials).¹ One case of contraceptive failure has been attributed to **cefalexin**,² and one to **cefalexin** used with clindamycin.³ In a case-control study, 356 women were who had received oral contraceptives and antibacterials (said to be cephalosporins, penicillins, tetracyclines) were identified over a 5-year period in 3 dermatological practices. The contraceptive failure rate in these women (1.6% per year; 2 pregnancies occurred in women taking a cephalosporin and 3 in women taking minocycline) was indistinguishable from the failure rate seen in control patients taking oral contraceptives and no antibacterials (1% per year).⁴

Mechanism

Suppression of intestinal bacteria, which results in reduced enterohepatic recirculation of ethinylestradiol and a fall in serum levels, is the suggested

explanation for any interaction (see 'Hormonal contraceptives and sex hormones', (p.975)). Note that broad-spectrum antibacterials do not affect progestogens, as their metabolites are inactive.⁵

Importance and management

The interaction between the combined hormonal contraceptives and cephalosporins that are summarised here are all that have been identified in the literature. These interactions are not adequately established and the whole issue remains very controversial.⁵ Bearing in mind the extremely wide use of both groups of drugs, any increased incidence of contraceptive failure above that normally seen is clearly very low indeed. On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. For this reason, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that patients taking antibacterials that do not induce liver enzymes should use a second form of non-hormonal contraception, such as condoms, while taking a short course of less than 3 weeks of a cephalosporin, and also for 7 days after the antibiotic has been stopped. This advice applies to both the oral and patch form of the combined contraceptive.⁵ For further comment and advice see also 'Hormonal contraceptives + Antibacterials; Penicillins', p.981.

Note that antibacterials that do not induce liver enzymes do not affect the reliability of the **progestogen-only contraceptives**, see 'Progestogen-only contraceptives + Antibacterials', p.1007, or the **progestogen-only emergency hormonal contraceptive**, see 'Emergency hormonal contraceptives + Antibacterials', p.977.

Hormonal contraceptives + Antibacterials; Macrolides

The macrolides clarithromycin, dirithromycin, roxithromycin and telithromycin appear unlikely to cause combined hormonal contraceptive failure. Erythromycin is also not considered to cause failure of combined hormonal contraceptives, but isolated anecdotal cases have been reported. An isolated case has also been reported with spiramycin.

Clinical evidence

(a) Clarithromycin

Ten women taking a combined oral contraceptive (**ethinylestradiol** with **levonorgestrel** or **desogestrel**) showed a very slight but not statistically significant rise in serum **ethinylestradiol** levels while taking clarithromycin 250 mg twice daily for 7 days. No changes in **levonorgestrel** levels occurred, but levels of the active metabolite of desogestrel were increased. Ovulation did not occur (progesterone levels remained suppressed, and FSH and LH levels were reduced). These hormonal changes suggest that clarithromycin may even *increase* the efficacy of combined oral contraceptives.¹

(b) Dirithromycin

Fifteen women taking a triphasic combined oral contraceptive (**ethinylestradiol/norethisterone**) were given dirithromycin 500 mg daily for 14 days starting on day 21 of the cycle. A small but statistically significant decrease of 7.6% occurred in the mean **ethinylestradiol** AUC, but no woman ovulated (as assessed by ultrasound and ovarian hormone levels).²

(c) Erythromycin

Isolated cases of contraceptive failure have been attributed to erythromycin, and two pregnancies were attributed to the use of erythromycin and an oral contraceptive (unspecified) in the adverse reactions register of the

CSM in the UK for the years 1968 to 1984 (61 cases were attributed to other antibacterials).³ Another survey of oral contraceptive failure identified 1 failure due to erythromycin (48 of 209 pill failures were attributed to antibacterials),⁴ and break-through bleeding due to erythromycin has also been described in 2 cases.⁵ Conversely, in 2 studies of contraceptive failures in dermatology patients, no pregnancies were identified in a total of 74 women taking erythromycin and an oral contraceptive.^{6,7}

(d) Roxithromycin

While taking roxithromycin 150 mg twice daily, the anti-ovulatory effects of a triphasic combined oral contraceptive (**ethinylestradiol/levonorgestrel**) remained unchanged during one cycle in 21 healthy women. Efficacy was measured by monitoring ovulation, which was assessed by ultrasound and progesterone levels.⁸

(e) Spiramycin

One case of contraceptive failure has been attributed to concurrent treatment with spiramycin.⁹

(f) Telithromycin

Telithromycin 800 mg once daily for 10 days had no effect on the pharmacokinetics of **ethinylestradiol**, but increased the plasma levels of **levonorgestrel** in 38 healthy women taking a triphasic combined oral contraceptive. None of the women ovulated, as assessed by progesterone levels.¹⁰

Mechanism

The macrolides such as erythromycin might possibly be expected to suppress the bacteria responsible for the enterohepatic recycling of ethinylestradiol, but good evidence that this is clinically important is scant (see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981). Erythromycin, and to a lesser extent the other macrolides discussed here, also inhibit the cytochrome P450 isoenzyme CYP3A4, which is responsible for the metabolism of the contraceptive steroids. Therefore they might be expected to increase rather than reduce contraceptive efficacy. This would be expected to offset any possible reduced enterohepatic recycling.

Importance and management

Information about erythromycin is very limited, but the fact that there are only isolated reports of pregnancies with this drug, coupled with its known enzyme-inhibiting properties, suggest that it is unlikely to cause contraceptive failure. The UK Family Planning Association considered that it was almost certain that erythromycin did not interact with combined oral contraceptives.¹¹ Information on the other macrolides seems to be limited to the studies cited, on the basis of which no interaction appears to be likely with clarithromycin, roxithromycin and telithromycin. Dirithromycin also appears unlikely to cause oral contraceptive failure. No cases of contraceptive failure with these newer macrolides appear to have been reported. If one accepts the theory that there are an as yet unidentifiable tiny group of women for whom enterohepatic recirculation of ethinylestradiol is important, then additional contraceptive precautions should be taken. However, if one tends to the theory that the anecdotal cases of contraceptive failure with broad-spectrum antibacterials are indistinguishable from the normal accepted failure rate, no special precautions are necessary. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of antibacterials with hormonal contraceptives. Although they recognise that there is poor evidence for contraceptive failure with the macrolides, they recommend that additional contraceptives, such as condoms, should be used for short courses of antibacterials, see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981, for more detailed information. This advice has usually been applied to only broad-spectrum antibacterials that do not induce liver enzymes, but the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be 'broad-spectrum', and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes, which would include the macrolides.¹² This applies to both the oral and the patch form of the combined hormonal contraceptive. Note that antibacterials that do not induce liver enzymes do not affect the reliability of the **progestogen-only contraceptives**, see 'Progestogen-only contraceptives + Antibacterials', p.1007), or the **emergency hormonal contraceptive**, see 'Emergency hormonal contraceptives + Antibacterials', p.977.

For a discussion of the adverse hepatic interaction between oral contraceptives and the macrolide troleandomycin, see 'Hormonal contraceptives or HRT + Antibacterials; Troleandomycin', p.984.

Hormonal contraceptives + Antibacterials; Metronidazole

Isolated cases of combined oral contraceptive failure have been reported with metronidazole. The interaction (if such it is) appears to be very rare indeed. In a controlled study, metronidazole did not affect contraceptive steroid levels.

Clinical evidence, mechanism, importance and management

In 10 women taking a combined oral contraceptive metronidazole 400 mg three times daily for 6 to 8 days had no effect on the AUC of **ethinylestradiol** and **norethisterone**. However, 2 of the 10 women had a rise in plasma progesterone levels suggesting that ovulation may have occurred. One of a further 15 women taking metronidazole and a combined oral contraceptive also appeared to ovulate. Of the 3 women who ovulated one also ovulated during a cycle while not taking metronidazole.¹ Another similar study in 10 women found that none ovulated while taking metronidazole and a combined oral contraceptive (**ethinylestradiol/norethisterone**).²

Only 3 reports of pregnancies were identified in women who took metronidazole and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984.³ A survey of oral contraceptive failure identified one failure due to metronidazole (48 of a total of 209 cases were attributed to antibacterials),⁴ and a follow-up study identified one further case.⁵ Another survey⁶ found one contraceptive failure in a woman taking metronidazole, but she was also taking **doxycycline** (see 'Hormonal contraceptives + Antibacterials; Tetracyclines', p.983). It is possible that these cases represent chance associations.

The interaction between metronidazole and combined oral contraceptives is not established, and the whole issue of any interaction with broad-spectrum antibacterials remains very controversial. Bearing in mind the extremely wide use of both metronidazole and combined oral contraceptives, any increased incidence of contraceptive failure above that seen in general usage is clearly very low indeed. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of antibacterials with combined hormonal contraceptives. Although they recognise that there is poor evidence for contraceptive failure, they recommend that additional form of contraception, such as condoms, should be used for short courses of antibacterials, see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981, for more detailed information. This applies to both the oral and the patch form of the combined contraceptive. This advice has usually been applied to only broad-spectrum antibacterials that do not induce liver enzymes but the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be 'broad-spectrum', and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes, which would include metronidazole.⁷

Note that antibacterials that do not induce liver enzymes do not affect the reliability of the **progestogen-only contraceptives**, see 'Progestogen-only contraceptives + Antibacterials, p.1007, or the progestogen-only **emergency hormonal contraceptive**, see 'Emergency hormonal contraceptives + Antibacterials', p.977.

Hormonal contraceptives + Antibacterials; Miscellaneous

One or two cases of combined oral contraceptive failure have been reported in patients given **chloramphenicol**, **clindamycin** (used with **cefalexin**), **dapsone**, **fusidic acid**, **isoniazid**, **nifurtoinol** and **nitrofurantoin**. These isolated cases are anecdotal and unconfirmed, and the interaction (if such it is) appears to be very rare indeed. The combination of **aminosalicylic acid**, **isoniazid** and **streptomycin** does not appear to affect contraceptive efficacy.

Clinical evidence, mechanism, importance and management

One woman taking a combined oral contraceptive was briefly reported to have developed breakthrough bleeding and to have become pregnant while taking **chloramphenicol**.^{1,2} One or two cases of contraceptive failure have been briefly attributed to **clindamycin** (used with **cefalexin**),³ **dapsone**,³ **fusidic acid**,⁴ **isoniazid**,^{3,5} **nifurtoinol**⁶ and **nitrofurantoin**.^{3,6} Breakthrough bleeding, due to **clindamycin** in one case and **chloramphenicol** in another case, have also been reported.⁷ Conversely, no evidence of ovulation or of changes in plasma **ethinylestradiol** and **norethisterone** levels were seen in a study of 8 women taking a combined oral contraceptive with **aminosalicylic acid**, **isoniazid** and **streptomycin**.⁸

The interactions between the oral contraceptives and antibacterials summarised here are all that have been identified in the literature involving the drugs cited. These interactions are not established, and given the few anecdotal cases with each drug, could just be coincidental. With **isoniazid** in particular, there is evidence that the drug does not cause contraceptive failure when used in combination antitubercular therapy (without rifampicin). On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. For this reason, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that women taking combined hormonal contraceptives should routinely use an additional form of contraception, such as condoms, while taking a short course of antibacterials that do not induce liver enzymes, and for 7 days after the antibiotic has been stopped.⁹ This advice applies to both the oral and patch form of the combined hormonal contraceptives. For further details of this advice see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981. Although this advice has previously been applied to only broad-spectrum antibacterials that do not induce liver enzymes, the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be 'broad-spectrum', and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes.⁹

Note that antibacterials that do not induce liver enzymes do not affect the reliability of the **progestogen-only contraceptives**, see 'Progestogen-only contraceptives + Antibacterials, p.1007, or the progestogen-only **emergency hormonal contraceptive**, see 'Emergency hormonal contraceptives + Antibacterials', p.977.

Hormonal contraceptives + Antibacterials; Penicillins

Combined oral contraceptive failure has been attributed to ampicillin, amoxicillin, flucloxacillin, oxacillin, phenoxymethylpenicillin, pivampicillin and talampicillin. However, the interaction (if such it is), appears to be very rare. Controlled studies have not shown any effect of ampicillin on contraceptive steroid levels and ovarian suppression.

Clinical evidence

A case report describes 3 women taking an oral contraceptive who became pregnant when given **ampicillin**.¹ One woman had two unwanted pregnancies while taking a combined oral contraceptive (**ethinylestradiol/norethisterone**). On both occasions conception occurred when she was being treated with **ampicillin** for tonsillitis.² Another woman taking **ethinylestradiol/norethisterone** for 5 years with no history of breakthrough bleeding, lost a quantity of blood similar to a normal period loss within a day of starting to take **ampicillin** (exact dose unknown). There was no evidence of diarrhoea or vomiting in either case.² Two other case reports attributed contraceptive failure to oxacillin,³ and to an intramuscular injection of **benethamine penicillin, procaine penicillin and benzylpenicillin**.⁴

The use of a penicillin (unspecified) was implicated in 32 pregnancies in women taking an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (a further 31 cases were attributed to other antibacterials).⁵ In an earlier review, the penicillins in 15 cases of contraceptive failure were named as **ampicillin** (alone or with fusidic acid, tetracycline or **flucloxacillin**), **amoxicillin, talampicillin, phenoxymethylpenicillin** (one also with **oxytetracycline**) and 'penicillin'.⁶ A survey of contraceptive failure described failures due to **amoxicillin** (16 cases), **flucloxacillin, phenoxymethylpenicillin, pivampicillin** (5 cases) and **amoxicillin with phenoxymethylpenicillin** (1 case),⁷ and a follow-up survey identified 9 further cases involving **amoxicillin** and one with 'penicillin'.⁸ Another similar survey described a total of 17 cases with **amoxicillin** and 5 cases with 'penicillin',⁹ and a follow-up survey identified 8 further cases with **amoxicillin** and 1 case with 'penicillin'.¹⁰

In contrast, 3 controlled studies have provided evidence that **ampicillin** does not alter the plasma levels of contraceptive steroids nor reduce their anti-ovulatory effects.^{11–13} In the first study, **ampicillin** 250 mg four times daily for 16 days was given to women taking **ethinylestradiol/etonogestrel**. No women ovulated, as assessed by FSH, LH and progesterone levels. Two women had breakthrough bleeding while receiving **ampicillin**, and one had spotting while receiving placebo.¹¹ In another study in 7 patients and 6 healthy women, **ampicillin** 500 mg three times daily for 8 days had no significant effect on the plasma levels of **ethinylestradiol and levonorgestrel**. However, one woman had a large fall in **ethinylestradiol** levels. Despite this, none of the women ovulated, as assessed by progesterone levels.¹² The third study in 6 women found that **ampicillin** 1 g twice daily had no effect on the plasma levels of **ethinylestradiol and norethisterone**, and ovulation did not occur.¹³ A crossover study involving 16 healthy women also found that a 10-day course of **amoxicillin** 875 mg twice daily did not affect **etonogestrel** or **ethinylestradiol** released from the *NuvaRing* vaginal contraceptive ring.¹⁴

Mechanism

Not understood. The oestrogen component of the contraceptive undergoes enterohepatic recirculation (i.e. it is repeatedly secreted in the bile as sulfate and glucuronide conjugates, which are hydrolysed by the gut bacteria before reabsorption). One idea is that if these bacteria are suppressed by the use of an antibacterial, the steroid conjugates are not hydrolysed and are therefore only poorly reabsorbed, resulting in lower than normal concentrations of circulating oestrogen in some women. This may result in inadequate suppression of ovulation.⁶ However, although the penicillins reduce *urinary* oestriol secretion in pregnant women,^{15–19} no marked changes in *serum* ethinylestradiol levels have been found in controlled studies in women taking an oral contraceptive with ampicillin or any other broad-spectrum antibacterial (see 'tetracyclines', (p.983), 'macrolides', (p.979), 'quinolones', (p.982)). It may be that the enterohepatic recirculation of ethinylestradiol is not clinically important: note that women with an ileostomy have normal serum contraceptive steroid levels.²⁰ Alternatively, it may be that the proportion of women for whom enterohepatic recirculation is important is extremely small.²⁰ The progestogens do not take part in enterohepatic recirculation in their active forms.

Importance and management

The interaction between combined hormonal contraceptives and penicillins is inadequately established and controversial. Almost all of the evidence is anecdotal with no controls. The total number of failures is extremely small when viewed against the number of women worldwide using combined hormonal contraceptives (estimated at 70 million in 1996 by WHO²¹), so most women are apparently not at risk.

On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. For this reason, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that women taking combined hormonal contraceptives should routinely use a second form of contraception, such as condoms, while taking a short course of less than 3 weeks of an antibacterial,²² and for 7 days after the antibacterial has been stopped.²² In addition, the FFPRHC recommends that if fewer than 7 active pills are left in the pack after the antibacterial has been stopped, the new packet should be started without a pill-free break, omitting any of the inactive tablets. For patients using the combined contraceptive patch, if the 7 days after the antibacterial has been stopped runs into the usual 7 day patch-free period, a new patch should be applied when it is due to be changed and the patch-free week delayed by 7 days.²²

Although this advice has previously only been applied to broad-spectrum antibacterials that do not induce liver enzymes the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be 'broad-spectrum', and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes, which would include penicillins.²² However, others contend that these instructions may confuse patients, and complicate pill taking, and could have the opposite effect of increasing the failure rate of oral contraceptives.²³

The FFPRHC also says that after 3 weeks of treatment the gut flora becomes resistant to the antibacterial. Therefore women taking a long-term antibacterial that does not induce liver enzymes (for example, for acne) no longer need additional contraceptive protection after the initial 3 weeks of concurrent use. However, if the antibacterial is changed or another antibacterial is started, additional contraceptive cover is required. Women who have already been taking long-term antibacterials that do not induce liver enzymes, who start a combined hormonal contraceptive, do not require additional contraception, unless the antibacterial is changed.²²

Note that antibacterials that do not induce liver enzymes do not affect the reliability of the **progestogen-only contraceptives**, see 'Progestogen-only contraceptives + Antibacterials', p.1007, or the progestogen-only **emergency hormonal contraceptive**, see 'Emergency hormonal contraceptives + Antibacterials', p.977.

Hormonal contraceptives + Antibacterials; Quinolones

Ciprofloxacin, moxifloxacin and ofloxacin have been shown not to affect the pharmacokinetics of combined oral contraceptives in controlled studies. No cases of contraceptive failure appear to have been reported, and ovarian suppression is not affected. The plasma levels of moxifloxacin may be modestly reduced by combined oral contraceptives.

Clinical evidence

(a) Ciprofloxacin

No ovulation occurred (as assessed by LH, FSH and estradiol levels) in 10 healthy women taking a combined oral contraceptive (**ethinylestradiol plus desogestrel, gestodene or levonorgestrel**) with ciprofloxacin 500 mg twice daily for 7 days (started on the first day of contraceptive intake). No breakthrough bleeding occurred.¹ Another study in 24 healthy women taking a combined oral contraceptive (**ethinylestradiol/desogestrel**) found that ciprofloxacin 500 mg twice daily for 10 days had no effect on the pharmacokinetics of **ethinylestradiol**. In addition, no subject ovulated, as assessed by progesterone and estradiol levels. However, 2 of the subjects were potentially ovulatory while taking a placebo instead of ciprofloxacin, as detected by an ultrasound of ovarian activity. A further 4 subjects taking ciprofloxacin and 2 taking placebo had lesser indications of ovarian activity.²

(b) Moxifloxacin

A placebo-controlled, crossover study in 29 young healthy women taking a combined oral contraceptive (**ethinylestradiol/levonorgestrel**) found that moxifloxacin 400 mg daily on cycle days 1 to 7 had no clinically relevant effect on the pharmacokinetics of either contraceptive steroid. The hormonal parameters measured (estradiol, progesterone, LH, FSH) were also unchanged by the presence of the quinolone, indicating that ovulation continued to be suppressed.³ Another study looking at the effects of combined oral contraceptives (unspecified) on the pharmacokinetics of a single 400-mg dose of moxifloxacin found that the total oral clearance of moxifloxacin was increased by 20% and its AUC and maximum plasma concentrations were reduced by approximately 15%. This was not considered to be clinically significant except in cases of borderline sensitivity of the bacteria to the drug.⁴

(c) Ofloxacin

Ofloxacin had no effect on the suppression of ovulation in 19 women taking a combined oral contraceptive (**ethinylestradiol/levonorgestrel**). In

this placebo-controlled, crossover study, two courses of ofloxacin 200 mg twice daily for 7 days were given on days 1 to 7 of two consecutive contraceptive cycles. Ovulation was assessed by ultrasound of the ovaries, and by measuring FSH, estradiol and progesterone levels. Four of the women showed signs of ovarian activity in both the placebo and ofloxacin cycles.⁵

Mechanism

The fluoroquinolones are broad-spectrum antibacterials, and so might be expected to interrupt the enterohepatic recirculation of ethinylestradiol,^{1,6} but the evidence that this is clinically important is scant (for a more detailed discussion of this mechanism see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981).

Importance and management

The pharmacokinetic and pharmacodynamic data indicate a likely absence of interactions between combined oral contraceptives and these quinolones. In addition, reports of cases of contraceptive failure with these or any other quinolone antibacterial seem to be lacking. No special extra contraceptive precautions would therefore seem to be necessary during concurrent use. However, if one accepts the theory that there are as yet unidentifiable tiny group of women for whom enterohepatic recirculation of ethinylestradiol is important, then it could be argued that insufficient patients were assessed in the above studies to include anyone from this group, and that the general precautions should be applied. However, if one tends to the theory that the anecdotal cases of contraceptive failure with broad-spectrum antibacterials are indistinguishable from the normal accepted failure rate, no special precautions are necessary with these quinolones, or indeed, any other antibacterials that do not induce liver enzymes. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of antibacterials with hormonal contraceptives. Although they recognise that there is poor evidence for contraceptive failure, they recommend that additional contraceptives, such as condoms, should be used for short courses of antibacterials, see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981, for more detailed information. This applies to both the oral and the patch form of the combined contraceptive. This advice has usually been applied to only broad-spectrum non-liver enzyme-inducing antibacterials but the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be 'broad-spectrum', and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes, which would include the quinolones.⁷

Note that antibacterials that do not induce liver enzymes do not affect the reliability of the **progestogen-only contraceptives**, see 'Progestogen-only contraceptives + Antibacterials, p.1007, or the progestogen-only **emergency hormonal contraceptive**, see 'Emergency hormonal contraceptives + Antibacterials', p.977.

Hormonal contraceptives + Antibacterials; Sulfonamides and/or Trimethoprim

Co-trimoxazole (sulfamethoxazole/trimethoprim) increases ethinylestradiol levels. However, there are about 15 anecdotal cases on record of contraceptive failure attributed to co-trimoxazole. There are also isolated cases of contraceptive failure attributed to various sulfonamides and trimethoprim.

Clinical evidence

(a) Co-trimoxazole

In a study in 9 women taking a triphasic combined oral contraceptive (**ethinylestradiol/levonorgestrel**) the use of co-trimoxazole (trimethoprim/sulfamethoxazole) 960 mg twice daily for 7 days starting on day 10 of the cycle increased **ethinylestradiol** plasma levels by 30 to 50%. **Levonorgestrel** plasma levels remained unaltered. No subjects ovulated, as assessed by progesterone and FSH levels: FSH levels actually decreased, indicating increased suppression of ovulation.¹

In contrast, 5 cases of oral contraceptive failure attributed to the use of co-trimoxazole were identified in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (58 cases were attributed to other antibacterials).^{2,3} Contraceptive failure has been reported in another 10 patients taking co-trimoxazole,⁴⁻⁸ and 3 further cases of contraceptive failure are attributed to the use of co-trimoxazole or trimethoprim.⁹

(b) Sulphonamides

One woman taking a combined oral contraceptive is briefly reported to have shown breakthrough bleeding and to have become pregnant while taking **sulfamethoxyypyridazine**.^{10,11} One case of a pregnancy, in a woman who had taken a sulphonamide (unspecified) and an oral contraceptive (unspecified), was identified in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (a total of 62 cases were attributed to other antibacterials).³ Three further cases of failure have been attributed to the use of **sulfafurazole (sulfisoxazole)** and a sulphonamide (unspecified).¹²

(c) Trimethoprim

Two pregnancies were attributed to the use of trimethoprim with an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (a total of 61 cases were attributed to other antibacterials).³ Another survey of oral contraceptive failure identified one pregnancy due to trimethoprim (23 of a total of 137 cases were attributed to antibacterials),⁶ while an earlier survey attributed 3 cases of contraceptive failure to either **co-trimoxazole** or trimethoprim.⁹ One case with trimethoprim and one with trimethoprim plus nitrofurantoin are briefly mentioned in another report.⁷

Mechanism

A possible explanation for the rise in ethinylestradiol levels is that co-trimoxazole inhibits the liver enzymes concerned with the metabolism of this oestrogen. Broad-spectrum antibacterials might be expected to interrupt the enterohepatic recirculation of ethinylestradiol leading to contraceptive failure, but the evidence that this is clinically important is scant (see also 'Hormonal contraceptives + Antibacterials; Penicillins', p.981).

Importance and management

Not established. The pharmacokinetic and pharmacodynamic evidence indicates that co-trimoxazole is not likely to reduce the effectiveness of combined oral contraceptives. Although there are a number of reports of contraceptive failure attributed to co-trimoxazole, these are anecdotal and unconfirmed, whereas the studies suggest *increased* contraceptive efficacy (but see below). It is possible that the cases are coincidental, and fit within the normal failure rate of combined oral contraceptives. The UK Family Planning Authority considered that it was almost certain that co-trimoxazole and sulphonamides did not interact with combined oral contraceptives.¹³ However, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of antibacterials with hormonal contraceptives. Although they recognise that there is poor evidence for contraceptive failure, they recommend that additional contraceptives, such as condoms, should be used for short courses of antibacterials, see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981, for more detailed information. This applies to both the oral and the patch form of the combined contraceptive. This advice has usually been applied to only broad-spectrum antibacterials that do not induce liver enzymes but the FFPRHC notes that some confusion has occurred over which antibacterials are considered to be 'broad-spectrum', and thus they recommend that this advice is applied to all antibacterials that do not induce liver enzymes, which would include co-trimoxazole, sulfonamides and trimethoprim.¹⁴

Note that antibacterials that do not induce liver enzymes do not affect the reliability of the **progestogen-only contraceptives**, see 'Progestogen-only contraceptives + Antibacterials', p.1007, or the progestogen-only

emergency hormonal contraceptive, see 'Emergency hormonal contraceptives + Antibacterials', p.977.

Aside from contraceptive failure the other aspect of using this drug combination is the potential for increased ethinylestradiol levels. The main concern is whether this would increase the risk of adverse effects of the oestrogen, but there are no data on the clinical significance of these modest (30 to 50%) increases on various adverse effects. It could be argued that a 40% increase would turn a standard-strength contraceptive (35 micrograms) into a high-dose contraceptive (50 micrograms). However, early studies showed that the interindividual variation in ethinylestradiol pharmacokinetics was greater than this anyway.² Further study is needed on this issue.

Hormonal contraceptives + Antibacterials; Tetracyclines

Contraceptive failure has been attributed to doxycycline, lymecycline, minocycline, oxytetracycline and tetracycline in about 40 reported cases, 7 of which specified long-term antibacterial use, but the interaction (if such it is) appears to be rare. Controlled studies have not shown any effect of tetracycline or doxycycline on contraceptive steroid levels.

Clinical evidence

A woman taking a combined oral contraceptive (**ethinylestradiol** with **levonorgestrel**) became pregnant, the evidence indicating that she had conceived during or in the week after taking **tetracycline** 500 mg every 6 hours for 3 days and then 250 mg every 6 hours for 2 days. There was no evidence of either nausea or vomiting, which might have been an alternative explanation for the contraceptive failure.¹ A case of breakthrough bleeding attributed to **tetracycline** was also mentioned in this report.¹ Two other case reports describe pregnancies in women taking a combined oral contraceptive and long-term **tetracycline** 500 mg daily² or long-term **minocycline** 100 mg daily.³ The latter also briefly mentions 2 cases of contraceptive failure with **doxycycline**.³

Twelve reports of pregnancies were attributed to the use of tetracyclines (unspecified) and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (51 cases were attributed to other antibacterials).⁴ In an earlier report, the tetracyclines in 6 cases were named as **tetracycline** and **oxytetracycline**.⁵ A survey of oral contraceptive failure identified 7 failures due to **doxycycline**, **lymecycline** or **minocycline** (37 of a total of 163 cases were attributed to antibacterials),⁶ and a follow-up survey identified 3 further cases involving short courses of **tetracycline**.⁷ Similar surveys identified 5 contraceptive failures with **tetracycline**,⁸⁻¹⁰ and 2 failures with **doxycycline**.⁹ Breakthrough bleeding was attributed to **doxycycline** or **oxytetracycline** in 3 other cases.¹¹

In a dermatological practice, of 124 women taking an oral contraceptive and antibacterials (mostly tetracyclines or erythromycin), 2 became pregnant, with a calculated failure rate of 1.2%. One patient was taking long-

term **minocycline** and **ethinylestradiol/norethisterone**, and one had taken a 5-day course of **oxytetracycline** while taking **ethinylestradiol/levonorgestrel**. This failure rate was reported to be sixfold higher than a normal failure rate of 0.2%.¹² However, a rate of 0.2% represents perfect rather than typical use of combined oral contraceptives. In a similar analysis,¹³ one of 34 women became pregnant after taking long-term **tetracycline** and **ethinylestradiol/norethisterone**. This failure rate of 1.4% was not considered to be significantly different from a normal failure rate of 0.27%. In a larger, better-designed, case-control study, 356 women were identified who had received oral contraceptives and antibacterials (cephalosporins, penicillins, tetracyclines) over a 5-year period in 3 dermatological practices. The failure rate in these women (1.6% per year, 3 pregnancies occurred in women taking long-term **minocycline** and 2 taking a cephalosporin) was indistinguishable from the failure rate seen in control patients taking oral contraceptives and no antibacterials (1% per year).¹⁴

Moreover, two controlled studies have shown that tetracyclines do not affect the pharmacokinetics of contraceptive steroids.^{15,16} In the first, in 7 healthy women taking a combined oral contraceptive, **tetracycline** 500 mg every 6 hours for 10 days had no effect on the AUC of **ethinylestradiol** and **norethisterone** (measured on days 1, 5 and 10).¹⁵ Similarly, in 23 healthy women taking a combined oral contraceptive, **doxycycline** 100 mg twice daily for 7 days had no effect on the serum levels of **ethinylestradiol** and **norethisterone** (measured on days 5 to 7). In addition, ovulation did not occur, as assessed by progesterone levels, but 2 women did experience breakthrough bleeding.¹⁶ A further study has found no pharmacokinetic interaction between a combined contraceptive patch and **tetracycline**.¹⁷ A crossover study involving 16 healthy women also found that a 10-day course of **doxycycline** did not affect **etonogestrel** or **ethinylestradiol** released from the *NuvaRing* vaginal contraceptive ring.¹⁸

The pharmacokinetics of **tetracycline** (4-hour AUC and peak level) were not significantly different between 7 healthy women taking a combined oral contraceptive (**ethinylestradiol/norethisterone**) and 4 healthy women not taking any medication.¹⁵ For reports of facial pigmentation due to **minocycline** and **ethinylestradiol**, see 'Tetracyclines; Minocycline + Ethinylestradiol', p.350.

Mechanism

Not understood. If an interaction occurs, suppression of intestinal bacteria resulting in a fall in enterohepatic recirculation of ethinylestradiol is the usual suggested explanation, but there is no evidence that this is clinically important. For a full discussion of this mechanism, see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981.

Importance and management

The interactions between the oral contraceptives and tetracyclines summarised here are all that have been identified in the literature. Much of the evidence is anecdotal with insufficient controls (if any). These interactions are not adequately established and the whole issue remains controversial. Bearing in mind the extremely wide use of both drugs, any increase in the incidence of contraceptive failure above the accepted failure rate is clearly very low indeed. On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. For this reason, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that an additional form of contraception, such as condoms, should be used while taking a short course of antibacterials that do not induce liver enzymes, and for 7 days after the antibacterial has been stopped.¹⁹ See 'Hormonal contraceptives + Antibacterials; Penicillins', p.981, for more detailed information on how to manage this interaction.

In the case of long-term use of tetracyclines for acne, at least 7 cases of contraceptive failure have been reported. Nevertheless, in statistical terms the only well-designed case-controlled study in dermatological practice indicated that the incidence of contraceptive failure due to this interaction could not be distinguished from the general and recognised failure rate of oral contraceptives.¹⁴

The FFPRHC advise that additional contraceptive protection is not required in established users of the combined hormonal contraceptive patch taking tetracycline.¹⁹ This is in line with the findings of the study cited above.

Note that antibacterials that do not induce liver enzymes do not affect the reliability of the **progestogen-only contraceptives**, see 'Progestogen-

only contraceptives + Antibacterials, p.1007, or the progestogen-only **emergency hormonal contraceptive**, see 'Emergency hormonal contraceptives + Antibacterials', p.977.

Hormonal contraceptives or HRT + Antibacterials; Troleandomycin

Severe pruritus and jaundice have been observed in women taking oral contraceptives shortly after starting treatment with troleandomycin. One case has also been reported with oestrogens for HRT.

Clinical evidence

A report describes 10 cases of cholestatic jaundice and pruritus in women taking oral contraceptives and troleandomycin. All had been using the contraceptive for 7 to 48 months and were given the antibacterial in daily doses of 1 to 3 g. The pruritus was intense, and started within 2 to 24 days of the first dose of troleandomycin, and preceding the jaundice. In 8 of the patients the pruritus and jaundice persisted for over a month.¹ A later report and letter by the same authors describes a total of 24 cases of this reaction.^{2,3}

There are numerous other reports of this adverse reaction in a total of over 40 other women.⁴⁻¹² The adverse reactions (fatigue, anorexia, severe itching, jaundice) can begin very rapidly, sometimes even within 2 days of starting the troleandomycin, and may last up to 14 weeks or more.^{3,4,12} One report also describes a similar reaction in a 48-year-old woman taking **oestrogens** for HRT.⁴

Mechanism

Uncertain. Hepatotoxicity has been associated with the use of both types of drug, but it is not common. The reaction suggests that their damaging effects on the liver may be additive or synergistic.^{10,11} Troleandomycin may cause an increase in levels of contraceptive steroids, since it is an liver enzyme inhibitor.^{12,13}

Importance and management

A well established, well documented and clinically important interaction. The incidence is unknown. Concurrent use should be avoided. Other mac-

rolides may be suitable alternatives, but see 'Hormonal contraceptives + Antibacterials; Macrolides', p.979.

Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin

Hormonal contraceptives are less reliable during the use of phenytoin and barbiturates such as phenobarbital and primidone. Intermenstrual breakthrough bleeding and spotting can take place, and pregnancies have occurred. Controlled studies have shown that phenytoin and phenobarbital can reduce contraceptive steroid levels.

Clinical evidence

An epileptic woman taking phenytoin 200 mg and sultiame 50 mg daily (with ferrous gluconate and folic acid) became pregnant despite the regular use of a combined oral contraceptive (**ethinylestradiol/norethisterone** 50 micrograms/3 mg).¹ Since this first report in 1972, at least 33 pregnancies have been reported in the literature in women taking a range of oral contraceptives (mostly combined) and a barbiturate (such as **phenobarbital** or **primidone**) and/or phenytoin (see 'Table 28.2', (p.986)). Note that most of these cases were with a combined oral contraceptive containing at least 50 micrograms of **ethinylestradiol**. In addition, between the years 1968 to 1984, a further 25 pregnancies in women who took phenytoin and an oral contraceptive, and 20 pregnancies in women who took **phenobarbital** and an oral contraceptive were reported to in the CSM in the UK. However, it is unclear how many of these patients were receiving just the antiepileptic mentioned, since the authors note that some women were taking multiple antiepileptics (combinations not stated).² Even so, the total number of unwanted pregnancies due to this interaction is fairly large. In this report, over half the cases of contraceptive failure with antiepileptics related to high-dose combined oral contraceptives (50 micrograms of oestrogen). Three were in women taking **progestogen-only oral contraceptives**.²

In one study, breakthrough bleeding (which was regarded as loss of reliability of the contraceptive) occurred in 30 of 51 women taking a combined oral contraceptive (**ethinylestradiol/norethisterone** or **mestranol/chlormadinone**) given **phenobarbital**.³ In another study, 7 out of 11 patients taking **phenobarbital** and 1 of 2 patients taking phenytoin had breakthrough bleeding.⁴ The incidence of breakthrough bleeding was 90% with preparations containing **ethinylestradiol** 30 micrograms and 29% with preparations containing 75 micrograms of ethinylestradiol. Similarly, with preparations containing **ethinylestradiol** 50 micrograms, decreasing the dose of **norgestrel** from 500 to 125 micrograms increased breakthrough bleeding from 50% to 62%.⁴

A pharmacokinetic study in 6 women taking a combined oral contraceptive found that the AUCs of **ethinylestradiol** 50 micrograms and **levonorgestrel** 250 micrograms were lowered by 49% and 42%, respectively, by phenytoin 200 to 300 mg daily for 8 to 12 weeks.⁵ In another

study, **phenobarbital** 30 mg twice daily did not significantly alter the plasma levels of contraceptive steroids in 4 women taking combined oral contraceptives (**ethinylestradiol** with **norethisterone** or **norgestrel**), but 2 of the women did have 54% and 60% falls, respectively, in their **ethinylestradiol** levels. These 2 women had breakthrough bleeding, but ovulation suppression was maintained.⁶

Mechanism

The likeliest explanation for the unreliability and failure of oral contraceptives is that phenytoin and the barbiturates (known potent liver enzyme inducers) increase the metabolism and clearance of the contraceptive steroids from the body, thereby reducing their effects, and in some instances, allowing ovulation to occur.

Importance and management

The interactions between combined oral contraceptives and phenobarbital and phenytoin are clinically important and well documented. As primidone is metabolised to phenobarbital it would be prudent to assume that it will interact similarly. The risk of breakthrough bleeding and spotting is high (bleeding disturbances are usually regarded as an indication of reduced efficacy if cycles were previously regular⁷). However, the actual incidence of contraceptive failure when combined oral contraceptives are given with these drugs is unknown. It appears that the incidence of unintended pregnancies is quite small: in one series, a failure rate of 3.1 per 100 woman years was calculated, compared with an expected 0.7 per 100 woman years.⁸ Note that this failure rate is still less than that seen with barrier methods such as condoms.

Reliable contraception in most patients is said to be achievable with ethinylestradiol 80 to 100 micrograms daily.^{4,9,10} If these larger doses are required for good cycle control, there should be no increase in adverse effects because the enzyme-inducing effects of the antiepileptics reduce the blood levels of the steroids. However, note that many of the cases of unintended pregnancies were with products containing 50 micrograms of ethinylestradiol or more, and one review of contraceptive interactions suggested that women taking low-dose oestrogen contraceptives may not be at a greater risk of an interaction.¹¹

Nevertheless, since the personal and ethical consequences of an unplanned pregnancy can be very serious, it is important to take the necessary practical steps to reduce this increased risk. Moreover, pregnancy in women with epilepsy should ideally be planned so that therapy can be reviewed to minimise the risks of foetal malformation.⁹ In this regard, it is of concern that some surveys have shown a lack of knowledge of these interactions and their management among prescribers,¹² and the frequent use of enzyme-inducing antiepileptics with hormonal contraceptives containing less than 50 micrograms of ethinylestradiol.¹³ Almost all of the evidence cited here originates from studies with combined oral contraceptives, but the enzyme-inducing antiepileptics can also increase the metabolism of progestogens thereby reducing their efficacy, so that there is also a risk of contraceptive failure with **progestogen-only oral contraceptives**.¹⁴ This is of particular concern since progestogen-only oral contraceptives are not as effective as combined oral contraceptives. Some have suggested at least doubling the dose of the progestogen-only oral contraceptive.⁹ However, others consider that this is not an option as it tends to increase the rate of irregular bleeding (a common adverse effect of these contraceptives). They consider that progestogen-only oral contraceptives are not suitable for use in women taking enzyme-inducing antiepileptics.^{14,15} The use of an alternative, non-interacting antiepileptic drug should be considered in patients taking hormonal contraceptives. Note that 'ethosuximide', (p.987), 'gabapentin', (p.988), 'lamotrigine', (p.988), 'levetiracetam', (p.989), 'sodium valproate', (p.990), 'tiagabine', (p.990), and 'vigabatrin', (p.991) do not appear to interact with the hormonal contraceptives.

The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit have issued guidance on the use of drugs that induce liver enzyme with hormonal contraceptives:¹⁵

- Women taking **combined oral contraceptives** should use an ethinylestradiol dose of at least 50 micrograms daily. The dose may be increased further above 50 micrograms if breakthrough bleeding occurs. Omitting or reducing the pill-free interval has not been shown to reduce the risk of ovulation with liver enzyme inducers. Additional non-hormonal methods of contraception, such as condoms, should also be used by patients using combined hormonal contraceptives, both when taking the

Table 28.2 Case reports of pregnancies in women taking hormonal contraceptives with barbiturates and/or phenytoin

Antiepileptic	Oestrogen	Progestogen	Number of cases	Refs
Phenytoin + Sultiame	Ethinylestradiol 50 micrograms	Norethisterone 3 mg	1	1
Phenytoin + Primidone, Phenobarbital or Methylphenobarbital	Not stated	Not stated	7	2, 3
Primidone	Ethinylestradiol 50 or 100 micrograms	Norgestrel 0.5 mg or Megestrol 1 mg	2	4, 5
Phenytoin + Primidone or Phenobarbital	Ethinylestradiol 50 micrograms	Norgestrel 0.25 or 0.5 mg or Norethisterone 1 mg	3	4, 5
Phenytoin + Primidone or Phenobarbital + Other	Ethinylestradiol 50 micrograms	Norgestrel 0.5 mg	2	4, 5
Phenytoin + Carbamazepine	Ethinylestradiol 50 micrograms	Norgestrel 0.25 mg	1	4, 5
Primidone or Phenobarbital	Ethinylestradiol	Norgestrel	3	6
Phenobarbital or Butobarbital	Ethinylestradiol or Mestranol	Norethisterone	3	7
Phenytoin	Ethinylestradiol 100 micrograms	Dimethisterone 25 mg	1	8
Phenobarbital or Methylphenobarbital	Ethinylestradiol 50 micrograms or Mestranol 80 micrograms	Etyndiol 1 mg or Chlormadinone 2 mg	2	8
Phenytoin + Phenobarbital	Mestranol 100 micrograms	Noretynodrel 2.5 mg	1	8
Phenobarbital	Ethinylestradiol 50 micrograms	Desogestrel 75 mg	1	9
Phenytoin + Phenobarbital	Ethinylestradiol	Levonorgestrel	1	10
Phenytoin then Carbamazepine	Ethinylestradiol	Lynestrol	1	10
Phenytoin with or without other antiepileptics	Ethinylestradiol 30 or 50 micrograms or Mestranol 50 micrograms	Megestrol, Norethisterone, Etyndiol, Norgestrel or Levonorgestrel	25	11
Phenobarbital with or without other antiepileptics		Progestogen-only pill	20	11
Phenytoin	Ethinylestradiol 50 micrograms	Not stated	1	12
Phenytoin	Ethinylestradiol less than 50 micrograms	Not stated	2	13
Phenobarbital	Ethinylestradiol 35 micrograms ('back up' contraception also used)	Norgestimate 0.18 to 0.25 mg	1	14

liver enzyme inducers and for at least 4 weeks after stopping the drug. Alternatives to all forms of combined hormonal contraceptives should be considered with long-term use of liver enzyme inducers.

- The **combined contraceptive patch** may be continued in the usual manner. Using more than one patch is not recommended. Additional, non-hormonal methods of contraception, such as condoms, should also be used by patients using the combined contraceptive patch, both when taking the liver enzyme inducers and for at least 4 weeks after stopping the drug.
- The **progestogen-only implant** may be continued with *short* courses of enzyme inducers. Additional non-hormonal methods of contraception, such as condoms, should also be used by patients using the progestogen-only implant, both when taking the liver enzyme inducers and for at least 4 weeks after stopping the drug. Alternatives to the progestogen-only implant should be considered with long-term use of liver enzyme inducers.
- The **progestogen-only pill** is not recommended for use with liver enzyme inducers and alternative methods of contraception are advised.
- The effectiveness of the **progestogen-only emergency hormonal contraceptive** will be reduced in women taking liver enzyme inducers, see 'Emergency hormonal contraceptives + Enzyme inducers', p.977, for further guidance.
- **Copper or levonorgestrel-releasing intrauterine devices (IUD) and depot progestogen-only injections** may be used as alternative contraceptive methods, particularly for women requiring hormonal contracep-

tion who are likely to be taking the enzyme inducer in the long-term, as these are unaffected by liver enzyme inducers.

Hormonal contraceptives + Antiepileptics; Carbamazepine or Oxcarbazepine

Hormonal contraceptives are less reliable during treatment with carbamazepine and oxcarbazepine. Breakthrough bleeding and spotting can take place, and unintended pregnancies have occurred with carbamazepine. Controlled studies have shown that carbamazepine and oxcarbazepine can reduce contraceptive steroid levels.

Clinical evidence

(a) Carbamazepine

In a pharmacokinetic study, carbamazepine 300 to 600 mg daily reduced the AUC of **ethinylestradiol** by 42% and **levonorgestrel** by 40% in 4 women given a single dose of a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 50/250 micrograms) before and after 8 to 12 weeks of carbamazepine use.¹ Another study compared the effects of topiramate or carbamazepine on a combined oral contraceptive containing **norethisterone/ethinylestradiol** 1 mg/35 micrograms (*Ortho-Novum*). In the 10 patients who received carbamazepine 600 mg daily, the AUC of norethisterone and ethinylestradiol were reduced by 58% and 42%, respectively.²

In an early study, 6 of 12 women taking a combined oral contraceptive (**ethinylestradiol/norethisterone**) developed spotting or breakthrough bleeding while taking carbamazepine (this is regarded as a possible loss of reliability of the contraceptive).³ A similar study reported breakthrough bleeding in 4 of 6 patients taking carbamazepine and a combined oral contraceptive,⁴ and the same author later briefly reported 37 out of 59 patients had breakthrough bleeding while taking this combination.⁵

One woman taking a low-dose combined oral contraceptive (not specified) conceived 6 weeks after starting carbamazepine, initially 200 mg daily then 600 mg daily.⁶ In two other cases the failure of a combined oral contraceptive containing **ethinylestradiol** 30 micrograms has been attributed to carbamazepine.^{7,8} Six pregnancies were identified in women who took carbamazepine and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984. However, it is unclear how many of these 6 women were taking carbamazepine alone, as the authors note that some women were taking multiple antiepileptics.⁹ Two further pregnancies have been reported in women taking combined oral contraceptives and antiepileptics including carbamazepine

and phenytoin,¹⁰ and one in a woman who was switched from phenytoin to carbamazepine.¹¹

(b) Oxcarbazepine

Preliminary observations revealed that 4 of 6 women receiving oxcarbazepine had breakthrough bleeding when they were given a combined oral contraceptive containing **ethinylestradiol** 30 micrograms. This resolved in two women when they took double the dose of **ethinylestradiol**.⁵ In a pharmacokinetic study in 10 healthy women taking a triphasic combined oral contraceptive, oxcarbazepine 300 mg three times daily for 4 weeks reduced the AUCs of **ethinylestradiol** and **levonorgestrel** by 47% and 36%, respectively. Three women had menstrual bleeding disturbances.¹² Similar results were reported in a later study with oxcarbazepine 1.2 g daily and a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 50/250 micrograms).¹³ So far, no cases of unintended pregnancy have been reported.

Mechanism

The most likely explanation for these interactions is that both carbamazepine and oxcarbazepine reduce the levels of the contraceptive steroids, presumably by inducing their metabolism. This may result in loss of contraceptive efficacy.

Importance and management

The reduction in contraceptive steroid levels caused by carbamazepine and oxcarbazepine is well established. However, the actual incidence of contraceptive failure when oral contraceptives are given with these drugs is unknown. Given the few published reports, it appears that unintended pregnancies with carbamazepine are rare, and still less frequent than that seen with barrier methods such as condoms. No pregnancies have been reported in patients taking an oral contraceptive and oxcarbazepine. Nevertheless, given the personal and ethical consequences of an unwanted pregnancy, any reduction in contraceptive efficacy is of concern. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidelines on the management of patients taking liver enzyme inducers with hormonal contraceptives. These are discussed in further detail under 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985.

Hormonal contraceptives + Antiepileptics; Ethosuximide

Ethosuximide appears not to alter the efficacy of combined oral contraceptives.

Clinical evidence, mechanism, importance and management

Four pregnancies were identified in women who took ethosuximide and an oral contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984. However, the authors note that in only one of the cases reported was ethosuximide the sole antiepileptic prescribed.¹ Since ethosuximide is not an inducer of hepatic enzymes, it is likely that this one case is a chance association. Another case describes pregnancy in a woman who had been taking ethosuximide, phenytoin, and phenobarbital, with a combined oral contraceptive for 6 years.² If indeed this case does represent an interaction, the known enzyme-inducers phenytoin and phenobarbital are more likely to be implicated than ethosuximide (see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985). There do not appear to have been any pharmacokinetic or pharmacodynamic studies of the use of ethosuximide with oral contraceptives and no further case reports have been published. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions state that ethosuximide does not induce liver enzymes and causes no reduction in ethinylestradiol or progestogens.³ No special contraceptive precautions appear to be necessary on concurrent use.

Hormonal contraceptives + Antiepileptics; Felbamate

Felbamate increases the clearance of gestodene from a combined oral contraceptive but it is not known if this reduces contraceptive efficacy.

Clinical evidence, mechanism, importance and management

In a randomised, placebo-controlled study 23 healthy women were given a combined oral contraceptive (**ethinylestradiol/gestodene** 30/75 micrograms) for 3 months or more. During months 1 and 2 they were also given either felbamate in a dose of up to 2.4 g daily, or a placebo, from day 15 of month 1 to day 14 of month 2. None of the women showed any evidence of ovulation during the entire 3 months, although one had intermenstrual spotting. However, felbamate reduced the **gestodene** AUC by 42% and the **ethinylestradiol** AUC by 13%.¹ The reasons for this effect are not understood. What this change means in terms of the reliability of the oral contraceptive is not known, but some reduction in its efficacy might be expected. More study is needed to assess the clinical relevance and to see whether other progestogens are similarly affected.

1. Saano V, Glue P, Banfield CR, Reidenberg P, Colucci RD, Meehan JW, Haring P, Radwanski E, Nomeir A, Lin C-C, Jensen PK, Affrime MB. Effects of felbamate on the pharmacokinetics of a low-dose combination oral contraceptive. *Clin Pharmacol Ther* (1995) 58, 523-31.

Hormonal contraceptives + Antiepileptics; Gabapentin

In a controlled study, gabapentin did not alter the levels of ethinylestradiol or norethisterone.

Clinical evidence, mechanism, importance and management

Gabapentin 400 mg every 8 hours for 7 days had no effect on the AUC of **ethinylestradiol** or **norethisterone** in 13 healthy women taking a combined oral contraceptive (**ethinylestradiol/norethisterone** 50 micrograms/2.5 mg). Ovulation suppression was not assessed.¹ The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions state that gabapentin does not induce liver enzymes responsible for the metabolism of contraceptive steroids and causes no reduction in ethi-

nylestradiol or progestogens.² Thus, no special contraceptive precautions appear to be required during concurrent use.

2. Faculty of Family Planning and Reproductive Health Care Clinical Effectiveness Unit. FFPRHC Guidance: Drug interactions with hormonal contraception. April 2005. Available at: <http://www.ffprhc.org.uk/admin/uploads/DrugInteractionsFinal.pdf> (accessed 23/08/07).

Hormonal contraceptives + Antiepileptics; Lamotrigine

One study suggests that lamotrigine does not alter the contraceptive efficacy or plasma levels of combined oral contraceptives. Another study found a slight reduction in levonorgestrel levels but no evidence of ovulation, however, based on this, the manufacturer says that the possibility of reduced contraceptive efficacy cannot be ruled out.

Hormonal contraceptives may reduce the levels of lamotrigine, which can lead to a decrease in seizure control.

Clinical evidence and mechanism

(a) Contraceptive efficacy

Preliminary results of a study showed that lamotrigine 150 mg daily for 10 to 14 days had no significant effect on the mean plasma levels of **ethinylestradiol** and **levonorgestrel** in women taking a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 30/150 micrograms). No ovulation occurred (assessed by progesterone levels) and no changes in menstrual pattern were observed. Furthermore, lamotrigine did not induce hepatic enzymes (assessed by 6- β -hydroxycortisol excretion).¹ A study by the manufacturer in 16 healthy women taking the combined oral contraceptive *Microgynon 30* (**ethinylestradiol/levonorgestrel** 30/150 micrograms) and given lamotrigine (titrated to 300 mg daily) found a slight but non-significant reduction in the AUC and the maximum serum concentration of **levonorgestrel** of 19% and 12%, respectively, compared with hormone levels before starting lamotrigine. **Ethinylestradiol** levels were not affected. Significant increases in FSH and LH were also seen, although there was no increase in the levels of progesterone, indicating that ovulation probably did not occur. Intermenstrual bleeding was reported in 32% of subjects when receiving lamotrigine.²

(b) Lamotrigine efficacy

A case report describes 7 women in whom lamotrigine plasma levels were decreased by 41 to 64% by combined oral contraceptives (**ethinylestradiol** with **desogestrel** or **norethisterone**). Five had increased seizure frequency or recurrence of seizures after starting an oral contraceptive, and two had lamotrigine adverse effects on stopping the oral contraceptive. It was suggested that hormonal contraceptives can increase the glucuronidation of lamotrigine, thereby increasing its clearance.³ A subsequent study found a more than 50% reduction in lamotrigine levels in women taking the combined oral contraceptive.⁴ A study by the manufacturer in 16 healthy women taking the combined oral contraceptive *Microgynon 30* (**ethinylestradiol/levonorgestrel** 30/150 micrograms) and lamotrigine (titrated to 300 mg daily) found that the maximum serum concentration and AUC of lamotrigine were decreased by approximately 39% and 52%, respectively, when compared with lamotrigine alone.² A further study in 8 epileptic women found that lamotrigine plasma concentrations varied with hormonal contraceptive monthly cycles. The median lamotrigine plasma concentration was 15% higher during the hormonal contraceptive washout week than during the phase of hormonal contraceptive intake, although there was a wide interpatient variability.⁵

Another study in 45 women found that a reduction in lamotrigine levels occurred with **ethinylestradiol** (given as a combined hormonal contraceptive in 11 subjects and a vaginal ring also containing etonogestrel in one subject) compared with 18 women using no hormonal contraception. However, lamotrigine serum concentrations were not affected in 16 women using a progestogen-only contraceptive (4 using oral **desogestrel** or **norethisterone**, 8 using subdermal **etonogestrel** or **levonorgestrel**, 1 using depot **medroxyprogesterone**, and 3 using intrauterine **levonorgestrel**).⁶

Importance and management

Based on the small reduction in levonorgestrel levels the manufacturer of lamotrigine suggests that the possibility of decreased contraceptive efficacy cannot be ruled out, and advises that the use of non-hormonal contraceptives is preferable. If a hormonal contraceptive is used as the only form of contraception, they advise that women should be alert for signs of breakthrough bleeding, which may be a sign of reduced contraceptive efficacy.⁷ Note that the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of lamotrigine in patients taking hormonal contraceptives in response to the manufacturer's guidance. They found no evidence of reduced contraceptive effectiveness in patients taking combined oral contraceptives (tablets, patch or vaginal ring) or progestogen-only contraceptives (tablets, implant, injectable or intrauterine system) with lamotrigine. They concluded that there is no good evidence that non-hormonal methods of contraception are preferable in patients taking lamotrigine.⁸

Lamotrigine can be started as normal in patients already taking hormonal contraceptives.⁷ In those already taking lamotrigine with inducers of lamotrigine glucuronidation, such as phenytoin and carbamazepine, changes in the dose of lamotrigine are unlikely to be necessary when starting hormonal contraceptives. However, for women already taking lamotrigine and *not* taking inducers of lamotrigine glucuronidation, the maintenance dose of lamotrigine may need to be increased by as much as twofold, according to clinical response when hormonal contraceptives are started. If this group of patients stop taking an oral contraceptive, the lamotrigine dose should be reviewed (and may need to be decreased by as much as 50%) to reduce the risk of adverse effects occurring.^{7,8} Note that apart from interindividual variations, lamotrigine plasma concentrations may vary with the hormonal contraceptive monthly cycles.⁵ Patients should also be advised that an increase in seizure frequency may occur when the combined oral contraceptive is started.⁸

Hormonal contraceptives + Antiepileptics; Levetiracetam

Levetiracetam appears not to alter the contraceptive efficacy and plasma levels of ethinylestradiol and levonorgestrel given as a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of a combined oral contraceptive (**ethinylestradiol/levonorgestrel**) were found not to be affected by levetiracetam 500 mg twice daily, nor was ovulation suppression altered (there were no changes in LH or progesterone levels). The pharmacokinetics of levetiracetam also remained unaffected.¹ A placebo-controlled study in 18 subjects taking a combined oral contraceptive containing **ethinylestradiol** 30 micrograms and **levonorgestrel** 150 micrograms with levetiracetam 500 mg twice daily found that levetiracetam did not affect the serum levels of either steroid or alter the contraceptive efficacy of these drugs, as measured by progesterone and LH levels.² The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of drug interactions with hormonal contraceptives

state that levetiracetam does not induce liver enzymes and causes no reduction in ethinylestradiol or progestogens.³ These findings indicate that no special or additional precautions are needed if oral contraceptives and levetiracetam are used concurrently.

Hormonal contraceptives + Antiepileptics; Pregabalin

Pregabalin does not appear to affect the pharmacokinetics or contraceptive efficacy of ethinylestradiol or norethisterone. In addition, the pharmacokinetics of pregabalin were not affected by the contraceptive steroids.

Clinical evidence, mechanism, importance and management

A study in 16 subjects found that pregabalin 200 mg every 8 hours had no effect on the pharmacokinetics of **ethinylestradiol** or **norethisterone** taken as a combined oral contraceptive (*Orthonovum*) and did not reduce the contraceptive effect as measured by progesterone levels. Neither contraceptive steroid had an effect on the pharmacokinetics of pregabalin.¹ No special contraceptive precautions therefore appear to be required during concurrent use.

1. Bockbrader HN, Posvar EL, Hunt T, Randinitis EJ. Pharmacokinetics of pregabalin and a concomitantly administered oral contraceptive show no-drug drug interaction. *Epilepsia* (2004) 45 (Suppl 3), 153.

Hormonal contraceptives + Antiepileptics; Remacemide

Remacemide appears not to interact with combined oral contraceptives.

Clinical evidence, mechanism, importance and management

Preliminary results of a study show that remacemide 200 mg twice daily for 14 days had no effect on the pharmacokinetics of **ethinylestradiol**, **desogestrel**, or **levonorgestrel**, when compared with placebo, in women taking a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 30/150 micrograms or **ethinylestradiol/desogestrel** 30/150 micrograms). Inhibition of ovulation was maintained (assessed by measurement of progesterone, FSH, and LH levels).¹ It appears that no special contraceptive precautions are needed during concurrent use.

1. Blakey GE, Lockton JA, Corfield J, Oliver SD, Back D. Absence of interaction of remacemide with oral contraceptives. *Epilepsia* (1999) 40 (Suppl 2), 95.

Hormonal contraceptives + Antiepileptics; Retigabine

Retigabine did not alter the plasma levels of ethinylestradiol or norgestrel given as a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

Preliminary results of a study show that retigabine 150 mg three times daily had no effect on the pharmacokinetics of **ethinylestradiol** or **norgestrel** in women taking a combined oral contraceptive (**ethinylestradiol/norgestrel** 30/300 micrograms).¹ This suggests that no special contraceptive precautions are needed during concurrent use.

1. Paul J, Ferron GM, Richards L, Getsy J, Troy SM. Retigabine does not alter the pharmacokinetics of a low-dose oral contraceptive in women. *Neurology* (2001) 56 (Suppl 3), A335.

Hormonal contraceptives + Antiepileptics; Rufinamide

Rufinamide caused a modest decrease in the plasma levels of ethinylestradiol and norethisterone given as a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

Preliminary results of a study show that rufinamide 800 mg twice daily for 14 days decreased the AUC of **ethinylestradiol** 35 micrograms by 22% and of **norethisterone** 1 mg by 14% in healthy women taking a combined oral contraceptive. Inhibition of ovulation was not assessed.¹ These reductions in plasma levels of the contraceptive hormones are similar to those seen with topiramate (see 'Hormonal contraceptives + Antiepileptics; Topiramate', below), and their clinical relevance is unknown. However, given these findings, low-dose contraceptives (**ethinylestradiol** 20 micrograms) may be considered unsuitable for use with rufinamide. Further study is needed.

1. Svendsen KD, Choi L, Chen B-L, Karolchik MA. Single-center, open-label, multiple-dose pharmacokinetic trial investigating the effect of rufinamide administration on Ortho-Novum 1/35 in healthy women. *Epilepsia* (1998) 39 (Suppl 6), 59.

Hormonal contraceptives + Antiepileptics; Tiagabine

Tiagabine appears not to alter the contraceptive efficacy and plasma levels of combined oral contraceptives.

Clinical evidence, mechanism, importance and management

A study in 10 healthy women found that tiagabine 2 mg, four times daily from day 24 to day 7 of the next cycle, had no effect on the mean plasma levels of any of steroids in two combined oral contraceptives (**ethinylestradiol/levonorgestrel** or **ethinylestradiol/desogestrel**, both 30/150 micrograms). There was no evidence that the suppression of ovulation was altered in any way (no significant changes in the plasma concentrations of progesterone, FSH, or LH were seen between the first and second cycles, and progesterone levels remained in the non-ovulatory range). Tiagabine did not induce hepatic enzymes, as assessed by 6 β -hydroxycortisol excretion. Two women did develop breakthrough bleeding, but given the above findings, this was not thought to represent reduced efficacy of the contraceptive.¹ There would appear to be no reason for any special contraceptive precautions during concurrent use.

1. Mengel HB, Houston A, Back DJ. An evaluation of the interaction between tiagabine and oral contraceptives in female volunteers. *J Pharm Med* (1994) 4, 141–50.

Hormonal contraceptives + Antiepileptics; Topiramate

The serum levels of ethinylestradiol may be reduced by topiramate, increasing the risk of breakthrough bleeding in women taking combined oral contraceptives. It is suggested that oral contraceptives with a higher dosage of oestrogen should be used.

Clinical evidence

Eleven epileptic women taking sodium valproate and a combined oral contraceptive (**ethinylestradiol/norethisterone** 35 micrograms/1 mg) were also given three escalating doses of topiramate 100, 200 and 400 mg twice daily for 28-day periods.¹ The mean AUC of the **ethinylestradiol** fell by 18%, 21%, and 30%, with the three doses respectively. Although no significant changes were found in the **norethisterone** AUC, the authors considered that the study was not sufficiently powered to detect small changes. No ovulation occurred, as assessed by progesterone levels, but one patient had breakthrough bleeding.² A follow-up study evaluated the effect of lower doses of topiramate on the pharmacokinetics of a combined oral contraceptive containing **ethinylestradiol/norethisterone** 35 micrograms/1 mg (*Ortho-Novum*). Subjects were randomised to take daily doses of topiramate of 50 mg (11 subjects), 100 mg (10 subjects) or

200 mg (2 groups of 12 subjects). This study found a minor, non-significant change in the pharmacokinetics of both **ethinylestradiol** and **norethisterone**; this change was further reduced when the data from 2 subjects were excluded due to compliance issues. The authors noted that the difference between this study and the study cited above² was due to the difference in the doses of topiramate used, as topiramate is a weak liver enzyme-inducer, and this effect is dose-related.³

Mechanism

Not understood. It is suggested that topiramate weakly induces enzymes in the liver, which increases the metabolism of the ethinylestradiol.^{2,3}

Importance and management

An established interaction but supported by limited evidence. The modest changes in pharmacokinetics of the combined oral contraceptive seen here are lower than those seen with other enzyme-inducing antiepileptics (see 'Hormonal contraceptives + Antiepileptics; Carbamazepine or Oxcarbazepine', p.987, and 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985) and may be dose-dependent. However, it is possible that they would be sufficient to cause failure of combined oral contraceptives in rare cases, particularly at high therapeutic doses of topiramate. As there is a risk of failure of contraception with the concurrent use of topiramate, and possibly more importantly, because topiramate is teratogenic, the manufacturer of topiramate advises the use of a non-hormonal contraceptive or a high-dose combined oral contraceptive (at least 50 micrograms of oestrogen), and also that patients should be told to report any changes in their bleeding patterns.¹ The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of liver enzyme inducers, including topiramate, with hormonal contraceptives, see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985, for details of this guidance.

3. Doose DR, Wang S-S, Padmanabhan M, Schwabe S, Jacobs D, Bialer M. Effect of topiramate or carbamazepine on the pharmacokinetics of an oral contraceptive containing norethindrone and ethinyl estradiol in healthy obese and nonobese female subjects. *Epilepsia* (2003) 44, 540–9.

Hormonal contraceptives + Antiepileptics; Valproate

Sodium valproate and valproate semisodium do not appear to alter the efficacy of combined oral contraceptives. In one study, sodium valproate increased ethinylestradiol levels. Ethinylestradiol may reduce valproate levels but there appears to be only one case where this resulted in a loss of seizure control.

Clinical evidence and mechanism

(a) Contraceptive efficacy

In a series of 32 patients taking an oral contraceptive, none of 7 taking sodium valproate 600 mg to 1.8 g daily had breakthrough bleeding, whereas about two-thirds of those taking carbamazepine or phenobarbital had breakthrough bleeding (a sign of possible reduced contraceptive efficacy). Most of the 7 patients taking valproate were taking combined oral contraceptives containing 50 micrograms of **ethinylestradiol**; one was taking less than 50 micrograms, and one was using a **progestogen-only oral contraceptive**. One of the 7 patients had previously experienced breakthrough bleeding while taking phenobarbital, but this stopped when it was replaced with sodium valproate. Two further patients did not have breakthrough bleeding while taking sodium valproate and benzodiazepines, but breakthrough bleeding started when phenytoin was also given.¹

In a pharmacokinetic study, sodium valproate 200 mg twice daily had no effect on the AUC of a single dose of a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 50/250 micrograms) given to women with epilepsy 8 to 16 weeks after they started sodium valproate. However, a 50% increase in the peak plasma levels of **ethinylestradiol** was noted.²

Conversely, one pregnancy was identified in a woman who took sodium valproate and an oral contraceptive (unspecified) in the adverse reactions

register of the CSM in the UK for the years 1968 to 1984. However, the authors consider this one case to be a chance association.³

(b) Valproate efficacy

A study in 9 women with epilepsy taking valproic acid found an increase in the apparent oral clearance of both total and unbound valproic acid during oral contraceptive intake compared with the pill-free period. The authors report that this may be due to induction of glucuronosyltransferase by ethinylestradiol and that the magnitude of this effect can differ between individuals.⁴ Reduced valproate levels and an increase in seizure frequency have been reported to occur in one patient taking a combined oral contraceptive during the active pill phase, when compared with the inactive 7-day period.⁵ No further cases appear to have been published.

Importance and management

The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions state that valproate does not induce liver enzymes and causes no reduction in ethinylestradiol or progestogens.⁶ The manufacturers of sodium valproate and valproate semisodium state that valproate does not affect the efficacy of hormonal contraceptives.^{7,8} No special contraceptive precautions are required during concurrent use.

The significance of the reduction in valproate levels and the case report above is unclear.

Hormonal contraceptives + Antiepileptics; Vigabatin

Vigabatin appears not to alter the pharmacokinetics of ethinylestradiol or levonorgestrel given as a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

Vigabatin 3 g daily had no statistically significant effect on the pharmacokinetics of **ethinylestradiol** and **levonorgestrel** in 13 healthy women given a single dose of a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 30/150 micrograms); although 2 of the women had a 39% and a 50% fall in the AUC of **ethinylestradiol**. Vigabatin did not induce hepatic enzymes as assessed by antipyrine clearance and 6 β -hydroxycortisol excretion.¹

This study would seem to confirm the lack of reports of an interaction between oral contraceptives and vigabatin, but the authors of the report introduce a small note of caution because it is not clear whether the reduced **ethinylestradiol** AUCs seen in two of the women resulted from an interaction or were simply normal individual variations.¹ The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidelines on the management of hormonal contraceptives and drug interactions state that vigabatin does not induce liver enzymes and causes no reduction in ethinylestradiol or progestogens.² No special precautions are recommended.

Hormonal contraceptives + Antiepileptics; Zonisamide

A study in healthy women taking a combined oral contraceptive found that steady-state zonisamide 100 to 400 mg daily did not affect the levels of ethinylestradiol or norethisterone. Contraceptive efficacy was not reduced.¹

1. Griffith SG, Dai Y. Effect of zonisamide on the pharmacokinetics and pharmacodynamics of a combination ethinyl estradiol-norethindrone oral contraceptive in healthy women. *Clin Ther* (2004) 26, 2056–65.

Hormonal contraceptives + Antihistamines

The pharmacokinetics of single doses of doxylamine and diphenhydramine do not appear to be altered by combined oral contraceptives.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of a single 25-mg dose of **doxylamine** in 13 subjects and the pharmacokinetics of a single 50-mg dose of **diphenhydramine** in 10 subjects were not significantly altered by the use of low-dose combined oral contraceptives.¹ Cases of oral contraceptive failure have been attributed to the use of **doxylamine**, **chlorpheniramine**, and an unnamed antihistamine,² but these antihistamines were all used in conjunction with penicillins, which would seem to be a more likely cause of contraceptive failure (see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981). The effect of the antihistamines on the pharmacokinetics and pharmacodynamics of contraceptive steroids appear not to have been studied. No particular precautions would seem necessary during concurrent use.

1. Luna BG, Scavone JM, Greenblatt DJ. Doxylamine and diphenhydramine pharmacokinetics in women on low-dose estrogen oral contraceptives. *J Clin Pharmacol* (1989) 29, 257–60.
2. DeSano EA, Hurley SC. Possible interactions of antihistamines and antibiotics with oral contraceptive effectiveness. *Fertil Steril* (1982) 37, 853–4.

Hormonal contraceptives + Antimalarials

No clinically significant interaction appears to occur between combined oral contraceptives and chloroquine or primaquine, or between oral contraceptives and mefloquine or quinine. There is some evidence to suggest that a combined oral contraceptive reduced the conversion of proguanil to its active metabolite, cycloguanil.

Clinical evidence and mechanism

(a) Chloroquine

A pharmacokinetic study in 12 healthy women taking a combined oral contraceptive (**ethinylestradiol/norethisterone** 30 micrograms/1 mg) found that the prophylactic use of chloroquine phosphate 500 mg once a week for 4 weeks caused a small 15% increase in the AUC of **ethinylestradiol**, and no change in the levels of **norethisterone**. Chloroquine use did not alter ovulation inhibition, as assessed by mid-luteal progesterone levels and the lack of breakthrough spotting and bleeding. In a further group of 7 women, the same combined oral contraceptive did not alter the pharmacokinetics of a single 500-mg dose of chloroquine phosphate.¹ Another study in 6 healthy women given a single dose of a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 30 micrograms/150 micrograms) confirmed that a single 300-mg dose of chloroquine had no significant effect on the pharmacokinetics of either the oestrogen or the progestogen.² Furthermore studies in *rhesus monkeys* infected with malaria, suggest that the curative efficacy of chloroquine is not altered by the use of combined oral contraceptives (**ethinylestradiol/norethisterone** or **ethinylestradiol/norgestrel**).³

(b) Mefloquine

A study in 12 Thai women with falciparum malaria, 6 of whom were taking unnamed oral contraceptives, found that their response to mefloquine (parasite and fever clearance) was not affected by oral contraceptives.

Similarly, the pharmacokinetics of mefloquine were not affected by oral contraceptives in patients with malaria.⁴

(c) Primaquine

A study in 6 healthy women given a single dose of a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 30 micrograms/150 micrograms) confirmed that a single 45-mg dose of primaquine had no significant effect on the pharmacokinetics of either the oestrogen or the progestogen.²

(d) Proguanil

In women who were CYP2C19 extensive metabolisers the use of a combined oral contraceptive (**ethinylestradiol/levonorgestrel**) reduced the levels of cycloguanil (the active metabolite of proguanil) by 34% after 3 weeks, when compared with the cycloguanil levels before starting the contraceptive.⁵ It was suggested that the oestrogen might have inhibited the metabolism of proguanil by the cytochrome P450 isoenzyme CYP2C19. However, inhibition of CYP2C19 makes extensive metabolisers into poor metabolisers, and there is some evidence that CYP2C19 poor metaboliser status does not reduce the efficacy of proguanil for prophylaxis⁶ or treatment⁷ of malaria (see also 'Proguanil + Fluvoxamine', p.238).

(e) Quinine

A controlled study in Thai women showed that the pharmacokinetics of a single 600-mg dose of quinine sulfate in 7 women taking oral contraceptives were not significantly different from those in 7 other women not taking contraceptives. The contraceptives being used were combined oral contraceptives (**ethinylestradiol/levonorgestrel** or **ethinylestradiol/norgestrel**) and a progestogen-only oral contraceptive (**norethisterone**).⁸ There seem to be no reports that quinine affects the reliability of the oral contraceptives.

Importance and management

No clinically significant interaction appears to occur between the combined oral contraceptives and chloroquine, primaquine or quinine, between oral contraceptives and mefloquine, or between a progestogen-only oral contraceptive and quinine. There would seem to be no reason for avoiding concurrent use.

The decrease in the active metabolite of proguanil caused by a combined oral contraceptive has not been fully assessed, although the authors recommended that the dose of proguanil should be increased by 50% in women taking oral contraceptives.⁵ However, there is limited evidence that this pharmacokinetic interaction may not be clinically relevant. More study is needed.

The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance (adapted from the World Health Organization Medical Eligibility Criteria (WHOMEC) guidance on contraceptive use) stating that malaria as a condition does not restrict the choice of various contraceptive methods including combined and progesterone-only oral contraceptives.⁹

Note that **doxycycline** is increasingly used in the treatment of malaria. See 'Hormonal contraceptives + Antibacterials; Tetracyclines', p.983, for further information on possible combined hormonal contraceptive failure with tetracyclines.

Hormonal contraceptives + Aprepitant

Aprepitant reduced the levels of ethinylestradiol and norethisterone given as an oral contraceptive.

Clinical evidence

The manufacturers^{1,2} note that aprepitant 100 mg daily for 14 days given with a combined oral contraceptive (**ethinylestradiol/norethisterone** 35 micrograms/1 mg) decreased the AUC of **ethinylestradiol** and **norethisterone** by 43% and 8%, respectively. Reduced contraceptive steroid levels were reported in another study using a recommended antiemetic regimen including aprepitant (125 mg on the first day, then 80 mg daily for 2 days with dexamethasone 12 mg on the first day, then 8 mg daily for 3 days and ondansetron 32 mg on the first day), which was started on day 8 of a 21-day cycle of a combined oral contraceptive (**ethinylestradiol/norethisterone**).^{1,2} Within 2 days of starting the antiemetics (day 10) the **ethinylestradiol** AUC was reduced by 19% and the **norethisterone** level was unchanged.² However, the trough level of **ethinylestradiol** was reduced by as much as 64% and that of **norethisterone** by 60% during days 9 to 21.^{1,2}

Mechanism

During the first few days of use aprepitant is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and therefore it would be expected to *increase* the levels of the contraceptive steroids. However, aprepitant then becomes an inducer of CYP3A4 (which is usually after the end of a standard 3-day course), reaching a maximal induction effect within 3 to 5 days of stopping aprepitant. This effect lasts only a few days and then reduces to become clinically insignificant within 2 weeks of stopping aprepitant,¹ and hence reduces the levels of the contraceptive steroids.

Importance and management

Although the effects of these reduced contraceptive steroids levels on ovulation were not assessed, it is likely that they could result in reduced efficacy. The manufacturer therefore recommends that alternative or additional contraceptive methods should be used during, and for 2 months (UK advice)¹ or one month (US advice)² after, aprepitant use. This seems a sensible precaution. No studies have been done on the effect of a single 40-mg dose of aprepitant 40 mg, as licensed in the US for postoperative nausea and vomiting. However, the US manufacturer states that the timing of the dose may cause contraceptive failure and the same guidance, as stated above, should be used.²

Hormonal contraceptives or HRT + Ascorbic acid (Vitamin C)

Ascorbic acid does not appear to cause a clinically important alteration in the levels of ethinylestradiol or levonorgestrel, but there are a few unconfirmed anecdotal reports of contraceptive failure associated with ascorbic acid. There is some evidence that ascorbic acid may modestly increase estradiol levels in women receiving HRT.

Clinical evidence

(a) Combined oral contraceptives

One study found that ascorbic acid 1 g raised serum **ethinylestradiol** levels by 16% at 6 hours post-dose and 48% at 24 hours post-dose in 5 women taking combined oral contraceptives.¹ However, a later well-controlled study found that ascorbic acid 1 g daily caused no significant changes in **ethinylestradiol** serum levels in 37 women taking a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 30/150 micrograms).² A similar study by the same workers found that ascorbic acid 1 g did not affect the pharmacokinetics of **levonorgestrel**.³

A single case report describes a woman taking a combined oral contraceptive (**ethinylestradiol/levonorgestrel**) who experienced heavy break-

through bleeding in 3 cycles within 2 to 3 days of stopping ascorbic acid 1 g daily. This did not occur in 3 other cycles when no ascorbic acid was taken. This was postulated to be due to a fall in **ethinylestradiol** levels when the vitamin C was stopped, which could increase the risk of contraceptive failure.⁴ One report attributed contraceptive failure in one case to ascorbic acid and **multivitamins**.⁵ Another two studies of pregnancies in oral contraceptive users found that vitamin C had been taken in 44 of 209 cases⁶ and 15 of 137 cases,⁷ although other drugs and/or factors may possibly have been involved in some of these cases.

(b) Hormone replacement therapy

Ascorbic acid 500 mg twice daily for one month caused a non-significant 21% increase in plasma estradiol levels in 25 postmenopausal women receiving **transdermal estradiol HRT**. However, in the 9 women with initially low estradiol levels, ascorbic acid doubled the levels, and this reached significance.⁸

Mechanism

Both ascorbic acid and ethinylestradiol undergo sulfate conjugation. It was suggested that large doses of ascorbic acid might compete for the metabolism of ethinylestradiol, and therefore increase its levels.¹ This would be expected to increase the efficacy of the oral contraceptive. However, some have postulated that enhanced levels could be followed by rebound ovulation,⁴ but there is no evidence to support this. Ascorbic acid may reverse the oxidation of oestrogens.⁸

Importance and management

Documentation about an interaction with contraceptives is limited. From the point of view of reliability, there seems to be little reason for avoiding the use of oral contraceptives and ascorbic acid. No special precautions are required.

The authors of the report on ascorbic acid and HRT say that their findings do not support the general use of ascorbic acid as an adjuvant to HRT, but that further study is needed. No special precautions are required.

Hormonal contraceptives or HRT + Azoles

There are isolated reports of breakthrough bleeding and failure of combined oral contraceptives with fluconazole (including single 150 mg doses), itraconazole and ketoconazole. Conversely, fluconazole, itraconazole and voriconazole have been shown to modestly increase the serum levels of the contraceptive steroids. Ketoconazole slightly increases the levels of estrone following oestrogen administration. Miconazole slightly increases the serum levels of ethinylestradiol and etonogestrel released from an intravaginal contraceptive ring.

Clinical evidence

(a) Fluconazole

Up to 1990 the UK manufacturer of fluconazole had received 11 reports of menstrual disorders possibly associated with single-dose fluconazole 150 mg. Eight of these were in women taking an oral contraceptive who developed breakthrough bleeding (5 cases), no withdrawal bleeding (1 case), unintended pregnancies (2 cases).¹ Three other cases of unintended pregnancy have been very briefly mentioned elsewhere.²

However, one study found that a single 150-mg dose of fluconazole increased the AUC of **ethinylestradiol** by 29% in women taking a combined oral contraceptive (**ethinylestradiol** and **norethisterone** or **levonorgestrel**).³ Similarly, fluconazole 300 mg once weekly for 4 weeks caused a 24% increase in the AUC of **ethinylestradiol** and a 13% increase in the AUC of **norethisterone**.⁴ Moreover, the manufacturer has data on file showing that multiple doses of fluconazole 200 mg daily raised the levels of **ethinylestradiol** by 40% and of **levonorgestrel** by 24%,⁵ whereas a lower dose of fluconazole (a single 50-mg dose or 50 mg of fluconazole daily for 10 days) had no significant effect on the pharmacokinetics of **ethinylestradiol** and **norgestrel**.⁶ One other study in 10 women taking combined oral contraceptives found no changes in progesterone levels (suggesting no ovulation occurred) and no menstrual disorders while they were taking fluconazole 50 mg daily.⁷ Furthermore, during clinical studies in which single 150-mg doses of fluconazole were used by over 700 women taking oral contraceptives, no evidence of an interaction was seen.⁸

(b) Itraconazole

A 25-year-old woman who had been taking a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 30/150 micrograms) for a year, without problems, became pregnant when she was given itraconazole 200 mg daily for 3 months for a fungal infection. The patient was said to be compliant, had suffered no gastrointestinal upset, and was not taking any other drugs that might have accounted for the failure of the pill.²

The Netherlands Pharmacovigilance Foundation (LAREB) have 9 cases of menstrual changes on their records in women taking an oral contraceptive during or after taking itraconazole 100 to 400 mg daily for 1 to 4 weeks. Seven women reported delayed withdrawal bleeding (2 to 5 days). In 2 of them the menstrual flow was decreased and one transiently had a positive pregnancy test after having previously experienced an intermenstrual blood loss. The remaining two reports were of amenorrhoea during one cycle, and breakthrough bleeding. The women were taking **ethinylestradiol** plus either **desogestrel** or **levonorgestrel**.⁹ A later extension of this report from LAREB, covering the period 1991 to 1997, describes 12 women taking contraceptives containing **ethinylestradiol** with **desogestrel**, whose withdrawal bleeding was either delayed or did not occur at all while taking itraconazole. Three other women taking **ethinylestradiol** with **levonorgestrel** had breakthrough bleeding, and yet another taking **ethinylestradiol** with **cyproterone** became pregnant while taking itraconazole.¹⁰

However, the manufacturer has data on file of a study showing that itraconazole 200 mg daily for 15 days had no effect on the pharmacokinetics of **ethinylestradiol**, and increased the bioavailability of **norethisterone** by about 40%. In this study, a single dose of **ethinylestradiol/norethisterone** was given before the first dose and with the last dose of itraconazole.¹¹

(c) Ketoconazole

An early report described 7 out of 147 women taking combined oral contraceptives (**ethinylestradiol/norgestrel**) who experienced breakthrough bleeding or spotting within 2 to 5 days of starting a 5-day course of ketoconazole 400 mg daily. No pregnancies occurred.¹² One unintended pregnancy attributed to contraceptive failure due to ketoconazole has been very briefly mentioned elsewhere.² A study in 6 postmenopausal women given a single 2-mg dose of **estradiol** found that ketoconazole 100 mg twice daily for 4 days increased the AUC and maximum plasma levels of estrone (a metabolite of estradiol) by 16% and 30%, respectively. The small increases were not thought to be clinically significant.¹³

(d) Miconazole

A study found that both single and multiple-dose intravaginal regimens of miconazole pessaries and cream slightly increased the serum levels of **ethinylestradiol** and **etonogestrel** released from an intravaginal ring (*NuvaRing*).¹⁴

(e) Voriconazole

The maximum levels and AUC of **ethinylestradiol** 35 micrograms (given as a combined oral contraceptive) were increased by 36% and 61%, respectively, by concurrent use of voriconazole. Similarly, the maximum levels and AUC of **norethisterone** 1 mg were also increased by 15% and 53%, respectively, by voriconazole. The maximum levels and AUC of voriconazole were increased by 14% and 46%, respectively, by these contraceptive steroids.¹⁵

Mechanism

The azole antifungals are, to varying degrees, inhibitors of the cytochrome P450 isoenzyme CYP3A4. They would therefore be expected to increase the levels of the contraceptive steroids, as has been shown for fluconazole, itraconazole and voriconazole. Similarly, ketoconazole and miconazole have been seen to raise the levels of some oestrogens. Therefore the azoles would *not* be expected to increase the incidence of breakthrough bleeding or contraceptive failure when used with combined oral contraceptives. It should be noted that the manufacturers list menstrual irregularities as adverse effects of itraconazole, ketoconazole and **posaconazole** irrespective of the use of combined oral contraceptives,^{16–18} and menstrual disorders have also been reported with fluconazole alone.¹

Importance and management

The picture presented by these reports is somewhat confusing and contradictory. The anecdotal reports of contraceptive failure and the cases of breakthrough bleeding would suggest that these antifungals can, rarely, make oral contraception less reliable in some individuals. However, the problem with this interpretation is that the pharmacokinetic data suggest that, if anything, an *enhanced* effect of the combined oral contraceptives is likely. Note that, of all the drugs proven to decrease the efficacy of combined oral contraceptives, all have also been shown to decrease the steroid levels. Menstrual disorders have occurred with the azole antifungals alone, and may not be indicative of reduced contraceptive efficacy. Since there are so few reports of pregnancy, it could just be that they fall within the accepted failure rate of combined oral contraceptives, and it was just coincidental they occurred when the antifungal was being taken. Note that the manufacturers do not advise any special precautions when taking oral contraceptives and these azole antifungals.^{5,15,16} However, some consider that the data warrant consideration being given to the use of additional contraceptive measures.¹⁰ The theoretical teratogenic risk^{5,15–18} from these azole antifungals may have a bearing on this, and the UK manufacturers of a number of the azoles recommend using effective contraception during azole treatment to reduce this risk.^{5,15,16,18} More study is clearly needed.

The main concern regarding the increased levels of ethinylestradiol or progestogens is whether this would increase the risk of adverse effects of the steroid. There are no data on the effect of these modest 25 to 40% increases in steroid levels on adverse effects. It could be argued that a 40% increase would turn a standard-strength contraceptive (35 micrograms) into a high-dose contraceptive (50 micrograms). However, early studies showed that the interindividual variation in ethinylestradiol pharmacokinetics was greater than this anyway.¹⁹ Further study is needed.

Hormonal contraceptives + Bosentan

Bosentan reduces the levels of ethinylestradiol and norethisterone given as a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

In randomised, crossover study in 19 healthy subjects a single dose of a combined oral contraceptive containing **norethisterone** 1 mg and **ethinylestradiol** 35 micrograms (*Ortho-Novum*) was given with bosentan 125 mg twice daily for one week. Bosentan reduced the mean AUC of norethisterone by 14% (maximum reduction 56%) and the mean AUC of ethinylestradiol by 31% (maximum reduction 66%). Note that there was marked inter-individual variability. The maximum concentration and half-life of both contraceptive steroids were not significantly affected. The contraceptive steroids are metabolised by the cytochrome P450 isoenzyme CYP3A4, and it was thought that the changes in their pharmacokinetics may have been caused by induction of CYP3A4 by bosentan. However other mechanisms could not be excluded. The link between these results and actual contraceptive failure is unclear.¹

The Pulmonary Hypertension Association has suggested that there is the potential for bosentan to reduce the effectiveness of hormonal contraceptives by any route. They also state that bosentan may have teratogenic effects and therefore it should not be used as the only method of contraception in patients taking bosentan.² Similarly, the manufacturer contraindicates the use of bosentan in women who are not using reliable methods of contraception and recommends that additional or alternative methods to hormonal contraceptives are used. This must be continued for at least 3 months after treatment is stopped.³

Hormonal contraceptives + Candesartan

Candesartan cilexetil 8 mg daily had no effect on the pharmacokinetics of ethinylestradiol and levonorgestrel in a combined oral contraceptive, and no ovulation occurred during concurrent treatment.¹ No special precautions would therefore appear to be needed. Consider also 'Drospirenone + Potassium-sparing drugs', p.977, for a possible interaction between angiotensin II receptor antagonists and drospirenone, and 'Antihypertensives + Hormonal contraceptives', p.880.

1. Jonkman JHG, van Lier JJ, van Heiningen PNM, Lins R, Sennewald R, Högemann A. Pharmacokinetic drug interaction studies with candesartan cilexetil. *J Hum Hypertens* (1997) 11 (Suppl 2), S31–S35.

Hormonal contraceptives or HRT + Coxibs

Rofecoxib increases contraceptive steroid levels to a small extent, and would not therefore be expected to reduce contraceptive efficacy. Etoricoxib raises ethinylestradiol levels by 50 to 60%, and also appears to raise the levels of conjugated oestrogens in HRT. Celecoxib appears to have no effect on combined oral contraceptive levels. One case of pulmonary embolism has been reported in a patient taking valdecoxib with a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

(a) Celecoxib

Celecoxib had no clinically significant effects on the pharmacokinetics of a combined oral contraceptive containing **norethisterone** 1 mg and **ethinylestradiol** 35 micrograms.¹ No precautions seem necessary.

(b) Etoricoxib

A study in women taking a combined oral contraceptive (**ethinylestradiol/norethisterone** 35 micrograms/0.5 to 1 mg) for 21 days found that the

addition of etoricoxib 120 mg with or 12 hours after the oral contraceptive increased the 24-hour steady-state levels of **ethinylestradiol** by 50 to 60%. It is thought that etoricoxib increases **ethinylestradiol** levels because it inhibits human sulfotransferase activity. The manufacturer suggests that this increase in **ethinylestradiol** levels should be considered when choosing the oral contraceptive because of the possible increased risk of adverse events.² It may therefore be appropriate to use a contraceptive with a lower dose of **ethinylestradiol**.

Etoricoxib 120 mg taken with HRT containing 0.625 mg of conjugated oestrogens (*Premarin*) increased the AUC₀₋₂₄ of unconjugated estrone, equilin and 17- β estradiol by 41%, 76%, and 22%, respectively; however, the AUCs of these metabolites were less than those seen with 1.25 mg of conjugated oestrogens. The effects of lower doses of etoricoxib have not been studied. The manufacturers say that these increases should be taken into account when selecting HRT in patients taking etoricoxib.²

(c) Rofecoxib

In a placebo-controlled, crossover study in 18 healthy women taking a combined oral contraceptive (**ethinylestradiol/norethisterone** 35 micrograms/1 mg), rofecoxib 175 mg daily for 2 weeks raised the AUCs of **ethinylestradiol** and **norethisterone** by 13% and 18%, respectively. These small changes, although statistically significant, are within the accepted criteria for bioequivalence, and are unlikely to be clinically important. No abnormal menstrual bleeding was reported.³ No special precautions are required during concurrent use.

(d) Valdecocixib

A single case of pulmonary embolism has been reported with the concurrent use of a combined oral contraceptive containing **norgestimate/ethinylestradiol** (*Ortho Tri-Cyclen*) and valdecocixib. The patient had been taking the same combined oral contraceptive (containing ethinylestradiol doses of 35 and then 25 micrograms) for 3 years prior to taking valdecocixib with no adverse effects. The authors note that multiple factors may have contributed to this case, as prolonged stasis (a 6-hour car journey) and oral contraceptives themselves can cause venous thromboembolism.⁴ There appear to be no further similar published reports and the clinical significance of this case is unclear. Note that valdecocixib has been withdrawn.

Hormonal contraceptives + Danazol or Gestrinone

There is a theoretical risk that the effects of danazol or gestrinone and hormonal contraceptives might be altered or reduced by concurrent use.

Clinical evidence, mechanism, importance and management

(a) Danazol

Danazol inhibits ovulation, but it is not considered reliable enough to be used as a hormonal contraceptive.¹⁻³ Danazol should not be used during pregnancy, because it can cause virilisation of a female foetus. The manufacturer advises the use of reliable non-hormonal contraceptive methods while taking danazol,⁴ and by inference the avoidance of hormonal contraceptives. They say that there is a theoretical risk that danazol and exogenously administered oestrogens and/or progestogens, including oral contraceptives, might possibly compete for the same oestrogen, progestogen, and androgen receptors, thereby altering the effects of both drugs.³ This would also apply to other hormonal contraceptives such as **etonogestrel** implants and depot preparations of **medroxyprogesterone** and **norethisterone**. However, as yet there appears to be no direct evidence that any interaction actually occurs.

(b) Gestrinone

Although gestrinone, at the dose used for endometriosis, can inhibit ovulation, it is not sufficiently reliable to be used as a contraceptive. The manufacturer strongly emphasises the importance of using a barrier method of contraception while taking gestrinone because they say that not only are

the effects of gestrinone possibly modified by oral contraceptives, but its use in pregnancy is totally contraindicated (high doses have been shown to be embryotoxic in some *animal* species).⁵

5. Dimetriose (Gestrinone). Sanofi-Aventis. UK Summary of product characteristics, October 2003.

Hormonal contraceptives + Ezetimibe

No significant pharmacokinetic interaction appears to occur between ezetimibe and an ethinylestradiol/norgestrel-containing oral contraceptive.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 18 healthy women who had been taking a triphasic oral contraceptive (containing **ethinylestradiol/norgestrel**) were also given ezetimibe 10 mg daily or placebo on days 8 to 14 of two consecutive contraceptive cycles. Ezetimibe did not significantly affect the pharmacokinetics of ethinylestradiol or norgestrel.¹ The manufacturers note that ezetimibe had no effect on the pharmacokinetics of **ethinylestradiol/levonorgestrel**-containing contraceptives, therefore no additional precautions seem necessary if ezetimibe is given to women taking these contraceptives.²

1. Keung ACF, Kosoglou T, Statkevich P, Anderson L, Boutros T, Cutler DL, Batra V, Sellers EM. Ezetimibe does not affect the pharmacokinetics of oral contraceptives. *Clin Pharmacol Ther* (2001) 69, P55.
2. Ezetrol (Ezetimibe). MSD-SP Ltd. UK Summary of product characteristics, December 2006.

Hormonal contraceptives + Griseofulvin

The effects of the oral contraceptives may possibly be disturbed (either intermenstrual bleeding or amenorrhoea) if griseofulvin is taken concurrently. Reports describe women taking oral contraceptives who became pregnant while taking griseofulvin.

Clinical evidence

In 1984, regulatory authorities in the UK and the Netherlands noted that they had received a total of 22 reports of possible interactions between oral contraceptives and griseofulvin. These included 15 reports of transient intermenstrual bleeding and 5 of amenorrhoea, occurring during the first or second cycle, after griseofulvin 500 mg to 1 g daily was started. Four of these patients were rechallenged with griseofulvin (2 with intermenstrual bleeding and 2 with amenorrhoea) and all developed their original reactions. The other two women were reported to have become pregnant while taking griseofulvin and a sulphonamide ('co-trimoxazole', (p.982) in one instance and an unknown sulphonamide in the other).¹ One other case of contraceptive failure has been reported from an analysis of the database of the CSM in the UK from 1968 to 1984,² but note this case may be included in the two already reported.¹ One other case report describes a woman taking a triphasic combined oral contraceptive who became pregnant about 2 months after she started to take griseofulvin 330 mg twice daily,³ and another report describes a woman taking an oral contraceptive who became pregnant 6 weeks after starting to take griseofulvin 500 mg daily for 3 months and a 7-day course of 'erythromycin', (p.979).⁴ Irregular menses and reduced menstrual flow have been described in another woman taking a combined oral contraceptive (**ethinylestradiol** 35 micrograms/**norethisterone** 0.5 to 1 mg) with griseofulvin 250 to 500 mg daily. When the oral contraceptive was substituted with another with more oestrogen (**ethinylestradiol/norgestrel** 50/500 micrograms), the menstrual cycle became normal again.⁵ Break-through bleeding has also been seen in one other woman taking an oral contraceptive with griseofulvin.⁶

Mechanism

Not understood. Griseofulvin may possibly stimulate the activity of the liver enzymes concerned with the metabolism of the contraceptive ster-

oids, thereby reducing their effects (see 'Hormonal contraceptives and sex hormones', (p.975)).

Importance and management

Information about this interaction is very limited. The risk of contraceptive failure is uncertain but probably very small. However, it would be prudent for prescribers to warn women taking a **combined oral contraceptive** who are given griseofulvin that menstrual disturbances may possibly be signs of contraceptive unreliability, and that additional contraceptive precautions should be taken. The CSM in the UK has pointed out the importance of ensuring adequate contraception during and for one month after taking griseofulvin because it can induce aneuploidy (abnormal segregation of chromosomes during cell division), which carries the potential risk of teratogenicity.⁷ For maximal contraceptive protection additional contraceptive measures (such as a barrier method) should be used routinely while taking griseofulvin and for one month afterwards.

The situation with **progestogen-only contraceptives** is not clear, but it has been suggested that they are not the contraceptive of choice in those taking griseofulvin, not because of reduced efficacy but because of increased menstrual irregularities.⁸ The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit states that griseofulvin may reduce the efficacy of hormonal contraceptives as it is a liver enzyme inducer and additional contraceptive protection is advised with concurrent use.⁹ They have issued guidance on the use of contraceptives with liver enzyme inducers, see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985.

Hormonal contraceptives + Immunosuppressants

No clinically relevant interactions have been seen between leflunomide, mycophenolate or sirolimus and combined oral contraceptives, but the manufacturer of sirolimus suggests some caution. Mycophenolate has been shown to be teratogenic in animals and so the manufacturer suggests contraceptive precautions in addition to the use of hormonal contraceptives. Tacrolimus may increase the plasma levels of hormonal contraceptives.

Clinical evidence, mechanism, importance and management

(a) Ciclosporin

For the interactions of ciclosporin with hormonal contraceptives see, 'Ciclosporin + Hormonal contraceptives and Progestogens', p.1038.

(b) Leflunomide

Leflunomide was given to healthy women taking a triphasic oral contraceptive containing 30 micrograms of **ethinylestradiol**. During the study it was found that the leflunomide had no effect on the activity of the oral contraceptive and the pharmacokinetics of the active metabolite of leflunomide (A771726) were not changed to a clinically relevant extent.¹ No special precautions would therefore appear to be needed on concurrent use.

(c) Mycophenolate

The manufacturer says that no pharmacokinetic interaction was seen in a single-dose study in 15 healthy women taking mycophenolate and *Orthonovum* (**norethisterone/ethinylestradiol** 1 mg/35 micrograms).² A

study of mycophenolate 1 g twice daily given with a combined oral contraceptive (containing **ethinylestradiol** 20 to 40 micrograms and **levonorgestrel** 50 to 150 micrograms, **desogestrel** 150 micrograms or **gestodene** 50 to 100 micrograms) over 3 consecutive menstrual cycles in 18 women not previously taking immunosuppressants found no clinically relevant influence of mycophenolate on the suppression of ovulation by the oral contraceptives.^{3,4} Large interpatient variability was seen especially for **ethinylestradiol**. However, the mean **levonorgestrel** AUC was decreased by about 15%.⁴ In addition, mycophenolate has been shown to be teratogenic in *animal* studies at doses lower than those causing maternal toxicity. The manufacturers say that effective contraception must be used before mycophenolate, during, and for 6 weeks after mycophenolate has been stopped.^{3,4} The US manufacturer also advises that oral contraceptives should be used with caution, and additional birth control methods used.⁴

(d) Sirolimus

A single-dose study found that the pharmacokinetics of an oral contraceptive (**ethinylestradiol/norgestrel** 30/300 micrograms) were unaffected by sirolimus. This suggests that the efficacy of the contraceptive is likely to be unchanged, but the UK manufacturer cautiously points out that the effects of long-term sirolimus on oral contraception are unknown.⁵ They advise that contraception should be continued for 12 weeks after sirolimus is stopped.

(e) Tacrolimus

The UK manufacturer of tacrolimus says that during clinical use **ethinylestradiol** has been shown to be a weak inhibitor of tacrolimus metabolism and may increase tacrolimus levels, presumably because it inhibits the cytochrome P450 isoenzyme CYP3A4. *In vitro* data suggest that **gestodene** and **norethisterone** may do the same. In addition, tacrolimus may reduce the clearance of steroid-based contraceptives, leading to increased hormone exposure, and therefore the manufacturers suggest that care should be taken when deciding upon contraceptive measures.⁶

Hormonal contraceptives + Leukotriene antagonists

Montelukast and zafirlukast do not alter the contraceptive efficacy of oral contraceptives.

Clinical evidence, mechanism, importance and management

(a) Montelukast

The manufacturers of montelukast say that it does not affect the pharmacokinetics of an oral contraceptive (**ethinylestradiol/norethisterone** 35 micrograms/1 mg).^{1,2} No special precautions are therefore needed if both drugs are given together.

(b) Zafirlukast

A single-blind, parallel-group study in 39 healthy women taking unnamed oral contraceptives found that zafirlukast 40 mg twice daily had no effect on the serum levels of **ethinylestradiol** nor on its contraceptive efficacy.³ This study suggests that concurrent use need not be avoided.

- Accolate (Zafirlukast). AstraZeneca Pharmaceuticals LP. US Prescribing information, July 2004.

Hormonal contraceptives + Moclobemide

Moclobemide did not alter the efficacy of combined oral contraceptives, as assessed by measures of ovulation suppression.

Clinical evidence, mechanism, importance and management

A study in 7 women taking combined oral contraceptives found no evidence of any significant alterations in estradiol, progesterone, FSH, or LH levels when they took mocllobemide 200 mg three times daily for one cycle. This suggests that ovulation did not occur. No serious adverse reactions occurred. It was considered that the efficacy of the oral contraceptives is likely to be maintained during concurrent use.¹

Hormonal contraceptives + Modafinil

Modafinil slightly reduces the levels of ethinylestradiol given as part of a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

In 16 healthy women taking a combined oral contraceptive (**ethinylestradiol/norgestimate**), modafinil 200 mg daily for 7 days followed by 400 mg daily for 21 days decreased the AUC and the maximum plasma levels of **ethinylestradiol** by 18% and 11%, respectively. Increases in plasma FSH and LH were not significant.¹ Modafinil is an inducer of the cytochrome P450 isoenzyme CYP3A4, which is partially responsible for the metabolism of **ethinylestradiol**. These small changes are lower than those seen with other enzyme inducers known to reduce the reliability of combined oral contraceptives (e.g. see 'phenytoin', p.985). However, it cannot be ruled out that they would be sufficient to cause failure of combined oral contraceptives in very rare cases. The UK manufacturer recommends that additional or alternative methods of contraception should be used during and for up to 2 cycles after stopping modafinil.² The US manufacturer gives similar guidance but advises that additional or alternative contraceptive methods need only be continued for one month after stopping modafinil.³ Note that this advice applies to other forms of hormonal contraception including implants and patches.^{3,4} The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has issued guidance on the use of liver enzyme inducers with hormonal contraceptives,⁴ see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985, for further information.

Hormonal contraceptives + Nefazodone

A woman experienced increased combined oral contraceptive adverse effects while taking nefazodone.

Clinical evidence, mechanism, importance and management

Within a week of starting to take nefazodone 50 mg twice daily, a woman taking a low-dose combined oral contraceptive (**ethinylestradiol** 20 micrograms/**desogestrel**) reported breast tenderness, bloating, weight gain, and increased premenstrual irritability. She had previously experienced identical symptoms while taking a combined oral contraceptive with a higher dose of oestrogen. Nefazodone was discontinued after 6 weeks, and within 24 hours the adverse effects resolved.¹ Nefazodone is a known inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which **ethinylestradiol** is metabolised, and might therefore be expected to increase **ethinylestradiol** levels. However, the general importance of this isolated case is unknown.

1. Adson DE, Kotlyar M. A probable interaction between a very low-dose oral contraceptive and the antidepressant nefazodone: a case report. *J Clin Psychopharmacol* (2001) 21, 618–19.

Hormonal contraceptives + NNRTIs

Nevirapine modestly reduces ethinylestradiol and norethisterone levels. Efavirenz and delavirdine increased the levels of ethinylestradiol, while ethinylestradiol had no effect on efavirenz levels. Potential contraceptive failures have been reported in two women taking efavirenz.

Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

The manufacturer of delavirdine notes that it may increase the levels of **ethinylestradiol**, but the clinical relevance of this is unknown.¹

(b) Efavirenz

The manufacturer notes that efavirenz *increased* the AUC of a single dose of **ethinylestradiol** by 37% while the maximum plasma levels remained unchanged. **Ethinylestradiol** had no effect on the AUC of maximum plasma levels of efavirenz.^{2,3} These findings suggest that efavirenz does not adversely alter the efficacy of combined oral contraceptives. Nevertheless, the manufacturer notes that because the interaction has not been fully characterised, a reliable method of barrier contraception must be used in addition to other methods of contraception such as hormonal contraceptives.^{2,3} Furthermore, a retrospective review identified 22 women who were prescribed oral contraceptives and also received an NNRTI. Two of the 16 women taking efavirenz experienced contraceptive failure. However, medication adherence could not be confirmed.⁴ The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit states that efavirenz can induce liver enzymes and may *reduce* ethinylestradiol and progestogens. They therefore recommend that their guidance on hormonal contraceptives and liver enzyme inducers is followed,⁵ see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985 for further detail. Note that, a barrier method of contraception would usually be considered advisable to reduce the risk of HIV transmission.

(c) Nevirapine

A study in 10 HIV-positive women found that nevirapine 200 mg once daily for 2 weeks then twice daily for a further 2 weeks decreased the median AUC and elimination half-life of **ethinylestradiol** by 29% and 31%, respectively, and decreased the median AUC of **norethisterone** by 19%. The women received two single doses of a combined oral contraceptive (**ethinylestradiol/norethisterone** 35 micrograms/1 mg); 2 days before the nevirapine and on the last day of the nevirapine. Nevirapine was added to established antiretroviral therapy (commonly 3 drugs), which had been unchanged for at least 4 weeks.⁶ A retrospective study identified 22 women who were prescribed oral contraceptives and also received an NNRTI. None of the 6 women taking nevirapine experienced contraceptive failure. However, medication adherence could not be confirmed.⁴

It is likely that nevirapine induces the metabolism of the components of the oral contraceptive by cytochrome P450 isoenzymes.⁶ Although it is not known whether these modest reductions in levels would reduce the anti-ovulatory efficacy of the combined oral contraceptive, it would be prudent to assume they could. The manufacturers recommend that combined oral contraceptives and other hormonal methods of birth control should not be used as the sole method of contraception in women taking nevirapine. They suggest that a barrier method (e.g. condoms) should also be used, and note that this is also advisable to reduce the risk of HIV transmission.^{6,7} The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit notes that nevirapine can induce liver enzymes and may reduce the levels of ethinylestradiol and progestogens. They therefore recommend that their guidance on hormonal contraceptives and liver enzyme inducers is followed,⁵ see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985 for further detail.

The manufacturer also suggests that if combined oral contraceptives are used for reasons other than contraception (e.g. endometriosis), that the therapeutic effect should be monitored and the dose increased if necessary.^{6,7} These precautions seem prudent.

7. Viramune (Nevirapine anhydrate). Boehringer Ingelheim Ltd. UK Summary of product characteristics, January 2007.

Hormonal contraceptives + NRTIs

There do not appear to have been any reports of hormonal contraceptive or NRTI failure during concurrent use. Tenofovir does not appear to affect the pharmacokinetics of ethinylestradiol or norgestimate. *In-vitro* evidence suggests that ethinylestradiol might possibly reduce the metabolism of zidovudine but the significance of this is unclear.

Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

Clinical evidence and mechanism

(a) Tenofovir

In a study in 20 women taking a combined oral contraceptive containing ethinylestradiol and norgestimate (*Ortho Tri-Cyclen*), tenofovir 300 mg daily for 7 days had no effect on the pharmacokinetics of ethinylestradiol or norgestimate. The pharmacokinetics of tenofovir were also not affected when compared with historical data.¹

(b) Zidovudine

An *in vitro* study using human liver microsomes found that ethinylestradiol inhibited the glucuronidation of zidovudine by 50% or more, suggesting that ethinylestradiol may increase the effects and toxicity of zidovudine.² However, note that other drugs that had a similar effect *in vitro* did not alter zidovudine pharmacokinetics in subsequent clinical studies, see 'NRTIs; Zidovudine + Drugs that inhibit glucuronidation', p.808. Further study is needed.

Importance and management

There appears to be no published evidence at present of a clinically significant interaction between the NRTIs (**abacavir**, **didanosine**, **emtricitabine**, **lamivudine**, **stavudine**, **tenofovir**, **zalcitabine** and **zidovudine**) and hormonal contraceptives. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit guidance on drug interactions with hormonal contraception also notes this.³ A study⁴ found no evidence to suggest that hormonal contraceptives affect the efficacy of HAART. The specific HAART drugs were not named, however most patients were noted to be on a regimen containing an NRTI and a protease inhibitor, but no NNRTI.

Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

Hormonal contraceptives + Orlistat

Studies suggest that orlistat does not interact with combined oral contraceptives. However, the manufacturers say that pregnancies have occurred.

Clinical evidence, mechanism, importance and management

Two groups of 10 healthy women taking a combined oral contraceptive were given orlistat 120 mg three times daily or a placebo on days 1 to 23 of two menstrual cycles.¹ Orlistat had no effect on ovulation (measured by luteinising hormone and progesterone levels). The contraceptives used all contained ethinylestradiol, but the progestogens differed: 10 contained desogestrel, 4 levonorgestrel, 3 gestodene, 2 cyproterone acetate and 1 lynestrenol. However, the manufacturer has received reports of unexpected pregnancies in patients taking orlistat and hormonal contraceptives. They state that orlistat may indirectly reduce the bioavailability of oral contraceptives as it can cause severe diarrhoea. Therefore, as is standard practice, they recommend using additional contraceptives in patients who develop severe diarrhoea.² Note that the contraceptive effect of the combined hormonal patch is said not to be affected by diarrhoea.

1. Hartmann D, Güzelhan C, Zuiderwijk PBM, Odink J. Lack of interaction between orlistat and oral contraceptives. *Eur J Clin Pharmacol* (1996) 50, 421–4.
2. Xenical (Orlistat). Roche Products Ltd. UK Summary of product characteristics, May 2006.

Hormonal contraceptives or HRT + Protease inhibitors

Amprénnavir and atazanavir, given alone increase the levels of ethinylestradiol and norethisterone. Ritonavir and nelfinavir, in contrast to the effect that would normally be expected decrease the levels of ethinylestradiol. Reduced ethinylestradiol and norethisterone levels occur with fosamprenavir, lopinavir and tipranavir given with ritonavir. Indinavir does not appear to interact.

A combined oral contraceptive modestly reduced amprenavir levels, but did not affect the levels of amprenavir derived from fosamprenavir, nor saquinavir levels.

Note that whatever other methods of contraception are being used, barrier methods are also advisable to reduce the risk of HIV transmission.

Clinical evidence

(a) Amprenavir

The UK manufacturer briefly notes that amprenavir increased the minimum plasma concentrations of ethinylestradiol and norethisterone, given as a combined oral contraceptive, by 32% and 45%, respectively. Conversely, the amprenavir minimum concentration and AUC were decreased by 20% and 22%, respectively.¹

(b) Atazanavir

Atazanavir 400 mg once daily alone increased the concentration of ethinylestradiol 35 micrograms (when given as a combined oral contraceptive with norethisterone) to a level between the mean concentrations produced by a 35-microgram and a 50-microgram ethinylestradiol dose. The AUC of norethisterone was increased about twofold.²

(c) Fosamprenavir

When fosamprenavir 700 mg twice daily with ritonavir 100 mg twice daily was given with an oral contraceptive containing ethinylestradiol/norethisterone 35/500 micrograms the AUC and maximum plasma concentration of ethinylestradiol were decreased by 37% and 28%, respectively, and the AUC and maximum concentration of norethisterone were decreased by 34% and 38%, respectively. The pharmacokinetics of amprenavir (derived from fosamprenavir) were not significantly affected.³ However, the AUC and maximum concentration of ritonavir were 45% and 63% higher, respectively, compared with historical data in female subjects taking fosamprenavir and ritonavir alone.³ Coadministration of fosamprenavir with ritonavir and a combined oral contraceptive containing ethinylestradiol and norethisterone also resulted in clinically significant increases in liver transaminases in some healthy subjects.³ The clinical relevance of this is not known.

(d) Indinavir

The manufacturer briefly notes that no clinically significant interaction was seen between indinavir and a combined oral contraceptive containing ethinylestradiol and norethisterone.⁴ In a retrospective study there were no reports of contraceptive failure in 9 patients taking indinavir (overall

there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.⁵

(e) *Lopinavir*

A study in 12 healthy subjects found that lopinavir/ritonavir 400/100 mg twice daily for 14 days *decreased* the AUC of **ethinylestradiol** and **norethisterone** (given as a combined oral contraceptive for 21 days) by 42% and 17%, respectively.⁶

(f) *Nelfinavir*

The manufacturer briefly notes that in women taking a combined oral contraceptive (ethinylestradiol/norethisterone 35/400 micrograms) nelfinavir 750 mg three times daily for one week *decreased* the AUCs of **ethinylestradiol** and **norethisterone** by 47% and 18%, respectively.⁷ In a retrospective study of 21 women taking nelfinavir experienced contraceptive failure (overall there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.⁵

(g) *Ritonavir*

In a study in 23 healthy women ritonavir 500 mg every 12 hours for 16 days *decreased* the AUC of **ethinylestradiol** by 41% and decreased its elimination half-life from 17 to 13 hours. The women received a single dose of a combined oral contraceptive (**ethinylestradiol/ethynodiol** 50 micrograms/1 mg), 14 days before the ritonavir and on day 15 of ritonavir.⁸ In a retrospective study there were no reports of contraceptive failure in 6 women taking ritonavir (overall there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.⁵

(h) *Saquinavir*

A study in 8 healthy women found that the pharmacokinetics of a single 600-mg dose of saquinavir were not affected by a combined oral contraceptive containing **ethinylestradiol/gestodene** 30/75 micrograms (*Minulet*) taken for 21 days.⁹ In a retrospective study there was one report of contraceptive failure out of 5 women taking saquinavir (overall there were 8 contraceptive failures out of 33 women taking protease inhibitors). However, medication adherence could not be confirmed.⁵

(i) *Tipranavir*

Tipranavir given with low-dose **ritonavir** *decreased* the AUC and maximum concentration of **ethinylestradiol** by 50%, but did not significantly alter the pharmacokinetics of **norethisterone**.^{10,11}

Mechanism

Ritonavir more commonly *inhibits* the cytochrome P450 isoenzyme CYP3A4 and the results for ritonavir are the opposite of those originally predicted based on *in vitro* data showing *inhibition* of ethinylestradiol metabolism (cytochrome P450 isoenzyme CYP3A mediated 2-hydroxylation).¹² It is possible that ritonavir induces the metabolism of hormonal contraceptives rather than inhibits CYP3A after chronic use. It is also likely that ritonavir induces ethinylestradiol glucuronosyl transferase activity.⁸ Nelfinavir probably interacts similarly. Amprenavir, atazanavir, fosamprenavir, indinavir and tipranavir (when combined with ritonavir) may inhibit CYP3A4. However, note that, although indinavir is a relatively potent inhibitor of CYP3A4, it does not appear to interact.

Importance and management

Although information is limited, the pharmacokinetic interaction between the ethinylestradiol component of **combined hormonal contraceptives** and nelfinavir or ritonavir appears to be established and is likely to be clinically important. Similar *decreases* in plasma levels of ethinylestradiol caused by other drugs have resulted in reduced efficacy and reliability of combined oral contraceptives, and one retrospective report suggests that this has occurred with nelfinavir.⁵ It seems likely that the reduced contraceptive levels seen with fosamprenavir, lopinavir and tipranavir were due to the concurrent use of ritonavir (as would be common in practice). Similarly, although no interaction was reported with saquinavir, and *raised* contraceptive steroid levels were reported with amprenavir and atazanavir, in practice these drugs would be given with ritonavir (as a pharmacokinetic enhancer), and so the levels of combined hormonal contraceptives can reasonably be expected to be reduced. The Faculty of Family Planning

and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has given general guidance on how to manage the interaction of combined hormonal contraceptives with liver enzyme inducers. See 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985. Note that there appears to be no clinically significant interaction between indinavir and combined oral contraceptives.

There is no direct information about **progestogen-only contraceptives** but since lopinavir/ritonavir and nelfinavir cause small *reductions* in the levels of norethisterone (when given as part of a combined oral contraceptive) it is possible that these protease inhibitors could reduce the contraceptive efficacy of progestogen-only contraceptives containing norethisterone. The progestogen-only oral contraceptives have a higher failure rate than the combined oral contraceptives, so it would seem prudent to use additional or alternative contraceptive measures in this situation as well. Whether this applies to other progestogens used in progestogen-only contraceptives does not appear to have been specifically studied. See 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985, for the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit general guidance on how to manage the interaction between liver enzyme inducers and hormonal contraceptives in women using the progestogen-only pill or implant. The progestogen-only depot injection and progestogen-releasing intrauterine system are not affected by liver enzyme inducers.¹³

However, note that whatever other methods of contraception are being used, barrier methods are always advisable to reduce the risk of HIV transmission.

The effects of the protease inhibitors on **HRT** does not appear to have been studied, although it would be prudent to anticipate some reduction in their effects. The manufacturers of tipranavir specifically note that patients using oestrogens as HRT together with tipranavir and ritonavir should be monitored for signs of oestrogen deficiency. They also note that women using oestrogens with tipranavir may also have an increased risk of non-serious rash.^{10,11}

Amprenavir levels are decreased by combined hormonal contraceptives, but the effects are modest. There appears to be no evidence to suggest that combined hormonal contraceptives decrease the antiretroviral efficacy of HAART.¹⁴ but evidence is preliminary and more study is needed.

Hormonal contraceptives or HRT + Proton pump inhibitors

Lansoprazole and pantoprazole appear not to interact with combined oral contraceptives. Ethinylestradiol may inhibit the me-

tabolism of omeprazole, but levonorgestrel appears to have no effect. Omeprazole does not appear to interact with estradiol.

Clinical evidence, mechanism, importance and management

(a) Lansoprazole

In a placebo-controlled, crossover study, 24 healthy women were given a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 30/150 micrograms) for two monthly cycles, with and without lansoprazole 60 mg daily. The levels of the oral contraceptive steroids were not significantly altered by lansoprazole, nor were endogenous progesterone levels raised, suggesting that ovulation did not occur.¹ The manufacturer has information about 3 other unpublished studies in a total of 59 women, which have also found no evidence to suggest that lansoprazole interacts with oral contraceptives in any way which would affect their reliability.² No special precautions are necessary on concurrent use.

(b) Omeprazole

A study in 10 subjects taking a combined oral contraceptive containing **ethinylestradiol/levonorgestrel** 40/75 micrograms (*Trikvilar*) for 10 days found that the combined contraceptive increased the AUC of a single 40-mg dose of omeprazole (*Losec MUPS*) by 38%. This increase was not seen when patients were given **levonorgestrel** alone. Changes in hormonal steroid levels were not studied.³ No cases of contraceptive failure appear to have been reported with omeprazole. No special precautions appear to be necessary on concurrent use. Note that the UK manufacturer of omeprazole says that there is no evidence of an interaction with **estradiol**.⁴

(c) Pantoprazole

A study over four menstrual cycles was completed by 64 pre-menopausal women. The women were confirmed to be ovulating before taking a low-dose triphasic oral contraceptive (**ethinylestradiol/levonorgestrel**), and not ovulating during contraceptive use. They continued not ovulating when pantoprazole 40 mg daily was given, so it was concluded that pantoprazole does not affect the efficacy of oral contraception.⁵

Hormonal contraceptives + Retinoids

There seems to be no evidence that the reliability of the combined oral contraceptives is affected by acitretin, etretinate or isotretinoin, and they are the contraceptive method of choice with these teratogenic drugs. It is unclear whether the effects of the progestogen-only oral contraceptives are altered by acitretin, but, in any case, progestogen-only oral contraceptives are not generally considered reliable enough for use with these teratogenic drugs. The adverse effects of isotretinoin on lipids may be additive with those of oral contraceptives.

Clinical evidence

(a) Combined oral contraceptives

1. *Acitretin*. Eight women taking a combined oral contraceptive (**ethinylestradiol/levonorgestrel**) were given acitretin 25 to 40 mg daily for at least two cycles. Suppression of ovulation was not affected by acitretin, as assessed by plasma progesterone levels.¹

2. *Etretinate*. In a study in 12 women taking a combined oral contraceptive (**ethinylestradiol plus levonorgestrel, norethisterone, norgestrel, or cyproterone**) the use of **etretinate** 0.7 to 1 mg/kg did not affect the suppression of ovulation.²

3. *Isotretinoin*. A pharmacokinetic study in 9 women taking a combined oral contraceptive found that the plasma levels of **ethinylestradiol** and **levonorgestrel** were not significantly changed by the use of isotretinoin 500 micrograms/kg. Suppression of ovulation was maintained.³ Another study in 26 women taking a combined oral contraceptive containing **ethinylestradiol** 35 micrograms and **norethisterone** 0.5/0.75/1 mg (*Ortho Novum 7/7/7*) found a small reduction in the levels of ethinylestradiol and norethisterone when isotretinoin 1 mg/kg daily was also given. These changes were not associated with significant changes in the levels of FSH, LH or progesterone. However large inter-patient variability in the results was noted and two patients showed increases in progesterone levels, possibly indicating that ovulation had occurred. One of these patients was noted to be non-compliant.⁴

The adverse effects of isotretinoin and combined oral contraceptives on plasma lipids may be additive. A case-control study found that women who had hypertriglyceridaemia and/or hypercholesterolaemia while taking isotretinoin were 2 to 12 times as likely to be also taking an oral contraceptive.⁵

(b) Progestogen-only oral contraceptives

One woman taking a progestogen-only contraceptive (**levonorgestrel** 30 micrograms) had a significant increase in her progesterone levels after 3 cycles while taking **acitretin** 400 micrograms/kg daily. Plasma progesterone levels rose from 2.15 nanograms/mL before taking the **acitretin** to 3.87 to 13.46 nanograms/mL with **acitretin**. This rise in progesterone levels was taken as evidence that ovulation had occurred.¹

Mechanism, importance and management

Information is limited, but it appears that these retinoids do not usually alter the efficacy of combined oral contraceptives. The one available case suggests that acitretin reduces the efficacy of progestogen-only oral contraceptives. However, note that **progestogen-only oral contraceptives** do not reliably suppress ovulation in all cycles, and that this is not considered their primary mechanism of action (see 'Hormonal contraceptives and Sex hormones', (p.975)). The single report cannot therefore be taken as evidence that acitretin reduces the efficacy of progestogen-only contraceptives.

Also note that because the retinoids are established human teratogens, it is very important that women taking them do not become pregnant. For this reason, progestogen-only oral contraceptives are generally not considered suitable for use with retinoids.⁶ Unless contraindicated, combined oral contraceptives are the method of choice.^{6–8} The combined oral contraceptive should be started one month before the retinoids and continued for one month after stopping isotretinoin,^{7,8} and for 2 years after stopping etretinate or acitretin.⁶ In the US, it is standard practice to recommend that a second form of contraception, such as a barrier method, should also be used.⁹ This is also recommended by the UK manufacturer of isotretinoin.¹⁰ This is because, even though hormonal methods of contraception are highly effective, they do, on rare occasions, fail.⁷ The general significance of the reduction in steroid levels seen in one study with isotretinoin is unclear and the results were subject to wide inter-patient variability, however the authors state that their results reinforce the advice of using two forms of contraception,⁴ one of which should usually be a barrier method, such as condoms.⁹ Note that an oral contraceptive containing a non-androgenic (third generation) progestogen (e.g. desogestrel, gestodene, norgestimate) is preferred, since these have less detrimental effects on lipids,⁶ and some favour the use of the anti-androgen cyproterone.⁸

Hormonal contraceptives + Rifamycins

Hormonal contraceptives are less reliable during treatment with rifampicin. Breakthrough bleeding and spotting commonly occur, and pregnancy may not be prevented. Rifabutin also reduces the reliability of hormonal contraceptives, although it interacts to a lesser extent, and no contraceptive failures appear to have been reported.

Clinical evidence

(a) Rifabutin

In two studies rifabutin 300 mg daily for 10 or 14 days reduced the plasma levels of **ethinylestradiol** and **norethisterone** in women taking a combined oral contraceptive, but to a lesser extent than rifampicin. The AUC for **ethinylestradiol** decreased by about 35% in both studies, and the AUC of **norethisterone** decreased by 17%. In one study, spotting occurred in 21.7% of women when they took rifabutin (compared with 3.7% in the control cycle and 36% with rifampicin).¹ Ovulation did not occur with rifabutin or rifampicin in either study.^{1,2} There appear to be no reports of contraceptive failure attributed to rifabutin.

(b) Rifampicin (Rifampin)

A report in 1971 noted a marked increase in the frequency of intermenstrual breakthrough bleeding (regarded as loss of reliability of the contraceptive) in women taking a **combined oral contraceptive** and rifampicin.³ In a later report by the same researchers, 62 out of 88 women taking a combined oral contraceptive had menstrual cycle disorders of various kinds (spotting, bleeding, failure to menstruate) while taking a rifampicin-based regimen for tuberculosis, compared with only 1 of 26 treated with a streptomycin-based regimen. In addition, 5 pregnancies occurred in women taking the rifampicin-based regimen.^{4,5} Other case reports have confirmed this interaction, and there have been a total of at least 11 other pregnancies reported.⁶⁻¹³ Combined oral contraceptives commonly mentioned in these reports include **ethinylestradiol** with **norgestrel** or **norethisterone**.^{7,9-13} There has also been a report of a pregnancy occurring in a woman who was using a **progestogen-only implant**: a 29-year-old woman who had been fitted with an **etonogestrel** implant (*Implanon*) for approximately 2 years was prescribed rifampicin 300 mg twice daily for hidradenitis suppurativa and was found to be 5 weeks pregnant about 6 months later.¹⁴

One pharmacodynamic study found that 11 out of 21 women taking a triphasic oral contraceptive (**ethinylestradiol/levonorgestrel** 30 to 40 micrograms/50 to 125 micrograms) ovulated (assessed by increased progesterone levels) while taking rifampicin 300 mg daily.¹⁵ In another study, 2 out of 7 women taking a combined oral contraceptive (**ethinylestradiol/norethisterone** 30 micrograms/1 mg) ovulated while taking rifampicin. In addition, rifampicin reduced the AUC of **norethisterone** by 30%.¹⁶ Conversely, two other studies did not detect ovulation in 34 women taking a combined oral contraceptive (**ethinylestradiol/norethisterone** 35 micrograms/1 mg) and rifampicin.^{1,2} However, an increased incidence of spotting was noted in one of these studies (36% versus 3.7% in the control cycle).¹ Furthermore, both of these studies found that rifampicin 300 mg daily for 10 days or 600 mg daily for 14 days reduced the AUC of **ethinylestradiol** by about 63% and **norethisterone** by about 55%. These pharmacokinetic results confirm the findings of earlier studies.^{17,18} Rifampicin plasma levels¹⁹ and efficacy³ are reported to be unchanged by oral contraceptives.

Mechanism

Rifampicin is a potent non-specific enzyme inducer, which has been shown to increase the hydroxylation of ethinylestradiol fourfold in an *in vitro* study,^{20,21} and twofold in an *in vivo* study.²² Another study showed that the metabolism of ethinylestradiol derived from mestranol was similarly affected.²³ As a result, the reduced steroid levels may be insufficient to prevent the re-establishment of a normal menstrual cycle with ovulation, which would explain the breakthrough bleeding and pregnancies that have occurred. Rifabutin similarly acts as an enzyme inducer, but it is less

potent than rifampicin (said to be half as potent in reducing contraceptive steroid levels).²

Importance and management

The interaction between the combined oral contraceptives and rifampicin is well documented, well established and clinically important. Menstrual cycle disturbances of 36 to 70%,^{1,3,4} and an ovulation rate of up to 52%^{15,16} show very clearly that women receiving **combined oral contraceptives** should use an alternative or additional form of contraception while taking rifampicin, and for 4 to 8 weeks after its withdrawal.^{24,25} Direct information about the interaction between combined oral contraceptives and rifabutin seems to be limited to the pharmacodynamic studies cited, but it is supported by the well-recognised enzyme-inducing properties of rifabutin. It would clearly be prudent for women receiving rifabutin to take the same precautions as with rifampicin, although the risks are lower because rifabutin is a less potent enzyme inducer. No cases of contraceptive failure appear to have been attributed to the use of rifabutin. Nevertheless, to be on the safe side, the Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit, the manufacturers and the CSM in the UK say that patients using these contraceptives and rifabutin should be advised to use other methods of contraception.²⁵⁻²⁷ Note that the combined hormonal contraceptive patch is also affected by liver enzyme-inducers such as rifamycins.

No contraceptive failures due to rifampicin or rifabutin have been reported with the **progestogen-only oral contraceptives**, but their reliability in the presence of either drug is doubtful because both rifampicin and rifabutin are known to increase the metabolism of the progestogen component of combined oral contraceptives.^{1,2,16,17} The FFPRHC recommends that alternative methods of contraception to the progestogen-only oral pill should be used when receiving liver-enzyme inducing antibacterials.²⁵

There has been a report of a pregnancy in a woman who was using a **progestogen-only implant** about 6 months after starting rifampicin.¹⁴ The FFPRHC recommends that patients with a progestogen-only implant should use additional methods of contraception during and for 4 weeks after stopping a short course of a liver enzyme-inducing antibacterial. Alternative forms of contraception should be considered in patients requiring long-term treatment with these antibacterials.²⁵

The **progestogen-only injection** and **levonorgestrel-releasing IUD** do not appear to be affected, so no additional protection is required.²⁵

The effectiveness of the **emergency progestogen-containing oral contraceptive** will also be reduced in women taking liver enzyme inducers. In the UK it is possible to purchase this type of emergency hormonal contraceptive without a prescription; however, it is recommended that patients taking liver enzyme inducing antibacterials should not be supplied with the emergency contraceptive but should be referred to a doctor or family planning service.²⁵

The FFPRHC has issued guidance on the use of liver enzyme inducers, such as rifampicin and rifabutin, with all forms of hormonal contraceptives, including the emergency hormonal contraceptive, and these are given in detail elsewhere, see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985.

Hormonal contraceptives + St John's wort (*Hypericum perforatum*)

St John's wort may affect the pharmacokinetics of desogestrel, ethinylestradiol, and norethisterone. Both breakthrough bleeding and, more rarely, combined oral contraceptive failure have been reported in women taking St John's wort. Two cases describe the failure of emergency hormonal contraception, which was attributed to the use of St John's wort.

Clinical evidence

(a) Combined hormonal contraceptives

A study in 17 healthy women taking **ethinylestradiol/desogestrel** 20/150 micrograms daily found that St John's wort (300 mg twice or three times daily) did not affect the AUC or maximum levels of **ethinylestradiol**. However, the AUC and maximum levels of the active metabolite of **desogestrel** were significantly decreased by about 40% and 20%, respectively. There was no evidence that ovulation occurred. However, the frequency of breakthrough bleeding increased significantly from 35% to around 80%, which may affect compliance.¹ Another study in 12 healthy women taking **ethinylestradiol/norethisterone** 35 micrograms/1 mg (*Ortho-Novum*) found that St John's wort 300 mg three times daily for 8 weeks increased the oral clearance of **norethisterone** and reduced the half-life of **ethinylestradiol**, but the serum levels of LH, FSH and progesterone were unaffected. However, of more importance, was the increase in breakthrough bleeding, which the authors state as a major cause of patients stopping hormonal contraceptives.² A further study in 16 subjects also found reductions in the levels of low-dose **ethinylestradiol/norethisterone** 20 micrograms/1 mg. Furthermore, they found increased progesterone levels of more than 3 nanograms/mL (an indication that ovulation occurred) in 3 patients who also took St John's wort compared with one subject who took placebo. Breakthrough bleeding occurred in was also increased.³

The Adverse Drug Reactions Database of the Swedish Medical Products Agency has on record 2 cases of pregnancy due to the failure of a combined oral contraceptive, which was attributed to the use of products containing St John's wort (*Esbericum* and *Kira*). One woman was taking **ethinylestradiol** and **norethisterone** and the other was taking **ethinylestradiol** and **levonorgestrel**.⁴ This follows an earlier report from the Swedish Medical Products Agency of 8 cases of breakthrough bleeding in women aged 23 to 31 taking long-term oral contraceptives and St John's wort. Breakthrough bleeding occurred within about a week of starting St John's wort in 5 of the cases, and was known to have resolved in 3 cases when the St John's wort was stopped.⁵ The CSM in the UK has on record a further 7 cases of pregnancy in women taking St John's wort and oral contraceptives in the two-year period from February 2000 to February

2002.⁶ Another earlier brief report describes 3 women taking a combined oral contraceptive (**ethinylestradiol/desogestrel** 30/150 micrograms) who developed breakthrough bleeding one week (2 cases) and 3 months (1 case) after starting to take St John's wort.⁷ A single case of pregnancy has also been reported in a patient taking St John's wort with **ethinylestradiol/dienogest** (*Valette*).⁸ The German Federal Institute for Drugs and Medical Devices has received a total of 8 case reports of ineffective contraception with St John's wort.⁹

(b) Emergency hormonal contraceptives

The CSM in the UK has received reports of 2 women taking St John's wort who became pregnant despite taking **emergency hormonal contraception**. One of them was also taking an oral contraceptive.⁶

Mechanism

It is believed that St John's wort can induce the cytochrome P450-mediated metabolism of the contraceptive steroids, thereby reducing their serum levels and their effects.^{5,7,10} This can lead to breakthrough bleeding and, in some cases, contraceptive failure. This is consistent with the way St John's wort appears to lower the serum levels of some other drugs. Note that St John's wort is a herbal preparation, and the specific constituents responsible for enzyme induction are currently unknown. Also, the levels of individual constituents can vary between different preparations of the herb.

Importance and management

Information appears to be limited to these reports but the interaction between hormonal contraceptives and St John's wort appears to be established. Its incidence is not known but the evidence so far suggests that breakthrough bleeding may be a problem, although pregnancy resulting from this interaction appears to be uncommon. However, since it is not known who is particularly likely to be at risk, women taking oral contraceptives should either avoid St John's wort (the recommendation of the CSM/MCA and the FFPRHC in the UK^{10,11}) or they should use an additional form of contraception. Only two cases of emergency hormonal contraceptive failure attributed to an interaction with St John's wort have so far been reported, but the effects of any interaction here would be very difficult to assess. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit is in agreement with the CSM advice but recommends that, if St John's wort must be continued, the guidelines for the use of liver enzyme inducers with hormonal contraceptives should be followed, see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985, for details of this guidance. Note that combined hormonal contraceptive patch, progestogen-only pills and implants may also be affected.

See also 'Emergency hormonal contraceptives + Enzyme inducers', p.977 for information on how to manage the interaction with emergency hormonal contraception.

Although the considerable worldwide popularity of St John's wort is fairly recent, it is currently the most widely used antidepressant in Germany and has been used for very many years in both Germany and Austria. Yet, there seems to be no published evidence that oral contraceptive failure in those countries is more frequent than anywhere else. This would seem to confirm that contraceptive failure leading to pregnancy occurring as a result of this interaction is very uncommon, or perhaps that it has failed to be identified as a possible cause.

Hormonal contraceptives or HRT + Statins

Atorvastatin and rosuvastatin may modestly increase the plasma levels of combined oral contraceptives. Rosuvastatin pharmacokinetics and lipid-lowering effects were unaffected by an oral contraceptive containing ethinylestradiol and norgestimate. The pharmacokinetics of a single dose of pravastatin were also unaffected by combined oral contraceptives. However, norethisterone abolished the beneficial effects of atorvastatin and/or estradiol on the lipid profile.

Clinical evidence, mechanism, importance and management

(a) Atorvastatin

A study in 12 healthy women taking a combined oral contraceptive (ethinylestradiol/norethisterone 35 micrograms/1 mg) found that atorvastatin 40 mg daily increased the AUC of norethisterone and ethinylestradiol by about 28% and 19%, respectively, and increased their maximum plasma levels by 24% and 30%, respectively.¹ These increases are only moderate and unlikely to be clinically important, but the manufacturers say that they should be considered when selecting an appropriate oral contraceptive dosage for women given atorvastatin.^{2,3}

A double-blind, randomised, placebo-controlled study in postmenopausal women with hypercholesterolaemia and arterial hypertension found that whilst atorvastatin alone, estradiol alone, or the combination of both had beneficial effects on the lipid profile and endothelium-dependent vasodilatation, these effects were abolished by the addition of norethisterone. It was suggested that progesterone derivatives with high androgenic activity, such as norethisterone, have a negative effect on lipid profile.⁴

(b) Pravastatin

The pharmacokinetics of a single 20-mg dose of pravastatin were found to be unaffected in 15 young women taking combined oral contraceptives (ethinylestradiol with norethisterone, norgestrel or levonorgestrel), when compared with similar women not taking contraceptives. No adverse effects attributable to concurrent use were seen.⁵

(c) Rosuvastatin

A non-randomised study in 18 healthy women taking a combined oral contraceptive (*Ortho Tri-Cyclen*; ethinylestradiol 35 micrograms for 21 days with norgestimate 180/215/250 micrograms, 7 days of each) found that the addition of rosuvastatin 40 mg daily increased the AUC and maximum concentration of ethinylestradiol by 26% and 25%, respectively, and increased the AUC and maximum concentration of norgestrel, an active metabolite of norgestimate, by 34% and 23%, respectively. The contraceptive efficacy was unchanged as measured by FSH, LH and progesterone levels.⁶ These increases in hormonal steroid levels are unlikely to be clinically significant in patients taking low-dose oral contraceptives,⁶ although the manufacturer notes that these changes should be considered when choosing a hormonal contraceptive preparation.⁷ The pharmacokinetics and lipid-lowering effects of rosuvastatin were unaffected.⁶

Hormonal contraceptives + Sucrose polyesters

Sucrose polyesters do not interact with oral contraceptives.

Clinical evidence, mechanism, importance and management

When 28 healthy women took 18 g of sucrose polyester (*Olestra*) daily for 28 days, the pharmacokinetics of the components of a combined oral contraceptive (ethinylestradiol/norgestrel 30/300 micrograms) were unchanged. Serum progesterone levels also remained unaltered, suggesting no ovulation occurred.¹ This agrees with the findings of earlier single-dose studies, which found that sucrose polyester had no effect on the bio-availability of single doses of ethinylestradiol or norethisterone.² No special contraceptive precautions appear to be necessary.

Hormonal contraceptives + Terbinafine

Terbinafine does not have a clinically significant interaction with oral contraceptives.

Clinical evidence, mechanism, importance and management

An *in vitro* study in human livers found that terbinafine did not alter the pharmacokinetics of ethinylestradiol.¹ However, the manufacturer of terbinafine notes that menstrual disturbances have occurred in patients taking both oral contraceptives and terbinafine.² In a post-marketing survey, which included 314 patients taking both oral contraceptives and terbinafine, the rate of menstrual disorders was within the rate reported for patients taking oral contraceptives alone.³

Hormonal contraceptives + Tobacco

There is some evidence that smoking increases the risk of breakthrough bleeding with combined oral contraceptives, although smoking appears not to alter contraceptive steroid levels. The risk of cardiovascular disease in women taking combined oral contraceptives is greatly increased if they smoke, particularly in the older age group. Progesterone-only oral contraceptives are an alternative.

Clinical evidence

(a) Cardiovascular effects

Early after the introduction of combined oral contraceptives it was realised that they increase the risk of cardiovascular effects such as thromboembolism, myocardial infarction, and stroke, and that the risks were markedly increased in women who also smoked.¹⁻⁵ For example, one of these studies found a relative risk of non-fatal myocardial infarction in women taking an oral contraceptive of 4.5 in non-smokers and 39 in heavy smokers.⁴ Another study found a relative risk of subarachnoid haemorrhage in women taking oral contraceptives of 6.5 for non-smokers and 22 for smokers.⁵ Heavy smokers (who smoke more than 15 cigarettes daily) have a three-fold increased risk of myocardial infarction and a twofold increase in the risk of stroke compared with non-smokers, and these risks are further increased by the use of combined oral contraceptives.⁶ A study involving 17,032 women aged 25 to 39 years at entry, who had used oral contraceptives (mainly containing 50 micrograms of oestrogen), a diaphragm, or an intrauterine device, found that the risk of death from ischaemic heart disease was slightly, but not statistically significantly, raised in all oral contraceptive users. However, smoking had a substantial effect on mortality from ischaemic heart disease; in heavy smokers (more than 15 cigarettes

daily) the mortality rate ratios for oral contraceptive use for 48 months or less, for 49 to 96 months, and for 97 months or more compared with non-use were 2.4, 4.8, and 2.8, respectively.⁷

(b) Contraceptive efficacy

An analysis of data from three large clinical studies in a total of 2956 women found that smoking was associated with an increased incidence of spotting and bleeding in users of combined oral contraceptives. The relative risk was 1.3 during the first cycle of use and increased to 1.9 by the sixth cycle.⁸ Similarly, in a study of women who became pregnant while taking oral contraceptives, smokers were more likely to have menstrual disturbances, and smokers taking the combined oral contraceptive had a 20% greater pill failure rate than expected.⁹ This association was not noted for **progestogen-only oral contraceptive** failure.⁹ Conversely, in a large cohort study in the UK, the failure rate of oral contraceptives was not increased in smokers.¹⁰ In one study in 311 women taking oral contraceptives, plasma levels of ethinylestradiol and norgestrel were similar in smokers and non-smokers,¹¹ and another study found only a small increase in ethinylestradiol clearance in smokers.¹²

Mechanism

The cardiovascular effects reported do not appear to be attributable to any effect of smoking on the metabolism of contraceptive steroids (see below). Rather, the adverse effects of combined oral contraceptives on cardiovascular risk factors, such as plasma lipids and coagulation parameters, appear to be accentuated by smoking.

Smoking increased the metabolism (2-hydroxylation) of *endogenous* estradiol in one study in premenopausal women.¹³ Smoking does not appear to alter the levels of contraceptive steroids to a clinically relevant extent.

Importance and management

The cardiovascular interaction between smoking and **combined hormonal contraceptives** is well established. The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit and Royal College of Obstetricians and Gynaecologists guidelines on criteria for the use of contraceptives recommend that the combined hormonal contraceptive should not be used in women aged over 35 who are current smokers or who stopped smoking less than one year ago as the risks, particularly of cardiovascular disease, outweigh the benefits.^{6,14} Women over the age of 35 years with no additional risk factors (such as diabetes, hypertension etc) and who stopped smoking more than one year ago may consider using a combined hormonal contraceptive. This is because the risk of cardiovascular disease reduces by as much as 50% one year after stopping smoking, although it may not become comparable to that of a non-smoker for up to 4 to 10 years.^{6,14} Women aged under 35 years who smoke and have no other associated risk factors may use a combined hormonal contraceptive, but should be informed about the increased risk of cardiovascular disease. Any woman with multiple risk factors for cardiovascular disease (older age, smoking, diabetes, hypertension, obesity, family history of arterial disease, migraine) should not take the combined hormonal contraceptive.^{14,15} The BNF recommends that women who smoke 40 or more cigarettes a day should not receive combined oral contraceptives.¹⁵ In women who smoke, for whom a combined oral contraceptive is not contraindicated, ones with the lowest doses of ethinylestradiol may be safer.¹⁶ All smokers should be encouraged to stop.¹⁶ In the UK, **progestogen-only oral contraceptives** are considered suitable for women who are heavy smokers,¹⁴ although it should be remembered that they have a higher failure rate than the combined oral contraceptives.

Smoking may increase the incidence of breakthrough bleeding. This may decrease the acceptability of the oral contraceptive, and lead to the use of less effective contraceptive methods.⁸ However, it also raises the question of whether smoking increases the failure rate of oral contraceptives. The only evidence that this may occur is anecdotal. Further study is needed.

Hormonal contraceptives + Tolterodine

Tolterodine does not appear to interact with combined oral contraceptives.

Clinical evidence, mechanism, importance and management

A randomised, crossover study in 24 women found that tolterodine 2 mg twice daily on days 1 to 14 of two 28-day contraceptive cycles had no effect on the pharmacokinetics of the steroids in a combined oral contraceptive (**ethinylestradiol/levonorgestrel** 30/150 micrograms). The pharmacokinetics of the tolterodine were also not significantly altered, and the serum levels of estradiol and progesterone indicated that suppression of ovulation continued during both periods of treatment.¹ No special precautions would therefore seem to be needed if these drugs are used concurrently.

1. Olsson B, Landgren B-M. The effect of tolterodine on the pharmacokinetics and pharmacodynamics of a combination oral contraceptive containing ethinyl estradiol and levonorgestrel. *Clin Ther* (2001) 23, 1876–88.

Hormonal contraceptives or HRT + Triptans

Oral contraceptives appear to modestly raise the levels of frovatriptan, naratriptan and zolmitriptan, and slightly increase those of sumatriptan. These changes are not considered clinically significant. HRT did not appear to affect the pharmacokinetics of naratriptan.

Almotriptan, rizatriptan and sumatriptan appear not to alter the levels of oral contraceptives.

Clinical evidence

(a) Almotriptan

A study in 21 women found that a single 12.5-mg dose of almotriptan had no clinically significant effect on the pharmacokinetics of a combined oral contraceptive containing **ethinylestradiol** 30 micrograms and **desogestrel** 150 micrograms, taken for two cycles.¹

(b) Frovatriptan

In a retrospective analysis of pharmacokinetic data from phase I studies, the mean maximum concentration and AUC of frovatriptan were 25% and 30% higher, respectively, in women taking oral contraceptives than in women not taking oral contraceptives.²

(c) Naratriptan

The clearance of naratriptan was reduced by 32% by oral contraceptives leading to a slightly higher level of naratriptan. HRT had no effect on the pharmacokinetics of naratriptan.³ A case of ischaemic colitis has been reported in a patient taking an oral contraceptive containing ethinylestradiol 30 micrograms and drospirenone 3 mg long-term with naratriptan 2.5 mg, taken to relieve migraine attacks.⁴

(d) Rizatriptan

A placebo-controlled study in 20 healthy young women taking a combined oral contraceptive (**ethinylestradiol/norethisterone** 35 micrograms/1 mg) found that the concurrent use of rizatriptan (6 days of 10 mg daily followed by 2 days of 10 mg every 4 hours to a total of 3 doses daily) did not affect the pharmacokinetics of either contraceptive steroid. Blood pressure, heart rate and temperature were unaffected and adverse effects were similar to those seen with placebo.⁵

(e) Sumatriptan

A study to investigate the effects of a combined oral contraceptive (**ethinylestradiol/norethisterone** 35 micrograms/1 mg) on the pharmacokinetics of sumatriptan was done in 26 women who had been taking this contraceptive for at least 3 months. A single 50-mg oral dose of sumatriptan was given once after 21 days of active treatment with the oral contraceptive, and again after 7 days of placebo (day 28). A 16% higher AUC and a 17% higher maximum concentration of sumatriptan was noted on day 21, compared with day 29. There was an 18% reduction in the maximum concentration of **norethisterone** when it was given with sumatriptan, but no change in its AUC. Similarly, there was no change in the AUC or maximum concentration of **ethinylestradiol** when it was given with sumatriptan.⁶

(f) Zolmitriptan

In a retrospective analysis of pharmacokinetic data from several studies, the mean maximum concentration and AUC of zolmitriptan were 30 to 50% higher, respectively, in women taking oral contraceptives than in women not taking oral contraceptives.⁷ The effects of zolmitriptan on oral contraceptive steroids have not been studied.⁷

Mechanism

Not known.

Importance and management

Although data are limited, the minor to modest possible increases in frovatriptan, naratriptan, sumatriptan and zolmitriptan pharmacokinetics described are not likely to produce clinically relevant adverse effects. Almotriptan, rizatriptan and sumatriptan do not appear to have any clinically important effect on levels of contraceptive steroids. The significance of the single case report of ischaemic colitis associated with concurrent use of naratriptan and a combined oral contraceptive is unclear. Note that ischaemic colitis has, rarely, been reported with naratriptan itself.⁸ The manufacturers have found no cases of ischaemic colitis in approximately 450 women on oral contraceptives and taking naratriptan for prophylaxis for 5 to 6 days.⁸ However, caution may be needed with concurrent use in those patients with risk factors for ischaemic colitis, such as those with a history of abdominal surgery, low blood pressure, diabetes, cardiovascular disease or stroke.

More importantly, women who suffer from migraine and take a combined oral contraceptive are at increased risk of a stroke compared with those using combined oral contraceptives who do not suffer from migraine.⁹⁻¹¹ The Faculty of Family Planning and Reproductive Health Care (FFPRHC) guidance states that women of all ages who currently have migraines *with* aura should not use a combined hormonal contraceptive. Women over the age of 35 who have migraine attacks *without* aura and those of any age with a past history of migraine *with* aura should also not use combined hormonal contraceptives.¹¹ Women taking any hormonal contraceptive who develop migraine with aura as a new symptom should have their contraceptive choices reviewed. The FFPRHC guidance gives advice on alternative choices of contraceptive method for women with migraine or a history of migraine.¹¹

Hormonal contraceptives + Ziprasidone

Ziprasidone appears not to interact to a clinically relevant extent with combined oral contraceptives.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study, 18 women taking an oral contraceptive (**ethinylestradiol/levonorgestrel** 30/150 micrograms) for at least 3 months were also given ziprasidone 20 mg twice daily for 8 days. The only change in the pharmacokinetics of the two steroids was an approximately 30-minute increase in the time to maximum plasma concentration of the **levonorgestrel**, but this was not considered to be clinically significant. No adverse effects occurred. It was concluded that combined use is safe and that ziprasidone does not affect the efficacy of this oral contraceptive¹ and is also unlikely to affect the metabolism and therefore efficacy of other similar contraceptives.

1. Muirhead GJ, Harness J, Holt PR, Oliver S, Anziano RJ. Ziprasidone and the pharmacokinetics of a combined oral contraceptive. *Br J Clin Pharmacol* (2000) 49 (Suppl 1), 49S-56S.

HRT + Enzyme inducers

Enzyme inducers that increase the metabolism of contraceptive steroids might also be expected to reduce the efficacy of menopausal HRT. An isolated case describes reduced efficacy of oral conjugated oestrogens in a patient taking phenytoin.

Clinical evidence, mechanism, importance and management

A report describes a 28-year-old woman taking oral **conjugated oestrogens** (*Premarin*) 1.25 mg daily after ovidectomy, who had a dramatic increase in the incidence of hot flushes when she began to take **phenytoin** 300 mg daily. Her estrone and estradiol levels were found to be very low, and they subsequently increased by four to sixfold after the **phenytoin** was stopped, at which point the incidence of hot flushes decreased.¹ This seems to be the only report of this interaction.

However, it is not unreasonable to assume that enzyme inducers that increase the metabolism of contraceptive steroids (see 'Table 28.1', (p.975)) would also increase the metabolism of oestrogens used for HRT. Some manufacturers state that these drugs may reduce the efficacy of HRT preparations. This would be most likely to be noticed where HRT is prescribed for menopausal vasomotor symptoms, but might be difficult to detect where the indication is osteoporosis. The interaction is not relevant to HRT applied locally for menopausal vaginitis. It has also been suggested that any interaction is less likely with transdermal HRT, which bypasses hepatic first-pass metabolism. Further study is needed to confirm the importance of this possible interaction.

HRT + Moexipril

Moexipril is reported not to interact adversely with HRT.

Clinical evidence, mechanism, importance and management

A placebo-controlled study involving 95 hypertensive postmenopausal women taking HRT found that moexipril, given for 12 weeks, did not affect metabolic parameters associated with cardiovascular disease and concurrent use was considered to be safe and effective.¹ HRT had no effect on

the blood pressure-lowering ability of moexipril.¹ Consider also 'Drosiprenone + Potassium-sparing drugs', p.977, for a possible interaction between ACE inhibitors and drosiprenone.

IUDs; Copper + Anti-inflammatory drugs

There are a few early reports suggesting that the very occasional contraceptive failure of a copper IUD may have been due to an interaction with a corticosteroid, aspirin or NSAID.

Clinical evidence, mechanism, importance and management

The cases of 4 women who, despite being fitted with copper IUDs, each had two successive pregnancies have been reported. Two were taking **corticosteroids** regularly and the other two often took **aspirin** for migraine.^{1,2} Unwanted pregnancies have also been reported in 3 women with copper IUDs who were taking **corticosteroids**,^{3–5} and in 2 women taking **NSAIDs (indometacin and naproxen)**.⁵ A later case-control study found that **aspirin** and **NSAIDs** were used more frequently in 717 women who became pregnant while using IUDs than in 717 non-pregnant IUD users (the majority of IUDs were copper). The difference was significant only for **aspirin** (102 IUD failures, 59 control failures). It is possible that this finding could have resulted from bias in recall or reporting.² The postulated mechanism for any interaction was that part of the efficacy of copper IUDs may be based on local inflammatory effects, and that anti-inflammatory drugs might reduce this.

The evidence for this possible interaction is very slim and inconclusive, and there appear to be no further reports of any problems. Modern copper-containing IUDs are one of the most effective methods of contraception. Also, intermittent use of anti-inflammatory drugs such as NSAIDs is widespread. A recent Cochrane Database Systematic Review of studies on the use of NSAIDs to reduce pain and/or bleeding with IUDs recommends the use of NSAIDs as first-line drugs to reduce these adverse effects.⁶ One manufacturer of copper IUDs states that the evidence does not justify general precautions.⁷ No special precautions therefore appear to be necessary.

Medroxyprogesterone acetate or Megestrol + Aminoglutethimide

Aminoglutethimide markedly reduces the plasma levels of medroxyprogesterone and megestrol.

Clinical evidence

(a) Medroxyprogesterone acetate

In 6 postmenopausal women with breast cancer aminoglutethimide 250 mg two to four times daily approximately halved the plasma levels of medroxyprogesterone acetate 500 mg three times daily.¹ Another study in 6 postmenopausal women found that aminoglutethimide 250 mg four times daily reduced medroxyprogesterone levels by 63% after oral, but not intravenous, medroxyprogesterone.² In another study in 6 women with advanced breast cancer, it was found that as the dosage of aminoglutethimide was gradually reduced from 250 mg twice daily and finally withdrawn, the plasma levels of medroxyprogesterone steadily climbed to three times their initial level, although the dose remained constant at a total of 800 mg daily.³

(b) Megestrol

Aminoglutethimide 250 mg four times daily reduced the serum levels of megestrol 160 mg daily by 78% in 6 postmenopausal women.²

Mechanism

The most likely reason for this interaction is that aminoglutethimide acts as an enzyme inducer, increasing the metabolism of the progestogens, thereby decreasing their levels. When the aminoglutethimide is withdrawn, the enzyme induction ceases, and the progestogen level rises.

Importance and management

Both interactions appear to be established and are possibly clinically important. A 50% reduction in the plasma levels of medroxyprogesterone and megestrol should be expected during concurrent use, and this may reduce the adrenal suppressive effect.¹ The authors of one report³ say that to achieve adequate plasma medroxyprogesterone acetate levels in breast cancer (above 100 nanograms/mL) a daily dose of 800 mg of *Provera* is probably necessary in the presence of aminoglutethimide 125 or 250 mg twice daily. This is double the usual recommended dose for this condition.

3. Halpenny O, Bye A, Cranny A, Feely J, Daly PA. Influence of aminoglutethimide on plasma levels of medroxyprogesterone acetate. *Med Oncol Tumor Pharmacother* (1990) 7, 241–7.

Oestrogens + Diltiazem

Diltiazem may slightly raise estradiol levels but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management

A study in 5 healthy postmenopausal women given diltiazem 30 mg twice daily for 4 days with a single 2-mg oral dose of estradiol on day 2, found that there was a slight but non-significant increase in the maximum levels of estrone. Diltiazem is a moderate inhibitor of the cytochrome P450 isoenzyme CYP3A4 and would be expected to decrease the metabolism of estradiol. This single-dose study appears to suggest that the increase in oestrogen levels caused by diltiazem is small and unlikely to cause any clinically significant adverse effects. However, the dose of diltiazem given was much lower than commonly prescribed doses, the number of patients involved in the study was small, and therefore these results may not accurately reflect the effect of concurrent use.¹ More study is needed.

Oestrogens + Grapefruit juice

No clinically significant interaction appears to occur between grapefruit juice and a single dose of either estradiol or ethinylestradiol, although their levels are modestly increased by grapefruit juice.

Clinical evidence, mechanism, importance and management

(a) Estradiol

In women given a single 2-mg dose of estradiol, grapefruit juice produced a small 16% increase in the AUC of estrone, a metabolite of estradiol, but did not affect the AUC of estradiol.¹

(b) Ethinylestradiol

In 13 healthy young women given a single 50-microgram dose of ethinylestradiol, grapefruit juice increased the mean maximum plasma level and AUC_{0–8} of ethinylestradiol by 37% and 30%, respectively, when compared with a control drink (herb tea). There was wide intersubject variation in the increase, but the mean 28% rise in the AUC_{0–12} was not significant. The subjects drank grapefruit juice 100 mL or herb tea

30 minutes before the ethinylestradiol, a further 100 mL with the ethinylestradiol, and then 200 mL every 3 hours for 12 hours after taking the ethinylestradiol. It is thought that this increase in bioavailability probably occurs because grapefruit juice inhibits intestinal cytochrome P450 isoenzyme CYP3A4, which metabolises ethinylestradiol.² Grapefruit juice may be taken at the same time of day as the combined oral contraceptive (which usually contains ethinylestradiol) but it seems unlikely that this interaction is of practical importance because the increased bioavailability is still less than the extent of known variability between individuals. However, this requires confirmation in a longer-term study. The authors suggest that diet may be a factor in the known inter-individual variability of contraceptive steroid levels.²

Progestogen-only contraceptives + Antibacterials

The reliability of progestogen-only methods of hormonal contraception are not affected by antibacterials that do not induce liver enzymes, such as the penicillins and tetracyclines.

Clinical evidence, mechanism, importance and management

Four of the 63 contraceptive failures attributed to antibacterials in the records of the CSM in the UK for 1968 to 1984 occurred with a progestogen-only contraceptive (unspecified).¹ In another study, 2 of 37 cases of contraceptive failure attributed to antibacterials occurred with a progestogen-only contraceptive (unspecified).²

Note that the mechanism behind the rare cases of failure of *combined* oral contraceptives seen with various broad-spectrum antibacterials is postulated to be reduced enterohepatic recycling of ethinylestradiol (see 'Hormonal contraceptives + Antibacterials; Penicillins', p.981). Since progestogens are largely metabolised to inactive substances before they are conjugated, they do not undergo enterohepatic recycling of the active substance.

Pharmacokinetic data show that the progestogen component (**levonorgestrel**, **norethisterone**) of *combined* oral contraceptives is not affected by **ampicillin**,^{3,4} **clarithromycin**,⁵ **doxycycline**,⁶ **metronidazole**,⁴ **moxifloxacin**,⁷ or **tetracycline**.⁸ There is no reason to expect that the contraceptive efficacy of the various progestogen-only methods (tablets, implants, injections, IUDs) would be affected by antibacterials that alter gut flora and do not induce liver enzymes.

It is generally accepted that no interaction occurs,⁹ and it is likely that the few cases seen with progestogen-only contraceptives are chance associations.¹ The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit does not recommend any additional contraceptive precautions when antibacterials that do not induce liver enzymes are taken with any method of progestogen-only hormonal contraception, including the emergency contraceptive pill.¹⁰ However, note that **rifampicin** and **rifabutin** are likely to reduce the efficacy of most forms of hormonal contraceptives, as they induce the metabolism of both oestrogens and progestogens, see 'Hormonal contraceptives + Rifamycins', p.1001.

Progestogen-only contraceptives + Enzyme inducers

Enzyme inducers appear to reduce the contraceptive reliability of the levonorgestrel implant, and pregnancies have been reported following the use of carbamazepine, phenytoin, and phenobarbital. Pregnancies have also been reported when the etonogestrel implant was used in women taking enzyme-inducing antiepileptics, particularly carbamazepine. The efficacy of medroxyprogesterone depot injection does not appear to be affected by enzyme inducers. Similarly, norethisterone depot injection is thought unlikely to be affected. The contraceptive reliability of the progestogen-releasing intrauterine system is also not thought to be affected.

Clinical evidence, mechanism, importance and management

(a) Implants

A woman taking **phenytoin** 300 mg daily became pregnant 9 months after the insertion of a **levonorgestrel**-releasing subdermal contraceptive implant (*Norplant*). **Levonorgestrel** levels increased by 50% after discontinuation of the **phenytoin**, and progesterone levels fell, suggesting greater suppression of ovulation.¹ In another report plasma **levonorgestrel** levels (from an implant) were 38% lower in 6 women taking **phenytoin** alone or in combination with **carbamazepine** or valproate than in 10 subjects taking no medication. Two of the 6 women became pregnant (one taking **phenytoin** and one taking **phenytoin** with **carbamazepine**).² Similarly, one woman taking **phenobarbital** 210 mg daily became pregnant about 17 months after the insertion of a **levonorgestrel** implant.³ Another report⁴ briefly mentions that one woman taking enzyme-inducing antiepileptics became pregnant while using a **levonorgestrel** implant, and mentions that the manufacturer had 30 other similar cases on file as of 1995.

Pregnancy has been reported in a patient taking **carbamazepine** 600 mg daily and using the **etonogestrel** implant (*Implanon*).⁵ A report describes 8 other cases of contraceptive failure with this implant in Australian patients who were taking liver enzyme-inducing antiepileptics (7 of the 8 were taking carbamazepine).⁶ The Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that the progestogen-only implant may be continued with short courses of enzyme inducers but only if combined with additional contraceptive methods, see 'Hormonal contraceptives + Antiepileptics; Barbiturates or Phenytoin', p.985, for more detailed guidance. The progestogen-only implant should be reviewed to an alternative form of contraceptive with long-term use of liver enzyme inducers.⁷ A list of enzyme inducers can be found in 'Table 28.1', (p.975).

(b) Injectable preparations

The manufacturer states that the clearance of **medroxyprogesterone acetate** is approximately equal to hepatic blood flow, and as such, would not be expected to be affected by drugs that alter hepatic enzyme activity. Therefore, they say that no dosage adjustment is needed.⁸ This is in line with the FFPRHC guidance.⁷

There are data showing that **rifamycins** can reduce the plasma levels of **norethisterone** when it is used as a component of combined oral contraceptives (see 'Hormonal contraceptives + Rifamycins', p.1001). The manufacturer of *Noristerat* notes that enzyme inducers may reduce the efficacy of the norethisterone enantate injection.⁹ However, guidance from the FFPRHC Clinical Effectiveness Unit is to continue with the normal injection schedule for norethisterone.⁷

(c) Progestogen-releasing intrauterine system (IUS)

Some enzyme inducers increase the metabolism and reduce the efficacy of combined oral contraceptives (see 'Table 28.1', (p.975), for a list). The manufacturer has not studied the influence of these drugs on the efficacy of the **levonorgestrel**-releasing IUS (*Mirena*),¹⁰ and has said that they cannot be sure that the foreign body effect (i.e. the effect whereby the presence of the IUS prevents implantation) and/or locally acting hormone will provide reliable contraception when systemic hormone levels and sup-

pression of ovaries are reduced by drug interactions.¹¹ However, this appears to be overly cautious. The systemic absorption of **levonorgestrel** from the IUS leads to lower blood levels than are seen with standard progestogen-only oral contraceptives, and women using a **levonorgestrel** IUS usually continue to ovulate. Thus, the contraceptive effects of the **levonorgestrel** IUS are mainly local.¹⁰ Also, a pilot study in 56 women (49 epileptics) using a **levonorgestrel** IUS, most of them also taking enzyme inducers, who accumulated 1075 months of use, found only one apparent contraceptive failure.¹²

The FFPRHC Clinical Effectiveness Unit considers that the levonorgestrel-releasing IUS is unlikely to be affected by enzyme inducers and recommends that no additional contraceptive protection is required.⁷ It is therefore a suitable contraceptive for women taking these drugs.¹³

Tibolone + Enzyme inducers

On theoretical grounds the manufacturer of tibolone says that the effects of tibolone may be reduced by enzyme-inducing antiepileptics and rifampicin.

Clinical evidence, mechanism, importance and management

The manufacturer says that on a theoretical basis enzyme inducers such as the **barbiturates**, **carbamazepine**, **phenytoin** and **rifampicin** may accelerate the metabolism of tibolone and thus decrease its efficacy.¹ However, they note that no examples of these interactions have been reported in clinical practice, and pharmacokinetic studies are required to demonstrate this interaction. Nevertheless it would be prudent to monitor concurrent use.

29

Immunosuppressants

The immunosuppressants dealt with in this section are the corticosteroids, basiliximab, daclizumab, etanercept, infliximab, ciclosporin, everolimus, leflunomide, muromonab-CD3, mycophenolate, sirolimus, and tacrolimus. A classification is given in 'Table 29.1', (see below). When any of these drugs acts as the interacting agent the relevant monograph is categorised in the section dealing with the drug whose effects are changed. Other drugs that are also used for immunosuppression (e.g. azathioprine and methotrexate) are found in the section on antineoplastic drugs.

Table 29.1 Immunosuppressant drugs

<i>Group</i>	<i>Drugs</i>
Corticosteroids	Beclometasone, Budesonide, Ciclesonide, Deflazacort, Dexamethasone, Fludrocortisone, Fluticasone, Hydrocortisone, Methylprednisolone, Prednisolone, Predisone, Triamcinolone
Monoclonal antibodies	
Causing lysis of B-lymphocytes	Alemtuzumab, Rituximab
Preventing T-lymphocyte proliferation	Basiliximab, Daclizumab
Blocking T-cell generation and function	Muromonab-CD3
Inhibitors of tumour necrosis factor	Adalimumab, Infliximab
Others	
Calcineurin inhibitors	Ciclosporin (Cyclosporine), Tacrolimus
Inhibitors of tumour necrosis factor	Etanercept
Miscellaneous	Everolimus, Leflunomide (DMARD), Mycophenolate, Sirolimus

Basiliximab + Miscellaneous

The concurrent use of basiliximab with azathioprine, muromonab-CD3 or mycophenolate is not associated with an increase in adverse effects or infections. The dose requirements of ciclosporin or tacrolimus may be altered by basiliximab. Basiliximab is reported not to interact with analgesics, anti-infective drugs, diuretics, beta blockers or calcium-channel blockers.

Clinical evidence, mechanism, importance and management

(a) Azathioprine

Azathioprine, added to regimens including basiliximab, ciclosporin microemulsion and corticosteroids reduced the clearance of basiliximab by 22%. However, the use of basiliximab in triple regimens with azathioprine did not increase adverse effects or infections.¹

(b) Ciclosporin

A study in 39 paediatric renal transplant patients taking ciclosporin found that in 24 patients, who were also given basiliximab 10 or 20 mg on days 0 and 4 after transplantation, lower doses of ciclosporin resulted in significantly higher trough levels and some evidence of early ciclosporin toxicity within the first 10 days. At days 28 to 50 ciclosporin levels declined and 20% higher doses were required to maintain adequate trough levels in the basiliximab group.² Another study in 54 paediatric liver transplant patients found that the addition of basiliximab to ciclosporin and corticosteroids did not significantly alter the overall ciclosporin dose requirements. However, 9 basiliximab-treated patients experienced acute rejection at 21 to 28 days after transplantation, and this was associated with low ciclosporin trough levels, requiring an increased ciclosporin dosage in 6 of the 9 patients.³ It was considered that the effect on ciclosporin was due to an interleukin-2 receptor mediated alteration of the cytochrome P450 enzyme system.² This was considered to only play a minor role in the liver-transplant patients because of significantly lower target trough levels in these patients.³ However, a further study found no increase in rejection episodes between days 28 to 50 in kidney-transplant patients treated with basiliximab and ciclosporin.⁴

The authors of the first study² recommend that the initial dose of ciclosporin should be limited to 400 mg/m² in children receiving renal transplants who are also given with basiliximab. Dose reductions were not considered necessary by other authors, but close monitoring was recommended.^{3,4}

A retrospective analysis of renal transplant patients compared the rates of acute rejection within 6 months in patients given ciclosporin, mycophenolate mofetil and prednisone, with or without basiliximab. Overall the rates of acute rejection were 11% and 23% in the basiliximab and no-basiliximab groups, respectively. In 74 patients not given basiliximab, low therapeutic ciclosporin exposure on day 3 was associated with increased acute rejection within the first 6 months post-transplantation (45% with ciclosporin AUC less than 4400 nanogram.h/mL compared with 15% with a ciclosporin AUC of greater than 4400 nanogram.h/mL). In 93 patients given basiliximab, rates of acute rejection were similar (about 10%) in patients with low or therapeutic ciclosporin exposure at day 3. It was suggested that achieving early ciclosporin therapeutic targets may not be required if basiliximab is also used.⁵

(c) Muromonab-CD3

The manufacturers of basiliximab say that patients in phase 3 studies received basiliximab with muromonab-CD3 for episodes of rejection, with no increase in adverse events or infections. Human antimurine antibody responses were reported in 2 of 138 patients receiving basiliximab and 4 of 34 patients receiving both basiliximab and muromonab-CD3. Therefore, the manufacturers say that if basiliximab has been given, muromonab-CD3 or other murine antilymphocytic antibody preparations can still subsequently be given.¹

(d) Mycophenolate

Azathioprine, added to regimens including basiliximab, ciclosporin microemulsion and corticosteroids, reduced the clearance of basiliximab by 51%. However, the use of basiliximab in triple regimens with mycophenolate did not increase adverse effects or infections.¹

(e) Tacrolimus

A study in 12 adult renal-transplant patients found that trough tacrolimus levels on day 3 were increased by 63% in patients also given basiliximab and in 50% of these patients this was associated with the development of acute tubular necrosis. By day 30, tacrolimus trough levels showed a downward trend in the basiliximab treated group, despite similar dose requirements to those on day 10. Tacrolimus dose requirements were lower in the basiliximab group compared to the control group throughout the 60-day study period.⁶ Dose reductions were not considered necessary by the authors, but close monitoring was recommended.⁶

(f) Other drugs

The manufacturers report that basiliximab has been used with **analgesics, antibacterials, antifungals, antivirals, diuretics, beta blockers and calcium-channel blockers** without any increase in adverse reactions. None of the drugs was individually named.¹

Ciclosporin + ACE inhibitors and Angiotensin II receptor antagonists

Acute renal failure developed in four kidney transplant patients taking ciclosporin when they were given enalapril. Oliguria was seen in another patient taking ciclosporin with captopril. Other studies have found no significant changes in renal function with candesartan and losartan or with enalapril. Hyperkalaemia may develop in patients taking ACE inhibitors or angiotensin II receptor antagonists with ciclosporin.

Clinical evidence

(a) ACE Inhibitors

Two kidney transplant patients on ciclosporin developed acute renal failure 10 to 42 days after starting to take **enalapril** 5 to 10 mg twice daily. Recovery was complete when the **enalapril** was stopped in one of the patients, and when both **enalapril** and ciclosporin were stopped in the other. The latter patient had no problems when the ciclosporin was restarted. Both recovered renal function after 10 to 30 days. Neither had any previous evidence of renal artery stenosis or chronic rejection, which are conditions known to predispose to renal failure during ACE inhibitor treatment. Two other patients appeared to tolerate concurrent use well.¹ Two further kidney transplant patients developed acute renal failure when given **enalapril**. Neither had renal arterial stenosis or acute rejection.² The manufacturer briefly mentions that transient oliguria was seen in a kidney transplant patient given ciclosporin and **captopril**.³

A study in 13 kidney transplant patients taking ciclosporin found that concurrent treatment with **enalapril** 5 or 10 mg daily for 3 weeks caused a larger increase in potassium levels (mean increase of 0.5 mmol/L) than in those patients given **losartan** 50 mg daily (mean increase of 0.2 mmol/L). Potassium levels were not increased above 5.5 mmol/L in any of the patients studied. Uric acid levels were also increased by **enalapril** but decreased by **losartan**, although this was not statistically significant. No changes in ciclosporin trough levels were seen during the study and the serum creatinine remained stable.⁴ Another study in kidney transplant patients taking ciclosporin with either **enalapril** (33 patients) or **enalapril** plus amlodipine (32 patients) found that the potassium and serum creatinine levels did not increase in the **enalapril**/amlodipine group whereas they increased by 0.2 mmol/L and 9 micromol/L, respectively, in the group who received **enalapril** alone. Ciclosporin levels remained stable in all patients.⁵

(b) Angiotensin II receptor antagonists

A study in kidney transplant patients taking ciclosporin with **losartan** found that the serum creatinine was only slightly and non-significantly increased in 5 patients. Losartan was stopped in 3 patients because of a rise in creatinine levels. Transient hyperkalaemia (potassium above 5.5 mmol/L) developed in 4 patients but the potassium had fallen to below 5.5 mmol/L by week 12 in all patients. Ciclosporin levels were remained stable during the study and no significant dose changes were made, although one patient was withdrawn from the study due to ciclosporin toxicity which the authors state was not related to the use of losartan.⁶ Another study in 14 kidney transplant patients taking ciclosporin with **losartan** 50 to 100 mg daily for 8 weeks found serum creatinine, potassium and ciclosporin levels were unaffected.⁷ Another study in 41 kidney transplant patients with proteinuria taking ciclosporin found that the addition of **candesartan** 4 to 12 mg daily had no significant effects on the creatinine clearance or ciclosporin levels.⁸

Mechanism

Not understood. One suggestion is that ciclosporin reduces renal blood flow and reduces perfusion through the glomerulus, which is worsened when angiotensin II is inhibited by the ACE inhibitor.¹ One study suggested that the larger increase in potassium levels may be related to changes in aldosterone levels seen with enalapril.⁴

Importance and management

There have been few specific case reports of renal failure and hyperkalaemia with ciclosporin and ACE inhibitors or angiotensin II receptor antagonists. Data from the efficacy studies above suggest that the incidence of renal failure and hyperkalaemia is low, nevertheless care and good monitoring are needed if ACE inhibitors or angiotensin II receptor antagonists and ciclosporin are used concurrently. Also note that the manufacturers of ciclosporin warn about the possible risk of hyperkalaemia with ACE inhibitors and angiotensin II receptor antagonists with ciclosporin as these drugs may raise potassium levels.⁹ Monitor potassium levels more closely in the initial weeks of concurrent use, bearing in mind that an increase in potassium levels may be due to worsening renal function as well as these drugs.

Ciclosporin + Acetazolamide

There is some limited evidence to suggest that acetazolamide can cause a marked and rapid rise in ciclosporin serum levels, possibly accompanied by renal toxicity.

Clinical evidence, mechanism, importance and management

A study in 3 men found that 72 hours after they started taking acetazolamide (dose not stated) their trough serum ciclosporin levels rose by more than sixfold, from a range of 54 to 270 nanograms/mL up to 517 to 1827 nanograms/mL.¹ Another man with a heart transplant had a fivefold increase in his serum ciclosporin levels, marked renal impairment, and neurotoxicity when he was given oral acetazolamide for raised intra-ocu-

lar pressure secondary to panuveitis.² The increase in ciclosporin serum levels has also been seen in *animal* studies.³

Information seems to be limited to these reports but it seems that the concurrent use of ciclosporin and acetazolamide should be closely monitored, being alert of the need to reduce the ciclosporin dosage. The interaction can apparently develop very rapidly.

Ciclosporin + Aciclovir and related drugs

Aciclovir does not normally seem to affect ciclosporin serum levels nor worsen renal function, but a very small number of cases of nephrotoxicity and increased serum ciclosporin levels have been seen following concurrent use. Valaciclovir, a prodrug of aciclovir, is expected to interact similarly.

Clinical evidence

A retrospective study in kidney transplant patients taking ciclosporin (serum levels in the range 100 to 250 nanograms/mL) found that in 12 patients oral aciclovir 800 mg four times daily for 3 months had no significant effect on their ciclosporin serum levels or on nephrotoxicity when compared with 9 control subjects.¹ No significant changes in renal function were seen in 11 patients taking ciclosporin when they were given intravenous aciclovir 750 to 1500 mg/m² daily for at least 7 days to treat herpes infections.² No significant changes in serum creatinine or ciclosporin levels were seen during the 14 days following kidney transplant in 17 patients given aciclovir 800 mg daily.³ Fifty-three kidney transplant patients were given ciclosporin and aciclovir 800 mg to 3.2 g daily for 12 weeks. The aciclovir was withdrawn from 2 patients because of unexplained and temporary increases in serum creatinine levels. The serum ciclosporin levels were not reported.⁴ Five patients (2 adults and 3 children) taking ciclosporin, prednisone and azathioprine were given aciclovir 200 mg five times daily for 6 days for herpes zoster or chicken pox. Ciclosporin serum levels remained unchanged and renal function improved.⁵

In contrast to the cases cited above, 3 of 7 bone marrow transplant patients given ciclosporin and intravenous aciclovir 500 mg/m² every 8 or 12 hours (depending on renal function) developed nephrotoxicity, which was fatal in one case. Histological evidence suggested ciclosporin nephrotoxicity.⁶ The manufacturer briefly notes that an increase in serum creatinine was seen in ciclosporin recipients in one report, and increased aciclovir levels accompanied by reversible acute tubular necrosis in another.⁷ Yet another report describes a threefold increase in ciclosporin serum levels, which occurred when a child with a heart transplant was given intravenous aciclovir.⁸

Mechanism

Not understood; although both drugs are known to be nephrotoxic, all be it rarely in the case of aciclovir.

Importance and management

Well documented. The evidence available indicates that ciclosporin levels and renal function are usually unaltered by the concurrent use of aciclovir, but the handful of cases where problems have arisen clearly indicate that renal function should be well monitored. One group of workers suggest that aciclovir, in doses of 250 mg/m² by slow infusion, does not adversely affect renal function in well-hydrated patients taking ciclosporin if their ciclosporin levels are carefully monitored.² **Valaciclovir**, a prodrug of aciclovir, is rapidly converted to the active drug, aciclovir. Therefore the advice given for aciclovir equally applies to valaciclovir. The manufacturers recommend that renal function is closely monitored if high doses of valaciclovir (more than 4 g daily) are given with drugs that affect renal function, such as ciclosporin.⁹

Ciclosporin + Alcohol

An isolated report describes a marked increase in serum ciclosporin levels in a patient after an episode of binge drinking, but a subsequent study found that moderate, single doses of alcohol in other patients had no such effect. Red wine decreases ciclosporin bioavailability.

Clinical evidence

The serum ciclosporin levels of a kidney transplant patient doubled, from 101 to 205 nanograms/mL, and remained high for about 4 days after he went on a 2-day alcohol binge. A subsequent study in 8 other patients with kidney transplants found no changes in serum ciclosporin or creatinine levels when they drank 50 mL of 100% alcohol in orange juice (about equivalent to 4 oz of whisky).¹

A crossover study in 12 healthy subjects given a single 8 mg/kg dose of ciclosporin with water or 350 mL (12 oz) of Californian red wine found that red wine caused a 50% increase in the oral clearance of ciclosporin. The ciclosporin AUC was reduced by 30% and the maximum blood levels were reduced by 38%, from 1258 to 779 micrograms/L. There was a high degree of variability, with increases in oral clearance ranging from 1.5 to 129%, with Caucasians experiencing a greater degree of change than Asians.²

Mechanism

A study in *animals* found that pretreatment with oral ciclosporin had no effect on the pharmacokinetics of alcohol or acetaldehyde. This suggests that any difference in the alcohol consumption of patients taking ciclosporin is unlikely to have a pharmacokinetic basis.³ The mechanism by which red wine exerts its effect is not known. White wine does not appear to affect ciclosporin pharmacokinetics,⁴ so the interaction is not believed to be an effect of alcohol. Antioxidants in red wine such as resveratrol may inactivate the cytochrome P450 isoenzyme CYP3A4 and this would also be expected to increase ciclosporin levels. The solubility of ciclosporin is decreased in red wine and it is possible that substances in red wine bind ciclosporin in the gastrointestinal tract and reduce its bioavailability.² Another study by the same authors suggested that ciclosporin absorption is possibly impaired by P-glycoprotein induction.⁵

Importance and management

The authors of the first study¹ say that they currently advise their renal transplant patients to avoid heavy drinking, but that an occasional drink probably does not affect ciclosporin levels. Patients may be advised to avoid alcohol after transplantation, but those who do drink alcohol should exercise caution if drinking red wine while taking ciclosporin.

Ciclosporin + Allopurinol

Isolated cases of markedly raised ciclosporin levels have been reported in patients given allopurinol. However, in two clinical studies, a trend towards lower ciclosporin levels with low-dose allopurinol has been seen.

Clinical evidence, mechanism, importance and management

The ciclosporin levels of a kidney transplant patient rose by about threefold, accompanied by an increase in serum creatinine from 124 to 194 micromol/L, after allopurinol 100 mg daily was taken for 12 days.¹ Another previously stable kidney transplant patient had a two- to threefold rise in her ciclosporin level when allopurinol 200 mg daily was given. Her serum creatinine remained unchanged throughout.² The general importance of these two reports of increased ciclosporin levels is unknown, although increases in ciclosporin levels are associated with increased risk of nephrotoxicity.

Two clinical studies in renal transplant patients taking ciclosporin, azathioprine and prednisolone with low-dose allopurinol 25 mg daily or on alternate days found a reduction in ciclosporin levels (significant in one group), as well as a beneficial reduction in the acute rejection rate.³ Note that azathioprine levels can be raised significantly by allopurinol usually requiring a dose reduction, see 'Thiopurines + Allopurinol', p.664. The case reports above and the clinical studies are probably insufficient to recommend increased monitoring of ciclosporin levels in all patients given allopurinol, but bear them in mind in the event of an unexpected response to treatment.

Ciclosporin + Amiodarone

Ciclosporin serum levels can be increased or decreased by amiodarone, and nephrotoxicity has occurred as a result of increased levels. Increased amiodarone levels and pulmonary toxicity have been reported in patients also given ciclosporin.

Clinical evidence

(a) *Ciclosporin affected*

Eight patients with heart transplants and 3 patients with heart-lung transplants taking ciclosporin were also given amiodarone for atrial flutter or fibrillation. Their serum ciclosporin levels rose by 9% despite a 13 to 14% reduction in the ciclosporin dosage, serum creatinine levels rose by 38% (from 157 to 216 micromol/L), and blood urea nitrogen rose by 30%.¹ In another report by some of the same authors, one patient is said to have shown a 50% decrease in the clearance of ciclosporin when given amiodarone.² Eight other patients with heart or heart-lung transplants were effectively treated with amiodarone for atrial flutter and/or atrial fibrillation, but they had a 31% rise in serum ciclosporin levels, from 248 to 325 nanograms/mL despite a 44% reduction in the ciclosporin dosage (from 6.2 to 3.5 mg/kg daily). Serum creatinine levels rose by 39%.³ The serum ciclosporin levels of a kidney transplant patient doubled when amiodarone was given.⁴

In contrast, in 5 heart transplant patients amiodarone was discontinued and ciclosporin initiated, but the metabolism of ciclosporin was increased for 4 to 5 weeks (total plasma metabolites increased from 720 to 1437 nanograms/mL). The mean maintenance ciclosporin level was *reduced* by 15 nanograms/mL.⁵

(b) *Amiodarone affected*

In two heart transplant patients who had stopped amiodarone and started ciclosporin an increase in the plasma levels of amiodarone and its main metabolite, desethylamiodarone, was seen for 4 to 5 weeks. During this period increased adverse effects, including pulmonary toxicity, were seen.⁵

Mechanism

Uncertain. A reduction² or an increase⁵ in the metabolism of the ciclosporin by the amiodarone has been suggested. An interaction between amiodarone and phospholipids in the plasma membrane may inhibit transport processes. Blocking of P-glycoprotein in the intestinal mucosa and liver by both amiodarone and ciclosporin may result in decreased excretion and increased toxicity of amiodarone as well as accumulation of ciclosporin metabolites.⁵

Importance and management

An established and clinically important interaction. Concurrent use need not be avoided but close monitoring and ciclosporin dosage reductions are needed to minimise the potential nephrotoxicity. Remember to re-adjust the ciclosporin dosage if the amiodarone is stopped, bearing in mind that it may take weeks before the amiodarone is totally cleared from the body.

The significance of the increase in amiodarone levels in two patients and the occurrence of pulmonary toxicity in another, all of whom had stopped amiodarone and started ciclosporin, is unclear but bear these reports in mind.

Ciclosporin + Amphotericin B

There is some good evidence to suggest that the risk of nephrotoxicity is increased if ciclosporin and amphotericin B are used concurrently. However, other evidence suggests that a liposomal form of amphotericin B (*AmBisome*) does not increase nephrotoxicity or hepatotoxicity when given to infants taking ciclosporin. Ciclosporin blood levels may be increased or decreased by amphotericin B.

Clinical evidence

(a) Toxic effects

1. **Nephrotoxicity.** The concurrent use of ciclosporin and amphotericin B increased the incidence of nephrotoxicity in 47 patients with bone marrow transplants. Out of 10 patients who had received both drugs, 5 doubled and 3 tripled their serum creatinine levels within 5 days. In contrast only 8 out of 21 (38%) taking ciclosporin alone and 3 out of 16 (19%) taking methotrexate and amphotericin B doubled their serum creatinine within 14 to 30 days and 5 days, respectively.¹ Two studies of the risk factors associated with amphotericin B identified the concurrent use of ciclosporin as posing a particularly significant risk for the development of the moderate to severe nephrotoxicity in 8 to 12% of patients given amphotericin.^{2,3} Two other studies in bone marrow transplant patients taking ciclosporin found that amphotericin B contributed significantly to nephrotoxicity and renal failure.^{4,5} It can apparently develop even after amphotericin B has been withdrawn.⁴ Marked nephrotoxicity is described in one patient in another report.⁶ However, a retrospective study of patients taking ciclosporin also found an increase in creatinine levels during the concurrent use of a continuous infusion of amphotericin B (sodium deoxycholate complex; *Fungizone*) in 22 patients (compared with 62 patients taking ciclosporin alone), but severe reductions in renal function (creatinine clearance less than 30 mL/minute) were not found.⁷ In contrast, a study including 8 severely ill infants undergoing bone marrow transplantation for severe immunodeficiency, found no evidence of significant nephrotoxicity or hepatotoxicity when liposomal amphotericin B (*AmBisome*) was given with ciclosporin. The average course of treatment lasted for 29 days.⁸

2. **Neurotoxicity.** An isolated case report described severe tremors, later becoming myoclonic, attributed to the concurrent use of liposomal amphotericin B (*AmBisome*) and ciclosporin. Serum ciclosporin levels were unaltered and creatinine levels only rose slightly.⁹ This alleged neurotox-

icity was challenged in a letter citing 187 transplant patients who had received ciclosporin and *AmBisome*, none of whom developed neurotoxicity attributable to an interaction.¹⁰

3. **Other adverse effects.** Renal tubular acidosis and hypomagnesaemia were noted to be the most common adverse effects of concurrent low-dose amphotericin B 5 to 10 mg daily with ciclosporin in a retrospective analysis in bone marrow transplant patients.¹¹

(b) Ciclosporin levels

A retrospective analysis in allogeneic bone marrow transplant patients found that those patients taking high-dose prednisone with continuous infusion ciclosporin and also given prophylactic amphotericin B 5 to 10 mg daily had 13 to 23% lower plasma levels of ciclosporin in the first four weeks post-transplant when compared with those on the same GVHD (graft-versus-host-disease) prophylaxis regimen who did not receive amphotericin B. No obvious dose reductions or changes in renal function were noted in these patients. It was also noted in this study that patients with ciclosporin plasma levels of 500 nanograms/mL had a 2.2-fold increased risk of developing GVHD when compared with patients with levels of 1000 nanograms/mL.¹¹

In contrast, a study in 187 transplant patients given an average dose of ciclosporin 10 mg/kg daily found that ciclosporin blood levels increased significantly from 275 nanograms/mL to 328 nanograms/mL during treatment with liposomal amphotericin B (*AmBisome*) and decreased to 242 nanograms/mL one week after amphotericin B was stopped.¹² A retrospective study found a non-significant increase in mean ciclosporin blood levels (from 259 to 296 nanograms/mL) with the concurrent use of amphotericin B (0.6 to 2 mg/kg daily for 3 to 112 days) in 22 patients who had undergone allogeneic stem cell transplants. However, a lower maximum mean ciclosporin blood level of 775 nanograms/mL was seen in those patients who received amphotericin B compared with 1240 nanograms/mL in 62 patients receiving ciclosporin without amphotericin B, although again this was not significant.⁷

Mechanism

The precise mechanism of the effects of amphotericin B on ciclosporin blood levels and the nephrotoxicity is not understood, although simple additive nephrotoxicity is a likely explanation for the latter.

Importance and management

The increased nephrotoxicity associated with ciclosporin and amphotericin B appears to be established and clinically important. The authors of one report¹ say that “if amphotericin must be given, withholding ciclosporin until the serum level is less than about 150 nanograms/mL may be a means of decreasing renal toxicity without losing the immunosuppressive effect.”

The reports supporting a lack of significant nephrotoxicity all used liposomal amphotericin B, a formulation that is recommended when amphotericin toxicity (particularly nephrotoxicity) is considered to be a significant risk. This would seem to suggest that in patients taking ciclosporin, the less nephrotoxic forms of amphotericin B are advisable. Renal function should be closely monitored during concurrent use.

The changes in ciclosporin blood levels reported with amphotericin B are inconsistent. However, these studies should be borne in mind when using both drugs, and ciclosporin levels as well as renal function should be closely monitored.

Ciclosporin + Anabolic steroids and Androgens

Raised ciclosporin levels occurred in two patients given methyltestosterone. Hepatotoxicity has been seen in three patients given ciclosporin and norethandrolone.

Clinical evidence

(a) Methyltestosterone

A man with a kidney transplant who had been stable taking ciclosporin, prednisolone and azathioprine for 23 months was given methyltestosterone 5 mg three times daily for impotence. After 4 weeks he developed anorexia and pruritus. He was found to have a raised bilirubin level and his ciclosporin level had risen from 70 to 252 nanograms/mL, with an accompanying decrease in his renal function. The methyltestosterone was withdrawn and he was later restabilised.¹ Another case describes abnormally high ciclosporin levels (in excess of 2000 nanograms/mL) when a patient taking methyltestosterone was given ciclosporin 15 mg/kg daily.²

(b) Norethandrolone

Three out of four patients with bone marrow aplasia taking ciclosporin and prednisone developed liver toxicity. The adverse effects developed in 2 of them when norethandrolone was added. No toxicity occurred when they were given either of the drugs alone.³ Jaundice associated with toxic hepatitis that occurred in a 14-year-old girl during the post-transplant period was attributed to the concurrent use of ciclosporin and norethandrolone.⁴

Mechanism

Uncertain. In the first case, the increase in ciclosporin levels were attributed to cholestatic jaundice brought on by the methyltestosterone.² Both norethandrolone and ciclosporin are known to be hepatotoxic, so additive hepatotoxicity may occur.

Importance and management

Information is limited. However, it would seem prudent to avoid the use of androgens or anabolic steroids in patients taking ciclosporin wherever possible. If no alternative is available it may be prudent to increase the frequency of liver function monitoring.

Ciclosporin + Antibacterials; Aminoglycosides

Both animal and human studies indicate that nephrotoxicity may be increased by the concurrent use of ciclosporin and gentamicin. This has also been shown for tobramycin. Cases of renal impairment have been reported for amikacin and gentamicin.

Clinical evidence

A comparative study in patients given **gentamicin** 30 mg with lincomycin just before renal transplantation found that the concurrent use of ciclosporin increased the incidence of nephrotoxicity from 5% to 67%.¹ When **gentamicin** and lincomycin were replaced with ampicillin, ceftazidime and lincomycin the incidence of nephrotoxicity was 10%.¹ Another study describes increased nephrotoxicity associated with the concurrent

use of ciclosporin and **tobramycin** in bone marrow transplant recipients.^{2,3} The interaction between ciclosporin and **gentamicin** has also been well demonstrated in *animals*.^{4,5} One case report describes reversible acute worsening of renal function in a renal transplant patient receiving ciclosporin with **gentamicin**,⁶ and another case report describes impaired renal function in a heart transplant patient taking ciclosporin and given **amikacin**.⁷

In contrast, a retrospective analysis of the medical records of bone marrow transplant patients suggested that aminoglycosides can be safely given with a continuous infusion of ciclosporin without excessive nephrotoxicity, if the patient is carefully monitored.⁸

Mechanism

Uncertain. Since both ciclosporin and the aminoglycosides can individually be nephrotoxic, it seems that their toxicities can be additive.

Importance and management

Established and clinically important interactions. The concurrent use of ciclosporin and aminoglycosides should be avoided where possible, and only undertaken with care and very close monitoring of renal function.

Ciclosporin + Antibacterials; Aztreonam

Aztreonam does not appear to alter ciclosporin levels.

Clinical evidence, mechanism, importance and management

A study in 20 kidney transplant patients taking ciclosporin found that when aztreonam was added for the treatment of various infections the ciclosporin serum levels were not significantly changed. The ciclosporin blood levels before, during, and after aztreonam treatment were 517, 534, and 592 nanograms/mL, respectively.¹ On the basis of this study there would seem to be no need to take special precautions if ciclosporin and aztreonam are used concurrently.

- Alonso Hernandez A. Effects of aztreonam on cyclosporine levels in kidney transplant patients. *Transplantation J Cell Organ Transplant* (1993) 4, 85–6.

Ciclosporin + Antibacterials; Cephalosporins

Isolated case reports suggest that ceftazidime, ceftriaxone, and latamoxef may increase ciclosporin levels, whereas one report suggested ceftazidime, ceftriaxone, and cefuroxime did not, although ceftazidime caused deterioration in some measures of renal function.

Clinical evidence, mechanism, importance and management

Two kidney transplant patients had two- to fourfold rises in ciclosporin blood levels within 2 to 3 days of starting **ceftriaxone** 1 g twice daily. Levels fell when the antibacterial was stopped. The reason is uncertain but it was suggested that **ceftriaxone** possibly inhibits the metabolism of ciclosporin by the liver.¹ However, a report of 51 kidney transplant patients stated that **ceftriaxone** and **cefuroxime** had no effect on ciclosporin blood levels and also that they were not nephrotoxic. This report also stated that **ceftazidime** did not affect serum ciclosporin levels, but it increased blood urea nitrogen and creatinine levels, indicating that it was nephrotoxic.² A report briefly mentions that **ceftazidime** and **latamoxef** have also

been implicated in an increase in ciclosporin plasma levels.³ However, the manufacturers of **ceftazidime** state that there is no evidence to suggest that **ceftazidime** itself is nephrotoxic when used in the recommended doses, although dose adjustment is required in renal failure.⁴ A study in 28 bone marrow transplant patients taking ciclosporin found no evidence that **ceftazidime** 2 g three times daily worsened renal function.⁵

Information about these cephalosporins is very limited indeed. The general relevance of these reports is uncertain, but bear them in mind in the event of unexpected response to treatment.

Ciclosporin + Antibacterials; Chloramphenicol

Four patients had a marked rise in serum ciclosporin levels when they were given chloramphenicol. A small study supports these findings.

Clinical evidence

A retrospective study identified 3 transplant patients taking ciclosporin who had received a total of 6 courses of intravenous chloramphenicol, each lasting for at least 12 days. By day 4 of concurrent use ciclosporin blood levels had increased on average by 41.3%. Ciclosporin doses tended to be slightly reduced over the course of treatment, and by day 10, ciclosporin levels were about 31% below baseline.¹

A woman with a heart-lung transplant and with a trough ciclosporin level of 84 nanograms/mL started taking oral chloramphenicol (dosage not stated) to treat an infection with *Xanthomonas maltophilia*. On the next day the ciclosporin levels had risen to 240 micrograms/L. The chloramphenicol was continued but the ciclosporin dosage was reduced from 300 to 225 mg daily. By day 8 the ciclosporin levels were back within the therapeutic range.²

Two kidney transplant patients had marked increases in ciclosporin blood levels (almost doubled in one case) when they were given chloramphenicol for urinary tract infections.³

There is another report of this interaction, but the case is greatly complicated by the presence of ciprofloxacin, vancomycin, ceftazidime, and a recent course of rifampicin taken by the patient.⁴

Mechanism

Uncertain. Chloramphenicol is a recognised enzyme inhibitor and it seems possible that it may reduce the metabolism of the ciclosporin by the liver.⁴

Importance and management

Information seems to be limited to these reports, so although the interaction appears to be established, its incidence is obviously uncertain. It would now be prudent to monitor ciclosporin levels if systemic chloramphenicol is added, being alert for the need to reduce the ciclosporin dosage. The study¹ highlights the need to monitor levels closely throughout the whole chloramphenicol course.

It seems doubtful if there will be enough chloramphenicol absorbed from eye drops to interact with ciclosporin, but this needs confirmation.

Ciclosporin + Antibacterials; Clindamycin

Two patients had a marked reduction in their serum ciclosporin levels when they took clindamycin.

Clinical evidence, mechanism, importance and management

A lung transplant patient receiving ciclosporin in a dose to maintain levels of 100 to 150 nanograms/mL required dose increases to achieve this level when clindamycin 600 mg three times daily was given. Initially the levels were almost halved by the addition of clindamycin. Ciclosporin was reduced to the original dose when the clindamycin was stopped.¹

In a second lung transplant patient, the use of clindamycin 600 mg three times daily necessitated ciclosporin dose increases from 325 mg daily to 1.1 g daily over 4 weeks to maintain serum levels of about 200 nanograms/mL. The reasons for the interaction are not understood, but the authors suggest close monitoring of ciclosporin levels to prevent underdosing if clindamycin is given;¹ however, this seems exceptionally cautious as these two cases appear to be all that have been reported.

1. Thurnheer R, Laube I, Speich R. Possible interaction between clindamycin and cyclosporin. *BMJ* (1999) 319, 163.

Ciclosporin + Antibacterials; Imipenem/Cilastatin

Several transplant patients with impaired renal function have experienced adverse CNS effects (including convulsions and tremors) while taking imipenem/cilastatin and ciclosporin. Imipenem/cilastatin may affect ciclosporin levels.

Clinical evidence, mechanism, importance and management

A woman taking ciclosporin following a kidney transplant developed a urinary-tract infection for which she was given imipenem/cilastatin 500 mg intravenously every 12 hours (dose adjusted for renal function). About 20 minutes after the second dose she became confused, disorientated, agitated, and developed motor aphasia and intense tremor. This was interpreted as being a combination of the adverse CNS effects of both drugs. The imipenem/cilastatin was not given again and the effects subsided over the next few days. However, it was noted that the ciclosporin blood levels rose over the next 4 days from about 400 to 1000 nanograms/mL.¹

Four transplant patients who were taking ciclosporin developed seizures when they were given imipenem/cilastatin 1 g daily, and a fifth patient developed myoclonia. These patients all had chronic renal impairment.² In contrast, imipenem/cilastatin 2 g daily for 4 weeks, given with ciprofloxacin, was effectively and successfully used in another patient taking ciclosporin after a heart transplant. This patient was switched to imipenem/cilastatin and ciprofloxacin after developing acute renal failure while receiving amikacin.³ Reduced serum ciclosporin levels following the use of imipenem/cilastatin have been seen in *rats*.⁴

It should be noted that focal tremors, myoclonus and convulsions are a known adverse effects of imipenem/cilastatin and are most likely to occur in patients with reduced renal function. However, the patients cited above received imipenem/cilastatin in doses adjusted for their renal function. The manufacturers of imipenem/cilastatin recommend that patients who develop focal tremors, myoclonus and convulsions while receiving the antibacterial should be started on an antiepileptic drug. If symptoms persist the dose should be reduced, or the drug withdrawn.⁵

Ciclosporin + Antibacterials; Macrolides

Ciclosporin levels can be markedly raised by clarithromycin, erythromycin, josamycin, pristinamycin and possibly midecamycin. Rokitamycin and troleandomycin are predicted to interact similarly. Roxithromycin appears to interact minimally, while no interaction is normally seen with azithromycin, dirithromycin or spiramycin, although there are isolated reports of an interaction with azithromycin.

Clinical evidence

(a) Azithromycin

Eight healthy subjects were given ciclosporin 3.75 to 7.5 mg/kg alone and then after taking azithromycin 500 mg initially then 250 mg daily for 4 days. Azithromycin did not alter ciclosporin levels.¹ Other studies have also found no evidence of a clinically significant interaction between ciclosporin and azithromycin in a total of 62 kidney transplant patients,^{2–4} but there are case reports describing a marked increase in ciclosporin levels in 2 patients attributed to azithromycin.^{5,6}

(b) Clarithromycin

In a study in 8 healthy subjects, ciclosporin 3.75 to 7.5 mg/kg was given alone and after they took clarithromycin 250 mg every 12 hours for 7 days. The maximum ciclosporin levels were raised by 50% by the clarithromycin. In another study a mean 30% reduction in the dosage of ciclosporin was needed in 6 transplant patients also given clarithromycin.⁷ Clarithromycin 500 mg twice daily as part of a *Helicobacter pylori* eradication regimen caused a two- to threefold increase in ciclosporin levels in 27 kidney transplant patients.^{8,9} The ciclosporin levels in 4 renal transplant patients with stable renal function increased by approximately 72% when clarithromycin 250 mg twice daily for 6 days was added to treat gingival hyperplasia. Ciclosporin levels returned to baseline levels within 7 days of stopping clarithromycin. Only two patients required a ciclosporin dose reduction.¹⁰

Numerous case reports also describe this interaction: ciclosporin levels or AUC have been increased by two- to threefold,^{11–14} with changes being seen within 3 to 6 days of clarithromycin 250 or 500 mg twice daily being started.^{11,14} Another patient had a seven- to twelvefold rise in serum ciclosporin levels and acute renal failure within 3 weeks of starting to take clarithromycin 1 g daily.¹⁵ Another case report in a heart transplant patient taking ciclosporin found that the addition of rifampicin to clarithromycin negated the increase in ciclosporin levels seen with clarithromycin alone, and the ciclosporin dose requirement with concurrent clarithromycin plus rifampicin was similar to that before clarithromycin or rifampicin were started.¹⁶

(c) Dirithromycin

Dirithromycin 500 mg daily for 14 days did not significantly affect the pharmacokinetics of a single 15-mg/kg oral dose of ciclosporin in 8 healthy subjects.¹⁷

(d) Erythromycin

A study in 9 transplant patients taking ciclosporin found that erythromycin increased the mean trough serum levels of 3 kidney transplant patients sevenfold, from 147 to 1125 nanograms/mL, and of 6 heart transplant patients four- to fivefold, from 185 to 815 nanograms/mL. Acute nephrotoxicity occurred in all 9 patients, and 7 showed mild to severe hepatotoxicity caused by the increased ciclosporin levels.¹⁸

Markedly raised ciclosporin blood levels and/or toxicity have been described in a number of other studies and case reports with erythromycin given orally or intravenously to about 50 other patients.^{19–34} The interaction has also been demonstrated in healthy subjects.^{1,35} Oral erythromycin may possibly have a greater effect than intravenous erythromycin.^{30,36} Erythromycin-related ototoxicity, possibly associated with the use of ciclosporin, has been reported in liver transplant patients.³⁷

(e) Josamycin

A man with a renal transplant who was taking azathioprine, prednisone and ciclosporin 330 mg daily had a marked rise in his plasma ciclosporin levels from about 90 to 600 nanograms/mL when he took josamycin 2 g daily for 5 days. He responded in the same way when later rechallenge with josamycin. Another patient also reacted in the same way.³⁸ Two- to fourfold rises in ciclosporin levels have been seen in 9 other patients given josamycin 2 to 3 g (50 mg/kg) daily.^{39–41} Another patient had a 40% rise in ciclosporin levels when given josamycin 500 mg twice daily.⁴²

(f) Midecamycin

The steady-state ciclosporin blood levels of 10 kidney transplant patients were roughly doubled when they took midecamycin 800 mg twice daily.⁴³ A 43-year-old kidney transplant patient taking ciclosporin, azathioprine and prednisone, began further treatment on day 27 after the transplant with midecamycin diacetate 600 mg twice daily and co-trimoxazole three times daily for pneumonia. By day 33 the concentration/dose ratio of the ciclosporin had doubled, and ciclosporin levels had reached 700 nanograms/mL, accompanied by a rise in serum creatinine levels. When the midecamycin was replaced by cefuroxime, the concentrations of both ciclosporin and creatinine fell to their former levels within 3 days.⁴⁴ Ciclosporin levels in another kidney transplant patient taking ciclosporin 120 mg twice daily increased from 95 to 380 nanograms/mL 3 days after starting midecamycin 800 mg twice daily.⁴⁵ Blood levels of ciclosporin in a kidney transplant patient also increased from 97 to 203 nanograms/mL 4 days after starting midecamycin diacetate 600 mg twice daily.⁴⁶

(g) Pristinamycin

A kidney transplant patient had a tenfold increase in plasma ciclosporin levels from 30 to 290 nanograms/mL after taking pristinamycin 2 g daily for 8 days. Blood creatinine levels rose from 75 to 120 micromol/L. Another patient given pristinamycin 1.25 g had a rise in ciclosporin levels from 78 to 855 nanograms/mL after 6 days. Ciclosporin and creatinine levels fell to normal levels within 2 days of stopping both drugs.⁴⁷

Pristinamycin 50 mg/kg daily raised the ciclosporin blood levels of 10 patients by 65% from 560 to 925 nanograms/mL. Ciclosporin levels fell when the pristinamycin was stopped.⁴⁸ Within 5 days of starting to take pristinamycin 4 g daily the ciclosporin levels of another patient more than doubled. His serum creatinine levels also rose. Both fell back to baseline levels within 3 days of stopping the antibacterial.⁴⁹

(h) Roxithromycin

Eight patients with heart transplants taking ciclosporin 8 mg/kg daily, prednisolone and azathioprine for at least one month, were given roxithromycin 150 mg twice daily for 11 days. A 37.5% rise in plasma ciclosporin levels occurred at the time the roxithromycin was given, and a 60% rise occurred 4 hours later. Ciclosporin levels fell again when the roxithromycin was stopped. A small (10%) increase in serum creatinine levels occurred. There was no evidence of a deterioration in renal function.⁵⁰ The half-life of roxithromycin was found in one study to be doubled, from 17 to 34.4 hours, in patients with kidney transplants who were taking ciclosporin.⁵¹

(i) Spiramycin

The ciclosporin plasma levels of 6 heart transplant patients taking corticosteroids, azathioprine and ciclosporin remained unchanged when they were given spiramycin 3 MIU twice daily for 10 days.⁵² Similarly, no interaction was found between ciclosporin and spiramycin in other studies in patients with renal transplants.^{53–56}

(j) Telithromycin

There appears to be no clinical reports of an interaction between ciclosporin and telithromycin. However, the manufacturers of telithromycin note that it is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and it may therefore increase ciclosporin levels, requiring dose adjustment.⁵⁷

(k) Other macrolides

In vitro studies (see 'Mechanism' below) suggest that **rokitamycin** and **troleandomycin** interact with ciclosporin in the same way as erythromycin,⁵⁸ but as yet there seems to be no direct clinical evidence of an interaction.

Mechanism

In vitro studies with human liver microsomes have found that clarithromycin, erythromycin, josamycin, rokitamycin, roxithromycin and trolean-

domycin (but not spiramycin) inhibit ciclosporin metabolism in the liver, which is catalysed by the cytochrome P450 isoenzyme CYP3A.^{15,58} This would be expected to result in raised ciclosporin levels. Telithromycin is also an inhibitor of CYP3A4 and may increase ciclosporin levels.⁵⁷ Erythromycin^{30,34} and clarithromycin¹³ also possibly increase the absorption of ciclosporin from the gut by inhibiting intestinal wall metabolism.

Azithromycin is believed to be metabolised by routes independent of the cytochrome P450 enzyme system. Intravenous azithromycin was thought to have increased ciclosporin levels through P-glycoprotein inhibition and/or competition for biliary excretion in one case report.⁶

Importance and management

The interaction between ciclosporin and erythromycin is well documented, well established and potentially serious. If concurrent use is thought appropriate, monitor the ciclosporin blood levels closely and reduce the dosage appropriately. A reduction of about 35% has been calculated to be necessary.³² The dosage should be increased again when the erythromycin is stopped. The effect of intravenous erythromycin is less than oral erythromycin so if the route of administration is changed, be alert for the need to change the ciclosporin dosage.^{30,36}

Information about the interactions with clarithromycin, josamycin, midecamycin, and pristinamycin is much more limited, but they appear to behave like erythromycin. The same precautions should be taken. There seems to be no direct clinical information about telithromycin, troleanomycin and rokitamycin but they would be expected to interact like erythromycin. Note that troleanomycin is usually a more potent inhibitor of CYP3A4 than erythromycin, so it may be expected to have a larger effect on ciclosporin levels.

Dirithromycin and spiramycin normally appear not to interact and roxithromycin appears only to interact very minimally. Also bear in mind that roxithromycin serum levels may be increased.

Although most reports suggest that azithromycin does not interact, increased monitoring is recommended by some, because of the isolated reports of increased ciclosporin levels.⁶

Ciclosporin + Antibacterials; Metronidazole

Three reports describe an increase in ciclosporin levels in patients given metronidazole.

Clinical evidence, mechanism, importance and management

The ciclosporin blood levels of a kidney transplant patient rose from 850 to 1930 nanograms/mL when metronidazole 2.25 g daily and cimetidine 800 mg daily were started. The levels fell to about 1500 nanograms/mL when the metronidazole dosage was halved and the cimetidine stopped. Because the levels of ciclosporin were still so high, the dose of ciclosporin

was reduced from 7.1 to 5.7 mg/kg daily, which resulted in a further decrease in the ciclosporin level to about 1200 to 1380 nanograms/mL. Finally the metronidazole was stopped and the ciclosporin levels fell to a range of 501 to 885 nanograms/mL.¹

Another kidney transplant patient developed a raised serum creatinine (increased from 223 to 304 micromol/L) with virtually doubled ciclosporin blood levels when metronidazole 1.5 g daily was given.²

Ciclosporin levels in yet another kidney transplant patient doubled (from 134 to 264 micrograms/L) accompanied by a modest elevation in serum creatinine when metronidazole 400 mg three times daily was also given. The levels fell again when metronidazole was stopped.³

These three cases appear to be the only reports of an interaction, one of which is confused by the presence of cimetidine (see also 'Ciclosporin + H₂-receptor antagonists', p.1035). There is insufficient evidence to advocate monitoring every patient given the combination, but it would be prudent to at least bear this interaction in mind if using metronidazole in patients taking ciclosporin.

Ciclosporin + Antibacterials; Penicillins

Ampicillin does not interact adversely with ciclosporin. Increased nephrotoxicity has been seen in lung transplant patients given nafcillin prophylactically, whereas an isolated report describes a fall in ciclosporin levels in a patient treated with nafcillin. A case of raised ciclosporin levels in a patient taking ticarcillin has been described.

Clinical evidence

(a) Ampicillin

Seventy-one kidney transplant patients taking ciclosporin had no changes in serum urea, creatinine or ciclosporin levels when ampicillin was given.¹

(b) Nafcillin

A retrospective study of 19 lung transplant patients taking ciclosporin found that those given nafcillin for one week as prophylaxis against staphylococci had a greater degree of renal impairment than those not taking nafcillin. Serum creatinine levels rose steadily over 6 days until the nafcillin was stopped, whereas the patients not taking nafcillin had no changes in creatinine levels. Three of the nafcillin group temporarily needed haemodialysis. Ciclosporin doses in the nafcillin group were higher but the blood levels in both groups were not significantly different. The incidence of viral infections was also greater in the nafcillin group.²

A kidney transplant patient taking ciclosporin and prednisone experienced a marked fall in her serum ciclosporin levels on two occasions when given nafcillin 2 g every 6 hours. Trough blood levels fell from 229 to 119 nanograms/mL and then to 68 nanograms/mL after 3 and 7 days of nafcillin, respectively, and rose when the nafcillin was stopped. On the second occasion ciclosporin levels fell from 272 to 42 nanograms/mL after 9 days of treatment with nafcillin.³

(c) Ticarcillin

Rises in plasma ciclosporin levels from 90 to 230 nanograms/mL, and from 120 to 300 nanograms/mL occurred in a man within 5 to 10 days of starting ticarcillin 10 g daily.⁴

Mechanism

The authors of the study using nafcillin² postulate that it may have interfered with the ciclosporin assay, resulting in an underestimate of the actual levels, so that the nephrotoxicity was simply due to higher ciclosporin levels.² The fall in ciclosporin levels in the individual patient taking nafcillin³ is not understood, nor is the rise in levels seen in the patient taking ticarcillin.⁴

Importance and management

Information seems to be limited to the studies and cases cited. No special precautions would seem necessary with ampicillin, but an alternative to

nafcillin would seem prudent for anti-staphylococcal prophylaxis. The isolated report with ticarcillin is of unknown general significance. More study is needed.

Ciclosporin + Antibacterials; Quinolones

Ciclosporin serum levels are normally unchanged by the use of ciprofloxacin, but increased serum levels and nephrotoxicity may occur in a small number of patients. There is also some evidence that the immunosuppressant effects of ciclosporin are reduced by ciprofloxacin. One study, and two case reports describe rises in ciclosporin levels in patients given norfloxacin, but another study found no change. Similar results have been found with levofloxacin. No significant interaction appears to occur between ciclosporin and enoxacin, ofloxacin, pefloxacin and trovafloxacin.

Clinical evidence

(a) Ciprofloxacin

A single-dose study in 10 healthy subjects found that after taking ciprofloxacin 500 mg twice daily for 7 days the pharmacokinetics of oral ciclosporin 5 mg/kg were unchanged.¹ Five other studies confirm the lack of a pharmacokinetic interaction in:

- kidney transplant patients taking ciprofloxacin 750 mg twice daily for 13 days;²
- kidney transplant patients taking ciprofloxacin 500 mg twice daily for 7 days;³
- bone marrow transplant patients given ciprofloxacin 500 mg twice daily for 4 days;⁴
- heart transplant patients given ciprofloxacin 250 to 500 mg for 7 to 140 days;⁵
- heart transplant patients given ciprofloxacin 800 mg to 1.5 g daily.⁶

There were no changes in serum ciclosporin levels or evidence of nephrotoxicity.

In contrast, a handful of cases of nephrotoxicity have been reported, with three cases of increased ciclosporin levels.^{7,8} A heart transplant patient developed acute renal failure within 4 days of being given ciprofloxacin 750 mg every 8 hours.⁹ Another patient who had undergone a kidney transplant developed reversible nephrotoxicity.¹⁰ Decreased renal function in a heart-lung transplant patient has been described in another report.⁷ This patient and another also had increased ciclosporin blood levels when given ciprofloxacin 500 mg three times daily.⁷ Acute interstitial nephritis in a cardiac transplant patient has also been reported.^{11–13} A patient taking ciclosporin for red cell aplasia had an increase in ciclosporin levels from 120 nanograms/mL to 297 nanograms/mL, requiring a dose reduction from 250 mg to 200 mg daily, when intravenous ciprofloxacin 200 mg two or three times daily [exact dose unclear] was started. A ciclosporin dose increase back to 250 mg daily was required when the ciprofloxacin course was finished.⁸

A case-control study in 42 kidney transplant patients suggested that the proportion of cases experiencing at least one episode of biopsy-proved rejection within 1 to 3 months of receiving a transplant were significantly greater in those who had taken ciprofloxacin (45%) than in those who had not (19%). There was also a marked increase in the incidence of rejection associated with ciprofloxacin use (29%) compared with the controls (2%).¹⁴

(b) Enoxacin

Enoxacin 400 mg twice daily for 5 days had little effect on either blood or plasma levels of single doses of ciclosporin in 10 healthy subjects.¹⁵

(c) Levofloxacin

A single-dose study in 12 healthy subjects found that levofloxacin 500 mg had no effect on the pharmacokinetics of ciclosporin oral solution (*Sandimmune*).¹⁶ A case report in a patient taking oral ciclosporin 250 mg daily (as the emulsion formulation) found no change in ciclosporin levels

when he was given intravenous levofloxacin 500 mg daily for 9 days.⁸

In contrast, in a study in 5 kidney transplant patients taking ciclosporin (microemulsion formulation) the maximum ciclosporin blood concentration was increased by 23% when levofloxacin 500 mg twice daily for 5 days was taken for a urinary-tract infection. The authors concluded that this interaction may be clinically significant, and warned about extrapolating the results from single-dose studies in healthy subjects (as above) to patients with transplants.¹⁷

(d) Norfloxacin

Six renal transplant patients given norfloxacin 400 mg twice daily for 3 to 23 days for urinary tract infections,¹⁸ and 4 heart transplant patients given norfloxacin 400 mg for 7 to 140 days had no changes in their serum ciclosporin levels.⁵ However, two reports describe rises, one marked, in serum ciclosporin levels in a heart transplant patient and a kidney transplant patient given norfloxacin.¹⁹ A comparative study in 5 children (mean age, 8 years) found that while receiving norfloxacin 5 to 10 mg/kg daily their daily dose of ciclosporin was 4.5 mg/kg daily compared with a control group of 6 children not taking norfloxacin who needed 7.4 mg/kg daily.²⁰

(e) Ofloxacin

Thirty-nine patients with kidney transplants taking ciclosporin and prednisolone had no evidence of nephrotoxicity nor of any other interaction when they were given ofloxacin 100 to 400 mg daily for periods of 3 to 500 days.²¹

(f) Pefloxacin

A study in kidney transplant patients taking corticosteroids, azathioprine and ciclosporin found that the pharmacokinetics of the ciclosporin were not significantly changed by pefloxacin 400 mg twice daily for 4 days.²²

(g) Trovafloxacin

A placebo-controlled crossover study in 7 stable kidney transplant patients treated with ciclosporin (*Sandimmune*) found that the pharmacokinetics of the ciclosporin were not significantly altered by trovafloxacin 200 mg daily for 7 days.²³

Mechanism

The interaction between ciclosporin and norfloxacin probably occurs because norfloxacin inhibits the cytochrome P450 isoenzyme CYP3A4, resulting in a reduction in ciclosporin metabolism.²⁰ The interaction between ciclosporin and ciprofloxacin may possibly be due to some antagonism by ciprofloxacin of the ciclosporin-dependent inhibition of interleukin-2, which thereby opposes its immunosuppressant action.¹⁴

Importance and management

Information seems to be limited to these reports. They indicate that in children and adults the dosage of ciclosporin will probably need to be reduced in the presence of norfloxacin. Information with levofloxacin is currently limited, but a modest increase in ciclosporin levels may occur, and increased monitoring seems advisable.

No pharmacokinetic interaction usually occurs between ciclosporin and ciprofloxacin but very occasionally and unpredictably an increase in serum ciclosporin levels and/or kidney toxicity occurs. There is also some evidence that the immunosuppressant effects of ciclosporin may be reduced.¹⁴ Bear these interactions in mind if both drugs are given.

There seem to be no reports of problems with enoxacin, ofloxacin, pefloxacin or trovafloxacin.

Ciclosporin + Antibacterials; Quinupristin/Dalfopristin

A study found that quinupristin/dalfopristin increased the AUC and maximum blood levels of ciclosporin. In an isolated case quinupristin/dalfopristin was found to increase ciclosporin levels by about threefold.

Clinical evidence, mechanism, importance and management

In a study in 24 subjects given a single 300-mg dose of ciclosporin, taken 1.5 hours before the fourth of 9 infusions of quinupristin/dalfopristin (7.5 mg/kg given at intervals of 8 hours) the AUC and maximum blood levels of ciclosporin were increased by 63% and 30%, respectively, and ciclosporin clearance was decreased by 34%.¹

A kidney transplant patient taking ciclosporin with trough blood levels of between 80 and 105 nanograms/mL developed a vancomycin-resistant enterococcal infection. After a series of antibacterials had failed to clear the infection she was given intravenous quinupristin/dalfopristin 300 mg every 8 hours. After 3 days of treatment her ciclosporin trough level rose to almost 300 nanograms/mL. A ciclosporin dose reduction from 75 to 50 mg twice daily returned her levels to baseline. However, 2 days after the antibacterials were discontinued she was found to have a trough ciclosporin level of only 34 nanograms/mL. She was subsequently stabilised on her original dose of ciclosporin.²

Information is limited. However, the manufacturers state that quinupristin/dalfopristin has been shown *in vitro* to inhibit the cytochrome P450 isoenzyme CYP3A4 and advise that ciclosporin levels are closely monitored during concurrent use;^{3,4} ciclosporin dose reductions may be necessary.

Ciclosporin + Antibacterials; Sulfonamides and/or Trimethoprim

In isolated cases, sulfadiazine given orally or sulfadimidine given intravenously with trimethoprim have caused a reduction in se-

rum ciclosporin levels. Sulfametoxydiazine possibly caused a minor reduction in ciclosporin levels in one case. Although co-trimoxazole increases serum creatinine levels in kidney transplant patients taking ciclosporin, it normally appears to be safe and effective.

Clinical evidence

(a) Co-trimoxazole

A large-scale study in 132 kidney transplant patients taking ciclosporin encompassing 33 876 patient days found that co-trimoxazole was effective and well tolerated. Ciclosporin pharmacokinetics remained unchanged. A 15% rise in serum creatinine levels occurred, which reversed when the co-trimoxazole was stopped. This rise was not interpreted as a sign of nephrotoxicity but appeared to be due to inhibition of the tubular excretion of creatinine by the co-trimoxazole.¹

Other reports describe a few patients given ciclosporin with co-trimoxazole who developed rises in creatinine levels (interpreted as evidence of nephrotoxicity),²⁻⁵ interstitial nephritis,⁶ granulocytopenia and thrombocytopenia.^{7,8} Apparent nephrotoxicity has also been seen with **trimethoprim** and ciclosporin.⁹

(b) Sulfadiazine or Sulfametoxydiazine

Three heart transplant patients treated for toxoplasmosis had a reduction in their ciclosporin levels when they were given sulfadiazine 4 to 6 g daily. Their dosage-to-level ciclosporin ratios rose by 58%, 82%, and 29%, respectively. Two had previously been given sulfametoxydiazine and this had caused a minor reduction in ciclosporin levels in one of these patients.¹⁰

(c) Sulfadimidine with trimethoprim

A heart transplant patient taking ciclosporin and prednisolone developed undetectable serum ciclosporin levels 7 days after starting intravenous sulfadimidine 2 g four times daily and **trimethoprim** 300 to 500 mg twice daily. Doubling the ciclosporin dosage had little effect and evidence of transplant rejection was seen. Within 10 days of starting to take the antibacterials orally instead of intravenously the serum ciclosporin levels returned to roughly their former levels and the rejection problems disappeared.¹¹

Another report by some of the same authors describes a similar marked fall in serum ciclosporin levels in 5 heart transplant patients (one of them the same as the report already cited¹¹) when given sulfadimidine and **trimethoprim** intravenously.¹²

Mechanism

Uncertain. Co-trimoxazole and trimethoprim can raise serum creatinine levels, possibly due to inhibition of creatinine secretion by the kidney tubules.¹³ The reduction in serum ciclosporin levels apparently caused by the sulfonamides is not understood.

Importance and management

The documentation is only moderate, and these interactions are not firmly established. Be aware that intravenous sulfadimidine with trimethoprim may cause a marked reduction in serum ciclosporin levels with accompanying inadequate immunosuppression. Sulfadiazine may also reduce ciclosporin levels. The evidence suggests that oral sulfadimidine with trimethoprim, sulfametoxydiazine, and co-trimoxazole do not interact adversely and are normally safe and effective, although toxicity can apparently occur in a small number of patients. Until more information is available it would be prudent to keep a close check on ciclosporin levels if any sulphonamide is added to established treatment with ciclosporin. The manufacturer recommends close monitoring of renal function when ciclosporin is used with co-trimoxazole.¹⁴

Ciclosporin + Antidiabetics

Some preliminary evidence suggests that glibenclamide (glyburide) can raise serum ciclosporin levels to a moderate extent. Glipizide caused about a twofold increase in ciclosporin levels in 2 patients, but no change was noted in a study in 11 patients. A single-dose study found ciclosporin significantly increased repaglinide bioavailability. However a study in kidney transplant patients found no consistent increase in blood glucose-lowering effects in patients taking both drugs. Pioglitazone and rosiglitazone are predicted to not interact with ciclosporin.

Clinical evidence, mechanism, importance and management

(a) Pioglitazone

In vitro and human studies have shown that pioglitazone does not affect cytochrome P450 isoenzymes, including CYP3A4. Therefore no interaction would be expected with ciclosporin, which is mainly metabolised by CYP3A4.¹

(b) Repaglinide

A placebo-controlled study in 12 healthy subjects given ciclosporin 100 mg twice daily for two doses, with a single 250-microgram dose of repaglinide on day 2, found that ciclosporin significantly increased the maximum plasma level and AUC of repaglinide by 175% and 244%, respectively. It was suggested that ciclosporin inhibited the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of repaglinide, as well as affecting OAT-mediated liver uptake of repaglinide.^{2,3}

No significant changes were seen in ciclosporin, sirolimus or tacrolimus blood levels and no dosage changes were required in a study in kidney transplant patients taking repaglinide (18 as monotherapy and 5 combined with either metformin or rosiglitazone). The effects of ciclosporin on repaglinide metabolism were not investigated in this study, although concurrent use was found to be effective.⁴ Commenting further, the authors noted that they were unable to demonstrate a consistent, increased blood glucose-lowering effect with concurrent use of repaglinide and ciclosporin,⁵ although other authors, citing the study above,² noted that ciclosporin may markedly increase plasma repaglinide levels and enhance its blood glucose-lowering effects.³

Although the clinical study found no serious adverse effects with concurrent ciclosporin and repaglinide, the situation is not clear. The large increases in repaglinide levels seen were significant, although they were found in a single-dose study in healthy subjects taking no other potentially interacting medication. The possibility of increased hypoglycaemia should be borne in mind if ciclosporin and repaglinide are used concurrently. Patients should be advised to report any adverse effects, particularly an increase in the number of hypoglycaemic events.

(c) Sulphonylureas

A review of 6 post-transplant diabetic patients taking ciclosporin found that their steady-state plasma ciclosporin levels rose by 57% when they were given **glibenclamide (glyburide)**. Hepatic and renal function were unchanged. The reason for this reaction is not known, but it is suggested that **glibenclamide** possibly inhibits the cytochrome P450 isoenzyme CYP3A4, the major isoenzyme involved in the metabolism of ciclosporin,

resulting in a reduction in its clearance.⁶

Ciclosporin blood levels in 2 patients were more than doubled, and they needed reductions of 20 to 30% in their ciclosporin dosage when they were also given **glipizide** 10 mg daily.⁷ In contrast, a study in 11 post-transplant diabetic patients found no significant alterations in ciclosporin pharmacokinetics when **glipizide** was given.⁸ This interaction is unconfirmed and of uncertain clinical significance. However, note that one of the rare adverse effects of ciclosporin is hyperglycaemia. There is insufficient evidence to recommend increased monitoring, but be aware of the potential for an interaction in the case of an unexpected response to treatment. Information about other sulphonylureas appears not to be available.

Ciclosporin + Antiepileptics

Serum ciclosporin levels are markedly reduced by carbamazepine, phenobarbital, or phenytoin. The dosage of ciclosporin may need to be increased two- to fourfold to maintain adequate immunosuppression. Oxcarbazepine may cause a small decrease in ciclosporin levels. Valproate appears not to affect ciclosporin levels but two case reports suggest that it may damage renal grafts and cause hepatotoxicity in patients taking ciclosporin.

Clinical evidence

(a) Carbamazepine

The ciclosporin serum levels of a kidney transplant patient fell from 346 to 64 nanograms/mL within 3 days of starting to take carbamazepine 200 mg three times daily. A week later serum levels were down to 37 nanograms/mL. They rose again when the carbamazepine was stopped but fell once more when it was restarted. The ciclosporin dosage was increased to keep the levels within the therapeutic range.¹

The mean average steady-state blood levels of ciclosporin (adjusted for dose) in a group of 3 children with kidney transplants taking carbamazepine were 50% lower than in 3 other matched patients not taking carbamazepine.² Four other individual patients have also shown this interaction.^{3–5} One needed her ciclosporin dosage to be doubled in order to maintain adequate blood levels while taking carbamazepine 800 mg daily.³ When the carbamazepine was replaced by sodium valproate in 3 patients, the ciclosporin dosages could be reduced to their previous level.^{3,4}

(b) Oxcarbazepine

A kidney transplant patient taking ciclosporin 270 mg daily and valproate, gabapentin, prednisone, doxepin, allopurinol, levothyroxine and pravastatin was also given oxcarbazepine. Fourteen days later, with the dose of oxcarbazepine at 750 mg daily, the ciclosporin trough level fell below 100 nanograms/mL and after a further 2 days was 87 nanograms/mL. The ciclosporin dose was increased to 290 mg daily and the oxcarbazepine dose reduced to 600 mg daily. Ciclosporin levels then remained stable above 100 nanograms/mL and seizure frequency was reduced by 95%.⁶

(c) Phenobarbital

A 4-year-old child with a bone marrow transplant who was receiving phenobarbital 50 mg twice daily had serum ciclosporin levels of less than 60 nanograms/mL even after raising the ciclosporin dosage to 18 mg/kg daily. When the phenobarbital dosage was reduced to 25% of the original dose the trough serum ciclosporin levels rose to 205 nanograms/mL.⁷ Another report describes an increase in ciclosporin levels from 512 to

810 nanograms/mL after phenytoin and phenobarbital were replaced by sodium valproate in one patient.⁸

A threefold increase in ciclosporin clearance was seen in another child with a kidney transplant while taking phenobarbital.⁹ Reductions in ciclosporin levels due to phenobarbital have been described in other patients.^{10–13}

(d) Phenytoin

The observation that 5 patients taking ciclosporin needed dosage increases while taking phenytoin prompted a further study in 6 healthy subjects. Phenytoin 300 or 400 mg daily reduced the maximum ciclosporin blood levels and AUC by 37% (from 1325 to 831 micrograms/L) and 47%, respectively.¹⁴

Other reports describe patients who needed two- to fourfold increases in their ciclosporin dosages when they were given phenytoin.^{15–19}

Another report describes an increase in ciclosporin levels from 512 to 810 nanograms/mL after phenytoin and phenobarbital were replaced by sodium valproate.⁸

A report of severe gingival overgrowth in a kidney transplant patient was attributed to the additive adverse effects of ciclosporin and phenytoin. Ciclosporin was replaced by tacrolimus, which may have fewer oral adverse effects, and almost complete reversal of gingival overgrowth was achieved within 6 months.²⁰

(e) Sodium valproate

In 5 cases an interacting antiepileptic was successfully replaced by sodium valproate,^{3,4,8,21} see *Carbamazepine, Phenobarbital and Phenytoin*, above.^{13,21} However, sodium valproate may not always be without problems because interstitial nephritis was suspected in one patient with a renal graft taking ciclosporin and valproate,¹⁰ and fatal valproate-induced hepatotoxicity occurred in another patient taking ciclosporin.²²

Mechanism

It is thought that phenytoin,^{14,15} carbamazepine^{1,2} and phenobarbital^{7,11} increase the metabolism of the ciclosporin by the liver (hepatic cytochrome P450 oxygenase system) thereby decreasing the serum levels. Oxcarbazepine produced only small reductions in ciclosporin levels, and the effect is probably due to weak induction of the cytochrome P450 isoenzyme CYP3A.⁶ Phenytoin also possibly reduces the absorption of the ciclosporin.²³

Importance and management

None of these interactions is extensively documented but all appear to be established and of clinical importance. Serum ciclosporin levels should be well monitored if carbamazepine, phenobarbital or phenytoin are added and the ciclosporin dosage increased appropriately. **Primidone** is metabolised to phenobarbital by the liver, and therefore would be expected to reduce ciclosporin levels. Information about oxcarbazepine is very limited but small reductions in its dose, together with an increase in ciclosporin dose, may be adequate to control any interaction. However, more study is required before oxcarbazepine can be recommended as a suitable alternative.⁶ The effects of the interaction may persist for a week or more after the anticonvulsant is withdrawn. Sodium valproate seems not to alter ciclosporin levels, but the case reports of nephritis and hepatotoxicity suggest some caution is warranted.

Ciclosporin + Antimycobacterials

Ciclosporin serum levels are markedly reduced by rifampicin and transplant rejection can rapidly develop. Rifampicin seems to interact similarly, but limited evidence suggests that rifabutin interacts to a lesser extent. Ethambutol and isoniazid do not generally appear to interact with ciclosporin although case reports have described alterations in ciclosporin levels.

Clinical evidence

(a) Rifabutin

The clearance of ciclosporin in a patient with a kidney transplant doubled when isoniazid, ethambutol, pyridoxine and rifampicin 600 mg daily were given. When these drugs were replaced by rifabutin 150 mg and clofazimine 100 mg daily the ciclosporin clearance fell to about its former levels, but after about 3 weeks the clearance was about 20% greater than before the antimycobacterial drugs were given.¹

(b) Rifampicin (Rifampin)

A study in 39 kidney transplant patients taking ciclosporin at a mean dose of 158 mg daily found that the ciclosporin dose needed to be increased by between 150 to 525 mg daily (an average dose of 469 mg daily) when rifampicin 450 to 600 mg daily was taken as part of a regimen for tuberculosis. An increased incidence of acute rejection occurred during treatment with ciclosporin and rifampicin and 16 patients had kidney graft failure and needed to go back on haemodialysis because of this interaction.²

A heart transplant patient taking ciclosporin started taking rifampicin 600 mg daily with amphotericin B for the treatment of an *Aspergillus fumigatus* infection. Within 11 days her serum ciclosporin levels had fallen from 473 to less than 31 nanograms/mL and severe acute graft rejection occurred. The dosage of ciclosporin was increased stepwise and the levels climbed to a plateau before suddenly falling again. The dosage had to be increased to more than 30 mg/kg daily to achieve serum levels in the range 100 to 300 nanograms/mL.³

A considerable number of other reports about individual patients, both adult and paediatric, confirm that a very marked fall in serum ciclosporin levels occurs, often to undetectable levels, accompanied by transplantation rejection in many instances, if rifampicin is given either intravenously or orally without raising the ciclosporin dosage.^{1,4–28} Ciclosporin levels become toxic within 2 weeks of stopping the rifampicin unless the previously adjusted ciclosporin dosage is reduced.^{4,6}

Three patients needed increases in the dosage of ciclosporin when given rifampicin and erythromycin, although the latter normally reduces ciclosporin requirements.^{19,29,30} Another patient whose ciclosporin levels had been raised by ‘clarithromycin’, (p.1016), had a fall in their levels when rifampicin was added.³¹

(c) Rifampicin sodium

Rifampicin sodium used to irrigate a wound has been reported to reduce the serum levels of ciclosporin in a kidney transplant patient.³²

(d) Other antituberculars

Isoniazid^{12,22,23} and **ethambutol**^{22,23} do not normally interact with ciclosporin. However, there is one case report describing a patient who had a gradual rise in serum ciclosporin levels when isoniazid and ethambutol were stopped,¹⁴ and another which attributed a marked rise in ciclosporin levels to the use of isoniazid.³³ There have been several other case reports of successful treatment of tuberculosis in heart and kidney transplant patients using **isoniazid**, **ethambutol**, pyrazinamide with ofloxacin, or **streptomycin**.^{34,35} Consider also ‘pyrazinamide’, (p.1044), and ‘quinolones’, (p.1018).

Mechanism

Rifampicin stimulates the metabolism of the ciclosporin by the cytochrome P450 isoenzyme CYP3A³⁶ resulting in a marked increase in ciclosporin clearance. In addition, rifampicin decreases ciclosporin absorption by inducing its metabolism by the gut wall,³⁷ thus producing a significant fall in ciclosporin levels. If rifampicin is given with erythromycin or clarithromycin, the enzyme inhibitory effects of the macrolides are swamped by the more potent enzyme-inducing effects of rifampicin. Rifabutin has some enzyme-inducing properties but the extent is quite small compared with rifampicin, and the onset may be delayed.³⁸

Importance and management

The interaction between ciclosporin and rifampicin is very well documented, well established and clinically important, as transplant rejection may occur unless the ciclosporin dosage is markedly increased. In one study 27% of patients taking rifampicin lost grafts due to rejection, and this was directly attributed to the interaction.²² The interaction develops within a few days (within a single day in one case²⁰). Monitor the effects of concurrent use and increase the ciclosporin dosage appropriately. Three- to fivefold dosage increases (sometimes frequency-increases from two to three times daily) have proved to be effective, with daily monitoring. Remember also to reduce the ciclosporin dosage when rifampicin is stopped to reduce the risk of ciclosporin toxicity.

The authors of one large study concluded that it is better to avoid rifampicin in patients taking ciclosporin and to use other antimycobacterials instead.²² They found that the use of three antitubercular drugs (not including rifampicin) for at least 9 months reduced mortality. Other reports similarly found that regimens without rifampicin were suitable for the treatment of tuberculosis in transplant patients.^{23,34,35}

Another suggested alternative is to replace the ciclosporin with another non-interacting immunosuppressant, such as azathioprine and low-dose prednisolone for immunosuppression, if rifampicin is needed.¹³

Other rifamycins may also be an option; limited evidence suggests that rifabutin interacts minimally. However, the manufacturer³⁹ and the CSM in the UK⁴⁰ caution about the possibility of an interaction, and close monitoring of ciclosporin levels would still be advisable. Topical rifampicin interacted like rifampicin in one patient when it was applied to a wound.³²

Ciclosporin + Azoles

The evidence suggests that all the azole antifungals can raise ciclosporin levels to a greater or lesser degree. Ketoconazole may cause five- to tenfold rises, while itraconazole, fluconazole and voriconazole may cause two- to threefold rises. A case report suggests that intravenous miconazole interacts similarly and in theory, miconazole oral gel may also interact. Posaconazole may also modestly raise ciclosporin levels. Rhabdomyolysis has been reported with the combination of ciclosporin and itraconazole, but four of these cases were complicated by the presence of statins.

Clinical evidence

(a) Fluconazole

Fluconazole 200 mg daily for 14 days roughly doubled the ciclosporin trough blood levels of 8 kidney transplant patients, from 27 to 58 nanograms/mL. The AUC increased 1.8-fold but serum creatinine levels were unchanged.^{1,2}

Other reports describe two- to threefold rises in ciclosporin blood levels in kidney transplant patients within 6 to 11 days of starting treatment with fluconazole 100 to 200 mg daily.^{3–8} One patient developed nephrotoxicity, which resolved when the dosages of both drugs were reduced.⁹

In contrast, some patients have had little or no changes in serum ciclosporin or creatinine levels when fluconazole was given.^{8,10–15} This may have been because the interaction is dose-dependent.^{14,16} One study found a lack of interaction in females and African-American patients, suggesting that gender and ethnicity may also be factors.¹⁷ Another study found that there was only a 20% increase in ciclosporin levels when intravenous ciclosporin was given with high-dose intravenous fluconazole, which was not considered clinically relevant.¹⁸

An *in vitro* study suggests that the activity of fluconazole against *Candida albicans* may be enhanced by ciclosporin.¹⁹

(b) Itraconazole

In 4 heart-lung, 2 heart and one lung transplant patient an average 56% reduction (range 33 to 84%) in the ciclosporin dosages were needed when itraconazole (dosage not stated) was given. Serum creatinine levels rose temporarily until the ciclosporin dosage had been readjusted.²⁰ Two- to threefold rises in ciclosporin levels were seen in another 2 patients given itraconazole 200 mg daily,^{21,22} and in one case the raised levels persisted for more than 4 weeks after the itraconazole was stopped.²² Intravenous itraconazole 200 mg twice daily for 2 days then 200 mg daily caused a twofold increase in the levels of intravenous ciclosporin in 2 patients.²³

Other case reports and studies suggest that dosage reductions of about 50 to 80% (where stated) were needed when patients taking ciclosporin were given itraconazole.^{24, 25, 26} Enhanced itraconazole absorption in the presence of a carbonated drink that increased stomach acidity was found to allow decreases in ciclosporin dose and increases in its dose interval.²⁷

These reports contrast with another describing 14 bone marrow transplant patients taking ciclosporin. Those given itraconazole 100 mg twice daily had no significant changes in ciclosporin or creatinine serum levels.²⁸ Another patient required only a 10% reduction in ciclosporin dose when given itraconazole 400 mg daily for 40 days.⁸

Rhabdomyolysis has been reported in 3 lung transplant patients^{24,29} and 2 heart transplant patients^{30,31} when itraconazole was used in combination with ciclosporin. However, in three of these cases the concurrent use of simvastatin and in one case concurrent simvastatin and gemfibrozil would also have been factors,^{24,29–31} as both ciclosporin and itraconazole can increase simvastatin levels (see 'Statins + Ciclosporin', p.1097, and also 'Statins + Azoles', p.1093).

(c) Ketoconazole

Ketoconazole 200 mg daily caused a marked and rapid rise in the ciclosporin blood levels of 36 renal transplant patients. On the basis of experience with previous patients, the ciclosporin dosage was reduced by 70% when ketoconazole was started, and after a year the dosage reduction was 85% (from 420 mg to 66 mg daily). Minimal nephrotoxicity was seen.^{32–34} A study in children with nephrotic syndrome found the addition of ketoconazole allowed a ciclosporin dose reduction of approximately 37%. They also found that those in the ketoconazole treated group (153 patients) had a lower frequency of renal impairment, were more likely to be able to stop taking steroids and had a better chance of staying in remission than those not given ketoconazole (54 patients).³⁵

Other reports^{8,36–50} describe essentially similar rises in ciclosporin levels during the use of ketoconazole. The effects of ketoconazole on ciclosporin were found to be slightly increased (from 80 to 85%) when diltiazem was also given.⁵¹ Ketoconazole 2% cream has been found not interact with ciclosporin 1 mg/kg daily in the treatment of contact allergic dermatitis and the ciclosporin dosage does not need to be reduced.⁵² Impaired glucose tolerance has been attributed to the use of ketoconazole and ciclosporin in one patient.⁵³

(d) Miconazole

A single case report describes a rise of about 65% in ciclosporin serum levels within 3 days of intravenous miconazole 1 g every 8 hours being started. Ciclosporin levels rose again during subsequent treatment with miconazole.⁵⁴

(e) Posaconazole

Posaconazole 200 mg daily was given to 4 heart transplant patients receiving stable doses of ciclosporin. Three of the 4 required dose reductions of between about 15 and 27% to maintain ciclosporin levels.⁵⁵ Although these dosage adjustments were considered low, they do indicate that posaconazole interacts in a similar manner to the other azoles. The manufacturers also report cases of ciclosporin toxicity which resulted in significant adverse effects, including nephrotoxicity and one fatal case of leukoencephalopathy.⁵⁶

(f) Voriconazole

In a placebo-controlled, crossover study, 14 kidney transplant patients receiving stable doses of ciclosporin were given voriconazole 200 mg every 12 hours for 15 doses. Of the 14 patients, 7 discontinued treatment during the voriconazole phase due to adverse effects, 4 due to raised ciclosporin levels (mean 2.48-fold), one due to raised liver function, one due to asthenia, dyspnoea and oedema, and one due to an underlying condition unrelated to the voriconazole. In the remaining 7 patients voriconazole caused 1.7-fold increases in the ciclosporin AUC.⁵⁷ Ciclosporin levels were significantly reduced in a bone marrow transplant patient, from a range of 150 to 184 nanograms/mL to 56 to 111 nanograms/mL, when prophylactic voriconazole was stopped due to abnormal liver function tests. The levels returned to range when the voriconazole was restarted.⁵⁸

Mechanism

In vitro studies show that these azole antifungals inhibit the metabolism of ciclosporin by human liver microsomal enzymes, ketoconazole being the most potent.^{59,60} As a result ciclosporin blood levels rise. Fluconazole and ketoconazole also appear to inhibit the metabolism of ciclosporin by the gut wall.^{18,46}

Importance and management

The interaction between ciclosporin and ketoconazole is very well established and clinically important. Ciclosporin blood levels rise rapidly and sharply, but they can be controlled by reducing the ciclosporin dosage by about 70 to 80%^{8,25,32,38,50} thereby preventing kidney damage. A ciclosporin dosage reduction of 68 to 89% was required over a 13-month period in one study, with no adverse changes in immunosuppressive activity, resulting in a total cost saving of about 65%, partially offset because of the need for more frequent patient follow-up and the cost of the ketoconazole.^{32,33} Other studies have suggested that this interaction can be exploited to make cost savings.^{47,48,50} Reviews of the pros and cons of concurrent use have been published.^{34,61} Ketoconazole may possibly have a kidney-protective effect.^{32,33} A study in renal transplant patients suggested that variability in absorption and in the response to metabolic inhibition by ketoconazole made the ciclosporin blood level response difficult to predict and monitor.⁶² There are also other confounding factors. For example, a patient who was given ketoconazole to increase ciclosporin levels was subsequently given famotidine. The famotidine raised gastric pH, which resulted in a reduction in the ketoconazole absorption, and the ciclosporin levels consequently fell.⁶³

Information about ciclosporin with fluconazole or itraconazole is less extensive, but concurrent use should be closely monitored, being alert for the need to reduce the ciclosporin dosage, in some cases by up to 50% or more, although some patients may demonstrate no significant changes at all. There is also some evidence that in the case of fluconazole, the interaction may possibly depend on its dosage,¹⁴ gender and ethnicity,¹⁷ and the route of ciclosporin administration.¹⁸

The interaction between *intravenous* miconazole and ciclosporin may be potentially serious and of clinical importance. There is no evidence of an interaction with other forms of miconazole. However, a large proportion of miconazole *oral* gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur for interactions with other medications. The manufacturers of miconazole oral gel recommend close monitoring and possible dose reduction of ciclosporin if given concurrently.⁶⁴ An interaction with *intravaginal* miconazole would not normally be expected because its systemic absorption is usually very low (less than 2%) in healthy women of child-bearing age.⁶⁵

The manufacturers of voriconazole suggest that the dose of ciclosporin should be halved when initiating voriconazole, and that ciclosporin levels should be carefully monitored during voriconazole treatment. It is important that the ciclosporin dose is increased again as necessary if voriconazole is withdrawn.^{58,66,67}

The dose of ciclosporin should be reduced by about 25% when posaconazole is started, with careful monitoring of ciclosporin levels and dose adjustment as needed.^{55,56}

Additional caution is required where ciclosporin and azoles are used in patients taking statins, and either ciclosporin dose reduction,²⁴ replace-

ment of ciclosporin with tacrolimus,²⁹ reducing the statin dose or stopping the statin³⁰ have been recommended.

Ciclosporin + Benzbromarone

Benzbromarone does not interact adversely with ciclosporin.

Clinical evidence, mechanism, importance and management

Twenty-five kidney transplant patients taking ciclosporin were given benzbromarone 100 mg daily to treat hyperuricaemia. The plasma uric acid levels decreased from 579 to 313 micromol/L and the 24-hour urinary uric acid secretion rose from 2082 to 3233 micromol after 4 weeks of treatment. The plasma uric acid levels normalised in 21 of the patients who had creatinine clearances of over 25 mL/minute. No significant adverse effects developed and the ciclosporin serum levels remained unchanged. The authors of the report emphasise the advantages of benzbromarone over allopurinol because of its efficacy, lack of significant adverse effects and because, unlike allopurinol, it does not interact with azathioprine, which often accompanies ciclosporin treatment.¹

1. Zürcher RM, Bock HA, Thiel G. Excellent uricosuric efficacy of benzbromarone in cyclosporin-A-treated renal transplant patients. A prospective study. *Nephrol Dial Transplant* (1994) 9, 548-51.

Ciclosporin + Beta blockers

Carvedilol may increase ciclosporin levels in some patients. Atenolol and metoprolol do not appear to interact with ciclosporin.

Clinical evidence, mechanism, importance and management

A study in 21 kidney transplant patients found that when **atenolol** was gradually replaced by **carvedilol** in a stepwise manner, starting with **carvedilol** 6.25 mg daily, gradually increasing to 50 mg daily, the ciclosporin dosage had to be gradually reduced. At 90 days the daily ciclosporin dosage had been reduced by 20% (from 3.7 to 3 mg/kg) to maintain levels within the therapeutic range but considerable inter-individual variations were seen.¹ A retrospective study in 12 heart transplant patients found that **carvedilol** increased the ciclosporin level in 10 patients from a mean of 257 nanograms/mL to 380 nanograms/mL. This required a mean dose reduction of 31 mg daily (10%). In the same study, 20 patients taking **metoprolol** did require any significant ciclosporin dosage alterations.² A study in 30 renal transplant patients found no change in the ciclosporin levels of those taking **atenolol** 25 to 100 mg daily.³

The reason for the interaction with **carvedilol** is not understood. The manufacturers of carvedilol recommend close monitoring of ciclosporin levels with appropriate dose adjustment when carvedilol is added.⁴ Information about other beta blockers seems to be lacking, although metoprolol and atenolol do not appear to interact.

Ciclosporin + Bifendate

Two case reports show that bifendate can cause a gradual fall in the serum levels of ciclosporin.

Clinical evidence, mechanism, importance and management

Two kidney transplant patients were successfully treated with ciclosporin and prednisolone for 30 and 36 months, respectively. When they were given bifendate 75 mg daily for the treatment of chronic hepatitis, both of them had a gradual fall in their trough serum ciclosporin levels. The ciclosporin levels of the first patient fell from 97.7 to 78 nanograms/mL at 4 weeks and to 49 nanograms/mL at 6 weeks. The other patient had a fall from 127.5 to 70.5 nanograms/mL at 8 weeks and to 45 nanograms/mL at 16 weeks. The reasons are not understood. The ciclosporin dosages remained unchanged throughout, and despite the low serum levels that occurred, no graft rejection was seen. When the bifendate was stopped, the ciclosporin levels gradually climbed again, at about the same rate as their decline, to about their former levels.¹ There would seem to be no clear reason for avoiding concurrent use but it would be prudent to monitor the outcome, being alert for the need to increase the ciclosporin dosage. Bifendate is derived from *Schisandra* and is a 'hepatonic' preparation with actions that are not understood.

Ciclosporin + Bile acids or Ursodeoxycholic acid (Ursodiol)

Ursodeoxycholic acid unpredictably increases the absorption and raises the serum levels of ciclosporin in some but not all patients. Bile acids (cholic/dehydrocholic acids) appear not to interact with ciclosporin.

Clinical evidence

(a) Bile acids (Cholic/dehydrocholic acids)

Eleven healthy subjects were given a single oral dose of ciclosporin on three occasions: while fasting, with breakfast, and with breakfast plus bile acid tablets (**cholic acid 400 mg, dehydrocholic acid 100 mg**). The mean ciclosporin AUCs were 7283, 7453 and 9078 nanograms/mL, respectively, indicating that the bile acids increased the absorption of the ciclosporin by 22%. However, a related study in 19 transplant patients found that their 12-hour trough ciclosporin serum levels were unchanged by the concurrent use of this dosage of bile acids over an 8-day period.¹

(b) Ursodeoxycholic acid

A patient who had previously had his entire ileum removed and about 1 metre of the residual jejunum anastomosed to the transverse colon, had a heart transplant. It was possible to reduce his ciclosporin dosage from 1.6 to 1.2 g daily when he started taking ursodeoxycholic acid 1 to 2 g daily. However, when the ursodeoxycholic acid was stopped, his ciclosporin serum levels became subtherapeutic and severe acute rejection developed. The ciclosporin levels rose once again when ursodeoxycholic acid was restarted, and the ciclosporin AUC was increased by more than threefold.² The trough serum ciclosporin levels of a patient with chronic active hepatitis C increased from 150 to 500 nanograms/mL when he was given ursodeoxycholic acid, and it was necessary to halve his daily ciclosporin dosage to keep the ciclosporin levels at 150 nanograms/mL.³

In contrast, a study in 7 liver transplant patients found no statistically significant changes in mean ciclosporin levels when a single 600-mg dose of ursodeoxycholic acid was given at the same time as the ciclosporin.⁴ Yet another study in 12 liver transplant patients, 6 of whom were cholestatic, found that ciclosporin was absorbed more rapidly after a single dose of ursodeoxycholic acid in 8 patients, but, although 7 patients had some rise in their AUC, the mean 24-hour AUC was not significantly changed. There was no consistent improvement in ciclosporin pharmacokinetics in the cholestatic patients.⁵

Mechanism

When an interaction occurs it is thought to do so because the ursodeoxycholic acid improves micellation of the oil-containing oral ciclosporin formulation so that its absorption is increased.²

Importance and management

Information is limited but bile acids do not apparently interact with ciclosporin, while the interaction with ursodeoxycholic acid appears to be uncertain and unpredictable. It would therefore be prudent to monitor the effects of adding or stopping ursodeoxycholic acid in any patient taking ciclosporin, being alert for the need to adjust the ciclosporin dosage. More study is needed.

Ciclosporin + Bosentan

Bosentan modestly decreases ciclosporin levels, and ciclosporin increases bosentan levels. The manufacturer of bosentan contraindicates the combination, because of the possible increased risk of liver toxicity.

Clinical evidence, mechanism, importance and management

In a study designed to assess the effects of bosentan on ciclosporin renal toxicity, 7 healthy subjects were given bosentan 500 mg and ciclosporin 300 mg, both twice daily, for 7 days. Bosentan did maintain renal plasma flow, which is markedly decreased by ciclosporin. However, bosentan was calculated to have reduced the AUC of ciclosporin by about 50%. In ad-

dition, bosentan had no effect on the ciclosporin-induced rise in blood pressure, and headache, nausea, and vomiting were a problem with the combination. Moreover, the steady-state AUC of bosentan was raised 1.7-fold when compared with the AUC of a single dose of bosentan.¹ It should be noted that bosentan induces its own metabolism, and after 7 days, plasma levels are about 50 to 65% of those seen after a single dose.² Therefore, the effect of ciclosporin on the bosentan AUC may be twice those described in this study (i.e. up to a fourfold increase in the AUC of bosentan). The manufacturers of bosentan say that when bosentan is given with ciclosporin its plasma levels were markedly raised (30-fold after a single dose and three- to fourfold at steady state). They also list ciclosporin as an example of a drug, like bosentan, that inhibits the bile salt export pump, and is therefore expected to increase the risk of liver toxicity when used with bosentan. They therefore contraindicate the combination.² Further study is needed, as some consider the combination to have clinical potential.

The combination of **tacrolimus** or **sirolimus** with bosentan has not been studied but based on the information available for ciclosporin, the manufacturers of bosentan advise against concurrent use, but if it is required, close monitoring is recommended.²

Ciclosporin + Bupropion

An isolated case describes a large fall in ciclosporin levels in a 10-year-old boy given bupropion.

Clinical evidence, mechanism, importance and management

A 10-year-old boy, who had received a heart transplant 6 years previously started taking bupropion 75 mg twice daily in addition to his usual transplant medication, which included ciclosporin. After taking bupropion for 22 days, his ciclosporin level was found to be only 39 nanograms/mL. The last level taken before bupropion treatment had been 197 nanograms/mL. Despite an increase in his ciclosporin dose from 420 to 500 mg daily, the ciclosporin levels fell further, to 27 nanograms/mL. The ciclosporin dosage was then increased to 550 mg daily and bupropion was stopped.¹

The reason for this probable interaction is unclear, although an interaction via the cytochrome P450 isoenzyme CYP3A4 is a possibility. This appears to be the only reported case of an interaction between ciclosporin and bupropion, and its general importance is unknown.

Ciclosporin + Busulfan and Cyclophosphamide

The development of seizures in patients taking ciclosporin after bone marrow transplants has been attributed to previous treatment with busulfan and cyclophosphamide. Cyclophosphamide was found to reduce ciclosporin levels.

Clinical evidence, mechanism, importance and management

A study in stem cell transplant patients found that the ciclosporin levels in 47 patients whose pre-transplant conditioning regimens contained cyclophosphamide were reduced to a mean of 149.7 nanograms/mL, compared with a mean of 217.3 nanograms/mL in 56 patients whose regimens did not contain cyclophosphamide.¹ Five of 182 patients receiving allogeneic bone marrow transplants developed seizures within 22 to 61 days of starting ciclosporin and methylprednisolone. All of them had received busulfan 16 mg/kg and cyclophosphamide 120 mg/kg as preparative therapy without radiation. Magnetic resonance imaging found brain abnormalities, which resolved a few days after the ciclosporin was withdrawn.² The reasons for the effects on ciclosporin levels and the increase in adverse effects seen are not understood, nor is the association between the use of the preparative drugs, the ciclosporin, and the development of the seizure clearly

established. The authors of the report² recommend that if seizures develop the ciclosporin should be stopped and antiepileptics started.

Ciclosporin + Calcium-channel blockers

Diltiazem, nifedipine and verapamil markedly raise serum ciclosporin levels but also appear to possess kidney protective effects. A single case describes elevated ciclosporin levels caused by nisoldipine. Nifedipine normally appears not to interact, but rises and falls in ciclosporin levels have been seen in a few patients. Felodipine, isradipine, lacidipine and nitrendipine normally appear not to raise serum ciclosporin levels. Amlodipine has modestly increased ciclosporin levels in some studies, but not in others, and it may also have kidney-protective properties.

Clinical evidence

(a) Amlodipine

Ten hypertensive patients with kidney transplants taking ciclosporin (3 of them also taking azathioprine) were also given amlodipine 5 to 10 mg daily for 4 weeks. The hypertension was well controlled, the drug well tolerated, and the pharmacokinetics of the ciclosporin remained unaltered.¹ However, another study in 11 hypertensive kidney transplant patients found that amlodipine, given for 7 weeks, raised the ciclosporin levels by an average of 40%, without affecting creatinine levels.² A review identified two other studies that have found increases in ciclosporin levels of 23% and 43% with amlodipine, whereas four studies have found no change.³ Amlodipine is reported to reduce ciclosporin-associated nephrotoxicity in a study in patients with psoriasis,⁴ and in a review of kidney-transplant recipients.³

(b) Diltiazem

A pharmacokinetic study in 9 patients taking ciclosporin found that the addition of diltiazem 180 mg daily increased the trough blood level, maximum blood level and half-life of ciclosporin by 112%, 37%, and 43%, respectively.⁵ Sixty-five kidney transplant patients taking ciclosporin and diltiazem were found to need less ciclosporin when compared with 63 control patients not given diltiazem (7.3 mg/kg daily compared with 9 mg/kg daily). There were considerable individual differences in dose requirements.⁶ Other studies clearly confirm that diltiazem can raise ciclosporin blood levels.^{7–32} In some cases the ciclosporin blood levels were not only controlled by reducing the ciclosporin dosage by 30 to 60%, but it appeared that diltiazem had a kidney protective role (reduced nephrotoxicity, fewer rejection episodes and haemodialysis sessions).^{11,22,33–37} Another study found that a reduction in ciclosporin dose of about 21% was required for both men and women during chronic administration of diltiazem 90 mg twice daily, despite reports of higher activity of the cytochrome P450 isoenzyme CYP3A4 in women than in men.³⁸

(c) Felodipine

Thirteen kidney transplant patients had no significant changes in their serum ciclosporin levels when they took felodipine 2.5 to 10 mg daily and serum creatinine levels were also unchanged. Mean blood pressures fell from 161/100 to 152/90 mmHg.³⁹ Another study found no significant changes in ciclosporin levels in patients also given felodipine.⁴⁰ A single 10-mg dose of felodipine was found to have beneficial effects on blood pressure, renal haemodynamics, renal tubular sodium and water handling in ciclosporin-treated kidney transplant patients. The effects of long-term use were not studied.⁴¹ A single-dose study in 12 healthy subjects found that the maximum serum levels of ciclosporin 5 mg/kg were slightly raised by 16% by felodipine 10 mg, while the AUC and maximum plasma level of the felodipine were raised by 58% and 151%, respectively, but blood pressures were unchanged.⁴² The same group of workers also briefly described acute and short-term studies in groups of kidney transplant and dermatological patients, which found that felodipine 5 to 10 mg reduced blood pressure and opposed ciclosporin nephrotoxicity.⁴³ A study in heart transplant patients taking ciclosporin found that felodipine attenuated the hypertrophic effects of ciclosporin on transplanted hearts.⁴⁴

(d) Isradipine

Twelve kidney transplant patient had no changes in their ciclosporin levels over 4 weeks while taking up to 2.5 mg of isradipine twice daily.⁴⁵ Similar findings are noted in another study.⁴⁰ Three other studies in 31 kidney transplant patients confirmed that ciclosporin blood levels are unchanged by isradipine and blood pressures are reduced.^{46–48}

(e) Lacidipine

Ten kidney transplant patients taking ciclosporin, prednisone and azathioprine started taking lacidipine 4 mg daily. A very small increase in the trough blood levels (6%) and AUC (14%) of the ciclosporin occurred. The blood pressures fell from 142/93 to 125/79 mmHg, and the 14-hour urinary output rose from 1401 to 2050 mL.⁴⁹

(f) Lercanidipine

The manufacturers of lercanidipine contraindicate the concurrent use of ciclosporin as the plasma levels of lercanidipine were raised threefold by ciclosporin, and the ciclosporin AUC was raised by 21% by lercanidipine.⁵⁰

(g) Nicardipine

Nicardipine 20 mg three times daily raised the ciclosporin blood levels in 9 patients by 110% (from 226 to 430 nanograms/mL, range 24 to 341%). Their serum creatinine concentrations rose from 136 to 147 micromol/L.⁵¹

Other studies have found increases in serum ciclosporin levels, in some cases as much as two to threefold, when nicardipine was given.^{52–58}

(h) Nifedipine

Five of 9 patients who had an interaction with nicardipine (see above) had no interaction when they were given nifedipine.⁵¹ No changes in ciclosporin levels were seen in other studies,^{36,59–63} but raised^{17,20} and reduced levels⁶⁴ have been reported in others. Two studies found that nifedipine appeared to protect patients against the nephrotoxicity of ciclosporin.^{65,66} However, there is some evidence that the adverse effects of nifedipine such as flushing, rash⁶⁷ and gingival overgrowth may be increased.^{68–71} However, another study in 121 renal transplant patients found the prevalence of gingival overgrowth in patients taking ciclosporin was increased (but not to a statistically significant extent) by the concurrent use of calcium-channel blockers (not specified).⁷²

(i) Nisoldipine

A 46-year-old man taking azathioprine, prednisolone and ciclosporin after a kidney transplant 18 months previously was given nisoldipine 5 mg twice daily. During the following month his ciclosporin levels rose from a range of 100 to 150 micrograms/L up to 200 micrograms/L and an increase in serum creatinine levels occurred. His ciclosporin dose was gradually reduced from 325 to 250 mg daily, and his ciclosporin and creatinine levels returned to the acceptable range.⁷³

(j) Nitrendipine

Nitrendipine 20 mg daily for 3 weeks had no significant effect on the ciclosporin blood levels in 16 kidney transplant patients.⁷⁴

(k) Verapamil

Twenty-two kidney transplant patients given ciclosporin and verapamil had ciclosporin blood levels that were 50 to 70% higher than in 18 other patients not given verapamil, despite similar ciclosporin doses in both groups. Serum creatinine levels were lower in those taking verapamil. Moreover, only 3 of the 22 had rejection episodes within 4 weeks compared with 10 out of 18 not given verapamil.⁷⁵

Other studies have found that verapamil 120 to 320 mg daily can increase, double or even triple ciclosporin blood levels in individual patients with kidney or heart transplants.^{24,40,62,64,76–80} Combined use does not apparently increase the severity or prevalence of gingival overgrowth caused by ciclosporin.⁸¹

Mechanism

The increased ciclosporin levels are largely due to the calcium-channel blockers inhibiting ciclosporin metabolism by the cytochrome P450 isoenzyme CYP3A4 in the liver. Note that, of the calcium-channel blockers, diltiazem and verapamil are the strongest CYP3A4 inhibitors (see 'Calcium-channel blockers', (p.860)). Diltiazem also appears to reduce ischaemia-induced renal tubular necrosis.⁸² Other calcium-channel blockers also seem to have a kidney-protective effect. The raised felodipine levels are possibly due to competitive inhibition by ciclosporin of intestinal and liver metabolism, or changes in P-glycoprotein activity.

Importance and management

The interactions of ciclosporin with diltiazem, nicardipine and verapamil are established and relatively well documented. Concurrent use need not be avoided, but ciclosporin levels should be well monitored and dosage reductions made as necessary. Even though ciclosporin blood levels are increased, these calcium-channel blockers appear to have a kidney-protective effect. One study⁸³ noted that, although calcium-channel blockers increase ciclosporin blood levels, this is of no harm to the patient, since no changes in renal function were observed. With diltiazem and verapamil the ciclosporin dosage can apparently be reduced by about 25 to 50% and possibly more with nicardipine. One case suggests that this is also true with nisoldipine. Several studies suggest that substantial cost savings can be made by combining either diltiazem^{13,84,85} or verapamil²⁴ with ciclosporin. Take care not to substitute one diltiazem product for another after the patient has been stabilised because there is evidence that their bioequivalence differences may alter the extent of the interaction.^{27,86} Concurrent use with lercanidipine is contraindicated by the manufacturers.⁵⁰

The situation with nifedipine is not totally clear (no effect or decreases or increases) but it appears to have a kidney-protective effect⁶³ as does felodipine. The manufacturers of ciclosporin recommend avoiding nifedipine in patients who develop gingival overgrowth.⁸⁷

The situation with amlodipine is also uncertain, but isradipine, lacidipine and nitrendipine appear to be non-interacting alternatives. Many of the calcium channel blockers have a kidney-protective effect.

Ciclosporin + Chlorambucil

An isolated report describes a reduction in ciclosporin levels in a patient given chlorambucil.

Clinical evidence, mechanism, importance and management

A woman with B-chronic lymphocytic leukaemia and autoimmune haemolytic anaemia controlled with ciclosporin started taking chlorambucil 5 mg daily because of disease progression. When she reached a total cumulative dose of chlorambucil of 200 mg she suddenly relapsed, and her serum ciclosporin levels were found to have dropped to 60 nanograms/mL from a range of 200 to 400 nanograms/mL. The ciclosporin levels remained low despite a doubling of the ciclosporin dosage and withdrawal of the chlorambucil. Only after one month did the anaemia respond and the ciclosporin levels rise again.¹

This appears to be an isolated report so the general significance of this interaction is unclear.

Ciclosporin + Chloroquine or Hydroxychloroquine

Three patients had rapid rises in serum ciclosporin levels, with evidence of nephrotoxicity in two of them, when they were given chloroquine. Some loss of renal function has even been seen with low doses of ciclosporin used with chloroquine for rheumatoid arthritis. Hydroxychloroquine is expected to interact similarly

Clinical evidence

A kidney transplant patient taking ciclosporin, azathioprine and prednisolone had a threefold rise in ciclosporin blood levels, from 148 to 420 nanograms/mL, accompanied by a rise in serum creatinine levels within 48 hours of starting chloroquine 900 mg daily for suspected malarial fever. On days 2 and 3 the chloroquine dosage was reduced to 300 mg daily. The ciclosporin and creatinine returned to their former levels 7 days

after the chloroquine was stopped.¹

When another kidney transplant patient taking ciclosporin, azathioprine and prednisolone was given chloroquine 100 mg daily for 6 days, his ciclosporin serum levels rose from 105 to 470 nanograms/mL and his serum creatinine levels rose from 200 to 234 micromol/L, accompanied by a rise in blood pressure from 130/80 to 160/100 mmHg. These changes reversed when the chloroquine was stopped, and occurred again when chloroquine was restarted.² The ciclosporin serum levels of another patient were doubled by chloroquine 100 mg daily.³

A randomised, controlled study in 88 patients with recent onset rheumatoid arthritis found that the addition of ciclosporin (1.25 or 2.5 mg/kg daily) to chloroquine 100 mg daily was moderately effective, but changes in serum creatinine levels occurred. In the presence of chloroquine the creatinine was not significantly altered by placebo or ciclosporin 1.25 mg/kg, but was raised by 10 micromol/L by ciclosporin 2.5 mg/kg, indicating that some renal effects can occur.⁴

Mechanism

Not understood. Both chloroquine and ciclosporin can impair renal function.⁴

Importance and management

Information is limited but it would be prudent to monitor the effects of giving chloroquine to any patient taking ciclosporin, being alert for any changes in renal function, even with low doses of both drugs, and additionally looking for increases in serum ciclosporin levels when using high ciclosporin doses. The authors of the study do not recommend further studies of the combination in rheumatoid arthritis.⁴ There do not appear to be any published case reports or studies of an interaction with **hydroxychloroquine**, but the manufacturers note that it has a similar metabolic profile to chloroquine,⁵ and would therefore be expected to interact similarly. The same precautions would therefore seem appropriate if hydroxychloroquine is given with ciclosporin.

Ciclosporin + Clodronate

Clodronate does not appear to alter ciclosporin blood levels.

Clinical evidence, mechanism, importance and management

Ten heart transplant patients taking ciclosporin, azathioprine and diltiazem were also given clodronate 800 mg daily for one week. No statistically significant differences were seen in their ciclosporin blood levels or AUCs while they were taking clodronate. Three of them were also taking simvastatin, two were taking ranitidine and one was taking propafenone, furosemide and cyclophosphamide. There would seem to be no reason for avoiding concurrent use, but the authors of the report suggest that longer-term use of clodronate should be well monitored.¹ There seems to be no information about other bisphosphonates.

1. Baraldo M, Furlanut M, Puricelli C. No effect of clodronate on cyclosporin A blood levels in heart transplant patients simultaneously treated with diltiazem and azathioprine. *Ther Drug Monit* (1994) 16, 435.

Ciclosporin + Clonidine

A child taking ciclosporin had a marked rise in his ciclosporin blood levels when clonidine was also given.

Clinical evidence, mechanism, importance and management

A 3-year-old kidney transplant patient taking ciclosporin, azathioprine and prednisone was given a combination of propranolol, hydralazine,

furosemide and nifedipine postoperatively in an attempt to control his blood pressure. Minoxidil was added, but was considered unacceptable because of adverse cosmetic effects. When it was replaced with clonidine, the ciclosporin levels increased about threefold to 927 nanograms/mL, despite a dose reduction. Ciclosporin levels returned to the patient's normal range of 150 to 300 nanograms/mL when the clonidine was withdrawn, and blood pressure was controlled by the addition of an ACE inhibitor. It is possible that clonidine inhibited the metabolism of ciclosporin by cytochrome P450.¹

As this appears to be the only report of an interaction, there is insufficient evidence to recommend routinely increasing the monitoring of ciclosporin levels in every patient taking these drugs. However, the possibility of an interaction should still be considered if both drugs are given.

1. Gilbert RD, Kahn D, Cassidy M. Interaction between clonidine and cyclosporine. *A. Nephron* (1995) 71, 105.

Ciclosporin + Colchicine

A number of cases of ciclosporin toxicity, multiple organ failure and serious muscle disorders (myopathy, rhabdomyolysis) have been seen when colchicine and ciclosporin were given concurrently.

Clinical evidence and mechanism

A patient with a kidney transplant had a transient rise (lasting 2 to 3 days) in serum creatinine and ciclosporin blood levels, from 100 to 200 nanograms/mL up to 1519 nanograms/mL one day after receiving a total of 4 mg of colchicine.¹ Another kidney transplant patient taking ciclosporin, azathioprine and prednisone developed colchicine neuromyopathy (possibly rhabdomyolysis), ciclosporin nephrotoxicity and liver function abnormalities when given colchicine.² Acute myopathy (muscle weakness, myalgia) or rhabdomyolysis occurred in a further 11 patients who took ciclosporin and colchicine.³⁻⁹ There is also a report of colchicine-induced myopathy and hepatonephropathy in a heart transplant patient who took both ciclosporin and colchicine.¹⁰ A syndrome of myopathy, gastrointestinal disturbances and mild hepatic and renal impairment has been described in 6 patients and was attributed to the use of colchicine with ciclosporin.¹⁰⁻¹² This may be due to inhibition of P-glycoprotein by ciclosporin and subsequent impairment of colchicine excretion in to the bile and urine, resulting in elevated, toxic colchicine levels.¹⁰

Importance and management

The overall picture presented by these reports is unclear. It is not known whether the colchicine toxicity is made worse by ciclosporin, or the ciclosporin toxicity is made worse by colchicine, or the reaction is a result of both effects. If concurrent use is thought to be appropriate, it should be very carefully monitored because the outcome can be serious. Rhabdomyolysis appears to be a rare complication and the manufacturer of ciclosporin advises a change of treatment if any signs and symptoms develop.⁵ Patients should be reminded to report any unexplained muscle pain, tenderness or weakness. More study is needed.

Ciclosporin + Colestyramine

Colestyramine can interact with ciclosporin in some patients but the outcome appears to be unpredictable.

Clinical evidence, mechanism, importance and management

Four transplant patients taking ciclosporin and prednisolone, given colestyramine for one week, then simultaneously with ciclosporin on the day of testing, had only a very small average increase (6%) in the AUC of ciclosporin, but one patient had a 55% increase and another a 23% decrease.¹ Another study² in 6 kidney transplant patients found that colestyramine 4 g daily caused no significant changes in ciclosporin pharmacokinetics. The ciclosporin was given at 8 am and 8 pm, with the colestyramine at noon.

It would seem prudent to separate administration of colestyramine and ciclosporin. It is usually advised that colestyramine is given 1 hour before or 4 to 6 hours after other drugs.

Ciclosporin + Corticosteroids

The concurrent use of ciclosporin and corticosteroids is very common, but some evidence suggests that ciclosporin serum levels are raised by corticosteroids. Ciclosporin can reduce the clearance of corticosteroids. Convulsions have also been described during concurrent use, and the incidence of diabetes mellitus may be increased following the use of ciclosporin with methylprednisolone. One case of osteonecrosis has been reported with topical betamethasone and ciclosporin.

Clinical evidence

(b) Betamethasone

A patient with psoriasis taking ciclosporin and applying an average of betamethasone 30 mg daily (as 15 g to 150 g of topical betamethasone 0.05% cream or ointment) developed avascular osteonecrosis of the femoral heads of both hip joints.¹

(b) Methylprednisolone

A study found that the pharmacokinetics of methylprednisolone in patients taking ciclosporin and azathioprine varied widely between individual kidney transplant patients, but the mean values were similar to those found in normal subjects.²

The plasma ciclosporin levels of 22 out of 33 patients were reported to be more than doubled by intravenous methylprednisolone and the ciclosporin dosage needed to be reduced in 6 patients.^{3,4} Other studies have found that high doses of methylprednisolone increased or more than doubled ciclosporin levels.⁵⁻⁷ However, another study found that the clearance of ciclosporin was increased by high-dose methylprednisolone, although trough ciclosporin levels were unchanged.⁸

A report describes 4 young patients (aged 10, 12, 13 and 18 years) who had undergone bone marrow transplants for severe aplastic anaemia and who developed convulsions when given high-dose methylprednisolone (5 to 20 mg/kg daily) and ciclosporin.⁹ Convulsions also occurred in a 25-year-old woman given ciclosporin with high-dose methylprednisolone.¹⁰

A study of 314 kidney transplant patients during the period 1979 to 1987 found that the incidence of diabetes mellitus in those given ciclosporin and methylprednisolone was twice that of other patients given azathioprine and methylprednisolone. The diabetes developed within less than 2 months.¹¹

(c) Prednisolone or Prednisone

A pharmacokinetic study in 40 patients found that the clearance of prednisolone was reduced by about 30% in those taking ciclosporin when compared with those taking azathioprine.¹²

Another study in patients with kidney transplants by the same group of workers reported a 25% reduction in the clearance of prednisolone in the presence of ciclosporin.¹³ Other studies^{3,14,15} confirm that ciclosporin reduces the clearance of prednisolone by about one-third, and as a result some patients develop signs of steroid toxicity (cushingoid symptoms such as steroid-induced diabetes, osteonecrosis of the hip joints).³ These studies have all been questioned by the authors of another study, which found that the metabolism of prednisolone was not affected by ciclosporin.¹⁶

A comparative study over a year, in two groups of kidney transplant patients taking ciclosporin and azathioprine, one group with and the other without prednisone, found that those taking prednisone had lower trough ciclosporin levels (about 10 to 20%) despite using the same or higher doses of ciclosporin.¹⁷

There is other evidence that low-dose prednisolone does not increase the immunosuppression of ciclosporin, but it can reduce ciclosporin nephrotoxicity.¹⁸

Mechanism

The evidence suggests that ciclosporin reduces the metabolism of the corticosteroids by the liver thereby raising their levels.^{14,19} Corticosteroids are known to cause osteonecrosis and ciclosporin may depress bone resorption as well as bone remodelling.¹

Importance and management

None of these adverse interactions is well established, and the picture is confusing. Concurrent use is common and advantageous but be alert for any evidence of increased ciclosporin and corticosteroid effects. It is not clear whether high-dose corticosteroids cause a rise in serum ciclosporin levels or not. Ciclosporin levels measured by RIA (radioimmunoassay) should be interpreted with caution in patients taking high-dose corticosteroids as the levels of ciclosporin metabolites, which can interfere with the test, may be altered.²⁰ The authors of one report point out that this interaction could possibly lead to a misinterpretation of clinical data as a rise in serum creatinine levels in patients with kidney transplants is assumed to be due to rejection, unless proven otherwise. If a corticosteroid is then given, this could lead to increased ciclosporin levels, which might be interpreted as ciclosporin nephrotoxicity.⁴ The contribution of ciclosporin and *topical* corticosteroid to the development of osteonecrosis in the isolated case report is not known. More study is needed.

Ciclosporin + Coumarins

The ciclosporin levels of a patient were reduced when warfarin was given. When the ciclosporin dosage was raised an increase in the warfarin dosage was needed. The INR of another patient taking warfarin was reduced when she was given ciclosporin. A further report describes a rise in serum ciclosporin levels when an unnamed anticoagulant was given. Other reports describe increased or decreased acenocoumarol effects and decreased ciclosporin levels in two patients.

Clinical evidence*(a) Acenocoumarol*

The anticoagulant dosage of a patient taking acenocoumarol needed to be reduced by about half to maintain a therapeutic INR when he was given ciclosporin after a kidney transplant. The required dose of ciclosporin slightly decreased.¹ Conversely, a patient taking acenocoumarol 32 mg per week was given ciclosporin for nephrotic syndrome. After 10 days his acenocoumarol dose needed to be increased to maintain a therapeutic INR, and the ciclosporin level was considered too low and so the dose was increased from 100 to 150 mg daily. However, a further 10 days later (after the increase in acenocoumarol dose) the ciclosporin level was even lower. Eventually the patient achieved therapeutic levels in the presence of acenocoumarol with a ciclosporin dose of 200 mg daily.²

(b) Warfarin

A man with erythrocyte aplasia effectively treated with ciclosporin for 18 months, relapsed within a week of starting warfarin. His ciclosporin levels had fallen from a range of 300 to 350 nanograms/mL down to 170 nanograms/mL. He responded well when the ciclosporin dosage was increased from 3 to 7 mg/kg daily, but his prothrombin activity rose from 17% of control to 64% and he needed an increase in the warfarin dosage to achieve satisfactory anticoagulation.³ The patient was also taking 'phenobarbital', (p.1021). A woman with angioimmunoblastic T-cell lymphoma receiving chemotherapy developed a deep vein thrombosis and was therefore treated firstly with heparin and later warfarin. When ciclosporin 300 mg daily was added, her INR decreased by about 40% and she needed a progressive warfarin dosage increase from 18.75 to 27.5 mg per week.⁴ Another report briefly says that serum ciclosporin levels rose in a patient given a warfarin derivative.⁵

Mechanism

Acenocoumarol, warfarin and ciclosporin are all metabolised, at least in part, by the cytochrome P450 isoenzyme CYP3A4. It is possible that some competition occurs for metabolism, leading to increased or decreased effects of the anticoagulants and decreased ciclosporin levels.

Importance and management

Information about the interactions of the oral anticoagulants and ciclosporin seems to be limited to these reports. They simply serve to emphasise the need to monitor concurrent use because the outcome is clearly uncertain.

Ciclosporin + Danazol

Marked increases in serum ciclosporin levels have been seen in seven patients taking danazol.

Clinical evidence

A 15-year-old girl, one-year post kidney transplant, taking ciclosporin and prednisone, had a marked rise in serum ciclosporin levels over about 2 weeks (from a range of 250 to 325 nanomol/mL up to 700 to 850 nanomol/mL) when she was given danazol 200 mg twice daily, even though the ciclosporin dosage was reduced from 350 to 250 mg daily.¹

Similar rises in ciclosporin levels, from about 400 to 600 nanograms/mL, and from 150 to about 450 nanograms/mL, were seen in another patient on two occasions over about a 6-week period when danazol 400 mg daily and later 600 mg daily was given.² A 12-year-old boy needed a reduction in his ciclosporin dosage from 10 to 2 mg/kg daily when danazol 400 mg twice daily was added.³ A marked rise in ciclosporin blood levels has been described in 2 other patients when given danazol 200 mg three or four times daily.^{4,5}

A pharmacokinetic study in one kidney transplant patient found that danazol 200 mg three times daily for 16 days reduced the ciclosporin clearance by 50%, prolonged its half-life by 66%, and raised its AUC by 65%.⁶

A patient with aplastic anaemia taking ciclosporin was given danazol 200 mg daily for pancytopenia and endometriosis. Within 4 days the patient had epigastric pain and elevated serum ciclosporin and creatinine levels. Danazol was stopped and the ciclosporin dose was halved. Two weeks later abrupt severe hepatic injury occurred and the patient died of hepatic failure, although this was thought to be due to danazol toxicity rather than the interaction.⁷

Mechanism

Danazol is a known inhibitor of the cytochrome P450 isoenzyme system.^{3,7} Ciclosporin is predominantly metabolised by the cytochrome P450 isoenzyme CYP3A4. It therefore seems likely that danazol raises ciclosporin levels by inhibiting its metabolism.

Importance and management

Although the information seems to be limited to these few reports the interaction is established. The ciclosporin levels of any patient who is given danazol should be carefully monitored, and dosage adjustments made as necessary.

Ciclosporin + Disopyramide

An isolated report describes the development of nephrotoxicity, which was attributed to an interaction between ciclosporin and disopyramide.

Clinical evidence, mechanism, importance and management

Ten months after receiving a kidney transplant a 40-year-old woman developed premature ventricular beats and was therefore given oxprenolol in

addition to her usual ciclosporin and methylprednisolone. After 2 months she had shown no improvement so she started taking disopyramide 100 mg three times daily. Over the next week her serum creatinine rose from 88 to 159 micromol/L, at which point the disopyramide was stopped. Her renal function returned to normal over the next week. As she had previously been stable taking ciclosporin, and, as nephrotoxicity had not been reported with disopyramide, an interaction was suspected.¹

This interaction is unconfirmed and of uncertain clinical significance. There is insufficient evidence to recommend increased monitoring, but be aware of the potential for an interaction in the case of an unexpected response to treatment.

- Nanni G, Magalini SC, Serino F, Castagneto M. Effect of disopyramide in a cyclosporine-treated patient. *Transplantation* (1988) 45, 257.

Ciclosporin + Diuretics

Isolated cases of nephrotoxicity have been described when patients taking ciclosporin were given either amiloride with hydrochlorothiazide, metolazone, or mannitol. Furosemide can possibly protect the kidney against ciclosporin damage. The concurrent use of ciclosporin with thiazides, but not loop diuretics, may increase serum magnesium levels. The concurrent use of ciclosporin with potassium-sparing diuretics may cause hyperkalaemia.

Clinical evidence, mechanism, importance and management

A 39-year-old man taking ciclosporin, whose second kidney transplant functioned subnormally, and who required treatment for hypertension with atenolol and minoxidil, developed ankle oedema, which was resistant to furosemide, despite doses of up to 750 mg daily. When metolazone 2.5 mg daily was added for 2 weeks his serum creatinine levels more than doubled, from 193 to 449 micromol/L. When metolazone was stopped the creatinine levels fell again. Ciclosporin serum levels were unchanged and neither graft rejection nor hypovolaemia occurred.¹

The kidney transplant of another patient taking ciclosporin almost ceased to function when mannitol was given, and a biopsy indicated severe ciclosporin nephrotoxicity. Transplant function recovered when the mannitol was stopped.² The same reaction was demonstrated in rats.²

A woman taking ciclosporin had a rise in serum creatinine levels from 121 to 171 micromol/L three weeks after she started to take Moduretic (amiloride with [hydro]chlorothiazide). Trough serum ciclosporin levels were unchanged.³

Although animal studies suggested that furosemide might increase the nephrotoxicity of ciclosporin,⁴ more recent human studies suggest that it may have a protective effect.⁵

Although ciclosporin and loop diuretics are both known to cause magnesium wasting, a review of magnesium serum levels, magnesium replacement doses and diuretic use in 50 heart transplant recipients indicated that magnesium requirements were not altered by the use of ciclosporin with loop diuretics. However, the use of thiazides with ciclosporin resulted in increases in serum magnesium and decreases in magnesium replacement.⁶

Ciclosporin alone can cause hyperkalaemia, especially if renal function is impaired. Because of this, the US manufacturers suggest that ciclosporin should not be used with potassium-sparing diuretics,⁷ whereas the UK manufacturers suggest that caution is required with combined use, with close control of potassium levels.⁸

The general importance of all these adverse interactions is not clear, but good monitoring is obviously needed if diuretics are given with ciclosporin.

Ciclosporin + Fibrates

The use of bezafibrate with ciclosporin has resulted in significantly increased serum creatinine and reductions, no change, or increased serum ciclosporin levels. The use of fenofibrate has also been associated with reduced renal function and possibly reduced serum ciclosporin levels. Two studies found no pharmacokinetic interaction between ciclosporin and gemfibrozil while a third found gemfibrozil caused a significant reduction in ciclosporin levels.

Clinical evidence, mechanism, importance and management

(a) Bezafibrate

A kidney transplant patient had a rise in his previously stable ciclosporin blood levels from a range of 150 to 200 nanograms/mL to about 340 nanograms/mL over a 6-week period after bezafibrate 200 mg twice daily was given. The rise was accompanied by increases in blood urea nitrogen and creatinine levels. Renal biopsy found evidence of possible ciclosporin toxicity, and rejection. The patient recovered when the bezafibrate was stopped.¹

Two other transplant patients (one kidney and the other heart) had a reversible deterioration in renal function when they were given bezafibrate. This was severe in one, and the other had the effect on two occasions. Neither had any changes in ciclosporin blood levels.^{2,3} Two other similar cases have been reported, one of whom was subsequently given gemfibrozil without problems.⁴

Another study over 3 months in 40 heart transplant patients taking ciclosporin found that bezafibrate was associated with a rise in serum creatinine levels, although none of the patients had to be withdrawn from the study because of this. The ciclosporin level tended to be lower (198 nanograms/mL at baseline, compared with 144 nanograms/mL after 3 months).⁵

Neither the incidence nor the reasons for these reactions are known, but because the outcome is uncertain and potentially serious, keep a close check on the effects of adding bezafibrate to ciclosporin in any patient. The manufacturers of bezafibrate suggest close monitoring of renal function.⁶

(b) Fenofibrate

Fenofibrate 200 mg once daily effectively reduced the blood cholesterol levels of 10 heart transplant patients from 7.7 to 6.5 mmol/L without significantly altering ciclosporin blood levels over a 2-week period. The only possible adverse effect was an increase in creatinine levels from 145 to 157 mmol/L, suggesting some possible nephrotoxicity. No other clinically adverse effects were seen. However, the authors of this study suggested that longer follow-up studies were needed to confirm the safety of using these drugs together.⁷ They followed this up with a 1-year study⁸ in 43 heart transplant patients, only 14 of whom completed the study (67% withdrew for various reasons). Fourteen patients had a rise in blood creatinine levels and a decrease in renal function, which improved when the fenofibrate was stopped. There was also some evidence of a reduction in ciclosporin levels in 5 patients, who developed rejection, and 14 patients, who had to stop fenofibrate because ciclosporin levels could not be maintained without adversely affecting renal function.

The evidence from these reports emphasises the importance of monitoring the long-term concurrent use of these two drugs because there are clearly some potential hazards.

(c) Gemfibrozil

Forty kidney transplant patients taking ciclosporin had a reduction in their hypertriglyceridaemia when gemfibrozil was added, and their ciclosporin blood levels and serum creatinine remained unaltered.⁹ Another study in 12 patients similarly found that gemfibrozil did not affect ciclosporin blood levels.¹⁰

However, in contrast to these findings, another study in 7 kidney transplant patients with hyperlipidaemia found that gemfibrozil 450 mg once or twice daily was associated with a decline in trough ciclosporin levels. Levels declined from 93 to 76 nanograms/mL after 6 weeks of treatment and after dose increases in 3 patients the level at 3 months was

88 nanograms/mL. In 8 similar patients not given gemfibrozil, and with the same ciclosporin dose throughout, trough levels changed from 99 to 98 nanograms/mL at 6 weeks and to 123 nanograms/mL at 3 months. In 2 patients there was a significant increase in serum creatinine, and biopsy revealed chronic rejection in one and ciclosporin toxicity in the other. The study was stopped at 6 months because a drug interaction was suspected. The mechanism is not known, but changes in distribution of lipoproteins during gemfibrozil treatment may cause changes in the free fraction of ciclosporin. Ciclosporin absorption may also be reduced. Close monitoring is recommended during concomitant use.¹¹

Ciclosporin + Food or Drinks

Food and milk can increase the bioavailability of ciclosporin. Lipid admixtures for parenteral nutrition appear not to affect ciclosporin pharmacokinetics.

Clinical evidence

(a) Food or Milk

Patients taking ciclosporin with milk had a 39% higher AUC after food and 23% higher AUC when fasting, compared with other patients taking ciclosporin with orange juice (which is not known to interact).¹ Food more than doubled the AUC of ciclosporin (bioavailability increased from about 21% to 53%) and almost tripled its maximum serum levels, from 783 to 2062 nanograms/mL.² When 18 patients with kidney transplants were given ciclosporin mixed with 240 mL of chocolate milk and taken with a standard hospital breakfast, their peak ciclosporin levels rose by 31%, from 1120 to 1465 nanograms/mL, trough blood levels rose by 17%, from 228 to 267 nanograms/mL, and the AUC rose by 45%. Very considerable individual variations occurred.³

A study in 10 patients undergoing bone-marrow transplantation and given isocaloric and isonitrogenous parenteral nutrition with or without lipids found that ciclosporin pharmacokinetics are not affected by **lipid-enriched admixtures**.⁴

(b) Soft drinks

A lung transplant patient taking ciclosporin had large variations in his ciclosporin levels, which ranged between 319 and 761 nanograms/mL, on discharge from hospital, which were unexplained by changes in his current medication or ciclosporin dose changes. It was found that on the days when the ciclosporin levels were increased, the patient had drunk a citrus soft drink (*Sun Drop*) at breakfast. These fluctuations resolved when he stopped drinking the soft drink.⁵ However, a subsequent pharmacokinetic study in 12 healthy subjects found that neither *Sun Drop* nor another citrus soft drink, *Fresca*, had any significant effects on the pharmacokinetics of a single 2.5-mg/kg dose of ciclosporin. Both *Sun Drop* and *Fresca* were tested, and found to contain bergamottin 0.078 and 6.5 mg/L, respectively (note that 'grapefruit', (p.1034), contains about 5.6 mg/L). The authors note that factors that such as genetic and disease-related variability in ciclosporin metabolism as well as changes in the bergamottin content between batches of the drinks may account for the contrasting results.⁶

Mechanism

The authors of the report of an interaction with a citrus soda drink confirmed with the manufacturers that it contained furanocoumarins such as bergamottin which are thought to inhibit CYP3A4,^{5,6} the major isoenzyme involved in the metabolism of ciclosporin.

Importance and management

The food and milk interactions are established, clinically important, and result in an increase in the bioavailability of ciclosporin. The situation should therefore be monitored if any changes are made to the diet of patients taking ciclosporin. Patients should be warned because increased ciclosporin levels are associated with increased nephrotoxicity. Lipid admixtures in parenteral nutrition do not appear to affect ciclosporin pharmacokinetics and it is speculated that they may protect against ciclosporin-induced nephrotoxicity. Close supervision and monitoring is required. There is insufficient evidence to allow extrapolation of the results to bone-marrow transplant recipients with risk factors such as dyslipidaemia, liver, or renal impairment.⁴

The isolated report⁵ of an interaction between a citrus soft drink (containing furanocoumarins) and ciclosporin was not confirmed by a subsequent single-dose pharmacokinetic study in healthy subjects⁶ and therefore its significance is unclear. The case does highlight the influence diet can have on ciclosporin and it should be borne in mind should any unexpected changes in ciclosporin levels occur.

Ciclosporin + Foscarnet

Acute but reversible renal failure occurred in two transplant patients when foscarnet was given with ciclosporin.

Clinical evidence

A man with a kidney transplant taking corticosteroids and ciclosporin developed a cytomegalovirus infection that was treated with foscarnet 85 mg/kg daily. Despite efforts to minimise the nephrotoxic effects of the foscarnet (hydration with 2.5 litres of isotonic saline daily and nifedipine 80 mg the day before and during treatment) the patient developed non-oliguric worsening of his renal function after 8 days. Nine days after stopping the foscarnet, the former renal function was restored.¹

A liver transplant patient taking steroids, azathioprine and ciclosporin was given foscarnet 180 mg/kg daily for a hepatitis B infection. Acute renal failure occurred 5 days after the foscarnet was started, and renal function was restored 10 days after the foscarnet was stopped. The ciclosporin blood levels were therapeutic and not significantly altered at any time in either patient.¹

Mechanism

Not understood. It seems that the nephrotoxic effects of the ciclosporin and foscarnet may be additive.

Importance and management

Direct information appears to be limited to this report, but it is consistent with the known potential toxicity of both drugs. Acute renal failure can clearly occur despite the preventative measures taken. The authors of this

report¹ say that monitoring of renal function is mandatory when both drugs are given.

1. Morales JM, Muñoz MA, Fernández Zatarain G, García Cantón C, García Rubiales MA, Andrés A, Aguado JM, Pinto IG. Reversible acute renal failure caused by the combined use of foscarnet and cyclosporin in organ transplanted patients. *Nephrol Dial Transplant* (1995) 10, 882–3.

Ciclosporin + Ganciclovir

Four patients given ciclosporin and ganciclovir developed an acute but reversible eye movement disorder.

Clinical evidence, mechanism, importance and management

In a USA hospital, 582 allogeneic bone marrow transplants were carried out between 1988 and 1994. All the patients were given ciclosporin and about 45% also had ganciclovir at some time during the first 3 months after the transplant. Four patients (0.7%) developed an acute eye movement disorder (unilateral or bilateral sixth nerve palsies) within 4 to 34 days of starting ganciclovir. Three of the 4 patients also had bilateral ptosis. The problem cleared 24 to 48 hours after withdrawal of both drugs from 3 patients, and the withdrawal of just ciclosporin from the other patient. Objective eye movement abnormality with diplopia recurred in one patient when both drugs were restarted, but not when ciclosporin alone was given.¹

The reason for this toxic reaction is not known but the authors of the report postulate a transient brain stem or neuromuscular dysfunction caused by both drugs.¹ It is an uncommon reaction and reversible, so that concurrent use need not be avoided but both drugs should be stopped if it happens. The report cited here seems to be the only report of this interaction.

1. Openshaw H, Slatkin NE, Smith E. Eye movement disorders in bone marrow transplant patients on cyclosporin and ganciclovir. *Bone Marrow Transplant* (1997) 19, 503–5.

Ciclosporin + Grapefruit and other fruit juices

Grapefruit juice and pomelo juice, but not cranberry or orange juice, can increase the bioavailability of ciclosporin.

Clinical evidence

A considerable number of single and multiple dose studies in healthy subjects, transplant recipients, and other patients with haematological diseases have shown that if oral ciclosporin is taken with 150 to 250 mL (5 to 8 ozs) of **grapefruit juice**, the trough and peak blood levels and the bioavailability of the ciclosporin may be significantly increased. The increases reported vary considerably. Increases in trough blood levels range from 23 to 85%,^{1–8} increases in peak blood levels range from 0 to 69%,^{4–6,9–13} and increases in AUCs range from 0 to 72%.^{2–6,9,10,14,15}

In one study the AUC of the microemulsion formulation of ciclosporin was increased by 38% (range 12 to 194%) by **grapefruit juice** but the maximum levels were unchanged.¹⁶ A further study with the microemulsion formulation found that both the peak levels and AUC were increased by **grapefruit juice**, but while increases of 39% and 60%, respectively, were observed in African-American patients, smaller increases of 8% and 44% were observed in Caucasian patients.¹⁷

A study in 6 paediatric kidney transplant patients found that giving ciclosporin oral solution with **grapefruit juice** produced a significant increase (109%) in the 12-hour trough level although the AUC was not significantly changed. When ciclosporin was given as a microemulsion, **grapefruit juice** did not significantly affect the pharmacokinetics of ciclosporin.¹⁸ **Grapefruit juice** has no effect on ciclosporin levels when the ciclosporin is given intravenously.¹⁹

Ciclosporin levels are unaffected by **orange juice**.^{2,8}

A study in 12 healthy subjects given a single 200-mg dose of ciclosporin found that **pomelo juice** significantly increased the AUC and maximum level of ciclosporin by about 19% and 12%, respectively, whereas **cranberry juice** did not have any significant effects on ciclosporin pharmacokinetics.²⁰

Mechanism

It is suggested that grapefruit juice inhibits the activity of the cytochrome P450 isoenzyme CYP3A in the gut wall and liver. Ciclosporin is primarily

metabolised by CYP3A4 and so its levels rise. Pomelo is related to grapefruit and therefore potentially interacts by the same mechanism.

Importance and management

The interaction between grapefruit juice and ciclosporin is established and clinically important, and results in increases in the bioavailability of ciclosporin. Patients taking ciclosporin should be warned about drinking grapefruit juice because increased ciclosporin levels are associated with increased nephrotoxicity. In general, grapefruit juice should be avoided.

It has been suggested² that the interaction between grapefruit juice and ciclosporin could be exploited to save money. One group of authors has suggested that grapefruit juice is roughly as effective as diltiazem in raising ciclosporin blood levels, and has the advantage of being inexpensive, nutritious and lacking the systemic effects of diltiazem and ketoconazole which have been used in this way, see 'Ciclosporin + Calcium-channel blockers', p.1027 and 'Ciclosporin + Azoles', p.1023. However, it has also been pointed out that it may be risky to try to exploit this interaction in this way because the increases appear to be so variable and difficult, if not impossible, to control. This is because batches of grapefruit juice vary so much, and also considerable patient variation occurs with this interaction.²¹⁻²³ The US manufacturers suggest that patients taking ciclosporin should avoid whole grapefruit, as well as the juice.²⁴

The significance of the single report of the small increases in ciclosporin bioavailability and blood levels seen with pomelo juice in healthy subjects is unclear.²⁰ However, a similar interaction has been seen in a kidney transplant patient taking tacrolimus, see 'Tacrolimus + Grapefruit and other fruit juices', p.1079. There is insufficient evidence to recommend avoiding pomelo juice or pomelo fruit when taking ciclosporin but bear this potential interaction in mind. More study is needed.

Ciclosporin + Griseofulvin

An isolated report describes decreased ciclosporin levels in a patient given griseofulvin.

Clinical evidence, mechanism, importance and management

A 57-year-old-man, who had been stable for almost one year taking ciclosporin, azathioprine and prednisolone following a kidney transplant, was given griseofulvin 500 mg daily for onychomycosis. Two weeks later his trough ciclosporin levels had dropped from 90 to 50 nanograms/mL and remained low, despite an increase in his ciclosporin dose from 2.8 to 4.8 mg/kg. When the griseofulvin was later stopped, his ciclosporin levels rose to over 200 nanograms/mL and his dose of ciclosporin was readjusted.¹

This appears to be the only report of an interaction with griseofulvin, and its general significance is unclear.

- Abu-Romeh SH, Rashed A. Ciclosporin A and griseofulvin: another drug interaction. *Nephron* (1991) 58, 237.

Ciclosporin + H₂-receptor antagonists

Reports are inconsistent. Cimetidine and famotidine have been reported to increase ciclosporin levels, whereas in other studies cimetidine, famotidine and ranitidine have been reported to not affect ciclosporin levels. Both cimetidine and ranitidine have been reported to cause an increase in serum creatinine levels, in some but not all studies, but this may possibly not be a reliable indicator of increased nephrotoxicity. Isolated cases of thrombocytopenia and hepatotoxicity have been reported with ranitidine and ciclosporin.

Clinical evidence

(a) Cimetidine

A study in 5 liver transplant patients taking ciclosporin found that cimetidine 800 mg given every 12 hours for 3 doses raised peak ciclosporin levels, but no changes in trough levels were seen after 4 hours. Similarly, no change in trough ciclosporin levels was seen in 2 patients who received cimetidine 400 mg four times daily for 4 weeks, and the conclusion was reached that it was safe to use cimetidine over at least a 4-week period.¹ In a retrospective study it was reported that heart transplant patients taking cimetidine had a lower dosage/level quotient leading to higher ciclosporin blood levels for the same dosage.² Similarly, a study in 6 healthy subjects found a 30% rise in the AUC of ciclosporin 300 mg given after a 3-day course of cimetidine 400 mg daily.³ Raised ciclosporin blood levels have also been seen in a patient given cimetidine and metronidazole⁴ (see 'Ciclosporin + Antibacterials; Metronidazole', p.1017).

Cimetidine or ranitidine increased the mean serum creatinine levels in 7 kidney transplant patients taking ciclosporin by 41%, from 202 to 285 micromol/L. All of the patients had a rise, whereas only 2 out of 5 other patients with heart transplants had a rise in their serum creatinine levels when given either cimetidine or ranitidine, nevertheless the mean rise was 37%, from 152 to 209 micromol/L. Ciclosporin levels were not altered.⁵ A transient increase in creatinine serum levels at days 2 and 5 was seen in another study of 7 kidney transplant patients given cimetidine 400 mg daily for 7 days. Again ciclosporin levels were not altered.⁶ Similarly, cimetidine did not alter ciclosporin blood levels in 2 studies in healthy subjects.^{7,8}

(b) Famotidine

Famotidine is reported not to affect ciclosporin blood levels.⁹⁻¹¹ However, higher ciclosporin blood levels were found in a study of heart transplant patients given famotidine.² No significant changes in the pharmacokinetics of ciclosporin was seen in a single-dose study in 8 healthy subjects⁸ and no changes in serum creatinine or BUN levels were seen in 7 kidney transplant patients.¹¹

(c) *Ranitidine*

One report (see *Cimetidine* above), where the effects of cimetidine and ranitidine were examined together, suggests that ranitidine raises creatinine levels in patients taking ciclosporin, without affecting ciclosporin levels.⁵ Similarly, several other reports say that ranitidine does not alter ciclosporin blood levels.¹²⁻¹⁵ One also notes that ranitidine does not alter creatinine levels and inulin clearance.¹³

A report describes thrombocytopenia in a man taking ciclosporin after a kidney transplant who was given ranitidine.¹⁶ Another patient experienced hepatotoxicity while taking ciclosporin with ranitidine.¹⁷

Mechanism

It is not clear why these reports are inconsistent, nor how the H₂-receptor antagonists might raise ciclosporin blood levels. It has also been suggested that any rise in serum creatinine levels could simply be because these H₂-receptor antagonists compete with creatinine for secretion by the kidney tubules, and therefore rises are not an indicator of nephrotoxicity^{18,19}

Importance and management

Information about the possible interactions of ciclosporin and cimetidine, famotidine or ranitidine is inconsistent, but there appear to be very few reports of confirmed toxicity. Moreover the reported increases in serum creatinine levels seen with the H₂-receptor antagonists may not be a reflection of increased nephrotoxicity (see 'Mechanism'). Thus there is little to suggest that concurrent use should be avoided, but good initial monitoring is advisable.

Ciclosporin + Herbal medicines; Alfalfa and Black cohosh

An isolated report describes acute rejection and vasculitis with black cohosh and/or alfalfa in a renal transplant patient taking ciclosporin.

Clinical evidence, mechanism, importance and management

A stable kidney transplant patient taking ciclosporin 75 mg twice daily began to take alfalfa (*Medicago sativa*) and black cohosh (*Cimicifuga racemosa*) supplements on medical advice. Her serum creatinine rose from between about 97 to 124 micromol/L up to 168 micromol/L in 4 weeks and, to 256 micromol/L at 6 weeks with no associated change in her ciclosporin levels. Severe acute rejection with vasculitis was diagnosed and treated with corticosteroids and anti-T lymphocyte immunoglobulin. Alfalfa has been reported to cause worsening of lupus and immunostimulation and it was suggested that immunostimulation may have contributed to the acute rejection in this patient.¹ The evidence of for this interaction is limited, but as the effects were so severe in this case it would seem prudent to avoid concurrent use.

1. Light TD, Light JA. Acute renal transplant rejection possibly related to herbal medications. *Am J Transplant* (2003) 3, 1608-9.

Ciclosporin + Herbal medicines; Berberine

Berberine appears to increase the bioavailability and trough blood levels of ciclosporin.

Clinical evidence, mechanism, importance and management

A study in 6 kidney transplant patients looked at the effects of the Chinese herbal medicine berberine on the pharmacokinetics of ciclosporin. The patients were taking ciclosporin 3 mg/kg twice daily for an average of 12 days before berberine 200 mg three times daily for 12 days was added. The AUC and trough blood levels of ciclosporin were increased by 34.5% and 88.3%, respectively. The peak ciclosporin level was decreased but this was not statistically significant.¹ A clinical study by the same authors in 52 kidney transplant patients stable taking ciclosporin and given berberine 200 mg three times daily for 3 months found that the ciclosporin trough levels were increased by 24.4% in the berberine-treated group, when compared with 52 similar patients taking ciclosporin without berberine. The ciclosporin levels in 8 patients fell after berberine was stopped.¹

A single-dose study in healthy subjects found conflicting results. Six subjects given a single 6-mg/kg dose of ciclosporin daily found that berberine 300 mg twice daily, taken for 10 days before the dose of ciclosporin, had no significant effects on the pharmacokinetics of ciclosporin. However, a separate study in another 6 subjects given a single 3-mg/kg dose of ciclosporin found that a single 300 mg dose of berberine increased the AUC of ciclosporin by 19.2%.²

The mechanism for the increase in ciclosporin levels is unclear. Although the increase is not sufficiently severe to suggest that concurrent use should be avoided, it may make ciclosporin levels less stable and therefore be undesirable (see 'drug-herb interactions', (p.10)). If concurrent use is undertaken it should be well monitored.

2. Xin HW, Wu XC, Li Q, Yu AR, Zhong MY, Liu YY. The effects of berberine on the pharmacokinetics of cyclosporin A in healthy volunteers. *Methods Find Exp Clin Pharmacol* (2006) 28, 25-9.

Ciclosporin + Herbal medicines; *Geum chiloense*

A single case report describes a marked and rapid increase in the serum ciclosporin levels of a man after he drank an infusion of *Geum chiloense*.

Clinical evidence, mechanism, importance and management

A 54-year-old kidney transplant patient taking ciclosporin, prednisone, azathioprine, diltiazem and nifedipine had a sudden and very marked rise in his ciclosporin levels from his usual range of 60 to 90 [mg/dL] up to a range of 469 to 600 [mg/dL]. He had been taking ciclosporin 2 to 3 mg/kg daily for 15 months since the transplant. His serum creatinine levels were found to be 115 micromol/L. It eventually turned out that about 2 weeks earlier he had started to drink an infusion of *Geum chiloense* (or *Geum quellyon*), a herbal remedy claimed to increase virility and to treat prostatism. When the herbal remedy was stopped, his serum ciclosporin levels rapidly returned to their normal values. The reasons for this apparent interaction are not known.¹

This appears to be the only case on record but it serves, along with reports about other herbs, to emphasise that herbal remedies may not be safe just because they are 'natural'. In this instance the herbal remedy markedly increased the potential nephrotoxicity of the ciclosporin. Patients should be warned.

1. Duclos J, Goecke H. "Hierba del clavo" (*Geum chilense*) interfiere niveles de ciclosporin: potencial riesgo para trasplantados. *Rev Med Chil* (2001) 129, 789–90.

Ciclosporin + Herbal medicines; Quercetin

A study found that quercetin increased the bioavailability of ciclosporin.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects a single 300-mg dose of ciclosporin was given four times: alone, with oral quercetin 5 mg/kg, 30 minutes after oral quercetin 5 mg/kg, or after a 3-day course of quercetin 5 mg/kg twice daily. It was found that the AUC of ciclosporin was increased by 16% by the concurrent use of a single dose of quercetin, by 36% when given after single-dose quercetin, and by 46% when given after multiple-dose quercetin. These correlate with results from previous *animal* studies.¹ Quercetin is a flavonoid, found in many foods and drinks as well as supplements such as ginkgo, and it has also been found to affect the cytochrome P450 isoenzyme CYP3A4, the main isoenzyme involved in ciclosporin metabolism. Quercetin is also found in citrus fruits. Although the increase in ciclosporin levels is modest, and the interaction is not sufficiently severe to suggest that concurrent use should be avoided, it may make ciclosporin levels less stable as the quercetin content of different herbs and preparations is likely to vary. Concurrent use may therefore be undesirable. If concurrent use of ciclosporin and a quercetin-containing product is undertaken it should be well monitored.

1. Choi JS, Choi BC, Choi KE. Effect of quercetin on the pharmacokinetics of oral ciclosporine. *Am J Health-Syst Pharm* (2004) 61, 2406–9.

Ciclosporin + Herbal medicines; Red yeast rice (*Monascus purpureus*)

Red yeast rice has been reported to cause rhabdomyolysis in a kidney transplant patient taking ciclosporin.

Clinical evidence, mechanism, importance and management

A kidney transplant patient taking ciclosporin 300 mg daily developed asymptomatic rhabdomyolysis when she started to take a herbal preparation of red yeast rice (*Monascus purpureus*) containing rice fermented with red yeast, beta-sitosterol, danshen root (*Salvia mitoriza*) and garlic bulb (*Allium sativum*). Two months later, her creatine phosphokinase rose to 1050 units/L but reduced to 600 units/L 2 weeks after stopping the herbal preparation. It is thought that a component of the red yeast rice called monacolin K (identical to lovastatin) probably caused the muscle toxicity.¹ Although this appears to be an isolated case it would be expected to be generally significant as ciclosporin is well known to interact with the statins, and this interaction appeared to be mediated by a statin-like component. Concurrent use need not be avoided, but it would seem prudent to discuss the potential effects with patients and describe the symptoms of myopathy. Patients should report any unexplained muscle pain, tenderness or weakness.

1. Prasad GVR, Wong T, Meliton G, Bhaloo S. Rhabdomyolysis due to red yeast rice (*Monascus purpureus*) in a renal transplant recipient. *Transplantation* (2002) 74, 1200–1.

Ciclosporin + Herbal medicines; St John's wort (*Hypericum perforatum*)

Marked reductions in ciclosporin blood levels and transplant rejection can occur within a few weeks of starting St John's wort.

Clinical evidence

A marked drop in ciclosporin blood levels was identified in one kidney transplant patient as being due to the addition of St John's wort extract 300 mg three times daily. When the St John's wort was stopped the ciclosporin levels rose. The authors of this report identified another 35 kidney and 10 liver transplant patients whose ciclosporin levels had dropped by an average of 49% (range 30 to 64%) after starting St John's wort. Two of them had rejection episodes.^{1,2} In addition, subtherapeutic ciclosporin levels in 7 kidney transplant patients,^{3–7} one liver transplant patient,⁸ and 6 heart transplant patients^{9–11} have been attributed to self-medication with St John's wort. Acute graft rejection episodes occurred in 7 cases,^{3,5,7–9,11} and one patient subsequently developed chronic rejection, requiring a return to dialysis.⁵ Another case of subtherapeutic ciclosporin levels occurred in a kidney transplant patient during the concurrent use of a herbal tea containing St John's wort. The patient's levels remained subtherapeutic despite a ciclosporin dose increase from 150 to 250 mg daily. The levels recovered within 5 days of stopping the herbal tea and the ciclosporin dose was reduced to 175 mg daily.¹²

These case reports are supported by a small study in which 11 renal transplant patients, with stable dose requirements for ciclosporin, were given St John's wort extract (*Jarsin 300*) 600 mg daily for 14 days. Pharmacokinetic changes were noted 3 days after the St John's wort was added. By day 10 the ciclosporin dose had to be increased from an average of 2.7 to 4.2 mg/kg daily in an attempt to keep ciclosporin levels within the therapeutic range. Two weeks after the St John's wort was stopped, only 3 patients had been successfully re-stabilised on their baseline ciclosporin dose. Additionally, the pharmacokinetics of various ciclosporin metabolites were substantially altered.¹³

Another study in 10 kidney transplant patients stable taking ciclosporin found that the content of hyperforin in the St John's wort affected the extent of the interaction with ciclosporin. In patients taking St John's wort with a high hyperforin content (hyperforin 7 mg; hypericin 0.45 mg) the reduction in the AUC_{0–12} of ciclosporin was 45% greater than that in patients taking St John's wort with a low hyperforin content (hyperforin 0.1 mg; hypericin 0.45 mg). The maximum blood ciclosporin level and the trough ciclosporin level were also reduced by 36% and 45%, respectively, in the patients taking the higher hyperforin-containing St John's wort preparation, when compared with the patients taking the preparation with a lower hyperforin content. The patients taking the high-hyperforin preparation required a mean ciclosporin dose increase of 65% whereas the patients taking the low-hyperforin preparation did not require any ciclosporin dose alterations.¹⁴

Mechanism

St John's wort is a known inducer of the cytochrome P450 isoenzyme CYP3A4 by which ciclosporin is metabolised. Concurrent use therefore reduces ciclosporin levels. It has also been suggested that St John's wort affects ciclosporin reabsorption by inducing the drug transporter protein, P-glycoprotein, in the intestine.^{9,13}

Importance and management

An established and clinically important interaction. The incidence is not known, but all patients taking ciclosporin should avoid St John's wort because of the potential severity of this interaction. Transplant rejection can develop within 3 to 4 weeks. It is possible to accommodate this interaction by increasing the ciclosporin dosage¹¹ (possibly about doubled) but this raises the costs of an already expensive drug. Also, the varying content of natural products would make this hard to monitor. The advice of the CSM in the UK is that patients receiving ciclosporin should avoid or stop taking St John's wort. In the latter situation, the ciclosporin blood levels should be well monitored and the dosage adjusted as necessary.¹⁵ The study described above suggests that increased monitoring will be needed for at least 2 weeks after the St John's wort is stopped.¹³

Ciclosporin + Hormonal contraceptives and Progestogens

Hepatotoxicity has been described in two patients given ciclosporin and combined oral contraceptives. Rises in serum ciclosporin levels may also occur. Some increase in ciclosporin levels has been seen with norethisterone.

Clinical evidence

(a) Contraceptives

A woman with uveitis taking ciclosporin 5 mg/kg daily had an increase in her trough plasma ciclosporin levels (roughly doubled) on two occasions within 8 to 10 days of starting an oral contraceptive (**levonorgestrel/ethinylestradiol** 150/30 micrograms). She also experienced nausea, vomiting and hepatic pain, and had evidence of severe hepatotoxicity (very marked increases in AST and ALT, and rises in serum bilirubin and alkaline phosphatase). The woman had previously taken this oral contraceptive for 5 years without problems.¹

Another report describes hepatotoxicity in a patient taking ciclosporin 2 weeks after she started an oral contraceptive (**desogestrel/ethinylestradiol** 150/30 micrograms). The contraceptive was stopped, and liver enzyme levels promptly started to fall, but ciclosporin levels continued to rise, and peaked about 10 days later, at a level about threefold higher than they had been.²

(b) Norethisterone

A 15-year-old girl taking ciclosporin who had a marked increase in serum ciclosporin levels when she was given 'danazol', (p.1032), continued to have elevated levels, but not as high, when the danazol was replaced by norethisterone 5 mg three times daily. The levels returned to her previous normal range when the norethisterone was stopped.³ No changes in ciclosporin levels were seen in another patient who was intermittently given norethisterone.⁴ Two women had a mild rise in ciclosporin levels with no changes in creatinine levels when they were given norethisterone 10 mg daily for 10 days.⁵

Mechanism

Uncertain. It seems possible that some of these compounds inhibit the metabolism of the ciclosporin by the liver, thereby leading to an increase in its serum levels. The mechanism of the hepatotoxicity is not understood, but in some cases it seems that it occurs simply as a rare adverse effect of the sex hormone.

Importance and management

This interaction with oral contraceptives and norethisterone is unconfirmed and of uncertain clinical significance. There is insufficient evidence to recommend increased monitoring but be aware of the potential for an interaction in the case of an unexpected response to treatment.

Ciclosporin + Melphalan

Melphalan appears to increase the nephrotoxic effects of ciclosporin.

Clinical evidence, mechanism, importance and management

A comparative study found that 13 out of 17 patients receiving bone marrow transplants and given ciclosporin 12.5 mg/kg daily with high-dose melphalan (single injection of 140 to 250 mg/m²) developed renal failure, compared with no cases of renal failure in 7 other patients given melphalan but no ciclosporin.¹ In another study, one out of 4 patients given both drugs developed nephrotoxicity.² The reasons are not understood. Renal function should be monitored closely on concurrent use.

Ciclosporin + Methotrexate

Previous or concurrent treatment with methotrexate may possibly increase the risk of liver and other toxicity in those given ciclosporin, but effective and valuable concurrent use has also been reported. Ciclosporin causes a moderate rise in serum methotrexate levels, but methotrexate does not appear to affect the pharmacokinetics of ciclosporin.

Clinical evidence

(a) Evidence of an interaction

A limited comparative study in patients with chronic plaque psoriasis suggested that the previous use of methotrexate, which can cause liver damage, possibly increases the risk of ciclosporin toxicity (higher ciclosporin blood levels and serum creatinine levels, hypertension).¹ This was confirmed by another study in 4 patients with resistant psoriasis in whom ciclosporin 5 mg/kg daily given with methotrexate 2.5 mg every 12 hours for three doses at weekly intervals increased the blood levels of both drugs, and increased the adverse effects (nausea, vomiting, mouth ulcers). Rises in creatinine levels and liver enzymes (AST, ALT) also occurred.²

An open-label pharmacokinetic study in 26 patients with rheumatoid arthritis taking methotrexate 7.5 to 22.5 mg weekly with ciclosporin 1.5 mg/kg every 12 hours for 14 days, found that the AUC of the weekly dose of methotrexate increased by 26%, whereas the plasma levels of its major metabolite (7-hydroxymethotrexate), which is much less active and may be associated with toxicity, were reduced by 80%.³ Another study in patients with rheumatoid arthritis found that the pharmacokinetics of ciclosporin after the first dose did not differ between those who had been receiving intramuscular methotrexate 10 mg each week for 6 months and those not receiving methotrexate.⁴

(b) Evidence of concurrent use without toxicity

A pilot study described the effective use of ciclosporin and methotrexate for the control of acute graft-versus-host disease in bone marrow transplant patients, with the ciclosporin dosage reduced by 50% to 1.5 mg/kg/day during the first 2 weeks. The methotrexate dosages were 10 to 15 mg/m² on days 1, 3, 6, and 11 after grafting. Hepatotoxicity appeared to be reduced.⁵ Another study in three bone marrow transplant patients found that low-dose methotrexate (15 mg/m² on day 1, and 10 mg/m² on days 3, 6 and 11) given with ciclosporin did not significantly affect clinical care and no interaction of clinical significance was seen.⁶

Mechanism

Not understood.

Importance and management

The reports cited here give an inconsistent picture. On the one hand there is the strong recommendation by the authors of the second study² that combined use should be avoided, even in patients with severe unresponsive psoriasis, whereas it seems from the other studies in patients with rheumatoid arthritis, or those undergoing bone marrow transplant^{5,6} that concurrent use can be valuable, effective and apparently safe. Patients receiving ciclosporin should routinely be monitored for renal effects, and those receiving methotrexate routinely monitored for hepatotoxicity. If both drugs are used concurrently it may be worth increasing the frequency of this monitoring to aid rapid detection of any adverse effects.

Ciclosporin + Methoxsalen

In a single-dose study, methoxsalen increased the bioavailability of ciclosporin.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that a single 40-mg dose of methoxsalen significantly increased the AUC and peak plasma level of a single 200-mg dose of ciclosporin by about 14% and 8%, respectively. In two patients the AUCs increased by 1.8-fold and 2.7-fold, respectively. The half-life and time to peak levels were not affected. As methoxsalen absorption is subject to high interindividual variation, this particular study was unable to detect a significant difference in methoxsalen pharmacokinetics although the AUC and peak levels tended to be reduced by concurrent ciclosporin.¹

Methoxsalen may act by reducing the absorption of ciclosporin. Further study is required to see if this interaction is clinically significant. However, bear this interaction in mind in patients taking ciclosporin if levels are increased.

1. Rheeders M, Bouwer M, Goosen TC. Drug-drug interaction after single oral doses of the furanocoumarin methoxsalen and cyclosporine. *J Clin Pharmacol* (2006) 46, 768–75.

Ciclosporin + Methylphenidate

In an isolated case, the ciclosporin levels of a 10-year-old-boy were raised by 50% after he started to take methylphenidate.

Clinical evidence, mechanism, importance and management

A 10-year-old boy, who had received a heart transplant 6 years previously, started taking methylphenidate 5 mg twice daily in addition to his transplant medication, which included ciclosporin. After 4 days his ciclosporin level was found to have risen from 195 to 302 nanograms/mL. His ciclosporin dosage was therefore reduced from 550 to 500 mg daily, and at the same time the methylphenidate was increased to 7.5 mg twice daily. As the next ciclosporin level was still elevated at 251 nanograms/mL, the ciclosporin dose was further reduced to 450 mg daily. The boy then remained on this dose of ciclosporin with acceptable levels, despite further dose increases in the methylphenidate to an eventual dose of 20 mg daily.¹

The reason for this probable interaction is unclear. This appears to be the only reported case of an interaction between ciclosporin and methylphenidate, and its general importance is unknown.

1. Lewis BR, Aoun SL, Bernstein GA, Crow SJ. Pharmacokinetic interactions between cyclosporin and bupropion or methylphenidate. *J Child Adolesc Psychopharmacol* (2001) 11, 193–8.

Ciclosporin + Metoclopramide

Metoclopramide moderately increases the absorption of ciclosporin and raises its blood levels.

Clinical evidence, mechanism, importance and management

When 14 kidney transplant patients were given metoclopramide their peak ciclosporin blood levels were increased by 46%, from 388 to 567 nanograms/mL and the ciclosporin AUC was increased by 22%. The dosage of metoclopramide was 10 mg by mouth 30 minutes before, 5 mg with, and 5 mg 30 minutes after the morning dose of ciclosporin.¹ Ciclosporin is largely absorbed by the small intestine so the likely mechanism for this interaction is increased absorption of ciclosporin because metoclopramide hastens gastric emptying. The clinical importance of this interaction is uncertain. Concurrent use should be well monitored to ensure that any increase in ciclosporin peak levels does not increase adverse effects. Note that the increase in the AUC of ciclosporin is only modest.

1. Wadhwa NK, Schroeder TJ, O'Flaherty E, Pesce AJ, Myre SA, First MR. The effect of oral metoclopramide on the absorption of cyclosporine. *Transplant Proc* (1987) 19, 1730–3.

Ciclosporin + Midazolam

On the basis of an experimental study in 9 patients it was concluded that the dosage of midazolam needs no adjustment in those taking ciclosporin. Midazolam also appears to have no effect on ciclosporin pharmacokinetics.¹

1. Li G, Treiber G, Meinshausen J, Wolf J, Werringerloer J, Klotz U. Is cyclosporin A an inhibitor of drug metabolism? *Br J Clin Pharmacol* (1990) 30, 71–7.

Ciclosporin + Minoxidil

The concurrent use of ciclosporin and minoxidil can cause excessive hairiness (hypertrichosis).

Clinical evidence, mechanism, importance and management

Six male kidney transplant patients taking ciclosporin (blood levels of 100 to 200 nanograms/mL) were given methyl dopa, a diuretic and minoxidil 15 to 40 mg daily for intractable hypertension. After 4 weeks of treatment all of them complained of severe and unpleasant hypertrichosis (excessive hairiness). Two months after stopping the minoxidil the hypertrichosis had significantly improved.¹ Both ciclosporin and minoxidil cause hypertrichosis and it would seem that their effects may be additive. The authors of the report point out that this is not a life-threatening problem, but it limits the concurrent use of these drugs in both men and women.¹

1. Sever MS, Sonmez YE, Kocak N. Limited use of minoxidil in renal transplant recipients because of the additive side-effects of cyclosporine on hypertrichosis. *Transplantation* (1990) 50, 536.

Ciclosporin + Modafinil

Ciclosporin serum levels were reported to be reduced by modafinil in one patient.

Clinical evidence, mechanism, importance and management

A kidney transplant patient, stabilised for 9 years taking ciclosporin 200 mg daily, developed Gélinau's syndrome (narcoleptic syndrome) and was given modafinil 200 mg daily. Within a few weeks her ciclosporin blood levels were noted to have fallen, and it was necessary to raise her ciclosporin dosage stepwise to 300 mg daily before her blood

levels were back to their former values.¹ This is the first reported case of an interaction between ciclosporin and modafinil, and its general importance is unknown. However, the manufacturers state that in interaction studies modafinil induced the cytochrome P450 isoenzyme CYP3A4, the major enzyme involved in the metabolism of ciclosporin,² which would suggest that the interaction may be of general importance.

1. LeCacheux Ph, Charasse C, Mourtada R, Muh Ph, Boulahrouz R, Simon P. Syndrome de Géliveau chez une transplantée rénale. Mise en évidence d'une interaction ciclosporine-modafinil. *Presse Med* (1997) 26, 466.
2. Provigil (Modafinil). Cephalon Ltd. UK Summary of product characteristics, July 2007.

Ciclosporin + Muromonab-CD3

Muromonab-CD3 increases ciclosporin blood levels.

Clinical evidence, mechanism, importance and management

When muromonab-CD3 5 mg daily for 10 days was given to 10 kidney transplant patients to treat acute rejection, their mean trough ciclosporin levels on day 8 were higher than before the muromonab-CD3 was started, despite a 50% reduction in the ciclosporin dosage. When the muromonab-CD3 was withdrawn, the ciclosporin dosage needed to be increased again.¹ The reasons are not understood. It is clearly necessary to titrate the dosage of ciclosporin downwards if muromonab-CD3 is given to prevent an excessive rise in ciclosporin levels with the attendant risks of renal toxicity.

1. Vrahnos D, Sanchez J, Vasquez EM, Pollak R, Maddux MS. Cyclosporine levels during OKT3 treatment of acute renal allograft rejection. *Pharmacotherapy* (1991) 11, 278.

Ciclosporin + NNRTIs

The ciclosporin levels of one patient dramatically decreased following the addition of efavirenz.

Clinical evidence

A patient was diagnosed as HIV-positive 3 years after a kidney transplant, for which he was taking ciclosporin. He was started on efavirenz 600 mg daily, lamivudine and zidovudine, and 7 days later, after an initial rise, his ciclosporin level dropped from about 203 to 80 nanograms/mL. A nadir of 50 nanograms/mL was reached one month later.¹

Mechanism

Efavirenz induces the cytochrome P450 isoenzyme CYP3A4. Ciclosporin is extensively metabolised by CYP3A4, so concurrent use decreases ciclosporin levels.

Importance and management

There appears to be only one report of a reduction in ciclosporin levels with efavirenz. However, as subtherapeutic levels of ciclosporin may have significant consequences, including transplant rejection, it would be prudent to monitor ciclosporin levels closely in patients given efavirenz.

1. Tseng A, Nguyen ME, Cardella C, Humar A, Conly J. Probable interaction between efavirenz and ciclosporine. *AIDS* (2002) 16, 505–6.

Ciclosporin + NRTIs

No change in ciclosporin levels was seen in a study in 6 kidney transplant patients taking ciclosporin when lamivudine 100 to 150 mg daily was added to treat chronic hepatitis B.¹ Another study in 15 kidney transplant patients also found that lamivudine 50 to 100 mg daily did not affect ciclosporin levels.²

1. Jung YO, Lee YS, Yang WS, Han DJ, Park JS, Park S-K. Treatment of chronic hepatitis B with lamivudine in renal transplant recipients. *Transplantation* (1998) 66, 733–7.
2. Mouquet C, Bernard B, Poynard T, Thibault V, Opolon P, Coriat P, Bitker MO. Chronic hepatitis B treatment with lamivudine in kidney transplant patients. *Transplant Proc* (2000) 32, 2762.

Ciclosporin + NSAIDs, Aspirin or Paracetamol (Acetaminophen)

NSAIDs sometimes reduce renal function in individual patients, which is reflected in serum creatinine level rises and possibly in changes in ciclosporin levels, but concurrent use can also be uneventful. Diclofenac serum levels can be doubled by ciclosporin. There is an isolated report of colitis in a child treated with ciclosporin and diclofenac or indometacin.

Clinical evidence

(a) Aspirin

No pharmacokinetic interaction was found when ciclosporin was given with aspirin 960 mg three times daily in healthy subjects.¹

(b) Diclofenac

A study in 20 patients with rheumatoid arthritis given ciclosporin and diclofenac found that 7 of them had a high probability of an interaction (rises in serum creatinine levels and blood pressures), and 9 possibly had an interaction.² A kidney transplant patient taking ciclosporin, digoxin, furosemide, prednisolone, and spironolactone had a marked rise in serum creatinine levels immediately after starting to take diclofenac 25 mg three times daily. A fall in serum ciclosporin levels from 409 to 285 nanograms/mL also occurred.³ Increased nephrotoxicity was seen in another patient taking ciclosporin for idiopathic uveitis when given diclofenac 150 mg daily.⁴

A 6-month study in 20 patients with severe rheumatoid arthritis given diclofenac 100 to 200 mg with ciclosporin 3 mg/kg daily found that the AUC of diclofenac was doubled and serum creatinine levels raised from 71 to 88.4 micromol/L. The overall pattern of adverse events and laboratory abnormalities were similar to those in patients with rheumatoid arthritis treated with ciclosporin and other NSAIDs. It was suggested that it would be prudent to start with low doses of diclofenac and to monitor well.⁵ A study in 24 healthy subjects found that diclofenac 50 mg every 8 hours for 8 days caused no changes in the pharmacokinetics of ciclosporin, but there was some inconclusive evidence that diclofenac serum levels were increased.⁶

A child with rheumatoid arthritis taking ciclosporin 10 mg/kg daily developed colitis when diclofenac was given. The NSAID was stopped and her symptoms resolved while the ciclosporin was continued.⁷

(c) Dipyrrone (Metamizole sodium)

A placebo-controlled, crossover study in 6 kidney and 2 heart transplant patients taking ciclosporin found that while they were taking dipyrrone 500 mg three times daily for 4 days the pharmacokinetics of the ciclosporin (AUC, trough and peak blood levels, elimination half-life) were unchanged, but the time to reach maximum blood levels was slightly prolonged, from 2.1 to 3.8 hours. It is not known what the effects of more prolonged use might be.⁸

(d) Indometacin

A study in 16 healthy subjects found that indometacin 100 mg twice daily for 9 days reduced the maximum blood levels of a single 300-mg dose of ciclosporin by 18% and slowed its absorption (time to maximum concentration increased by 30 minutes) but the extent of absorption was not changed, indicating the absence of a clinically relevant pharmacokinetic interaction. Further, the pharmacokinetics of indometacin were not affected by ciclosporin.⁹ A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 6% in those taking indometacin 50 mg four times daily, but this was not considered to be clinically important.¹⁰ An experimental study in healthy subjects found that ciclosporin 10 mg/kg twice daily for 4 days had no effect on effective renal plasma flow (ERPF) or the glomerular filtration rate (GFR), but when indometacin 50 mg twice daily was added the ERPF fell by 32% and the GFR by 37%.¹¹

A child with rheumatoid arthritis on ciclosporin 10 mg/kg daily developed colitis when indometacin was given. The NSAID was stopped and her symptoms resolved while the ciclosporin was continued.⁷

(e) Ketoprofen

A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 2.3% in those taking ketoprofen 50 mg four times daily, but this was not considered to be clinically significant.

ically important.¹⁰ Another report describes increased serum creatinine levels in a patient with rheumatoid arthritis who took ciclosporin and ketoprofen.¹²

(f) *Mefenamic acid*

The ciclosporin blood levels in a renal transplant patient doubled, accompanied by rise in creatinine levels from 113 to 168 micromol/L within a day of starting to take mefenamic acid. Levels fell to normal within a week of stopping the mefenamic acid.¹³

(g) *Naproxen*

In 11 patients with rheumatoid arthritis taking ciclosporin, naproxen and sulindac increased serum creatinine levels by 24% and reduced renal function (glomerular filtration rate reduced from 98 mL/minute at baseline to 67 mL/minute while taking an NSAID and ciclosporin). All patients had a clinical improvement in their rheumatoid arthritis.¹⁴

(h) *Paracetamol (Acetaminophen)*

A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 3.5% in those taking paracetamol 650 mg four times daily, but this was not considered to be clinically important.¹⁰

(i) *Piroxicam*

Piroxicam is reported to have increased the serum creatinine levels of a patient with rheumatoid arthritis by an unknown amount (but classed as a significant adverse event). This resolved when the piroxicam was withdrawn.¹² A study in healthy subjects given piroxicam 20 mg daily for 11 days and a single 300-mg dose of ciclosporin on day 10 found no clinically relevant pharmacokinetic interaction.⁹

(j) *Sulindac*

A study in rheumatoid arthritis patients taking ciclosporin 2.5 mg/kg daily, found that creatinine clearances were reduced by 2.6% in those taking sulindac 100 mg four times daily, but this was not considered to be clinically important.¹⁰

A patient with a kidney transplant had a rise in serum creatinine levels when sulindac was used. Ciclosporin blood levels fell and rose again when the sulindac was stopped.³ Another report states that the ciclosporin levels of a woman with a kidney transplant were more than doubled within 3 days of her starting to take sulindac 150 mg twice daily.¹⁵ In 11 patients with rheumatoid arthritis taking ciclosporin, both sulindac and naproxen increased serum creatinine levels by 24% and reduced renal function (glomerular filtration rate reduced from 98 mL/minute at baseline to 67 mL/minute while taking an NSAID and ciclosporin). All patients had a clinical improvement in their rheumatoid arthritis.¹⁴

Another report describes a patient with rheumatoid arthritis taking ciclosporin who developed increased serum creatinine levels when given ketoprofen, but not when given sulindac.¹²

Mechanism

Uncertain. One idea is that intact kidney prostacyclin synthesis is needed to maintain the glomerular filtration rate and renal blood flow in patients given ciclosporin, which may possibly protect the kidney from the development of ciclosporin-induced nephrotoxicity. If NSAIDs that inhibit prostaglandin production in the kidney are given, the nephrotoxic effects of the ciclosporin manifest themselves, possibly independently of changes in serum ciclosporin levels.³ A study in *rats* found that indometacin and ciclosporin together can cause rises in serum creatinine levels that are much greater than with either drug alone.¹⁶

The occurrence of colitis in a child receiving ciclosporin and either diclofenac or indometacin appeared to be independent of changes in ciclosporin levels and may be a result of additive effects of both drugs.⁷

Importance and management

Information about the NSAIDs listed here is sparse and limited, but the overall picture appears to be that concurrent use in rheumatoid arthritis need not be avoided but renal function should be very well monitored. The manufacturers of ciclosporin also specifically recommend that patients

with rheumatoid arthritis taking ciclosporin and an NSAID should have their hepatic function measured as well as renal function, because hepatotoxicity is a potential adverse effect of both drugs.¹⁷ It has been suggested that gastrointestinal symptoms should also be carefully evaluated.⁷ It is clearly difficult to generalise about what will or will not happen if any particular NSAID is given but in the case of diclofenac it has been recommended that doses at the lower end of the range should be used at the start because its serum levels can be doubled by ciclosporin.

Ciclosporin + Opioids

An isolated report describes neuropsychosis in a patient who was given intravenous ciclosporin and morphine. A single case report describes a patient taking ciclosporin who developed opioid withdrawal on stopping low-dose, transdermal fentanyl.

Clinical evidence, mechanism, importance and management

A patient who underwent renal transplantation was given ciclosporin 6 mg/kg daily by intravenous infusion over 2 hours and intravenous methylprednisolone postoperatively. He also received patient-controlled analgesia (PCA) as bolus doses of **morphine** 0.5 mg to a total dose of 13 mg on the first day and 11 mg on the second day. On the third day he developed insomnia, anxiety, amnesia, aphasia and severe confusion. The morphine was discontinued and the symptoms subsided after treatment with propofol, diazepam and haloperidol. It was suggested that ciclosporin may have decreased the excitation threshold of neuronal cells, which potentiated the dysphoric effects of **morphine**.¹

A patient taking ciclosporin following a stem cell transplant developed opioid withdrawal symptoms when transdermal **fentanyl** 25 micrograms/hour was discontinued. The authors suggested that elevation of **fentanyl** levels due to inhibition of the cytochrome P450 isoenzyme CYP3A4 by ciclosporin during concurrent use may have been a possible cause, as withdrawal symptoms are not usual with this dose of **fentanyl**. However, they also note that other factors may have played a role, such as the physical and mental status of the patient after the stem cell

transplant.² Further, ciclosporin does not usually appear to interact with other drugs by inhibiting CYP3A4.

These appear to be isolated cases and almost certainly not of general importance.

Ciclosporin + Orlistat

The absorption of ciclosporin is significantly reduced by orlistat. In one case, orlistat appeared to have less effect on the microemulsion formulation of ciclosporin (*Neoral*) than the oil formulation (*Sandimmun*). Nevertheless, an episode of acute graft rejection (said to be non-significant) has been reported with the microemulsion formulation.

Clinical evidence

In a heart transplant patient taking ciclosporin (*Sandimmun*), orlistat 120 mg three times daily reduced the trough blood levels of ciclosporin by 47%, to 52 nanograms/mL. The peak levels and the AUC of ciclosporin were increased by 86% and 75%, respectively.¹ Another heart transplant patient taking ciclosporin (*Neoral*) had a nonsignificant acute rejection episode on routine endocardial biopsy, with trough ciclosporin levels of 38 nanograms/mL, 24 days after starting to take orlistat. Ciclosporin trough levels increased to about 90 to 110 nanograms/mL when the orlistat was stopped.² In a further patient taking ciclosporin (*Sandimmun*) 250 mg daily, orlistat 360 mg daily reduced the ciclosporin levels from 150 to 50 nanograms/mL. Increasing the dose of ciclosporin did not result in an increased level, so the patient was given *Neoral* instead. Adequate levels of 160 nanograms/mL were finally achieved with ciclosporin (*Neoral*) 375 mg daily.³ Details of this patient are also briefly given elsewhere.⁴ Another report describes 6 transplant recipients who developed subtherapeutic ciclosporin trough levels after also taking orlistat.⁵ Another heart transplant patient had a progressive reduction in her ciclosporin (*Sandimmune*) level when she started to take orlistat. Note that this patient was also reported to have severe diarrhoea secondary to poor adherence to a low-fat diet when taking orlistat, which may have contributed to the low levels seen.⁶

Mechanism

Orlistat inhibits pancreatic lipase and prevents the absorption of dietary fat and lipophilic molecules such as ciclosporin. Absorption of ciclosporin from the oil suspension formulation (*Sandimmun*) is more dependent on the lipid absorption stage and thus may be more affected by orlistat than the microemulsion form (*Neoral*).³

Importance and management

Information appears to be limited to these reports, but the interaction seems to be established. It has been suggested that the effects of the interaction may be reduced by using the microemulsion formulation of ciclosporin (*Neoral*)³ (which has generally replaced the corn oil suspension). Monitoring is required if the two drugs are used together, either in the standard or microemulsion form because there is a risk of subtherapeutic levels even with the microemulsion preparation.² Some authors recommend avoidance of the combination.¹ The UK manufacturers of orlistat do not recommend concurrent use, but if such use is unavoidable more frequent ciclosporin monitoring is recommended.⁷ The US manufacturers recommend taking ciclosporin at least 2 hours before or 2 hours after orlistat, and that ciclosporin levels should be monitored more frequently in these patients.⁸

Ciclosporin + Oxybutynin

Oxybutynin did not appear to affect ciclosporin levels in two children.

Clinical evidence, mechanism, importance and management

In a retrospective analysis, one child with a kidney transplant taking ciclosporin had no change in his ciclosporin level and dosage over the 2 months before and the 2 months after he started oxybutynin 2 mg twice daily. Another patient had no change in ciclosporin levels and dosage over the 3 months before and 3 months after stopping oxybutynin 5 mg twice daily.¹ This analysis was prompted by evidence suggesting oxybutynin may induce the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of ciclosporin. Although the evidence is limited, it suggests that oxybutynin is unlikely to have an important effect on ciclosporin levels.

1. Springate JE. Oxybutynin does not affect ciclosporin blood levels. *Ther Drug Monit* (2001) 23, 155–6.

Ciclosporin + Pancreatic enzymes

Pancreatic enzyme extracts do not increase the bioavailability of ciclosporin in cystic fibrosis patients.

Clinical evidence, mechanism, importance and management

A study in heart-lung transplant patients with cystic fibrosis found that they needed almost five times the oral dose of ciclosporin of other patients, confirming other studies in these patients that had shown a very much reduced bioavailability of oral ciclosporin. This is probably a reflection of the generally poor digestion and absorption in cystic fibrosis patients. The addition of pancreatic enzymes (*Creon*) was not found to improve this poor ciclosporin bioavailability. No adverse effects were reported.¹

Ciclosporin + Prazosin

Preliminary studies show that prazosin causes a small reduction in the glomerular filtration rate in kidney transplant patients taking ciclosporin.

Clinical evidence, mechanism, importance and management

A study in 8 patients with kidney transplants found that prazosin 1 mg twice daily for one week did not alter their ciclosporin blood levels, and arterial blood pressures and renal vascular resistance were reduced. However, the glomerular filtration rate (GFR) was reduced by about 10% (from 47 to 42 mL/minute).¹ Previous studies in kidney transplant patients taking azathioprine, prednisone and prazosin found no reduction in GFR.² There would seem to be no strong reasons for totally avoiding prazosin in patients taking ciclosporin, but the authors of the report point out that the fall in GFR makes prazosin a less attractive antihypertensive than a calcium-channel blocker.

2. Curtis JR, Bateman FJA. Use of prazosin in management of hypertension in patients with chronic renal failure and in renal transplant recipients. *BMJ* (1975) 4, 432.

Ciclosporin + Probuco

Probuco reduces blood ciclosporin levels by about 40%.

Clinical evidence

A study in 6 heart transplant patients taking ciclosporin found that the concurrent use of probucol 500 mg every 12 hours decreased trough whole blood ciclosporin levels from 139 to 81 nanograms/mL and the AUC₀₋₉ by 28%. The clearance was increased by 60% and volume of distribution also increased.¹

Another group of workers similarly found that 9 out of 10 kidney transplant patients had a reduction in their trough blood ciclosporin levels while taking probucol.²

Mechanism

Not understood. Evidence from *in vitro* and *animal* studies suggest that probucol may form complexes with ciclosporin in the gut, preventing absorption. The studies also found that probucol does not affect ciclosporin absorption via P-glycoprotein-mediated transport.³

Importance and management

Information appears to be limited to these studies, but the interaction appears to be well established. The ciclosporin dosage may need to be increased if probucol is added. Monitor the effects and adjust the dosage appropriately.

Ciclosporin + Propafenone

In an isolated report, propafenone caused a 60% increase in the ciclosporin levels of a patient.

Clinical evidence

A heart transplant patient taking ciclosporin, azathioprine and prednisolone developed ventricular tachycardia 9 months after transplantation, for which he was given propafenone 600 or 750 mg daily. After the first day, his ciclosporin level had risen from about 160 to 190 nanograms/mL, and after 5 days the levels had reached around 260 nanograms/mL. Over the same time period his serum creatinine rose from 168 to 212 micromol/L. His ciclosporin dose was reduced from 240 mg daily to a final dose of 200 mg daily after which his renal function and ciclosporin levels were re-established at about the level before propafenone was started.¹

Mechanism

The authors suggest that propafenone interferes with the metabolism of ciclosporin by affecting hepatic cytochrome P450, or that propafenone may enhance the absorption of ciclosporin.

Importance and management

Information appears to be limited to this one report, the general importance of which is unknown.

Ciclosporin or Tacrolimus + Potassium compounds

Ciclosporin and tacrolimus can cause or worsen pre-existing hyperkalaemia. The concurrent use of potassium compounds should be closely monitored.

Clinical evidence, mechanism, importance and management

Both ciclosporin and tacrolimus can cause hyperkalaemia.^{1,2} Tacrolimus has been reported in one study in 34 liver transplant patients to cause hyperkalaemia (defined in this study as potassium greater than 4.5 mmol/L)

in 21% of patients, even when the trough level was within therapeutic range.³ Another study in kidney transplant patients found that the incidence of hyperkalaemia was higher in tacrolimus treated patients, when compared with ciclosporin treated patients.⁴

Hyperkalaemia can in itself be a sign of worsening renal function but may be exacerbated by ciclosporin or tacrolimus. This can be worsened further by the use of potassium supplements.

The manufacturers of tacrolimus recommend that patients should avoid a high potassium intake, such as in supplements.¹ The manufacturers of ciclosporin however recommend potassium level monitoring with concurrent use of any potassium supplement or a potassium-rich diet.²

Ciclosporin + Protease inhibitors

Protease inhibitors significantly increase the levels of ciclosporin. Ciclosporin may increase the time to maximum nelfinavir levels.

Clinical evidence

(a) Fosamprenavir

A HIV-positive patient taking ciclosporin 250 to 350 mg twice daily (to maintain a therapeutic ciclosporin trough level of 300 to 400 nanograms/mL) was restarted on his usual HAART regimen of tenofovir, lamivudine and fosamprenavir 1.4 g twice daily on day 12 post-liver transplantation. Within 2 days, the ciclosporin level had increased to 600 nanograms/mL, requiring a ciclosporin dose reduction to 100 mg twice daily.¹

(b) Nelfinavir

A pilot study in 7 HIV-positive subjects taking nelfinavir 1.25 g twice daily found that a single 4-mg/kg oral dose of ciclosporin increased the time to maximum serum level for nelfinavir from 2.6 to 3.2 hours. The AUC of nelfinavir was also increased but this was not significant. In the same study, a single 2-mg/kg intravenous dose of ciclosporin given over 2.5 hours had little effect on the pharmacokinetics of oral nelfinavir. Nelfinavir did not significantly affect the pharmacokinetics of either oral or intravenous ciclosporin.²

(c) Ritonavir-boosted regimens

Three HIV-positive patients who had undergone liver transplantation required reductions in their ciclosporin doses when they started taking ritonavir-boosted HAART. One patient taking ciclosporin 150 mg twice daily had an increase in his ciclosporin levels to 900 nanograms/mL when ritonavir-boosted HAART was started, and needed a dose reduction of 95% to maintain a usual ciclosporin trough level of 75 to 150 nanograms/mL. A second patient also required a similar reduction. The third patient needed a dose reduction of 80% when taking ritonavir-boosted **lopinavir**, but no further ciclosporin dose alteration was needed when his treatment was changed to ritonavir-boosted indinavir.³

(d) Saquinavir

An HIV-positive patient taking lamivudine and zidovudine, and ciclosporin for a kidney transplant, started taking saquinavir 1.2 g three times daily. Within 2 days he started to complain of fatigue, headache and gastrointestinal discomfort. On investigation his ciclosporin level was found to have risen from a range of 150 to 200 nanograms/mL up to 580 nanograms/mL, and his saquinavir AUC was increased 4.3-fold (by comparison with subjects not taking ciclosporin). His ciclosporin dose was reduced from 150 mg twice daily to 75 mg twice daily, and his saquinavir dose was reduced to 600 mg three times daily, which resulted in ciclosporin levels similar to those achieved previously.⁴

Mechanism

All protease inhibitors can inhibit the cytochrome P450 isoenzyme CYP3A4 to varying degrees, see 'Antivirals', (p.772). Ciclosporin is ex-

tensively metabolised by CYP3A4, so any inhibition of this isoenzyme is likely to increase ciclosporin levels. Ciclosporin and the protease inhibitors are substrates for P-glycoprotein, which may explain the raised nelfinavir and saquinavir levels.

Importance and management

The increase in ciclosporin levels seen with ritonavir may occur irrespective of whether it is used as an antiretroviral in its own right or as a pharmacokinetic enhancer with other antiretrovirals⁵ (usually in a lower dose of 100 mg twice daily). The inhibition of ciclosporin metabolism by other protease inhibitors, either alone or in combination with ritonavir, may lead to significant increases in ciclosporin levels. Therefore, ciclosporin levels should be carefully monitored and the dose adjusted accordingly during concurrent use, bearing in mind that large dose reductions may be required in some patients, as seen with ritonavir. It is also important to reduce or alter the ciclosporin dose should the protease inhibitor be stopped or changed to avoid ciclosporin toxicity. The clinical significance of the effects of ciclosporin on nelfinavir pharmacokinetics are unclear, and further study is needed.

Ciclosporin + Proton pump inhibitors

Omeprazole does not normally appear to affect serum ciclosporin levels, but two isolated reports describe doubled serum ciclosporin levels in one patient, and more than halved serum ciclosporin levels in another. Pantoprazole does not affect serum ciclosporin levels.

Clinical evidence

(a) Omeprazole

Ten kidney transplant patients had no significant changes in ciclosporin levels when given omeprazole 20 mg daily for 2 weeks.¹ Eight kidney transplant patients similarly had no significant changes in ciclosporin levels when given omeprazole 20 mg daily for 6 days.² No significant changes in ciclosporin levels were seen in another kidney transplant patient when omeprazole 20 mg daily was given for 8 weeks.³

In contrast, the ciclosporin blood levels of a liver transplant patient roughly doubled (from a range of 187 to 261 up to 510 nanograms/mL) about 2 weeks after omeprazole 40 mg daily was started. His ciclosporin levels were readjusted by reducing the dose from 130 to 80 mg twice daily. The levels then remained steady at about 171 nanograms/mL for the following 4 months.⁴ In contrast, the serum ciclosporin levels of a bone marrow transplant patient fell from 254 to about 100 nanograms/mL over 14 days in the presence of omeprazole 40 mg daily. The ciclosporin levels climbed again rapidly when the omeprazole was stopped.⁵

(b) Pantoprazole

Studies in kidney transplant patients have found that pantoprazole 40 mg once daily does not affect ciclosporin blood levels when given in the evening,⁶ or when both drugs are given together in the morning.⁷

Mechanism

Not understood.

Importance and management

Information is limited but what is known suggests that no interaction normally occurs. However, bear the case reports in mind in the case of an

unexpected response to treatment. Note that, in the studies cited in which no interaction occurred, the dose of omeprazole was 20 mg daily, whereas the two cases of interaction involved 40 mg daily so some caution would be appropriate if initiating omeprazole at this higher dose. There would seem to be no reason for avoiding concurrent use of ciclosporin and pantoprazole.⁸

Ciclosporin + Pyrazinamide

Pyrazinamide does not normally appear to interact with ciclosporin but one isolated report suggests that it may possibly have contributed to the effects of rifampicin in one patient, which resulted in lowered ciclosporin levels. Another patient developed toxic myopathy attributed to the use of pyrazinamide with ciclosporin.

Clinical evidence, mechanism, importance and management

A 12-year-old girl with a kidney transplant taking ciclosporin and prednisolone had a rejection episode while taking rifampicin and isoniazid, apparently due to the fall in serum ciclosporin levels caused by the rifampicin. The rejection settled when the rifampicin was replaced by pyrazinamide.¹ Other patients taking ciclosporin have been given pyrazinamide combined with ethambutol and/or streptomycin without any apparent interaction problems.² However, an anecdotal report suggested that when pyrazinamide was given with rifampicin and isoniazid it appeared to add to the effects of the rifampicin causing an additional reduction in ciclosporin blood levels.³ Another report attributed the development of toxic myopathy in a kidney transplant patient to the concurrent use of pyrazinamide and ciclosporin.⁴

There would therefore seem to be no reason for avoiding pyrazinamide in patients taking ciclosporin, but be aware of these rare complications.

Ciclosporin + Quinine

An isolated case suggests that quinine reduces ciclosporin levels.

Clinical evidence, mechanism, importance and management

A man with a kidney transplant and mild cerebral falciparum malaria had a gradual decrease in his ciclosporin blood levels, from 328 to 107 nanograms/mL, over 7 days when he was given quinine 600 mg every 8 hours, and a gradual rise when the quinine was stopped.¹

The reason for this apparently isolated report is unclear and its general importance is unknown. There is insufficient evidence to recommend increased monitoring, but be aware of the potential for an interaction in the

case of an unexpected response to treatment. The effects of lower quinine doses used for cramps are unclear.

1. Tan HW, Ch'ng SL. Drug interaction between cyclosporine A and quinine in a renal transplant patient with malaria. *Singapore Med J* (1991) 32, 189–90.

Ciclosporin + Retinoids

An increase in ciclosporin blood levels occurred in one patient given etretinate, but studies have not found this effect. In two patients taking isotretinoin and ciclosporin, rises in ciclosporin levels occurred, although another patient taking both drugs had no alteration in ciclosporin levels.

Clinical evidence

(a) Etretinate

In one case, a woman with generalised pustular psoriasis who had been taking ciclosporin 200 mg daily had a considerable rise in her ciclosporin blood levels to 540 micrograms/L when the dosage was raised to 300 mg daily and etretinate 50 mg daily was added. An interaction was suspected as contributing to this effect because it was found possible to reduce the ciclosporin dosage gradually to 150 mg daily (accompanied by a fall in the trough ciclosporin blood levels to 168 micrograms/L), without any loss in the control of the disease.¹ However, only a modest ciclosporin dosage reduction was needed in another study when etretinate was given.²

Other reports suggest successful and uncomplicated concurrent use. There was no improvement when a patient with erythrodermic psoriasis was given ciclosporin 5 to 10 mg/kg daily, but ciclosporin 5 mg/kg daily with etretinate 700 micrograms/kg daily cleared the psoriasis by 90%. Reducing the dose of either drug resulted in exacerbation of symptoms.³ Another 5 patients with plaque-type psoriasis had a relapse when the ciclosporin dosage was reduced in the presence of etretinate, but no additive therapeutic effect was seen. All of them had elevated serum creatinine levels.⁴ No obvious advantages but no increase in adverse effects were found in another study that gave ciclosporin with etretinate.⁵

(b) Isotretinoin

A 27-year old man with a heart transplant taking ciclosporin was given isotretinoin 40 mg daily for 2 months, then 80 mg daily up to 20 weeks. His ciclosporin trough levels remained within the recommended range, and there was no evidence of graft rejection.⁶ Another man with a heart transplant taking ciclosporin received isotretinoin 1 mg/kg daily for 4 months. His daily ciclosporin dose was reduced from 7 mg/kg to 6 mg/kg one month after starting isotretinoin because of a rise in ciclosporin level to 587 nanograms/mL. However, it was noted that this may have had nothing to do with the isotretinoin, since the patient required alterations in ciclosporin dose in 3 instances before isotretinoin was started. No laboratory abnormalities were noted, nor was ciclosporin toxicity seen, and the heart transplant function remained satisfactory.⁷ A 13-year-old girl with aplastic anaemia and taking ciclosporin was given isotretinoin 40 mg daily for 20 weeks. She had a threefold increase in trough ciclosporin level at week 17, which was considered probably unrelated to isotretinoin, and was managed by reducing her ciclosporin dose. Serum lipids did not change during concurrent use.⁸

Mechanism

Uncertain. An *in vitro* study using human liver microsomes found that concentrations of 100 micromol of acitretin, etretinate and isotretinoin inhibited the total ciclosporin metabolism and total primary ciclosporin metabolite production to the same extent (32 to 45%).¹ These figures suggest that the retinoids may inhibit ciclosporin metabolism. However, another *in vitro* study using human liver microsomes did not find that etretinate inhibits the metabolism of ciclosporin.⁹

Importance and management

The overall picture seems to be that etretinate has only a modest effect, or no effect at all, on ciclosporin blood levels in most patients. Nevertheless, this possible interaction is worth bearing in mind because of the possibility of isolated cases of raised ciclosporin levels. There seems to be no marked therapeutic advantage in using both drugs together for psoriasis. From the cases presented, it is unclear if isotretinoin alters ciclosporin levels. In addition, it has been suggested that serum lipids should be monitored be-

cause both drugs can cause an increase.⁶ **Acitretin** (the major metabolite of etretinate) probably behaves like etretinate, although this needs confirmation.

Ciclosporin + Sevelamer

One study suggests sevelamer does not appear to alter ciclosporin levels, but a report describes markedly reduced ciclosporin levels in a patient who took sevelamer.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of ciclosporin were unchanged in a study in 18 kidney transplant patients taking ciclosporin, (with 9 patients also taking mycophenolate) after they took sevelamer as a single 1.6- or 1.2-g dose and when sevelamer was given in the same dose, three times daily for 4 days.¹ Eight of the patients were children (average age 12 years).¹ However, the findings in this study have been criticised by other authors,² who, in contrast, report a case of reduced ciclosporin levels in a liver transplant patient. The patient had been stable taking ciclosporin 60 mg daily, but when she was given sevelamer 806 mg three times daily a dose increase to 85 mg daily was needed to maintain ciclosporin levels.³ This may be due to binding of sevelamer with ciclosporin in the gut preventing ciclosporin absorption.^{3,4} The manufacturers of sevelamer recommend close monitoring of ciclosporin levels with concurrent use or when sevelamer is stopped, and they also recommend that ciclosporin is taken at least 1 hour before or 3 hours after sevelamer.⁵

Ciclosporin + Sibutramine

Ciclosporin is predicted to raise sibutramine levels. One case report describes an increase in ciclosporin levels when a patient was changed from orlistat to sibutramine.

Clinical evidence, mechanism, importance and management

A kidney transplant patient taking ciclosporin 100 mg twice daily took orlistat for 27 months with no problems or changes in her ciclosporin levels or dosage reported. As orlistat was unsuccessful for weight reduction in this patient, sibutramine 10 mg daily was given instead. One week later her trough ciclosporin level had increased from 79 to 152 nanograms/mL and her ciclosporin daily dose was reduced by 25 mg. Her ciclosporin level was still raised one week later at 162 nanograms/mL and her ciclosporin daily dose was again reduced by 25 mg. No increase in blood pressure or serum creatinine occurred.¹

Sibutramine is metabolised by the cytochrome P450 isoenzyme CYP3A4 although it is not known to have any effects on this isoenzyme. Ciclosporin is also metabolised by CYP3A4 and the changes in levels seen

may therefore have been due to competition for metabolism. In contrast to what was seen in this case, the manufacturers predict that inhibitors of CYP3A4 (they name ciclosporin, but note that this drug does not usually interact by inhibiting this isoenzyme) may lead to an increase in levels of the active metabolite of sibutramine, but no effects on ciclosporin levels are expected.²

This appears to be the only case report of an increase in ciclosporin levels with sibutramine.¹ However, orlistat has been reported to reduce ciclosporin absorption, and therefore levels, see 'orlistat', (p.1042), so there is a possibility that the increase in ciclosporin levels was due to stopping orlistat rather than starting sibutramine, but this was not investigated.

Ciclosporin + Somatostatin analogues

Octreotide causes a marked reduction in the blood levels of ciclosporin and inadequate immunosuppression may result. Lanreotide is predicted to interact similarly.

Clinical evidence

A diabetic man with kidney and pancreatic segment transplants was successfully immunosuppressed with azathioprine, methylprednisolone and ciclosporin. When he was also given subcutaneous **octreotide** 100 micrograms twice daily to reduce fluid collection around the pancreatic graft, his trough ciclosporin blood levels fell below the assay detection limit of 50 nanograms/mL. Serum creatinine increased dramatically, which was interpreted as a selective rejection episode of the kidney transplant. Nine other diabetics similarly treated with **octreotide** for peripancreatic fluid collection and fistulas after pancreatic transplantation also had significant falls in their ciclosporin blood levels within 24 to 48 hours, in 3 of them to undetectable levels.¹ A similar interaction was seen in another patient.²

Mechanism

Uncertain. A suggestion is that the octreotide reduces the intestinal absorption of the ciclosporin.^{1,2}

Importance and management

The interaction between octreotide and ciclosporin is established and clinically important, although the documentation is limited. The authors of one report recommend that before giving octreotide the oral dosage of ciclosporin should be increased on average by 50% and the serum levels monitored daily.¹ The manufacturers of **lanreotide** say that, as with other somatostatin analogues, it may reduce the absorption of ciclosporin from the gut.³ As yet there appear to be no reports of this interaction in practice; however, it would be prudent to monitor the outcome of the use of lanreotide with ciclosporin.

Ciclosporin + SSRIs and related antidepressants

Four cases of raised ciclosporin levels have been seen in patients taking nefazodone and ciclosporin, one with raised creatinine levels and tremor, and one with raised liver enzymes. A small study found no evidence of an interaction between fluoxetine and ciclosporin although one case of increased ciclosporin levels has been seen with fluoxetine. Fluvoxamine may inhibit the metabolism of ciclosporin and one case of increased ciclosporin levels has been reported with fluvoxamine. The serotonin syndrome has

been seen in a patient taking ciclosporin and sertraline. Limited evidence suggests that citalopram and sertraline do not alter ciclosporin levels.

Clinical evidence

(a) Citalopram

In 5 transplant patients the pharmacokinetics of ciclosporin were not significantly affected by citalopram 10 to 20 mg daily.¹

(b) Fluoxetine

A small, retrospective study in 9 liver transplant and 4 heart transplant patients found no evidence that fluoxetine 5 to 20 mg daily increased ciclosporin blood levels.² However, the ciclosporin blood levels of a heart transplant patient were doubled by fluoxetine 20 mg daily for 10 days. They fell when the ciclosporin dosage was reduced and needed to be increased again when the fluoxetine was stopped.³

(c) Fluvoxamine

A patient had increased ciclosporin blood levels and serum creatinine levels and fine tremor 2 weeks after starting fluvoxamine 100 mg daily, and the ciclosporin dosage was subsequently reduced by 33%.⁴

(d) Sertraline

A 53-year-old man taking ciclosporin following a renal transplant developed the serotonin syndrome 5 days after starting to take sertraline 50 mg daily. Ciclosporin is known to increase serotonin turnover within the brain, and so the reaction was attributed to an interaction between sertraline and ciclosporin.⁵ One report briefly mentions that a patient taking ciclosporin had her antidepressant medication switched from nefazodone to sertraline, because sertraline did not affect ciclosporin levels.⁶

(e) Nefazodone

A kidney transplant patient had a 70% rise in trough serum ciclosporin levels within 3 days of starting to take nefazodone 25 mg twice daily.⁷ Another kidney transplant patient had a two- to threefold rise in ciclosporin levels associated with raised creatinine levels and marked generalised tremors after starting nefazodone 100 mg twice daily. The patient was eventually stabilised on a 50% lower dose of ciclosporin.⁴ Similarly, a cardiac transplant patient taking ciclosporin had a tenfold increase in ciclosporin levels shortly after the addition of nefazodone 150 mg twice daily. Levels returned to baseline over 6 days after nefazodone was stopped.⁶ A patient taking nefazodone developed significantly raised liver enzymes AST and ALT one month after kidney transplantation. His ciclosporin level was high, at 614 nanograms/mL, and both ciclosporin and nefazodone were stopped. He had previously taken nefazodone uneventfully, and subsequently took ciclosporin uneventfully, so the raised liver enzymes were attributed to a pharmacokinetic interaction between the two drugs.⁸ However, note that nefazodone has generally been withdrawn due to its adverse effects on the liver.

Mechanism

Fluvoxamine and nefazodone are inhibitors of the cytochrome P450 isoenzyme CYP3A4, the main isoenzyme by which ciclosporin is metabolised. Concurrent use can therefore lead to increased ciclosporin levels. Fluoxetine may interact similarly. Citalopram and sertraline do not usually significantly inhibit CYP3A4 and would therefore not be expected to interact.

Importance and management

Although the evidence is limited, it appears that nefazodone can cause a marked rise in ciclosporin levels, with an increase in adverse effects. Alternative antidepressants should probably be used, or concurrent therapy very well monitored. Similar caution would seem prudent with fluvoxamine, and possibly fluoxetine. Citalopram, and sertraline do not appear to alter ciclosporin levels and may therefore be suitable alternatives. Serotonin syndrome is a rare adverse effect, usually associated with the use of more than one serotonergic drug (see 'The serotonin syndrome', (p.9)).

Ciclosporin + Sucrose polyesters

Sucrose polyesters (e.g. *Olestra*) may reduce the bioavailability and peak levels of ciclosporin.

Clinical evidence, mechanism, importance and management

A study in 7 kidney transplant patients aged 9 to 18 years, found that the addition of sucrose polyesters (*Olestra*), in a single 0.35-g/kg dose (maximum of 16 g) reduced the ciclosporin AUC and peak levels by almost 19% and 27%, respectively. Ciclosporin trough levels and elimination rate were not affected by *Olestra*. The reduced bioavailability was thought to be due to *Olestra* reducing the absorption of ciclosporin. *Olestra* is marketed as a non-absorbable, non-calorific fat ingredient in snack foods. The authors note that *Olestra* is mainly consumed by children and adolescents, with the age group of 13 to 17-year-olds being reported to eat 16.2 g of *Olestra* per snack, and therefore this interaction could be of particular significance for young transplant patients taking ciclosporin.¹ However, note that changes in the AUC of ciclosporin of this size are very modest.

- Terrill CJ, Lill J, Somerville KT, Sherbotie JR. Modifications in cyclosporine (CsA) microemulsion blood concentrations by *Olestra*. *J Ren Nutr* (2003) 13, 26–30.

Ciclosporin + Sulfasalazine

An isolated report describes elevated ciclosporin levels in a kidney transplant patient that developed when sulfasalazine was stopped.

Clinical evidence

A patient with a kidney transplant was taking azathioprine, ciclosporin, prednisone and sulfasalazine 1.5 g daily. After initial adjustments the dose of ciclosporin remained at 480 mg daily for 8 months. The dose of prednisone was reduced and treatment stopped at 8 months, and azathioprine was stopped at 12 months without any need to adjust the ciclosporin dosage. Sulfasalazine was stopped 13.5 months after transplantation and the mean ciclosporin level increased from 205 nanograms/mL to 360 nanograms/mL within 5 days, and to 389 nanograms/mL after 10 days. The ciclosporin dosage was reduced over the following 2 months from 9.6 mg/kg to 5.6 mg/kg to maintain blood levels at about 200 nanograms/mL.¹

Mechanism

Not understood. The time course of the interaction, noted after 5 days probably excludes decreased absorption. It is possible that the interaction is due to induction of the cytochrome P450 enzymes.

Importance and management

Information appears to be limited to this isolated case report. There is insufficient evidence to recommend increased monitoring, but be aware of the potential for an interaction in the case of an unexpected response to treatment.

- Du Cheyron D, Debruyne D, Lobbedez T, Richer C, Ryckelynck J-P, Hurault de Ligny B. Effect of sulfasalazine on cyclosporin blood concentration. *Eur J Clin Pharmacol* (1999) 55, 227–8.

Ciclosporin + Sulfapyrazone

Sulfapyrazone can reduce ciclosporin levels and episodes of transplant rejection have resulted.

Clinical evidence

A study in 120 heart transplant patients found that sulfapyrazone 200 mg daily was effective in the treatment of hyperuricaemia. The mean uricaemia over 4 to 8 months fell by 22%, from 0.51 to 0.4 mmol/L, but unexpectedly the mean trough ciclosporin levels fell by 39%, from 183 to 121 micrograms/L, despite a 7.7% increase in the ciclosporin daily dosage. Two of the patients developed rejection: one after 4 months of taking sulfapyrazone when the ciclosporin levels fell to 50 micrograms/L, and the other after 7 months of taking sulfapyrazone, when the ciclosporin levels fell to 20 micrograms/L.¹

Another report describes a patient who needed unusually high doses of ciclosporin while taking sulfapyrazone,² while yet another report describes *increased* ciclosporin levels in a patient taking sulfapyrazone. In this latter case there is the possibility that it may have been an artefact due to interference with the assay method.³

Mechanism

Not understood.

Importance and management

Information appears to be limited to these reports but the interaction would seem to be established and clinically important. If sulfapyrazone is added to established treatment with ciclosporin, be alert for the need to raise the ciclosporin dosage. The mean fall in trough ciclosporin levels seen in the major study cited was 39%.¹ This study does comment on how quickly this interaction develops but the two cases of transplant rejection occurred after 4 months and 7 months, which implies that it can possibly be slow. Long-term monitoring would therefore be a prudent precaution. The authors of this report say that sulfapyrazone is an effective alternative to allopurinol and no additional adverse effects occur including myelotoxicity when it is used with azathioprine.

Ciclosporin + Terbinafine

Terbinafine causes a small but usually clinically unimportant reduction in ciclosporin serum levels.

Clinical evidence, mechanism, importance and management

After taking terbinafine 250 mg daily for 6 to 7 days the mean AUC of a single 300-mg dose of ciclosporin was decreased by 13% and the maximum blood level was reduced by 14% in a study in 20 healthy subjects. It was suggested that as *Sandimmun* was used in the study, inter- and intra-individual variations in ciclosporin absorption caused these differences, rather than any drug interaction.^{1,2} Another study in 11 patients with kidney, heart or lung transplants found that terbinafine 250 mg daily for 12 weeks caused a small but clinically irrelevant decrease in serum ciclosporin levels.³ Another study in 30 kidney transplant patients taking ciclosporin and given terbinafine 250 mg daily for 6 to 12 weeks found no significant interaction and none of the patients required ciclosporin dose changes.⁴

Four kidney transplant patients taking ciclosporin were given terbinafine 250 mg daily for fungal skin and nail infections. Ciclosporin levels were reduced during concurrent treatment in all patients. However, in 3 of the patients ciclosporin levels remained within the therapeutic range and therefore no dose adjustment was made. One patient required an increase in the ciclosporin dose to maintain levels within the therapeutic range, and then a reduction in dose on stopping terbinafine.⁵ These studies broadly confirm previous *in vitro* work with human liver microsomal enzymes, which found that terbinafine either does not inhibit ciclosporin metabolism or only causes modest inhibition.^{6–8} In general, the changes in the

pharmacokinetics of ciclosporin appear to be clinically unimportant. However, patients whose ciclosporin levels are at the lower end of the therapeutic range should be closely monitored if they are given terbinafine.⁵

Ciclosporin + Ticlopidine

Three case reports describe marked falls in ciclosporin blood levels, and one study noted that trough ciclosporin levels were halved by ticlopidine. However, another study reported that ticlopidine did not affect ciclosporin bioavailability.

Clinical evidence

The ciclosporin blood levels of a patient with nephrotic syndrome were roughly halved on two occasions when he was given ticlopidine 500 mg daily.¹ Another two patients with kidney transplants had similar falls (one patient on two occasions) when ticlopidine 250 mg daily was given.^{2,3}

Twelve heart transplant patients were given ticlopidine 250 mg twice daily. The mean whole blood trough ciclosporin levels were noted to be halved but the mean ciclosporin dosage was not altered over a 3-month period. The neutrophil, platelet and whole blood leucocyte counts and haemoglobin levels were not significantly altered, but adverse effects included epistaxis (1 patient), haematuria (1 patient), which both necessitated a 50% dosage reduction, and neutropenia (1 patient), which resolved when the ticlopidine was withdrawn.⁴

A later study by the same group in 20 heart transplant patients given ticlopidine 250 mg daily found that the bioavailability of the ciclosporin was not clearly altered by ticlopidine, although one patient was withdrawn from the study after 3 days because of a 60% fall in ciclosporin levels, attributed to poor compliance rather than an interaction. No clinically significant adverse haematological, biochemical or ECG or echocardiography changes occurred.⁵

Mechanism

Not understood.

Importance and management

Information appears to be limited to the reports cited. It appears that the occasional patient may unpredictably have marked reductions in ciclosporin blood levels. For this reason close monitoring of ciclosporin levels is needed, particularly when ticlopidine is first added, so that any problems can be quickly identified and any dosage alterations made as needed.

Ciclosporin + Trimetazidine

Trimetazidine appears not to alter the pharmacokinetics or immunosuppressive effects of ciclosporin.

Clinical evidence, mechanism, importance and management

To find out if the concurrent use of trimetazidine and ciclosporin was associated with any adverse effects, 12 kidney transplant patients taking ciclosporin were given trimetazidine 40 mg twice daily for 5 days. No changes in the pharmacokinetics of the ciclosporin were seen, and there were no alterations in interleukin-2 concentrations or soluble interleukin-2 receptors.¹ An associated study by the same group of workers using two models (the lymphoproliferative response of normal human lymphocytes to phytohaemagglutinin and a delayed mouse hypersensitivity model) similarly found that trimetazidine did not interfere with the effects of ciclosporin.² It was concluded on the basis of these two studies that the concurrent use of ciclosporin and trimetazidine need not be avoided.

Ciclosporin + Vitamins

In a single-dose study, the ciclosporin AUC was increased by vitamin E, while in another study vitamin E decreased the ciclosporin AUC. Ciclosporin levels were also reduced by vitamin C and vitamin E with or without betacarotene.

Clinical evidence and mechanism

Ten healthy subjects were given a single 10-mg/kg oral dose of ciclosporin with and without a 0.1-mL/kg oral dose of vitamin E (d-alpha tocopheryl polyethylene glucose 1000 succinate; *Liqui-E*). The AUC of the ciclosporin increased by 60%, and it was suggested that absorption was increased due to improved solubilisation and micelle formation within the gut, or that decreased intestinal metabolism occurred.¹ In contrast, another study in 12 healthy subjects found that vitamin E 800 units daily for 6 weeks reduced the AUC of a single 5-mg/kg dose of ciclosporin by 21%.²

A study in 10 kidney transplant patients taking ciclosporin found that the addition of an antioxidant vitamin supplement for 6 months containing vitamin C 500 mg, vitamin E 400 units and betacarotene (vitamin A precursor) 6 mg daily reduced the ciclosporin blood level by 24%. An associated improvement in renal function, indicated by an increase in glomerular filtration rate (GFR) of 17%, was also seen and may have been associated with reduced ciclosporin levels. The reason for the reduction is unclear.³ A study in 56 kidney transplant patients taking ciclosporin with vitamin C 1000 mg daily and vitamin E 300 mg daily found that ciclosporin levels were significantly lower in the vitamin-treated group when compared with a placebo group. A reduction in serum creatinine was also seen.⁴

Importance and management

The clinical significance of these studies is unclear as there appear to be no published case reports of any adverse effects due to this interaction. However, in some patients, changes in ciclosporin levels may significantly affect ciclosporin immunosuppression, and dose modification may be required. Patients should be questioned about their intake of vitamin sup-

plements before starting or when taking ciclosporin, particularly if a sudden or unexplained reduction in stable ciclosporin levels occurs. More study is needed, particularly with regard to the concurrent use of standard, commercially available multivitamin preparations.

Corticosteroids + Aminoglutethimide

The effects of dexamethasone, but not hydrocortisone, can be reduced or abolished by aminoglutethimide.

Clinical evidence

(a) Dexamethasone

Aminoglutethimide 500 to 750 mg daily reduced the half-life of dexamethasone 1 mg from 264 to 120 minutes in 6 patients.¹ In another 22 patients it was found that larger doses of dexamethasone (1.5 to 3 mg daily) compensated for the increased dexamethasone metabolism caused by aminoglutethimide and complete adrenal suppression was achieved over a prolonged period.¹ Another study found a fourfold increase in dexamethasone clearance in 10 patients taking aminoglutethimide 1 g daily.²

A patient, dependent on dexamethasone due to brain oedema caused by a tumour, deteriorated rapidly, with headache and lethargy, when aminoglutethimide was also given. The problem was solved by withdrawing the aminoglutethimide and temporarily increasing the dexamethasone dosage from 6 to 16 mg daily.³

(b) Hydrocortisone

One study found that aminoglutethimide did not affect the response to hydrocortisone, and that hydrocortisone 40 mg was adequate replacement therapy in patients taking aminoglutethimide 1 g daily. In this study, aminoglutethimide did not affect the half-life of ³H-cortisol, which suggests that it does not affect hydrocortisone metabolism.² Hydrocortisone 30 mg daily is normally adequate replacement in patients taking aminoglutethimide.⁴

Mechanism

Aminoglutethimide is an enzyme inducer and it seems likely that it interacts by increasing the metabolism and clearance of dexamethasone by the liver, thereby reducing its effects.⁵

Importance and management

Information is limited but the interaction between dexamethasone and aminoglutethimide is established. The reduction in the serum corticosteroid levels can be enough to reduce or even abolish the effects of corticosteroid replacement therapy¹ or to cause loss of control of a disease condition.³ This has been successfully accommodated by increasing the dosage of the dexamethasone. Hydrocortisone is routinely used with aminoglutethimide as replacement therapy, and would seem to be a suitable alternative to dexamethasone, where clinically appropriate. Other synthetic corticosteroids are predicted to interact in the same way as dexamethasone, but this needs confirmation.

Corticosteroids + Antacids

The absorption of prednisone, and probably prednisolone, can be reduced by large but not small doses of aluminium/magnesium hydroxide antacids. Dexamethasone absorption is reduced by magnesium trisilicate.

Clinical evidence

(a) Dexamethasone

In 6 healthy subjects **magnesium trisilicate** 5 g in 100 mL of water considerably reduced the bioavailability of a single 1-mg oral dose of dexamethasone. Using the urinary excretion of 11-hydroxycorticosteroids as a measure, the reduction in bioavailability was about 75%.¹

(b) Prednisolone or Prednisone

Gastrogel (aluminium/magnesium hydroxide and magnesium trisilicate) 20 mL had no significant effect on the serum levels, half-life or AUC of 10- or 20-mg doses of prednisone in 5 patients and 2 healthy subjects.²

Another study in 8 healthy subjects given a 20-mg dose of prednisolone found that 30 mL of **Magnesium Trisilicate Mixture BP** or **Aludrox (aluminium hydroxide gel)** caused small changes in peak prednisolone levels and absorption, but these did not reach statistical significance. However, one subject given **magnesium trisilicate** had considerably reduced prednisolone levels.³ **Aluminium phosphate** has also been found not to affect prednisolone absorption.^{4,5} In contrast, another study in healthy subjects and patients given 60 mL of **Aldrox** or **Melox** (both containing **aluminium/magnesium hydroxide**) found that the bioavailability of prednisone 10 mg was reduced by 30% on average, and even by 40% in some individuals.⁶

Mechanism

The reduction in dexamethasone absorption is attributed to adsorption onto the surface of the magnesium trisilicate.^{1,7}

Importance and management

Information seems to be limited to these studies. The indication is that large doses of some antacids can reduce the bioavailability of corticosteroids, but small doses do not, although this needs confirmation. One manufacturer of dexamethasone suggests that the doses of antacid should be spaced as far as possible from the dexamethasone,⁸ while another suggests an interval of at least 2 hours.⁹ In other similar antacid interactions 2 to 3 hours is usually sufficient. The manufacturers of **deflazacort** also suggest an interval of at least 2 hours between administration of deflazacort and antacids.¹⁰ Concurrent use should be monitored to confirm that the therapeutic response is adequate. Information about the interaction of other corticosteroids and antacids is lacking.

Corticosteroids + Antithyroid drugs

Prednisolone clearance is increased by the use of carbimazole or thiamazole.

Clinical evidence

A comparative study was conducted in:

- A. 8 women taking levothyroxine with thiamazole 2.5 mg daily or carbimazole 5 mg daily for Graves' ophthalmology,
- B. 6 women taking levothyroxine who had undergone subtotal thyroidectomy, and
- C. 6 other healthy women.

All were euthyroid. It was found that the clearance of a 540 microgram/kg dose of intravenous **prednisolone** in those in group A was much greater than in groups B and C (0.37, 0.24 and 0.2 L/h.kg respectively). After 6 hours the plasma **prednisolone** levels in group A were only about 10% of those in the healthy women (group C) and was undetectable after 8 hours, whereas total and unbound **prednisolone** levels were much higher and measurable over the 10 hour study period in groups B and C.¹

In another group of previously hyperthyroid patients, now euthyroid because of carbimazole treatment, the total **prednisolone** clearance was 0.4 L/hour.¹

Mechanism

Not established. It seems possible that the thiamazole and carbimazole increase the metabolism of the prednisolone by the liver microsomal enzymes, thereby increasing its clearance.

Importance and management

Direct information seems to be limited to this study, although the authors point out that there is a clinical impression that higher doses of prednisolone are needed in patients with Graves' disease. Be alert for the need to use higher doses of prednisolone in patients taking either thiamazole or carbimazole. Also note that a hypothyroid state may increase corticosteroid effects, and thus corticosteroids are cautioned in hypothyroid patients.

Corticosteroids + Aprepitant

In the short-term, aprepitant increases the plasma levels of dexamethasone and methylprednisolone.

Clinical evidence

(a) Dexamethasone

In a crossover study in 20 subjects, aprepitant 125 mg on day one, and 80 mg on days 2 to 5 given with a standard dexamethasone regimen (20 mg on day one, and 8 mg on days 2 to 5) increased the dexamethasone AUC by 2.2-fold. When the same dose of aprepitant was given with a reduced-dose dexamethasone regimen (12 mg on day one, and 4 mg on days 2 to 5), the AUC of dexamethasone was similar to that seen with the standard dexamethasone regimen given alone. All regimens in this study also included intravenous ondansetron 32 mg on day one.¹

(b) Methylprednisolone

In a crossover study in 10 subjects, aprepitant 125 mg on day one, and 80 mg on days 2 and 3, given with a methylprednisolone regimen (125 mg intravenously on day one, and 40 mg orally on days 2 and 3), increased the AUC of methylprednisolone by 1.3-fold on day one and 2.5-fold on day 3.¹

Mechanism

Aprepitant is a moderate inhibitor of the cytochrome P450 isoenzyme CYP3A4, and probably raises levels of these corticosteroids in the short-term by inhibiting their metabolism via CYP3A4. However, if the corticosteroids were given longer term, at later time points within 2 weeks after starting aprepitant, an inductive effect on CYP3A4 may occur; see 'Benzodiazepines + Aprepitant', p.721 for a more detailed explanation.

Importance and management

An established interaction of clinical importance. The manufacturer^{2,3} recommends that the usual dose of dexamethasone should be reduced by about 50% when given with aprepitant (although note that the dose given

in the manufacturer's dexamethasone/aprepitant antiemetic regimen accounts for the interaction). In clinical studies a dexamethasone regimen of 12 mg on day one and 8 mg on days 2 to 4 was used, and this is the recommended regimen. The manufacturer recommends that the usual dose of intravenous methylprednisolone should be reduced by 25%, and the usual oral dose by 50%, when given with aprepitant. However, the manufacturer also notes that during continuous treatment with methylprednisolone, corticosteroid levels would be expected to *decrease* at later time points within 2 weeks of starting aprepitant and the effect is expected to be greater if methylprednisolone is given orally rather than intravenously.

Corticosteroids + Azoles; Itraconazole

There is some evidence to suggest that itraconazole can increase the levels and/or effects of inhaled budesonide, the active metabolite of ciclesonide, deflazacort, dexamethasone and methylprednisolone, and, to a lesser extent, prednisolone and prednisone. A few case reports describe the development of secondary Cushing's syndrome in patients taking itraconazole and budesonide, fluticasone and deflazacort.

Clinical evidence

(a) Budesonide

A 70-year-old patient receiving long-term treatment for asthma, which included inhaled budesonide 1.2 to 1.6 mg daily and diltiazem, developed Cushing's syndrome after taking itraconazole 200 mg twice daily for 8 weeks for a fungal infection of the skin and subcutaneous tissues. Corticosteroid levels may already have been increased by the use of 'diltiazem', (p.1054), with the effects becoming more pronounced after starting itraconazole. Budesonide and itraconazole were discontinued but she subsequently required long-term oral hydrocortisone for secondary adrenal insufficiency. A recurrence of the fungal infection was treated with voriconazole 200 mg twice daily, which appeared not to interact with the oral hydrocortisone.¹

Two other reports describe the development of Cushing's syndrome in patients with cystic fibrosis given inhaled budesonide, and then itraconazole for bronchopulmonary aspergillosis.² One patient was also taking clarithromycin, which may have contributed to the increased budesonide effects (see also 'Corticosteroids + Macrolides', p.1056). The other patient was a 4-year-old boy who developed Cushing's syndrome 2 weeks after starting treatment with itraconazole 200 mg daily and inhaled budesonide 400 micrograms daily.³

In a double-blind, randomised, crossover study, 10 healthy subjects were given 1 mg of inhaled budesonide over a period of 2 minutes after taking itraconazole 200 mg daily for 5 days. The AUC of budesonide was increased 4.2-fold by the itraconazole, and the plasma cortisol levels of the patients were suppressed, indicating an increased budesonide effect.⁴ Another study compared the results of the ACTH (tetracosactide) test in 25 patients taking itraconazole 400 to 600 mg daily and high-dose inhaled budesonide 800 micrograms to 1.6 mg daily with patients receiving either drug alone. Adrenal insufficiency was detected in 44% of those treated with both drugs, but in none of the patients taking itraconazole or budesonide alone.⁵

(b) Ciclesonide

The manufacturer notes that giving itraconazole with ciclesonide may increase serum levels of the active metabolite of ciclesonide (seen with ketoconazole) and that the risk of adverse effects such as Cushing's syndrome may be increased.⁶

(c) Deflazacort

A patient with cystic fibrosis taking deflazacort developed Cushing's syndrome soon after starting itraconazole 200 mg twice daily. The effects gradually disappeared when the itraconazole was stopped.⁷

(d) Dexamethasone

A study in 8 healthy subjects found that itraconazole 200 mg daily for 4 days increased the AUC, peak plasma level, and elimination half-life of a single 4.5-mg dose of dexamethasone by 3.7-, 1.7-, and 2.8-fold, respectively. In another phase of the study itraconazole decreased the systemic clearance of intravenous dexamethasone 5 mg by 68% and increased the AUC and elimination half-life 3.3- and 3.2-fold, respectively. The adrenal-suppressant effects of dexamethasone were enhanced by itraconazole.⁸

(e) Fluticasone

A case report describes profound adrenal suppression with secondary Cushing's syndrome in a patient with cystic fibrosis given itraconazole 200 mg twice daily and low-dose inhaled fluticasone 250 micrograms daily.⁹ Another report describes a patient with asthma who had been taking inhaled fluticasone 1 to 1.5 mg twice daily for 2 years who developed secondary Cushing's syndrome and adrenal suppression 6 weeks after starting itraconazole (initially 100 mg daily then 200 mg daily).¹⁰

(f) Methylprednisolone

A study in 14 healthy subjects found that itraconazole 400 mg for one day and then 200 mg daily for the next 3 days, increased the AUC of a single 48-mg dose of methylprednisolone by more than 2.5-fold.¹¹ Other studies in healthy subjects have found that itraconazole decreases the clearance, and increases the elimination half-life and AUC of both oral and intravenous methylprednisolone. Enhanced adrenal suppression also occurred.^{12,13}

A man with a lung transplant taking methylprednisolone, ciclosporin and azathioprine was given itraconazole 200 mg twice daily to treat a suspected *Aspergillus fumigatus* infection. Three weeks later signs of corticosteroid toxicity developed, namely myopathy (confirmed by electromyography) and diabetes mellitus. Ten days after stopping the itraconazole the muscle force had improved and the daily dose of insulin had decreased from 120 to 20 units.¹⁴

(g) Prednisolone or Prednisone

Six patients with allergic bronchopulmonary aspergillosis (3 with underlying cystic fibrosis and 3 with severe asthma) were given itraconazole 200 mg twice daily for 1 to 6 months. Four of the patients also taking systemic prednisone were able to reduce the corticosteroid dosage by 44% (from 43 to 24 mg daily) without any clinical deterioration.¹⁵ Another study found no clinically significant pharmacokinetic interaction between itraconazole (400 mg on day one then 200 mg daily for 3 days) and a single 60-mg dose of prednisone in healthy subjects.¹¹

A study in 10 healthy subjects found that itraconazole 200 mg daily for 4 days increased the AUC of a single 20-mg oral dose of prednisolone by 24%, but this was considered to be of limited clinical significance.¹⁶

Mechanism

It seems probable that the itraconazole inhibits the metabolism of these corticosteroids by the cytochrome P450 isoenzyme CYP3A4 in the liver leading to higher levels and therefore increased effects. The active metabolite of ciclesonide is also metabolised by CYP3A4.⁶ Prednisolone is less likely than methylprednisolone to interact with CYP3A4 inhibitors.¹⁶

Importance and management

These interactions appear to be established. There is currently too little data to assess the incidence, but it would be prudent to monitor the outcome of adding itraconazole to any patient taking deflazacort, dexamethasone or methylprednisolone, being alert for the need to reduce the steroid dosage. The manufacturers of ciclesonide suggest that the concurrent use of itraconazole should be avoided unless the benefits outweigh the risks.⁶ Adrenal function should also be monitored in patients receiving inhaled budesonide or fluticasone given itraconazole, as Cushing's syndrome has been reported in a few patients during concurrent use. Itraconazole appears to interact with prednisone and prednisolone to a lesser extent, but the effects may still be clinically important in some patients. Information about other corticosteroids is lacking but good monitoring seems advisable with all of them.

Corticosteroids + Azoles; Ketoconazole

Ketoconazole reduces the metabolism and clearance of methylprednisolone. Ketoconazole may increase levels of the active metabolite of ciclesonide. Ketoconazole modestly increases the systemic effect of inhaled budesonide and possibly fluticasone, and markedly increases the AUC of oral budesonide. The situation with prednisone and prednisolone is uncertain: studies have shown some moderate pharmacokinetic effects, but this does not appear to alter the action of either drug.

Clinical evidence*(a) Budesonide*

Sixteen healthy subjects were given a single 1-mg inhaled dose of budesonide after taking ketoconazole 200 mg daily for 2 days. Plasma cortisol levels and urinary cortisol excretion were used as a measure of how much budesonide was absorbed systemically, and ketoconazole was found to cause a 37% decrease in the AUC₀₋₂₄ of cortisol.¹

Another study in 8 healthy subjects found that the AUC of a single 3-mg oral dose of budesonide was increased 6.5-fold when it was given with the last dose of ketoconazole 200 mg daily for 4 days. When budesonide was given 12 hours before the last dose of ketoconazole, the AUC was increased 3.8-fold.²

(b) Ciclesonide

The manufacturer notes that the use of ketoconazole with ciclesonide increase the serum levels of the active metabolite of ciclesonide 3.5-fold and that an increased risk of adverse effects such as cushingoid syndrome cannot be excluded.³

(c) Fluticasone

Sixteen healthy subjects were given a single 500-microgram inhaled dose of fluticasone after taking ketoconazole 200 mg daily for 2 days. Plasma cortisol levels and urinary cortisol excretion were used as a measure of how much fluticasone was absorbed systemically, and it was found that ketoconazole had no effect on fluticasone absorption.¹ However, the manufacturers of fluticasone cite a study in which the exposure to fluticasone was increased by 150% by ketoconazole, which resulted in reductions in plasma cortisol levels.⁴

(d) Methylprednisolone

In 6 healthy subjects ketoconazole 200 mg daily for 6 days increased the mean AUC of a single 20-mg intravenous dose of methylprednisolone by 135% and decreased the clearance by 60%. The 24-hour cortisol AUC was reduced by 44%.⁵ These findings were confirmed in another study by the same group of workers.⁶

(e) Prednisolone or Prednisone

In 10 healthy subjects ketoconazole 200 mg daily for 6 to 7 days caused a 50% rise in the levels of both total and unbound prednisolone, following a dose of either oral prednisone or intravenous prednisolone.⁷ In contrast, two other studies found that ketoconazole 200 mg daily for 6 days did not affect either the pharmacokinetics or the pharmacodynamics of prednisolone, as measured by the suppressive effects on serum cortisol, blood basophil and helper T-lymphocyte values of prednisolone.^{8,9}

Mechanism

Ketoconazole inhibits the cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and liver so that the metabolism of some corticosteroids is reduced and therefore their levels increase. The active metabolite of ciclesonide is also metabolised by CYP3A4,³ and it may therefore be similarly affected.

Importance and management

The interaction between methylprednisolone and ketoconazole appears to be established and clinically important. A 50% reduction in the dose of methylprednisolone was recommended by the authors of one study.⁶ It has been pointed out that increased corticosteroid serum levels have an increased immunosuppressive effect, which may be undesirable in those with a fungal infection needing treatment with ketoconazole.⁷ The situation with prednisone and prednisolone is as yet uncertain,^{10,11} and more study is needed. The study using inhaled budesonide indicates that ketoconazole increases the systemic effect of inhaled budesonide. Some manufacturers^{12,13} recommend that if the combination cannot be avoided the interval between giving the two drugs should be as great as possible; a reduction in the dose of budesonide should also be considered. In addition, a significant interaction may occur with oral budesonide; the effects of ketoconazole on budesonide may be reduced by about half by separating the administration of the two drugs by 12 hours.² The manufacturers suggest reducing the oral budesonide dose if adverse effects occur.¹⁴

The situation with inhaled fluticasone is less clear, with one study finding an effect and another finding no effect. The manufacturers of fluticasone suggest that caution is warranted and where possible long-term concurrent use should be avoided.⁴ Similarly, the manufacturer of ciclesonide suggests that it should not be used with ketoconazole unless the benefits outweigh the risks.³ It would seem prudent to bear this possible interaction in mind if any corticosteroid is given with ketoconazole. Patients should be warned to be alert for any evidence of increased corticosteroid effects (such as moon face, weight gain, hyperglycaemia) and to seek medical advice if these occur.

Corticosteroids + Azoles; Voriconazole

Voriconazole increases plasma levels of prednisolone but not to a clinically significant extent. A case report notes that voriconazole appears not to interact with oral hydrocortisone.

Clinical evidence

In healthy subjects, voriconazole 200 mg twice daily for 30 days increased the maximum plasma levels and AUC of a single 60-mg dose of **prednisolone** by 11% and 34%, respectively.^{1,2}

A patient who developed Cushing's syndrome and secondary adrenal insufficiency during treatment with itraconazole and inhaled budesonide was given oral **hydrocortisone** replacement. The patient was then also given voriconazole 200 mg twice daily for 3 months without any apparent effects on the **hydrocortisone**.³

Mechanism

Voriconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, but its inhibitory effects are much less than those of itraconazole.³ Therefore voriconazole is less likely than 'itraconazole', (p.1050), or 'ketoconazole', (p.1051) to affect the pharmacokinetics of the corticosteroids.

Importance and management

No dosage adjustment of the corticosteroid is said to be necessary if voriconazole is given with prednisolone,^{1,2} and this also appears to be the case if voriconazole is given with hydrocortisone.³

Corticosteroids + Barbiturates

The therapeutic effects of systemic dexamethasone, methylprednisolone, prednisone and prednisolone are decreased by phenobarbital. Other barbiturates, including primidone, probably interact similarly.

Clinical evidence*(a) Dexamethasone*

A 14-year-old girl with congenital adrenal hyperplasia taking dexamethasone rapidly became over-treated (weight gain, signs of hypercortisolism) when treatment with **primidone** 250 mg twice daily was withdrawn over a month. Satisfactory control was only achieved when the dexamethasone dosage was reduced threefold.¹ A reduction in the effects of dexamethasone has also been described when another patient with congenital adrenal hyperplasia was given **primidone** for petit mal seizures.²

(b) Methylprednisolone

Phenobarbital increased the clearance of methylprednisolone in asthmatic children by 209%.³

(c) Prednisolone or Prednisone

Three prednisone-dependent patients with bronchial asthma taking prednisone 10 to 40 mg daily had a marked worsening of their symptoms within a few days of starting to take **phenobarbital** 120 mg daily. There was a deterioration in their pulmonary function tests (FEV₁, degree of bronchospasm) and a rise in eosinophil counts, all of which improved when the **phenobarbital** was stopped. The prednisone clearance was increased by the **phenobarbital**.⁴ In a group of 75 children with kidney transplants taking azathioprine and prednisone, the incidence of graft failure was increased in those taking **phenobarbital** 60 to 120 mg daily. Two of the 11 epileptic children were also taking phenytoin 100 mg daily.⁵ Another study in renal

transplant patients found that prednisolone elimination is increased by **phenobarbital**.⁶

Nine patients with rheumatoid arthritis taking prednisolone 8 to 15 mg daily had strong evidence of clinical deterioration (worsening joint tenderness, pain, morning stiffness, fall in grip strength) when they took **phenobarbital** for 2 weeks (plasma levels 0 to 86.2 micromol/L). The prednisolone half-life fell by 25%.⁷

In contrast, the prednisone requirements of children were unaltered when they took a compound preparation containing **phenobarbital** 24 mg daily.⁸

Mechanism

Phenobarbital is a recognised potent liver enzyme inducer that increases the metabolism of corticosteroids, thereby reducing their effects. Pharmacokinetic studies have shown that phenobarbital reduces the half-lives of these corticosteroids and increases their clearances by 40 to 209%.^{3,4,9} Primidone interacts in a similar way because it is metabolised in the body to phenobarbital.¹

Importance and management

The interaction between the corticosteroids and phenobarbital is well documented, well established and of clinical importance. Concurrent use need not be avoided but the outcome should be monitored. Increase the corticosteroid dosage as necessary. The extent of the increase is variable. Dexamethasone,⁴ **hydrocortisone**,¹⁰ methylprednisolone,^{3,9} prednisone^{4,5} and prednisolone^{3,7} are all known to be affected. Prednisone and prednisolone appear to be less affected than methylprednisolone and may be preferred.³ Be alert for the same interaction with other corticosteroids and other barbiturates, which also are enzyme-inducers, although direct evidence seems to be lacking. The dexamethasone adrenal suppression test may be expected to be unreliable in those taking phenobarbital, just as it is with phenytoin, another potent enzyme-inducer. See 'Corticosteroids + Phenytoin', p.1059.

Corticosteroids + Bile-acid binding resins

Colestyramine and possibly colestipol reduce the absorption of oral hydrocortisone. Colestyramine does not appear to affect prednisolone absorption.

Clinical evidence

(a) Colestyramine

In 10 healthy subjects, colestyramine 4 g reduced the AUC of a 50-mg oral dose of **hydrocortisone** by 43%. Peak levels were reduced and delayed (by about 50 minutes).¹ Two of the subjects were given both 4 g and 8 g of colestyramine, and their AUCs were reduced by 47% and 59% by the 4-g dose and by 97% and 86% by the 8-g dose.¹

In contrast, an 8-g dose of colestyramine did not affect the bioavailability of **prednisolone** in 2 patients receiving long-term **prednisolone**.²

(b) Colestipol

A man with hypopituitarism taking **hydrocortisone** 20 mg each morning and 10 mg each evening became lethargic, ataxic, and developed headaches (all signs of **hydrocortisone** insufficiency) within 4 days of starting to take colestipol 15 g three times daily for hypercholesterolaemia. He re-

sponded rapidly when given intravenous **hydrocortisone** 100 mg, and was discharged with the colestipol replaced by a statin.³

Mechanism

It seems that hydrocortisone can become bound to colestyramine or colestipol in the gut, thereby reducing its absorption.^{1,4}

Importance and management

Information is limited, but these interactions with hydrocortisone appear to be established (they are consistent with the interactions of both of these bile-acid resins with other drugs). Separate the administration of the drugs as much as possible to minimise admixture in the gut, although the authors of one report warn that this may not necessarily avoid this interaction because their data show that the colestyramine may remain in the gut for a considerable time.¹ The usual recommendation is to give other drugs one hour before or 4 to 6 hours after taking colestyramine, and one hour before or 4 hours after taking colestipol. Monitor the effects and increase the hydrocortisone dosage, or use an alternative to colestyramine, if necessary. Prednisolone may be a non-interacting alternative, but the evidence for this is extremely limited.

Corticosteroids + Caffeine

The results of the dexamethasone suppression test can be falsified by the acute ingestion of caffeine but chronic caffeine use does not appear to have an effect.

Clinical evidence, mechanism, importance and management

In one study, 22 healthy subjects and 6 depressed patients were given a single 480-mg dose of caffeine or placebo at 2 pm following a single 1-mg dose of **dexamethasone** given at 11 pm the previous evening. Caffeine significantly increased the cortisol levels following the **dexamethasone** dose; cortisol levels taken at 4 pm were about 146 nanomol/L with caffeine, compared with about 64 nanomol/L with placebo.¹ Thus the equivalent of about 4 to 5 cups of coffee may effectively falsify the results of the **dexamethasone** suppression test. However, in a study in 121 patients with depression, there was no correlation between chronic low to high intake of caffeine (6 mg to 2.3 g daily) and cortisol levels at 8 am, 4 pm or 11 pm on the day after a 1-mg dose of **dexamethasone** given at 11 pm the previous evening. It was suggested that chronic caffeine intake produces tolerance to the effects of acute caffeine on the hypothalamic-pituitary-adrenal (HPA) axis.²

Corticosteroids + Carbamazepine

The clearance of dexamethasone, methylprednisolone and prednisolone is increased in patients taking carbamazepine, and the results of the dexamethasone suppression test may be invalid in those taking carbamazepine.

Clinical evidence

A study in 8 patients receiving long-term treatment with carbamazepine found that the elimination half-life of **prednisolone** was about 45 minutes shorter, and the clearance was 42% higher, than in 9 healthy subjects not taking carbamazepine.¹

A study in asthmatic children found that carbamazepine increased the clearance of **prednisolone** by 79% and increased the clearance of **methylprednisolone** by 342%.² A patient taking carbamazepine and valproate required high-dose **prednisolone** (20 to 60 mg daily) for polymyalgia

rheumatica. It was noted that when carbamazepine was discontinued her response to **prednisolone** improve, allowing the dose to be reduced to 20 mg then 10 mg daily.³

A report describes two patients suspected of having Cushing's syndrome because the overnight suppression test with **dexamethasone** 1 mg had not suppressed their cortisol levels. Further investigation found no clinical evidence of Cushing's syndrome and the false-positive test results were attributed to the fact that both patients were taking carbamazepine 400 mg three times daily at the time of the test. The test was repeated in one patient 3 weeks after carbamazepine was stopped and it indicated normal cortisol suppression.⁴ A study in 8 healthy subjects found that, in the presence of carbamazepine 800 mg daily, the dosage of **dexamethasone** needed to suppress cortisol secretion (as part of the **dexamethasone** adrenal suppression test) was increased two to fourfold.⁵ A further study found that it took 2 to 13 days for false-positive results to occur after carbamazepine was started, and 3 to 12 days to recover when the carbamazepine was stopped.⁶

Mechanism

Carbamazepine induces liver enzymes, which results in the increased metabolism of the steroids.

Importance and management

Information is limited but the interaction appears to be established. Patients taking carbamazepine are likely to need increased doses of dexamethasone, methylprednisolone or prednisolone. Prednisolone is less affected than methylprednisolone and is probably preferred. The same interaction seems likely with other corticosteroids but more study is needed to confirm this. Note that **hydrocortisone** and **prednisone** are affected by another potent enzyme inducer, 'phenobarbital', (p.1052), and would therefore also be expected to interact with carbamazepine.

Corticosteroids + Diltiazem

Diltiazem increases the AUC of intravenous and oral methylprednisolone, but the clinical significance of this is unclear.

Clinical evidence

In a study, 5 healthy subjects were given diltiazem 180 mg daily for 4 days, with and without *intravenous* **methylprednisolone** 300 micrograms/kg (based on ideal body-weight) on day 5. Diltiazem increased the AUC of **methylprednisolone** by 50%, prolonged its half-life by 37% and reduced the **methylprednisolone** clearance by 33%. Although the morning cortisol concentration was only 12% of that during the placebo phase, overall the suppressive effects of **methylprednisolone** on cortisol excretion were unchanged.¹ Another similar study in which patients were given diltiazem and a single 16-mg oral dose of **methylprednisolone** found much larger effects: the AUC of **methylprednisolone** was increased 2.6-fold, and the morning cortisol excretion was only 12% of that in the absence of diltiazem,² suggesting an enhanced effect.

Mechanism

Diltiazem is an inhibitor of the cytochrome P450 isoenzyme CYP3A4. As methylprednisolone is metabolised by CYP3A4 any inhibition of its activity would be expected to raise methylprednisolone levels.^{1,2} It has been suggested that P-glycoprotein may also play a role.^{1,2} Inhibition of intestinal/hepatic CYP3A4 may increase the oral bioavailability of methylprednisolone, which could contribute to the pharmacokinetic differences

seen in the interaction when methylprednisolone is given orally rather than intravenously.

Importance and management

Information about the interaction between diltiazem and methylprednisolone seems limited to these two studies, but the effect of concurrent use is clear. However, the clinical significance of the raised methylprednisolone levels has not been established. Monitoring for an increase in the adverse effects of methylprednisolone, as suggested by one of the authors, seems a prudent measure.¹

Corticosteroids + Diuretics; Potassium-depleting

Since both corticosteroids and the loop or thiazide diuretics can cause potassium loss, severe depletion is possible if they are used together.

Clinical evidence, mechanism, importance and management

There seem to be no formal clinical studies about the extent of the additive potassium depletion that can occur when potassium-depleting diuretics and corticosteroids are given together but an exaggeration of the potassium loss undoubtedly occurs (e.g. seen with **hydrocortisone** and **furosemide**¹). One study looking at hypokalaemia with potassium-depleting diuretics found that corticosteroids were a significant risk factor for hypokalaemic events; 19.9% of patients taking a potassium-depleting diuretic developed hypokalaemia, whereas 31.1% of patients taking a potassium-depleting diuretic and a corticosteroid developed hypokalaemia.² Hypokalaemia in patients taking potassium-depleting diuretics should be corrected before a corticosteroid is started. Concurrent use should be well monitored and the potassium intake increased as appropriate to balance this loss.

The greatest potassium loss occurs with the naturally occurring corticosteroids such as **cortisone** and **hydrocortisone**. **Corticotropin (ACTH)**, which is a pituitary hormone, and **tetracosactrin** (a synthetic polypeptide) stimulate corticosteroid secretion by the adrenal cortex and can thereby indirectly cause potassium loss. **Fludrocortisone** also causes potassium loss. The synthetic corticosteroids (**glucocorticoids**) have a less marked potassium-depleting effect and are therefore less likely to cause problems. These include **betamethasone**, **dexamethasone**, **prednisolone**, **prednisone** and **triamcinolone**.

The potassium-depleting diuretics (i.e. **loop diuretics** or **thiazide** and related diuretics) are listed in 'Table 26.1', (p.944). **Acetazolamide**, a weak diuretic, has also been predicted to cause hypokalaemia in the presence of corticosteroids. However, hypokalaemia seen with **acetazolamide** is rarely clinically significant, and therefore the risks are lower

Corticosteroids + Ephedrine

Ephedrine increases the clearance of dexamethasone.

Clinical evidence, mechanism, importance and management

Nine asthmatic patients had a 40% increase in the clearance and a similar reduction in the half-life of **dexamethasone** when they were given ephedrine 100 mg daily for 3 weeks.¹ This would be expected to reduce the overall effects of **dexamethasone**, but this requires confirmation. Be alert

for any evidence that the **dexamethasone** effects are reduced if both drugs are given. It is not clear whether other corticosteroids behave similarly.

1. Brooks SM, Sholiton LJ, Werk EE, Altenau P. The effects of ephedrine and theophylline on dexamethasone metabolism in bronchial asthma. *J Clin Pharmacol* (1977) 17, 308–18.

Corticosteroids + Fluoxetine

Fluoxetine does not affect the pharmacokinetics of prednisolone or its effects on cortisol suppression.

Clinical evidence, mechanism, importance and management

In healthy subjects, fluoxetine 20 mg daily for 5 days then 60 mg daily for 9 days did not significantly affect the pharmacokinetics of a single 40-mg dose of **prednisolone succinate**, given as an intravenous bolus, or the duration of cortisol suppression.¹ Fluoxetine is a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6 but it also inhibits other isoenzymes including CYP3A4 and thus may inhibit the metabolism of corticosteroids that are CYP3A4 substrates. However, **prednisolone** is less likely than other corticosteroids, such as **methylprednisolone**, to interact with CYP3A4 inhibitors.² No clinically important interaction is likely if **prednisolone** and fluoxetine are given concurrently. The situation with other corticosteroids that may be more likely to interact is not known. More study is needed.

Corticosteroids + Glycyrrhizin (Liquorice)

Glycyrrhizin can reduce the clearance of prednisolone.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects found that after taking 50-mg oral doses of glycyrrhizin every 8 hours for 4 doses, followed by a bolus injection of **prednisolone hemisuccinate** 96 micrograms/kg, the AUC of total **prednisolone** was increased by 50% and the AUC of free **prednisolone** was increased by 55%.¹ This confirms the findings of two previous studies in which the glycyrrhizin was given orally,¹ or by intravenous infusion,² and one study where the route of administration is not clear.³

A study that included 4 patients taking **hydrocortisone** found glycyrrhizin also increased the corticosteroid AUC and half-life.³

The probable reason for this reaction is that glycyrrhizin inhibits the metabolism of **prednisolone** by the liver. In one of the studies it was also found that glycyrrhizin increased the effects of **prednisolone** in some patients with rheumatoid arthritis and polyarteritis nodosa.²

The clinical importance of these observations is uncertain, but some increase in effects may be beneficial whereas excess effects may be toxic. Concurrent use should be well monitored.

Corticosteroids + Grapefruit juice

Grapefruit juice increases plasma levels of methylprednisolone and is predicted to increase plasma levels of rectal budesonide. Grapefruit juice does not affect the pharmacokinetics of prednisone or prednisolone.

Clinical evidence, mechanism, importance and management

(a) Budesonide

One of the manufacturers of rectal budesonide predict that grapefruit juice will increase budesonide levels and therefore advise that concurrent use should be avoided. Even though budesonide plasma levels are higher after

rectal use than after oral or inhaled use, this seems a very cautious approach.¹

(b) Methylprednisolone

In a crossover study, 10 healthy subjects were given either double-strength grapefruit juice 200 mL, or water, three times daily for 2 days. On day 3, grapefruit juice 200 mL or water was given with, and 30 and 90 minutes after, a single 16-mg dose of methylprednisolone. Grapefruit juice increased the AUC and peak plasma level of methylprednisolone by 75% and 27%, respectively. The time to reach peak levels was increased from 2 to 3 hours and the elimination half-life was increased by 35%. Plasma cortisol levels after methylprednisolone was given with grapefruit juice or water were not significantly different, although grapefruit juice slightly decreased plasma cortisol levels before the morning dose of methylprednisolone. As the effects on plasma cortisol levels were slight this interaction is unlikely to be of clinical significance in most patients' although the authors note that in some sensitive subjects large amounts of grapefruit juice might enhance the effects of oral methylprednisolone.²

(c) Prednisolone or Prednisone

A study in 12 kidney transplant patients taking ciclosporin and corticosteroids found that grapefruit juice, given every 3 hours for 30 hours, increased ciclosporin levels, but had no significant effect on the AUC of prednisone or prednisolone. It was concluded that grapefruit juice does not affect the metabolism of prednisone or prednisolone.³ No special precautions are therefore needed if patients drink grapefruit juice while taking these corticosteroids.

Corticosteroids + H₂-receptor antagonists

Cimetidine does not interact with prednisolone, prednisone or dexamethasone, and ranitidine does not interact with prednisone.

Clinical evidence, mechanism, importance and management

Prednisone is a pro-drug, which must be converted to prednisolone within the body to become active. A double-blind crossover study in 9 healthy subjects found that **cimetidine** 300 mg every 6 hours or **ranitidine** 150 mg twice daily for 4 days did not significantly alter the pharmacokinetics of prednisolone after a single 40-mg oral dose of **prednisone**.¹ Another double-blind, crossover study found that **cimetidine** 1 g daily only caused minor changes in plasma **prednisolone** levels following a 10-mg dose of enteric-coated **prednisolone**.² Similarly, another study found that **cimetidine** 600 mg twice daily for 7 days had no effect on the pharmacokinetics of a single 8-mg intravenous dose of **dexamethasone sodium phosphate**.³

There would therefore seem to be no reason for avoiding concurrent use. Information about other corticosteroids appears to be lacking, but no interaction is anticipated.

1. Sirgo MA, Rocci ML, Ferguson RK, Eshelman FN, Vlasses PH. Effects of cimetidine and ranitidine on the conversion of prednisone to prednisolone. *Clin Pharmacol Ther* (1985) 37, 534–8.

Corticosteroids + Hormonal contraceptives and Sex hormones

The serum levels of prednisone, prednisolone, cloprednol, methylprednisolone and possibly other corticosteroids are increased by oral contraceptives. In theory, both the therapeutic and toxic effects would be expected to be increased, but in practice it is uncertain whether these changes are important. Flucortolone and oral budesonide levels were not affected by oral contracep-

tives. Prasterone did not affect the pharmacokinetics of prednisone or the effects of prednisolone on cortisol secretion. Progesterone appears not to affect the metabolism of prednisolone.

Clinical evidence

(a) Oral contraceptives

1. *Budesonide*. In 20 women taking an oral contraceptive (**ethinylestradiol/desogestrel**) the plasma levels of an oral budesonide 4.5 mg daily for 7 days, and cortisol suppression were no different, when compared with 20 women not taking an oral contraceptive.¹

2. *Cloprednol*. The clearance of cloprednol 20 mg was decreased by about one-third in 7 women taking an oral contraceptive (**ethinylestradiol/norethisterone**), when compared with women not taking an oral contraceptive.²

3. *Fluocortolone*. A study in 7 women found that the pharmacokinetics of fluocortolone 20 mg were unaffected by an oral contraceptive (**ethinylestradiol/norethisterone**).³

4. *Methylprednisolone*. A study in two groups of 6 patients found that the clearance of methylprednisolone was decreased to about half in the group taking oral contraceptives, when compared with the group not taking oral contraceptives. The oral contraceptive group were less sensitive to the suppressive effects of methylprednisolone on the secretion of cortisol, and had more suppression of basophils, but no changes in the T-helper cell response patterns.⁴

5. *Prednisolone or prednisone*. In a placebo-controlled study, 20 healthy women took an oral contraceptive (**ethinylestradiol/desogestrel** 30/150 micrograms) for at least 4 months before being given prednisolone 20 mg daily for 7 days. The prednisolone AUC and steady-state levels were 2.3-fold higher, when compared with those in 20 women not taking oral contraceptives.¹ Several other studies have found similar results, with the prednisolone AUC increasing 1.6- to 6-fold,^{5,6} and the clearance reducing by about 35 to 85%⁵⁻¹⁰ in the presence of oral contraceptives containing **ethinylestradiol** or **mestranol** and various progestogens such as **levonorgestrel**, **norgestrel** and **norethisterone**. Similarly, a 2.3-fold increase in the AUC of prednisolone and a 45% decrease in its clearance was seen when prednisone was given to women taking an oral contraceptive.¹¹

(b) Prasterone

In a study in 14 healthy women, prasterone 200 mg daily for one menstrual cycle (approximately 28 days) did not affect the pharmacokinetics of a single 20-mg dose of **prednisone** or its inhibition of cortisol secretion.¹²

(c) Progesterone

Intravenous and oral **prednisolone** was given to 6 post-menopausal women before and after they took progesterone 5 mg for 2 months. The pharmacokinetics of the **prednisolone** were not significantly altered.¹³

Mechanism

Not understood. The possibilities include a change in the metabolism of the corticosteroids, or in their binding to serum proteins.¹¹ The absence of an interaction with progesterone suggests that the oestrogenic component of the oral contraceptives is possibly responsible for any interaction.¹³

Importance and management

It is established that the pharmacokinetics of some corticosteroids are affected by oral contraceptives, but the clinical importance of any such changes is not known. The therapeutic and adverse effects would be expected to be increased but there appear to be no clinical reports of adverse reactions arising from concurrent use. In fact the authors of one study⁴ concluded that women can be dosed similarly with methylprednisolone irrespective of oral contraceptive use.

However, until more is known it would be prudent to bear this interaction in mind when using any corticosteroid and oral contraceptive together. Only prednisone, prednisolone, cloprednol and methylprednisolone have been reported to interact and other corticosteroids possibly behave similarly, the exception apparently being fluocortolone and oral budesonide. Progesterone appears not to interact with prednisolone.

Corticosteroids + Macrolides

Troleandomycin and, to a lesser extent, clarithromycin and erythromycin can reduce the clearance of methylprednisolone, thereby increasing both its therapeutic and adverse effects. A patient receiving long-term clarithromycin developed Cushing's syndrome after starting treatment with inhaled budesonide. There appears to be no pharmacokinetic interaction between erythromycin and inhaled ciclesonide. Similarly, prednisolone appears not to be affected by macrolides, except possibly in those also taking enzyme-inducers such as phenobarbital. Isolated case reports describe the development of acute mania and psychosis in two patients, apparently due to an interaction between prednisone and clarithromycin.

Clinical evidence

(a) Budesonide

A 40-year-old woman with cystic fibrosis given **clarithromycin** 500 mg twice daily for 4 years for a *Mycobacterium abscessus* infection developed Cushing's syndrome with adrenal suppression 6 weeks after starting to use inhaled budesonide 400 micrograms daily. A slow rise in morning free cortisol levels was found 4 weeks after stopping budesonide, but she died 8 weeks later of severe respiratory failure.¹

(b) Ciclesonide

In a crossover study, healthy subjects were given a single 500-mg dose of **erythromycin** and inhaled ciclesonide 640 micrograms, alone or together. Concurrent use did not alter the pharmacokinetics of either drug.²

(c) Methylprednisolone

1. *Azithromycin*. A review by the manufacturers briefly mentions that azithromycin did not alter the pharmacokinetics of methylprednisolone.³

2. *Clarithromycin*. A study in 6 asthmatic patients found that clarithromycin 500 mg twice daily for 9 days reduced the clearance of a single dose of methylprednisolone by 65% and resulted in significantly higher plasma methylprednisolone levels.⁴

3. *Erythromycin*. A study in 9 asthmatic patients aged 9 to 18 found that after taking erythromycin 250 mg four times daily for a week, the clearance of methylprednisolone was decreased by 46% (range 28 to 61%) and the half-life was increased by 47%, from 2.34 to 3.45 hours.⁵

4. *Troleandomycin*. A pharmacokinetic study in 4 children and 6 adult corticosteroid-dependent asthmatics found that troleandomycin 14 mg/kg daily for one week increased the half-life of methylprednisolone by 88%, from 2.46 to 4.63 hours, and reduced the total body clearance by 64%. All 10 had cushingoid symptoms (cushingoid facies and weight gain), which resolved when the methylprednisolone dosage was reduced, without any loss in the control of the asthma.⁶ Another study found that the dose of methylprednisolone could be reduced by 50% in the presence of troleandomycin, without loss of disease control.⁷ Other studies have found similar effects.⁸⁻¹³ However, a randomised, placebo-controlled 2-year study found that although troleandomycin modestly reduced the required dose

of methylprednisolone, this did not reduce corticosteroid-related adverse effects.¹³ A case report describes a fatal varicella infection attributed to the potentiation of steroid effects by troleandomycin.¹⁴

(d) Prednisolone or Prednisone

1. *Clarithromycin*. A 30-year-old woman with no history of mental illness was treated for acute sinusitis with prednisone 20 mg daily for 2 days, followed by 40 mg for a further 2 days and clarithromycin 1 g daily. After 5 days she stopped taking both drugs (for unknown reasons), but a further 5 days later she was hospitalised with acute mania (disorganised thoughts and behaviour, pressured speech, increased energy, reduced need for sleep and labile effect). She spontaneously recovered after a further 5 days and had no evidence of psychiatric illness 4 months later.¹⁵ A 50-year-old man with emphysema was given prednisone 20 mg daily to improve dyspnoea. After about 2 weeks he was also given clarithromycin 500 mg twice daily for purulent bronchitis. Shortly afterwards his family noticed psychiatric symptoms characterised by paranoia, delusions and what was described as dangerous behaviour. He recovered following treatment with low-dose olanzapine, a gradual reduction of the prednisone dosage and discontinuation of the clarithromycin. An interaction was suspected as the patient had previously received prednisone on a number of occasions without the development of psychosis.¹⁶

A study in 6 asthmatic patients found that clarithromycin 500 mg twice daily for 9 days had no significant effect on prednisone pharmacokinetics.⁴

2. *Troleandomycin*. A study found that prednisolone clearance was not affected by troleandomycin in 3 patients, but was reduced by about 50% by troleandomycin in one patient who was also taking **phenobarbital**, which is an enzyme inducer.⁸

Mechanism

What is known suggests that clarithromycin, erythromycin and troleandomycin can inhibit the metabolism of methylprednisolone. The volume of distribution is also decreased.^{5,6,8,17} Clarithromycin may inhibit the metabolism of budesonide.¹

Importance and management

Information about the clarithromycin or erythromycin interactions with methylprednisolone is much more limited than with the interaction between troleandomycin and methylprednisolone, but they all appear to be established and of clinical importance. The effect should be taken into account during concurrent use and appropriate dosage reductions made to avoid the development of corticosteroid adverse effects. The authors of one study⁶ suggest that this reduction should be empirical, based primarily on clinical symptomatology. Another group found that a 68% reduction in methylprednisolone dosage was possible within 2 weeks.¹⁰ Troleandomycin appears to have a greater effect than erythromycin or clarithromycin.

Prednisolone seems not to interact with troleandomycin and may be a non-interacting alternative, except possibly in those taking enzyme-inducers (e.g. phenobarbital).

The evidence for the interaction leading to psychosis between prednisone and clarithromycin is limited and its general importance is uncertain, but prescribers should be aware of the reports of psychosis if both drugs are used together. Note that psychosis is a rare adverse effect of high-dose corticosteroids given alone.

One case report indicates that clarithromycin may enhance the effects of inhaled budesonide and although the authors suggest that prolonged use of clarithromycin and the terminal condition of the patient may have been factors, they advise close monitoring if the combination is used.¹ Note that rectal budesonide produces higher plasma levels than the oral or inhaled use. The manufacturers of one UK rectal preparation advise that potent inhibitors of CYP3A4 (they name clarithromycin) should be avoided.¹⁸ However, given the evidence available, this seems a very cautious approach.

In general the concurrent use of corticosteroids and macrolides need not be avoided, but it would seem prudent to monitor for corticosteroid adverse effects and suspect an interaction if symptoms occur.

Corticosteroids + Mifepristone

The UK manufacturers of mifepristone say that the efficacy of corticosteroids (included inhaled corticosteroids) is expected to be reduced in the 3 to 4 days following the use of mifepristone, because of the antiglucocorticoid activity of mifepristone.¹ Patients taking corticosteroids should be monitored during this time, and consideration given to increasing the corticosteroid dose. However, the US manufacturers contraindicate the use of mifepristone in those receiving long-term corticosteroid therapy.²

Corticosteroids + Nefazodone

Nefazodone inhibits the metabolism of methylprednisolone and prolongs its effects on cortisol suppression.

Clinical evidence

In healthy subjects, nefazodone for 9 days (initial dose of 100 mg, increased to 150 mg, then 200 mg, twice daily) increased the AUC of a single 0.6-mg/kg intravenous dose of **methylprednisolone** by twofold and increased its half-life from 2.28 to 3.32 hours. **Methylprednisolone** clearance was decreased from 28.7 to 14.6 L/hour. The duration of cortisol suppression after **methylprednisolone** alone was 23.3 hours, which increased to more than 32 hours when nefazodone was also given.¹

Mechanism

Nefazodone probably inhibits methylprednisolone metabolism by cytochrome P450 isoenzyme CYP3A4.¹

Importance and management

At clinically relevant doses nefazodone decreases methylprednisolone clearance and significantly prolongs methylprednisolone induced cortisol

suppression. Care is recommended during concurrent use.¹ Note that nefazodone has been generally withdrawn from the market.

Corticosteroids + NSAIDs

Corticosteroids or NSAIDs alone may be risk factors for gastrointestinal bleeding and ulceration. The concurrent use of NSAIDs and corticosteroids increases the risk of gastrointestinal bleeding and probably ulceration.

Ibuprofen, indometacin and naproxen may increase the levels of free prednisolone, and plasma levels of diclofenac are modestly increased by triamcinolone.

Clinical evidence, mechanism, importance and management

(a) Gastrointestinal bleeding and ulceration

A retrospective study of more than 20 000 patients who had received corticosteroids found that the incidence of upper gastrointestinal bleeding was no greater than in the control group who had not received corticosteroids (bleeds occurred in 95 patients compared with 91 patients). However, the risk of bleeding was increased if the patients were also taking aspirin or other NSAIDs.¹ This is consistent with the results of another study in patients taking **prednisone** and **indometacin**.²

A case control study reviewed 1415 patients aged 65 years or older, hospitalised between 1984 and 1986 for peptic ulcer or upper gastrointestinal haemorrhage of unknown cause, and 7063 control patients. The relative risk for the development of peptic ulcer disease was estimated to be 2 in those taking oral corticosteroids, and 4.4 in those taking corticosteroids with NSAIDs. It was estimated that patients taking corticosteroids with NSAIDs have a 15-fold greater risk for peptic ulcer disease than patients taking neither drug.³ Another study compared 1121 patients aged 60 or over who were admitted to hospital with bleeding peptic ulcers, with 989 control patients, to investigate factors other than NSAIDs that may have contributed to the risk of bleeding.⁴ The risk was threefold greater for the use of corticosteroids alone, but when corticosteroids were used with NSAIDs, the risk was tenfold greater.⁴

NSAIDs alone increase the risk of gastrointestinal adverse effects.^{5–8} Most patients with NSAID-associated ulcers are elderly: this is because there is a greater prevalence of ulcer disease in the elderly, and they are more likely to be taking NSAIDs and be sensitive to them.⁷ A history of ulcer disease is a further risk factor.⁷ Corticosteroids alone are reported not to be a risk factor in some studies,^{1,2,9} while other studies found they were a risk factor for gastrointestinal adverse effects.^{4,10} However, several studies have found that the risk of gastrointestinal adverse effects is increased by the combined use of corticosteroids and NSAIDs^{3–5,10} and caution with concurrent use has been suggested.³ It may be prudent to consider the use of gastroprotection in patients taking NSAIDs and corticosteroids, especially if they are elderly.

Consider also 'Aspirin or other Salicylates + Corticosteroids or Corticotropin', p.136.

(b) Pharmacokinetic interactions

A patient with rheumatoid arthritis taking **prednisolone** 5 to 10 mg daily with an NSAID (aspirin 700 mg to 2.8 g daily, **ibuprofen** 400 mg to 1.2 g daily, or **naproxen** 250 to 500 mg daily) intermittently, developed osteonecrosis of the upper third of the femoral head that was attributed to increased free levels of **prednisolone** due to displacement by the NSAID.¹¹ A study in 11 patients with stable rheumatoid disease regularly taking a corticosteroid found that **indometacin** 75 mg or **naproxen** 250 mg twice daily for 2 weeks did not alter the total plasma levels of a single 7.5-mg dose of **prednisolone** but the amount of unbound (free) **prednisolone** increased by 30 to 60%.¹² The probable reason is that these NSAIDs displace both administered and endogenous corticosteroids from their plasma protein binding sites, although the clinical relevance of this change is unclear. In a double-blind, crossover study 12 healthy subjects were given **rofecoxib** 250 mg daily or placebo for 14 days, with a single 30-mg dose of either intravenous **prednisolone** or oral **prednisone** on days 10 and 14. **Rofecoxib** did not affect the pharmacokinetics of the corticosteroids, even in a dose 10 times greater than that used clinically.¹³

In a double-blind, crossover study in healthy subjects given a single intramuscular dose of **diclofenac sodium** 75 mg alone and with **triamcinolone diacetate** 40 mg, the maximum plasma levels of **diclofenac** were increased by 24% by **triamcinolone**. This was possibly due to an increased rate of absorption but this is unlikely to be of clinical relevance. Other pharmacokinetic parameters of **diclofenac** were not significantly changed.¹⁴ The majority of these pharmacokinetic interactions seem unlikely to be of clinical significance, but they may well contribute to the adverse effects of both drugs, particularly the corticosteroids. No particular action appears to be necessary to account for these pharmacokinetic effects.

Corticosteroids + Omeprazole

Omeprazole had no effect on oral budesonide or prednisone pharmacokinetics in healthy subjects, but an isolated and unexplained report describes a reduction in the effects of prednisone in a patient taking omeprazole.

Clinical evidence, mechanism, importance and management

A placebo-controlled, randomised study in 18 healthy subjects found that omeprazole 40 mg daily had no effect on the pharmacokinetics of a single 40-mg dose of **prednisone**.¹ This contrasts with an isolated and unexplained report of a patient suffering from pemphigus who was given **prednisone** 1 mg/kg daily with, a week later, ranitidine 200 mg daily for a gastric ulcer. Four weeks later, when the skin lesions were well controlled, it was decided to replace the ranitidine with omeprazole 40 mg daily. Within 4 days the skin lesions began to worsen progressively, although the **prednisone** dosage remained unchanged. After 3 weeks it was decided to stop the omeprazole and restart the ranitidine because an adverse interaction between the **prednisone** and the omeprazole was suspected. Within about a week, the skin condition had begun to improve.² The suggested explanation for the interaction is that the omeprazole inhibited the liver enzyme (11 β -hydroxylase) that normally converts **prednisone** into its active form (prednisolone) resulting in inadequate treatment of the pemphigus.²

A placebo-controlled, randomised study in 11 healthy subjects found that omeprazole 20 mg daily for 5 days had no effect on the pharmacokinetics of a single 9-mg dose of **budesonide** (*Entocort CR* capsules).³

It would seem that adverse interactions between oral **budesonide** or **prednisone** and omeprazole are unlikely, but the isolated case should be borne in mind in the event of an unexpected response to treatment.

Corticosteroids + Phenytoin

The therapeutic effects of dexamethasone, methylprednisolone, prednisolone, prednisone (and probably other glucocorticoids) and fludrocortisone can be markedly reduced by phenytoin. One study suggested that dexamethasone may modestly increase serum phenytoin levels, but another study and two case reports of patients with brain metastases suggest that an important decrease can occur. The results of the dexamethasone adrenal suppression test may prove to be unreliable in those taking phenytoin.

Clinical evidence

(a) Reduced corticosteroid levels

A comparative pharmacokinetic study in 6 neurological or neurosurgical patients taking oral dexamethasone and phenytoin found that the average amount of dexamethasone that reached the general circulation was a quarter of that observed in 9 other patients taking dexamethasone alone (mean oral bioavailability fractions of 0.21 and 0.84, respectively).¹ Another report describes patients who needed increased doses of dexamethasone while taking phenytoin.²

The fludrocortisone dosages of two patients required 4-fold and 10- to 20-fold increases, respectively, in the presence of phenytoin.³

Renal allograft survival is decreased in patients taking prednisone and phenytoin, due (it is believed) to a reduction in the immunosuppressant effects of the corticosteroid.⁴

Several studies suggest that phenytoin may affect the half-life and clearance of a number of corticosteroids. These are shown in 'Table 29.2', (see above).

(b) Interference with the dexamethasone adrenal suppression test

A study in 7 patients found that phenytoin 300 to 400 mg daily reduced the plasma cortisol levels in response to dexamethasone from 22 to 19 microgram%, compared with a reduction from 18 to 4 microgram% in the absence of phenytoin.⁵ Other studies confirm that plasma cortisol and urinary 17-hydroxycorticosteroid levels are suppressed far less than might be expected with small doses of dexamethasone (500 micrograms every 6 hours for 8 doses), but with larger doses (2 mg every 6 hours for 8 doses) suppression was normal.⁶ However, one case describes a patient in whom even 16 mg of dexamethasone failed to cause cortisol depression while she was taking phenytoin, but when she was re-tested in the absence of phenytoin only 1 mg of dexamethasone was needed to elicit a response.⁷

(c) Serum phenytoin levels increased or decreased

A study into epilepsy prophylaxis post-trauma found that the serum phenytoin levels in those taking dexamethasone 16 to 150 mg (mean 63.6 mg) was 40% higher than those taking phenytoin alone (17.3 micrograms/mL compared with 12.5 micrograms/mL). The phenytoin

was given as a loading dose of 11 mg/kg intravenously and then 13 mg/kg intramuscularly.⁸

Conversely, a retrospective study of 40 patient records (diagnosis unspecified) indicated that dexamethasone reduced serum phenytoin levels: the serum phenytoin levels of 6 patients receiving fixed doses of phenytoin were halved by dexamethasone.⁹ Another report describes a patient with brain metastases who required over 8 mg/kg of phenytoin (600 mg) to achieve therapeutic phenytoin levels in the presence of dexamethasone 16 mg. When the dexamethasone was increased to 28 mg daily he experienced seizures, and an increase in his phenytoin dose from 600 mg to 1 g only resulted in an increase in his levels from 13.9 to 16.4 micrograms/mL.¹⁰ Another patient, also with a brain metastasis, needed a large dose of phenytoin (greater than 10 mg/kg) while taking dexamethasone. He had an almost fourfold rise in serum phenytoin levels when dexamethasone was stopped.¹¹

Mechanism

Phenytoin is a potent liver enzyme inducer that increases the metabolism of the corticosteroids so that they are cleared from the body more quickly, reducing both their therapeutic and adrenal suppressant effects.

Importance and management

The fall in serum corticosteroid levels is established and of clinical importance in systemic treatment, but it seems unlikely to affect the response to steroids given topically or by inhalation, intra-articular injection or enema.¹² The interaction can be accommodated in several ways:

- Increase the corticosteroid dosage proportionately to the increase in clearance (see 'Table 29.2', (see above)). With prednisolone an average increase of 100% (range 58 to 260% in 5 subjects) proved effective.¹² A fourfold increase may be necessary with dexamethasone,¹ and much greater increases have been required with fludrocortisone.³
- Exchange the corticosteroid for another that is less affected (see 'Table 29.2', (see above)). A switch from dexamethasone to equivalent doses of methylprednisolone has been reported to be effective¹³ but another report found that methylprednisolone was more affected than prednisolone.¹⁴ In another case the exchange of dexamethasone 16 mg daily for prednisone 100 mg daily was successful.¹⁵
- Exchange the phenytoin for another antiepileptic: barbiturates (including primidone¹⁶) and carbamazepine, are also enzyme-inducers, but valproate is a possible non-interacting alternative² where clinically appropriate. However, remember that corticosteroids should only be given to epileptics with care and good monitoring because of the risk that they will exacerbate the disease condition.

The effects of phenytoin on the dexamethasone adrenal suppression test can apparently be accommodated by using larger than usual doses of dexamethasone (2 mg every 6 hours for 8 doses)⁶ or by an overnight test using 50 mg of hydrocortisone.¹³

The reports on the changes in serum phenytoin levels are inconsistent (both increases and decreases have been seen). The effects of concurrent use should be closely monitored.

Corticosteroids + Protease inhibitors

Several cases of Cushing's syndrome have been seen in patients using inhaled or intranasal fluticasone when ritonavir was also given. Ritonavir may reduce the clearance of prednisone, and ritonavir or nelfinavir may increase levels of the active metabolite of ciclesonide. Dexamethasone may reduce the levels of indinavir and saquinavir.

Clinical evidence

An HIV-positive 32-year-old man who had been using intranasal **fluticasone** 200 micrograms twice daily for 3 years for allergic rhinitis, developed a cushingoid face and gained 6.5 kg in weight within 5 months of starting to take **ritonavir**, zidovudine and lamivudine.¹ Another HIV-positive man receiving inhaled **beclometasone** 400 to 800 micrograms daily for asthma and intranasal **fluticasone** 800 micrograms daily for allergic rhinitis was also given **ritonavir**, **saquinavir**, stavudine and nevirapine, after which he developed mild cushingoid facial changes. Both patients had high plasma levels of **fluticasone**. The problems resolved when the **fluticasone** was withdrawn. A third HIV-positive patient receiving inhaled **beclometasone**, intranasal **fluticasone**, **ritonavir**, zidovudine and lamivudine had increased **fluticasone** levels but no signs of Cushing's syndrome.¹

There are reports of at least 9 other patients, including 2 children,² who have developed Cushing's syndrome within 2 to 5 months of using regimens of inhaled^{2–7} or intranasal⁸ **fluticasone**, with **ritonavir**,⁸ **ritonavir/amprenavir**,^{3,7} **ritonavir/lopinavir**,^{2,5} **ritonavir/saquinavir**,⁴ **ritonavir/indinavir**⁷ or **ritonavir/lopinavir/saquinavir**.⁶ The interaction was confirmed in one patient by replacing the **ritonavir** with nevirapine for 3 weeks and then restarting the **ritonavir**.⁸ Another six HIV-positive patients taking protease inhibitors including low doses of **ritonavir** and with HIV-lipodystrophy developed symptomatic Cushing's syndrome when also given inhaled **fluticasone**. All had adrenal suppression, and after withdrawal of **fluticasone**, 3 patients required oral corticosteroids for several months. Exacerbation of pre-existing diabetes mellitus occurred in one patient and 4 patients had osteoporosis (1 with fractures).⁹ The manufacturer of ciclesonide notes that giving **ritonavir** or **nelfinavir** with ciclesonide may increase the serum levels of the active metabolite of ciclesonide and that an increased risk of adverse effects such as cushingoid syndrome cannot be excluded.¹⁰

A study in healthy subjects found that the AUC of a single 20-mg dose of **prednisone**, given before and on days 4 and 14 of a 14.5 day course of **ritonavir** 200 mg twice daily, were increased by about 30% by the **ritonavir**. The apparent oral clearance of **prednisolone** was reduced from 8.84 L/hour to 6.45 and 6.88 L/hour on days 4 and 14, respectively.¹¹

Mechanism

Ritonavir, and all protease inhibitors, inhibit the cytochrome P450 isoenzyme CYP3A4 to varying degrees. Fluticasone is metabolised by this isoenzyme and therefore the protease inhibitors cause its plasma levels to rise. The active metabolite of ciclesonide is also metabolised by CYP3A4,¹⁰ and is therefore similarly affected.

Importance and management

Information is limited but the interaction between ritonavir and fluticasone appears to be an established and clinically important. The incidence is not known. Patients using these two drugs should be very well monitored for any signs of corticosteroid overdose. The problem may take months to manifest itself. It has been suggested that if an inhaled corticosteroid is required by a patient taking ritonavir, a corticosteroid with less systemic availability should be given at the lowest effective dose.¹² The manufacturers of the fluticasone inhaler^{13,14} and nasal spray^{15,16} advise against their concurrent use with ritonavir unless the potential benefit is considered to outweigh the risk of systemic corticosteroid adverse effects.

Ritonavir may increase the levels of prednisone and some manufacturers of **betamethasone**,¹⁷ **budesonide**,¹⁸ ciclesonide,¹⁰ or **dexamethasone**^{19,20} predict a similar interaction with ritonavir or nelfinavir.¹⁰

The manufacturers of **dexamethasone** note that it is a modest inducer of CYP3A4 and state that it may reduce the plasma levels of **indinavir**,^{20,21} and **saquinavir**,²⁰ or other drugs metabolised by CYP3A4.²¹ The clinical outcome of this predicted effect is unknown, but until more is known, it would seem prudent to monitor antiviral efficacy if these combinations are used.

Corticosteroids + Rifampicin (Rifampin)

The effects of systemic cortisone, dexamethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisone and prednisolone can be markedly reduced by rifampicin, but aldosterone appears not to be affected. Rifabutin and rifapentine are predicted to interact similarly, all be it to a lesser extent.

Clinical evidence

(a) Aldosterone

Seven patients with Addison's disease due to tuberculosis had no changes in the pharmacokinetics of intravenous aldosterone after being given rifampicin 600 mg daily for 6 days.¹

(b) Cortisone and fludrocortisone

A patient with Addison's disease taking cortisone and fludrocortisone had typical signs of corticosteroid overdosage when the rifampicin he was taking was replaced by ethambutol,² suggesting that the rifampicin reduces the levels of these corticosteroids. Another Addisonian patient needed an increase in her dosage of cortisone from 37.5 to 50 mg daily, plus fludrocortisone 100 micrograms daily, when rifampicin 450 mg daily was started.³ When rifampicin was added to prednisolone or dexamethasone and fludrocortisone it caused an Addisonian crisis in two patients.⁴

(c) Dexamethasone

Rifampicin markedly increases the clearance of dexamethasone.^{5,6} See also under (b) above.

(d) Hydrocortisone

A metabolic study in an Addisonian patient taking hydrocortisone found that rifampicin shortened its half-life and reduced its AUC.⁷

(e) Methylprednisolone, Prednisone or Prednisolone

A child with nephrotic syndrome taking prednisolone, and accidentally given a BCG vaccine, was given rifampicin and isoniazid to prevent possible dissemination of the vaccine. When the nephrotic condition did not respond, the prednisolone dosage was raised from 2 to 3 mg/kg daily without any evidence of corticosteroid overdosage. Later when the rifampicin and isoniazid were withdrawn, remission of the nephrotic condition was achieved with the original dosage of prednisolone.⁸ A number of other reports describe a reduction in the response to prednisone, prednisolone or methylprednisolone in patients given rifampicin.^{4,9-17} Pharmacokinetic studies in patients have shown that the AUC of prednisolone is reduced by about 60% by rifampicin, and its half-life is decreased by 40 to 60%.^{11,15,18}

Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism of the corticosteroids by the liver,^{10,19} thereby decreasing their levels and reducing their effects.

Importance and management

The interactions between the corticosteroids and rifampicin are established, well documented and clinically important. The need to increase the dosages of cortisone, dexamethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisolone and prednisone should be expected if rifampicin is given. It has been suggested that as an initial adjustment the dosage of prednisolone should be increased two to threefold, and reduced proportionately if the rifampicin is withdrawn.^{10,11,18,20} The dosage increases needed for other corticosteroids await assessment. In the case of prednisolone the interaction develops maximally by 14 days and disappears about 14 days after withdrawal of the rifampicin.²¹ There seems to be no direct information about other glucocorticoids but be alert for them to be similarly affected. It is not clear whether any of the topically applied corticosteroids will interact with rifampicin but any clinically significant interaction would be expected to be very rare. The systemic corticosteroids are usually considered as contraindicated, or only to be used with great care, in patients with active or quiescent tuberculosis. There does not seem to be any information regarding the other rifamycins, **rifabutin** (a weak enzyme inducer) and **rifapentine** (a moderate enzyme inducer). However, the UK manufacturers and the CSM in the UK warn that rifabutin may possibly reduce the effects of a number of drugs, including corticosteroids,^{22,23} and therefore some caution is probably prudent.

Corticosteroids + Sucralfate

Sucralfate appears not to interact with prednisone.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects sucralfate 1 g every 6 hours had no significant effect on the pharmacokinetics of a single 20-mg dose of **prednisone**; however, the peak plasma levels were delayed by about 45 minutes when the drugs were given at the same time, but not when the sucralfate was given 2 hours after the **prednisone**.¹ No particular precautions are likely to be needed in patients given both drugs. Information about other corticosteroids is lacking.

- Gambertoglio JG, Romac DR, Yong C-L, Birnbaum J, Lizak P, Amend WJC. Lack of effect of sucralfate on prednisone bioavailability. *Am J Gastroenterol* (1987) 82, 42-5.

Corticosteroids + Vaccines; Live

Patients who are immunised with live vaccines while receiving immunosuppressive doses of corticosteroids may develop generalised, possibly life-threatening, infections.

Clinical evidence, mechanism, importance and management

The use of corticosteroids can reduce the number of circulating lymphocytes and suppress the normal immune response, so that concurrent immunisation with live vaccines can lead to generalised infection. It is suggested that **prednisone** in doses of greater than 10 to 15 mg daily will suppress the immune response, whereas 40 to 60-mg doses on alternate days probably does not,¹ although this is debated.

A patient with lymphosarcoma and hypogammaglobulinaemia, taking **prednisone** 15 mg daily, developed a generalised vaccinal infection

when she was given **smallpox vaccine**.² A fatal vaccinia infection developed following **smallpox vaccination** in another patient taking **cortisone**.³ This type of problem can be controlled with immunoglobulin to give cover against a general infection while immunity develops, and this has been successfully used in steroid-dependent patients needing **smallpox vaccination**.⁴

The principles applied to **smallpox** may be generally applicable to other live attenuated vaccines (e.g. **measles, mumps, rubella, poliomyelitis, BCG**), but no studies seem to have been done to establish what is safe.¹ It is generally accepted that patients taking immunosuppressants should not be given live vaccines. Problems with topical or inhaled steroids in normal dosages seem unlikely because the amounts absorbed are relatively small.¹ However, this needs confirmation. The British National Formulary states that live vaccination should be postponed for at least 3 months after stopping high-dose corticosteroids.⁵

Corticosteroids + Valspodar

Dexamethasone does not affect the pharmacokinetics of valsopodar. Valsopodar modestly increases the AUC of dexamethasone.

Clinical evidence, mechanism, importance and management

In a crossover study healthy fasting subjects were given single doses of **dexamethasone** 8 mg and valsopodar 400 mg either alone or together. **Dexamethasone** had no effect on the pharmacokinetics of valsopodar. The AUC of **dexamethasone** was increased by 24% by valsopodar. This change is modest and therefore dosage alterations are probably not required if concurrent use is of a short duration.¹

Corticosteroids + Zileuton

No clinically relevant pharmacokinetic interaction occurs between prednisone and zileuton.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, crossover study, 16 healthy subjects were given zileuton 600 mg every 6 hours for a week, with either a 40-mg dose of **prednisone** or placebo on day 6. The pharmacokinetics of both drugs were slightly altered but this was not considered to be clinically relevant. The **prednisone** half-life increased from 2.8 to 2.9 hours, while the zileuton AUC and the time to achieve maximum serum levels were decreased by 13% and 26%, respectively. It was concluded that concurrent use carries a minimal risk of a clinically important pharmacokinetic interaction.¹ No special precautions would appear to be needed.

1. Awni WM, Cavanaugh JH, Tzeng T-B, Witt G, Granneman GR, Dube LM. Pharmacokinetic interactions between zileuton and prednisone. *Clin Pharmacokinet* (1995) 29 (Suppl 2), 105–111.

Daclizumab + Miscellaneous

No adverse drug interactions appear to have been reported with daclizumab, although its use with another antilymphocyte antibody in transplant patients receiving intensive immunosuppression may be a factor in fatal infection.

Clinical evidence, mechanism, importance and management

The manufacturers of daclizumab say that because it is an immunoglobulin, no metabolic drug interactions (i.e. those mediated by inhibitory or inducing effects on cytochrome P450 enzymes) would be expected,^{1,2} and none seems to have been reported. The manufacturers say that daclizumab has been given in clinical studies with the following drugs without any adverse interactions: **aciclovir, azathioprine, antithymocyte immune globulin, ciclosporin, corticosteroids, ganciclovir, muromonab-CD3, mycophenolate mofetil and tacrolimus**.¹

However, in one clinical study in heart transplant patients taking ciclosporin, **mycophenolate**, and corticosteroids, use of daclizumab with another antilymphocyte (such as **muromonab-CD3** or **antithymocyte immunoglobulin**) appeared to be associated with a higher incidence of fatal infection: 8 of 40 patients died, compared with 2 of 37 who received an antilymphocyte and placebo. The manufacturer suggests that concurrent use of daclizumab with another antilymphocyte antibody in patients receiving intensive immunosuppression may be a factor leading to fatal infection.^{1,2} Caution may be warranted, and more study is needed.

2. Zenapax (Daclizumab). Roche Pharmaceuticals. US Prescribing information, September 2005.

Etanercept + Miscellaneous

An increased risk of serious infection and neutropenia is reported if etanercept is given with anakinra. A higher incidence of malignancies has been reported in patients with Wegener's granulomatosis when given both cyclophosphamide and etanercept. No clinically significant pharmacokinetic interactions occur between etanercept and methotrexate. Etanercept did not affect the pharmacodynamics of warfarin. A reduced neutrophil count may occur in patients treated with etanercept and sulfasalazine. No interactions have been found when etanercept was given with salicylates (other than sulfasalazine), corticosteroids, or NSAIDs. Live vaccines should not be given to patients taking etanercept.

Clinical evidence, mechanism, importance and management

(a) Anakinra

In a study in patients with active rheumatoid arthritis taking etanercept and anakinra for up to 24 weeks, serious infections occurred in 7% of patients, compared with none in patients taking etanercept alone. Neutropenia occurred in 2% of patients taking both drugs.¹ Infections are very common adverse effects of treatment with etanercept but serious infections are reported to be uncommon (occurring in about 1% of etanercept- and placebo-treated groups in clinical studies).^{1,2} Further, the combination of etanercept with anakinra has not increased clinical benefit and the manufacturers say that concurrent use is not recommended.^{1,2}

(b) Cyclophosphamide

The US manufacturers say that etanercept is not recommended in patients receiving cyclophosphamide. They state that in a study in patients with Wegener's granulomatosis, the addition of etanercept to standard treatment, including cyclophosphamide, was associated with a higher incidence of non-cutaneous solid malignancies.¹

(c) Methotrexate

A double-blind study in 98 patients with rheumatoid arthritis receiving subcutaneous etanercept 25 mg twice weekly, or etanercept with oral methotrexate (median weekly dose of 20 mg) were randomly selected for a pharmacokinetic study from 682 patients in a clinical study. The pharmacokinetics of etanercept were not altered by concurrent methotrexate and no dosage adjustment is required during concurrent use.³

(d) Sulfasalazine

A study in patients taking sulfasalazine found that when etanercept was also given, patients had a decrease in neutrophil counts, when compared to other groups of patients receiving either drug alone. The clinical significance is not known.^{1,2}

(e) Vaccines, live

As no data are available on the secondary transmission of infection by live vaccines in patients receiving etanercept, the manufacturers recommend that live vaccines should not be given.^{1,2}

(f) Other drugs

The UK manufacturers note that no interactions have been found when etanercept was given with **corticosteroids**, **salicylates** (except sulfasalazine, see under (e) above), **NSAIDs** or other analgesics.²

Everolimus + Azoles

Ketoconazole significantly increases everolimus levels. A case report describes reduced everolimus clearance in a patient also given itraconazole. Pharmacokinetic modelling suggests that fluconazole will not interact to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In a study, 12 healthy subjects were given a single 1-mg dose of everolimus on day 4 of an 8-day course of **ketoconazole** 200 mg twice daily. Ketoconazole increased the AUC, peak blood level and half-life of everolimus by 15-fold, 3.9-fold, and 1.9 fold, respectively.¹ Similarly, a patient taking everolimus with ciclosporin and prednisone had a 74% decrease in everolimus clearance when **itraconazole** was given. However, in 16 patients, pharmacokinetic modelling suggested that everolimus clearance was reduced by a non-significant 7% when fluconazole was given.² More study is needed to confirm this finding.

Patients who are given **ketoconazole**, and possibly any azole that is also a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, such as **itraconazole**, should have their everolimus levels monitored closely and dose adjustments made as required.¹

2. Kovarik JM, Hsu C-H, McMahon L, Berthier S, Rordorf C. Population pharmacokinetics of everolimus in de novo renal transplant patients: impact of ethnicity and comedications. *Clin Pharmacol Ther* (2001) 70, 247–54.

Everolimus + Ciclosporin

Ciclosporin increases the AUC of everolimus. Everolimus appears to have no significant effects on ciclosporin levels.

Clinical evidence

(a) Effects on ciclosporin

In a placebo-controlled study in 54 kidney transplant patients taking ciclosporin (93% also taking prednisone), everolimus 0.75 mg to 10 mg daily in single or divided doses in 44 patients had no consistent, clinically significant effect on ciclosporin levels, when compared with the 10 patients given placebo, although because of wide interpatient variability, there is a possibility that a significant interaction could occur in some patients.¹ Another study in 101 kidney transplant patients taking ciclosporin and prednisone with everolimus 0.5 to 2 mg twice daily for 1 year also found no evidence that everolimus affected ciclosporin pharmacokinetics.²

(b) Effects on everolimus

The possibility of a drug interaction was assessed in a crossover study in 24 healthy subjects who were given a single 2-mg dose of everolimus, alone and with single doses of ciclosporin, either *Neoral* (microemulsion) 175 mg or *Sandimmune* (corn oil suspension) 300 mg. *Neoral* increased the peak levels and AUC of everolimus by 82% and 168% respectively. *Sandimmune* did not affect the peak levels of everolimus but increased its AUC by 74%.³

Mechanism

Not fully understood. Both everolimus and ciclosporin are metabolised by the cytochrome P450 isoenzyme CYP3A4 and both are substrates of P-glycoprotein. Competition via one or both of these pathways in the liver or gut wall may contribute to the interaction.³

Importance and management

Information on the effects on everolimus levels when it is used with ciclosporin appear to be limited to the single-dose study.³ However, it has been suggested if ciclosporin (either *Neoral* or *Sandimmune*) is removed from an everolimus/ciclosporin regimen, a two- to threefold decrease in everolimus exposure could be expected. Monitoring is recommended.³ Note that sirolimus (of which everolimus is a derivative) interacts similarly, see 'Sirolimus + Ciclosporin', p.1072.

It would appear that, in general, everolimus has no clinically significant effects on the pharmacokinetics of ciclosporin.

3. Kovarik JM, Kalbag J, Figueiredo J, Rouilly M, O'Bannon LF, Rordorf C. Differential influence of two cyclosporine formulations on everolimus pharmacokinetics: a clinically relevant pharmacokinetic interaction. *J Clin Pharmacol* (2002) 42, 95–9.

Everolimus + Macrolides

Erythromycin increases everolimus levels. Other macrolides probably interact similarly.

Clinical evidence, mechanism, importance and management

Sixteen healthy subjects were given a single 4-mg dose of everolimus before and on day 5 of a 9-day course of erythromycin 500 mg three times daily. The peak blood levels and AUC of everolimus were increased twofold and 4.4-fold, respectively, and its half-life was prolonged by 39%. Erythromycin probably inhibited the metabolism of everolimus by the cytochrome P450 isoenzyme CYP3A4. There was wide inter-subject variability in the levels of erythromycin and therefore they could not be correlated with the extent of the interaction with everolimus. The authors recommend that appropriate everolimus dose reductions based on frequently monitored blood levels should be made when patients are given erythromycin.¹ Other macrolides that inhibit CYP3A4 (such as **clarithromycin** and **telithromycin**, but not **azithromycin**) would be expected to interact similarly, and therefore concurrent use of these drugs with everolimus should also be monitored.

1. Kovarik JM, Beyer D, Bizot MN, Jiang Q, Shenouda M, Schmoeder R. Effect of multiple-dose erythromycin on everolimus pharmacokinetics. *Eur J Clin Pharmacol* (2005) 61, 35–8.

Everolimus + Rifampicin (Rifampin)

Rifampicin reduces the bioavailability and increases the clearance of everolimus.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects were given a single 4-mg dose of everolimus before and after taking rifampicin 600 mg daily for 7 days. Rifampicin increased the clearance of everolimus by 172%, and increased its AUC and peak blood levels by 63% and 58%, respectively, although there was a large inter-individual variation in the AUC. Induction of both cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein (everolimus is metabolised by CYP3A4 and is a substrate for P-glycoprotein) by rifampicin may have increased metabolism and reduced the bioavailability of everolimus.¹

There appear to be no other published clinical studies or case reports of this interaction but what happened is in line with the way both drugs are

known to interact. Monitor concurrent use for everolimus efficacy, anticipating the need to increase the dose of everolimus.

1. Kovarik JM, Hartmann S, Figueiredo J, Rouilly M, Port A, Rordorf C. Effect of rifampicin on apparent clearance of everolimus. *Ann Pharmacother* (2002) 36, 981–5.

Everolimus + Verapamil

Increased levels of both everolimus and verapamil can occur on concurrent use.

Clinical evidence, mechanism, importance and management

A study in 16 healthy subjects given a single 2 mg dose of everolimus before and on day 2 of a 6-day course of verapamil 80 mg three times daily found that verapamil increased the AUC and peak blood level of everolimus by 3.5-fold and 2.3-fold, respectively. Everolimus also increased the plasma levels of verapamil by 2.3-fold.¹

Verapamil is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, the isoenzyme primarily involved in the metabolism of everolimus, and inhibits P-glycoprotein, a transporter for which everolimus is a substrate. Therefore concurrent use raises everolimus levels. It is not known exactly why verapamil levels are raised. This appears to be the only evidence for an interaction, but it is in line with the way these drugs are known to interact. If both drugs are given it would seem prudent to monitor everolimus blood levels as well as monitor for adverse effects due to verapamil, such as hypotension, flushing and oedema, and adjust the dose of both drugs as needed.

Immunosuppressants + Vaccines

The body's immune response is suppressed by immunosuppressants such as ciclosporin, mycophenolate, sirolimus, and tacrolimus. The antibody response to vaccines may be reduced, although even partial protection may be of benefit. In general, the use of live attenuated vaccines is considered contraindicated because of the possible risk of generalised infection. Inactivated vaccines may be used.

Clinical evidence

(a) Diphtheria, tetanus, and inactivated polio vaccines

In organ transplant recipients taking immunosuppressants, tetanus vaccines^{1,2} and inactivated polio vaccines¹ produced protective antibody titres. The response to diphtheria vaccine was lower than in healthy controls¹ and the antibody titre had fallen below the protective level by 12 months in 38% of patients in one study,¹ and 24% in another.² Note that live polio vaccines are not recommended in immunosuppressed patients (see *Live vaccines*, below).

(b) Hepatitis vaccines

The antibody response to **hepatitis B vaccine** is generally poor in patients taking immunosuppressants after organ transplantation,^{3,4} although one research group reported a sustained antibody response in half of their patients,⁵ and an overall 85% seroconversion rate was seen in one study in children (aged between 4 and 16 years).⁶ In this latter study,⁶ children receiving **ciclosporin** monotherapy had a higher seroconversion rate (100%) than those receiving **ciclosporin** and **corticosteroids** (84%) and those receiving **ciclosporin**, **azathioprine**, and **corticosteroids** (66%).

The antibody response to **hepatitis A vaccine** in patients taking immunosuppressants after organ transplantation is variable,^{7–9} and declines quicker than in healthy controls.⁹ In renal transplant recipients, there is some evidence that the response is inversely related to the number of immunosuppressant drugs.⁸

(c) Influenza vaccine

A number of studies have been published on the efficacy of influenza vaccination in organ transplant recipients taking immunosuppressants. Many have found a reduction in the proportion of patients developing a protective antibody titre compared with healthy control subjects,^{10,11} whereas some have found no reduction.¹² A few studies have looked at the effects

of individual drugs in the immunosuppressive regimen. In one comparative study in 59 kidney transplant patients, 21 patients taking **ciclosporin** and **prednisone** had a significantly lower immune response to influenza vaccine (inactivated trivalent) than 38 patients taking **azathioprine** and **prednisone** or 29 healthy subjects taking no drugs. All of the immune response measurements were reduced by 20 to 30% in those taking **ciclosporin**.¹³ In another study, 13 patients taking **mycophenolate**, **ciclosporin**, and **prednisolone** had a marked reduction in antibody response to influenza vaccine, when compared with 25 patients taking **ciclosporin**, **azathioprine** and **prednisolone**.¹⁴ In yet another study, patients receiving **ciclosporin** had lower antibody responses when compared with patients receiving **tacrolimus**.¹⁵ Patients given a higher dose of **prednisolone** per kg had a reduced antibody response to influenza vaccine in one study, and those given a daily dose had a reduced response, when compared with those given an alternate day schedule.¹⁶

Confirmation of the practical importance of the reduced antibody titre in some patients is described in a case report of a heart transplant patient taking **ciclosporin** who did not respond to influenza vaccination while taking **ciclosporin** and **prednisone**. He had two episodes of influenza, one serologically confirmed, and it was later shown that vaccination had not resulted in seroconversion.¹⁷ Similarly, a patient taking **tacrolimus** after a liver transplant developed influenza A myocarditis despite prophylactic vaccination.¹⁸

(d) Live vaccines

The use of live vaccines in patients receiving corticosteroids has caused generalised infection, see 'Corticosteroids + Vaccines; Live', p.1061. Similarly, the use of live vaccines in patients taking other immunosuppressants is not recommended; probably as a consequence of this there are few published reports about the use of live vaccines with immunosuppressants. One study found that measles vaccine was effective in 7 of 18 children under 3 years old after liver transplantation, and that there were no complications directly attributable to the vaccine.¹⁹

(e) Pneumococcal vaccines

Good responses to pneumococcal vaccines in patients taking immunosuppressant drugs after organ transplantation have been seen,^{10,20} but protective antibody titres may not persist as long as in healthy subjects.²¹

Mechanism

Immunosuppression by these drugs diminishes the ability of the body to respond immunologically both to transplants and to vaccination.

Importance and management

These are established and clinically important interactions. The UK Department of Health²² recommends the following:

- Live vaccines: patients taking immunosuppressive drugs such as ciclosporin, methotrexate, cyclophosphamide, leflunomide, and cytokine inhibitors should not be given live vaccines during or for up to 6 months after treatment has stopped, as they can cause severe or fatal infections.
- Inactivated vaccines: ideally should be given at least 2 weeks before immunosuppressive therapy is started.
- Bone marrow transplant patients may lose their antibodies against most diseases and should be considered for re-immunisation under specialist supervision.

The proportion of patients developing protective antibody titres to vaccines is often reduced in patients taking immunosuppressants. Nevertheless, for many vaccines, the reduced response seen is still considered clinically useful, and, for example, in the case of kidney transplant patients,²³ and in patients who are immunosuppressed (either by drugs or disease), influenza vaccination is actively recommended.^{22,23} Pneumococcal vaccine should also be given to these patients. If a vaccine is given, it may be prudent to monitor the response, so that alternative prophylactic measures can be considered where it is considered inadequate. For influenza vaccine, one suggestion is that if patients remain unprotected after a single vaccination and a booster dose, amantadine 200 mg daily should be given during an influenza epidemic. It will protect against influenza A but not B infection.¹⁷ Note that, even where effective antibody titres are produced, these may not persist as long as in healthy subjects, and more frequent booster doses may be required.

There appears to be little published experience of the use of live vaccines in patients receiving immunosuppressants (apart from 'corticosteroids',

(p.1061)), and live vaccines should generally not be used in these patients. The manufacturers of **leflunomide** say that no clinical data are available on the efficacy of vaccines given to patients taking leflunomide, and live vaccines are not recommended.^{24,25}

Infliximab + Miscellaneous

Live vaccines should not be given to patients undergoing treatment with infliximab. Serious infection and neutropenia is predicted to occur if infliximab is given with anakinra. Infliximab may increase serum levels of azathioprine metabolites, and a rare T-cell lymphoma has been reported in adolescents and young adults treated with infliximab and also given azathioprine or mercaptopurine. Serum levels of infliximab appear to be unaffected by aminosalicylates, corticosteroids, ciprofloxacin or metronidazole.

Clinical evidence, mechanism, importance and management

(a) Anakinra

Infliximab inhibits the activity of tumour necrosis factor (TNF α). In clinical studies the use of anakinra with another TNF α inhibitor, 'etanercept', (p.1062) has been associated with an increased risk of serious infection and neutropenia and no additional benefit, when compared to the use of

these drugs alone.^{1,2} As a result of this the manufacturers of infliximab note that similar toxicity may occur if anakinra is given with infliximab and therefore advise against concurrent use.^{1,2}

(b) Azathioprine or Mercaptopurine

In 32 patients with Crohn's disease taking azathioprine (mean dose 2.81 mg/kg) and with stable levels of 6-thioguanine nucleotides (the active metabolites of azathioprine), infusions of infliximab 5 mg/kg over 2 hours resulted in a significant increase in 6-thioguanine nucleotide levels in 21 patients after 1 to 3 weeks, when compared to pre-infusion levels. The leucocyte count was significantly decreased and mean corpuscular volume increased. Significant increases in 6-thioguanine nucleotides were associated with good tolerance and favourable response to infliximab. These changes were transient: levels returned to normal 3 months later.³ Although this study suggests that concurrent use did not result in adverse effects the manufacturers report that rare post-marketing cases of an aggressive and usually fatal hepatosplenic T-cell lymphoma have been reported in adolescent and young adult patients with Crohn's disease treated with infliximab. All cases occurred in patients also receiving azathioprine or mercaptopurine. A causal relationship is unclear.^{1,2}

(c) Vaccines (live)

As no data are available on the response to vaccination with live vaccines or on the secondary transmission of infection by live vaccines in patients receiving anti-TNF therapy, the manufacturers recommend that live vaccines should not be given concurrently with infliximab.^{1,2}

(d) Miscellaneous

The manufacturers note that serum levels of infliximab appear to be unaffected by baseline use of medications to treat Crohn's disease including aminosalicylates, ciprofloxacin, corticosteroids and metronidazole.²

- Remicade (Infliximab). Schering-Plough Ltd. UK Summary of product characteristics, May 2007.

Leflunomide + Miscellaneous

The serum levels of the active metabolite of leflunomide are reduced by activated charcoal, and colestyramine. The manufacturers advise against the concurrent use of alcohol because of the potential for hepatotoxicity. Methotrexate may also increase leflunomide hepatotoxicity, so in general the combination is not recommended. A case of fatal fulminant hepatic failure has been reported in a patient taking leflunomide and itraconazole. A case of peripheral neuropathy has been reported in a patient taking leflunomide and tegafur/uracil. The manufacturers predict interactions between leflunomide and phenytoin or tolbutamide, and advise caution with rifampicin as it may increase leflunomide metabolite levels. No clinically relevant interaction occurs with cimetidine, corticosteroids or NSAIDs.

Clinical evidence, mechanism, importance and management

(a) Alcohol

The UK manufacturers say that because of the potential for additive hepatotoxic effects, it is recommended that alcohol should be avoided by patients taking leflunomide.¹

(b) Charcoal or Colestyramine

Studies in healthy subjects found that colestyramine 8 g three times daily reduced the serum levels of the active metabolite of leflunomide (A771726) by 48% after 24 hours and by 49 to 65% after 48 hours.^{1,2}

Treatment with activated charcoal 50 g every 6 hours for 24 hours, either orally or by nasogastric tube, reduced A771726 levels by 37% after 24 hours and by 48% after 48 hours.^{1,2}

These drugs are thought to bind with the A771726 in the gut, thereby interrupting the enterohepatic cycle or possibly its gastrointestinal dialysis.¹ Patients should therefore not be given either colestyramine or activated charcoal with leflunomide, unless the intention is to remove the leflunomide, for example following overdose or when switching from leflunomide to another DMARD (see (e) and (f), below), or where there is any other good reason to clear leflunomide from the body more quickly.^{1,2}

(c) *Cimetidine*

The manufacturers say that no clinically significant interaction occurs between leflunomide and cimetidine.^{1,2}

(d) *Corticosteroids*

The manufacturers say that corticosteroids may continue to be used if leflunomide is given.^{1,2}

(e) *CYP2C9 substrates*

The manufacturers advise caution if leflunomide is given with **phenytoin** or **tolbutamide**.¹ The reason is that the active metabolite of leflunomide (A771726) has been shown by *in vitro* studies to be an inhibitor of the cytochrome P450 isoenzyme CYP2C9, which is concerned with the metabolism of these two drugs. If this inhibition were to occur *in vivo* it could possibly lead to a decrease in their metabolism and an increase in their toxicity. Although so far there appear to be no clinical reports of an interaction, the manufacturers made a similar prediction with warfarin, another CYP2C9 substrate, which has, in isolated cases, been borne out in practice. See 'Coumarins + Leflunomide', p.423.

(f) *DMARDs other than methotrexate*

The manufacturers say that the concurrent use of leflunomide and other DMARDs (they list **azathioprine**, **chloroquine**, **hydroxychloroquine**, intramuscular or oral **gold** and **penicillamine**) has not yet been studied but they say that combined use is not advisable because of the increased risk of serious adverse reactions (haemo- or hepatotoxicity). As the active metabolite of leflunomide has a long half life of 1 to 4 weeks the manufacturers say that a washout of colestyramine or activated charcoal should be given if patients are to be started on other DMARDs.^{1,2} See also *Methotrexate*, below.

(g) *Itraconazole*

A 68-year-old woman who had been taking leflunomide 10 mg daily for about 4 months was started on itraconazole 300 mg daily for a fungal infection. About one month later her leflunomide dose was increased to 20 mg daily, and liver function tests were normal. The following month, she developed abdominal pain, vomiting, and weakness. Despite symptomatic treatment and washout with colestyramine, fatal fulminant hepatic failure occurred. The authors of the report attribute the reaction to additive hepatotoxicity between the leflunomide and itraconazole.³ This interaction serves to highlight the cautions about the use of other hepatotoxic drugs, see (a) and (h).

(h) *Methotrexate*

No pharmacokinetic interaction was seen in patients taking methotrexate (mean dose 17.2 mg per week) with leflunomide 100 mg daily for 2 days as a loading dose followed by 10 to 20 mg daily.⁴ However, elevated liver enzyme levels have been seen following concurrent use.¹ By March 2001, the European Agency for the Evaluation of Medicinal Products was aware of 129 cases of serious hepatic reactions in patients taking leflunomide, and 78% of these were in patients concurrently treated with hepatotoxic medications. In patients with elevated liver function tests, 58% were also being treated with methotrexate and/or NSAIDs.⁵ Because of the possible risks of additive or synergistic liver toxicity or haematotoxicity, particularly when used long-term, the UK manufacturers say that the concurrent use of methotrexate is not advisable.¹ The US manufacturers say that if concurrent use is undertaken, chronic monitoring should be increased to monthly intervals.² Close liver enzyme monitoring is also recommended if switching between these drugs, and colestyramine or activated charcoal washout should be performed when switching from leflunomide to methotrexate.^{1,2}

(i) *NSAIDs*

Leflunomide inhibits the activity of the cytochrome P450 isoenzyme CYP2C9 *in vitro* and might therefore be expected to increase the serum levels of NSAIDs that are metabolised by this isoenzyme (e.g. **diclofenac**, **ibuprofen**) but the manufacturers say that no safety problems were seen in clinical studies with leflunomide and NSAIDs. No special precautions would seem to be needed if any of these or any other NSAID drugs are given concurrently.¹

(j) *Rifampicin (Rifampin)*

When a single dose of leflunomide was given to subjects after taking multiple dose rifampicin, the peak levels of the active metabolite of leflunomide (A771726) were increased by 40% but the AUC was unchanged.^{1,2} The reasons are not understood. There would seem to be no reason for avoiding concurrent use, but the manufacturers advise caution as A771721

levels may build up over time.² It may be prudent to increase the frequency of leflunomide monitoring if these two drugs are used together.

(k) *Tegafur with Uracil*

A 75-year-old man with rectal cancer was given a 28-day course of tegafur/uracil 200 mg three times daily and calcium folinate 30 mg daily. Treatment was withheld because of an episode of minor duodenal bleeding and 3 months later he was given leflunomide 100 mg daily for 3 days followed by 20 mg daily to treat rheumatoid arthritis. A further two courses of tegafur/uracil (separated by 7 days) was given because of tumour progression, after which the patient had increasing numbness of the lower extremities, diagnosed as polyneuropathy. He also had severe diarrhoea and hand-foot syndrome. Tegafur is a prodrug of fluorouracil. Uracil prevents fluorouracil degradation by inhibiting dihydropyrimidine dehydrogenase. Both tegafur/uracil and leflunomide may cause neurotoxicity. As these symptoms had not occurred when tegafur/uracil had been given without leflunomide, it was suggested that leflunomide may increase fluorouracil toxicity by increasing its conversion to fluorouracil monophosphate, or by enhancing the effect of uracil by additional inhibition of dihydropyrimidine dehydrogenase.⁶ This is an isolated case and its general importance is unclear.

Muromonab-CD3 + Indometacin

One report suggested that indometacin may possibly increase the incidence of encephalopathy and psychosis in patients given muromonab-CD3.

Clinical evidence, mechanism, importance and management

A study of patient records found that 4 out of a total of 55 kidney transplant patients (7.3%) given muromonab-CD3 and indometacin 50 mg orally or rectally every 6 to 8 hours for 48 to 72 hours developed serious encephalopathy and psychosis compared with only two out of 173 patients (1.2%) who had received muromonab-CD3 without indometacin.¹ This appears to be an isolated report, and its general significance is unknown. Indometacin has been used to reduce the adverse effects of muromonab-CD3, and in one analysis concurrent use was associated with reduced fever, headache, and gastrointestinal disturbances.² Muromonab-CD3 alone is associated with encephalopathy and other CNS adverse effects, and the manufacturer warns that patients should be closely monitored for these effects.³

Mycophenolate + Allopurinol

No clinically relevant interactions have been seen between mycophenolate mofetil and allopurinol.

Clinical evidence, mechanism, importance and management

A study in 5 kidney transplant patients with gouty arthritis, who were switched from azathioprine to mycophenolate mofetil 2 g daily (to avoid the risk of an azathioprine/allopurinol interaction), found that no adverse effects occurred when they were given allopurinol 100 or 200 mg daily. On average, 10 weeks after the switch had taken place, uricaemia had fall-

en by 21%, mean serum creatinine levels were only slightly raised, by 12%, and white cell counts were unchanged.¹ Another study in 19 kidney transplant patients taking mycophenolate 2 g daily, ciclosporin and prednisolone also found a significant reduction in uricaemia without any adverse effects on white cell count, after allopurinol 100 mg daily was also taken, for 60 days.²

No special precautions would therefore seem necessary if allopurinol is used with mycophenolate, although the authors of both studies suggest that long-term randomised studies are needed to confirm safety.

Mycophenolate + Antacids

An aluminium/magnesium hydroxide antacid reduced the absorption of mycophenolate in one study, but the clinical relevance of this is uncertain.

Clinical evidence, mechanism, importance and management

When 10 mL of an aluminium/magnesium hydroxide antacid (*Maalox TC*) was given four times daily to 10 patients with a single 2-g dose of mycophenolate mofetil, the AUC of mycophenolic acid (the active form of the drug) was reduced by 17% and the maximum plasma concentration of mycophenolic acid was reduced by 38%.¹ The clinical importance of this reduction has not been assessed, but the authors of the report suggest that since 80% of transplant patients receive antacids, in practice, this interaction is of no great significance. The US manufacturers say that aluminium/magnesium antacids can be used in patients taking mycophenolate, but that they should not be given simultaneously.² With many other (but not all) antacid interactions, a 2-hour separation is usually sufficient to avoid an interaction. It would seem prudent to check that the immunosuppressant effects of mycophenolate remain adequate in the presence of this or any other antacid.

2. CellCept (Mycophenolate mofetil). Roche Laboratories Inc. US Prescribing information, October 2005.

Mycophenolate + Azathioprine

The manufacturers have recommended that mycophenolate mofetil should not be given with azathioprine because they say that concurrent use has not been studied,^{1,2} and both drugs have the potential to cause bone marrow suppression.¹

2. CellCept (Mycophenolate mofetil). Roche Products Ltd. UK Summary of product characteristics, March 2006.

Mycophenolate + Ciclosporin or Tacrolimus

Ciclosporin reduces the levels of mycophenolic acid. Tacrolimus may increase mycophenolic acid levels in some patient groups, but the clinical significance of this is unclear.

Clinical evidence

(a) Mycophenolate with Ciclosporin or Tacrolimus

A study in 78 kidney transplant patients taking corticosteroids with mycophenolate 1 g two or three times daily, and also taking either ciclosporin (68 patients) or tacrolimus (10 patients), found lower trough levels of the active metabolite, mycophenolic acid, and higher levels of the glucuronide metabolite in patients taking ciclosporin during the first 3 months post-transplant, when compared with those taking tacrolimus. Of interest is that of the 11 patients changed from ciclosporin to tacrolimus during the study,

5 patients subsequently required mycophenolate dose reductions because of adverse effects.¹ Another study found that despite a higher dose of mycophenolate, patients also taking ciclosporin had a 50% lower trough mycophenolic acid level when compared with those taking mycophenolate with tacrolimus.² Other studies have found similar results.^{3–5} In another study, 12 stable kidney transplant patients taking ciclosporin (*Neoral*) were given enteric-coated mycophenolate sodium (*Mycfortic*) 720 mg twice daily for 14 days. After pharmacokinetic assessment, they were then changed over to tacrolimus with the same dose and formulation of mycophenolate sodium. This study found that when tacrolimus was given the mycophenolic acid AUC was 20% greater than when ciclosporin was taken, but maximum concentration of mycophenolic acid was 24% greater with ciclosporin than with tacrolimus.⁶ However, a recent study in 22 kidney transplant patients taking mycophenolate found that neither ciclosporin (13 patients) nor tacrolimus (9 patients) affected the plasma levels of mycophenolic acid. Levels of the glucuronide metabolite were increased by ciclosporin but not tacrolimus.⁷ The manufacturers report that in one study in renal transplant patients receiving ciclosporin and mycophenolate mofetil, the AUC of mycophenolic acid was increased by about 30% when ciclosporin was replaced by tacrolimus.⁸

(b) Mycophenolate with Ciclosporin

There are reports that the trough levels of the active metabolite of mycophenolate, mycophenolic acid, may be reduced in the presence of ciclosporin.⁹ In a study, 52 kidney transplant patients were given mycophenolate mofetil 1 g twice daily with ciclosporin and prednisone. Six months after transplantation 19 patients continued triple therapy, 19 discontinued ciclosporin and 14 discontinued prednisone. Three months later, patients in whom ciclosporin had been discontinued had higher trough mycophenolic acid levels compared with the other groups of patients. Discontinuing ciclosporin resulted in almost a doubling of mycophenolic acid trough levels.¹⁰ Other studies note similar effects on mycophenolic acid levels in adult¹¹ and paediatric patients.¹²

A study in 33 children taking ciclosporin with prednisolone and 15 children additionally taking mycophenolate mofetil found that the ciclosporin levels 2 hours after the ciclosporin dose, was significantly reduced in those patients taking mycophenolate.¹³ Another study in children found similar results.¹⁴

(c) Mycophenolate with Tacrolimus

A study in stable kidney transplant patients taking tacrolimus long-term found that the addition of mycophenolate mofetil resulted in an increase in the tacrolimus AUC, but this was not considered significant.¹⁵ Another study in renal transplant patients found no change in tacrolimus levels when mycophenolate was given.⁸ However a 20% increase in tacrolimus levels has been reported in a study in liver transplant patients given mycophenolate 1.5 g twice daily.⁸

Mechanism

Mycophenolate is hydrolysed to its active drug, mycophenolic acid. This then undergoes glucuronidation by uridine diphosphate glucuronosyltransferase (UGT) to form an inactive glucuronide metabolite. This metabolite is then either excreted in urine or undergoes enterohepatic recirculation, where it is converted back into the active form, mycophenolic acid. Ciclosporin is thought to inhibit the enterohepatic conversion of the glucuronide metabolite back to the active metabolite, mycophenolic acid, leading to lower levels of the mycophenolic acid.⁸

Tacrolimus may inhibit uridine diphosphate glucuronosyltransferase (UGT) which metabolises mycophenolic acid to the glucuronide metabolite,^{1,7} and may also interfere with the enterohepatic recycling of the glucuronide metabolite.⁸

Importance and management

The addition of mycophenolate mofetil to ciclosporin has been found to reduce the incidence of rejection episodes in kidney transplant patients¹⁶ and it is licensed for combined use.⁸ From the studies above, ciclosporin appears to reduce the levels of the active metabolite, mycophenolic acid, and increase the levels of the glucuronide metabolite (which is associated with mycophenolate adverse effects). The UK manufacturers point out that as efficacy studies were conducted in patients using ciclosporin, mycophenolate and corticosteroids, the finding that ciclosporin reduces the mycophenolic acid AUC by 19% to 38% does not affect the recommended dose requirements.⁸ They also state that ciclosporin pharmacokinetics are not affected by mycophenolate.⁸ However, this is in contrast to the studies

in children reported above.^{13,14} It has also been observed that the use of triple therapy with corticosteroids, ciclosporin and mycophenolate mofetil rather than with azathioprine makes it possible to use a lower dose of ciclosporin.¹⁷ However, other studies have noted that adjusting ciclosporin doses affects mycophenolic acid levels, and therefore the overall effect on immunosuppression needs careful monitoring.¹²

The significance of the reported increases in mycophenolic acid levels with concurrent tacrolimus is not clear, and the manufacturers note that the benefit of concurrent use with tacrolimus has not been established.⁸ There are also inherent problems in interpretation of the results of studies comparing ciclosporin or tacrolimus with mycophenolate.^{2,4,18,19} It has been suggested that the changes in mycophenolic acid trough levels are because tacrolimus increases mycophenolic acid levels;⁴ however, another interpretation may be that the differences in mycophenolic acid trough levels and AUCs seen are because ciclosporin decreases mycophenolic acid exposure.¹⁸

Patients taking either ciclosporin or tacrolimus with mycophenolate should have their immunosuppressive response closely monitored, particularly if changing from ciclosporin to tacrolimus or *vice versa*, and dose adjustment of mycophenolate should be considered if patients develop mycophenolate-related adverse effects on switching from ciclosporin to tacrolimus.

Mycophenolate + Colestyramine

Colestyramine reduces the absorption of mycophenolate but the clinical relevance of this is uncertain.

Clinical evidence, mechanism, importance and management

Colestyramine 4 g three times daily for 4 days reduced the AUC of mycophenolic acid by 40% in a group of healthy subjects after they took a single 1.5-g oral dose of mycophenolate mofetil.¹ The UK manufacturers advise caution with concurrent use,¹ while the US manufacturers say that this combination is not recommended.² Separating the administration of

colestyramine and mycophenolate is not likely to eliminate this interaction, as colestyramine affects the enterohepatic recirculation of mycophenolate.²

The clinical importance of the reduction in mycophenolic acid levels has not been assessed but, if colestyramine is also given, it would seem prudent to confirm that the immunosuppressant effects of mycophenolate remain adequate.

- CellCept (Mycophenolate mofetil). Roche Products Ltd. UK Summary of product characteristics, March 2006.
- CellCept (Mycophenolate mofetil). Roche Laboratories Inc. US Prescribing information, October 2005.

Mycophenolate + Iron compounds

One study found that oral iron preparations significantly reduced the absorption of mycophenolate. However, other studies found that oral iron had no significant effect on the absorption of mycophenolate mofetil.

Clinical evidence, mechanism, importance and management

A study in 10 kidney transplant patients taking mycophenolate mofetil 1 g daily found that a single 105-mg dose of **ferrous sulfate** had no significant effect on the absorption of mycophenolate.¹ Another study in 40 kidney transplant patients found that two sustained-release tablets of **ferrous sulfate** (*Ferrogardumet*) daily, given either at the same time or 4 hours after the morning dose of mycophenolate (for 5 days after kidney transplantation), had no significant effect on the absorption of mycophenolate 1 g twice daily, when compared with patients not given an iron supplement. Mycophenolate toxicity occurred in 29% of the patients receiving concurrent iron, in 23% of the patients taking iron 4 hours after mycophenolate, and in 15% of patients not taking iron. Rejection occurred in 29%, 15%, and 8%, respectively, and anaemia in 0%, 21% and 15%, respectively, although the differences were not statistically significant (although this may have been due to the small study size).² A study in 16 healthy subjects given a single 1-g dose of mycophenolate mofetil with two sustained-release **ferrous sulfate** tablets (105 mg elemental iron per tablet) found no evidence of reduced mycophenolate absorption.³

These studies are in contrast with an earlier study in 7 healthy subjects, which found that a single 1050-mg dose of **ferrous sulfate** (210 mg of elemental iron) reduced the AUC and maximum levels of mycophenolic acid by more than 90%.⁴ In general, it would appear that no significant interaction usually occurs and concurrent use has no significant effect on the immunosuppressive effects of mycophenolate.

Mycophenolate + Methotrexate

A study in patients with rheumatoid arthritis found that the combination of methotrexate and mycophenolate mofetil was well tolerated and there were no pharmacokinetic interactions.¹ There would appear to be no need for dose adjustments if both drugs are given for rheumatoid arthritis.

- Yocum D, Kremer J, Blackburn W, Caldwell J, Furst D, Nunez M, Zuzga J, Zeig S, Gutierrez M, Merrill J, Dumont E, B Leishman. Cellcept® (mycophenolate mofetil - MMF) and methotrexate (MTX) safety and pharmacokinetic (PK) interaction study in rheumatoid arthritis patients. *Arthritis Rheum* (1999) 42 (9 Suppl), S83.

Mycophenolate + Metronidazole

Metronidazole may reduce the bioavailability of mycophenolate mofetil.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects found that metronidazole 500 mg three times daily for 5 days reduced the AUC of a single 1-g oral dose of mycophenolate mofetil given two hours after the antibacterial on day 4 by 19%. The AUC of the glucuronide metabolite was also reduced, by 27%. When norfloxacin 400 mg twice daily was also given, the AUC of mycophenolate and its glucuronide metabolite were reduced by 33% and 41%, respectively. This interaction was thought to be due to interference of the enterohepatic recirculation of mycophenolate by the antibacterials.¹ There appear to be no further clinical reports of an interaction between metronidazole and mycophenolate. The changes with metronidazole alone were modest, and possibly of minor clinical significance, but the larger reductions seen when norfloxacin was also given suggest that some caution may be prudent. Monitor the outcome of concurrent use to ensure that mycophenolate remains effective.

1. Naderer OJ, Dupuis RE, Heinzen EL, Wiwattanawongsa MS, Johnson MW, Smith PC. The influence of norfloxacin and metronidazole on the disposition of mycophenolate mofetil. *J Clin Pharmacol* (2005) 45, 219–26.

Mycophenolate + Miscellaneous

Co-trimoxazole appears to have no effect on the bioavailability of mycophenolic acid. Probenecid increased the AUC of the glucuronide metabolite of mycophenolic acid threefold in animals. However, as there appear to be no clinical reports of this interaction, the clinical significance of this is unclear. Further study is needed.¹

1. CellCept (Mycophenolate mofetil). Roche Products Ltd. UK Summary of product characteristics, March 2006.

Mycophenolate + Polycarbophil calcium

Polycarbophil calcium reduces the bioavailability of mycophenolate.

Clinical evidence, mechanism, importance and management

A study in 5 healthy subjects given a single 1-g dose of mycophenolate alone or with polycarbophil calcium 2.4 g found that the AUC and peak serum levels of mycophenolic acid were reduced by about 51% and 69%, respectively. The authors suggest that this interaction was probably the result of reduced absorption due to chelate-complex formation between mycophenolate and the calcium ions, which they demonstrated in an *in vitro* study. It was concluded that mycophenolate and polycarbophil calcium should not be taken at the same time.¹ A suitable interval was not specified, but a separation of 2 hours has been suggested with 'antacids', (p.1067), which interact by a similar mechanism. Further study is needed.

1. Kato R, Ooi K, Ikura-Morii M, Tsuchishita Y, Hashimoto H, Yoshimura H, Uenishi K, Kawai M, Tanaka K, Ueno K. Impairment of mycophenolate mofetil absorption by calcium polycarbophil. *J Clin Pharmacol* (2002) 42, 1275–80.

Mycophenolate + Quinolones

Norfloxacin may reduce the bioavailability of mycophenolate mofetil.

Clinical evidence, mechanism, importance and management

A study in 11 healthy subjects found that norfloxacin 400 mg twice daily reduced the AUC of a single 1-g oral dose of mycophenolate mofetil given two hours after the antibacterial on day 4 by 10%. The AUC of the glucuronide metabolite was also reduced by 10%. When norfloxacin 400 mg twice daily was also given, the AUC of mycophenolate and its glucuronide metabolite were reduced by 33% and 41%, respectively. This interaction was thought to be due to interference of the enterohepatic recirculation of mycophenolate by the antibacterials.¹ There appear to be no further clinical reports of an interaction between these antibacterials and mycophenolate. The changes with norfloxacin alone were modest, and unlikely to be

of clinical significance, but the larger reductions seen when metronidazole was also given suggest that some caution may be prudent. Monitor the outcome of concurrent use to ensure that mycophenolate remains effective. There is no information about the use of other quinolones and metronidazole given with mycophenolate, but, if the mechanism is correct, until more information is available, it would be prudent to assume that they will interact similarly.

1. Naderer OJ, Dupuis RE, Heinzen EL, Wiwattanawongsa MS, Johnson MW, Smith PC. The influence of norfloxacin and metronidazole on the disposition of mycophenolate mofetil. *J Clin Pharmacol* (2005) 45, 219–26.

Mycophenolate + Rifampicin (Rifampin)

Rifampicin reduces the levels of mycophenolic acid (the active metabolite of mycophenolate) and increases the levels of the metabolite associated with mycophenolate adverse effects.

Clinical evidence

A heart-lung transplant patient taking tacrolimus 7 mg twice daily and mycophenolate mofetil 1 g twice daily was given rifampicin 600 mg daily, pyrazinamide 1 g daily, isoniazid 300 mg daily and pyridoxine 250 mg weekly for suspected mycobacterial infection. As expected, the tacrolimus dose needed to be substantially increased when rifampicin was started, and the rifampicin dose was reduced to 450 mg daily to try to minimise the interaction. However, the mycophenolate mofetil dose also needed to be increased to 6 g daily without achieving an adequate level (target trough plasma level of 2.5 micrograms/mL). Rifampicin was then stopped and the patient continued taking isoniazid and pyrazinamide. Pharmacokinetic analysis of mycophenolate, before and 13 days after rifampicin was stopped, found that the dose-corrected trough level of mycophenolic acid increased 18-fold and the AUC₀₋₁₂ increased by 221%.

A subsequent study by the same authors in 8 kidney transplant patients taking mycophenolate 750 mg to 1 g twice daily found that rifampicin 600 mg daily for 8 days decreased the AUC₀₋₁₂ and peak levels of mycophenolic acid by 17.5% and 18.5%, respectively. Glucuronide levels were increased and the AUC₀₋₁₂ and peak levels of the acyl glucuronide metabolite, which has been associated with an increase in mycophenolate adverse effects, was significantly increased by 193% and 121%, respectively.¹

Mechanism

The exact mechanism of this interaction is unknown. Mycophenolate is a pro-drug and is metabolised to its active form, mycophenolic acid, which undergoes glucuronidation by uridine diphosphate-glucuronosyltransferases (UGTs) in the liver, kidney and intestine to its inactive 7-*O*-glucuronide metabolite. The authors of these reports suggest that rifampicin induces intestinal, kidney and liver glucuronidation of mycophenolic acid by UGT and reduces its enterohepatic recirculation and absorption.^{1,2}

Importance and management

These appear to be the only reports of an interaction between rifampicin and mycophenolate. However, the effects of reduced mycophenolic acid levels could be significant in terms of acute graft rejection. Also the increases in the levels of the acyl glucuronide metabolite could put the patient at greater risk of adverse effects, although this was not seen in these studies. Mycophenolate should be monitored closely during concurrent use with rifampicin and the dose adjusted as required, both on starting or stopping rifampicin.

Mycophenolate + Sevelamer

Sevelamer moderately reduces mycophenolate levels.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 3 adult and 6 paediatric kidney transplant patients taking mycophenolate and ciclosporin were given sevelamer, either as a single 1.6-g dose (adults), or 1.2-g dose (children), or for 4 days (same dose given three times daily). The average age of the children was 12 years. The single dose of sevelamer reduced the AUC of mycophenolate by 25%, and multiple-dosing with sevelamer reduced the AUC of mycophenolate by 30%. The interaction was thought to be due to sevelamer reducing the absorption of mycophenolate.¹

The clinical significance of this interaction is unclear although the manufacturers note that graft rejection has not been reported.² However, it would seem prudent to monitor mycophenolate levels in any patient given sevelamer. The manufacturers of sevelamer recommend that mycophenolate is given at least one hour before or three hours after taking sevelamer.³

Mycophenolate + Sirolimus

Higher levels of mycophenolic acid have been seen in kidney transplant patients taking mycophenolate with sirolimus when compared with similar patients taking mycophenolate with ciclosporin.

Clinical evidence and mechanism

A study in 12 kidney transplant patients taking mycophenolate 1 g twice daily at the same time as sirolimus (dose adjusted to attain therapeutic trough blood levels of 10 to 15 nanograms/mL), for 30 days found that the AUC₀₋₉ of the active metabolite of mycophenolate, mycophenolic acid, was 1.5-fold higher in the sirolimus-treated group when compared to a similar group of 19 patients taking ciclosporin instead of sirolimus.¹ A study in 13 kidney transplant patients taking mycophenolate 1 g twice daily with sirolimus (trough blood levels of 10 to 20 nanograms/mL), found that the mycophenolic acid trough levels and AUC were significantly higher in patients taking sirolimus, compared with a similar group of 17 patients given ciclosporin, although peak mycophenolic acid levels were similar. Mycophenolate dose reductions were required in 2 patients in the first month, another 3 patients in the second month and 6 patients in the third month (total of 11 patients), compared with the ciclosporin group where 5 patients needed mycophenolate dose reductions. A higher incidence of leucopenia at months 1 and 2 after transplantation was reported in patients taking sirolimus, rather than ciclosporin, with mycophenolate.²

Another study in 11 kidney transplant patients taking low-dose mycophenolate 500 mg twice daily with low-dose sirolimus (mean dose of between 3.6 to 4.3 mg daily adjusted to achieve a trough blood level of 5 to 10 nanograms/mL) found that the sirolimus-based regimen had a 4.4-fold higher dose-adjusted mycophenolic acid trough level than those found in another similar group of 10 patients taking a ciclosporin-based regimen.³

Yet another study in 15 kidney transplant patients taking mycophenolate with sirolimus looked at the effects of sirolimus on mycophenolate dose regimens of 500 mg, 750 mg, and 1 g twice daily and compared them with the effects of ciclosporin on mycophenolate 1 g twice daily in 12 similar patients. They found that mycophenolate 750 mg twice daily with sirolimus produced a comparable AUC₀₋₁₂ and trough mycophenolic acid levels to mycophenolate 1 g twice daily with ciclosporin.

Importance and management

Ciclosporin is known to inhibit the metabolism of mycophenolate, producing lower levels of mycophenolic acid, see 'Mycophenolate + Ciclosporin or Tacrolimus', p.1067. Whether sirolimus specifically raises mycophenolate levels compared with mycophenolate taken on its own is unclear, however raised mycophenolic acid levels have been associated with an increased risk of adverse effects.¹⁻³ The authors of one of the studies⁴ suggest that the mycophenolate dose should be reduced from 1 g to 750 mg twice daily in patients taking sirolimus, as this produced comparable mycophenolic acid levels values with the recommended dose of mycopheno-

late 1 g twice daily with ciclosporin.

However, until further information is available, patients taking mycophenolate and changed from ciclosporin to sirolimus should be closely monitored for signs of adverse effects, and the dose of mycophenolate reduced accordingly.

Mycophenolate + St John's wort (*Hypericum perforatum*)

St John's wort does not appear to alter the pharmacokinetics of mycophenolate.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 8 stable kidney transplant patients taking mycophenolate and tacrolimus were given 600 mg of St John's wort extract (*Jarsin 300*) daily for 14 days. The study intended to make dose adjustments to keep the trough mycophenolic acid levels within the desired range, but dosage adjustment was not found to be necessary in any of the 8 patients.¹

Mycophenolate + Voriconazole

Voriconazole had no effect on the pharmacokinetics of a single 1-g dose of mycophenolate.¹

1. Wood N, Abel, Fielding A, Nichols DJ, Bygrave E. Voriconazole does not affect the pharmacokinetics of mycophenolic acid. *Intersci Conf Antimicrob Agents Chemother* (2001) 41, 3.

Sirolimus + ACE inhibitors

Oedema of the tongue, face, lips, neck and chest has been reported in patients taking sirolimus with enalapril or ramipril.

Clinical evidence

A study in 52 kidney transplant patients taking sirolimus 2 to 5 mg daily with **ramipril** 2.5 to 5 mg daily found that 5 of these patients developed non-life threatening tongue oedema within one month of starting **ramipril**. All of these patients had taken **ramipril** before their transplant without any adverse effects or signs of angioedema. The tongue oedema resolved within 2 weeks of stopping ramipril. The authors noted that at that time all 5 patients were taking sirolimus 5 mg daily and ramipril 5 mg daily, with their sirolimus levels in the higher end of the range between 16 to 20 nanograms/mL. Three months after their transplant, when sirolimus had been stabilised at a lower dose of 2 to 4 mg daily, resulting in blood levels of 8 to 12 nanograms/mL, ramipril was restarted at a 2.5 mg daily with no adverse effects.¹

A kidney transplant patient taking sirolimus 9 mg daily developed non-pitting oedema of the eyelid, cheek and lips when he started to take **ramipril** (dose not specified).² Another kidney transplant patient who had taken **enalapril** 2.5 mg daily for two months developed erythematous skin lesions with non-pitting oedema of the neck, face and chest 9 days after she was switched from tacrolimus to sirolimus 2 mg daily. Symptoms resolved in both patients when the ACE inhibitor was stopped and corticosteroid therapy was increased.²

Mechanism, importance and management

ACE inhibitors alone can cause angioedema but in the study above, all 5 patients had previously taken an ACE inhibitor without any allergic reaction or adverse effects.¹ Although not life-threatening, these reports of oedema suggest that caution should be used when either starting an ACE inhibitor in a patient already taking sirolimus or when starting sirolimus in a patient taking an ACE inhibitor. The effect may be dose-related, with higher doses of both drugs potentially posing a greater risk.

Sirolimus or Tacrolimus + Amiodarone

There is an isolated case report of increased sirolimus and tacrolimus levels associated with the concurrent use of amiodarone in a paediatric patient.

Clinical evidence, mechanism, importance and management

A 2-year-old heart transplant patient given tacrolimus 0.02 mg/kg daily was given amiodarone to control ventricular arrhythmias. Her tacrolimus trough levels were reported as within target range of 8 to 10 micrograms/L on both day 1 and day 3 after starting the amiodarone. She was then switched from tacrolimus to sirolimus 0.06 mg/kg daily, increased to 0.12 mg/kg after 2 days, with tacrolimus continued until therapeutic sirolimus levels were achieved. The sirolimus levels and tacrolimus levels 9 days after starting amiodarone were found to be 53 micrograms/L and 13 micrograms/L, respectively. Subsequent sirolimus doses were put on hold and tacrolimus was stopped. The sirolimus levels were raised for a further 14 days. Sirolimus was restarted at a lower dose (0.03 mg/kg daily) but the levels remained above 10 micrograms/L and the sirolimus dose was reduced further to 0.02 mg/kg daily.¹ The elevated levels of both drugs were attributed to an interaction with amiodarone, which can inhibit the cytochrome P450 isoenzyme CYP3A4, and affect P-glycoprotein, which have effects on sirolimus and tacrolimus metabolism and clearance.¹

The authors of this report advise that, because of the long half-life of sirolimus, and the difficulty in reducing elevated levels quickly, prescribers should consider reducing the sirolimus and tacrolimus doses before starting amiodarone¹ rather than waiting for the interaction to occur. They also advise more frequent monitoring of sirolimus and tacrolimus levels if amiodarone is also given. This appears to be the only published report of this interaction at present.

Sirolimus + Azoles

Sirolimus levels are markedly raised by ketoconazole, and itraconazole, posaconazole and voriconazole appear to interact similarly. Clotrimazole is also predicted to interact with sirolimus. A case report suggests that fluconazole also raises sirolimus levels. In theory it is possible that miconazole oral gel may also interact with sirolimus.

Clinical evidence

(a) Fluconazole

A patient taking sirolimus after a kidney transplant was given fluconazole 200 mg daily for oesophageal candidiasis. Because an interaction was anticipated, the sirolimus dosage was reduced from 4 to 3 mg daily. After 4 days the sirolimus level had risen from about 10 micrograms/L to 22.8 micrograms/L. The dose of sirolimus was then reduced to 2 mg daily, but by the seventh day of fluconazole treatment the sirolimus level had reached 35 micrograms/L, after which they began to fall. The patient then had a hyperkalaemic arrest and died.¹ The sirolimus levels of another kidney transplant patient were raised almost fivefold about 3 weeks after she started to take fluconazole.²

(b) Itraconazole

A heart transplant patient needed only half of his normal sirolimus dose to maintain about the same trough levels when he took itraconazole 400 mg daily for a year.² A kidney transplant patient taking sirolimus 5 mg daily was given an initial dose of itraconazole 600 mg daily on post-transplant day 10 followed by 400 mg daily. The sirolimus trough level was subtherapeutic at 6.8 nanograms/mL one day after starting itraconazole so the sirolimus dose was increased to 10 mg daily. The sirolimus level then increased rapidly and reached a level of 82.5 nanograms/mL 6 days after itraconazole was started.³ A haematopoietic stem cell transplant patient taking itraconazole 200 mg twice daily was changed from tacrolimus to sirolimus 7 mg daily. The sirolimus dose was reduced to 5 mg daily 6 days later because the sirolimus level was 17.5 nanograms/mL (therapeutic range 5 to 15 nanograms/mL). The sirolimus level was found to be 35.6 nanograms/mL two days later and sirolimus was stopped until the level had fallen back to the normal range. It was subsequently restarted and the dose adjusted between 0.5 mg and 2 mg daily according to levels.⁴

(c) Ketoconazole

A clinical study in 23 healthy subjects found that while taking ketoconazole 200 mg daily for 10 days, the maximum serum levels and AUC of a single 5-mg dose of sirolimus were increased 4.3-fold and 10.9-fold, respectively.⁵ In a study in 6 kidney transplant patients, ciclosporin was stopped because of toxicity or rejection episodes and sirolimus was started. They were given a lower than recommended dose of sirolimus (250 to 500 micrograms daily) but were also given ketoconazole 100 to 200 mg daily, adjusted to maintain sirolimus levels within the therapeutic range. The serum creatinine of the patients improved and reduced from 230 micromol/L to 194 micromol/L.⁶

(d) Voriconazole

Voriconazole 400 mg twice daily for one day, then 200 mg twice daily for 8 days markedly raised the maximum serum levels and AUC of a single 2-mg dose of sirolimus by about 7-fold and 11-fold, respectively.⁷ In a retrospective study of allogeneic haematopoietic stem cell transplant patients, 11 patients were found to have received both sirolimus and voriconazole for a median of 33 days (range, 3 to 100 days). Three patients had increased trough sirolimus levels of between 10 and 19 nanograms/mL and serious toxicity occurred in 2 of them. The other eight patients had their sirolimus dose reduced by 90% when voriconazole was started, in anticipation of the interaction. Trough sirolimus levels were similar to those before voriconazole administration and no significant toxicity from either drug was found.⁸ A patient taking sirolimus, who had markedly raised sirolimus levels with itraconazole, was given voriconazole, and the sirolimus dose was decreased to 0.5 mg daily in anticipation of a similar interaction. The sirolimus trough level was 6.4 nanograms/mL, about the patients' usual range, two days after starting voriconazole.⁴

A case report describes a patient with a heart transplant who was given two doses of voriconazole 400 mg then 200 mg twice daily for 16 days. When sirolimus was started a dose of 1 mg gave a sirolimus trough level of 12.8 nanograms/mL, but after the voriconazole was stopped a dose of 3 mg only gave trough sirolimus levels of 7.4 nanograms/mL.² Voriconazole has been seen to markedly raise sirolimus levels in a number of other patients.^{2,9}

Mechanism

Ketoconazole, itraconazole, posaconazole and voriconazole are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, the isoenzyme that is at least partly responsible for the metabolism of sirolimus.¹⁰ Therefore these azoles probably cause raised sirolimus levels by inhibiting its metabolism. Fluconazole and miconazole also inhibit CYP3A4, but are less potent than ketoconazole. Hence sirolimus levels rise when fluconazole is given, but the rise is not as great as that seen with ketoconazole. Sirolimus is also a substrate for P-glycoprotein and, as azole antifungals may inhibit intestinal P-glycoprotein, this may also contribute to the interaction by increasing the oral bioavailability of sirolimus.³

Importance and management

The concurrent use of sirolimus is contraindicated by the manufacturers of **voriconazole**.^{7,11} The rises in sirolimus levels caused by voriconazole are probably too large to be easily accommodated by reducing the dosage of the sirolimus. One study found that an initial empiric reduction in

sirolimus dose by 90% at the start of treatment with voriconazole was adequate. However, more study is required to confirm the safety of such regimens.⁸

The manufacturers of sirolimus say that concurrent use of strong inhibitors of CYP3A4, including **ketoconazole**, voriconazole and **itraconazole** is not recommended,^{10,12} but note that any patient given these drugs should have their trough sirolimus levels closely monitored both during use and after they are stopped. **Clotrimazole**^{10,12} and **posaconazole**¹³ are predicted to interact similarly. **Fluconazole**, although a weaker inhibitor of CYP3A4 than ketoconazole, voriconazole or itraconazole, has been reported to interact in two cases. Sirolimus plasma levels should be monitored during treatment with and following the withdrawal of any of these antifungals.

There appear to be no reports of an interaction between **miconazole** and sirolimus. However, a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction. The manufacturers of miconazole oral gel recommend close monitoring and possible dose reduction of sirolimus if both drugs are given.¹⁴ An interaction with intravaginal miconazole would not normally be expected because its systemic absorption is usually very low (less than 2%).¹⁵

Sirolimus + Calcium-channel blockers

Diltiazem and verapamil raise sirolimus levels, and dosage adjustments may be necessary. Nicardipine is predicted to interact similarly. Nifedipine appears not to interact with sirolimus.

Clinical evidence, mechanism, importance and management

A randomised, crossover study in 18 healthy subjects found that a single 120-mg oral dose of **diltiazem** increased the AUC and the maximum serum levels of a single 10-mg oral dose of sirolimus by 60% and 43%, respectively. The pharmacokinetics of **diltiazem** and its metabolites were unchanged. The likely reason for this interaction is that **diltiazem** inhibits the cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and liver, which is the primary route of sirolimus metabolism. **Diltiazem** may also inhibit P-glycoprotein activity, which leads to increased sirolimus absorption.¹ This was a single-dose study, but the evidence suggests that this interaction will also occur with multiple doses of both drugs, for which reason the manufacturers recommend whole blood monitoring and a possible sirolimus dosage reduction (based on sirolimus levels) if **diltiazem** is used concurrently.^{2,3}

In 26 healthy subjects the concurrent use of sirolimus oral solution 2 g daily and **verapamil** 180 mg every 12 hours resulted in an increase in the sirolimus maximum levels and AUC, of 2.3-fold and 2.2-fold, respectively, and an increase in the maximum levels and AUC of **S-verapamil** of 1.5-fold.^{2,3} The manufacturer notes that other calcium-channel blockers that inhibit CYP3A4 might interact similarly, and they specifically name **nicardipine**.^{2,3}

Nifedipine [which does not inhibit CYP3A4] is said not to interact,^{2,3} and a study comparing 16 patients taking **nifedipine** and sirolimus with 10 patients taking sirolimus alone found no significant differences in sirolimus pharmacokinetics between the two groups.⁴

Sirolimus + Ciclosporin

Ciclosporin raises sirolimus serum levels, and this can be reduced by giving the drugs at least 4 hours apart. Concurrent use for longer than 3 to 4 months possibly increases renal toxicity, and should be used with caution only when the benefits outweigh the risks. Sirolimus has been reported to increase ciclosporin levels.

Clinical evidence

(a) Effects on ciclosporin

A randomised study found that when sirolimus was added to a ciclosporin/corticosteroid regimen in kidney transplant patients, the steady-state ciclosporin levels remained unchanged. Blood pressure, glomerular filtration rate, creatinine levels, triglyceride levels and liver enzymes (ALT, AST) were unchanged.¹ A 2-week pharmacokinetic study in 40 kidney transplant patients found that sirolimus 0.5 to 6.5 mg/m² given twice daily did not affect the pharmacokinetics of ciclosporin 75 to 400 mg twice daily. The patients were also taking prednisone.² Two related studies in kidney transplant patients confirmed the absence of an effect of sirolimus on ciclosporin pharmacokinetics.³ Similarly, in another study in healthy subjects, single doses of sirolimus did not affect the pharmacokinetics of a single dose of ciclosporin (microemulsion formulation, *Neoral*) when given either at the same time or 4 hours apart.⁴

However, another study in kidney transplant patients taking ciclosporin (*Neoral*) and sirolimus (taken 4 hours after ciclosporin) over a 6 month period found that the oral clearance of ciclosporin was decreased, and lower doses of ciclosporin were needed to maintain therapeutic levels.⁵ A kidney transplant patient taking ciclosporin 400 mg daily with prednisone started taking sirolimus 2 mg daily. Within 2 weeks, she was readmitted to hospital with signs of ciclosporin toxicity, including raised creatinine, urea, and high blood pressure, and her ciclosporin level was found to have increased to 536 nanograms/mL. The ciclosporin dose was reduced to 300 mg daily, sirolimus continued, and her ciclosporin level reduced to 276 nanograms/mL. The sirolimus levels remained at 5.2 to 10.6 nanograms/mL, within the therapeutic range.⁶

(b) Effects on sirolimus

In a single-dose study in healthy subjects, ciclosporin (microemulsion formulation, *Neoral*) given 4 hours before sirolimus increased the maximum serum levels of sirolimus 1.4-fold and increased its AUC 1.8-fold. When the drugs were given at the same time, the effect was even greater, with a 2.2-fold increase in maximum sirolimus level and 3.3-fold increase in the AUC.⁴ This study confirmed the findings of a previous multiple-dose study in kidney transplant recipients,⁷ and similar results have been seen in other studies.⁸ Ciclosporin 300 mg taken at the same time, 2 hours after, or 4 hours after sirolimus 5 mg increased the AUC of sirolimus by 183%, 141%, and 80%, respectively, but when sirolimus was taken 2 hours before ciclosporin, there was no increase in the AUC or peak levels of sirolimus.⁹ The US manufacturer of sirolimus also presents data showing that ciclosporin oral solution (*Sandimmune*) given at the same time as sirolimus, increased sirolimus trough levels by 67% to 86% in 150 patients with psoriasis.⁵

Mechanism

It appears that ciclosporin inhibits the metabolism of sirolimus by the cytochrome P450 isoenzyme CYP3A4 in the gut and liver leading to increased sirolimus levels.^{4,5,9} P-glycoprotein inhibition may also contribute to the interaction.

Importance and management

An established interaction. The manufacturers recommend that sirolimus should be given 4 hours after microemulsion ciclosporin, and consistently, either with or without food.^{5,9} Despite this, it may still be necessary to reduce the sirolimus dose.⁴ Renal function should be closely monitored, and if serum creatinine levels increase, discontinuation of sirolimus or ciclosporin should be considered.⁵ If ciclosporin is withdrawn, the sirolimus dosage will need to be raised fourfold to take into account the absence of the interaction (twofold increase needed) and the need for increased immunosuppression (twofold increase needed). A target trough sirolimus level of 12 to 20 nanograms/mL (chromatographic assay) is recommended when ciclosporin has been withdrawn.⁹

Until further clinical data are available, the manufacturer does not recommend continued usage of the combination beyond 3 months⁹ to 4 months.⁵ In patients taking sirolimus and ciclosporin for more than 3 months, higher serum creatinine levels and lower glomerular filtration rates have been seen. Patients who were successfully withdrawn from ciclosporin had improved creatinine levels, higher glomerular filtration rates and a lower risk of malignancy.⁹

The UK manufacturers do not recommend the use of sirolimus in high-risk patients (e.g. those with renal impairment, markers of rejection of multi-organ transplants) as insufficient numbers of this type of patient were studied.⁹ However, the US manufacturers state that it may be used in combination with ciclosporin in high-risk patients for up to 1 year.⁵

The concurrent use of both drugs increases the risk of developing calcineurin inhibitor-induced haemolytic uraemic syndrome/thrombotic thrombocytopenic purpura/thrombotic microangiopathy.^{5,9} An increased risk of hepatic artery thrombosis, leading to graft loss and/or death in most cases, has also been seen in clinical studies in *de novo* liver transplant patients taking sirolimus with ciclosporin, and the manufacturers do not recommend using sirolimus in liver or lung transplant patients as safety and effectiveness have not been proven.^{5,9}

Sirolimus + Corticosteroids

Intravenous methylprednisolone had no effect on trough sirolimus levels. Sirolimus slightly increased prednisolone levels (derived from prednisone), but this is probably not clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Methylprednisolone

When 14 patients taking sirolimus (and also taking either azathioprine or mycophenolate) were given methylprednisolone as a daily intravenous bolus for 1 to 5 days (total dose of between 500 mg and 3 g) the sirolimus trough concentrations were not significantly altered.¹ No additional precautions seem necessary on concurrent use.¹

(b) Prednisolone or Prednisone

In a study in kidney transplant patients taking ciclosporin and prednisone 5 to 20 mg daily, only minor to moderate changes occurred in the pharmacokinetics of prednisolone when sirolimus 6 to 13 mg/m² daily was given for 2 weeks.² The maximum plasma prednisolone levels were raised by

14%, and the AUC was raised by 18%. The clinical relevance of these findings is uncertain, but they are likely to be minor.

Sirolimus + CYP3A4 inducers

Drugs that induce the cytochrome P450 isoenzyme CYP3A4 are predicted to lower sirolimus levels. Close monitoring is recommended.

Clinical evidence, mechanism, importance and management

Sirolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and by the drug transporter protein P-glycoprotein: drugs that induce their activity are predicted to lower sirolimus levels.^{1,2}

'Rifampicin', (p.1074), and 'phenytoin', (p.1074), are known potent enzyme inducers, and have been seen to lower sirolimus levels, and the manufacturers predict that **carbamazepine**, **phenobarbital** (and thus, primidone), and **St John's wort** will interact similarly.^{1,2} These predictions are as yet unconfirmed, but it would certainly be prudent to monitor sirolimus levels closely if any of these drugs are used concurrently. In the case of **St John's wort**, it may be best to avoid the combination all together (see 'drug-herb interactions', (p.10)). What should be remembered is that the extent of the inducing effects of these drugs is not identical, so that very marked effects like those observed with rifampicin may not occur; nevertheless the interaction may still be clinically important.

Sirolimus + CYP3A4 inhibitors

Drugs that inhibit the cytochrome P450 isoenzyme CYP3A4 are predicted to raise sirolimus levels. Monitoring is recommended.

Clinical evidence, mechanism, importance and management

Sirolimus is extensively metabolised by cytochrome P450 isoenzyme CYP3A4 in the intestinal wall and by the drug transporter protein, P-glycoprotein: drugs that inhibit their activity may raise sirolimus levels.^{1,2}

'Ketoconazole and voriconazole', (p.1071), 'diltiazem and verapamil', (p.1072), 'erythromycin', (below) and 'nelfinavir', (p.1074) have been shown to raise sirolimus levels, and the manufacturers name a number of others that also inhibit CYP3A4, which they predict will interact similarly. They list **bromocriptine** (although there appear to be no reported interactions with bromocriptine due to CYP3A4 inhibition), **cimetidine**, and **danazol**.^{1,2}

These predictions are as yet unconfirmed, but it would certainly be prudent to monitor sirolimus levels closely if these drugs are used concurrently. What should be remembered is that the extent of the inhibitory effects of these drugs is not identical, so that very marked effects like those observed with ketoconazole may not occur, nevertheless the interaction may still be clinically important. **Grapefruit juice** also inhibits CYP3A4 (potentially raising sirolimus levels), and in this case the manufacturers recommend that concurrent use should be avoided.^{1,2}

2. Rapamune (Sirolimus). Wyeth Pharmaceuticals. UK Summary of product characteristics, March 2007.

Sirolimus + Macrolides

Two patients had large elevations in their sirolimus levels when they were given erythromycin. Other macrolides are expected to interact similarly.

Clinical evidence, mechanism, importance and management

A case report describes 2 patients taking sirolimus who were also given **erythromycin** 1 g three times daily for suspected *Legionella pneumoniae*. Despite reductions in the sirolimus dosage, the sirolimus levels of both patients rose fivefold.¹

In 24 healthy subjects the concurrent use of **erythromycin** 800 mg three times daily with sirolimus oral solution 2 mg daily resulted in a significant increase in the peak blood levels and AUC of sirolimus, by 4.2- and 4.4-fold, respectively. The peak plasma levels and AUC of erythromycin were also increased, by 1.6- and 1.7-fold, respectively.^{2,3}

Erythromycin is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, which is the main enzyme responsible for the metabolism of sirolimus. Therefore **erythromycin** probably inhibited the metabolism of sirolimus, causing the levels to rise.

The manufacturers predict that other inhibitors of CYP3A4 (they name **clarithromycin** and **telithromycin**) will interact similarly, and should be avoided.^{2,3} The manufacturers of **telithromycin** specifically advise that if concurrent use is needed, sirolimus levels should be closely monitored and the dose altered as required, both when starting treatment and also when telithromycin is stopped.⁴

The manufacturers of sirolimus also name **troleandomycin** as a moderate inhibitor of CYP3A4, which may possibly interact.^{2,3} However, **troleandomycin** tends to be a more potent inhibitor of CYP3A4 than **clarithromycin**, so it would seem prudent to at least monitor concurrent use closely, or even consider avoiding the combination, as recommended with **clarithromycin**.

4. Ketek (Telithromycin). Sanofi-Aventis. UK Summary of product characteristics, May 2007.

Sirolimus + Miscellaneous

The manufacturers of sirolimus note that **cisapride** and **metoclopramide** may increase sirolimus levels, although there do not appear to be any published reports of this interaction.^{1,2} No significant pharmacokinetic interaction has been found with **aciclovir**, **digoxin**, **glibenclamide** or **co-trimoxazole**.^{13,4} There is an isolated case report of **atorvastatin** increasing sirolimus trough serum levels twofold in one patient, and a reduction in the sirolimus dose was required.⁵

5. Barshes, NR, Goodpastor SE, Goss JA, DeBakey ME. Sirolimus-atorvastatin drug interaction in the pancreatic islet transplant recipient. *Transplantation* (2003) 76, 1649–50.

Sirolimus + Phenytoin

Two case reports describe increased sirolimus dose requirements in the presence of phenytoin.

Clinical evidence, mechanism, importance and management

An 11-year-old girl with a kidney transplant taking phenytoin started taking sirolimus 30 micrograms/kg twice daily following an episode of acute rejection. The dose of sirolimus was increased tenfold over the next few weeks in an attempt to achieve the target trough level of 10 to 20 nanograms/mL, and two further episodes of acute rejection occurred. About one month after the sirolimus had been started, tacrolimus was added, and her phenytoin was stopped. Over the next few weeks her sirolimus level rose to about 40 nanograms/mL. The patient subsequently recovered.¹

A 62-year-old woman started taking phenytoin 100 mg twice daily because she developed a seizure disorder following a liver transplant. At this

time she was taking ciclosporin, but it was decided to start sirolimus because of neurological complications. The initial sirolimus dose of 5 mg daily produced subtherapeutic sirolimus levels. She was subsequently stabilised taking sirolimus 15 mg daily, with trough levels of less than 5 nanograms/mL. Phenytoin was stopped, and about 5 days later her trough sirolimus level was found to be around 15 to 20 nanograms/mL. After a further 5 days, the sirolimus dose was reduced to 10 mg daily. The authors of this report suggest that the initial high sirolimus dose was necessary as phenytoin, a potent inducer of the cytochrome P450 isoenzyme CYP3A4, increased the metabolism of sirolimus, which is mainly metabolised by this isoenzyme. When the phenytoin was withdrawn, sirolimus metabolism returned to normal, resulting in high sirolimus levels.²

These appear to be the only reports of this interaction, but they are consistent with the way both drugs are known to interact. It would therefore seem prudent to monitor sirolimus levels in any patient in whom phenytoin is started or withdrawn, and to adjust the dose as necessary.

Sirolimus + Protease inhibitors

Nelfinavir increased the levels of sirolimus in one patient. Other protease inhibitors are predicted to also raise sirolimus levels.

Clinical evidence, mechanism, importance and management

An HIV-positive, liver transplant patient taking sirolimus 5 mg daily was given **nelfinavir** 250 mg twice daily (one-fifth of normal dose), lamivudine and zidovudine. Three weeks later, because of a reduced full blood count, her sirolimus blood levels were checked, and found to be 24.7 nanograms/mL. Her sirolimus dose was reduced to 3 mg daily and then 2 mg daily and her levels rechecked 5 days later. The trough sirolimus level was found to be 4.6 nanograms/mL, which was almost fivefold higher than the trough levels of 3 control patients taking sirolimus 5 to 7 mg daily but not taking nelfinavir. The peak level and AUC were also much higher in the patient taking nelfinavir.¹

The manufacturers point out that sirolimus is extensively metabolised by cytochrome P450 isoenzyme CYP3A4 and cleared by P-glycoprotein, so drugs such as the protease inhibitors, which inhibit their activity may raise sirolimus levels.^{2,3} Close monitoring with dose adjustments are recommended during the concurrent use of sirolimus and nelfinavir, or any other protease inhibitor.

2. Rapamune (Sirolimus). Wyeth Pharmaceuticals Inc. US Prescribing information, May 2007.
3. Rapamune (Sirolimus). Wyeth Pharmaceuticals. UK Summary of product characteristics, March 2007.

Sirolimus + Rifamycins

Rifampicin (rifampin) significantly decreases sirolimus levels. **Rifabutin** and **rifapentine** are predicted to interact similarly, although to a lesser extent.

Clinical evidence, mechanism, importance and management

A clinical study in 14 healthy subjects found that **rifampicin (rifampin)** 600 mg daily for 6 days increased the clearance of a single 10-mg oral dose of sirolimus 5.5-fold, and reduced the AUC and maximum serum levels of sirolimus by 82% and 71%, respectively. **Rifampicin** is a potent inducer of the cytochrome P450 isoenzyme CYP3A4, the isoenzyme by which sirolimus is metabolised.^{1,2} Therefore concurrent use increases sirolimus metabolism and reduces its levels. The manufacturers say that concurrent use is not recommended.¹ **Rifabutin** [a weak CYP3A4 inhibitor] and **rifapentine** [a moderate CYP3A4 inhibitor] are predicted to also

lower sirolimus levels,^{1,2} but not to the same extent as **rifampicin**. Nevertheless, the concurrent use of **rifabutin** is not recommended.¹

1. Rapamune (Sirolimus). Wyeth Pharmaceuticals. UK Summary of product characteristics, March 2007.
2. Rapamune (Sirolimus). Wyeth Pharmaceuticals Inc. US Prescribing information, May 2007.

Tacrolimus + ACE inhibitors and Angiotensin II receptor antagonists

Candesartan and losartan do not appear to affect the pharmacokinetics of tacrolimus, although concurrent use may increase the risk of developing hyperkalaemia.

Clinical evidence, mechanism, importance and management

A study in 12 kidney transplant patients taking tacrolimus twice daily for 12 days with **candesartan cilexetil** (2 mg daily for 3 days, then 4 mg daily for 3 days, and then 16 mg daily for 3 days) found that the pharmacokinetics of tacrolimus were unchanged. Renal function remained stable and unchanged, and no adverse effects were reported.¹ Another study in a group of 21 kidney transplant patients taking tacrolimus found no significant change in the serum creatinine or the levels of tacrolimus when they also took **candesartan cilexetil** 4 to 12 mg daily for one year. Serum potassium levels were reported to have increased by an average of 0.34 mmol/L, although it is unclear from the study if this was specifically in the tacrolimus group or also included another group taking candesartan and ciclosporin.² A study in kidney transplant patients taking tacrolimus and given losartan 50 mg daily for 12 weeks (some receiving 100 mg daily from week 8) for hypertension found no significant changes in the tacrolimus levels. Transient hyperkalaemia occurred in 4 of the 67 patients.³

Tacrolimus may cause nephrotoxicity and hyperkalaemia, and thus both renal function and potassium levels should be monitored when ACE inhibitors or angiotensin II receptor antagonists are also given.

Tacrolimus + Antacids

There is some evidence to suggest that some antacids may possibly reduce the blood levels of tacrolimus, but the clinical importance of this awaits confirmation.

Clinical evidence, mechanism, importance and management

A very brief report states that widely variable trough plasma tacrolimus levels have been seen in patients taking **sodium bicarbonate** close to the time when the tacrolimus was given, and that the use of **sodium bicarbonate** results in lower blood levels of tacrolimus. No details were given.¹ It was suggested that their administration should be separated by at least 2 hours, or the **sodium bicarbonate** replaced by **sodium citrate** and **citric acid**, to ensure stable trough tacrolimus levels are achieved.¹

A crossover study in healthy subjects found that a single dose of **aluminium/magnesium hydroxide** increased the mean AUC of tacrolimus by 21% and decreased the mean peak level of tacrolimus by 10%.²

In vitro studies also found that **aluminium hydroxide** gel and **magnesium oxide** can cause a significant reduction in tacrolimus concentrations due to pH-mediated degradation and as a result it was suggested that the administration of antacids and tacrolimus should be separated.³

However, a study in 18 renal transplant patients found that the concurrent use of **Maalox** (**aluminium/magnesium hydroxide**) or **sodium bicarbonate** did not reduce tacrolimus blood levels and no patients required a tacrolimus dose increase.⁴

More study is needed to confirm and assess the extent and clinical importance of these interactions, but good monitoring would be appropriate

if tacrolimus is given with any antacids, being alert for the need to separate the dosages by at least 2 hours.

Tacrolimus + Azoles

When tacrolimus is given orally, its serum levels are considerably increased by oral fluconazole, and tacrolimus dose reductions may be needed. Itraconazole, ketoconazole, posaconazole, voriconazole, and oral clotrimazole, also raise tacrolimus levels. There is some evidence that the levels of intravenous tacrolimus are minimally affected by fluconazole and ketoconazole. In theory it is possible that miconazole oral gel may also interact with tacrolimus.

Clinical evidence

(a) Clotrimazole

A study in 35 kidney transplant patients taking tacrolimus 150 micrograms/kg twice daily and clotrimazole 10 mg three times daily (17 patients) or nystatin (control group, 18 patients) found that clotrimazole significantly increased tacrolimus trough blood levels from 15 to 20 nanograms/mL up to 53 nanograms/mL at day 5. Tacrolimus levels were not affected by nystatin and by day 7 patients in the clotrimazole group were found to require significantly lower tacrolimus doses than those in the nystatin group.¹ In a liver transplant patient the trough plasma levels of tacrolimus 6 mg daily rose from 3.5 to 5.6 nanograms/mL within a day of clotrimazole 10 mg four times daily being started, and reached more than 9 nanograms/mL within 8 days. Later studies and rechallenge confirmed that the clotrimazole was responsible for the rise in tacrolimus levels. The tacrolimus AUC was nearly doubled.²

(b) Fluconazole

Twenty organ transplant patients (11 livers, 6 kidneys, 2 hearts and one bone marrow) taking tacrolimus were also given fluconazole 100 or 200 mg daily for various fungal infections. On day 1 the median plasma trough levels of those given fluconazole 100 mg rose 1.4-fold, and in those taking 200 mg it rose 3.1-fold. The dosage of tacrolimus was reduced to accommodate this rise: the median dosage reduction was 56% (range 0 to 88%). The highest tacrolimus level was seen within 3 days. A pharmacokinetic study in one patient found that when fluconazole 100 mg daily was stopped, the tacrolimus AUC fell by about 60%.³

Other studies in adult⁴ and paediatric patients⁵ and individual case reports^{6,7} have confirmed that tacrolimus levels are increased by oral fluconazole, increasing the risk of nephrotoxicity.⁵ In a retrospective study, patients given fluconazole required a 40% reduction in tacrolimus dose to achieve similar trough levels.⁸ A bone-marrow transplant patient taking tacrolimus and given fluconazole for oral candidiasis experienced headache and was found to have glycosuria, increased serum creatinine and Pelger-Huet anomaly of granulocytes, which disappeared after tacrolimus was discontinued. The effects were thought to be due to tacrolimus toxicity due to an interaction with fluconazole.⁹ However, one study found that if intravenous tacrolimus is given with intravenous fluconazole 400 mg, the steady-state levels of tacrolimus are only slightly increased (by about 16%), which was considered to be clinically unimportant.¹⁰

(c) Itraconazole

A study in 40 lung transplant patients taking tacrolimus with prophylactic itraconazole 200 mg twice daily for 6 months found that when itraconazole was stopped the mean tacrolimus dose to maintain therapeutic levels increased by 76% (to 5.74 mg daily). The adverse effects and rejection rate were not affected by itraconazole.¹¹ Similar findings are reported in another study in heart and lung transplant patients.¹² Trough blood levels of tacrolimus in a heart-lung transplant patient increased threefold from 16 to 57 nanograms/mL and serum creatinine levels also rose after she was given itraconazole 200 mg daily.¹³ A kidney transplant recipient taking tacrolimus 6 mg daily was given itraconazole 100 mg twice daily for a

urinary candida infection. Within a day, the tacrolimus trough levels increased from 12.6 to 21 nanograms/mL and the tacrolimus dose was progressively reduced to 3 mg daily. Four days after the itraconazole was discontinued tacrolimus had to be progressively increased back to its initial dose.¹⁴ The interaction has been reported in three other renal transplant recipients.¹⁵⁻¹⁷

(d) *Ketoconazole*

In a kidney transplant patient taking tacrolimus and prednisone, the addition of ketoconazole 200 mg daily resulted in an increase in tacrolimus blood levels from 11.1 to 27.9 nanograms/mL, despite a 45% decrease in the dose of tacrolimus. Eventually the dose of tacrolimus had to be reduced by 80% to keep the levels within the therapeutic range. Tacrolimus levels decreased to 5.8 nanograms/mL within a week of discontinuing ketoconazole and so the dose was raised.¹⁸ A pharmacokinetic study in 6 healthy subjects found that ketoconazole 200 mg orally at bedtime for 12 days increased the bioavailability of a single 100 microgram/kg dose of oral tacrolimus from 14% to 30%.¹⁹ The manufacturer notes that the clearance of intravenous tacrolimus was not significantly changed by ketoconazole, although it was highly variable between patients.²⁰

(e) *Posaconazole*

The peak blood level and AUC of a single 50 microgram/kg dose of tacrolimus was reported to be increased by 121% and 358%, respectively, by the addition of posaconazole.²¹

(f) *Voriconazole*

A small study comparing the tacrolimus levels of two patients, one taking voriconazole 200 mg twice daily, the other placebo, found that the tacrolimus levels were nearly tenfold higher in the patient taking voriconazole. This was originally designed as a larger study, but the study was stopped after the finding in these initial two subjects.²² Another study in 14 healthy subjects found that voriconazole 400 mg twice daily on day one, then 200 mg twice daily for 6 days increased the AUC and maximum plasma levels of a single 100 microgram/kg dose of tacrolimus by 3.2-fold and 2.3-fold, respectively.²³ A liver transplant patient taking tacrolimus was hospitalised with multiple complaints, and was found to have a high tacrolimus level. Tacrolimus was withheld and later restarted at 3 mg daily and then gradually reduced to 1.5 mg daily. When voriconazole 400 mg twice daily was started, the tacrolimus dose was reduced by one-third to 0.5 mg daily, but eventually needed to be reduced to 0.15 mg daily (90% overall dose reduction) as a result of rising tacrolimus levels.²⁴ A kidney transplant patient taking tacrolimus 2 mg daily had an increase in tacrolimus levels from less than 12 nanograms/mL to 25 nanograms/mL when voriconazole 4 mg/kg twice daily was added. His renal function also worsened. The tacrolimus dose was eventually reduced to 0.5 mg on alternate days, with an improvement in his renal function.²⁵

Mechanism

Fluconazole, itraconazole, ketoconazole, posaconazole and voriconazole inhibit the metabolism of the tacrolimus by the gut wall and/or liver by the cytochrome P450 isoenzyme CYP3A4, and/or inhibit the activity of P-glycoprotein so that more tacrolimus is absorbed.^{10,14,19,22} Therefore, intravenous tacrolimus is little affected.¹⁰

Importance and management

The interaction between tacrolimus and **fluconazole** is established, clinically important and can develop rapidly (within 3 days). The authors of one of the reports say that up to 200 mg of oral fluconazole daily can be used safely and effectively provided that the tacrolimus dosage is reduced by half.³ One study specifically examining dose adjustments suggests that fluconazole can be safely used if 60% of the original tacrolimus dose is given.⁸ If tacrolimus is given intravenously, no clinically important interaction appears to occur.¹⁰

The interactions of tacrolimus with **itraconazole** and **ketoconazole** also appear to be established, and the manufacturer states that nearly all patients will require tacrolimus dose reductions when given these drugs.^{20,26}

Information about **clotrimazole** is limited, but on the basis of the case report and study it would be prudent to monitor tacrolimus levels, and adjust the dose as necessary.

The manufacturers of **posaconazole** recommend that the tacrolimus dose is reduced by about two-thirds in patients given posaconazole.²¹ Tacrolimus levels should be closely monitored and further dose adjustments

made if needed.

The manufacturers of **voriconazole** advise reducing the tacrolimus dose to one-third when starting voriconazole, closely monitoring tacrolimus levels throughout, and increasing the tacrolimus dose in response to levels obtained when voriconazole is stopped.^{27,28} However, greater reductions in tacrolimus dose may be needed in some patients,^{22,24} and raised tacrolimus levels requiring a total 90% tacrolimus dose reduction were reported in one patient.²⁴

In vitro studies with human liver microsomes have shown that **miconazole**²⁹ also inhibits liver and small intestine microsomes that metabolise tacrolimus and it seems possible that it may interact like fluconazole but this needs confirmation. There appear to be no clinical reports of an interaction between miconazole and tacrolimus. However, a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction. The manufacturers of miconazole oral gel recommend close monitoring and possible dose reduction of tacrolimus if both drugs are given concurrently.³⁰ An interaction with intravaginal miconazole would not normally be expected because its systemic absorption is usually very low (less than 2%) in healthy women of child-bearing age.³¹ No interaction would be expected if miconazole is applied to the skin.

Tacrolimus + Calcium-channel blockers

Nifedipine causes a moderate rise in tacrolimus blood levels and also appears to be kidney protective. Case reports suggest that diltiazem and felodipine also elevate tacrolimus levels; nicardipine, nilvadipine and verapamil are predicted to interact similarly.

Clinical evidence

(a) Diltiazem

The trough blood levels of tacrolimus 8 mg twice daily increased from 12.9 to 55 nanograms/mL in a liver transplant patient within 3 days of him starting diltiazem (initially 5 to 10 mg/hour intravenously for one day, then 30 mg orally every 8 hours). The patient became delirious, confused and agitated. Both drugs were stopped, and over the next 3 days his mental state improved and his tacrolimus levels fell to 6.7 nanograms/mL. Tacrolimus was then restarted, gradually increasing to a dose of 5 mg twice daily, which produced levels of 9 to 10 nanograms/mL.¹

A study in 2 liver and 2 kidney transplant patients found that diltiazem increased the AUC of tacrolimus. In the kidney transplant patients the increase appeared to be dose related; a 20-mg dose of diltiazem caused a 26% and 67% rise, while a 180-mg dose caused a 48% and 177% rise in each patient, respectively. The liver transplant patients did not have any alteration in the AUC of tacrolimus until they were given higher doses of diltiazem; one patient had an 18% rise following a 120-mg dose, the other a 22% rise following a 180-mg dose.²

A study in 7 liver transplant patients given tacrolimus 100 micrograms/kg twice daily found that modified-release diltiazem 90 mg daily did not significantly alter the absorption or metabolism of tacrolimus when compared to 7 similar patients not given diltiazem.³ The authors of the other study² suggest that this lack of effect may have been because only 90 mg of diltiazem was used.

(b) Felodipine

A 13-year-old boy taking tacrolimus 4 mg twice daily was given felodipine 2.5 mg daily 15 days after receiving a kidney transplant. Two weeks later his tacrolimus level was reported as greater than 30 nanograms/mL (previous levels ranged from 10.6 to 20 nanograms/mL), and despite a reduction in the dose of tacrolimus to 3 mg twice daily a subsequent tacrolimus level was 53.9 nanograms/mL. He was eventually stabilised at the original tacrolimus levels with tacrolimus 500 micrograms twice daily. When the felodipine was stopped several months later, his tacrolimus dose needed to be raised to maintain therapeutic levels.⁴

(c) Nifedipine

A 1-year retrospective study of two groups of liver transplant patients found that in the 22 patients taking nifedipine 30 or 60 mg daily there was a 55% increase in the tacrolimus blood levels after 1 month. By 6 months the tacrolimus dosage had been reduced by a total of 25.5% in the nifedipine group and by 12 months by 31.4% when compared with the group not taking nifedipine. The nifedipine group also had improved renal function (lowered serum creatinine).⁵

Mechanism

Uncertain, but it seems likely that some calcium-channel blockers inhibit the cytochrome P450 isoenzyme CYP3A4 and/or P-glycoprotein, thereby reducing the metabolism of tacrolimus leading to increased blood levels.^{1,5} This is consistent with the findings of an *in vitro* study using human liver microsomes.⁶

Importance and management

In the case of nifedipine, this seems to be an established and clinically important interaction. However, the increase seems slow, and it seems likely that any decrease in the dose requirements of tacrolimus will be detected by routine monitoring. Although the information about diltiazem is less conclusive it would seem wise to follow the same precautions, as the effect

of diltiazem on tacrolimus seems to vary greatly between the few patients studied. The manufacturers of felodipine advise monitoring tacrolimus levels if felodipine is given.^{7,8} Direct information about other calcium-channel blockers appears to be lacking, but the US and UK manufacturers of tacrolimus^{9,10} predict that **nicardipine** and **verapamil** may raise tacrolimus levels by inhibiting CYP3A4 (see Mechanism), and the UK manufacturers additionally suggest that **nilvadipine** may interact similarly.¹⁰

Tacrolimus + Chloramphenicol

A marked rise in tacrolimus trough blood levels has been reported in several patients who were given systemic chloramphenicol.

Clinical evidence

A retrospective study identified 3 patients taking tacrolimus who had received a total of 5 courses of intravenous chloramphenicol, each lasting for at least 12 days. Tacrolimus trough blood levels were doubled by day 2, and had risen by 207% at their peak, on day 6. The tacrolimus dose had been decreased by about one-third by day 12, and the tacrolimus levels returned to around the baseline value.¹

An adolescent patient with a kidney transplant developed toxic tacrolimus levels on the second day of starting chloramphenicol for a vancomycin-resistant enterococcal infection. The tacrolimus dosage had to be reduced by 83% to achieve safe serum levels, and it was found that the dose-adjusted tacrolimus AUC was 7.5-fold greater in the presence of chloramphenicol.² Another report describes a similar interaction in a liver transplant patient taking tacrolimus 4 mg twice daily. The patient was given intravenous chloramphenicol, but at the unintentionally high dose of 1850 mg every 6 hours. After about 3 days the patient complained of lethargy, fatigue, headaches and tremors so both drugs were stopped. His tacrolimus trough level had increased from a range of 9 to 11 nanograms/mL to more than 60 nanograms/mL. Seven days after chloramphenicol had been stopped his tacrolimus level was 8.2 nanograms/mL and his symptoms had resolved.³ Another case report in a kidney-pancreas transplant patient taking tacrolimus 4 mg twice daily found that the addition of oral chloramphenicol 750 mg four times daily increased the tacrolimus trough blood level to more than 30 micrograms/L within 3 days. After 10 days, the dose of tacrolimus was reduced to 1.5 mg twice daily and the tacrolimus level fell to between 18 to 25 micrograms/L. Chloramphenicol was stopped 5 days later and the tacrolimus dose was increased to 3 mg twice daily. However the tacrolimus level fell to below 5 micrograms/L for several days leading to an episode of acute organ rejection. The tacrolimus level then returned to within the therapeutic range and the patient stabilised.⁴

Mechanism

Chloramphenicol (a known enzyme inhibitor) is thought to raise tacrolimus levels by rapidly reducing its metabolism.²

Importance and management

These appear to be the only reports of this interaction, but it is consistent with the known metabolic characteristics of both drugs and therefore it is expected to be an interaction of general importance. Monitor the outcome closely if systemic chloramphenicol is given to any patient taking tacrolimus, being alert for the need to reduce the tacrolimus dosage. It seems

doubtful if a clinically relevant interaction will occur with topical chloramphenicol because the dosage and the systemic absorption is small, but this needs confirmation.

Tacrolimus + Ciclosporin

The manufacturers say that tacrolimus and ciclosporin should not be used concurrently because of the increased risk of nephrotoxicity.

Clinical evidence, mechanism, importance and management

One study found that, in patients with normal bilirubin levels, the half-life of ciclosporin was prolonged from a range of 6 to 15 hours up to 26 to 74 hours, and the ciclosporin serum levels, measured by a fluorescent polarisation immunoassay, were raised by tacrolimus.¹ On the other hand another study found no changes in the pharmacokinetics of ciclosporin, as measured by HPLC, in patients given tacrolimus, but creatinine levels were almost doubled (suggesting kidney damage),² which confirmed a previous report suggesting that severe renal impairment may develop when both drugs are given.³ Tacrolimus levels may also be raised by ciclosporin.⁴ The manufacturers of tacrolimus say that it should not be given with ciclosporin because of the risk of additive/synergistic nephrotoxicity, and, if ciclosporin is being replaced by tacrolimus, 12 to 24 hours should elapse between stopping one drug and starting the other. If ciclosporin levels are raised, the introduction of tacrolimus should be further delayed.^{4,5}

Tacrolimus + Corticosteroids

The effects of methylprednisolone on tacrolimus pharmacokinetics are uncertain. Prednisone appears to reduce the levels of tacrolimus.

Clinical evidence, mechanism, importance and management

A review of early studies of tacrolimus stated that serum levels were said to have been increased on 10 occasions, decreased on 5 occasions, and unaltered on 2 occasions by **methylprednisolone**.¹

In a randomised study conducted over 3 months, 31 patients receiving tacrolimus, mycophenolate and daclizumab were compared with 34 patients receiving tacrolimus, mycophenolate and **prednisone**. Higher tacrolimus doses were required to maintain therapeutic tacrolimus levels in the **prednisone** group. This reached a maximum after one month, when a 30% larger tacrolimus dose was necessary.² A further study found that patients taking higher doses of **prednisone** (more than 0.25 mg/kg daily) also needed larger doses of tacrolimus to maintain therapeutic trough blood levels. The authors considered that this was possibly due to induction of the cytochrome P450 isoenzyme CYP3A4 by **prednisone** and recommended that tacrolimus levels be closely monitored and adjusted according to any changes in corticosteroid dose.³

Tacrolimus + Danazol

An isolated report describes an increase in tacrolimus levels in a patient given danazol.

Clinical evidence, mechanism, importance and management

The trough serum levels of tacrolimus 10 mg daily rose from 0.7 to 2.7 nanograms/mL in a kidney transplant patient within 4 days of danazol 400 mg to 1.2 g daily being started. Despite a reduction in the danazol dosage to 600 mg and then 400 mg daily, her tacrolimus and creatinine serum levels remained high for one month until the danazol was withdrawn. The reason is not known, but the authors suggest that danazol possibly inhibits the metabolism (demethylation and hydroxylation) of tacrolimus by the liver so that it is cleared from the body more slowly.¹ Tacrolimus is metabolised by the cytochrome P450 isoenzyme CYP3A4, and danazol has been shown to inhibit this pathway (consider 'Statins + Danazol', p.1099). Therefore although this is an isolated case it seems possible that it will be of general significance. Monitor the effects of concurrent use in any patient, reducing the tacrolimus dosage as necessary.

Tacrolimus + Echinocandins

Caspofungin moderately decreases tacrolimus levels. Anidulafungin and micafungin do not appear to affect tacrolimus pharmacokinetics, and tacrolimus does not affect the pharmacokinetics of anidulafungin, caspofungin, or micafungin.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

Thirty-five healthy subjects were given a single 5-mg oral dose of tacrolimus 3 days before and on day 10 of a course of intravenous anidulafungin (200 mg loading dose and then 100 mg daily). Anidulafungin did not have any significant effects on the pharmacokinetics of tacrolimus and no serious adverse effects were reported. The pharmacokinetics of anidulafungin were not affected by tacrolimus.¹ No additional monitoring would seem to be required with this combination; however, bear in mind that the study above was a single-dose study in healthy subjects. More study is required in patients taking long-term tacrolimus.

(b) Caspofungin

The preliminary results of one study suggest that caspofungin reduces the AUC of tacrolimus by 20% in healthy subjects,² and reduces the trough tacrolimus levels by 26%.³ Tacrolimus did not alter the pharmacokinetics of caspofungin.² The manufacturers of caspofungin advise that tacrolimus levels should be monitored if caspofungin is given, and tacrolimus doses adjusted as appropriate.^{3,4} Note that this change is relatively modest.

(c) Micafungin

Twenty-six healthy subjects were given single 5-mg doses of tacrolimus alone, after intravenous micafungin 100 mg, and one day after intravenous micafungin 100 mg daily for 5 days. The pharmacokinetics of tacrolimus were not affected by micafungin, and single-dose tacrolimus had no effects on the pharmacokinetics of micafungin.⁵ No additional monitoring would seem to be required with this combination.

Tacrolimus + Grapefruit and other fruit juices

Grapefruit juice can markedly increase the serum levels of tacrolimus. Pomelo may interact similarly.

Clinical evidence and mechanism

(a) Grapefruit juice

Eight liver transplant patients were given 12 oz (about 360 mL) of grapefruit juice twice daily, which they drank within 45 minutes of taking their dose of tacrolimus. After one week it was found that their 12-hour trough, and 1-hour and 4-hour tacrolimus levels were raised by 300%, 195%, and 400%, respectively. Two patients had headaches, one had diarrhoea and one had an increased creatinine level, that reversed, but none of the 12 developed rejection or irreversible toxicity. Two of the patients continued to drink the grapefruit juice and it was possible to halve their tacrolimus dosage.¹ Similarly, 6 kidney transplant patients had their dose of tacrolimus reduced by an average of 40% after drinking 100 mL of grapefruit juice daily for 5 days.² A liver transplant patient was advised to drink grapefruit juice in an effort to increase her tacrolimus trough blood levels, which were subtherapeutic (below 5 nanograms/mL) despite a dose of tacrolimus 10 mg daily. She drank 250 mL of grapefruit juice four times daily for 3 days during which time the tacrolimus level did not increase. However, one week after she stopped the grapefruit juice the tacrolimus level was found to have increased to 37 nanograms/mL.³

(b) Pomelo

A case report describes a kidney transplant patient taking tacrolimus whose tacrolimus level rose from a range of 8 to 10 nanograms/mL up to 25.2 nanograms/mL after he ate about 100 g of pomelo (*Citrus grandis*, a fruit related to grapefruit).⁴ The same authors subsequently found that pomelo juice extract inhibited the cytochrome P450 isoenzyme CYP3A4 *in vitro* but had no effect on P-glycoprotein.⁵

Importance and management

The reason for the rise in tacrolimus levels is not known, but it seems likely that it is due to inhibition of the metabolism of tacrolimus by some component of grapefruit juice and pomelo fruit. In practical terms the authors of the first report suggest that this interaction means that the dosage of tacrolimus can possibly be reduced (to save money) although there is a clear need to monitor the effects closely not only because of the inter-individual factors affecting tacrolimus dosing but also because of the difficulties of standardising grapefruit juice.¹ However, the manufacturers of tacrolimus suggest that the combination should be avoided.^{6,7} Patients should be informed of the potential risk of this interaction.

Tacrolimus + Macrolides

Patients have had marked increases in serum tacrolimus levels accompanied by evidence of renal toxicity when they were given erythromycin. The same interaction has been seen in patients given clarithromycin, and is predicted with josamycin and troleandomycin.

domycin. Although azithromycin would not be expected to interact, an isolated case reports an increase in tacrolimus levels on concurrent use.

Clinical evidence

(a) Azithromycin

One report briefly describes a patient taking tacrolimus following a bone marrow transplant who took a 10-day course of azithromycin (dose not stated) without any significant alteration in his serum creatinine or trough tacrolimus levels.¹ However, a isolated case report describes an increase in tacrolimus levels from a range of 15.8 to 17.5 nanograms/mL to greater than 30 nanograms/mL in a patient who had been receiving intravenous tacrolimus 20 micrograms/kg daily 3 days after azithromycin 500 mg daily was started.²

(b) Clarithromycin

A woman with a kidney transplant taking tacrolimus, prednisone and azathioprine was given clarithromycin 500 mg twice daily for 4 days, then 250 mg daily to treat a severe *Mycoplasma pneumoniae* infection. Despite a 64% reduction in the dosage of the tacrolimus, the trough tacrolimus concentrations rose sharply, from 2.8 to 36.1 nanograms/mL by day 6 and creatinine levels increased from 309 to 442 micromol/L. The tacrolimus dosage was further reduced and then stopped, and not restarted until the clarithromycin treatment was completed.³ In another 2 kidney transplant patients, tacrolimus levels increased by 146% and 131%, respectively, following 9 doses of clarithromycin 250 mg. Creatinine levels increased by 91% and 30%, respectively.⁴ Similarly the tacrolimus levels of a bone marrow transplant patient rose from below 1.1 to 10.1 nanograms/mL after he took clarithromycin 500 mg twice daily for about 4 days.¹ A similar increase in tacrolimus levels has been reported in a heart transplant patient, despite an initial reduction in tacrolimus dose in anticipation of the interaction,⁵ and in another kidney transplant patient.⁶

(c) Erythromycin

A liver transplant patient taking tacrolimus 6 mg twice daily for one year had a marked rise in serum tacrolimus levels from about 1.4 to 6.5 nanomol/L when intravenous ampicillin/sulbactam 3 g every 6 hours and oral erythromycin 250 mg every 6 hours were given for 4 days to treat pneumonia. Renal toxicity, demonstrated by increased blood urea and creatinine levels also occurred. The erythromycin was stopped, and the next day the tacrolimus was also stopped. Over the next week the plasma levels of the tacrolimus, blood urea nitrogen and creatinine fell.⁷ A kidney transplant patient had an increase in his plasma tacrolimus levels from 1.3 to 8.5 nanograms/mL 4 days after starting erythromycin 400 mg four times daily. His serum creatinine levels almost doubled.⁸ A man with a kidney transplant had a sixfold rise in tacrolimus blood levels when he took erythromycin.⁹ Another similar case has been described.¹⁰ Two children aged 3 and 7 years also had rises in tacrolimus blood levels, which were accompanied by renal toxicity when erythromycin was added.¹¹

Mechanism

The macrolides inhibit tacrolimus metabolism by the cytochrome P450 isoenzyme CYP3A. Azithromycin is less likely to interact with tacrolimus because it does not inhibit CYP3A.¹²

Importance and management

Direct information seems to be limited to these case reports. However, it would be prudent to closely monitor the effects of adding clarithromycin or erythromycin in any patient, being alert for the need to reduce the tacrolimus dosage to avoid nephrotoxicity. The manufacturers predict that **josamycin**¹³ and **troleandomycin**¹⁴ will interact similarly and so the same precautions would also be appropriate. The manufacturers of **telithromycin** also recommend close monitoring of tacrolimus levels and reducing the tacrolimus dose as required.¹⁵ Most other macrolides would also be expected to interact although they do not all behave identically.

The significance of the single case report of azithromycin increasing tacrolimus levels is unclear as azithromycin does not affect CYP3A4, and therefore has been predicted not to interact, as suggested by the other case.

Tacrolimus + Metoclopramide

In an isolated case, metoclopramide may have increased tacrolimus levels, resulting in tacrolimus toxicity and acute renal failure.

Clinical evidence, mechanism, importance and management

A case report describes a liver transplant patient taking several drugs, including tacrolimus up to 28 mg twice daily, who had subtherapeutic tacrolimus levels, which were increased when she took metoclopramide, initially 10 mg four times daily, then 20 mg four times daily, for gastric dysmotility. Her tacrolimus trough levels increased from less than 2 nanograms/mL to greater than 30 nanograms/mL within 5 to 6 days, and she developed tremor, weakness, nausea, vomiting, diarrhoea and acute renal failure. The authors considered that the increase in tacrolimus levels was due to metoclopramide, possibly due to its effects in increasing gut motility and hence, tacrolimus absorption. However several other factors may have contributed, such as diarrhoea and the use of cimetidine and ketoconazole.¹

This appears to be the only reported case of tacrolimus toxicity, with metoclopramide, and, because of the number of complicating factors, it is by no means established. Its general significance is unclear.

- Prescott WA, Callahan BL, Park JM. Tacrolimus toxicity associated with concomitant metoclopramide therapy. *Pharmacotherapy* (2004) 24, 532–7.

Tacrolimus + Metronidazole

Two reports describe increases in tacrolimus levels in patients also given metronidazole.

Clinical evidence

A kidney transplant patient taking tacrolimus 3 mg twice daily had a threefold increase in his tacrolimus levels when he was given metronidazole 500 mg four times daily for 14 days. His trough level increased from 9.2 nanograms/mL to 26.3 nanograms/mL within 4 days of starting the metronidazole, requiring a tacrolimus dose reduction to 1 mg twice daily. Five days after stopping the metronidazole his trough level had returned to 9.2 nanograms/mL and his dose was increased back up to 2 mg twice daily.¹ A similar increase in tacrolimus trough levels was seen in a kidney transplant patient taking tacrolimus 3 mg in the morning and 2 mg at night. His tacrolimus level rose from 9 nanograms/mL to nearly 18 nanograms/mL when he started taking metronidazole 400 mg three times daily for a *C. difficile* infection. The tacrolimus dose was reduced to 1 mg twice daily and the tacrolimus level fell to 8.1 nanograms/mL. When the metronidazole was stopped, his tacrolimus level decreased further to 5.2 nanograms/mL and his tacrolimus dosage needed to be increased to 2 mg twice daily.²

Mechanism

Metronidazole is a weak inhibitor of cytochrome P450 isoenzyme CYP3A4¹ and it has also been suggested that metronidazole is also an inhibitor or substrate for P-glycoprotein.¹ As tacrolimus is a metabolised by CYP3A4 and is also a substrate for P-glycoprotein, one or both of these mechanisms may be involved in this interaction.

Importance and management

These two cases appear to be the only reports of a possible interaction between tacrolimus and metronidazole. There is insufficient evidence to advocate monitoring in every patient given the combination, but it would be prudent to at least bear this interaction in mind if using metronidazole in patients taking tacrolimus.

Tacrolimus + Miscellaneous

Tacrolimus is metabolised by CYP3A4, the induction and inhibition of which may affect the serum levels of tacrolimus. The manufacturers also issue cautions about the concurrent use of tacrolimus and anticoagulants, antidiabetics, nephrotoxic and neurotoxic drugs.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers

In vitro studies with *rat* and human liver microsomes^{1,2} have found that tacrolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4. This means that drugs that induce CYP3A4 may potentially reduce the serum levels of tacrolimus.

Rifampicin (rifampin) and possibly **phenytoin**, known potent enzyme inducers, have been seen to lower tacrolimus levels (see 'Tacrolimus + Rifamycins', p.1083, and 'Tacrolimus + Phenytoin', p.1081), and the manufacturers suggest that **carbamazepine**, **isoniazid** and **phenobarbital** will interact similarly.^{3,4} However, note that there is little to suggest that **isoniazid** has a clinically significant effect on this isoenzyme.

These predictions are as yet unconfirmed, but it would certainly be prudent to monitor tacrolimus levels closely if any of these drugs (with the possible exception of isoniazid) are used concurrently. The manufacturers also note that in *animal* studies, tacrolimus has been shown to decrease the clearance and increase the half-life of **pentobarbital**,³ and a report also describes the use of a **phenobarbital** infusion to treat a tacrolimus overdose.⁵

(b) CYP3A4 inhibitors

In vitro studies with *rat* and human liver microsomes^{1,2} have found that tacrolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4. This means that drugs that inhibit CYP3A4 may potentially increase the serum levels of tacrolimus. Most of the known inhibitors of CYP3A4 (such as the 'azoles', (p.1075), 'protease inhibitors', (p.1082) and 'macrolides', (p.1079)) have clearly been shown to interact with tacrolimus. The manufacturers of tacrolimus suggest that other enzyme-inhibiting drugs may also inhibit tacrolimus metabolism and therefore suggest that its levels are monitored if they are given. They name **bromocriptine**, **cimetidine**, **dapsone**, **ergotamine**, **lidocaine**, **midazolam**, **quinidine** and **tamoxifen**.^{3,4} These predictions are as yet unconfirmed, and note that, with exception of **cimetidine**, these drugs are not commonly associated with clinically significant interactions by this mechanism.

(c) Neurotoxicity or nephrotoxicity

Other predicted interactions of tacrolimus include additive neuro- or nephrotoxicity with **aciclovir**, **aminoglycosides**, **co-trimoxazole**, **ganciclovir**, **gyrase inhibitors**, **NSAIDs** (see 'NSAIDs', (p.1081)) or **vancomycin** (nephrotoxicity has been seen with **amphotericin B** and tacrolimus).³

(d) Protein-binding interactions

Because tacrolimus is extensively bound to plasma proteins, the UK manufacturers mention the possibility of protein-binding interactions with oral

anticoagulants or **antidiabetics**,³ (but this has largely been discredited as a mechanism, see 'Protein-binding interactions', (p.3)).

Tacrolimus + NNRTIs

Efavirenz appears to decrease the metabolism of tacrolimus.

Clinical evidence, mechanism, importance and management

An HIV-positive liver transplant patient who had taken **efavirenz**, lamivudine and zidovudine pre-transplantation and then again post-transplantation with concurrent tacrolimus and corticosteroids, had therapeutic tacrolimus levels for 6 days despite tacrolimus and the antiretrovirals being stopped because of zidovudine-induced rhabdomyolysis.¹ **Efavirenz** is a known inducer of the cytochrome P450 isoenzyme CYP3A4 by which tacrolimus is metabolised. It seems likely that the effect of **efavirenz** was sufficient to dramatically reduce tacrolimus clearance. Although this is only an isolated case it is in line with the way both drugs are known to interact. It would seem prudent to closely monitor tacrolimus levels in any patient given **efavirenz**.

1. Antonini M, Ettore GM, Vennarecci G, D'Offizi G, Narciso P, Del Nonno F, Perracchio L, Visco G, Santoro E. Anti-retrovirals and immunosuppressive drug interactions in a HIV-positive patient after liver transplantation. *Hepato-gastroenterology* (2004) 51, 646-8.

Tacrolimus + NSAIDs

Two liver transplant patients taking tacrolimus developed acute renal failure after also taking ibuprofen.

Clinical evidence, mechanism, importance and management

Two patients with liver transplants taking tacrolimus developed acute but reversible renal failure, one after taking four *Motrin* (**ibuprofen**) tablets (strength not stated) and the other after three 400-mg tablets of **ibuprofen** taken over 24 hours. Both had stable renal function before taking the **ibuprofen**.¹

NSAIDs are known to inhibit prostaglandin synthesis and as a result may decrease renal blood flow, which in certain circumstances can lead to renal failure. Renal impairment is more likely to occur in the presence of renal vasoconstrictors. Tacrolimus is known to cause renal vasoconstriction and thus the combined effects of **ibuprofen** and tacrolimus may have led to acute renal failure. Both patients also had a degree of liver impairment, which the authors suggest may have potentiated the toxicity of tacrolimus with **ibuprofen**.

The authors of the report say that if renal toxicity develops, tacrolimus should be withdrawn. They used intravenous prostaglandin-E1 effectively in one patient. They also suggest that NSAIDs should not be given to patients taking tacrolimus, especially if it is being used as rescue therapy for abnormal graft function.¹ There seems to be nothing documented about adverse interactions with other NSAIDs but if the suggested mechanism is true, they may possibly behave like **ibuprofen**. The UK manufacturers of tacrolimus suggest that all NSAIDs may have additive nephrotoxic effects with tacrolimus.²

2. Prograf (Tacrolimus monohydrate). Astellas Pharma Ltd. UK Summary of product characteristics, May 2007.

Tacrolimus + Orlistat

Orlistat does not appear to significantly affect the pharmacokinetics of tacrolimus, although small dosage adjustments may be needed in some patients.

Clinical evidence, mechanism, importance and management

A study in 12 liver transplant patients taking tacrolimus with orlistat 120 mg three times daily for 6 months found that concurrent use was well tolerated. However, 4 patients required a reduction and 2 required an increase in their tacrolimus dose, although these adjustments were only minor dose changes. No diarrhoea was reported by the patients in this study, concurrent use was well tolerated and no episodes of rejection occurred. The authors concluded that orlistat could be safely used in patients taking tacrolimus provided that tacrolimus levels are carefully monitored.¹

Tacrolimus + Phenytoin

An isolated report describes an increase in serum phenytoin levels attributed to the use of tacrolimus. Phenytoin decreased tacrolimus levels in one case, and has been used to reduce tacrolimus levels after an overdose.

Clinical evidence

(a) Phenytoin levels

A kidney transplant patient taking phenytoin 500 and 600 mg on alternate days (and also taking azathioprine, bumetanide, digoxin, diltiazem, heparin, insulin and prednisone) had his immunosuppressant treatment changed from ciclosporin, to tacrolimus 14 to 16 mg daily. About 7 weeks later he presented to hospital because of a fainting episode and his phenytoin levels were found to have risen from 18.4 to 36.2 micrograms/mL. The phenytoin was temporarily stopped until his serum levels had fallen, and he was then discharged on a reduced phenytoin dosage of 400 and 500 mg on alternate days with no further problems.¹ The presumption is that the fainting episode was due to the raised serum phenytoin levels.

(b) Tacrolimus levels

In one kidney transplant patient taking phenytoin, tacrolimus 250 micrograms/kg daily was needed to give a blood level of 9 nanograms/mL. Three months later phenytoin was gradually stopped, with gradual tapering of the tacrolimus dose. The patient was eventually stabilised with a tacrolimus dose of 160 micrograms/kg daily giving a blood level of 11 nanograms/mL.²

Another report describes the use of an intravenous phenytoin infusion to treat acute tacrolimus overdoses in 2 patients, with the aim of enhancing tacrolimus metabolism.³

Mechanism

Tacrolimus is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4, and phenytoin is a known inducer of this system. Phenytoin is therefore predicted to decrease tacrolimus levels. In the first case, it was suggested that tacrolimus might have inhibited the metabolism of phenytoin, although other factors may have had some part to play in the raised phenytoin levels.¹

Importance and management

No interaction is established, but based on the known metabolism of these drugs it would be prudent to monitor tacrolimus levels in a patient given phenytoin. Similarly, based on the single case of phenytoin toxicity, it may also be advisable to monitor phenytoin levels.

Tacrolimus + Protease inhibitors

Protease inhibitors including lopinavir, nelfinavir, ritonavir and saquinavir significantly inhibit the metabolism of tacrolimus and increase its blood levels.

Clinical evidence

A retrospective study in 10 HIV-positive kidney transplant patients found that all of the patients taking a **protease inhibitor** (not specified) required a tacrolimus dose reduction, and 3 of them needed to be changed from a protease inhibitor to an alternative antiretroviral.¹

(a) Lopinavir

A liver transplant patient taking tacrolimus 5 mg twice daily to give a tacrolimus trough blood level of 10.6 nanograms/mL had a large increase in tacrolimus levels to 78.5 nanograms/mL when lopinavir/ritonavir was started, despite a tacrolimus dose reduction to 6 mg daily. Tacrolimus neurotoxicity developed, but no nephrotoxicity was seen. The patient was eventually stabilised taking tacrolimus 500 micrograms weekly while taking lopinavir/ritonavir. Other patients have developed raised tacrolimus levels and been eventually restabilised on tacrolimus dosages of 500 micrograms to 1 mg weekly, while taking lopinavir/ritonavir: tacrolimus levels have continued to increase despite tacrolimus doses being withheld.^{2,3}

(b) Nelfinavir

An HIV-positive patient, with hepatitis C following a liver transplant was given stavudine, lamivudine, and nelfinavir 500 mg three times daily. Tacrolimus 6 mg daily was started postoperatively but high blood levels were observed and the dose was reduced over the next 3 months to a maintenance dose of 500 micrograms weekly, which achieved levels of between 7 and 25.9 nanograms/mL.⁴ A patient had a tacrolimus level of 10.9 nanograms/mL while taking tacrolimus 4 mg twice daily without antiretrovirals. When he was given a combination of didanosine, nelfinavir and stavudine, he had a tacrolimus level of 23.7 nanograms/mL, despite a dosage reduction to tacrolimus 500 micrograms daily.⁵ A brief report describes petit mal seizures brought on by high tacrolimus levels, which were thought to be as a result of an interaction with nelfinavir. The patient was stabilised on once weekly tacrolimus.⁶ In a study HIV-positive patients who underwent liver transplantation were given tacrolimus and a HAART regimen, which included a protease inhibitor. Tacrolimus dosing was reduced in all patients on HAART to between 1 and 3 mg daily. A patient developed acute organ rejection due to low tacrolimus levels when nelfinavir was stopped without an increase in the tacrolimus dose.⁷

(c) Ritonavir

A case report describes an HIV-positive, kidney transplant patient who developed an increase in tacrolimus levels requiring a large dose reduction to tacrolimus 500 micrograms weekly when ritonavir and **saquinavir** were also given.⁸ A patient had a tacrolimus level of 10.9 nanograms/mL while taking tacrolimus 4 mg twice daily without antiretrovirals. When he was given a combination of didanosine, nelfinavir and stavudine, he had a tacrolimus level of 23.7 nanograms/mL, despite a reduction in the dose of tacrolimus to 500 micrograms daily. When nelfinavir was replaced by, ritonavir and **saquinavir**, tacrolimus 1 mg twice daily resulted in tacrolimus levels in excess of 120 nanograms/mL with severe, prolonged toxicity.⁵ In a study HIV-positive patients who underwent liver transplantation were given tacrolimus with a HAART regimen, which included a protease inhibitor. Tacrolimus dosing was reduced in all patients on HAART to between 1 to 3 mg daily. One patient taking ritonavir had a tacrolimus level of 50 nanograms/mL despite the initial dose of tacrolimus being reduced to 3 mg daily. Another patient developed tacrolimus toxicity due to ritonavir and her tacrolimus dose needed to be reduced to 250 micrograms every 4 days to keep the tacrolimus levels within range.⁷

Mechanism

All protease inhibitors are, to varying degrees, inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which tacrolimus is metabolised. It therefore seems likely that the protease inhibitors reduced tacrolimus metabolism resulting in the extremely high levels seen. The protease inhibitors also inhibit P-glycoprotein, of which tacrolimus is a substrate. See also 'Antiretrovirals', (p.772). It has been suggested that this could lead to increased levels of unmetabolised tacrolimus in the bile which may be reabsorbed through the enterohepatic circulation system, thus further increasing tacrolimus levels.²

Importance and management

An established and clinically important interaction. It is advised that when protease inhibitors are given to patients taking tacrolimus, a significant reduction in the dose of tacrolimus is required, with close and frequent monitoring of tacrolimus blood levels. One centre said that they routinely decreased the tacrolimus dose to 1 mg to 3 mg daily in patients requiring a protease inhibitor-based HAART regimen, although some patients still developed toxicity despite this initial reduction.⁷

Tacrolimus + Proton pump inhibitors

Lansoprazole may increase tacrolimus levels in patients with low levels of the cytochrome P450 isoenzyme CYP2C19. Pantoprazole and omeprazole are predicted to interact similarly. Rabeprazole appears not to interact with tacrolimus.

Clinical evidence

A 57-year-old woman taking tacrolimus following a kidney transplant started taking **lansoprazole** 30 mg daily 19 days after her transplant because of a peptic ulcer. After 3 days her tacrolimus trough level rose from a range of 16.3 to 17.6 nanograms/mL up to 26.7 nanograms/mL. The tacrolimus dose was reduced, and levels of 12 to 15.4 nanograms/mL were achieved. When **lansoprazole** was replaced by famotidine the tacrolimus levels reduced to 8 nanograms/mL. The patient was later switched from famotidine to **rabeprazole** 10 mg daily without any further alteration in tacrolimus levels.^{1,2}

Another report describes a patient who had no significant alteration in tacrolimus levels when **rabeprazole** 10 mg daily was started and stopped.²

A study in 6 transplant patients taking tacrolimus found that **pantoprazole** 40 mg once daily for 5 days did not significantly affect the trough levels of tacrolimus.³

A study in 51 kidney transplant patients taking tacrolimus and **omeprazole** 20 mg daily found no significant interaction.⁴ A retrospective study in 48 kidney transplant patients found that when patients switched from cimetidine 400 mg daily to **omeprazole** 20 mg daily resulted in a 15% decrease in the dose/weight normalised tacrolimus trough levels.⁵

Mechanism

Two of the patients reported above^{1,2} had decreased activity of the cytochrome P450 isoenzyme CYP2C19, by which lansoprazole is mainly metabolised. When levels of this enzyme are low, CYP3A4 (which normally only metabolises a fraction of lansoprazole) becomes more important in

the metabolism of lansoprazole, and interactions with drugs that affect CYP3A4 become more likely. Tacrolimus is metabolised by CYP3A4, and therefore competition with lansoprazole for metabolism may have led to raised tacrolimus levels in these patients. Pantoprazole may interact similarly in poor metabolisers.³ The decreased tacrolimus levels in one study with omeprazole⁵ may have been more to do with stopping the cimetidine (a known enzyme inhibitor) than an effect of omeprazole. Rabeprazole is metabolised non-enzymatically and therefore does not seem to interact.^{1,2}

Importance and management

The incidence of the interaction between tacrolimus and lansoprazole is unknown. It would seem to most frequently occur in those with decreased CYP2C19 activity,⁶ and therefore it is not easy to predict which patients would be affected. The manufacturers of tacrolimus say that this interaction may also occur with omeprazole, which is metabolised in the same way as lansoprazole. It would seem prudent to monitor tacrolimus levels if either of these proton pump inhibitors is started or stopped. Although no interaction was noted in the study with pantoprazole³ the authors do note that it may interact like lansoprazole in patients with CYP2C19 deficiency. Rabeprazole may be a suitable alternative proton pump inhibitor as limited evidence suggests that it does not interact, and nor would it be expected to do so.

Tacrolimus + Quinolones

Levofloxacin modestly increased the bioavailability of tacrolimus in one study. *In vitro*, enoxacin had no effect on tacrolimus metabolism.

Clinical evidence, mechanism, importance and management

A study in 5 kidney transplant patients found that **levofloxacin** 500 mg twice daily for 5 days increased the AUC_{0–12} of tacrolimus by about 27%.¹

On the basis of the study above¹ and of some quite unexpected rises in drug levels and subsequent nephrotoxicity in a handful of patients taking the similarly metabolised immunosuppressant, ciclosporin, with a quinolone antibacterial (see 'Ciclosporin + Antibacterials; Quinolones', p.1018), one review suggested that close monitoring would be appropriate if tacrolimus is given with any quinolone.² However, *in vitro* studies have suggested that enoxacin does not affect the metabolism of tacrolimus, and ciprofloxacin does not affect the immunosuppressant activity of tacrolimus. Further study is needed.

Tacrolimus + Quinupristin/Dalfopristin

Tacrolimus levels have been reported to increase by 15% during the concurrent use of quinupristin/dalfopristin. The manufacturers state that quinupristin/dalfopristin has been shown *in vitro* to inhibit the cytochrome P450 isoenzyme CYP3A4, the main isoenzyme involved in the metabolism of tacrolimus. Tacrolimus levels should therefore be closely monitored during concurrent use.¹

1. Synercid (Quinupristin/Dalfopristin). Monarch Pharmaceuticals. UK Summary of product characteristics, March 2005.

Tacrolimus + Rifamycins

A number of liver transplant patients have needed markedly increased tacrolimus dosages when rifampicin (rifampin) was added. A pharmacokinetic study has shown that rifampicin increases the clearance and decreases the bioavailability of intravenous and oral tacrolimus. Rifabutin is unlikely to interact to the same extent, but given the magnitude of the interaction with rifampicin, caution is still warranted.

Clinical evidence

The trough tacrolimus blood levels of a 10-year-old boy with a liver transplant fell from 10 nanograms/mL to unmeasurable levels within 2 days of **rifampicin (rifampin)** 150 mg twice daily being started. His tacrolimus dosage was therefore doubled from 4 to 8 mg twice daily. When the **rifampicin** was later stopped, the tacrolimus dosage had to be reduced to 3 mg twice daily to keep the blood levels in the region of 10 nanograms/mL.¹

An extremely marked reduction in tacrolimus trough levels occurred in a 10-month-old child with a liver transplant when **rifampicin** was given with tacrolimus. Tacrolimus levels fell to about one-tenth of baseline levels.² This case has also been reported elsewhere.³ In another case, this time in an adult, a tenfold increase was needed in the tacrolimus dosage to keep trough blood levels within the target range when **rifampicin** was started. However, despite levels within the acceptable range, a biopsy showed suspected tacrolimus nephrotoxicity, which was considered to be possibly due to the cumulative tacrolimus dose, or to high levels of tacrolimus metabolites (which were not measured).⁴ Another patient with a kidney transplant had a decrease in tacrolimus levels from 9.2 to 1.4 nanograms/mL 2 days after starting **rifampicin**. **Rifampicin** was stopped and replaced by pyrazinamide, with a gradual return to the baseline tacrolimus level.⁵ A study in 6 healthy subjects supports the findings of these case reports. In the study, **rifampicin** 600 mg daily significantly increased the clearance and decreased the bioavailability of both oral and intravenous tacrolimus.⁶

Mechanism

This interaction is thought to occur because rifampicin, a known enzyme inducer, increases the metabolism of the tacrolimus by the cytochrome P450 isoenzyme CYP3A4 in the liver and small bowel, and by inducing P-glycoprotein, so that the tacrolimus is cleared more rapidly.

Importance and management

These reports are consistent with the way rifampicin interacts with many other drugs and therefore this interaction would seem to be of general clinical importance. It would be prudent to be alert for the need to raise the dosage of tacrolimus if rifampicin is added in any patient.

Direct information about **rifabutin** seems to be lacking, but any interaction with tacrolimus is likely to be much less marked than with rifampicin because its enzyme-inducing effects are considerably less. Nevertheless until the situation is clear it would be prudent to closely monitor concurrent use with any rifamycin, being alert for the need to raise the tacrolimus dosage.

Tacrolimus + Sevelamer

Sevelamer may reduce the absorption of tacrolimus.

Clinical evidence, mechanism, importance and management

A kidney transplant patient had a progressive reduction in tacrolimus levels requiring an increase in his tacrolimus dose after he started to take sevelamer 800 mg three times daily. A small pharmacokinetic study in the same patient found that the peak level was increased from 9.9 to 13.1 nanograms/mL and the AUC₀₋₇ was increased 2.4-fold, 3 days after sevelamer was stopped.¹ Sevelamer can affect the absorption of drugs and the reduction in tacrolimus levels may be due to binding with sevelamer in the gut preventing its absorption.

This appears to be the only case report of an interaction between these two drugs, but sevelamer has been seen to have similar effects on a number of other drugs. It is recommended that any drug for which a reduction in the bioavailability may be clinically significant should be taken at least one hour before or three hours after sevelamer.² Tacrolimus levels should be closely monitored and the dose adjusted as needed if concurrent use is required.

Tacrolimus + Sildenafil

Sildenafil does not appear to affect the pharmacokinetics of tacrolimus. The levels of sildenafil were higher in patients taking tacrolimus than in healthy subjects, but it is not clear whether this was due to tacrolimus alone. A marked blood pressure drop occurred when both drugs were given in one study.

Clinical evidence, mechanism, importance and management

In 10 men with erectile dysfunction, taking tacrolimus after a kidney transplant, a single 50-mg dose of sildenafil did not affect the pharmacokinetics of tacrolimus. When the pharmacokinetics of sildenafil were compared with those quoted by the manufacturer it was found that the maximum plasma concentration and AUC of tacrolimus were increased by 55% and 90%, respectively in patients taking tacrolimus. The AUC of the sildenafil metabolite was also raised. There are several possible reasons for these differences. The pharmacokinetics quoted by the manufacturers are from healthy subjects, not patients, and the patients in the study were taking a multitude of other drugs, some of which could have affected sildenafil. Apart from the pharmacokinetic effects, it was noted that the mean blood pressure dropped by 27/20 mmHg after sildenafil was given, which could be of significance in patients with cardiovascular disease.¹ A subsequent study by the same authors, in 9 men with erectile dysfunction taking tacrolimus after a kidney transplant, found that sildenafil 25 mg daily for 9 days had no significant effects on the pharmacokinetics of tacrolimus.² Another study in 4 patients taking tacrolimus found that sildenafil 50 or 100 mg produced no change in tacrolimus levels.³

It would appear that sildenafil does not affect tacrolimus levels, however, given the reduction in blood pressure seen in one study,¹ it may be prudent to initially prescribe sildenafil at the 25 mg dose, as the authors of this study advise, and increase it as required and tolerated.

Tacrolimus + Sirolimus

Sirolimus may reduce tacrolimus blood levels. There is some evidence to suggest that tacrolimus may increase the clearance of sirolimus.

Clinical evidence, mechanism, importance and management

A study in 18 liver transplant and 7 kidney-pancreas transplant patients taking tacrolimus and sirolimus found no difference in the pharmacokinetics of either drug and no nephrotoxicity when the drugs were taken either

simultaneously or 4 hours apart.¹ A single-dose study in 28 healthy subjects found no pharmacokinetic interaction between sirolimus and tacrolimus when they were given either at the same time or 4 hours apart.²

However subsequent studies have found decreases in tacrolimus levels due to the concurrent use of sirolimus. A study in 7 children with kidney transplants taking tacrolimus and prednisone found that the addition of sirolimus to treat chronic allograft nephropathy resulted in a decrease in dose-normalised tacrolimus trough blood levels from 0.14 kg/L to 0.1 kg/L on day 3 and 0.08 kg/L on day 28. All patients required a tacrolimus dose increase, with a mean increase of about 70% (range 21.9 to 245.4%) in order to keep the tacrolimus blood levels above 3 nanograms/mL. This was thought to be due to a reduction in the bioavailability of tacrolimus rather than increased excretion.³ Another study in 28 kidney transplant patients taking tacrolimus and given sirolimus 0.5, 1, or 2 mg daily also found an initial reduction in the tacrolimus level with the first dose. The tacrolimus levels recovered, but a trend towards reduced tacrolimus levels was seen with continued dosing. Tacrolimus did not appear to alter sirolimus levels, when compared with previous data in studies with sirolimus alone.⁴

A study in 16 adult kidney transplant patients taking tacrolimus and fixed-dose sirolimus 500 micrograms or 2 mg daily found a significant, dose-dependent increase in the AUC of tacrolimus of 16% and 31%, respectively, and an increase in the peak levels of tacrolimus of 19% and 33%, respectively, when sirolimus was stopped.⁵

A study in paediatric kidney transplant patients found the clearance of sirolimus in patients was increased in those taking tacrolimus, when compared with those not taking a calcineurin inhibitor.⁶ A retrospective study in adult kidney transplant patients taking tacrolimus and sirolimus found that concurrent use may be associated with extensive tubular cell injury and a unique form of cast nephropathy.⁷

The manufacturers of sirolimus note that clinical studies in *de novo* liver transplant patients have found an increased risk of hepatic artery thrombosis when tacrolimus is also given: concurrent use is not recommended in this patient group.⁸

Patients taking sirolimus with tacrolimus should have their tacrolimus and probably sirolimus levels closely monitored and the dose adjusted if needed.

Tacrolimus + SSRIs and related antidepressants

Marked increases in tacrolimus levels and toxicity were observed when three patients were also given nefazodone. In theory, fluvoxamine may increase tacrolimus levels. Paroxetine and sertraline may not interact, but the situation is not clear.

Clinical evidence

A kidney transplant patient taking tacrolimus 5 mg daily developed delirium and renal failure 4 weeks after starting to take nefazodone 150 mg daily. The tacrolimus levels had been 9.4 nanograms/mL some 3 months earlier when he was taking a dose of 6 mg daily, but in the presence of nefazodone the tacrolimus level increased to 46.4 nanograms/mL with a tacrolimus dose of 5 mg daily. His serum creatinine had doubled. The tacrolimus level fell to 29.6 nanograms/mL within 2 days of the dose being reduced to 3 mg daily. Nefazodone was then replaced by paroxetine 20 mg daily. After 3 days the tacrolimus dose was increased to 5 mg daily and satisfactory levels of 12.4 nanograms/mL were observed.¹

A kidney transplant patient taking prednisone, azathioprine and tacrolimus 5 mg daily for 2 years experienced headache, confusion and 'grey areas' in her vision within one week of starting **nefazodone** 50 mg twice daily in place of **sertraline**, for depression. Her serum creatinine had risen from 132 to 195 micromol/L and her trough tacrolimus level was greater than 30 nanograms/mL. **Nefazodone** was replaced by **sertraline**, and tacrolimus was withheld for 4 days. Signs of tacrolimus-induced neurotoxicity disappeared within 36 hours and serum creatinine and tacrolimus levels returned to pretreatment levels within 2 weeks.²

Another patient developed raised liver enzymes and raised tacrolimus levels after taking **nefazodone** and tacrolimus for 2 weeks. When the **nefazodone** was stopped his liver enzymes normalised over the next 5 days, and his tacrolimus levels fell from 23 to 9.5 nanograms/mL over 10 days.³

Mechanism

Tacrolimus is metabolised by the cytochrome P450 isoenzyme CYP3A4, which is inhibited by nefazodone, concurrent use therefore results in increased levels of tacrolimus. Paroxetine and sertraline do not have significant effects on CYP3A4 and are therefore not expected to interact with tacrolimus.

Importance and management

Information appears to be limited but what is known indicates that tacrolimus levels or at least signs of toxicity should be well monitored if nefazodone is also given. In view of the narrow therapeutic index of tacrolimus, it may be advisable to avoid concurrent nefazodone.

Fluvoxamine is an inhibitor of CYP3A4⁴ and so theoretically could affect the metabolism of tacrolimus. Close monitoring of tacrolimus levels is therefore advised. Paroxetine and sertraline and possibly other SSRIs may be suitable alternative antidepressants, but the evidence is slim, so additional monitoring may still be warranted.¹ Further study on the use of antidepressants with tacrolimus is needed.

Tacrolimus + St John's wort (*Hypericum perforatum*)

St John's wort decreases tacrolimus levels.

Clinical evidence

In a clinical study, 10 healthy subjects were given a single 100-microgram/kg dose of tacrolimus alone, or after they took St John's wort 300 mg three times daily for 14 days. On average St John's wort decreased the maximum blood level of tacrolimus by 65% and its AUC by 32%. However, the decrease in AUC ranged from 15% to 64%, with one patient having a 31% increase in AUC.¹ Similar results have been found in a study in 10 kidney transplant patients given St John's wort (*Jarsin300*) 600 mg daily for 2 weeks. In order to achieve target levels, the tacrolimus dose was increased in all patients, from a median of 4.5 mg daily to 8 mg daily. Two weeks after stopping St John's wort, tacrolimus doses were reduced to a median of 6.5 mg daily, and then to the original dose of 4.5 mg daily after about 4 weeks.²

A case report describes a 65-year-old patient taking tacrolimus following a kidney transplant. The patient started to take St John's wort (*Neuroplant*) 600 mg daily, and after one month the tacrolimus trough blood levels had dropped from a range of 6 to 10 nanograms/mL down to 1.6 nanograms/mL, with an unexpected improvement in creatinine levels. When the St John's wort was stopped, tacrolimus levels and creatinine returned to the previous range. Subsequently a lower target range of tacrolimus was set.³

Mechanism

St John's wort induces the cytochrome P450 isoenzyme CYP3A4 and affects the transporter protein P-glycoprotein. CYP3A4 and P-glycoprotein are involved in the metabolism and clearance of tacrolimus, so an increase in their effects would be expected to result in a decrease in tacrolimus levels.^{1,3}

Importance and management

Although the evidence currently seems limited to these reports the interaction between tacrolimus and St John's wort has been predicted from the pharmacokinetics of these two drugs. Given the unpredictability of the interaction (and the variability in content of St John's wort products) it would seem prudent to avoid St John's wort in transplant patients, and possibly other types of patient taking tacrolimus. If St John's wort is started or stopped, monitor tacrolimus levels and adjust the dose accordingly.

Tacrolimus + Theophylline

An isolated report suggests that theophylline may increase tacrolimus blood levels.

Clinical evidence

A kidney transplant patient taking tacrolimus 7 mg daily was given theophylline 600 mg daily to treat post-transplant erythrocytosis. After 1 month serum creatinine increased from 110 to 145 micromol/L and the tacrolimus trough blood level increased to 16 nanograms/mL, from a range of 5 to 15 nanograms/mL. The theophylline dosage was reduced to 300 mg daily on 4 days of each week and one month later the serum creatinine was 175 micromol/L and the trough tacrolimus level was 48.5 nanograms/mL. Theophylline was discontinued and the renal function and trough tacrolimus levels rapidly returned to normal. The pharmacokinetics of tacrolimus were later assessed in the same patient. Theophylline 125 mg daily for 4 days was associated with an almost five-fold increase in the AUC of tacrolimus and an increase in the peak tacrolimus blood levels from 19.3 to 37.4 nanograms/mL, without significant alterations in renal function on this occasion.¹

Mechanism

Unclear. An *in vitro* study found that tacrolimus and theophylline each exhibited a negligible effect on the metabolism of the other drug.² However, the authors of the case report suggest that theophylline levels in their patient could have been sufficient to inhibit the cytochrome P450 isoenzyme-mediated metabolism of tacrolimus.¹

Importance and management

Direct information seems to be limited to this single case report. The authors conclude that low-dose theophylline may be given to transplant patients with erythrocytosis provided that tacrolimus levels are closely monitored.¹ However, this interaction is unconfirmed and of uncertain clinical significance. There is insufficient evidence to recommend increased monitoring in every patient, but be aware of the potential for an interaction in the case of an unexpected response to treatment.

Lipid regulating drugs

This section is concerned with the drugs that are used for dyslipidaemias (i.e. disturbed levels of lipids in the blood). In the very broadest of terms (and ideally) they lower the blood levels of cholesterol and low-density lipoprotein (LDL), and raise those of high-density lipoprotein (HDL). Such drugs include the statins (more properly known as HMG-CoA (hydroxymethylglutaryl-coenzyme A) reductase inhibitors), fibrates, ezetimibe, bile-acid binding resins (e.g. colestipol, colestyramine) and nicotinic acid (niacin) and related drugs. These are listed in 'Table 30.1', (below). Where lipid regulating drugs affect other drugs the interactions are covered elsewhere.

Table 30.1 Lipid-regulating drugs

Group	Drugs
Bile-acid binding resins	Colesevelam, Colestilan, Colestipol, Colestyramine
Fibrates	Bezafibrate, Ciprofibrate, Clofibrate, Fenofibrate, Gemfibrozil
Statins	Atorvastatin, Fluvastatin, Lovastatin, Pravastatin, Rosuvastatin, Simvastatin
Miscellaneous	Acipimox, Ezetimibe, Nicotinic acid, Omega-3 marine triglycerides

(a) Statins

1. *Muscle toxicity.* Statins are generally well-tolerated, but have two major but relatively uncommon adverse effects. They raise liver enzymes and can cause skeletal muscle disorders (e.g. myalgia, myopathy and rhabdomyolysis). Rhabdomyolysis is a syndrome resulting from skeletal muscle injury, which results in the release of the enzyme creatine kinase (among other things) into the circulation. Creatine kinase (CK) is also known as creatine phosphokinase (CPK). Both terms are used throughout the text, the choice being dependent on the term used in the source quoted. Rhabdomyolysis can range from asymptomatic elevations in creatine kinase to acute renal failure, and in its severest form may be life-threatening. As well as elevated creatinine kinase levels, signs and symptoms of rhabdomyolysis include muscle pain and weakness, reddish-brown urine (myoglobinuria).¹

Just how statins cause muscle disorders is as yet unclear, although it is thought to be connected to elevated statin levels.² Any pharmacokinetic interaction that results in a marked rise in statin levels is therefore to be regarded seriously.

One of the ways blood statin levels can become elevated is if the interacting drug inhibits the metabolism of the statin, with the result that it is cleared from the body more slowly and it begins to accumulate (see pharmacokinetics below). The overall risk of myopathy with the statins is quite low and commonly quoted as 0.5%, although one report³ puts the incidence of mild myopathies with a statin alone as up to 7%. The incidence seems to rise markedly if other drugs are being taken concurrently. Thus a literature review of published reports for the period 1985 to 2000 found 15 cases of rhabdomyolysis with statins alone, but 54 cases when combined with other drugs.² Other patient-related risk factors for myopathy include:⁴

- age greater than 80 years,
- frailty,

- multisystem disease (e.g. chronic renal impairment),
- perioperative periods,
- hypothyroidism,
- alcohol abuse,
- female sex.

In order to reduce the risk of myopathy the CSM in the UK have advised that statins should be used with care in patients who are at increased risk of this adverse effect. Among other risk factors, they mention concomitant use with fibrates, such as 'gemfibrozil', (p.1100), and with inhibitors of CYP3A4 such as 'ciclosporin', (p.1097), 'macrolides', (p.1104), 'azoles', (p.1093), and 'protease inhibitors', (p.1108). They also recommend that patients should be made aware of the risks of myopathy and rhabdomyolysis, and asked to promptly report muscle pain, tenderness, or weakness, especially if accompanied by malaise, fever, or dark urine.⁵ A 2002 advisory⁴ on the use of statins gives some important safety recommendations, which are useful in the context of interactions:

- Routine monitoring of creatinine kinase is of little value in the absence of clinical symptoms.
- If a patient has a creatinine kinase value 10 times the upper limit of normal, and is symptomatic, statin treatment should be immediately discontinued (if also taking a fibrate or nicotinic acid these too should be discontinued).
- If a patient has symptoms of muscle pain with a creatinine kinase of up to 10 times the upper limit of normal they should be monitored closely until either symptoms resolve or the creatinine kinase becomes greater than 10 times the upper limit of normal.
- If progressive creatinine kinase elevations occur consider a dose reduction or temporary discontinuation of the statin.
- Liver enzyme values of up to 3 times the upper limit of normal do not represent a contraindication to treatment but patients should be carefully monitored.

2. *Pharmacokinetics.* Lovastatin and simvastatin are extensively metabolised by the cytochrome P450 isoenzyme CYP3A4 so that drugs that can inhibit this enzyme can cause marked rises in blood statin levels. Atorvastatin is also metabolised by CYP3A4, but to a lesser extent than lovastatin or simvastatin. Some of the statins are not metabolised by this enzyme so they interact differently. Fluvastatin is metabolised primarily by CYP2C9 (with a minor contribution from CYP3A4), 10% of rosuvastatin is metabolised, and the isoenzymes involved appear to be CYP2C9 and CYP2C19, while the cytochrome P450 system does not appear to be involved in the metabolism of pravastatin.⁶

The statins are also P-glycoprotein substrates, and may therefore interact due to competition for this carrier, generally resulting in altered oral bioavailability.⁶ However, *in vitro* study has suggested that, due to the low affinity of atorvastatin and simvastatin for P-glycoprotein this is unlikely to be a clinically significant cause of statin drug interactions.⁷ Some metabolites of atorvastatin, lovastatin and simvastatin have been shown to inhibit P-glycoprotein, while fluvastatin and pravastatin seem to have little effect.⁸ There appears to be no data on the effect of rosuvastatin on P-glycoprotein.⁹

(b) Bile-acid binding resins

Bile-acid binding resins lower cholesterol by binding with bile acids in the gastrointestinal tract to form an insoluble complex that is excreted in the faeces. This predisposes them to interactions by binding with other drugs in the same way as they do with bile acids, which prevents absorption or local action of the affected drug. These binding interactions are not covered here, but are covered under the affected drugs. A new bile-acid bind-

ing resin, colestevlam, is supposed to be devoid of clinically significant drug-binding interactions.¹⁰

(c) *Ezetimibe*

Ezetimibe is a cholesterol absorption inhibitor, and, as the name suggests, it and the major metabolite, ezetimibe glucuronide, impair the intestinal absorption of cholesterol, both from the diet and biliary cholesterol.¹¹ The absorption of other fats is not affected. Ezetimibe has not been found to have significant effects on cytochrome P450, suggesting it is unlikely to interact by this mechanism.

(d) *Fibrates*

Fibrates are protein-bound drugs that are metabolised via the cytochrome P450 isoenzyme CYP3A4. They are not generally recognised as inhibitors of this enzyme. Although protein binding contributes to their interactions, this mechanism alone does not usually lead to serious interactions. This leaves their mechanism of interaction largely unexplained, although it has been suggested that they may act as inhibitors of glucuronidation.¹² As with the statins (see above), fibrates are also recognised as causing myopathies, and the risk of this appears to be greatly increased when they are given with statins, see 'Statins + Fibrates', p.1100.

(e) *Nicotinic acid*

Nicotinic acid has little effect on the cytochrome P450 isoenzyme system and is therefore unlikely to result in significant pharmacokinetic interactions. It also appears to increase the risk of myopathies when given with statins, see 'Statins + Nicotinic acid (Niacin)', p.1106. Also note that al-

though no interaction has been generally shown with **acipimox** the manufacturers recommend caution with drugs that interact with nicotinic acid.¹³ This is because nicotinic acid is an analog of **acipimox**, and so may share its interactions.

Acipimox + Colestyramine

Colestyramine does not appear to significantly affect the pharmacokinetics of acipimox.

Clinical evidence, mechanism, importance and management

A randomised crossover study in 7 healthy subjects given acipimox 150 mg with three 4-g doses of colestyramine (taken concurrently, and then 8 and 16 hours later) found that the pharmacokinetics of acipimox were slightly but not significantly altered by the colestyramine.¹ There would seem to be no good reason for avoiding concurrent use.

Colestyramine + Food

A study in 10 patients with type IIA hyperlipoproteinaemia found that the efficacy of colestyramine in controlling total cholesterol and low density lipoprotein levels was unaltered whether the colestyramine was taken with or before meals.¹

1. Sirtori M, Pazzucconi F, Gianfranceschi G, Sirtori CR. Efficacy of colestyramine does not vary when taken before or during meals. *Atherosclerosis* (1991) 88, 249–52.

Ezetimibe + Ciclosporin

The levels of ezetimibe and possibly ciclosporin may be elevated by their concurrent use, and so the combination should be used with caution.

Clinical evidence, mechanism, importance and management

A randomised, crossover study in 12 healthy subjects found that ezetimibe 20 mg daily for 8 days increased the AUC of a single 100-mg dose of ciclosporin by 15%. The authors noted that it would be difficult to determine the outcome of long-term concurrent use, but the modest effect seen suggested that caution was necessary if the combination was given.¹ However, an efficacy study noted that in 16 renal transplant patients the addition of ezetimibe 10 mg daily had no effect on ciclosporin levels.²

In one study, 8 stable renal transplant patients taking ciclosporin were given a single 10-mg dose of ezetimibe. When compared with other data from healthy control subjects, the AUC of ezetimibe was found to be 3.4-fold higher in the patients taking ciclosporin.³ A further patient with severe renal impairment taking multiple drugs, including ciclosporin, had a 12-fold increase in the AUC of ezetimibe.³ A case report describes a heart transplant patient taking ciclosporin 100 mg twice daily with atorvastatin 40 mg daily. As his LDL-cholesterol was inadequately lowered by the atorvastatin, and greater doses had not been tolerated due to elevated creatine kinase levels, ezetimibe 10 mg daily was added. His LDL-cholesterol then decreased from 126 mg/dL to 51 mg/dL (target less than 100 mg/dL), and so his dose of ezetimibe was decreased to 5 mg daily.⁴ The authors of this case report note that only about 50% of heart transplant patients are able to achieve LDL-cholesterol of less than 100 mg/dL and attribute the effects seen in their patient to an interaction. However, the validity of any interaction has been debated,^{5,6} and an efficacy study in which renal transplant patients taking ciclosporin and a statin were given ezetimibe 10 mg daily noted an enhanced but not excessive effect on lipids.²

Therefore it seems that ciclosporin can greatly raise ezetimibe levels, possibly resulting in an increased effect on lipid reduction, and that ciclosporin levels can be raised, possibly significantly in some patients, by ezetimibe. If concurrent use is necessary, until the effects of concurrent treatment are better established, it would seem prudent to monitor both ciclosporin levels and the effects on lipid levels, anticipating the need to reduce the dosage of either drug. The authors of the case report cited sug-

gest that, in patients taking ciclosporin, ezetimibe should be started at a dose of 5 mg daily or less and slowly titrated upwards.⁶

Ezetimibe + Colestyramine

In a study of 40 healthy hypercholesterolaemic subjects, colestyramine 4 g twice daily decreased the mean AUC of ezetimibe by about 80% and decreased the mean AUC of total ezetimibe (ezetimibe plus metabolites) by about 55%.¹ Colestyramine may therefore be expected to decrease the lipid-lowering effects of ezetimibe. Note that ezetimibe undergoes enterohepatic recirculation, so separating administration may not fully resolve this interaction.

1. Zetia (Ezetimibe). Merck/Schering-Plough Pharmaceuticals. US Prescribing information, June 2007.

Ezetimibe + Rifampicin (Rifampin)

Single-dose rifampicin increases ezetimibe levels without altering its effects on sterols, whereas multiple doses of rifampicin decrease ezetimibe levels and almost totally abolish its effects.

Clinical evidence

In a single-dose study investigating the disposition of ezetimibe 8 healthy subjects were given ezetimibe 20 mg with rifampicin 600 mg. Rifampicin increased the ezetimibe maximum serum levels by about 2.5-fold, without affecting the AUC. The maximum serum levels of ezetimibe glucuronide (the major active metabolite of ezetimibe) were similarly increased, and its AUC was also increased, by about twofold. The sterol-lowering effects of ezetimibe were also more rapid in the presence of rifampicin, but the overall effect was unchanged, possibly because ezetimibe and its glucuronide were excreted more rapidly.¹ In another study by the same researchers ezetimibe 20 mg was given 12 hours after the last dose of an 8-day course of rifampicin 600 mg daily. This time both the AUC and maximum serum levels of ezetimibe and its glucuronide were decreased (AUC decreased by more than 50%) and the effect of ezetimibe on sterols was almost completely abolished.²

Mechanism

The raised ezetimibe levels seen in the single-dose study are thought to occur because rifampicin enhances the absorption of ezetimibe, probably by inhibiting intestinal P-glycoprotein, and another transporter protein, MRP2. However, inhibition of MRP2 appears to reduce enterohepatic circulation, which is needed for the long duration of ezetimibe effects, and therefore shortens the sterol-lowering effects of ezetimibe.¹ It seems likely that the balance of these factors is altered when rifampicin is given in multiple doses, which leads to a reduction in the effects of ezetimibe. Other factors are possibly also involved.²

Importance and management

Information about the interaction between ezetimibe and rifampicin appears to be limited to these studies, which were primarily designed to investigate ezetimibe disposition. However, it seems likely that the effects of ezetimibe will be reduced in patients who are also given multiple doses

of rifampicin. If both drugs are given it would be prudent to closely monitor the effects on lipid levels.

Fibrates + Bile-acid binding resins

Colestyramine does not alter the pharmacokinetics of clofibrate when both drugs are given at the same time. Similarly colestipol does not alter the pharmacokinetics of clofibrate or fenofibrate, and colesvelam does not alter the pharmacokinetics of fenofibrate. Colestipol can reduce the absorption of gemfibrozil if given at the same time, but not if administration is separated by 2 hours. A similar interaction occurs between bezafibrate and colestyramine

Clinical evidence, mechanism, importance and management

(a) Bezafibrate

The manufacturers of bezafibrate recommend that there should be a 2-hour interval between administration of [drugs such as **colestyramine**] and bezafibrate, as the absorption of bezafibrate may otherwise be impaired.¹

(b) Clofibrate

Over a 6-day period no clinically relevant changes in the pharmacokinetics of clofibrate occurred in 24 healthy subjects, who were given daily doses of **colestipol** 10 g at the same time as clofibrate 500 mg.² **Colestyramine** 4 g four times daily had no effect on the fasting plasma levels, urinary and faecal excretion, or the half-life of clofibrate in 6 patients taking 1 g of clofibrate twice daily. In this study, the morning and evening doses of **colestyramine** were taken at the same time as the clofibrate.³

(c) Fenofibrate

Over a 6-day period no clinically relevant changes in the pharmacokinetics of fenofibrate occurred in 18 healthy subjects, who were given daily doses of **colestipol** 10 g at the same time as fenofibrate 200 mg in the morning, and **colestipol** 5 g at the same time as fenofibrate 100 mg in the evening.⁴ In a randomised, crossover study 27 healthy subjects took fenofibrate 160 mg with **colesvelam** 3.75 g, four hours before **colesvelam**, or alone. **Colesvelam** caused some slight changes in the pharmacokinetics of fenofibrate when both drugs were given simultaneously but this was not considered to be clinically significant.⁵

(d) Gemfibrozil

A study in 10 patients with raised serum cholesterol and triglyceride levels found that if gemfibrozil 600 mg was given alone, 2 hours before or 2 hours after **colestipol** 5 g, the serum gemfibrozil concentration curves were similar. However, when both drugs were given at the same time, the AUC of gemfibrozil was reduced by about a third.⁶ Another study found that combined use of gemfibrozil and **colestipol** (doses not separated) enhanced the LDL-lowering effects of both drugs, but tended to mitigate the HDL-raising effects of the gemfibrozil.⁷ Combined use is effective, but information is very limited about the clinical importance of the reduction in gemfibrozil bioavailability. However, the interaction can be avoided by separating the administration of the two drugs by at least 2 hours.

Fibrates + Colchicine

Case reports suggest that the current use of fibrates and colchicine can result in rhabdomyolysis or neuromyopathy.

Clinical evidence

A 40-year-old man with chronic hepatitis and nephritic syndrome, who had been taking colchicine 500 micrograms three times daily uneventfully for 2 to 3 years, started taking **gemfibrozil** 600 mg twice daily. About one month later he presented with muscle pain and dark brown urine, and had a creatinine kinase of 3 559 units/L, and he was diagnosed as having rhabdomyolysis. Both drugs were stopped, and he recovered over the following 9 days.¹ Another case report describes neuromyopathy (creatinine kinase level 15 084 units/L), in a patient who had been taking **bezafibrate** 400 mg daily with colchicine 3 mg daily for 14 days.² This patient was known to have renal impairment.

Mechanism

Colchicine alone can, rarely, cause myopathy. However, it is more common in those given colchicine long term (as in the case with gemfibrozil), in high dose, or in the presence or renal impairment (as in the case with bezafibrate).² As the fibrates can also, rarely, cause myopathy, an additive or synergistic effect seems possible.

Importance and management

Although information seems limited to these two cases, the effects seen are known to be associated with both colchicine and the fibrates, so an interaction, all be it rare, seems to be established. It would be prudent to suspect this interaction in any patient presenting with muscle pain or a raised creatinine kinase level. The section on ‘muscle toxicity’, (p.1086), discusses risk factors for myopathy and it would seem prudent to be aware of these, as both patients in the cases above had other risk factors for rhabdomyolysis.

Fibrates + Diuretics

Treatment with clofibrate in patients with nephrotic syndrome receiving furosemide has sometimes led to marked diuresis and severe and disabling adverse muscular effects. An isolated report describes rhabdomyolysis in a patient taking bezafibrate and furosemide.

Clinical evidence

(a) Bezafibrate

An isolated report attributed a case of acute renal failure and rhabdomyolysis to treatment with bezafibrate 400 mg daily and **furosemide** 25 mg on alternate days.¹

(b) Clofibrate

Three patients with hyperlipoproteinaemia secondary to nephrotic syndrome, taking **furosemide** 80 to 500 mg daily, developed severe muscle pain, low lumbar backache, stiffness, and general malaise with pronounced diuresis within 3 days of starting to take clofibrate 1 to 2 g daily. Similarly, a patient taking **bendroflumethiazide** 10 mg daily developed adverse muscle effects within 3 days of starting clofibrate. Of these 4 patients, 3 had documented raised serum transaminases or creatine phosphokinase.

Two other patients had raised levels of serum transaminases or creatine phosphokinase while taking clofibrate with **furosemide**.

A further study in 4 of the 6 patients discussed above and 4 healthy controls, free serum clofibrate was markedly higher in the patients, and this correlated with low serum albumin. Urinary clofibrate excretion was markedly delayed.²

Mechanism

Not understood. The marked diuresis may have been due to competition and displacement of the furosemide by the clofibrate from its plasma protein binding sites. Clofibrate occasionally causes a muscle toxicity, which could have been exacerbated by the urinary loss of Na⁺ and K⁺ and the increase in the half-life of clofibrate. The reason for the bezafibrate/furosemide-induced rhabdomyolysis is unknown.

Importance and management

The clinical documentation seems to be limited to these reports. It appears to be a combination of a drug-drug interaction (clofibrate with furosemide) with or without a drug-disease interaction (clofibrate with nephrotic syndrome). The authors of one report² suggest that serum proteins and renal function should be checked before giving clofibrate to any patient. If serum albumin is low, the total daily dosage of clofibrate should not exceed 500 mg for each 1 g per 100 mL of the albumin concentration. However, note that this guidance is old.

2. Bridgman JF, Rosen SM, Thorp JM. Complications during clofibrate treatment of nephrotic syndrome hyperlipoproteinaemia. *Lancet* (1972) ii, 506–9.

Fibrates + Ezetimibe

Ezetimibe does not alter fenofibrate or gemfibrozil pharmacokinetics. Fenofibrate and gemfibrozil may modestly increase ezetimibe levels, although this is unlikely to be clinically relevant. The manufacturers currently advise caution if ezetimibe is given with a fibrate, because of the theoretical increased risk of gallstone formation.

Clinical evidence

(a) Fenofibrate

In a randomised, crossover study 18 healthy subjects were given ezetimibe 10 mg daily with fenofibrate 145 mg daily for 10 days, or either drug alone. Ezetimibe did not affect the AUC of fenofibrate, and, although fenofibrate increased the total AUC of ezetimibe and ezetimibe-glucuronide by 1.5-fold this was not considered to be clinically significant.¹ This expectation appears to have largely been borne out by safety studies. In a randomised, placebo-controlled study, 32 otherwise healthy patients with hypercholesterolaemia were given fenofibrate 200 mg daily, ezetimibe 10 mg daily, both drugs in combination, or placebo daily for 14 days. The combination was well-tolerated, and resulted in an increased reduction in LDL-cholesterol than that achieved by either active drug alone. Concurrent use did not affect the pharmacokinetics of either drug.² A further efficacy and safety study in 172 patients taking ezetimibe 10 mg daily with fenofibrate 160 mg daily, found that there was a trend towards increased treatment-related adverse effects, when compared with patients taking either drug alone. However, the incidence of musculoskeletal disorders was similar.³

(b) Gemfibrozil

In a randomised, crossover study 12 healthy subjects were given ezetimibe 10 mg daily with gemfibrozil 600 mg twice daily for 7 days, or either drug alone. Ezetimibe did not affect the AUC of gemfibrozil, and, although gemfibrozil increased the total AUC of ezetimibe and ezetimibe glucuronide by about 1.7-fold this was not considered to be clinically significant.⁴

Mechanism, importance and management

Despite these seemingly favourable results, the UK manufacturers of ezetimibe state that the safety of combined use with fibrates is not yet established. This is because both fibrates and ezetimibe increase cholesterol excretion into the bile, which could promote the production of gallstones.⁵ They say that if gallstones or gall bladder disease is suspected then the combination should be discontinued.

Fibrates + Nifedipine

It has been suggested that three cases of rhabdomyolysis occurred because of an interaction between bezafibrate and nifedipine, but it seems more likely that the dose of bezafibrate was too high.

Clinical evidence, mechanism, importance and management

Rhabdomyolysis developed in 4 of 5 patients undergoing CAPD, who were given **bezafibrate** 200 to 400 mg daily for raised cholesterol and triglyceride levels. Of these, 3 patients were also taking nifedipine, and one of these 3 was also taking lovastatin. Raised creatinine kinase levels developed within 8 to 16 days of concurrent use, and resolved within 48 hours of stopping the **bezafibrate**. The authors suggest that nifedipine may have competed with **bezafibrate** for metabolism by the cytochrome P450 isoenzyme CYP3A4. They therefore say that patients with renal failure needing a fibrate should avoid taking CYP3A4 substrates.¹ However, as the recommended dose for **bezafibrate** in CAPD patients is 200 mg every 72 hours² it appears likely that the high dose, and not an interaction, was responsible for the rhabdomyolysis. No precautions therefore seem necessary.

Fibrates + Rifampicin (Rifampin)

Preliminary evidence suggests that rifampicin can reduce the plasma levels of the active metabolite of clofibrate, but rifampicin apparently has no effect on gemfibrozil pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Clofibrate

A 35% reduction in the steady-state plasma levels of the active metabolite of clofibrate, chlorophenoxyisobutyric acid (CIPB), was seen in 5 healthy subjects after they took rifampicin 600 mg daily for 7 days.¹ This appears to occur because the metabolism of CIPB by the liver and/or the kidneys is increased.¹ On the basis of this study it would now be prudent to monitor serum lipid levels of patients taking clofibrate if rifampicin is added, and to increase the clofibrate dosage if necessary. More study is needed to establish this interaction.

(b) Gemfibrozil

Rifampicin 600 mg daily for 6 days did not significantly affect the pharmacokinetics of gemfibrozil 600 mg in a study in 10 healthy subjects.² No special precautions seem necessary.

Fibrates; Ciprofibrate + Ibuprofen

An isolated report describes a patient taking ciprofibrate who developed acute renal failure and rhabdomyolysis after taking ibuprofen.

Clinical evidence, mechanism, importance and management

A 29-year-old man with type M hyperlipidaemia¹ who had been taking ciprofibrate 100 mg daily for 6 months began to take ibuprofen 200 mg and then 400 mg daily for a painful heel. The pain became general, his urine turned 'muddy', he complained of having a 'stiff body', and he rap-

idly developed acute renal failure. His serum creatinine concentration was found to be 647 micromol/L and his creatine kinase was 13 740 units/L.

The reasons for this reaction are not known, but the authors of the report postulate that the ibuprofen displaced the ciprofibrate from its binding sites, thereby turning a safe dose into a toxic one.¹ However, it should be said that this mechanism of interaction is rarely important on its own, so it seems likely that some other factors may have contributed to what happened.

This is an isolated case so that its general importance is unknown, but it is probably very small.

1. Ramachandran S, Giles PD, Hartland A. Acute renal failure due to rhabdomyolysis in presence of concurrent ciprofibrate and ibuprofen treatment. *BMJ* (1997) 314, 1593.

Fibrates; Clofibrate + Hormonal contraceptives

Oral contraceptives increase the clearance of clofibrate but the significance of this is unclear.

Clinical evidence, mechanism, importance and management

A comparative study in men, women, and women taking combined oral contraceptives found that the clearance of clofibrate was increased by 48% in those taking combined oral contraceptives, apparently due to an increase in clofibrate glucuronidation.¹ Another study found that combined oral contraceptives increased the excretion of clofibrinic acid glucuronide (the pharmacologically active form of clofibrate) by 25%.² None of these studies addressed the question of whether concurrent use significantly reduces clofibrate efficacy, but it would seem prudent to monitor for increases in blood lipid levels. It should be noted that combined oral contraceptives themselves can have various adverse effects on lipid levels, and these may impair the effects of treatment.

2. Liu H-F, Magdalou J, Nicolas A, Lafaurie C, Siest G. Oral contraceptives stimulate the excretion of clofibrinic acid glucuronide in women and female rats. *Gen Pharmacol* (1991) 22, 393–7.

Fibrates; Clofibrate + Probenecid

Plasma clofibrate levels can be approximately doubled by probenecid, but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 4 healthy subjects taking clofibrate 500 mg every 12 hours found that probenecid 500 mg every 6 hours for 7 days almost doubled the steady-state clofibrinic acid levels, from 72 to 129 mg/L, and raised the free clofibrinic acid levels from 2.5 to 9.1 mg/L. The suggested reason is that the probenecid reduces the renal and metabolic clearance of the clofibrate by inhibiting its conjugation with glucuronic acid.¹ The clinical importance of this interaction is uncertain. It appears not to have been assessed.

1. Veenendaal JR, Brooks PM, Meffin PJ. Probenecid-clofibrate interaction. *Clin Pharmacol Ther* (1981) 29, 351–8.

Fibrates; Gemfibrozil + Antacids

Antacids can reduce the absorption of gemfibrozil.

Clinical evidence, mechanism, importance and management

A study in patients with kidney and liver disease found that the concurrent use of antacids (**aluminium hydroxide, aluminium magnesium silica hydrate**) reduced the maximum plasma gemfibrozil levels by about 50 to 70%, and the AUC by about 30 to 60%. The precise values are not given in the text. The reasons for these reductions are not known, but it was suggested that the gemfibrozil is adsorbed onto the antacids in the gut. The authors recommend that gemfibrozil is given 1 to 2 hours before antacids.¹ More study is needed to confirm these findings.

Fibrates; Gemfibrozil + Psyllium

When 10 healthy subjects took gemfibrozil 600 mg with, or 2 hours after, 3 g of psyllium in 240 mL water, the AUC of gemfibrozil was reduced by about 10%.¹ This change in bioavailability is almost certainly too small to be clinically significant.

Nicotinic acid (Niacin) + Aspirin

Aspirin reduces the flushing reaction that often occurs with nicotinic acid, but there is some evidence that it can also increase nicotinic acid plasma levels.

Clinical evidence, mechanism, importance and management

Nicotinic acid (70 to 100 micrograms/kg per minute as an infusion over 6 hours) was given to 6 healthy subjects. When the subjects were also given aspirin 1 g orally 2 hours after the infusion was started, the plasma nicotinic acid levels rose markedly, and its clearance was reduced by 30 to 54%.¹ The probable reason is that the salicylate competes with the nicotinic acid for metabolism by glycine conjugation in the liver so that the clearance of nicotinic acid is reduced, resulting in a rise in its levels. The clinical importance of this effect when aspirin is given to reduce the annoying nicotinic acid flushing reaction² is not known. However, as nicotinic acid is titrated upwards, according to efficacy and tolerability, any increase in its levels caused by aspirin is probably naturally accounted for.

Nicotinic acid (Niacin) + Nicotine

An isolated report describes an unpleasant flushing reaction that developed in a woman taking nicotinic acid when she started to use nicotine transdermal patches.

Clinical evidence, mechanism, importance and management

A case report describes a woman who had taken nicotinic acid 250 mg twice daily for 3 years without problems, as well as nifedipine, ranitidine, colestyramine and ferrous sulfate. Following laryngectomy for cancer of the larynx, she restarted all of the drugs except the colestyramine and began to use nicotine transdermal patches 21 mg daily to try to give up smoking. On several occasions, shortly after taking the nicotinic acid, she developed unpleasant flushing episodes lasting about 30 minutes. No further episodes developed when the nicotinic acid was stopped.¹ The reasons are not understood, but flushing is a very common adverse effect of nicotinic acid, and it would seem that in this case the nicotine patch may have been responsible for its emergence. A comment on this report suggests that this reaction may possibly have an immunological basis.² Either way, this reaction is more unpleasant than serious.

Statins + ACE inhibitors

In general the statins do not appear to interact with the ACE inhibitors. An isolated report describes severe hyperkalaemia in a diabetic given lisinopril with lovastatin, and acute pancreatitis has been attributed to the use of lisinopril with atorvastatin.

Clinical evidence, mechanism, importance and management

Retrospective analysis of clinical study data found no evidence that the safety of **lovastatin** was altered by the use of unspecified ACE inhibitors in 142 patients.¹ Another retrospective analysis of clinical study data found no evidence that the safety or efficacy of **fluvastatin** was altered by the use of unspecified ACE inhibitors.² Likewise, the UK manufacturer of **atorvastatin**³ says that in clinical studies it was given with ACE inhibitors without evidence of significant adverse interactions. A study in healthy subjects found that **simvastatin** had no effect on the pharmacokinetics or ACE-inhibitory effects of **ramipril** or its metabolites.⁴ Similarly, no evidence of clinically important adverse interactions was found when **moexipril** was used with **cholesterol-lowering drugs** [not specifically named].⁵ An isolated report describes a type I diabetic (receiving insulin) with hypertension and hyperlipidaemia who developed myositis and severe hyperkalaemia (serum potassium 8.4 mmol/L) when given **lovastatin** 20 to 40 mg daily with **lisinopril** 50 mg daily. His serum potassium returned to about 5.5 mmol/L after the **lovastatin** was stopped and the dosage of **lisinopril** lowered (to 20 mg daily). About 3 months later, the patient resumed taking the **lovastatin**, but after only 2 doses he again had severe myositis and hyperkalaemia, which resolved after the **lovastatin** was discontinued. The reason seemed to be a combination of the hyperkalaemic effects of the **lisinopril**, the release of intracellular potassium into the blood stream associated with the myositis caused by the **lovastatin**, and a predisposition to hyperkalaemia due to the diabetes and mild renal impairment.⁶ Another case report describes the development of acute pancreatitis in a patient who had been taking **lisinopril** 10 mg daily with **atorvastatin** 20 mg daily for 9 months. No other cause for the pancreatitis was identified, and both drugs alone have, rarely, been associated with the development of pancreatitis.⁷ These are unusual cases and, given the widespread use of drugs from these classes they seem unlikely to be of general importance. No special precautions would seem to be necessary if ACE inhibitors are given with statins.

Statins + Amiodarone

There is some evidence of a high incidence of myopathy when amiodarone is given with high doses of simvastatin. Cases of myopathy and rhabdomyolysis have been reported in patients taking the combination.

Clinical evidence, mechanism, importance and management

The manufacturers of **simvastatin** note that in an ongoing unpublished clinical study, myopathy (clinically significant muscle pain with a creatinine kinase at least 10 times the upper limit of normal¹) has been reported in 6% of patients receiving **simvastatin** 80 mg daily with amiodarone.^{2–4} There is some evidence from reports to the US FDA that the concurrent use of **simvastatin** with amiodarone is associated with a higher incidence of muscle toxicity than **pravastatin** with amiodarone. They reported that the percentage of reports of muscle, liver, pancreas, and bone marrow toxicity associated with statins and involving concurrent amiodarone was 1% for **simvastatin** and 0.4% for **pravastatin**.⁵

A 63-year-old man developed diffuse muscle pain with generalised muscular weakness 4 weeks after starting to take **simvastatin** 40 mg daily, and about 2 weeks after starting to take amiodarone (1 g daily for 10 days, then 200 mg daily thereafter). There was a marked increase in creatinine kinase, which normalised after stopping both drugs.⁶ A 77-year-old man taking multiple medications including amiodarone 100 mg daily and **simvastatin** 20 mg daily, developed increasing lower-extremity pain and darkening of his urine 3 weeks after his **simvastatin** dose was increased to 40 mg daily. He was diagnosed with rhabdomyolysis secondary to **sim-**

vastatin use,⁷ although a later comment suggested that amiodarone could have contributed.⁸ Two other cases of rhabdomyolysis in patients taking amiodarone with **simvastatin**^{9,10} (one involving clarithromycin),¹⁰ have also been reported. One of these patients had pneumonia,¹⁰ and the other diabetes,⁹ both of which have been suggested as risk factors for rhabdomyolysis.

Amiodarone is an inhibitor of various cytochrome P450 isoenzymes. Whether it inhibits the metabolism of **simvastatin** and other extensively-metabolised statins, and thereby increases the risk of muscle toxicity, is not known. Amiodarone alone may sometimes cause myopathy.

The interaction is not established. However, one manufacturer in the UK recommends that the dose of **simvastatin** should not exceed 20 mg daily in patients also taking amiodarone unless the clinical benefit is likely to outweigh the increased risk of myopathy and rhabdomyolysis.² Another contraindicates the combination.³ The US manufacturer advises only using doses of **simvastatin** above 20 mg if the benefits outweigh the risks.⁴

Until more is known, caution is certainly warranted. See also 'muscle toxicity', (p.1086), for further guidance on monitoring and risk factors for muscle toxicity. **Lovastatin** is metabolised in the same way as **simvastatin**, and shares many of its interactions: the manufacturers of **lovastatin** suggest a maximum dose of 40 mg daily in the presence of amiodarone.¹¹ **Pravastatin** appears less likely to interact.

Statins + Angiotensin II receptor antagonists

Irbesartan and telmisartan appear not to alter the pharmacokinetics of simvastatin, fluvastatin does not alter the pharmacokinetics of losartan or its active metabolite, and olmesartan appears not to interact with pravastatin.

Clinical evidence, mechanism, importance and management

(a) Fluvastatin

In a crossover study 12 healthy subjects were given **losartan** 50 mg in the morning for 7 days, followed by fluvastatin 40 mg at bedtime for 7 days, and then both drugs together for another 7 days. It was found that the steady-state pharmacokinetics of **losartan** and its active metabolite, E-3174, were not significantly altered by fluvastatin.¹ It was anticipated that fluvastatin might inhibit the conversion of losartan to E-3174 by inhibiting the cytochrome P450 isoenzyme CYP2C9 (compare 'Angiotensin II receptor antagonists + Azoles', p.35). The findings of this study indicate that a clinically relevant pharmacokinetic interaction is unlikely, and no **losartan** dose adjustment is required on combined use.

(b) Pravastatin

The manufacturer of **olmesartan** states that it has no clinically relevant interaction with pravastatin in healthy subjects.²

(c) Simvastatin

A study in 12 healthy subjects found that **irbesartan** 300 mg had no significant effect on the pharmacokinetics of a single 50-mg dose of simvastatin, or its metabolite simvastatin acid, and the combination was well-tolerated.³ No clinically relevant interaction was noted when **telmisartan** was given with simvastatin.⁴

Statins + Antacids

An aluminium/magnesium hydroxide antacid (*Maalox*) causes a moderate reduction in the bioavailability of atorvastatin, pravastatin, and rosuvastatin, but the lipid-lowering efficacy of atorvastatin and pravastatin is not affected.

Clinical evidence, mechanism, importance and management

In a multiple-dose study, 18 patients were given **atorvastatin** 10 mg daily for 15 days with 30 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox TC*) four times daily for a further 17 days. The maximum serum levels and AUC of **atorvastatin** were reduced by 34%, and the absorption rate was also reduced by the antacid. However, the LDL-cholesterol reduction remained the same.¹ The concurrent use of the same antacid (*Maalox TC*) 15 mL four times daily, given one hour before **pravastatin**, reduced the bioavailability of a single 20-mg dose of **pravastatin** by 28%. This change was less than that seen with food, which did not alter **pravastatin** efficacy.² There is therefore no need to avoid the concurrent use of **aluminium/magnesium hydroxide** antacids such as *Maalox*, nor does the dosage of **atorvastatin** or **pravastatin** need to be raised.

The US manufacturers of **rosuvastatin** quote a study in which an **aluminium/magnesium hydroxide** antacid reduced the levels of a 40-mg dose of **rosuvastatin** by 54%. No clinically significant interaction was seen when the doses were given 2 hours apart, and a 2-hour separation is therefore recommended on concurrent use.³

Statins + Azoles

Fluconazole modestly increases the levels of fluvastatin and rosuvastatin, but not pravastatin. Miconazole would be expected to interact similarly. Itraconazole causes a marked rise in the serum levels of atorvastatin, lovastatin, pravastatin and simvastatin, but no change in fluvastatin or rosuvastatin levels. Ketoconazole would be expected to interact similarly. Rhabdomyolysis has been reported in some cases. Due to the risk of myopathy, the manufacturers of voriconazole caution, and the manufacturers of posaconazole contraindicate, concurrent use with atorvastatin, lovastatin and simvastatin.

Clinical evidence

(a) Atorvastatin

A case report describes a 76-year-old man taking multiple medications, including pravastatin 80 mg daily with **fluconazole** 150 mg daily, uneventfully for about 18 months. Due to an inadequate response to the pravastatin he was changed to atorvastatin 40 mg daily. Within one week he developed dyspnoea, myopathy, rhabdomyolysis and renal failure. Although both drugs were stopped he later died of multi-organ failure. The authors considered an interaction between atorvastatin and **fluconazole** as the most likely explanation for the rhabdomyolysis.¹

Ten healthy subjects were given **itraconazole** 200 mg daily for 5 days with a single 40-mg dose of atorvastatin on day 4. The **itraconazole** increased the AUC of atorvastatin acid and atorvastatin lactone fourfold and threefold, respectively, and increased their half-lives threefold and twofold, respectively. The AUC values of active and total HMG-CoA reductase inhibitors were increased 1.6- and 1.7-fold, respectively.² In a similar study,³ the same dose of **itraconazole** increased the AUC of atorvastatin by 2.5-fold and of atorvastatin lactone by about threefold. Another study has also shown that **itraconazole** raises atorvastatin levels.⁴

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, an azole antifungal was potentially implicated in 2 cases of rhabdomyolysis involving atorvastatin.⁵

(b) Fluvastatin

A randomised, double-blind study in 12 healthy subjects found that **fluconazole** (400 mg on day 1 followed by 200 mg daily for 3 days) increased the AUC of a single 40-mg dose of fluvastatin by 84% and increased its maximum plasma level by 44%. The pharmacokinetics of the **fluconazole** were unaffected.⁶ In a similar study, **itraconazole** 100 mg daily for 4 days did not significantly affect the pharmacokinetics of fluvastatin, apart from a small increase in its half-life.⁷

(c) Lovastatin

In a double-blind, crossover study in 12 healthy subjects **itraconazole** 200 mg daily or a placebo was given for 4 days with a single 40-mg oral dose of lovastatin on day 4. On average the peak plasma concentration and the 24-hour AUC of the lovastatin were increased more than 20-fold. The peak plasma concentration of the active metabolite of lovastatin, lovastatin acid, was increased 13-fold (range 10 to 23-fold) and its AUC was increased 20-fold. The creatine kinase activity of one subject increased 10-fold, but in the other 11 subjects it remained unchanged.⁸ Another study also found similar pharmacokinetic changes.⁷ Brief mention is also made of severe rhabdomyolysis in one patient given lovastatin and **itraconazole**.⁸

A 63-year-old woman who had been taking lovastatin 80 mg, nicotinic acid 3 g daily, timolol and aspirin for almost 10 years without problems, developed weakness and tenderness in her arms, back and legs within 2 weeks of starting to take **itraconazole** 100 mg twice daily. A few days later her urine became brown, and positive for haem. She was diagnosed as having acute rhabdomyolysis and hepatotoxicity. The lovastatin, nicotinic acid and **itraconazole** were stopped, and she was treated with ubidecarenone. Over the next 18 days her elevated serum enzymes returned to normal, although her plasma cholesterol levels almost doubled. She was restarted on nicotinic acid 11 weeks later without problems.⁹

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, an azole antifungal was potentially implicated in 6 cases of rhabdomyolysis involving lovastatin.⁵

(d) Pravastatin

A randomised, double-blind study in 12 healthy subjects found that **fluconazole** (400 mg on day 1 followed by 200 mg daily for 3 days) had no significant effect on the pharmacokinetics of a single 40-mg dose of pravastatin.⁶

The AUC of a single 40-mg dose of pravastatin was increased by 71% in 10 healthy subjects who took **itraconazole** 200 mg daily for 4 days, although this did not reach statistical significance.¹⁰ In a similar study, the same dosage of **itraconazole** caused a modest 51% increase in the AUC of pravastatin.³ In contrast, one study in 104 subjects found that **itraconazole** had no effect on pravastatin pharmacokinetics.⁴

(e) Rosuvastatin

Fluconazole 200 mg once daily for 11 days increased the AUC and maximum plasma concentration of rosuvastatin (given on day 8) by 14% and 9%, respectively, in 14 healthy subjects. The proportion of circulating active HMG-CoA reductase inhibitors was not affected by **fluconazole**.¹¹ In similar studies by the same workers, **itraconazole**¹² and **ketoconazole**¹³ also had no clinically significant effect on the levels of rosuvastatin.

(f) Simvastatin

An 83-year-old man who had been taking multiple medications including simvastatin 40 mg daily for 2 years was given **fluconazole** 400 mg daily as part of a prophylactic regimen against chemotherapy-induced neutropenic sepsis. After one week he developed generalised muscle weakness and was found to have brown urine and an elevated serum creatine kinase. His medication was stopped, and he was treated with hydration and diuretics, after which his symptoms resolved.¹⁴

In a two-phase crossover study, 10 healthy subjects were given **itraconazole** 200 mg daily or a placebo for 4 days, with a single 40-mg dose of simvastatin on day 4. The peak serum levels of total simvastatin acid (simvastatin acid plus simvastatin lactone) were increased 17-fold and the AUC was increased 19-fold. The maximum serum levels and the AUC of total HMG-CoA reductase inhibitors increased about 3-fold and 5-fold, respectively.¹⁰

A 74-year-old who had been taking simvastatin 40 mg daily, lisinopril and aspirin for about a year without problems developed pain in his feet, and then in his arms and neck, within 3 weeks of starting **itraconazole** 200 mg daily. His urine turned brown, his muscles were tender, and abnormal serum creatine kinase and other enzyme levels were found. A diagnosis of rhabdomyolysis was made.¹⁵ A 70-year-old with a kidney transplant was taking, among many other drugs, ciclosporin and simvastatin 40 mg daily. Despite the high dose of simvastatin, even in conjunction with ciclosporin (see also 'Statins + Ciclosporin', p.1097), he had experienced no problems. Within 2 weeks of starting **itraconazole** 100 mg twice daily he developed malaise and general muscle weakness with elevated creatine kinase levels, which was diagnosed as rhabdomyolysis. His serum simvastatin levels were found to be raised. A later subject also had an increase in simvastatin serum levels, from 0.5 to 6.5 nanogram/mL within a day of starting **itraconazole** 200 mg daily.¹⁶ Three further similar cases have also been reported with the combination of simvastatin, ciclosporin and **itraconazole**.¹⁷⁻¹⁹ Gemfibrozil was also taken in one of these cases.¹⁹ In addition, three similar cases have been reported in patients taking simvastatin, which developed between 10 days and 4 weeks after starting **ketoconazole** 200 or 400 mg daily.²⁰⁻²² In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, an azole antifungal was potentially implicated in 4 cases of rhabdomyolysis involving simvastatin.⁵

Mechanism

Fluconazole and **miconazole** inhibit the cytochrome P450 isoenzymes CYP2C9 and CYP3A4, whereas itraconazole and ketoconazole are potent inhibitors of CYP3A4. Consequently their interaction profiles differ amongst the various statins depending on which isoenzymes are involved in the metabolism of the statins in question: this has been shown in several studies.^{3,6,7} From these studies it appears that the effect of itraconazole is greatest on lovastatin and simvastatin, with a marked effect on atorvastatin, a modest effect on pravastatin or rosuvastatin, and no effect on fluvastatin. Fluconazole has a marked effect on fluvastatin, but no effect on pravastatin. See 'Lipid regulating drugs', (p.1086) for further discussion on the metabolism of the statins.

Importance and management

An established interaction of clinical importance, which differs depending on the drug pair used. The differing risks and management of the various drug pairs are discussed below. See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

1. *Lovastatin or simvastatin.* The very marked increases in levels of lovastatin and simvastatin that can occur considerably increase the risk of severe muscle damage and therefore the use of these statins with **itraconazole** or **ketoconazole** should be avoided. If a short course of an azole antifungal is considered essential, the manufacturers suggest temporary withdrawal of the statin.²³⁻²⁵ The manufacturers of **voriconazole** predict that it will interact with statins metabolised by the cytochrome P450 isoenzyme CYP3A4, resulting in elevated statin levels, and possibly rhabdomyolysis. They suggest that a dosage reduction of the statin should be considered during concurrent use.^{26,27} The manufacturer of **posaconazole** (also a CYP3A4 inhibitor) contraindicates its use with simvastatin or lovastatin.²⁸

2. *Atorvastatin.* Although the increase in the levels of atorvastatin are not as great as those with lovastatin or simvastatin, they are still marked, and unless the benefits outweigh the risks the combination of an azole antifungal with atorvastatin should, where possible, be avoided. As a general rule, any patient given atorvastatin with an azole should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. Note that the manufacturer of **posaconazole** contraindicates its use with atorvastatin,²⁸ and the manufacturers of **voriconazole** suggest considering a dosage reduction of the statin.^{26,27}

3. *Fluvastatin.* The clinical relevance of the modest changes in fluvastatin levels with different azole antifungals is unclear. Note that in a review of the FDA spontaneous reports of statin-associated rhabdomyolysis for the period November 1997 to March 2000, azole antifungals were not identified as a potentially interacting drug in any of the reports for fluvastatin.⁵ However, fluconazole and miconazole are inhibitors of CYP2C9 by which fluvastatin is metabolised and so a degree of caution seems warranted. Therefore any patient given fluconazole (or **miconazole** in preparations

such as the oral gel, which is absorbed) with fluvastatin should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately.

4. *Pravastatin.* The clinical relevance of the modest changes in pravastatin levels with different azole antifungals seems likely to be small, and a clinically significant interaction would not be expected. Note that in a review of the FDA spontaneous reports of statin-associated rhabdomyolysis for the period November 1997 to March 2000, azole antifungals were not identified as a potentially interacting drug in any of the reports for pravastatin.⁵

Statins + Beta blockers

Propranolol does not cause any clinically relevant changes to the pharmacokinetics of fluvastatin, lovastatin or pravastatin. In clinical studies, the safety and efficacy of statins were not altered by the concurrent use of beta blockers as a class.

Clinical evidence, mechanism, importance and management

In a study in 24 healthy subjects the pharmacokinetics of a single 40-mg dose of **fluvastatin** was not affected by the concurrent use of **propranolol** 40 mg every 12 hours for 3 days.¹ Similarly, the same dose of **propranolol** caused less than an 18% reduction in the AUC of **lovastatin** 20 mg and its metabolites, and modestly reduced the AUC of **pravastatin** 20 mg and its metabolites by 16 to 23%.² These changes are small and unlikely to be clinically relevant.

Retrospective analysis of clinical study data found no evidence that the safety or efficacy of **fluvastatin** was altered by the use of beta blockers

(unspecified).³ Similarly, in another analysis, there was no evidence that the safety or efficacy of **lovastatin** was altered by selective beta blockers (primarily **atenolol**, **metoprolol** and **labetalol**) or non-selective beta blockers (primarily **propranolol**, **nadolol** and **timolol**).⁴ Likewise, the manufacturer of **atorvastatin**⁵ says that in clinical studies it was used concurrently with beta blockers without evidence of significant adverse interactions.

No special precautions would seem to be necessary if beta blockers are given concurrently with statins.

Statins + Bile-acid binding resins

Although colestyramine and colestipol reduce plasma fluvastatin and pravastatin levels, the overall total lipid-lowering effect is increased by concurrent use. Separating their administration minimises this interaction. Colestipol appears to interact with atorvastatin similarly. Colesevelam appears not to interact with lovastatin.

Clinical evidence

(a) Atorvastatin

A study in which atorvastatin and **colestipol** were given concurrently found that although the serum levels of atorvastatin were reduced by about 25%, the total reduction in the LDL-cholesterol levels was greater than when each drug was given alone.¹

(b) Fluvastatin

Colestyramine 8 g given at the same time as fluvastatin 20 mg decreased the AUC and the maximum plasma levels of fluvastatin by 89 and 96%, respectively, in 19 healthy subjects. When the fluvastatin was given 2 hours after the **colestyramine**, the AUC and the maximum plasma levels of fluvastatin were reduced by just over 50%.² In another study in 20 healthy subjects, the AUC and maximum plasma levels of fluvastatin were reduced by 51 and 82%, respectively, when fluvastatin was taken 4 hours after **colestyramine** 8 g and a meal.²

Despite these marked reductions in fluvastatin bioavailability, other studies in large numbers of hypercholesterolaemic patients have shown that concurrent use actually has additive lipid-lowering effects.^{2,3} In the first of these studies, fluvastatin was given 4 hours after **colestyramine**,² but the other study did not indicate whether or not doses were separated.³

(c) Lovastatin

An open-label crossover study in 22 healthy subjects found that the pharmacokinetics of lovastatin 20 mg given with a meal were not significantly affected when **colesevelam** 2.25 g was given at the same time.⁴

(d) Pravastatin

In a randomised study 33 patients with primary hypercholesterolaemia were given pravastatin 5, 10, or 20 mg twice daily before their morning and evening meals for 4 weeks and then for a further 4 weeks they also took **colestyramine** 24 g daily. The **colestyramine** was taken at least an hour after the pravastatin. Despite the fact that the **colestyramine** reduced the bioavailability of the pravastatin by 18 to 49%, the reduction in blood lipid levels was enhanced by concurrent use.⁵ A related study in 18 subjects found that **colestyramine** reduced the bioavailability of pravastatin by about 40% when given at the same time, but only small and clinically insignificant pharmacokinetic changes occurred when the pravastatin was given one hour before, or 4 hours after the **colestyramine**.⁶ Similarly, a multicentre study involving 311 patients found that the combined use of pravastatin 40 mg daily and **colestyramine** 12 g daily was highly effective in the treatment of hypercholesterolaemia. The **colestyramine** was taken at least one hour after the pravastatin.⁷

Colestipol reduced the bioavailability of pravastatin in 18 subjects by about 50%, but no reduction in bioavailability was seen when pravastatin was given 1 hour before **colestipol** and a meal.⁶

Mechanism

It seems probable that these bile-acid binding resins bind with statins in the gut and thereby reduce the amount of statin available for absorption.

Importance and management

Established interactions but of only relatively minor importance. Despite the reduction in the bioavailability of pravastatin caused by colestyramine or colestipol, the overall lipid-lowering effect is increased by concurrent use.^{5,7} The effects of the interaction can be minimised by separating their administration as described above. This can be easily achieved by taking the colestyramine or colestipol with meals, and the pravastatin at bedtime. Similarly, any interaction between fluvastatin and colestyramine can be minimised by taking fluvastatin at least 4 hours after colestyramine. There would appear to be no reason for avoiding concurrent use of atorvastatin and colestipol, nor lovastatin and colesevelam.

Statins + Calcium-channel blockers

Marked rises in statin plasma levels have been seen when lovastatin or simvastatin were given with diltiazem, and when simvastatin was given with verapamil. Isolated cases of rhabdomyolysis have occurred as a result of these interactions. However, overall, it seems that problems with combinations of statins and calcium-channel blockers (particularly the dihydropyridine-type) are rare.

Clinical evidence

(a) Atorvastatin

The manufacturers of **amlodipine** state that it does not affect the pharmacokinetics of atorvastatin.¹ They also note that no clinically significant interactions were seen in clinical studies in which atorvastatin was used with antihypertensives, including unspecified calcium-channel blockers.¹ However, they do warn that drugs that are metabolised by the cytochrome P450 isoenzyme CYP3A4 (e.g. calcium-channel blockers) do have the potential to interact.¹

A 60-year-old man taking atorvastatin 20 mg daily, developed rhabdomyolysis 3 weeks after **diltiazem** (an inhibitor of CYP3A4) was started.² Another similar case has also been reported.³

(b) Fluvastatin

A retrospective study of the effects of antihypertensives on the efficacy of fluvastatin found that the concurrent use of unspecified calcium-channel blockers did not significantly affect the safety or lipid-lowering effects of fluvastatin, although there was a trend towards enhanced lowering of triglycerides.⁴

(c) Lovastatin

A retrospective study of the effects of lovastatin and antihypertensive medication found that when calcium-channel blockers (**diltiazem**, **nifedipine** or **verapamil**) were used in combination with lovastatin there was an additional 3 to 5% lowering in the LDL-cholesterol, which was of marginal significance.⁵ Pharmacokinetic studies have shown that oral **diltiazem** increases the AUC and maximum serum levels of lovastatin by about fourfold.^{6,7} In another study, lovastatin 20 mg and **isradipine** 5 mg

was given to 12 healthy subjects either alone or together for 5 days. **Isradipine** reduced the AUC of lovastatin by 40%, in males but not females.⁸

(d) Pravastatin

A study in 10 healthy subjects found that sustained-release **diltiazem** 120 mg twice daily had no effect on the pharmacokinetics of a single 20-mg dose of pravastatin.⁶ Similarly, a study in 15 healthy subjects found that extended-release **verapamil** 480 mg daily for 3 days did not affect the pharmacokinetics of pravastatin 40 mg daily.⁹

(e) Simvastatin

1. **Amlodipine**. In a study in 8 patients taking simvastatin 5 mg daily the addition of amlodipine 5 mg daily for 4 weeks increased the maximum levels and AUC of simvastatin by a modest 1.4- and 1.3-fold, respectively, without affecting the lipid profiles of the patients.¹⁰

2. **Diltiazem**. A single 20-mg dose of simvastatin was given to 10 healthy subjects after they had taken sustained-release diltiazem 120 mg twice daily for 2 weeks. Diltiazem caused about a fivefold increase in the simvastatin AUC, a fourfold increase in the maximum serum levels, and a 2.5-fold increase in the half-life.¹¹

The clinical relevance of the diltiazem interaction was demonstrated in a 53-year-old man, who developed rhabdomyolysis 3 months after diltiazem 30 mg four times daily was added to established treatment with simvastatin 40 mg daily. Both drugs were discontinued and he recovered over the following 10 days.¹² Other similar cases have also been reported.^{3,13}

An *in vitro* study using human liver microsomes also found that diltiazem moderately inhibits simvastatin metabolism.¹⁴

3. **Lacidipine**. In a randomised, crossover study simvastatin 40 mg daily was given for 8 days, with or without lacidipine 4 mg daily. Lacidipine raised the AUC of simvastatin by 35%, which was considered to be modest and unlikely to be of clinical significance.¹⁵

4. **Verapamil**. A study in which 12 subjects were given verapamil 80 mg three times daily, found a 4.6-fold increase in the AUC of simvastatin, a 2.6-fold increase in its maximum serum levels, and about a twofold increase in its half-life.¹⁶ Similarly, a study in 12 healthy subjects found that extended-release verapamil 480 mg daily for 3 days caused a fivefold increase in the maximum serum levels of simvastatin 40 mg, and about a fourfold increase in its AUC.⁹

The clinical relevance of the verapamil interaction was demonstrated in a 63-year-old man, who developed rhabdomyolysis about 1 month after extended-release verapamil 240 mg daily was added to established treatment with simvastatin 40 mg daily and ciclosporin. Verapamil and simvastatin were discontinued and he recovered over the following 14 days.¹⁷ An *in vitro* study using human liver microsomes also found that verapamil moderately inhibits simvastatin metabolism.¹⁴

Mechanism

Diltiazem and verapamil inhibit the cytochrome P450 isoenzyme CYP3A4, which is responsible for the metabolism of lovastatin, simvastatin and to an extent, atorvastatin. Therefore concurrent use of these drugs results in an increase in the levels of the statin. One study found that oral, but not intravenous diltiazem interacts, suggesting that it is CYP3A4 in the gut wall that is the site of the interaction.¹⁸ Isradipine and lovastatin are both metabolised by CYP3A4, and therefore the modest interaction may have occurred as a result of competition for metabolism. A similar mechanism probably accounts for the modest interaction between simvastatin and lacidipine or amlodipine. See 'Lipid regulating drugs', (p.1086), and 'Calcium-channel blockers', (p.860), for more information about the way these groups of drugs are metabolised.

Importance and management

Information is limited, but what is known suggests that the concurrent use of these drugs is normally uneventful. Even with those pairs of drugs where the increases in plasma levels are quite large (such as when simvastatin was given with diltiazem or verapamil) problems seem to be very rare. Indeed an analysis of the 4S study and the Heart Protection Study (which used maximum simvastatin doses of 40 mg) found no evidence that the concurrent use of a calcium-channel blocker increases the risk of myopathy.¹⁹ Therefore concurrent use need not be avoided, but it has been suggested that treatment with a statin in a patient taking diltiazem (and probably verapamil) should be started with the lowest possible dose and titrated upwards, or, if diltiazem (or verapamil) is started, the dose of the

statin should be considerably reduced.¹⁶ The manufacturers of lovastatin recommend restricting the dose to 40 mg daily if verapamil is given,²⁰ and the manufacturers of simvastatin suggest restricting the dose to 20 mg daily.^{21,22} Note that one UK manufacturer²³ recommends that the combination should be avoided, which seems somewhat over-cautious. In the UK it has been suggested that the dose of simvastatin should be restricted to 40 mg daily in the presence of diltiazem.²² See also 'muscle toxicity', (p.1086), for further guidance on monitoring and risk factors for muscle toxicity.

Statins + Carbamazepine

Carbamazepine dramatically reduces simvastatin levels.

Clinical evidence

In a randomised, crossover study 12 healthy subjects were given carbamazepine 200 mg daily for 2 days, then 300 mg twice daily for 12 days, with a single 80-mg dose of **simvastatin** 12 hours after the last dose of carbamazepine. The AUC and maximum serum levels of **simvastatin** were reduced by 75% and 68%, respectively, and the AUC and maximum serum levels of simvastatin acid (the active metabolite of **simvastatin**) were reduced by 82% and 69%, respectively.¹

Mechanism

Carbamazepine is a known potent inducer of the cytochrome P450 isoenzyme CYP3A4 by which simvastatin is metabolised. Carbamazepine therefore increases simvastatin metabolism, leading to reduced levels. **Lovastatin**, and to a lesser extent, **atorvastatin** are also metabolised by CYP3A4.

Importance and management

Although this appears to be the only study, the effects of concurrent use are consistent with both the way carbamazepine interacts with many other CYP3A4 substrates and the way simvastatin interacts with other CYP3A4

inducers. The effects of simvastatin are likely to be greatly reduced on concurrent use and a dose increase seems likely to be necessary. Monitor concurrent use to check simvastatin is effective. It seems unlikely that other statins, such as fluvastatin or pravastatin, which are not metabolised by CYP3A4, will interact, and they may therefore be preferable. However, this needs confirmation.

1. Ucar M, Neuvonen M, Luurila H, Dahlqvist R, Neuvonen PJ, Mjörndal T. Carbamazepine markedly reduces serum concentrations of simvastatin and simvastatin acid. *Eur J Clin Pharmacol* (2004) 59, 879–82.

Statins + Ciclosporin

Ciclosporin can cause marked rises in the plasma levels of atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, and simvastatin, and for some of the statins this has led to the development of serious myopathy (rhabdomyolysis) accompanied by renal failure. The plasma levels of ciclosporin appear not to be affected by fluvastatin, lovastatin, pravastatin, or rosuvastatin, but some moderate changes in ciclosporin levels have been seen when atorvastatin or simvastatin were given.

Clinical evidence

(a) Atorvastatin

1. *Effect on ciclosporin.* In a study of 10 patients taking ciclosporin following a kidney transplant, 4 showed increases in their trough ciclosporin levels of between 26 and 54% when atorvastatin 10 mg was added, necessitating a dosage reduction of ciclosporin. No changes were seen in 6 other patients, and the incidence of adverse effects was no greater than in a control transplant group not given atorvastatin.¹ When atorvastatin 10 mg daily was given to 21 renal transplant patients taking ciclosporin, the maximum serum levels of ciclosporin generally decreased (by a mean of 13.5%). However, 4 patients needed a decrease in their ciclosporin dose and one patient needed an increase.² Another study suggests that ciclosporin causes a negligible increase in ciclosporin levels in liver transplant patients.³

2. *Effect on atorvastatin.* In an open study the concurrent use of atorvastatin 10 mg daily with ciclosporin resulted in a sixfold increase in atorvastatin levels, when compared with historical controls not taking ciclosporin.² A further analysis of this study has been reported elsewhere.⁴ A case of rhabdomyolysis has been described in a woman who took both drugs for 2 months. She had also been taking diltiazem.⁵ In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, ciclosporin was potentially implicated in 5 cases of rhabdomyolysis involving atorvastatin.⁶

(b) Fluvastatin

1. *Effect on ciclosporin.* When fluvastatin 20 mg daily was given to 16 patients taking ciclosporin 21 to 103 months after renal transplantation, no significant changes were seen in their ciclosporin levels.^{7,8} Similar results were seen in other studies, one using fluvastatin 20 mg twice daily,⁹ and one in 17 renal transplant recipients taking extended-release fluvastatin.¹⁰

2. *Effect on fluvastatin.* In a double-blind study 52 heart transplant patients taking ciclosporin were randomised to receive fluvastatin 40 mg daily for 1 year. Fluvastatin had a positive effect on lipid profiles, and, although creatine phosphokinase levels rose, the maximum reached was 4.5 times normal, which did not require cessation of the fluvastatin and normalised without intervention. There was no increase in the reported rate of myalgia, and no patients developed rhabdomyolysis.¹¹ The AUC and maximum serum concentration of fluvastatin were found to be about 94% and 30% higher, respectively, in transplant patients taking ciclosporin than in historical control patients not taking ciclosporin.¹² Similarly, the AUC and maximum serum concentration of fluvastatin were threefold and sixfold greater in transplant patients taking ciclosporin than in healthy subjects not given ciclosporin.¹³ A further study in 20 renal transplant patients receiving fluvastatin 20 mg daily reported 2 patients with mild myalgia without creatine phosphokinase rises, and a patient with elevated creatine phosphokinase without myalgia, when ciclosporin was also given.¹⁴ Further studies suggest that concurrent use does not affect creatine phosphokinase or result in additional adverse effects.⁷⁻⁹

(c) Lovastatin

1. *Effect on ciclosporin.* Ciclosporin and creatine phosphokinase levels were not significantly changed in 6 renal transplant patients taking ciclosporin and lovastatin (10 mg for 8 weeks, then 20 mg for 12 weeks).¹⁵ Similar results were found in another study.¹⁶

2. *Effect on lovastatin.* The plasma levels of lovastatin 10 to 20 mg daily in 6 patients also taking ciclosporin were about the same as those seen in healthy subjects taking lovastatin 40 mg alone (i.e. the levels were increased by up to fourfold by ciclosporin).¹⁵ In another study in 21 renal transplant patients taking ciclosporin, the maximum serum levels and AUC of lovastatin 20 mg daily were 40 and 47% higher, respectively, 28 days after beginning therapy than on day 1 (suggesting accumulation) and were estimated to be 20-fold higher than values reported in healthy subjects not taking ciclosporin.¹⁷ A further study found that the AUC of lovastatin was five times greater in patients taking ciclosporin than in patients not taking ciclosporin, irrespective of whether the patients had received transplants or were receiving other immunosuppressants.¹⁸ There are at least 9 documented cases of rhabdomyolysis, often resulting in acute renal failure, in patients taking ciclosporin and lovastatin.¹⁹⁻²³ In each of these cases the patient was taking lovastatin 40 to 80 mg daily. Several other studies suggest that this interaction may be dose-related. In one study, 15 patients taking ciclosporin were given lovastatin 20 mg daily without problem, but 4 of 5 other patients, who were given lovastatin 40 to 80 mg daily developed rhabdomyolysis, which was associated with renal failure in two of them.²⁴ In a further study 24 patients were given lovastatin 10 or 20 mg daily in addition to ciclosporin. Of the 12 receiving the 20-mg dose, 7 developed either myalgia and muscle weakness or raised creatine phosphokinase levels, but only one patient from the 10-mg group did.²⁵ A report describes a case of rhabdomyolysis when clopidogrel was added to treatment with ciclosporin and lovastatin.²⁶ The incidence of myopathies with lovastatin is about 0.1 to 0.2%,¹⁷ but in the presence of ciclosporin the incidence is said to be as high as 30%.²⁷

(d) Pravastatin

1. *Effect on ciclosporin.* Several studies have shown no significant change in ciclosporin levels in patients also taking pravastatin.^{17,28}

2. *Effect on pravastatin.* A study in 19 paediatric and adolescent cardiac transplant patients (mean age 12.1 years) found that triple immunosuppressant therapy (17 patients taking ciclosporin) raised the maximum levels and AUC of pravastatin 10 mg daily for 8 weeks by about eightfold and tenfold, respectively, when compared with control subjects not receiving immunosuppressants. There was extremely large intersubject variation in the pravastatin AUC and maximum levels.²⁹ Similar results have been found in other studies in adults.^{30,31} Although a study in patients taking ciclosporin found that the AUC of pravastatin 20 mg daily did not differ between day 1 and day 28 of therapy (suggesting no accumulation), the AUC values were estimated to be five to sevenfold higher than in patients not taking ciclosporin.¹⁷ In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, ciclosporin was potentially implicated in 2 cases of rhabdomyolysis involving pravastatin.⁶

Several studies have shown no rises in creatine phosphokinase levels,^{28,32,33} and no increase in adverse effects^{17,32,34} when pravastatin in doses of 10 to 40 mg daily was given with ciclosporin.

(e) Rosuvastatin

In an open-label study 10 stable heart transplant patients taking ciclosporin were given rosuvastatin 10 mg daily for 10 days. When compared to healthy historical controls, the rosuvastatin maximum levels and AUC₀₋₂₄ were found to have been increased by 10.6-fold and 7.1-fold, respectively. Rosuvastatin had little effect on ciclosporin levels.³⁵

(f) Simvastatin

1. *Effect on ciclosporin.* A study found that the ciclosporin levels of 12 renal transplant patients fell from 334 to 235 micrograms/L after simvastatin 5 to 15 mg daily was added.³⁶ A retrospective study by the same authors confirmed these results in 12 patients.³⁶ In contrast, a single-dose pharmacokinetic study suggested that simvastatin increases the maximum levels and AUC of ciclosporin by a modest 8% and 13%, respectively.³⁷

2. *Effect on simvastatin.* A group of 20 heart transplant patients were given simvastatin 10 mg daily and ciclosporin over a period of 4 months. The plasma levels of simvastatin acid were at least 6 times higher in 7 patients taking ciclosporin than in 7 control patients not taking ciclosporin.³⁸ Similarly, a study comparing 5 renal transplant patients taking ciclosporin and

simvastatin 20 mg daily with 5 renal transplant patients not given ciclosporin found that the AUC and maximum serum levels of simvastatin were 2.5-fold and 2-fold greater, respectively, in the patients taking ciclosporin.³⁹

There are at least 5 documented cases of rhabdomyolysis,⁴⁰⁻⁴³ one of which was fatal,⁴¹ in patients given ciclosporin and simvastatin. Another report describes a case of rhabdomyolysis when clopidogrel was added to treatment with ciclosporin and simvastatin.²⁶ In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, ciclosporin was potentially implicated in 31 cases of rhabdomyolysis involving simvastatin.⁶ In the first study cited above,³⁸ significant changes in ciclosporin levels and creatine kinase were seen and the combination was well tolerated. Similar results were found in another study over 8 months.⁴⁴

Mechanism

The marked rises in statin levels and/or toxicity (rhabdomyolysis) probably occur because both the statin and ciclosporin compete for the same metabolising enzyme, the cytochrome P450 isoenzyme CYP3A4. The extent of the interaction seems to depend on the relative affinities of the different statins for this isoenzyme, and also on whether they can be metabolised by alternative pathways. P-glycoprotein and other transporter proteins may also have a part to play, especially in the raised ciclosporin levels seen with pravastatin. See 'Lipid regulating drugs', (p.1086) for more information about the metabolism of the statins.

In the cases where rhabdomyolysis developed when clopidogrel was added to treatment with ciclosporin and a statin it was thought that the addition of clopidogrel (which may also inhibit the cytochrome P450 enzyme system) may have destabilised the delicate metabolic equilibrium between the statins and ciclosporin precipitating the development of rhabdomyolysis.²⁶

Importance and management

The interacting effect of ciclosporin on the statins is well documented, well established and clinically important. Concurrent use need not be avoided (except in the case of rosuvastatin, where concurrent use is contraindicated in the UK⁴⁵) but it should be very well monitored, a precautionary recommendation being to start (or reduce) the statin to the lowest daily dose appropriate to the patient's condition.^{46,47} The manufacturers of simvastatin suggest that the dose should not exceed 10 mg daily,⁴⁸⁻⁵⁰ and the manufacturer of lovastatin suggests its dose should not exceed 20 mg daily.⁴⁶ The manufacturer of pravastatin suggests a starting dose of 20 mg.⁴⁷ Note that, unlike the UK manufacturers, the US manufacturers do not contraindicate rosuvastatin. However, they do warn that the risk of myopathy is increased, and advise that this should be taken into consideration when deciding on a dose. Therefore, as with other statins, it would seem that the lowest daily dose of rosuvastatin should be used.⁵¹ Any patient given ciclosporin with a statin should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, withdrawing the statin has been shown to resolve the symptoms.

Alterations in ciclosporin levels with the statins are generally small and seem likely to be identified by routine ciclosporin monitoring. However, note that of the statins, simvastatin, and possibly atorvastatin had somewhat larger effects, and an increase in the frequency of ciclosporin monitoring may be desirable if these statins are used. See also 'muscle toxicity', (p.1086), for further guidance on monitoring and risk factors for muscle toxicity.

Statins + Colchicine

Three case reports describe myopathy or rhabdomyolysis in patients given colchicine with fluvastatin, pravastatin or simvastatin. It seems possible that this interaction could occur with colchicine and any statin.

Clinical evidence

(a) Fluvastatin

A 70-year-old man who had been taking fluvastatin 80 mg daily for 2 years started taking colchicine 1.5 mg daily for an attack of gouty arthritis. Within 3 days he felt nauseous and began to develop muscle pains and weakness. On admission to hospital he was found to have acute renal failure and a raised creatine kinase, and was diagnosed with rhabdomyolysis. Both drugs were stopped and he made a full recovery over 2 months. He was eventually restabilised on fluvastatin without incident.¹

(b) Pravastatin

A 65-year-old woman who had been taking pravastatin 20 mg daily for 6 years was given colchicine 1.5 mg daily for an episode of gout. Within 20 days she had developed muscle weakness in the legs and had a slightly raised creatine kinase. A diagnosis of myopathy was made and so both the colchicine and pravastatin were stopped. The weakness resolved over the following week. The colchicine was subsequently given alone, and myopathy did not occur.²

(c) Simvastatin

A patient with chronic renal failure who had been taking simvastatin for 2 years was given colchicine for gout. Within 2 weeks he developed muscle weakness, which was diagnosed as myopathy. Both drugs were stopped and the symptoms resolved.³

Mechanism

It has been suggested that the interaction between simvastatin occurs because both drugs are metabolised by the cytochrome P450 isoenzyme CYP3A4.³ However, as the interaction has subsequently been seen with fluvastatin and pravastatin this seems unlikely to be the full explanation. P-glycoprotein has also been implicated.² Colchicine alone can, rarely, cause myopathy. However, it is more common in those given colchicine long term, in high dose, or in the presence of renal impairment.² As the statins can also cause myopathy, an additive or synergistic effect seems possible.¹

Importance and management

Although this interaction is rare it is serious. Given the evidence available it seems likely to occur with all statins, although this has not been clearly demonstrated. All patients taking statins should be warned about the symptoms of myopathy and told to report muscle pain or weakness. It would be prudent to reinforce this advice if they are given colchicine. See also 'muscle toxicity', (p.1086), for further guidance on monitoring and risk factors for muscle toxicity.

Statins + Danazol

Severe rhabdomyolysis and myoglobinuria developed in a man taking lovastatin about two months after danazol was added. Another report describes a similar interaction with simvastatin.

Clinical evidence

(a) Lovastatin

A 72-year-old man taking atenolol, aspirin, dipyridamole and lovastatin 20 mg twice daily was admitted to hospital after complaining of myalgia over the last 12 days, and brown urine over the last 5 days. His condition was diagnosed as severe rhabdomyolysis and myoglobinuria. About 2 months previously he had started taking danazol 200 mg three times daily and prednisone, and one month previously he had received a 10-day course of doxycycline 100 mg twice daily. The aspirin and lovastatin were stopped (danazol was stopped 4 days before admission and the doxycycline was stopped 5 days before the onset of symptoms), and all the symptoms resolved. Laboratory tests were normal within 2 weeks.¹

(b) Simvastatin

A 68-year-old man who had been taking simvastatin 40 mg daily long-term without problem developed rhabdomyolysis (progressive muscle pain and weakness, tea-coloured urine, renal impairment, and a raised creatine phosphokinase) within 3 weeks of starting to take danazol 200 mg three times daily. He was given haemodialysis and subsequently recovered.

Mechanism

It has been suggested that danazol (and the doxycycline) were possibly hepatotoxic, which led to decreased lovastatin metabolism, or that the danazol had a direct toxic effect on the muscles.¹ Danazol inhibits the cytochrome P450 isoenzyme CYP3A4 by which simvastatin and lovastatin are metabolised, which would result in raised statin levels, and therefore myopathy and rhabdomyolysis.^{1,2} This seems a more likely explanation for the effects seen.

Importance and management

These appear to be the only reports of this apparent interaction, but the pharmacokinetic basis of the interaction seems to be established. The US manufacturers of lovastatin³ suggest that the dose should not exceed 20 mg daily in the presence of danazol. Similarly the manufacturers of simvastatin suggest that the dose should not exceed 10 mg daily in the presence of danazol.^{4,5} It would seem prudent to reinforce the symptoms of myopathy and tell patients to report any unexplained muscle pain, tenderness or weakness. The authors of the lovastatin report¹ point out that, as in this case, severe lovastatin muscle toxicity may be very slow to develop. See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

The statins that are not significantly metabolised by CYP3A4 (**fluvastatin, pravastatin, rosuvastatin**) are not expected to interact.

Statins + Diuretics

In clinical studies, the safety and efficacy of statins were not altered by concurrent use of diuretics.

Clinical evidence, mechanism, importance and management

Retrospective analysis of clinical study data¹ found no evidence that the safety or efficacy of **lovastatin** was altered by the use of **potassium-sparing diuretics** (hydrochlorothiazide with **triamterene** or **amiloride**), or **thiazide diuretics** (mostly **hydrochlorothiazide**). Another retrospective study of 19 patients found that the addition of **lovastatin** to diuretic treat-

ment caused an initial 30% fall in total serum cholesterol levels for one month, followed by a rise of about 20%. In a further 13 patients, the addition of diuretic treatment to **lovastatin** caused a 20% fall in total serum cholesterol for one month and then a 20% rise back to baseline values. The diuretics used were **furosemide** (16 patients), **triamterene/hydrochlorothiazide** (7), **hydrochlorothiazide** (8), **indapamide** (1). The fall and subsequent rise in serum cholesterol levels occurred in all of the patients except just the one taking **indapamide**.² The reason for this initial fall in cholesterol, particularly when the diuretic was added to the statin, is unknown, and the findings of this study are difficult to interpret.

Retrospective analysis of clinical trial data found no evidence that the safety or efficacy of **fluvastatin** was altered by the use of unspecified **diuretics**.³ Likewise, the manufacturer of **atorvastatin**⁴ says that in clinical studies it was used concurrently with unnamed **diuretics** without evidence of significant adverse interactions.

The bulk of the evidence suggests no special precautions are necessary if diuretics are given concurrently with statins.

4. Lipitor (Atorvastatin). Pfizer Ltd. UK Summary of product characteristics, September 2006.

Statins + Everolimus

In a single-dose study in healthy subjects everolimus did not alter the pharmacokinetics or HMG-CoA reductase activity of atorvastatin or pravastatin to a clinically relevant extent. Everolimus pharmacokinetics were unaltered by the statins.¹

1. Kovarik JM, Hartmann S, Hubert M, Berthier S, Schneider W, Rosenkranz B, Rordorf C. Pharmacokinetic and pharmacodynamic assessments of HMG-CoA reductase inhibitors when coadministered with everolimus. *J Clin Pharmacol* (2002) 42, 222–8.

Statins + Ezetimibe

Ezetimibe does not appear to have adverse pharmacokinetic interactions with atorvastatin, fluvastatin, lovastatin, rosuvastatin or simvastatin. However, some evidence suggests that concurrent use may increase the risk of myopathy.

Clinical evidence

(a) Atorvastatin

In a three-arm study patients were given atorvastatin 80 mg daily, atorvastatin 80 mg daily with ezetimibe 10 mg daily, or atorvastatin 40 mg daily with ezetimibe 10 mg daily. No difference in adverse events was noted between each of the 3 groups and there were no significant elevations in creatine kinase. No cases of myopathy or rhabdomyolysis occurred, and the combination was well-tolerated.¹ Similarly, an efficacy study found that ezetimibe did not worsen statin intolerance or toxicity in 628 patients with hypercholesterolaemia who were taking atorvastatin.² However, a case report describes a 43-year-old man taking atorvastatin 80 mg daily who developed severe muscle pain with elevated creatinine kinase levels 3 weeks after he started taking ezetimibe 10 mg daily. Symptoms resolved when both drugs were withdrawn and he later restarted the atorvastatin without problems.³ A further similar case has also been reported.⁴

(b) Fluvastatin

In a randomised, crossover study 32 otherwise healthy subjects with hypercholesterolaemia were given either ezetimibe 10 mg daily, fluvastatin 20 mg daily or both drugs in combination for 14 days. The combination was well tolerated, no significant pharmacokinetic interaction occurred, and an enhanced lowering of LDL-cholesterol was noted, which was considered to be clinically favourable.⁵ However, a case report describes a 52-year-old man taking fluvastatin 80 mg daily who developed elevated creatinine kinase levels 8 weeks after ezetimibe 10 mg daily was added.

His creatinine kinase levels returned to normal 4 weeks after the ezetimibe was withdrawn.³

(c) Lovastatin

In a randomised, crossover study 18 healthy subjects were given either ezetimibe 10 mg daily, lovastatin 20 mg daily or both drugs in combination for 7 days. The combination was well tolerated, and no significant pharmacokinetic interaction was noted.⁶

(d) Rosuvastatin

In a placebo-controlled study 12 otherwise healthy subjects with hypercholesterolaemia were given ezetimibe 10 mg daily with rosuvastatin 10 mg daily for 14 days. The combination was well tolerated (no significant changes in liver enzymes or creatinine phosphokinase noted), the pharmacokinetics of both drugs were not significantly changed, and an enhanced lowering of LDL-cholesterol was noted, which was considered to be clinically favourable.⁷

(e) Simvastatin

In a three-arm study, patients were given simvastatin 80 mg daily, simvastatin 80 mg daily with ezetimibe 10 mg daily, or simvastatin 40 mg daily with ezetimibe 10 mg daily. No difference in adverse events was noted between each of the 3 groups and there were no significant elevations in creatine kinase. No cases of myopathy or rhabdomyolysis occurred, and the combination was well-tolerated.¹ In another study, ezetimibe 0.25 mg, 1 mg or 10 mg daily had no effect on the pharmacokinetics of simvastatin 10 mg daily, when both were given for 14 days. In addition, 10 and 20-mg doses of simvastatin were well-tolerated in combination with ezetimibe.⁸

Mechanism, importance and management

The available evidence suggests that on the whole the concurrent use of a statin with ezetimibe does not result in a change in the pharmacokinetics of either drug. However, there is some evidence to suggest that concurrent use may increase the risk of myopathy. Therefore any patient taking a statin who is also given ezetimibe should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Note that a combination preparation containing simvastatin and ezetimibe is widely available.

Statins + Fibrates

The plasma levels of lovastatin, simvastatin, atorvastatin and pravastatin are increased by gemfibrozil, the levels of fluvastatin are increased by bezafibrate, and the levels of pravastatin are increased by fenofibrate. No pharmacokinetic interactions occur with the combinations of fluvastatin with gemfibrozil, lovastatin with bezafibrate, and pravastatin, rosuvastatin or simvastatin with fenofibrate. Both statins and fibrates are known to cause rhabdomyolysis, and their concurrent use increases the risk of this reaction.

Clinical evidence

A. Bezafibrate

(a) Fluvastatin

In one study bezafibrate 200 mg three times daily increased the AUC and maximum levels of fluvastatin 20 mg daily by about 50 to 60%. Bezafibrate pharmacokinetics were not affected.¹

(b) Lovastatin

In a study in 11 healthy subjects the pharmacokinetics of a single 40-mg dose of lovastatin were not altered by bezafibrate 400 mg daily for 3 days.²

B. Fenofibrate

(a) Pravastatin

A single-dose study in 23 healthy subjects found that the concurrent use of pravastatin 40 mg and fenofibrate 201 mg had no effect on the pharmacokinetics of either drug, but a moderate increase in the formation of a non-toxic pravastatin metabolite was seen. This was not thought to be clinically important.³ In a multiple-dose study pravastatin 40 mg daily was given to 23 healthy subjects with fenofibrate 160 mg daily. Fenofibrate increased the maximum levels and AUC of pravastatin by about 40% and 30%, respectively. Similar increases were seen for the main pravastatin metabolite. The combination was well tolerated, and the increases were considered to be modest.⁴ However, a case report describes a patient taking fenofibrate 300 mg daily, who developed rhabdomyolysis after starting pravastatin 10 mg daily.⁵

(b) Rosuvastatin

A 7-day course of fenofibrate 67 mg three times daily and rosuvastatin 10 mg daily resulted in only minor changes in fenofibric acid and rosuvastatin exposure in 14 healthy subjects, when compared with either drug given alone.⁶

(c) Simvastatin

In a randomised, crossover study 25 healthy subjects were given simvastatin 80 mg daily with fenofibrate 160 mg daily for 7 days. The pharmacokinetics of both drugs and their main metabolites (as assessed in 12 subjects) were unchanged by concurrent use. All 25 subjects were assessed for safety, and the combination was found to be well tolerated.⁷

C. Gemfibrozil

(a) Atorvastatin

A pharmacokinetic study in 10 healthy subjects found that gemfibrozil 600 mg twice daily increased the AUC of atorvastatin and its metabolites by 24% and 30 to 80%, respectively, which was considered a moderate increase.⁸ A 43-year-old woman with multiple medical problems was taking gemfibrozil 600 mg twice daily. After a recurrent attack of pancreatitis, atorvastatin 10 mg and glibenclamide (glyburide) 2.5 mg, both twice daily, were added to her treatment. About 3 weeks later she developed brown and turbid urine (suggesting urinary myoglobin), creatine kinase levels of 4633 units/L and had myalgia. She was diagnosed as having rhabdomyolysis. Her serum creatine kinase levels rapidly fell when the atorvastatin and gemfibrozil were withdrawn.⁹

In a case series of 10 patients taking a statin who presented for muscle biopsy, one patient taking gemfibrozil developed myopathy 3 months after his dose of atorvastatin was increased from 10 to 20 mg.¹⁰

(b) Fluvastatin

In a randomised, crossover study 15 patients were given fluvastatin 20 mg and gemfibrozil 600 mg twice daily. The pharmacokinetics of both gemfibrozil and fluvastatin were unchanged by concurrent use and no significant adverse effects were noted.¹¹

(c) Lovastatin

In a pharmacokinetic study, 11 healthy subjects were given gemfibrozil 1.2 g daily for 3 days, with a single 40-mg dose of lovastatin on day 3. The AUC and maximum plasma level of lovastatin acid (a metabolite) were nearly threefold greater in the presence of gemfibrozil.²

By 1990 the FDA had documented 12 case reports of severe myopathy or rhabdomyolysis associated with the concurrent use of lovastatin and gemfibrozil. The mean serum creatine kinase levels of the patients reached 15 250 units/L. Four of those tested showed myoglobinuria and five had acute renal failure.¹² Details of cases of rhabdomyolysis associated with the concurrent use of these drugs,¹³⁻¹⁸ three involving renal failure,^{14,15,17} have been given elsewhere. Other cases of rhabdomyolysis have been seen

in patients taking lovastatin and gemfibrozil, with ciclosporin,¹⁹ or niacin.²⁰ Aside from these cases, a review of combined statin/fibrate use identified a further 4 cases of rhabdomyolysis involving gemfibrozil and lovastatin, all involving lovastatin doses of 40 mg and above.²¹

However, in contrast, other reports²²⁻²⁵ describe apparently safe and effective concurrent use under very well controlled conditions, although elevated creatine phosphokinase levels, without rhabdomyolysis, were seen in up to 8% of cases.

(d) Pravastatin

In a study in 18 healthy subjects gemfibrozil 600 mg caused no clinically significant changes in the bioavailability of a single 20-mg dose of pravastatin.²⁶ However, another study using pravastatin 40 mg found that the AUC and maximum levels of pravastatin were increased roughly threefold and twofold, respectively.²⁷ A 12-week study with pravastatin 40 mg daily and gemfibrozil 600 mg twice daily found that marked abnormalities in creatine kinase concentrations (four times the pretreatment values) occurred in 1 of 71 patients taking pravastatin alone, 1 of 73 patients taking placebo, 2 of 72 patients taking gemfibrozil alone, and 4 of 75 patients taking gemfibrozil with pravastatin. The differences between treatments were not statistically significant. Two patients taking combination therapy had this withdrawn because of asymptomatic creatine kinase elevations. Severe myopathy or rhabdomyolysis was not seen in any patient, although 14 patients had musculoskeletal pain, but in most cases this was not considered to be related to treatment.²⁸

(e) Rosuvastatin

In a randomised, crossover study 20 healthy subjects were given gemfibrozil 600 mg twice daily for 7 days, with a single 80-mg dose of rosuvastatin on day 4. The AUC of rosuvastatin was increased 1.88-fold (11 subjects assessed) and the maximum levels of rosuvastatin were increased 2.21-fold. Three subjects had asymptomatic increases in ALT levels (less than 2.5 times upper limit of normal).²⁹

(f) Simvastatin

A 62-year-old man with diabetes taking simvastatin 20 mg daily and gemfibrozil 600 mg daily (as well as acenocoumarol, glibenclamide (glyburide) and diclofenac) was hospitalised because of melaena, generalised myalgia, malaise and brown urine. Laboratory tests confirmed the diagnosis of rhabdomyolysis. He recovered when the simvastatin and gemfibrozil were stopped.³⁰ Another diabetic patient had been taking simvastatin and gemfibrozil 600 mg daily for 2½ years (as well as felodipine, indapamide, calcium carbonate, bumetanide, psyllium, acenocoumarol and insulin). She complained of tiredness, generalised myalgia and anuria 3 months after her dosage of simvastatin had been increased to 80 mg daily. Rhabdomyolysis with exaggerated renal impairment were diagnosed and confirmed. She recovered when the simvastatin and gemfibrozil were stopped.³⁰ Three further cases of rhabdomyolysis have been reported in patients taking simvastatin, 3 weeks to 3 months after starting gemfibrozil.³¹⁻³³ One of these cases was fatal.³¹

A pharmacokinetic study found that when gemfibrozil was given with simvastatin the AUC of simvastatin acid (an active metabolite of simvastatin) was increased nearly twofold and the peak concentration was doubled.³⁴

In a case series of 10 patients taking a statin who presented for muscle biopsy, two patients taking gemfibrozil developed myopathy while also taking simvastatin.¹⁰

D. Unspecified Fibrates

In a review³⁵ of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, fibrates (unspecified) were potentially implicated in 10 of 73 cases of rhabdomyolysis seen with **atorvastatin**, 4 of 10 with **fluvastatin**, 5 of 40 with **lovastatin**, 6 of 71 with **pravastatin**, and 33 of 215 with **simvastatin**.

Mechanism

Not understood. Myopathy can occur with statins and fibrates alone and their effects may therefore be additive or synergistic. There is also some evidence that the fibrates may inhibit the metabolism of the statins, but *not* because they inhibit the cytochrome P450 isoenzyme CYP3A4.^{2,34} More recent study has shown that gemfibrozil may inhibit the glucuronidation of some of the statin metabolites, and that gemfibrozil is an inhibitor of some of the CYP2C isoenzymes.³⁶ Other evidence suggests that drug transporter proteins (such as OATP2) may also be involved.^{27,29}

Importance and management

There are many studies showing efficacious use of many pairs of statins and fibrates, and the overall incidence of myopathy with a statin and a fibrate has been put at 0.12%.²¹ Nevertheless, the risks of these combinations are evident, at least for individual patients, and generally the combinations should only be used if the benefits of use outweigh the risks.

The manufacturer of bezafibrate contraindicates the use of a statin if a number of conditions considered to be risk factors for myopathy (such as renal impairment and hypothyroidism) are present.³⁷ Monitoring of creatine kinase has been suggested in patients taking a statin with a fibrate, but this will not necessarily identify all cases of developing rhabdomyolysis. As a general rule, any patient given a statin and a fibrate should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1086), for further guidance on monitoring and risk factors for muscle toxicity.

Individual combinations of statins and fibrates are associated with different levels of risk. The interactions of lovastatin and simvastatin with fibrates, particularly gemfibrozil, are established and clinically important. The FDA discourage the concurrent use of lovastatin with gemfibrozil in any patient, but suggest that it should be completely avoided in patients with compromised liver or renal function.¹² The manufacturers of lovastatin and simvastatin recommend that combined use with fibrates should generally be avoided, but if the benefits are considered to outweigh the risks, a low dose of the statin should be used. In the presence of a fibrate, the maximum generally recommended dose for lovastatin is 20 mg and for simvastatin is 10 mg. Fenofibrate is excluded from this recommendation for simvastatin, and gemfibrozil is particularly cautioned.³⁸⁻⁴⁰ The UK manufacturer of rosuvastatin recommends starting with a 5 mg dose of rosuvastatin, and contraindicates the 40-mg dose, in any patient taking a fibrate.⁴¹ Further, the US manufacturer recommends a maximum dose of 10 mg of rosuvastatin in patients taking gemfibrozil.⁴²

Statins + Fusidic acid

Rhabdomyolysis has been described in patients given atorvastatin or simvastatin with fusidic acid.

Clinical evidence, mechanism, importance and management

A patient with a renal transplant and diabetes taking various drugs was given **atorvastatin** 10 mg daily for hyperlipidaemia. Six weeks later, because of a resistant infection, clindamycin and ciprofloxacin were discontinued and fusidic acid 1.5 g daily was started. At this time serum creatine kinase was 54 units/L. Two weeks later the patient was admitted with progressive muscle weakness and pain in both legs. His serum creatinine kinase was 3550 units/L, and he also had raised myoglobin levels. Both continued to rise for 5 days after the **atorvastatin** and fusidic acid were stopped, then gradually returned to normal over one week. Serum levels of both fusidic acid and **atorvastatin** were higher than expected, and it was considered that an interaction was likely.¹ Another patient who had been taking **simvastatin** 10 mg daily for 10 months, developed rhabdomyolysis 15 days after starting to take fusidic acid. She recovered after stopping both drugs.² Another case involving **simvastatin** and fusidic acid, which was initially mistaken for drug induced hepatitis, has also been reported.³ Furthermore, fusidic acid was a possible contributing factor to another case of rhabdomyolysis seen in a patient given 'simvastatin and tacrolimus', (p.1109).

The clinical significance of this possible interaction is unclear, but it would seem wise to remind patients taking either **atorvastatin** or **simvastatin** with fusidic acid to be on the look out for the symptoms of myopathy and rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + Grapefruit and other fruit juices

Large amounts of grapefruit juice markedly increase the plasma levels of lovastatin and simvastatin, but only modestly affect the plasma levels of atorvastatin. Pravastatin seems not to interact. The clinical significance of the possible effects of pomegranate juice on rosuvastatin, and orange juice on pravastatin are unclear.

Clinical evidence

(a) Atorvastatin

Twelve healthy subjects were given 200 mL of double-strength grapefruit juice three times daily for 5 days. On day 3 they were given a single 40-mg dose of atorvastatin with the grapefruit juice then two more 200-mL doses of grapefruit juice, one after 30 minutes and the other after 90 minutes. The AUC₀₋₇₂ of atorvastatin acid and total HMG-CoA reductase inhibitors were increased 2.5-fold and 1.5-fold, respectively.¹ Other studies, using 250 mL of single-strength grapefruit three times a day, have found broadly similar increases in atorvastatin levels.^{2,3}

(b) Lovastatin

Ten healthy subjects were given 200 mL of double-strength grapefruit juice three times daily for 3 days. On day 3 they took lovastatin 80 mg with 200 mL of grapefruit juice, then two more 200-mL doses of grapefruit juice, one after 30 minutes and the other after 90 minutes. The mean peak serum levels of the lovastatin and its active metabolite, lovastatin acid, were increased 12-fold and 4-fold, respectively, and the mean AUCs were increased 15-fold and 5-fold, respectively.⁴ However, another study in which lovastatin 40 mg was given the evening after single-strength grapefruit juice was taken with breakfast found that the AUC and maximum serum level of lovastatin were approximately doubled, and the AUC and maximum serum level of lovastatin acid were only increased 1.6-fold.⁵ It has been suggested that if the grapefruit juice had been given at the same time as the lovastatin in the latter study⁵ then much greater increases in the AUC and maximum serum levels would have been found.⁶

(c) Pravastatin

Grapefruit juice did not significantly affect the pharmacokinetics of a single 40-mg dose of pravastatin. In this study, 200-mL of double-strength grapefruit juice was given three times daily for 2 days, and then on the third day 200 mL was given with the pravastatin and again after 30 and 90 minutes.¹ A further study using 10 mg of pravastatin similarly found that grapefruit juice did not significantly affect pravastatin pharmacokinetics.³

In a study in 14 healthy subjects a total of 800 mL of **orange juice**, was given over about 3 hours, starting 15 minutes before a 10-mg dose of pravastatin. **Orange juice** increased the AUC of pravastatin by a modest 1.5-fold, without affecting the maximum pravastatin levels.⁷

(d) Rosuvastatin

A case report describes a 48-year-old man taking ezetimibe 10 mg daily, and rosuvastatin 5 mg on alternate days, who developed rhabdomyolysis within 3 weeks of starting to drink 200 mL of **pomegranate juice** twice weekly. Although the patient had been stable taking ezetimibe with rosuvastatin for 15 months he had a history of myopathy with statins and had an elevated creatine kinase before statin treatment had started.⁸

(e) Simvastatin

Ten healthy subjects were given 200 mL of double-strength grapefruit juice three times daily for 2 days. On day 3 they took 60 mg of simvastatin with 200 mL of grapefruit juice, then two more 200-mL doses of grapefruit juice, one after 30 minutes and the other after 90 minutes. The mean peak serum levels of the simvastatin and simvastatin acid, were increased 9-fold and 7-fold, respectively, and the mean AUCs were increased 16-fold and 7-fold, respectively.⁹ In a further study by the same research group, when simvastatin was given 24 hours after the last dose of grapefruit juice (same dosage regimen as the previous study) the effect was only 10% of that observed during concurrent use, and had disappeared within 3 to 7 days.¹⁰ The manufacturer notes that the effect of 240 mL of standard grapefruit juice on simvastatin was minimal (13% increase in AUC of active plasma HMG-CoA reductase inhibitors).¹¹ However, another study found as little as 200 mL of grapefruit juice taken daily for 3 days could

increase the maximum levels of simvastatin and simvastatin acid by up to about fourfold.¹²

A case report describes rhabdomyolysis in a patient taking simvastatin 80 mg daily (dose increased 6 months prior to presentation), which occurred 4 days after she started to eat one fresh grapefruit a day.¹³

Mechanism

It seems almost certain that some components of the grapefruit juice (not yet positively identified but possibly naringenin), inhibit the activity of the cytochrome P450 isoenzyme CYP3A4 in the gut wall, thereby reducing the metabolism of the statins as they are absorbed, and allowing more to pass into the body. See 'Lipid regulating drugs', (p.1086) for more information about the metabolism of the statins.

Importance and management

Information about the interaction of statins and grapefruit juice seems to be mainly limited to pharmacokinetic reports (i.e. few adverse case reports) but they are consistent with the way other CYP3A4 inhibitors interact with the statins.

Large increases in the serum levels of lovastatin and simvastatin are potentially hazardous because elevated statin levels carry the risk of toxicity (muscle damage and the possible development of rhabdomyolysis). As even small quantities of grapefruit juice taken in the morning can significantly affect simvastatin levels the UK manufacturers say that concurrent use should generally be avoided.^{11,14} In the US the manufacturers suggest that intake of grapefruit juice should be restricted to less than 1 quart [roughly 1 litre] daily.^{15,16} See also 'muscle toxicity', (p.1086), for further guidance on monitoring and risk factors for muscle toxicity.

The modest increase in atorvastatin levels when taken with high doses of grapefruit juice seems less likely to be clinically relevant, but the UK manufacturer suggests that large quantities should be avoided.¹⁷ In general, the occasional glass of grapefruit juice would not appear to be a problem. Pravastatin seems not to interact. Information about other statins appears to be lacking, but no interaction would be expected with **fluvastatin** or **rosuvastatin**.

The interaction of **pomegranate juice** with rosuvastatin and ezetimibe seems to be limited to one case report, which is clouded by other possible contributory factors. Furthermore, although pomegranate juice has been shown to inhibit CYP3A4,⁸ rosuvastatin is not metabolised by this route. Although it is possible that other mechanisms may be responsible, no firm conclusions can be drawn from this case.

The interaction of pravastatin with **orange juice** would be expected to be of little clinical significance in most patients, but this needs confirmation.

Statins + H₂-receptor antagonists or Proton pump inhibitors

No clinically significant interaction appears to occur between cimetidine and atorvastatin, fluvastatin, or pravastatin, between ranitidine and fluvastatin, or between fluvastatin and omeprazole.

Clinical evidence, mechanism, importance and management

(a) Atorvastatin

In a crossover study, 12 healthy subjects were given atorvastatin for 15 days with and without cimetidine 300 mg four times daily. Cimetidine had no effect on the maximum serum levels or AUC of atorvastatin. Cimetidine had little effect on the lipid-lowering ability of atorvastatin, except that the reduction in triglycerides was slightly less, but this difference was considered to be of little clinical significance.¹ There would appear to be no reason for avoiding concurrent use. Esomeprazole has been implicated in a case of rhabdomyolysis involving atorvastatin and clarithromycin. See 'Statins + Macrolides', below.

(b) Fluvastatin

The manufacturers of fluvastatin say that its bioavailability is increased by cimetidine, omeprazole, and ranitidine (AUC increased by 24 to 33%²), but they say that this is of no clinical relevance.³ No special precautions would seem to be necessary.

(c) Pravastatin

Cimetidine 300 mg four times daily for 3 days increased the bioavailability of a single 20-mg dose of pravastatin by 58%. The dose of pravastatin was given on day 3, one hour after the first dose of cimetidine.⁴ However, the manufacturers say that it is unlikely that the changes caused by cimetidine will affect the clinical efficacy of pravastatin.⁴

Statins + Imatinib

Imatinib raises simvastatin serum levels, increasing the risk of toxicity. It seems likely that lovastatin and possibly atorvastatin may also be similarly affected.

Clinical evidence, mechanism, importance and management

In a single-dose study, 20 patients with chronic myeloid leukaemia were given simvastatin 40 mg prior to and on the last day of a 7-day course of imatinib 400 mg daily. Imatinib increased the maximum serum levels of simvastatin twofold and the AUC threefold. The authors conclude that caution is warranted if simvastatin and imatinib are taken concurrently.¹

Imatinib inhibits the cytochrome P450 isoenzyme CYP3A4,¹ by which simvastatin is metabolised. It therefore seems likely that lovastatin will be similarly affected, and atorvastatin may be affected to some extent (see 'Lipid regulating drugs', (p.1086)). These rises increase the risk of simvastatin toxicity (myopathy and rhabdomyolysis), for which reason a dosage reduction should be considered.

As a general rule, any patient given imatinib with atorvastatin, lovastatin or simvastatin should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + Macrolides

Cases of acute rhabdomyolysis have been reported between lovastatin and azithromycin, clarithromycin, or erythromycin and between simvastatin and clarithromycin or roxithromycin. Macrolide antibacterials have also been potentially implicated in cases of rhabdomyolysis with atorvastatin and pravastatin. Pharmacokinetic studies suggest that the macrolides increase the levels of the statins metabolised by CYP3A4 (namely atorvastatin, lovastatin and simvastatin).

Clinical evidence

(a) Azithromycin

A 51-year-old man who had been taking lovastatin 40 mg daily for 5 years developed muscle aches and fever one day after finishing a 5-day course of azithromycin 250 mg daily. His creatine phosphokinase levels were elevated and he was diagnosed as having rhabdomyolysis. This patient was also taking colestyramine, diltiazem, doxazosin, glibenclamide (glyburide), 'thyroid', allopurinol, naproxen, prednisone, loratadine and inhaled beclometasone.¹

In a randomised study, two groups of 12 healthy subjects were given atorvastatin 10 mg daily for 8 days with azithromycin 500 mg daily or placebo for the final 3 days. When the azithromycin group were compared with the placebo group no change in atorvastatin pharmacokinetics were noted.²

(b) Clarithromycin

A 76-year-old woman who had been taking lovastatin 40 mg daily for 5 years developed muscle pain and weakness 2 days after completing a 10-day course of clarithromycin 500 mg twice daily. Later, when hospitalised, she was found to have elevated creatine phosphokinase levels and was diagnosed as having acute rhabdomyolysis.¹ In a similar case, a 64-year-old man with multiple pathologies, including renal impairment, developed rhabdomyolysis 3 weeks after clarithromycin was added to his treatment, which included simvastatin 80 mg daily.³ Other reports describe 7 further cases of rhabdomyolysis in patients taking simvastatin,⁴⁻⁷ atorvastatin,^{8,9} or lovastatin,¹⁰ which in some cases occurred within days of the clarithromycin being started. In 5 of these cases the patients were also taking amiodarone,⁶ ciclosporin,^{5,7} efavirenz/lopinavir/ritonavir,⁹ esomeprazole,⁸ or gemfibrozil,¹⁰ which may also have had some part to play in the reaction.

A preliminary report of a pharmacokinetic study suggests that clarithromycin 500 mg twice daily for 7 days can increase the AUC and maximum levels of a single 40-mg dose of simvastatin eightfold.¹¹

In a randomised study, two groups of 12 healthy subjects were given atorvastatin 10 mg daily for 8 days with clarithromycin 500 mg twice daily or placebo for the final 3 days. When the clarithromycin group were compared with the placebo group the atorvastatin AUC was 82% higher and the maximum serum levels 50% higher.²

In a randomised study 3 groups of 15 healthy subjects were given atorvastatin 80 mg daily, pravastatin 40 mg daily or simvastatin 40 mg daily with clarithromycin 500 mg twice daily for 8 days. Clarithromycin increased the AUC of atorvastatin by fourfold, pravastatin by twofold and simvastatin by tenfold.¹²

(c) Erythromycin

Twelve healthy subjects were given a single 10-mg dose of atorvastatin on day 7 of an 11-day course of erythromycin 500 mg four times daily. The maximum serum atorvastatin levels were raised by 38% and the AUC was raised by 33% by the erythromycin.¹³ Either lovastatin or pravastatin 40 mg daily was given to 12 healthy subjects for 14 days, with erythromycin 500 mg three times daily for the last 7 days. The erythromycin caused the maximum serum levels and AUC of lovastatin to rise more than fivefold. The pharmacokinetics of the pravastatin remained unchanged.¹⁴ Similarly, fluvastatin levels are not significantly altered by erythromycin.¹⁵

A man taking lovastatin 20 mg three times daily, diltiazem, allopurinol and aspirin developed progressive weakness and diffuse myalgia after taking erythromycin 500 mg every 6 hours for 13 days. When admitted to hospital his creatine kinase level was high (35 200 units/L) and his urine was reddish-brown. The rhabdomyolysis was treated by stopping the lovastatin, and by giving furosemide with vigorous intravenous hydration.¹⁶

A woman who had been taking **lovastatin** for 7 years developed multiple organ toxicity (rhabdomyolysis, acute renal failure, pancreatitis, livedo reticularis and raised aminotransferase levels) when erythromycin was added.¹⁷ Four other cases of rhabdomyolysis attributed to an interaction between **lovastatin** and erythromycin have been reported,¹⁷⁻¹⁹ although it should be noted that one of these patients¹⁸ was also taking ciclosporin, which may have contributed to the effects seen.

A study in which 12 subjects were given erythromycin 500 mg three times daily, found a 6.2-fold increase in the AUC of a single 40-mg dose of **simvastatin**, and a 3.4-fold increase in its maximum serum levels. The major active metabolite, simvastatin acid, was similarly affected.²⁰

Erythromycin 500 mg four times daily for 7 days did not raise the levels of a single 80-mg dose of **rosuvastatin** in 11 healthy subjects. In fact, **rosuvastatin** levels were slightly lowered, although this was not considered to be of clinical relevance if short-term courses of erythromycin are used.²¹

(d) Roxithromycin

A 73-year-old woman, who had been stable for 6 months while taking a combination of gemfibrozil 600 mg twice daily, **simvastatin** 80 mg daily and diltiazem, developed muscular weakness and myalgia 7 days after starting roxithromycin. All drugs were stopped, and initially she developed myoglobinuria and had a further elevation in her creatine kinase level, but this normalised over the following 18 days. She was discharged after 6 weeks, by which time she had regained full strength.²² In a randomised, crossover study, 12 healthy subjects were given **lovastatin** 80 mg either alone or following 5 days of pre-treatment with roxithromycin 300 mg four times daily. Roxithromycin increased the maximum level and AUC of lovastatin acid by 38% and 42%, respectively, and decreased the maximum level and AUC of lovastatin lactone by a similar amount.²³

(e) Telithromycin

In a randomised, crossover study, 14 healthy subjects were given telithromycin 800 mg daily for 5 days, with a single 40-mg dose of **simvastatin** either with, or 12 hours after, the last dose of telithromycin. Although separating administration decreased the effect of telithromycin on **simvastatin** levels by over 50%, the AUC and maximum serum levels of **simvastatin** were still raised by 4-fold and 3.4-fold, respectively.²⁴

(f) Unspecified macrolides

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, macrolide antibacterials (unspecified) were potentially implicated in 13 of 73 cases of rhabdomyolysis seen with **atorvastatin**, 11 of 40 with **lovastatin**, 6 of 71 with **pravastatin**, and 10 of 215 with **simvastatin**.²⁵

Mechanism

Most macrolides inhibit the cytochrome P450 isoenzyme CYP3A4, by which lovastatin, simvastatin and, to some extent, atorvastatin are metabolised. Hence the concurrent use of a macrolide raises the levels of these statins, leading in some instances to toxicity (myopathy and rhabdomyolysis). No interaction would be expected with pravastatin because it is not metabolised by CYP3A4, (although a moderate effect has been found with clarithromycin) and no interaction would be expected with **azithromycin** as it does not appear to inhibit CYP3A4. See 'Lipid regulating drugs', (p.1086) for a more detailed discussion of statin metabolism.

Importance and management

Information about the interactions between statins and macrolide antibacterials seems to be limited to the reports cited here. In general it appears that the macrolides raise the levels of statins metabolised by CYP3A4 (i.e. atorvastatin, lovastatin and simvastatin), but not all patients are affected. One study found a large interpatient variation in results,²⁰ which may account for this. It should be noted that the manufacturers of lovastatin and simvastatin specifically recommend that these drugs are not used with clarithromycin, erythromycin or telithromycin, and suggest that the statin be temporarily withdrawn if these antibacterials are required.²⁶⁻²⁸ The risk is smaller with atorvastatin, but as the cases illustrate adverse interactions are possible. The US manufacturers therefore recommend that concurrent use should only be undertaken if the benefits outweigh the risks.²⁹ Pravastatin and fluvastatin are not metabolised by CYP3A4, and so would not be expected to interact with macrolides via this mechanism, but potential cases have been identified. This is worth noting when considering rosuvasta-

tin, which is also said to have a low propensity for interactions with CYP3A4.

To be on the safe side, any patient taking any statin who is given a macrolide (except probably azithromycin) should be warned to be alert for any signs of myopathy (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Statin + Nefazodone

Nefazodone has been implicated in cases of muscle toxicity and rhabdomyolysis in patients taking simvastatin, lovastatin, and possibly pravastatin.

Clinical evidence

(a) Lovastatin

In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, nefazodone was potentially implicated in 2 cases of rhabdomyolysis involving lovastatin.¹

(b) *Pravastatin*

A 74-year-old man taking atenolol, aspirin and pravastatin had his treatment with citalopram replaced by nefazodone 50 mg twice daily. Because the possibility of an interaction was suspected, his plasma creatine kinase levels were monitored and were found to be 877 units/L (range 0 to 190 units/L) at 36 hours. Lactate dehydrogenase, aspartate aminotransferase and alanine aminotransferase were all slightly elevated and this was interpreted as indicating muscle toxicity. The nefazodone was withdrawn and although creatine kinase levels were falling they were still above the normal range when the pravastatin was withdrawn 14 days later. Pravastatin was subsequently re-introduced and then venlafaxine 75 mg twice daily was added without problems.² However, the diagnosis of muscle toxicity has been questioned, and, because pravastatin levels were not measured, the possibility of an interaction has also been questioned.³

(c) *Simvastatin*

A 44-year-old man who had uneventfully taken simvastatin 40 mg daily for 19 weeks developed 'tea-coloured' urine, initially misdiagnosed as a urinary tract infection, a month after starting to take nefazodone 100 mg twice daily. A month later he was also complaining of severe myalgias of the thighs and calves, and was found to have muscle weakness and tenderness. Laboratory tests confirmed a diagnosis of rhabdomyolysis and myositis. He was asymptomatic within 3 weeks of stopping both drugs, and remained problem-free 5 weeks after restarting simvastatin 40 mg daily.⁴ A further case of rhabdomyolysis has been reported in a 72-year-old man taking simvastatin. Symptoms developed 6 weeks after nefazodone was initiated (2 weeks after a dose increment). He recovered with rehydration after the nefazodone was stopped.⁵ Similarly, another case report describes rhabdomyolysis in a 56-year-old man taking simvastatin, which developed about 5 weeks after nefazodone was initiated (4 weeks after a dose increment).⁶ In a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, nefazodone was potentially implicated in 2 cases of rhabdomyolysis involving simvastatin.¹

Mechanism

Uncertain. The suggestion is that nefazodone (an inhibitor of the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of simvastatin) caused a marked increase in the serum levels of the simvastatin with accompanying toxicity.⁴ The same mechanism might also account for the interaction with lovastatin, but the explanation for the case with pravastatin is less clear. See, 'Lipid regulating drugs', (p.1086) for a more detailed discussion of statin metabolism.

Importance and management

Information about interactions between nefazodone and the statins seems to be limited to these reports so that the risks associated with using nefazodone are uncertain. The manufacturers of lovastatin and simvastatin advise avoiding the combination.⁷⁻⁹ Some caution is probably prudent with atorvastatin as it is also metabolised by CYP3A4. Patients given atorvastatin with nefazodone should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Other statins seem unlikely to interact. Note that in 2003 nefazodone was withdrawn in many countries due to cases of liver toxicity.

Statins + Nicotinic acid (Niacin)

The risk of muscle toxicity, such as rhabdomyolysis, may be increased in patients taking a statin with nicotinic acid.

Clinical evidence, mechanism, importance and management

A patient taking **lovastatin** developed rhabdomyolysis, which was attributed to the addition of nicotinic acid 2.5 g daily.¹ A similar reaction occurred in another patient taking the same combination² as well as in a further patient taking ciclosporin, nicotinic acid and **lovastatin**³ (see also 'Statins + Ciclosporin', p.1097). Myositis has also been briefly reported in a patient taking **lovastatin** and nicotinic acid.¹ These adverse reports are isolated and it is by no means certain that nicotinic acid contributed to what happened. Myopathy does occur with **lovastatin** alone,⁴ with a reported incidence of 0.1%. A combined preparation of **lovastatin**/nicotinic acid is marketed (*Advicor*, USA), and in a 52-week study investigating efficacy and tolerability, none of the 814 patients experienced drug-induced myopathy, although 7 patients were withdrawn from the study due to elevated creatine kinase levels.⁵ Similarly, a review of the use of extended-release niacin with **lovastatin** found that myopathy, which was reported in 3% of patients, tended to be associated with higher initial doses of statins.⁶ There do not appear to be any published reports of myopathy occurring with nicotinic acid and any other statins. However, in a review of the FDA spontaneous reports of statin-associated rhabdomyolysis covering the period November 1997 to March 2000, nicotinic acid was identified as a potentially interacting drug in 2 of 215 cases for **simvastatin**, 1 of 71 cases for **pravastatin**, and 1 of 40 cases for **lovastatin**. Nicotinic acid was not identified as an interacting drug in any reports for **atorvastatin** or **fluvastatin**.⁷

Nicotinic acid does not alter the bioavailability of **fluvastatin**⁸ or **pravastatin**.⁹

Although these cases are isolated, some caution is certainly warranted. The US manufacturers of **lovastatin** recommend a maximum dose of 20 mg in patients taking nicotinic acid in doses of 1 g or more daily.¹⁰ Similarly the UK manufacturers of **simvastatin** recommend a maximum dose of 10 mg in patients taking nicotinic acid in doses of 1 g or more daily.¹¹ To be on the safe side, if the decision is made to use nicotinic acid with any statin the outcome should be very well monitored. Patients should be told to report otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + NNRTIs

Delavirdine is expected to raise the levels of atorvastatin, simvastatin and lovastatin. This expectation is supported by a case of rhabdomyolysis, which developed in a patient taking atorvastatin and delavirdine. Efavirenz (and possibly nevirapine) lower the levels of atorvastatin, simvastatin, and pravastatin.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

An isolated case report describes a 63-year-old HIV-positive man, who had been taking **atorvastatin** 20 mg daily with indinavir, lamivudine and stavudine, and who was admitted to hospital 2 months after indinavir was replaced with delavirdine. He had a one-month history of malaise, muscle pain, vomiting, and dark urine. Laboratory tests confirmed a diagnosis of rhabdomyolysis, and he was found to have acute renal failure. All drugs were withheld, and he gradually recovered over the following month. It was suggested that delavirdine inhibited the metabolism of **atorvastatin**.¹ Although the possible interaction between **simvastatin** or **lovastatin** and delavirdine does not appear to have been studied it would be expected to be similar, if not greater in magnitude, to that seen with **atorvastatin**. One of the manufacturers of **simvastatin** contraindicates concurrent use,² and the US manufacturer of delavirdine advises against the use of either **simvastatin** or **lovastatin**. They also advise caution with **atorvastatin**, due to the risk of rhabdomyolysis.³ See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

(b) Efavirenz

In an open-label study 42 healthy subjects were given efavirenz 600 mg daily for 11 days, with **atorvastatin** 10 mg daily, **simvastatin** 40 mg daily, or **pravastatin** 40 mg daily for the last 2 days. Efavirenz reduced the AUC of **simvastatin** and its active metabolites by about 45 to 55%, reduced the AUC of **atorvastatin** and its active metabolites by 35 to 45% and reduced the AUC of **pravastatin** by about 40%. The pharmacokinetics of efavirenz were not changed. Decreases in LDL-cholesterol were attenuated when efavirenz was given with **simvastatin**.⁴ The changes with **atorvastatin** and **simvastatin** were expected, as efavirenz induces the cytochrome P450 isoenzyme CYP3A4, by which **simvastatin**, and to an extent **atorvastatin** are metabolised. The authors note that similar results would be expected with **nevirapine**, which also induces CYP3A4. The reasons for the reduction in the **pravastatin** AUC are less clear, as it is not metabolised by CYP3A4.⁴ It would seem prudent to monitor the lipid-profile of patients taking efavirenz and any of these statins, although bear in mind that NNRTIs are often used with 'protease inhibitors', (p.1108), which dramatically raise the levels of some statins.

Statins + Orlistat

No clinically relevant interaction has been seen between orlistat and atorvastatin, pravastatin or simvastatin.

Clinical evidence, mechanism, importance and management

(a) Atorvastatin

In a randomised study, 32 healthy subjects were given atorvastatin 20 mg daily for 6 days, with or without orlistat 120 mg three times daily for 6 days. Orlistat had no significant effect on the pharmacokinetics of atorvastatin.¹

(b) Pravastatin

In a placebo-controlled, crossover study in 24 subjects with mild hypercholesterolaemia, orlistat 120 mg three times daily was reported to have no effect on the pharmacokinetics, or lipid-lowering effects, of pravastatin 40 mg daily, when both drugs were given for 6 days.²

A review includes brief details of a comparative study in two groups of healthy subjects given pravastatin, either with orlistat or placebo. After 10 days there was no significant difference in the pravastatin AUC between the groups, but the maximum serum concentration did show a tendency to be higher in the orlistat group.³

(c) Simvastatin

In a placebo-controlled, randomised study in 29 healthy subjects orlistat 120 mg three times daily had no effect on the pharmacokinetics of simvastatin 40 mg daily.⁴

Statins + Phenytoin

In an isolated case, phenytoin reduced the cholesterol-lowering effect of simvastatin, fluvastatin and atorvastatin. The concurrent use of phenytoin and fluvastatin modestly raises the levels of both drugs.

Clinical evidence, mechanism, importance and management

A 50-year-old woman taking **simvastatin** 10 mg daily had her antiepileptic medication changed from sodium valproate to phenytoin 325 mg daily. Over the following 3 months her total cholesterol rose from 9.4 to 15.99 mmol/L. The dose of **simvastatin** was gradually increased to 40 mg daily without significant effect on her cholesterol levels. Despite further changes (to **fluvastatin** 40 mg daily, then to **atorvastatin** 80 mg daily) her cholesterol level remained above 10 mmol/L. Finally phenytoin was discontinued and her cholesterol dropped to 6.24 mmol/L with **atorvastatin** 80 mg daily.¹ The reasons are not known, but it is possible that phenytoin induced the metabolism of the statins, so that they were cleared from the body more quickly and were therefore less effective. The concurrent use of phenytoin 300 mg and **fluvastatin** 40 mg increased the maximum levels and AUC of **fluvastatin** by 27% and 40%, respectively, and increased the maximum levels and AUC of phenytoin by 5% and 20%, respectively.² These changes are relatively modest and probably occur because both drugs are metabolised by the cytochrome P450 isoenzyme CYP2C9.

Evidence of an interaction currently appears to be limited to these two reports and the clinical significance remains unclear. The change in phenytoin levels seems unlikely to be clinically significant. There is a small risk that the concurrent use of **fluvastatin** and phenytoin could result in myopathy. Patients should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine). If myopathy does occur, the statin should be stopped immediately. See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Statins + Phosphodiesterase type-5 inhibitors

A man taking simvastatin developed symptoms of rhabdomyolysis after taking a single dose of sildenafil. The pharmacokinetics of atorvastatin and sildenafil do not appear to be altered by concurrent use, and tadalafil does not alter lovastatin pharmacokinetics.

Clinical evidence

(a) Sildenafil

A 76-year-old man who had been taking **simvastatin** 10 mg daily for 3 years, presented at a clinic with a 3-day history of severe and unexplained muscle aches, particularly in the lower part of his legs and feet. The problem had started within 10 hours of taking a single 50-mg dose of sildenafil. When examined he showed no muscle tenderness or swelling but his creatine phosphokinase level was slightly raised (406 units/L). There was also a mild elevation of blood urea nitrogen and an increase in creatinine and potassium levels. A tentative diagnosis of rhabdomyolysis

was made, there being no other obvious identifiable cause for the myalgia. Both **simvastatin** and sildenafil were stopped, and he made a full recovery.¹ A study in 24 healthy subjects found that the pharmacokinetics of sildenafil (single 100-mg dose) and **atorvastatin** (10 mg daily for 7 days) were unchanged by concurrent use.²

(b) Tadalafil

In a study in 16 healthy subjects, tadalafil 20 mg daily for 14 days did not affect the pharmacokinetics of a 40-mg dose of **lovastatin**.³

Mechanism, importance and management

The reasons for this possible interaction are not known. This is as yet an isolated case, and no broad generalisations can be based on such slim evidence. Based on the current evidence no further precautions currently seem necessary.

Statins + Protease inhibitors

The levels of atorvastatin and simvastatin are markedly increased by lopinavir and saquinavir (with ritonavir), nelfinavir, and ritonavir alone. Pravastatin seems only moderately affected. Several cases of rhabdomyolysis have been attributed to this interaction.

Clinical evidence

(a) Indinavir

In a non-randomised study patients receiving HAART were given **pravastatin** or **fluvastatin**. Neither of the statins altered the pharmacokinetics of indinavir, the combination was well tolerated, and no increase in adverse events was seen.¹

(b) Lopinavir/Ritonavir

Either **atorvastatin** 20 mg daily or **pravastatin** 20 mg daily were given to 24 healthy subjects for 4 days during a 14-day course of lopinavir/ritonavir 400/100 mg twice daily. The maximum serum levels and AUC of **atorvastatin** were increased by between 4.7- and 5.9-fold and the maximum serum levels and AUC of **pravastatin** were only increased by about 30%. **Atorvastatin** and **pravastatin** had no effect on the pharmacokinetics of lopinavir or ritonavir.²

(c) Nelfinavir

In an open label study, 31 healthy subjects were given either **atorvastatin** 10 mg daily or **simvastatin** 20 mg daily for 28 days, with nelfinavir 1.25 g twice daily for the last 14 days. Nelfinavir increased the maximum serum levels and AUC of **atorvastatin** approximately twofold and the maximum serum levels and AUC of **simvastatin** approximately sixfold. No significant adverse effects, or any signs of rhabdomyolysis were noted throughout the study.³

One study found that nelfinavir 750 mg three times daily increased the maximum serum levels and AUC of **pravastatin** 40 mg daily by 29% and 35%, respectively, and increased the maximum serum levels and AUC of **atorvastatin** 40 mg daily by 32% and 209%, respectively.⁴ A further study, in which 14 healthy subjects took nelfinavir 1.25 g twice daily for 12 days, with **pravastatin** 40 mg daily for the final 4 days, found that the AUC of **pravastatin** ranged from a decrease of 65% to an increase of 11%, and the maximum serum levels ranged from a decrease of 77% to an increase of 154%.⁵

In another study, 14 healthy subjects were given nelfinavir 1.25 g twice daily for 18 days, with **pravastatin** 40 mg daily for the last 4 days. No significant change was noted in the pharmacokinetics of nelfinavir, nor of its major metabolite.⁶

A case report describes a 70-year-old HIV-positive man taking nelfinavir who developed rhabdomyolysis and died, about 3 weeks after being given **simvastatin** 80 mg daily. He had previously tolerated both **pravastatin** 40 mg daily and **simvastatin** 10 mg daily.⁷

(d) Ritonavir

A 51-year-old woman was admitted to hospital with a 4-day history of muscular aches and weakness. Among other drugs, she had been taking zidovudine, lamivudine, indinavir, and **simvastatin** for 2 years. Ritonavir 100 mg twice daily had been added to her usual regimen 2 weeks previously. The rhabdomyolysis was therefore attributed to an interaction between ritonavir and **simvastatin**.⁸ Another similar case has also been reported.⁹ See also (b) above and (e) below for interactions of ritonavir combined with other protease inhibitors.

(e) Saquinavir/Ritonavir

Ritonavir 300 mg twice daily and saquinavir 400 mg twice daily were given to healthy subjects for 3 days, after which the dose was increased to ritonavir 400 mg twice daily and saquinavir 400 mg twice daily for a further 11 days. On the last 4 days **atorvastatin**, **pravastatin**, or **simvastatin** (all 40 mg daily) were also given. The mean **pravastatin** AUC was approximately halved (13 subjects), the mean **atorvastatin** AUC was increased approximately fourfold (14 subjects) and the mean **simvastatin** acid AUC was increased approximately 32-fold (14 subjects). No cases of rhabdomyolysis were noted.⁶

Mechanism

The protease inhibitors, especially ritonavir, are known to be strong inhibitors of the cytochrome P450 isoenzyme CYP3A4. The levels of statins metabolised by this isoenzyme (notably simvastatin, and to some extent atorvastatin) are therefore increased. See 'Lipid regulating drugs', (p.1086) for information on the metabolism of the individual statins.

Importance and management

The interactions of the protease inhibitors and atorvastatin or simvastatin appear to be established by the pharmacokinetic studies cited here, and supported by a few case reports. It is generally recommended that simvastatin and lovastatin, which is similarly metabolised, should be avoided in patients taking protease inhibitors, and several manufacturers of simvastatin contraindicate concurrent use.^{10,11} Atorvastatin should be used in low doses (i.e. 10 mg) with care. See also 'muscle toxicity', (p.1086), for further guidance on monitoring, and risk factors for muscle toxicity.

Pravastatin and fluvastatin can probably be used without dose adjustments, but monitoring is needed to confirm this as one study with nelfinavir and pravastatin⁵ suggested a trend towards *reduced* pravastatin efficacy.

Statins + Rifampicin (Rifampin)

Rifampicin lowers the serum levels of atorvastatin, fluvastatin, pravastatin, and simvastatin.

Clinical evidence, mechanism, importance and management

It was briefly mentioned in a review by the manufacturer of **fluvastatin** that rifampicin reduced the AUC and the maximum serum levels of **fluvastatin** by 51% and 59%, respectively. No further study details were given.¹ In a randomised, crossover study in 10 healthy subjects, 5 days pre-treatment with rifampicin 600 mg daily reduced the AUCs of **simvastatin** and **simvastatin acid** by 87% and 93%, respectively.² A study of the same design with a 40-mg dose of **atorvastatin** found that rifampicin decreased the AUC of **atorvastatin** by 80% and decreased the AUCs of its two active metabolites by 43% and 81%, respectively. There was considerable intersubject variation in these values.³ In a further study by the same authors, this time with **pravastatin** 40 mg, it was found that rifampicin reduced the AUC of **pravastatin** by 31%, but again there were large interindividual differences in the results, with some subjects having an increase in AUC.⁴ It might therefore be necessary to increase the dosage of **atorvastatin**, **fluvastatin**, **simvastatin**, and possibly **pravastatin** in some subjects, if rifampicin is given concurrently, but this needs confirmation.

Statins + St John's wort (*Hypericum perforatum*)

St John's wort modestly decreases the plasma level of simvastatin, but not pravastatin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study, 16 healthy subjects took St John's wort 300 mg three times daily for 14 days. On day 14 **simvastatin** 10 mg was given to 8 subjects and **pravastatin** 20 mg was given to the other 8 subjects. St John's wort did not affect the plasma concentration of **pravastatin**, but it tended to reduce the **simvastatin** AUC and significantly reduced the AUC of its active metabolite, **simvastatin hydroxy acid**, by 62%.¹ The reason for this interaction is unknown, but St John's wort may reduce the levels of **simvastatin** and its metabolite by inhibiting the cytochrome P450 isoenzyme CYP3A4 or by having some effect on P-glycoprotein. The clinical significance of these reductions is unclear, but it may be prudent to consider an interaction if lipid-lowering targets are not met.

1. Sugimoto K, Ohmori M, Tsuruoka S, Nishiki K, Kawaguchi A, Harada K, Arakawa M, Sakamoto K, Masada M, Miyamori I, Fujimura A. Different effects of St John's wort on the pharmacokinetics of simvastatin and pravastatin. *Clin Pharmacol Ther* (2001) 70, 518–24.

Statins + Tacrolimus

An isolated case of rhabdomyolysis occurred in a patient taking tacrolimus with simvastatin. Tacrolimus does not appear to affect atorvastatin pharmacokinetics.

Clinical evidence, mechanism, importance and management

A 51-year-old woman, who was taking tacrolimus after a kidney transplant, started taking **simvastatin** 10 mg daily following a stroke. After 5 months, the dose was increased to 20 mg daily, and fusidic acid was started for osteomyelitis. Muscle pain developed 2 weeks later, and after a further 3 weeks she was admitted to hospital, when her creatinine kinase level was found to be 24 000 units/mL (reported range 10 to 70 units/mL) and she had renal impairment. The **simvastatin** and fusidic acid were immediately stopped and the patient recovered over the following 2 weeks. She was later treated with a combination of **fluvastatin**, tacrolimus and fusidic acid without incident, leading the authors to suspect that the rhabdomyolysis was caused by an interaction between **simvastatin** and tacrolimus.¹ However, note that 'fusidic acid', (p.1102), has been implicated in cases of rhabdomyolysis with **simvastatin**. The clinical significance of this case report is therefore unclear.

A pharmacokinetic study in 13 healthy subjects found that the short-term use of tacrolimus (2 doses 12 hours apart) did not affect the pharmacokinetics of **atorvastatin**.²

1. Kotanko P, Kiristis W, Skrabal F. Rhabdomyolysis and acute renal graft impairment in a patient treated with simvastatin, tacrolimus, and fusidic acid. *Nephron* (2002) 90, 234–5.
2. Lemahieu WPD, Hermann M, Asberg A, Verbeke K, Holdaas H, Vanrenterghem Y, Maes BD. Combined therapy with atorvastatin and calcineurin inhibitors: no interactions with tacrolimus. *Am J Transplant* (2005) 5, 2236–43.

Statins; Atorvastatin + Sirolimus

A case report describes elevated sirolimus levels in a patient, which occurred after atorvastatin was started.

Clinical evidence, mechanism, importance and management

A case report describes a patient who had undergone a pancreatic islet transplant and who had been stable taking sirolimus 8 to 11 mg daily for 5 months. A routine lipid evaluation at 6 months found raised cholesterol and triglyceride levels, and so atorvastatin was started. Six weeks later the trough sirolimus level was 20.5 nanograms/mL (target 7 to 10 nanograms/mL) and so the sirolimus dose was reduced. Further reductions were subsequently needed, and 3 months after the atorvastatin was started the sirolimus dose had been halved.¹ The authors suggested that the atorvastatin competed with sirolimus for metabolism by the cytochrome P40 isoenzyme CYP3A4, which resulted in reduced sirolimus metabolism and the elevated levels seen.¹ This case report seems to be the only evidence of an interaction and so its general significance is unknown. However, it may be prudent to be aware of the possibility of an interaction if both drugs are given.

1. Barshes NR, Goodpastor SE, Goss JA, DeBakey ME. Sirolimus-atorvastatin drug interaction in the pancreatic islet transplant recipient. *Transplantation* (2003) 76, 1649–50.

Statins; Lovastatin + Fibre or Pectin

Pectin and oat bran can reduce the cholesterol-lowering effects of lovastatin.

Clinical evidence, mechanism, importance and management

The serum LDL-cholesterol levels of 3 patients taking lovastatin 80 mg daily showed a marked rise from 4.48 to 6.36 mmol/L when they were also given pectin 15 g daily. One patient had a 59% rise in LDL-cholesterol.¹ Two other patients taking lovastatin had a rise in LDL-cholesterol from 5.03 to 6.54 mmol/L when they were also given 50 to 100 g of **oat bran** daily. One patient had a 41% rise in LDL-cholesterol.¹ When the pectin and **oat bran** were stopped, the serum levels of the LDL-cholesterol fell. It is presumed that both pectin and **oat bran** reduced the absorption of lovastatin from the gut.¹ Evidence is still very limited but if patients are adding these fibres to their diets it would seem prudent to separate the ingestion of lovastatin by as much as possible.

1. Richter WO, Jacob BG, Schwandt P. Interaction between fibre and lovastatin. *Lancet* (1991) 338, 706.

Statins; Pravastatin + Aspirin

Aspirin 324 mg did not significantly affect the pharmacokinetics of a single 20-mg dose of pravastatin.¹

1. ER Squibb. A report on the effect of nicotinic acid alone and in the presence of aspirin on the bioavailability of SQ 31,000 in healthy male subjects. Data on file (Protocol No 27, 201-6), 1987.

Statins; Pravastatin + Mianserin

An isolated report describes rhabdomyolysis attributed to the long-term concurrent use of pravastatin and mianserin, triggered by a cold.

Clinical evidence, mechanism, importance and management

An isolated report describes a 72-year-old woman taking pravastatin 20 mg daily and mianserin 10 mg daily for 2 years, who was hospitalised because of weakness in her legs that began 2 days previously, shortly after she developed a cold. She could stand, but was unable to walk unaided. Laboratory data revealed evidence of increased serum enzymes, all of which suggested rhabdomyolysis. Within a week of stopping the pravastatin the leg weakness had disappeared and all of the laboratory results had returned to normal. The authors of the report attributed the toxicity to the long-term use of both drugs, ageing and the development of a cold.¹ However, what part these factors and/or the presence of mianserin actually played in the development of this toxicity is not known. It seems unlikely that this case is of general significance.

1. Takei A, Chiba S. Rhabdomyolysis associated with pravastatin treatment for major depression. *Psychiatry Clin Neurosci* (1999) 53, 539.

Statins; Pravastatin + Probuco

Probuco 500 mg did not cause any clinically significant changes in the bioavailability of a single 20-mg dose of pravastatin in a study in 20 healthy subjects.¹

1. ER Squibb. A report on the bioavailability of pravastatin in the presence and absence of gemfibrozil or probuconol in healthy male subjects. Data on file (Protocol No 27, 201-18), 1988.

Statins; Simvastatin + Bosentan

Bosentan modestly reduces the AUC of simvastatin and its active metabolite, which could lead to a reduction in simvastatin efficacy.

Clinical evidence

In a three-way, crossover study, 9 healthy subjects were given either bosentan 125 mg twice daily for 5.5 days, simvastatin 40 mg daily for 6 days, or both treatments together. Simvastatin had no effect on the pharmacokinetics of bosentan, but bosentan reduced the AUC of simvastatin and its β -hydroxyacid metabolite by 34% and 46%, respectively.¹

Mechanism

Bosentan is known to be a mild inducer of the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of simvastatin. Induction of simvastatin metabolism may have led to the reduced levels seen. See 'Lipid regulating drugs', (p.1086) for more information on the metabolism of all the statins.

Importance and management

A 40% reduction in the AUC of simvastatin is potentially clinically significant. If bosentan and simvastatin are used concurrently it would seem prudent to monitor the outcome to ensure that simvastatin is effective.

Statins; Simvastatin + Fish oils

In a randomised, crossover study in 23 subjects, omega-3-acid ethyl esters (*Omacor*) 4 g daily did not significantly affect the pharmacokinetics of simvastatin 80 mg daily when both drugs were given together for 14 days. The combination was also well tolerated.¹ No additional precautions would appear to be necessary on concurrent use.

Lithium

Lithium is used in the management of mania, bipolar disorder (formerly manic depression) and recurrent depressive illnesses. The dosage of lithium is adjusted to give therapeutic serum concentrations of 0.4 to 1 mmol/L, although it should be noted that this is the range used in the UK, and other ranges have been quoted.

Lithium is given under close supervision with regular monitoring of serum concentrations because there is a narrow margin between therapeutic concentrations and those that are toxic. Initially weekly monitoring is advised, dropping to every 3 months for those on stable regimens. It is usual to take serum-lithium samples about 10 to 12 hours after the last oral dose.

Adverse effects that are not usually considered serious include nausea, weakness, fine tremor, mild polydipsia and polyuria. If serum concentrations rise into the 1.5 to 2 mmol/L range, toxicity usually occurs, and may present as lethargy, drowsiness, coarse hand tremor, lack of coordination, muscular weakness, increased nausea and vomiting, or diarrhoea. Higher levels result in neurotoxicity, which manifests as ataxia, giddiness, tinnitus, confusion, dysarthria, muscle twitching, nystagmus, and even coma or seizures. Cardiovascular symptoms may also develop and include ECG changes and circulatory problems, and there may be a worsening of polyuria.¹⁻³ Lithium levels of over 2 mmol/L can be extremely dangerous and therefore require urgent attention. Chronic lithium toxicity has been reported to have a 9% mortality, whilst acute toxicity has a 25% mortality.⁴ However, patients with chronic lithium toxicity are more likely to experience severe symptoms at lower serum-lithium levels. Concurrent medications, older age and prior neurological illness may increase the susceptibility to lithium toxicity.⁵

In addition to the effects described above, lithium can induce diabetes insipidus and hypothyroidism in some patients, and is contraindicated in those with renal or cardiac insufficiency.

Just how lithium exerts its beneficial effects is not known, but it may compete with sodium ions in various parts of the body, and it alters the electrolyte composition of body fluids.

Many of the interactions involving lithium occur because of altered serum-lithium concentrations. Lithium is mainly excreted by the kidney; it undergoes glomerular filtration and then tubular reabsorption competitively with sodium. Therefore, drugs that affect renal excretion (e.g. 'thiazide diuretics', (p.1123)) or electrolyte balance (e.g. 'sodium compounds', (p.1128)) are likely to interact. Drug interactions may be an important cause of lithium neurotoxicity occurring when serum-lithium levels are within the therapeutic range.⁶ This tends to occur with centrally active drugs e.g. 'antipsychotics', (p.710), 'carbamazepine', (p.1118), 'SSRIs', (p.1115), and 'tricyclic antidepressants', (p.1117). Most of the interactions involving lithium are discussed in this section but a few are found elsewhere in this publication. Virtually all of the reports are concerned with the carbonate, but sometimes lithium is given as the acetate, aspartate, chloride, citrate, gluconate, orotate or sulphate instead. There is no reason to believe that these lithium compounds will interact any differently to lithium carbonate.

Lithium + ACE inhibitors

ACE inhibitors can raise lithium levels, and in some individuals two to fourfold increases have been recorded. Cases of lithium toxicity have been reported in patients when given captopril, enalapril or lisinopril (and possibly perindopril). One analysis found an increased relative risk of 7.6 for lithium toxicity requiring hospitalisation in elderly patients newly started on an ACE inhibitor. Risk factors for this interaction seem to be poor renal function, heart failure, volume depletion, and increased age.

Clinical evidence

An analysis of 10,615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for any ACE inhibitor (not specifically named) were compared between these 413 hospitalised patients and 1651 control patients. For any use of ACE inhibitor (63 cases and 110 controls) there was an increased relative risk of hospitalisation for lithium toxicity of 1.6. When patients who had started taking an ACE inhibitor within the last month were evaluated (14 cases and 5 controls), a dramatically increased risk of lithium toxicity was found (relative risk 7.6).¹

Studies and case reports of the interaction between lithium and specific named ACE inhibitors are outlined in the subsections below.

(a) Captopril

A patient taking lithium carbonate developed a serum-lithium level of 2.35 mmol/L and toxicity (tremor, dysarthria, digestive problems) within 10 days of starting to take captopril 50 mg daily. He was restabilised on half his previous dose of lithium.² A retrospective study also reports a case of increased lithium levels with captopril (see under (c) *Lisinopril*, below).

(b) Enalapril

A woman taking lithium carbonate developed signs of lithium toxicity (ataxia, dysarthria, tremor, confusion) within 2 to 3 weeks of starting to take enalapril 20 mg daily. After 5 weeks her plasma-lithium levels had risen from 0.88 to 3.3 mmol/L, and moderate renal impairment was noted.³ No toxicity occurred when the enalapril was later replaced by nifedipine.³ Lithium toxicity following the use of enalapril, and associated in some cases with a decrease in renal function, has been seen in another 5 patients,⁴⁻⁸ and a reduced lithium dosage was found adequate in another patient.⁹ Enalapril 5 mg daily for 9 days had no effect on the mean serum-lithium levels of 9 healthy male subjects. However, one subject had a 31% increase in lithium levels.¹⁰

A retrospective study also reports several cases of increased lithium levels with enalapril (see under (c) *Lisinopril*, below).

(c) Lisinopril

A retrospective study of patient records identified 20 patients who were stabilised on lithium and then started on an ACE inhibitor (13 given lisinopril, 6 enalapril and one captopril). Their serum-lithium levels rose by an average of 35% (from 0.64 to 0.86 mmol/L) and there was a 26% decrease in lithium clearance. Signs and symptoms suggestive of toxicity (increased tremor, confusion, ataxia), necessitating a dosage reduction or lithium withdrawal, developed in four (20%) of these patients. In three patients the development of the interaction was delayed for several weeks.¹¹ A woman taking lithium developed lithium toxicity and a trough-serum level of 3 mmol/L within 3 weeks of stopping clonidine and starting lisinopril 20 mg daily.¹² Other reports similarly describe acute lithium toxicity in 4 patients when they were given lisinopril.^{8,13-15} One of them was also taking verapamil,¹⁵ which has also been shown to interact with lithium, but not usually to raise lithium levels (see 'Lithium + Calcium-channel blockers', p.1121).

(d) Perindopril

A patient taking lithium developed toxicity 3 months after starting to take perindopril and bendroflumethiazide,¹⁶ which may also interact, see 'Lithium + Diuretics; Thiazide and related', p.1123.

(e) Ramipril

Ramipril has been shown to decrease renal lithium excretion in *rats*.¹⁷

Mechanism

Not fully understood. It has been suggested that as both ACE inhibitors and lithium cause sodium to be lost in the urine, and also ACE inhibitors reduce thirst stimulation, fluid depletion can occur. The normal compensatory reaction for fluid depletion is constriction of the efferent renal arterioles to maintain the glomerular filtration rate, but this mechanism is blocked by the ACE inhibitor. In addition, lithium and sodium ions are competitively reabsorbed, mainly in the proximal tubule, and with less sodium available, more lithium is retained. Consequently the renal excretion of lithium falls and toxicity develops.

Importance and management

The interaction between lithium and the ACE inhibitors is established and of clinical importance, although its incidence is probably small. One manufacturer has suggested that the concurrent use of ACE inhibitors and lithium carbonate should generally be avoided.¹⁸ However, although lithium levels can rise, this is not always of clinical importance. The risk of lithium toxicity increases when other risk factors are also present (see below).

If any ACE inhibitor is added to established lithium treatment, monitor well for symptoms of lithium toxicity (see 'Lithium', (p.1111)) and consider measuring lithium levels more frequently. Be alert for the need to reduce the lithium dosage (possibly by between one-third to one-half).^{12,14} The development of the interaction may be delayed, so monitoring lithium levels every week¹² or every two weeks¹¹ for several weeks has been advised.

Risk factors for increased lithium toxicity include: advanced age,^{1,11} congestive heart failure,^{10,12} renal insufficiency^{7,12} and volume depletion.^{6,12} Some consider these to be contraindications to the use of lithium.^{7,12,18} Only captopril, enalapril, lisinopril (and possibly perindopril) have been reported to interact, but it seems likely, given the proposed mechanism, that this interaction will occur with any other ACE inhibitor.

Lithium + Acetazolamide

There is some evidence that the excretion of lithium can be increased by the short-term use of acetazolamide. However, lithium toxicity has been seen in one patient given the combination for a month.

Clinical evidence, mechanism, importance and management

A single-dose study in 6 subjects given lithium 600 mg ten hours before acetazolamide 500 or 750 mg found a 31% increase in the urinary excretion of lithium.¹ A woman was successfully treated for a lithium overdose

with acetazolamide, intravenous fluids, sodium bicarbonate, potassium chloride and mannitol.²

Paradoxically, lithium toxicity occurred in another patient after a month of treatment with acetazolamide. Lithium levels rose from 0.8 to 5 mmol/L, although it should be noted that the later measurement was taken 8 hours post-dose.³ See 'Lithium', (p.1111) for details of lithium monitoring.

Lithium + Aciclovir

An isolated case report describes lithium toxicity caused by high-dose intravenous aciclovir.

Clinical evidence, mechanism, importance and management

A 42-year-old woman, taking lithium carbonate 450 mg twice daily, developed signs of lithium toxicity 6 days after starting treatment with intravenous aciclovir 10 mg/kg, which was given every 8 hours for a severe herpes zoster infection following chemotherapy. Her serum-lithium levels had risen over fourfold to 3.4 mmol/L. The reasons for this interaction are unknown but the authors of the report postulate that aciclovir may have inhibited the renal excretion of lithium.¹

This appears to be the first and only report of this interaction, but it would now be prudent to monitor for symptoms of lithium toxicity (see 'Lithium', (p.1111)) and consider monitoring lithium levels if high-dose intravenous aciclovir is given to any patient. The report recommends measuring lithium levels every second or third day.¹ Oral aciclovir is predicted not to interact because of its low bioavailability, and no interaction would be expected with topical aciclovir as the plasma levels achieved by this route are minimal.

1. Sylvester RK, Leitch J, Granum C. Does acyclovir increase serum lithium levels? *Pharmacotherapy* (1996) 16, 466–8.

Lithium + Angiotensin II receptor antagonists

Case reports describe lithium toxicity in patients given candesartan, losartan, valsartan, and possibly irbesartan. Other angiotensin II receptor antagonists would be expected to interact similarly.

Clinical evidence

(a) Candesartan

A 58-year-old woman taking long-term lithium for depression (stable serum-lithium levels between 0.6 and 0.7 mmol/L), and unnamed calcium antagonists for hypertension, was additionally given candesartan 16 mg daily. She was hospitalised 8 weeks later with a 10-day history of ataxia, increasing confusion, disorientation and agitation, and was found to have a serum-lithium level of 3.25 mmol/L. She recovered completely when all the drugs were stopped. She was later restabilised on her original lithium dosage with a change to urapidil for her hypertension.¹

(b) Irbesartan

A report describes a 74-year-old woman with increased lithium levels of 2.3 mmol/L and symptoms of lithium toxicity, which were associated with several drugs including irbesartan, lisinopril, escitalopram, levomepromazine, furosemide and spironolactone. It was suggested that these drugs could have delayed lithium excretion or worsened neurotoxic effects. An increase in the lisinopril dose and the addition of irbesartan several weeks before admission may have contributed to the lithium toxicity.²

(c) Losartan

An elderly woman taking lithium carbonate developed lithium toxicity (ataxia, dysarthria, and confusion) after starting to take losartan 50 mg daily. Her serum-lithium levels rose from 0.63 to 2 mmol/L over 5 weeks. The lithium and losartan were stopped and her symptoms had disappeared 2 days later. When lithium therapy was restarted and the losartan was re-

placed by nicardipine, her lithium levels were restabilised at 0.77 mmol/L within 2 weeks.³

(d) Valsartan

A woman with a long history of bipolar disorder was treated with lithium carbonate (serum levels consistently at 0.9 mmol/L) and a number of other drugs (L-tryptophan, lorazepam, glibenclamide, conjugated oestrogens and ciprofloxacin). Two weeks before being hospitalised for a manic relapse she was additionally started on valsartan 80 mg daily. While in hospital the ciprofloxacin was stopped, lorazepam was replaced by zopiclone, and quetiapine was added. On day 3 of her hospitalisation her serum-lithium levels were 1.1 mmol/L and she became increasingly delirious, confused and ataxic over the next week. By day 11 her serum-lithium levels had risen to 1.4 mmol/L. When an interaction was suspected, the valsartan was replaced by diltiazem. She later recovered and was stabilised on her original lithium carbonate dosage with lithium levels of 0.8 mmol/L.⁴

Mechanism

Not fully understood. It could be that, as with the ACE inhibitors, angiotensin II receptor antagonists inhibit aldosterone secretion, resulting in increased sodium loss by the kidney tubules. This causes lithium retention and thus an increase in lithium levels. However, angiotensin II receptor antagonists have less effect on aldosterone than the ACE inhibitors, making a clinically significant interaction less likely. *Animal* studies show that ramipril,⁵ but not losartan,⁶ decreases the excretion of lithium by the kidney, which would support this idea.

Importance and management

Direct information about interactions between lithium and angiotensin II receptor antagonists seems to be limited to these reports, although the interaction has been predicted to occur with all drugs of this class. Such sparse evidence is not enough to recommend contraindicating the concurrent use of angiotensin II receptor antagonists with lithium, although the UK manufacturers of irbesartan⁷ and olmesartan⁸ do not recommend the combination. Several manufacturers (including the UK manufacturers of eprosartan and telmisartan)^{9,10} advise careful monitoring of serum-lithium levels, and this seems a sensible precaution, even though the risk of an interaction is probably fairly low. One report suggests weekly monitoring for the first month of concurrent use,⁴ but any rise in serum-lithium levels may be gradual so that toxicity might take as long as 3 to 7 weeks to develop fully. Be mindful that the lithium dosage may need to be decreased.¹¹

Patients on lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given angiotensin II receptor antagonists. As with 'ACE inhibitors', (p.1112), the risk of lithium toxicity would be expected to increase when risk factors such as advanced age, renal insufficiency, heart failure and volume depletion are also present.

Lithium + Antibacterials

A retrospective study of patients receiving long-term lithium therapy found that concurrent medication, especially antibiotics, tended to be associated with a higher risk of elevated serum-lithium levels. However, the underlying infection and poor fluid intake might have contributed.

Clinical evidence, mechanism, importance and management

A multicentre, retrospective study of patients receiving long-term lithium therapy found 51 patients with elevated serum-lithium levels (greater than or equal to 1.3 mmol/L) which was at least 50% greater than the previous serum level. Fifteen patients had used potentially interacting medication and, of these, 7 patients had used antibacterials (6 different unnamed antibacterials). It was suggested that the underlying infection, associated fever and poor fluid intake might have contributed to the elevated lithium levels in these patients rather than the use of the antibacterial *per se*.¹ See under 'co-trimoxazole or trimethoprim', (below), 'quinolones', (below), 'metronidazole', (below), 'spectinomycin', (below), and 'tetracyclines', (below) for case reports of lithium toxicity with specific antibacterials.

1. Wiltig I, Movig KLL, Moolenaar M, Hekster YA, Brouwers JRB, Heerndink ER, Nolen WA, Egberts ACG. Drug-drug interactions as a determinant of elevated lithium serum levels in daily clinical practice. *Bipolar Disord* (2005) 7, 274–80.

Lithium + Antibacterials; Co-trimoxazole or Trimethoprim

Two reports describe lithium toxicity in three patients given co-trimoxazole; in two of these patients toxicity was paradoxically accompanied by a fall in serum-lithium levels. A further report describes lithium toxicity accompanied by an increase in serum-lithium levels in a patient given trimethoprim.

Clinical evidence, mechanism, importance and management

Two patients stabilised on lithium carbonate (serum level 0.75 mmol/L) showed signs of lithium toxicity (tremor, fasciculations, muscular weakness, dysarthria, apathy) within a few days of being given co-trimoxazole [dose not stated], yet their serum-lithium levels were found to have fallen to about 0.4 mmol/L. Within 48 hours of withdrawing the co-trimoxazole, the signs of toxicity had gone, and their serum-lithium concentrations had returned to their former levels.¹ Another report very briefly states that ataxia, tremor and diarrhoea developed in a patient on lithium and timolol when co-trimoxazole was given.²

A 40-year-old woman taking lithium 1.2 g daily, experienced nausea, diarrhoea, malaise, difficulty concentrating, trembling, an uncertain gait and muscle spasms after trimethoprim 300 mg daily was started; her serum-lithium levels appeared to be elevated. She made a good recovery following rehydration.³

The reasons for this interaction are not understood, although trimethoprim may affect the renal excretion of lithium.³ The general importance of this interaction is uncertain. If concurrent use is undertaken it would clearly be prudent to monitor the clinical response, as it would appear that in this situation serum level monitoring might not always be a reliable guide to toxicity. Consider also 'Lithium + Antibacterials', p.1113.

Lithium + Antibacterials; Metronidazole

The lithium levels of three patients rose, to toxic levels in two cases, after they took metronidazole. Renal impairment was also reported in two of these patients.

Clinical evidence, mechanism, importance and management

A 40-year-old woman taking lithium carbonate 1.8 g daily, levothyroxine 150 micrograms daily and propranolol 60 mg daily developed signs of lithium toxicity (ataxia, rigidity, poor cognitive function, impaired co-ordination) after completing a one-week course of metronidazole 500 mg twice daily. Her serum-lithium levels had risen by 46% (from 1.3 to 1.9 mmol/L).¹ Another report describes 2 patients whose serum-lithium levels rose by about 20 and 125%, 5 to 12 days, respectively, after they finished a one-week course of metronidazole (750 mg or 1 g daily in divided doses).² A degree of renal impairment occurred during concurrent treatment and was still present 5 and 6 months later.² In contrast, one other

patient is said to have taken both drugs together uneventfully.¹

There seems to be no reason for avoiding concurrent use, but the outcome should be well monitored. Some have recommended that a reduction in the lithium dose should be considered, especially in patients maintained at relatively high serum-lithium levels.^{1,2} Patients taking lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given metronidazole. The authors of one of the reports also recommend frequent analysis of creatinine and electrolyte levels and urine osmolality in order to detect any renal problems in patients on this combination.²

2. Teicher MH, Altesman RI, Cole JO, Schatzberg AF. Possible nephrotoxic interaction of lithium and metronidazole. *JAMA* (1987) 257, 3365–6.

Lithium + Antibacterials; Quinolones

An isolated case of lithium toxicity has been reported in a patient taking lithium and levofloxacin. Another possible case has been reported with ciprofloxacin.

Clinical evidence, mechanism, importance and management

A 56-year-old man taking lithium carbonate 400 mg three times daily for a bipolar disorder was admitted to hospital with bronchitis. He was started on levofloxacin 300 mg daily, and within 2 days was noted to have developed gait ataxia, dysarthria, coarse tremor, dizziness, vomiting, and confusion. Lithium toxicity was suspected, and because of the time course of the symptoms, an interaction with levofloxacin was considered responsible. Serum-lithium levels were found to have risen from 0.89 mmol/L (measured 2 weeks previously) to 2.53 mmol/L, and a reduction in his renal function was noted. Both drugs were stopped and the patient recovered over the following 4 days. His lithium level was found to be 1.12 mmol/L at that time.¹

The mechanism of this interaction between lithium and levofloxacin is unclear, and this appears to be the only report. However, it would seem prudent to bear this interaction in mind if a patient on lithium is prescribed levofloxacin. Patients on lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given levofloxacin. For a report of lithium toxicity with raised lithium levels in a patient started on ciprofloxacin and nimesulide, which was attributed to the NSAID, see *Nimesulide*, under 'Lithium + NSAIDs', p.1125, and consider also 'Lithium + Antibacterials', p.1113.

1. Takahashi H, Higuchi H, Shimizu T. Severe lithium toxicity induced by combined levofloxacin administration. *J Clin Psychiatry* (2000) 61, 949–50.

Lithium + Antibacterials; Spectinomycin

An isolated case report describes a patient who developed lithium toxicity when given spectinomycin.

Clinical evidence, mechanism, importance and management

A woman developed lithium toxicity (tremor, nausea, vomiting, ataxia and dysarthria) when given spectinomycin injections [dose not stated] in addition to her long-term treatment with lithium.¹ Her serum-lithium levels had risen from a range of 0.8 to 1.1 mmol/L up to 3.2 mmol/L. Spectinomycin reduces urinary output, and so it was suggested that a reduced renal clearance of lithium led to these elevated levels. Information seems to be limited to this report, but it would seem prudent to bear this interaction in mind in any patient given both drugs.

Consider also 'Lithium + Antibacterials', p.1113.

1. Conroy RW. Quoted as a personal communication by Ayd FJ. Possible adverse drug-drug interaction report. *Int Drug Ther Newslett* (1978) 13, 15.

Lithium + Antibacterials; Tetracyclines

The concurrent use of lithium and the tetracyclines is normally uneventful, but two isolated reports describe increased serum-lithium levels and lithium toxicity, one in a woman taking tetracy-

cline, and the other in a man taking doxycycline. An isolated case of pseudotumor cerebri occurred in one patient taking lithium and minocycline.

Clinical evidence

(a) Doxycycline

A man on long-term treatment with lithium carbonate became confused within a day of starting to take doxycycline 100 mg twice daily. By the end of a week he had developed symptoms of lithium toxicity (ataxia, dysarthria, worsened tremor, fatigue, etc.). His serum-lithium levels had risen from a range of 0.8 to 1.1 mmol/L up to 1.8 mmol/L; his renal function remained normal. He recovered when the doxycycline was withdrawn.¹

(b) Minocycline

A case report describes pseudotumor cerebri in an obese 15-year-old girl taking lithium, 4 months after she started taking minocycline 75 mg twice daily for acne.²

(c) Tetracycline

An isolated report describes a woman, who had been taking lithium for 3 years, with serum levels within the range of 0.5 to 0.84 mmol/L. Within 2 days of starting to take a sustained-release form of tetracycline (*Tetrabid*) her serum-lithium levels had risen to 1.7 mmol/L, and 2 days later they had further risen to 2.74 mmol/L. By then she showed clear symptoms of lithium toxicity (slight drowsiness, slurring of the speech, fine tremor and thirst).³

In contrast, 13 healthy subjects taking lithium carbonate 450 mg twice daily or 900 mg once daily had a small reduction in serum-lithium levels (from 0.51 to 0.47 mmol/L) when they were given tetracycline 500 mg twice daily for 7 days.⁴ The incidence of adverse reactions remained largely unchanged, except for a slight increase in CNS and gastrointestinal adverse effects.

Mechanism

Not understood. One suggested reason for increased serum-lithium levels is that tetracycline (known to have nephrotoxic potential) may have adversely affected the renal clearance of lithium.³

Importance and management

These adverse interaction reports are isolated and unexplained. Two reports make the point that these drugs are commonly used for acne caused by lithium,^{1,5} so any common interaction resulting in raised lithium levels would be expected to have come to light by now. The case of pseudotumor cerebri also appears rare, but note that the female gender and obesity are risk factors for its development and so greater caution may be warranted in this type of patient.² The authors advise frequent enquiry about headaches and visual changes.

There would seem to be no reason for avoiding the concurrent use of lithium and tetracycline, doxycycline or minocycline, but be aware of the potential for a rare interaction. Consider also 'Lithium + Antibacterials', p.1113.

Lithium + Antidepressants; Mirtazapine

No pharmacokinetic or pharmacodynamic interactions appeared to occur between lithium and mirtazapine in one study in healthy subjects.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind, crossover study, 12 healthy subjects were given lithium carbonate 600 mg daily or placebo for 10 days, with a single 30-mg dose of mirtazapine on day 10. The pharmacokinetics of both mirtazapine and lithium were unaltered by concurrent use. In addition, no

pharmacodynamic changes, as studied by psychometric testing, were identified.¹

1. Sitsen JMA, Voortman G, Timmer CJ. Pharmacokinetics of mirtazapine and lithium in healthy male subjects. *J Psychopharmacol* (2000) 14, 172–6.

Lithium + Antidepressants; Nefazodone

No pharmacokinetic interaction occurs between lithium and nefazodone.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, nefazodone 200 mg twice daily was given alone for 5 days. After a washout period, lithium was given for 11 days, in escalating doses from 250 mg twice daily to 500 mg twice daily. When therapeutic steady-state lithium levels were achieved nefazodone 200 mg twice daily was added for 5 days. The pharmacokinetics of both nefazodone and lithium were unaltered by concurrent use, although there were some small changes in the pharmacokinetics of the nefazodone metabolites. However, since the combination was well tolerated, no dosage adjustments were considered necessary on concurrent use.¹

Lithium + Antidepressants; SSRIs

The concurrent use of lithium and SSRIs can be advantageous and uneventful, but various kinds of neurotoxicities have occurred in some patients. Isolated reports describe the development of symptoms similar to those of the serotonin syndrome in patients taking lithium and fluoxetine, fluvoxamine, paroxetine and possibly citalopram. In addition, increases and decreases in serum-lithium levels have been seen with fluoxetine.

Clinical evidence

(a) Citalopram

No pharmacokinetic changes were seen in one study in 8 healthy subjects when lithium 30 mmol/day (as lithium sulfate 1.98 g daily) was added to citalopram 40 mg daily.¹ Another study, in 24 patients who had previously not responded to citalopram alone, found that the concurrent use of citalopram 40 or 60 mg and lithium carbonate 800 mg daily was effective and did not increase adverse effects.² Even so, the manufacturers of citalopram suggest that concurrent use should be undertaken with caution, as they are aware of reports of enhanced serotonergic effects when lithium and SSRIs are used together.^{3,4}

For a report of the serotonin syndrome in a patient with bipolar affective disorder treated with lithium, citalopram and olanzapine, see 'Olanzapine + Lithium', p.756.

(b) Fluoxetine

A woman with bipolar affective disorder, successfully maintained for 20 years on lithium carbonate 1.2 g daily, developed stiffness of her arms and legs, dizziness, unsteadiness in walking and speech difficulties within a few days of starting fluoxetine 20 mg daily. Her serum-lithium levels had risen from a range of 0.75 to 1.15 mmol/L up to 1.7 mmol/L. The lithium dosage was reduced to 900 mg daily and the fluoxetine withdrawn. Within 7 days, the toxic symptoms had disappeared and the lithium levels had fallen to 0.9 mmol/L.⁵ Two other patients had increases in serum-lithium levels of about 45 and 70% (but no lithium toxicity) about a month after starting fluoxetine 20 or 40 mg daily, respectively. The problem resolved when the lithium dosage was reduced by 40 and 30%, respectively, and in the second case, the fluoxetine was withdrawn. Both patients also developed mania, either after readjustment of the lithium dose or during the combined treatment.⁶ The US manufacturer of fluoxetine⁷ says that concurrent use of these two drugs has resulted in both increased and decreased serum-lithium concentrations.

Toxicity (confusion, ataxia, coarse tremor, incoordination, movement disorders, fever) was seen in a patient when lithium was added to fluoxetine treatment, although the serum-lithium levels remained within the therapeutic range.⁸ A woman maintained on clonazepam and then started on fluoxetine 20 mg then 40 mg daily, developed tremor and ataxia 6 days af-

ter lithium carbonate 100 mg increased to 400 mg daily was added. The problems resolved when the lithium and fluoxetine were withdrawn.⁹ Extrapyramidal effects and ataxia were seen in one patient on lithium and fluoxetine, and dystonia in another patient who was also taking carbamazepine, captopril and trimipramine.¹⁰ The development of the serotonin syndrome is also reported to have occurred in 2 patients on lithium and fluoxetine.^{11,12} Heat stroke developed in a man on lithium and fluoxetine, attributed to synergistic impairment of his temperature regulatory system by the two drugs.¹³ Absence seizures occurred in another patient given both drugs.¹⁴

(c) Fluvoxamine

A woman taking fluvoxamine became somnolent within a day of starting lithium. The lithium level 20 hours after the last dose was 0.2 mmol/L. She recovered when both drugs were stopped and she was discharged on lithium alone. The excessive somnolence was considered to have been possibly caused by increased serotonin levels caused by this drug combination.¹⁵ A woman on long-term lithium treatment was started on fluvoxamine 50 mg daily, increased to 200 mg daily over 10 days. She gradually developed tremor, difficulties in making fine hand movements, impaired motor co-ordination and hyperreflexia. Serum lithium-levels remained therapeutic throughout. The reaction was interpreted as a mild form of the serotonin syndrome.¹⁶

The Committee on Safety of Medicines in the UK had received 19 reports of adverse reactions when fluvoxamine was given with lithium (5 reports of convulsions and one of hyperpyrexia) by 1989.¹⁷

In contrast to these reports, a study in 6 patients found that lithium (dosed to achieve plasma levels of 0.3 to 0.65 mmol/L) and fluvoxamine 100 to 150 mg daily (for between 3 and 23 weeks) was safe and effective, and no adverse interaction of any kind occurred.¹⁸ Another study in 6 depressed patients found that lithium did not affect the pharmacokinetics of fluvoxamine 100 mg daily and combined use was more effective than fluvoxamine alone.¹⁹ It would seem therefore that concurrent use can be valuable, but there is a clear need to monitor the outcome so that any problems can be quickly identified.

(d) Paroxetine

A study in 14 patients taking lithium found that tremor increased significantly when paroxetine 20 to 40 mg daily was added. The greatest increments occurred approximately 3 weeks after combined treatment was started, but tremor activity was still significantly greater than baseline after 6 weeks. No patient discontinued treatment because of the increase in tremor.²⁰

A 59-year-old woman with a long-standing bipolar disorder who had taken paroxetine 10 mg increased to 30 mg daily for 3 weeks, developed symptoms suggestive of the serotonin syndrome (shivering, tremor of her arms and legs, flushed face, agitation, and some impairment of mental focussing) after lithium 400 mg daily was added.²¹ Her serum lithium and paroxetine levels were found to be 0.63 mmol/L and 690 nanograms/mL respectively (the latter being sixfold higher than the upper levels seen in other patients). The paroxetine dosage was reduced to 10 mg daily, which decreased the serum levels to 390 nanograms/mL, whereupon she became symptom-free and her depression was relieved. It is not clear whether this reaction was due to an interaction or not as she never took the higher dose of paroxetine in the absence of lithium.

There is a report of seizures, unsteady gait and blurred speech in a patient with bipolar disorder and cystic fibrosis taking lithium and paroxetine; both drugs were discontinued. However, this patient was abusing oxycodeone and clonazepam and was also on a variety of anti-asthma medications (salbutamol, salmeterol, budesonide, montelukast and cromoglicic acid), so the exact cause of the seizures is unclear.²²

(e) Sertraline

In a randomised, placebo-controlled study, 16 healthy subjects were given lithium 600 mg twice daily for 9 days. On day 8, half of the subjects received two 100-mg doses of sertraline 8 hours apart, while the other half received placebo. Sertraline caused a statistically insignificant fall of 1.4% in steady-state lithium levels, and a statistically insignificant rise in renal lithium excretion. However, there was a high incidence of adverse effects (mainly tremor and nausea) with the combined treatment: tremor occurred in 7 out of the 8 taking sertraline, whereas no adverse effects were reported in the placebo group.²³

Severe priapism occurred in a patient taking lithium carbonate 600 mg daily within 2 weeks of having the dosage of sertraline increased from 50 to 100 mg daily. It was not clear whether this was purely a reaction to

the increased sertraline dosage, although it was suggested that the effect may have been due to the serotonergic effects of both drugs.²⁴

The UK manufacturer of sertraline suggests that reports of increased tremor indicate a possible pharmacodynamic interaction, and therefore they advise caution if both drugs are used.²⁵

Mechanism

Not fully understood although it seems likely that many of the symptoms could be due to the effects of both lithium and SSRIs on serotonin.

Importance and management

Concurrent use can be uneventful. A review of the safety of the combined use of lithium and the SSRIs identified 503 subjects who had received the combination without any evidence of serious adverse events.²⁶ However, occasionally and unpredictably adverse reactions develop, but the precise incidence is not known. Most manufacturers of the SSRIs, and the US manufacturers of lithium,²⁷ suggest that the combination of lithium and the SSRIs should be used with caution, and patients should be monitored closely. The UK manufacturers of lithium say that the combination may precipitate a serotonergic syndrome,^{28,29} which justifies immediate discontinuation of treatment.²⁸

If lithium is used in conjunction with an SSRI be alert for any evidence of toxicity. The symptoms may include tremor, dysarthria, ataxia, confusion, and many other symptoms of the serotonin syndrome. Heat stroke has also been seen and the serum-lithium levels may rise. It would clearly be prudent to monitor concurrent use carefully. For more information on the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

Lithium + Antidepressants; Tricyclic and related

The concurrent use of a tricyclic antidepressant and lithium can be successful in some patients, but others may develop adverse effects, a few of them severe. Cases of neurotoxicity, the serotonin syndrome and the neuroleptic malignant syndrome have been reported.

Clinical evidence

A study in 14 treatment-resistant depressed patients aged between 61 and 82 found that 7 showed complete improvement and 3 showed partial improvement, 3 to 21 days after lithium was added to treatment with the tricyclic or related antidepressants. Lithium adverse effects occurred in 6 patients; 4 of whom stopped lithium as a result. One of them was successfully restarted at a lower dose. Tremor was the most frequent adverse effect, and reversible neurotoxicity with a stroke-like syndrome was the most severe. The antidepressants used were **amitriptyline**, **doxepin**, **maprotiline** and **trazodone**.¹ A meta-analysis of 9 studies on the acute treatment of unipolar or bipolar depression indicated that the combined use of a mood stabiliser (lithium in 6 studies) and a tricyclic antidepressant was associated with an increased risk of switches into (hypo)mania, when compared with a mood stabiliser alone. It was suggested that monotherapy with a mood stabiliser should be tried to see if it is effective, before adding an antidepressant. Tricyclics were considered to be second-line antidepressants, with SSRIs the preferred choice.²

Reports relating to specific tricyclics are outlined below.

(a) Amitriptyline

A study in 17 lithium-maintained patients found that tremor increased significantly when amitriptyline 75 to 150 mg daily was added. The greatest increments occurred within approximately 3 weeks of starting the combined treatment, but tremor activity was still significantly greater than baseline after 6 weeks. No patient discontinued treatment because of the increase in tremor.³ Seizures occurred in a patient on amitriptyline 300 mg daily, 13 days after lithium carbonate 300 mg three times daily was started. After recovery, combined therapy was resumed, but further seizures occurred 10 days later. Her lithium levels were 0.9 mmol/L three days before this second episode. She later took amitriptyline 500 mg daily without adverse effect.⁴ Another patient developed neuroleptic malignant syndrome after one week of treatment with lithium carbonate 300 mg and amitriptyline 25 mg, both three times daily. The patient had also received chlorpromazine for one week, just before the lithium-antidepressant therapy was started.⁵ No pharmacokinetic interaction was found in 10 therapy-resistant patients with major depression who were given amitriptyline and lithium for 4 weeks.⁶

(b) Clomipramine

A depressed man taking clomipramine 175 mg, levomepromazine 25 mg and flunitrazepam 2 mg daily, was started on lithium 600 mg daily. About one week later, after his dosage of lithium was raised to 1 g daily and he developed the serotonin syndrome (myoclonus, shivering, tremors, incoordination). Due to this reaction, and because his serum-lithium levels were 1.6 mmol/L, the lithium was stopped. The serotonin syndrome then abated. The clomipramine dosage was reduced, but some mild symptoms remained until the clomipramine was stopped. He responded well to lithium 600 mg daily alone, without developing the serotonin syndrome.⁷

(c) Doxepin

A 64-year-old man developed periods of confusion and disorientation within 2 weeks of starting to take lithium 300 mg twice daily with doxepin 100 mg at bedtime. He was admitted to hospital because of urinary retention, and he was also lethargic and became confused, but despite the withdrawal of both drugs he developed a condition similar to the neuroleptic malignant syndrome (fever, muscle rigidity, changes in consciousness, autonomic dysfunction), which was successfully treated with dantrolene.⁸

(d) Nortriptyline

A 65-year-old woman developed tremor, memory difficulties, disorganised thinking and auditory hallucinations when given lithium carbonate

300 mg twice daily (lithium level 0.82 mmol/L) and nortriptyline 50 mg daily. However, because she only ever received lithium with nortriptyline, the possibility that this was an effect of lithium alone cannot be excluded.⁹

Mechanism

Not fully understood. Tremor is a relatively frequent adverse effect of both lithium and antidepressants with serotonergic properties. It might be expected that combinations of lithium (which is itself serotonergic) with such antidepressants will enhance not only efficacy, but also increase the incidence of adverse effects.³ For more information about the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

Importance and management

The concurrent use of lithium and tricyclics can be valuable, but the reports cited here clearly show the need to monitor the outcome closely so that any problems can be dealt with quickly. The incidence of these serious reactions is not known.

Lithium + Antidepressants; Venlafaxine

Symptoms similar to those of the serotonin syndrome have developed in a few patients taking lithium with venlafaxine. No clinically significant pharmacokinetic interaction appears to occur between these two drugs.

Clinical evidence, mechanism, importance and management

In an open study of 13 major depressive patients who did not respond to a 4-week course of venlafaxine 300 mg daily, lithium was added and continued for 4 weeks. After 12 days of combined treatment, 2 patients experienced symptoms of hypomania, marked nausea and trembling (considered to be a moderate form of the serotonin syndrome), and had to stop lithium treatment. Their lithium-plasma levels were within the therapeutic range (0.83 and 0.77 mmol/L on day 7). Lithium was well tolerated by most of the other patients, with trembling being the most frequent adverse effect (4 out of 11).¹

A case report describes a 50-year-old woman who developed the serotonin syndrome 45 days after starting to take lithium and venlafaxine (and within 10 days of the most recent dose increase of venlafaxine). Both drugs were immediately stopped and she recovered over the next 4 to 5 days. Plasma levels of venlafaxine, its metabolite *O*-desmethylvenlafaxine (ODV), and lithium had remained within the normal therapeutic range throughout. As she had previously experienced profound adverse effects with two different SSRIs, the authors concluded that the patient was unusually sensitive to serotonergic medication.²

In a pharmacokinetic study, 12 healthy subjects were given a single 600-mg dose of lithium carbonate on day 1 and day 8, with venlafaxine 50 mg every 8 hours for 7 days from day 4. The renal clearance of venlafaxine was reduced by about 50% and that of its active metabolite ODV was reduced by 15%. Neither of these changes was considered clinically relevant, as the total clearance was not affected. The maximum serum levels of the lithium were increased by about 10%, and the time to reach this was reduced by about 30 minutes, but these changes met the criteria for bioequivalence, and the other pharmacokinetic parameters of lithium were unchanged.³ The general picture that emerged was that no clinically important pharmacokinetic interaction normally occurs if these two drugs are used together.

There seems to be no good reason for avoiding concurrent use, but be aware that an interaction is possible and monitor the outcome carefully. For more information about the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

Lithium + Antiepileptics; Carbamazepine

Although the combined use of lithium and carbamazepine is beneficial in many patients, it may increase the risk of neurotoxicity. Sinus node dysfunction has also occurred in a few patients. An isolated report describes a patient who had a marked rise in lithium levels and lithium toxicity, which was apparently caused by carbamazepine-induced renal impairment.

Clinical evidence

(a) Neurotoxicity with normal drug levels

A patient taking lithium 1.8 g daily developed severe neurotoxicity (ataxia, truncal tremors, nystagmus, limb hyperreflexia, muscle fasciculation) within 3 days of starting to take carbamazepine 600 mg daily. Blood levels of both drugs remained within the therapeutic range. The symptoms resolved when each drug was withdrawn in turn, and re-occurred within 3 days of restarting concurrent treatment.¹ Five patients with rapid-cycling bipolar disorder developed similar neurotoxic symptoms (confusion, drowsiness, generalised weakness, lethargy, coarse tremor, hyperreflexia, cerebellar signs) when they were given lithium carbonate with carbamazepine [doses not stated]. Plasma levels of both drugs remained within the accepted range.² Other reports describe adverse neurological effects during the concurrent use of lithium and carbamazepine, which were also not accompanied by significant changes in lithium levels,^{3–7} although in one patient raised serum levels of both drugs were seen.⁸ A systematic search through the Medline database, for reports of neurotoxic adverse effects in patients taking lithium at low therapeutic concentrations, found a total of 41 cases over approximately 30 years from 1966. Carbamazepine had been taken concurrently in 22% of these cases, in some instances with other potentially interacting drugs.⁹ Another retrospective study of 46 type I bipolar patients found significant benefits of long-term combined lithium and carbamazepine therapy compared with monotherapy with lithium (31 patients) or carbamazepine (15). However, rates of adverse effects increased 2.5-fold compared with monotherapy, and there were particular excesses of tremor and drowsiness.¹⁰

In other patients the combined use of lithium and carbamazepine was said to be well tolerated and beneficial,^{11,12} but one report suggests that the dosages may need to be carefully titrated to avoid adverse effects.¹³

(b) Sinus node dysfunction

A 9-year study in a psychiatric hospital found that, of 5 patients on lithium who developed sinus node dysfunction, 4 were also on carbamazepine.¹⁴

(c) Toxic lithium levels

An isolated case report describes carbamazepine-induced acute renal failure, which resulted in a 3.5-fold rise in lithium levels and lithium toxicity 3 weeks after carbamazepine was started.¹⁵

Mechanism

Not understood. A paper that plotted the serum levels of lithium and carbamazepine on a two-dimensional graph failed to find any evidence of synergistic toxicity.¹⁶ Sinus node dysfunction can be caused by either lithium or carbamazepine, but this is rare. However, the effects may possibly be additive.

Importance and management

The neurotoxic interaction is established, but its incidence is not known. The incidence of severe neurotoxicity may be quite small, but increased mild adverse events such as tremor and drowsiness seem to be fairly common.¹⁰ The authors of one paper suggest that the risk factors appear to be

a history of neurotoxicity with lithium, and compromised medical or neurological function.² If concurrent use is undertaken, the outcome should be closely monitored. This is particularly important because neurotoxicity can develop even though the levels remain within the accepted therapeutic range. If severe neurotoxicity develops the lithium treatment should be discontinued promptly, whatever the lithium level.⁹

Lithium + Antiepileptics; Gabapentin

Gabapentin did not alter the pharmacokinetics of single-dose lithium in patients with normal renal function.

Clinical evidence, mechanism, importance and management

In a double-blind study, 13 patients with normal renal function were given a single 600-mg dose of lithium either with or without gabapentin at steady state. Gabapentin did not significantly alter the pharmacokinetics of the lithium, and no increase in adverse effects was noted. More long-term studies will be needed to confirm this lack of interaction, especially in patients with impaired renal function as both drugs are eliminated by renal excretion.¹

Lithium + Antiepileptics; Lamotrigine

Lamotrigine does not appear to cause a clinically significant alteration in lithium levels. Cognitive adverse effects have been reported in one patient taking the combination.

Clinical evidence, mechanism, importance and management

In an open, randomised, two-period, crossover study, 20 healthy men were given 2 g of anhydrous lithium gluconate (9.8 mmol of lithium) every 12 hours for 11 doses, either with or without lamotrigine 100 mg daily. It was found that the serum-lithium levels were decreased by about 8% by lamotrigine, but these small changes were not considered to be clinically relevant.¹

A 2002 review of the few published reports on the use of lithium with lamotrigine suggested that the combination appears to be well tolerated.² However, one woman taking lithium who had been treated with lamotrigine 50 mg for 4 weeks, experienced delirium when the dose of lamotrigine was increased to 150 mg daily. The symptoms disappeared when the lamotrigine dose was reduced to 100 mg daily.³ It is not clear whether these effects were directly caused by the combination of lithium and lamotrigine. However; the author of the review considered that if cognitive ad-

verse effects occur, it might be worth considering a reduction in the dose of either or both drugs.² More study is needed.

Lithium + Antiepileptics; Phenytoin

Symptoms of lithium toxicity (sometimes with unchanged lithium levels) have been seen in a few patients concurrently treated with phenytoin, although the interaction has not been clearly demonstrated.

Clinical evidence, mechanism, importance and management

A patient with a history of depression and convulsions was treated with increasing doses of lithium carbonate and phenytoin over a period of about 4 years. Although the serum levels of both drugs remained within the therapeutic range, he eventually began to develop symptoms of lithium toxicity (thirst, polyuria, polydipsia and tremor) that disappeared when the lithium was stopped. Later, when lithium was restarted, the symptoms returned, this time abating when the phenytoin was replaced by carbamazepine. The patient then claimed that he felt normal for the first time in years.¹ Another report describes symptoms of lithium toxicity in a patient with lithium levels within the normal range. This patient was also taking phenytoin.²

In a further case³ a man taking phenytoin became ataxic within 3 days of starting to take lithium. He had no other toxic symptoms and his serum-lithium level was 2 mmol/L. However, as he only ever took lithium in the presence of phenytoin, it is not possible to say whether the effects were as a result of an interaction, or whether toxic levels would have occurred with the lithium alone. Another similar case has also been reported.⁴

Information seems to be limited to these reports and none of them presents a clear picture of the role of phenytoin in the reactions described.^{1–4} The interaction is not well established. Patients taking lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given phenytoin. Increased serum lithium monitoring does not appear to be of value in this situation as the interaction occurred in patients with lithium levels within the normally accepted range.

Lithium + Antiepileptics; Topiramate

Two isolated reports describe elevated serum-lithium levels and evidence of toxicity in patients also taking topiramate. No important pharmacokinetic interaction has been seen in healthy subjects.

Clinical evidence, mechanism, importance and management

A 42-year-old woman with type II bipolar disorder was started on lithium carbonate 1.5 g and topiramate 500 mg daily, resulting in a steady-state trough serum-lithium level of 0.5 mmol/L after 10 days. She was also started on citalopram 10 mg daily. The patient raised the topiramate dose to 800 mg daily in an attempt to lose weight, and 5 weeks later began to complain of severe anorexia, nausea, fatigue and impaired concentration. She had managed to lose 35 lb (almost 16 kg) of weight she had gained whilst on a previous drug combination. When examined she was lethargic, with tremors, nystagmus, bradycardia and memory loss. Her trough serum-lithium level had risen by 180% to 1.4 mmol/L. The symptoms disappeared over 4 days when the lithium was stopped. Two months later she was stabilised once again on lithium carbonate 1.2 g and topiramate 500 mg daily, with a steady-state serum-lithium level of 0.5 mmol/L.¹ Another report describes a case of increased lithium levels and toxicity (worsening concentration, confusion, lethargy) after topiramate was added to

lithium therapy. The lithium was stopped and then restarted at half the original dose, which produced therapeutic lithium levels of 0.67 mmol/L. In addition, while maintaining the dose of lithium at 450 mg daily, further increases in the topiramate dose from 75 to 125 mg daily over 4 weeks resulted in parallel elevations of lithium levels (from 0.67 to 0.92 mmol/L).²

However, a review of the pharmacokinetic interactions of topiramate reported a study that had found that there was little pharmacokinetic interaction with lithium when topiramate (50 mg twice daily titrated to 100 mg twice daily) was given to 12 healthy subjects receiving lithium carbonate 300 mg three times daily. The AUC of lithium was about 18% lower and the clearance 21.7% higher. When compared with historical data, the clearance of topiramate appeared to be lower.³

The reasons for these reactions are not known, but topiramate is mainly eliminated by renal excretion and high doses of topiramate may competitively interfere with lithium excretion.¹ Similarly, lithium may affect topiramate clearance.³ Some of the toxicity could have been due to the adverse effects of either drug, with the weight loss in the first case possibly disturbing the sodium excretion, which could have affected the loss of lithium in the urine.

These cases highlight the possible risk of elevated serum-lithium levels especially if high doses of topiramate are used. Patients on lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given topiramate. Consider monitoring lithium levels in patients newly started on this combination and carefully adjusting the dose of topiramate and/or lithium to minimise adverse effects.^{4,5}

Lithium + Antiepileptics; Valproate

No clinically relevant adverse interaction appears to occur between lithium carbonate and valproate.

Clinical evidence, mechanism, importance and management

In a crossover study, 16 healthy subjects were given valproate (as valproate semisodium) or a placebo twice daily for 12 days, to which lithium carbonate 300 mg three times daily was added on days 6 to 10. The valproate-serum levels and AUC rose slightly, while the serum-lithium levels were unaltered. Adverse events did not change significantly. It was concluded that the concurrent use of these drugs is safe.¹ A review on the efficacy of lithium/anticonvulsant combinations in bipolar disorder lists several studies in which the combination of valproate (as valproate semisodium) and lithium was used. On the whole the combination was considered safe and well tolerated, although a few patients discontinued treatment due to adverse effects, which included gastrointestinal symptoms and raised liver transaminases. It was, however, difficult to know if these adverse effects were due to the individual drugs or the result of an interaction. Other adverse effects that have been reported with the combined treatment include tremor, cognitive impairment and alopecia.²

Lithium + Aspirin or other Salicylates

No clinically significant pharmacokinetic interaction appears to occur between aspirin, lysine aspirin and sodium salicylate and lithium.

Clinical evidence, mechanism, importance and management

In a steady-state study 10 healthy women with average plasma-lithium levels of 0.63 mmol/L had a slight 6% rise in their renal excretion of lith-

ium when they were given aspirin 1 g four times daily for 7 days. However, no statistically significant alteration in lithium levels was found.¹

No change in serum lithium levels was seen in 7 patients taking lithium when they were given aspirin 975 mg four times daily for 6 days.² Another report states that aspirin 600 mg four times daily had no effect on the absorption or renal excretion of single doses of lithium carbonate given to 6 healthy subjects.³ Further reports describe no change in serum lithium levels with **lysine aspirin**,⁴ intravenous aspirin,⁵ or intravenous **sodium salicylate**.⁵ However, lithium clearance was slightly reduced by 22% by intravenous **sodium salicylate**,⁵ and a study in one healthy subject found a 32% increase in mean serum-lithium levels from 0.41 to 0.54 mmol/L after 5 days of oral aspirin treatment (975 mg four times daily for 2 days, then 650 mg four times daily for 3 days).⁶

Lithium + Baclofen

The hyperkinetic symptoms of two patients with Huntington's chorea were aggravated within a few days of starting concurrent lithium and baclofen. One patient took lithium first, the other baclofen.

Clinical evidence, mechanism, importance and management

A patient with Huntington's chorea, treated with lithium and haloperidol, was additionally given baclofen, and another patient being treated with imipramine, clopenthixol, chlorpromazine and baclofen was additionally given lithium. Within a few days both patients showed a severe aggravation of their hyperkinetic symptoms, which disappeared within 3 days of withdrawing the baclofen.¹ Other patients with Huntington's chorea showed no major changes in their mental state or movement disorders when given up to 90 mg of baclofen daily,^{2,3} which suggests that an interaction with lithium may have been the cause of the hyperkinesia in these two patients. On the basis of this very limited evidence it would seem prudent to monitor the effects of concurrent use and consider stopping one of the drugs if hyperkinesia develops.

Lithium + Benzodiazepines

Neurotoxicity and increased serum-lithium levels were reported in five patients when clonazepam was added to treatment with lithium. An isolated case of serious hypothermia has been reported during the concurrent use of lithium and diazepam. Alprazolam seems unlikely to cause a clinically important rise in serum-lithium levels.

Clinical evidence, mechanism, importance and management

(a) Alprazolam

Alprazolam 2 mg daily for 4 days slightly increased the steady-state AUC of lithium by about 8% and reduced its urinary recovery from 93.6 to 78.2% in 10 healthy subjects taking lithium 900 mg to 1.5 g daily. It was suggested that these changes were unlikely to be clinically significant, but confirmation of this is needed.¹

(b) Clonazepam

A retrospective study of patient records revealed 5 patients with bipolar affective disorder, treated with lithium carbonate 900 mg to 2.4 g daily, who had developed a reversible neurotoxic syndrome with ataxia, dysarthria,

drowsiness and confusion when they were given clonazepam 2 to 16 mg daily. In one case the clonazepam was added to their antipsychotics (chlorpromazine, perphenazine, haloperidol) and in 4 cases the clonazepam replaced the antipsychotic treatment. In all cases the lithium levels rose, and in two of these cases they reached toxic levels. The authors of the report suggest that the neurotoxicity was caused either by the increase in lithium levels, or by synergistic toxicity, however, the use of antipsychotics may also have increased CNS sensitivity. It was recommended that lithium levels should be measured more frequently if clonazepam is added, and the effects of concurrent use well monitored.²

(c) Diazepam

A mentally retarded patient had occasional hypothermic episodes (below 35°C) while taking lithium and diazepam, but not while taking either drug alone. After taking lithium 1 g and diazepam 30 mg daily for 17 days, the patient's temperature fell from 35.4 to 32°C over 2 hours, and he became comatose with reduced reflexes, dilated pupils, a systolic blood pressure of 40 to 60 mmHg, a pulse rate of 40 and no piloerector response.³ The reasons for this reaction are not known. This is an isolated case and therefore concurrent use need not be avoided, but be alert for any evidence of hypothermia. There seems to be no evidence of this adverse interaction with any of the other benzodiazepines.

Lithium + Caffeine

The heavy consumption of caffeine-containing drinks may cause a small to moderate reduction in serum-lithium levels.

Clinical evidence, mechanism, importance and management

A study in 11 psychiatric patients taking lithium 600 mg to 1.2 g daily who were also regular **coffee** drinkers (4 to 8 cups daily containing 70 to 120 mg of caffeine per cup) found that when the **coffee** was withdrawn, their serum-lithium levels rose by an average of 24%, although the levels of 3 patients did not change.¹ These findings are consistent with another report of 2 patients with lithium-induced tremors that were aggravated when they stopped drinking large amounts of **coffee**. One of the patients had a 50% rise in lithium levels, and required a reduction in lithium dose from 1.5 g daily to 1.2 g daily.² An early single-dose study found that the intake of xanthines such as caffeine caused an increase in lithium excretion.³ However, another single-dose study did not find any significant changes in urinary clearance of lithium in 6 subjects given caffeine 200 mg four times daily compared with a caffeine-free control period.⁴

It is not clear exactly how caffeine affects the excretion of lithium by the renal tubules, but other xanthines have a similar effect (see 'Lithium + Theophylline', p.1129). The weight of evidence cited here suggests that although there is no need for those on lithium to avoid caffeine (**coffee, tea, cola drinks** etc.), in cases where a reduction in caffeine intake is desirable, it should be withdrawn cautiously. This is particularly important in those whose serum-lithium levels are already high, because of the risk of toxicity. When caffeine is withdrawn it may be necessary to reduce the dose of lithium. In addition, remember that there is a caffeine-withdrawal syndrome (headache and fatigue being the major symptoms) that might worsen some of the major psychiatric disorders (such as affective and schizophrenic disorders).¹

Lithium + Calcitonin (Salcatonin)

A study in 4 depressed women found that calcitonin (salcatonin) caused a small reduction in serum-lithium levels, the clinical importance of which is not known.

Clinical evidence

Prompted by the occasional observation of decreased serum-lithium levels in outpatients receiving calcitonin, a study was undertaken in 4 bipolar depressive women. The patients, who had been stable on lithium for 10 years, were additionally given salmon calcitonin (salcatonin) 100 units subcutaneously for 3 consecutive days for postmenopausal osteoporosis. It was found that their serum-lithium levels fell, on average, from 0.73 to 0.59 mmol/L. The clearance of lithium in the urine was tested in 2 of the patients, and both showed increases (9.8 and 16.2%).¹

Mechanism

Not known. Increased renal excretion and possibly some reduced intestinal absorption of the lithium have been suggested by the authors of the report.¹

Importance and management

Information seems to be limited to this study, which only lasted for 3 days. The study found only a small fall in serum-lithium levels, and did not assess the effect on the control of depression. It seems unlikely that this interaction will be clinically important in most patients, but as some patients may be affected, monitor the outcome of concurrent use, and consider monitoring lithium levels.

1. Passiu G, Bocchetta A, Martinelli V, Garau P, Del Zompo M, Mathieu A. Calcitonin decreases lithium plasma levels in man. Preliminary report. *Int J Clin Pharmacol Res* (1998) 18, 179–81.

Lithium + Calcium-channel blockers

The concurrent use of lithium and verapamil can be uneventful, but neurotoxicity (ataxia, movement disorders, tremors) with unchanged lithium levels has been reported in a few patients. Reduced and increased lithium levels have also occurred with verapamil. An acute parkinsonian syndrome and marked psychosis has been seen in at least one patient taking lithium and diltiazem. Reduced lithium clearance, and one possible case of increased lithium levels have been reported with nifedipine.

Clinical evidence

(a) Diltiazem

A woman stable on lithium for several years developed marked psychosis and parkinsonism within a week of starting to take diltiazem 30 mg three times daily.¹ An acute parkinsonism syndrome developed in a 58-year-old man within 4 days of adding 30 mg of diltiazem three times daily to his treatment with lithium and tiotixene.² However, this report has been questioned as the symptoms may have been attributable to an adverse effect of the tiotixene, and, even if the lithium toxicity was genuine, it is thought to have been more likely due to recent increases in the lithium dose, or the patient's diuretic therapy than diltiazem.³

(b) Nifedipine

In a study of patients with essential hypertension, two doses of nifedipine 20 mg did not affect single-dose lithium clearance, but nifedipine 40 to 80 mg daily for 6 and 12 weeks was found to decrease single-dose lithium clearance by 30%.⁴ A man, on lithium carbonate 1.5 g daily with a level of 0.8 mmol/L, developed ataxia and dysarthria 7 days after starting nifedipine 30 mg daily for 48 hours, then 60 mg daily. His lithium dose was reduced by 40%, but his serum-lithium level first increased to 1.1 mmol/L (about 2 weeks after starting the nifedipine), before restabilising at 0.9 mmol/L.⁵ In contrast, a patient taking lithium, who developed dysarthria and ataxia after verapamil was added to her treatment (see (c) below), was subsequently well controlled on lithium and nifedipine 40 mg daily.⁶

(c) Verapamil

A 42-year-old woman taking lithium carbonate 900 mg daily developed toxicity (nausea, vomiting, muscular weakness, ataxia and tinnitus) within 9 days of starting to take verapamil 80 mg three times daily. Her bipolar depressive disorder improved even though her serum-lithium levels remained unchanged at 1.1 mmol/L. The toxicity disappeared within 48 hours of stopping the verapamil, but her disorder worsened. The same pattern was repeated when verapamil was re-started and then withdrawn.⁷ Another 3 cases of movement disorders (including ataxia, tremors and

choreoathetosis) resulting from the concurrent use of lithium and verapamil have also been reported,^{6,8,9} two of which had documented unchanged serum-lithium levels.^{6,8} In one case the patient was restabilised by halving the dose of lithium.⁸

Conversely, a patient stable on lithium 900 mg to 1.2 g daily for over 8 years had a marked fall in his serum-lithium levels from about 1.04 to 0.5 mmol/L when he was given verapamil 80 mg four times daily. He was restabilised on approximately double the dose of lithium.¹⁰ Another patient had an increased lithium clearance when given verapamil for 3 days, and a fall in serum-lithium levels from 0.61 to 0.53 mmol/L.¹⁰

In addition to unchanged or decreased lithium levels with verapamil, one manufacturer notes that increased lithium levels have occurred.¹¹

Mechanism

Not understood. However, it has been suggested that calcium-channel blockers and lithium affect neurotransmitter production^{1,2,9} (several pathways have been described), which results in CNS sensitivity. This produces movement disorders, which are said to mimic lithium toxicity. In most of the cases mentioned above, symptoms of toxicity were present at therapeutic lithium levels, which would support this suggested mechanism.

Importance and management

The neurotoxic adverse reactions cited above for lithium and verapamil contrast with two other case reports describing uneventful concurrent use.^{12,13} Variable reports of altered serum-lithium levels have also occurred. This unpredictability emphasises the need to monitor the effects closely where it is thought appropriate to give lithium and verapamil. Only a couple of isolated reports of neurotoxicity have been reported with lithium and diltiazem, and their general relevance is uncertain, but bear them in mind in the event of an unexpected response to treatment. Some limited data suggest that nifedipine may slightly reduce lithium clearance, and the clinical relevance of this is again uncertain.

Lithium + Cisplatin

Isolated case reports describe either a fall or no alteration in serum-lithium levels in patients given cisplatin. However, note that cisplatin-induced renal impairment may cause an increase in lithium levels.

Clinical evidence, mechanism, importance and management

The serum-lithium levels of a woman taking lithium carbonate 300 mg four times daily fell, over a period of 2 days, from 1 to 0.3 mmol/L, and from 0.8 to 0.5 mmol/L, on two occasions when given cisplatin (100 mg/m² intravenously over 2 hours). To prevent cisplatin-induced renal toxicity, she was also given a fluid load over a total of 24 hours, which included one litre of sodium chloride 0.9% over 4 hours, one litre of mannitol 20% over 4 hours, and one litre of dextrose 5% in sodium chloride 0.9%. Serum-lithium levels returned to normal at the end of 2 days. No change in the control of the psychotic symptoms was seen.¹

A man had a transient 64% decrease in serum-lithium levels, without perceptible clinical consequences, during the first of four courses of cisplatin, bleomycin, and etoposide. The effect became less pronounced during the subsequent courses.² It is not clear whether the fall in serum-lithium levels in these cases was due to increased renal clearance caused by the cisplatin or the sodium load, dilution from the fluid load, or a combination of all three factors.

In contrast, one patient had no clinically significant changes in her serum-lithium levels when treated with cisplatin, but 2 months later her deteriorating renal function resulted in a rise in her serum-lithium levels.³

None of these interactions was of great clinical importance, but the authors of the first report pointed out that some regimens of cisplatin involve the use of higher doses (40 mg/m² daily) with a sodium chloride 0.9% fluid load over 5 days, and under these circumstances it would be prudent to monitor the serum-lithium levels carefully. Concurrent use should be monitored in all patients.

Lithium + Corticosteroids

Corticosteroids may disturb electrolyte balance, which in theory could affect serum-lithium levels, but there do not appear to be any reports of significant interactions.

Clinical evidence, mechanism, importance and management

A patient with systemic lupus erythematosus suffering from steroid-induced depression and moderate renal impairment was given lithium 600 mg daily and her depression improved. However, serum-lithium levels increased from 0.4 to 0.8 mmol/L within one week and the lithium treatment caused an exacerbation of a finger tremor. The lithium was discontinued and then restarted at 400 mg daily, resulting in serum levels of 0.4 mmol/L, which improved her depression and was associated with only a fine finger tremor. Three other patients with steroid-induced depression were also successfully treated with lithium.¹

One UK manufacturer warns that drugs affecting electrolyte balance, such as corticosteroids, may alter lithium excretion and should therefore be avoided,² but other manufacturers do not appear to mention this potential interaction. An early study in *rats* reported increased lithium clearance with methylprednisolone.³ The available evidence is insufficient to recommend routine monitoring. However, it may be prudent to consider monitoring lithium effects in patients with renal impairment, or other conditions pre-disposing to lithium toxicity, taking levels if early symptoms suggest a potential problem.

Lithium + Diuretics; Loop

The concurrent use of lithium carbonate and furosemide can be safe and uneventful, but serious lithium toxicity has been described. Bumetanide interacts similarly. The risk of lithium toxicity with a loop diuretic is greatly increased during the first month of concurrent use.

Clinical evidence

An analysis of 10,615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for any loop diuretic (not specifically named) were compared between these 413 hospitalised patients and 1651 control patients. For any use of a loop diuretic (54 cases and 71 controls) there was an increased relative risk of hospitalisation for lithium toxicity of 1.7. When patients who were newly started on a loop diuretic were

analysed (12 cases and 6 controls), a dramatically increased risk of lithium toxicity within a month of initiating treatment was found (relative risk 5.5).¹ Reports relating to specific named loop diuretics are discussed below.

(a) Bumetanide

Bumetanide has been responsible for the development of lithium toxicity in 2 patients,^{2,3} one of whom was on a salt-restricted diet.³

(b) Furosemide

Six healthy subjects stabilised on lithium carbonate 300 mg three times daily (mean serum levels 0.43 mmol/L) were given furosemide 40 mg daily for 14 days. Five experienced some minor adverse effects, probably attributable to the furosemide, without significant changes in serum-lithium levels, but one subject experienced such a marked increase in the toxic effects of lithium that she withdrew from the study after taking both drugs for only 5 days. Her serum-lithium levels were found to have risen from 0.44 to 0.71 mmol/L.⁴

There are another 4 case reports of individual patients who experienced serious lithium toxicity or other adverse reactions when given lithium and furosemide.^{5–8} One of the patients was also on a salt-restricted diet,⁵ which has also been implicated in episodes of lithium toxicity, see 'Lithium + Sodium compounds', p.1128. In contrast, 6 patients who had been stabilised on lithium for over 6 years had no significant changes in their serum-lithium levels over a 12-week period while taking furosemide 20 to 80 mg daily.⁹ Other studies in healthy subjects also found no significant changes in lithium levels when furosemide 40 or 80 mg daily was given.^{10,11}

Mechanism

Not fully understood. If and when a rise in serum-lithium levels occurs, it may be related to the salt depletion that can accompany the use of furosemide (for a more detailed explanation see 'Lithium + Sodium compounds', p.1128). As with the 'thiazide diuretics', (p.1123) such an interaction would take a few days to develop. This may explain why one study in subjects given a single dose of lithium failed to demonstrate that furosemide had any effect on the urinary excretion of lithium.¹²

Importance and management

Information seems to be limited to the reports cited. The incidence of this interaction is uncertain and its development unpredictable. It would be imprudent to give furosemide or bumetanide to patients stabilised on lithium unless the effects can be well monitored because some patients may develop serious toxicity. Patients on lithium should be aware of the symptoms of lithium toxicity (see 'Lithium', (p.1111)) and told to report them immediately should they occur. Consider increased monitoring of lithium levels in patients newly started on this combination.

Lithium + Diuretics; Potassium-sparing

There is evidence that the excretion of lithium can be increased by triamterene. In contrast, serum-lithium levels may rise if spironolactone is used. Amiloride appears not to interact. See also 'Lithium + Diuretics; Loop', above, and 'Lithium + Diuretics; Thiazide and related', p. 1123.

Clinical evidence and mechanism

(a) Amiloride

Amiloride has been found to have no significant effect on serum-lithium levels when used in the treatment of lithium-induced polyuria.^{1,2} One review briefly mentions a case report in which amiloride was successfully used as a replacement for bendroflumethiazide, which had caused lithium toxicity.³ However, some manufacturers^{4,5} suggest that, as a diuretic, amiloride reduces the renal clearance of lithium, thereby increasing the risk of lithium toxicity. There appears to be no evidence to confirm this alleged interaction.

(b) Spironolactone

One study found that spironolactone had no statistically significant effect on the excretion of lithium.⁶ Whereas, in another report, the use of spironolactone 100 mg daily was accompanied by a rise in serum-lithium levels from 0.63 to 0.9 mmol/L. The levels continued to rise for several days after the spironolactone was stopped.⁷

(c) Triamterene

Triamterene, given to a patient taking lithium while on a salt-restricted diet, is said to have led to a strong lithium diuresis.⁸ Similarly, triamterene increased lithium excretion in 8 healthy subjects.⁹

Importance and management

These diuretics have been available for a very considerable time and it might have been expected that by now any serious adverse interactions with lithium would have emerged, but information is very sparse. None of the reports available gives a clear indication of the outcome of concurrent use, but some monitoring would be a prudent precaution. Patients on lithium should be aware of the symptoms of lithium toxicity (see 'Lithium', (p.1111)) and told to report them immediately should they occur.

Lithium + Diuretics; Thiazide and related

Thiazide and related diuretics can cause a rapid rise in serum-lithium levels, leading to toxicity unless the lithium dosage is reduced appropriately. This interaction has been seen with bendroflumethiazide, chlorothiazide, chlortalidone, hydrochlorothiazide and indapamide, and potentially occurs with hydroflumethiazide. Other thiazides and related diuretics are expected to behave similarly.

Clinical evidence

A retrospective analysis of 10 615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for a thiazide-type diuretic were compared between these 413 hospitalised patients and 1651 control patients. For any use of a thiazide diuretic (16 cases and 37 controls) there was a non-significant increased relative risk of 1.3 for hospitalisation due to lithium toxicity. When treatment for patients who were newly started on a thiazide diuretic was analysed (5 cases and 6 controls), the increased relative risk of toxicity was also non-significant (1.3). The authors considered that these findings suggest that the use of thiazide diuretics and lithium may not be as hazardous as previously thought. However, the authors also suggest that another explanation is that clinicians were

aware of the potential interaction and so adjusted doses or observed patients more closely in the outpatient setting, thereby avoiding any hospitalisations for toxicity.¹

Case reports and studies for named thiazide diuretics are outlined below.

(a) Bendroflumethiazide

A study in 22 patients, who had been treated with either bendroflumethiazide 2.5 mg or hydroflumethiazide 25 mg daily for at least 2 months, found that these diuretics caused a 24% reduction in the urinary clearance of a single 600-mg dose of lithium carbonate.² There is also a case report of a roughly twofold increase in serum-lithium levels,³ and a case of lithium toxicity with a roughly threefold increase in serum-lithium levels mentioned in a review article,⁴ both following the addition of bendroflumethiazide to treatment with lithium. In a further case, lithium toxicity, with serum-lithium levels of 4.28 mmol/L was detected 3 months after the addition of bendroflumethiazide.⁵ However, this case was complicated by the presence of perindopril, which might also raise lithium levels, as has occurred with other 'ACE inhibitors', (p.1112).

In contrast to these reports, one single-dose study found that bendroflumethiazide 7.5 mg given 10 hours after lithium carbonate 600 mg had no effect on lithium clearance.⁶ However, it seems unlikely that single-dose studies will detect an interaction (see Mechanism below).

(b) Chlorothiazide

A single 300-mg dose of lithium carbonate was given to 4 healthy subjects alone and following 7 days of treatment with chlorothiazide 500 mg daily. Lithium-plasma levels were increased and lithium clearance was decreased by about 26% following chlorothiazide treatment.⁷

Lithium toxicity developed in a patient taking lithium after she was given chlorothiazide, spironolactone and amiloride.⁸ The lithium levels rose from 0.6 to 2.2 mmol/L.

A 54-year-old patient developed nephrogenic diabetes insipidus when she was treated with lithium carbonate. The addition of chlorothiazide reduced her polyuria, but resulted in an elevation in her lithium level from 1.3 to more than 2 mmol/L, with accompanying signs of toxicity. The patient was later successfully treated with chlorothiazide and a reduced dose of lithium.⁹

(c) Chlortalidone

A 58-year-old woman developed lithium toxicity within 10 days of starting chlortalidone [dose unknown].¹⁰ Her lithium levels rose from 0.8 to 3.7 mmol/L.

(d) Hydrochlorothiazide

In a placebo-controlled study, the serum-lithium levels of 13 healthy subjects taking lithium 300 mg twice daily rose by 23% (from 0.3 to 0.37 mmol/L), when they were given hydrochlorothiazide 25 mg twice daily for 5 days.¹¹ Similar results were found in another small study.¹²

In addition to these studies at least 6 cases of lithium toxicity have been seen when hydrochlorothiazide was given to patients taking lithium.^{13–17} Hydrochlorothiazide was either given with amiloride,^{13–15} spironolactone¹⁶ or triamterene.¹⁷ See also 'Lithium + Diuretics; Potassium-sparing', p.1122.

(e) Hydroflumethiazide

A study in 22 patients who had been treated with either bendroflumethiazide 2.5 mg or hydroflumethiazide 25 mg daily for at least 2 months found that these diuretics caused a 24% reduction in the urinary clearance of a single 600-mg dose of lithium carbonate.²

(f) Indapamide

A 64-year-old man developed lithium toxicity one week after starting to take indapamide 5 mg daily.¹⁸ His serum-lithium level was 3.93 mmol/L.

Mechanism

Not fully understood. The interaction occurs even though the thiazides and related diuretics exert their major actions in the distal part of the kidney tubule whereas lithium is mainly reabsorbed in the proximal part. However, thiazide diuresis is accompanied by sodium loss which, within a few days, is compensated by retention of sodium, this time in the proximal part of the tubule. Since both sodium and lithium ions are treated similarly, the increased reabsorption of sodium would include lithium as well, hence a significant and measurable reduction in its excretion.^{5,19}

Importance and management

Established, well-documented and potentially serious interactions. The rise in serum-lithium levels and the accompanying toxicity develops most commonly within about a week to 10 days,^{4,7,9-11,13,17} although it has apparently been seen after 19 days¹⁶ and even 3 months.⁵ Not every patient necessarily develops a clinically important interaction, but it is not possible to predict which patients will be affected. The lack of serious cases of toxicity in the case-control study either suggests the interaction is rare, or that appropriate precautions are used when the combination is prescribed.¹

Although only the diuretics named above have been implicated in this interaction, it seems likely that all thiazides and related diuretics will interact similarly. None of the thiazide or related diuretics should be given to patients on lithium unless the serum-lithium levels can be closely monitored and appropriate downward dosage adjustments made. The US manufacturers also say that caution should be used and serum-lithium levels monitored closely with adjustment of the lithium dosage.²⁰ One UK manufacturer says that if a thiazide diuretic has to be prescribed for a patient treated with lithium, then the lithium dosage should first be reduced, and the patient then stabilised by frequent monitoring of lithium levels. Similar precautions should be exercised on diuretic withdrawal.²¹ However, this does not seem to be in line with most other recommendations. Patients on lithium should be aware of the symptoms of lithium toxicity (see 'Lithium', (p.1111)) and told to report them immediately should they occur.

Concurrent use under controlled conditions has been advocated for certain psychiatric conditions and for the control of lithium-induced nephrogenic diabetes insipidus. A successful case is described above.⁹ It has been suggested that a 40 to 70% reduction in the lithium dose would be needed with doses of 0.5 to 1 g of chlorothiazide,^{22,23} but it would seem sensible to base any dose adjustments on individual lithium levels.

Lithium + Herbal medicines

A woman developed lithium toxicity after taking a herbal diuretic remedy. A brief report describes mania in a patient taking lithium who also took St John's wort.

Clinical evidence, mechanism, importance and management

(a) Herbal diuretics

A 26-year-old woman who had been taking lithium 900 mg twice daily for 5 months, with hydroxyzine, lorazepam, propranolol, risperidone and sertraline, came to an emergency clinic complaining of nausea, diarrhoea, unsteady gait, tremor, nystagmus and drowsiness, (all symptoms of lithium toxicity). Her lithium level, which had previously been stable at 1.1 mmol/L was found to be 4.5 mmol/L. For the past 2 to 3 weeks she had been taking a non-prescription **herbal diuretic** containing **corn silk**, **Equisetum hyemale**, **juniper**, **ovate buchu**, **parsley** and **uva ursi**, all of which are believed to have diuretic actions. The other ingredients were bromelain, paprika, potassium and vitamin B₆.¹

The most likely explanation for what happened is that the **herbal diuretic** caused the lithium toxicity. It is impossible to know which herb or combination of herbs actually caused the toxicity, or how, but this case once again emphasises that herbal remedies are not risk-free just because they are natural. It also underscores the need for patients to avoid self-medication without first seeking informed advice and supervision if they are taking potentially hazardous drugs like lithium.

(b) St John's wort (*Hypericum perforatum*)

A search of Health Canada's database of spontaneous adverse reactions identified one case in which St John's wort was suspected of inducing mania in a patient also taking lithium.² No further details were given of this case.

Lithium + Iodides

The hypothyroid and goitrogenic effects of lithium carbonate and iodides may be additive if given concurrently. Other factors such as geographical location, age and gender may also be important.

Clinical evidence

A man with normal thyroid function showed evidence of hypothyroidism after 3 weeks of treatment with lithium carbonate 750 mg to 1.5 g daily. After 2 further weeks, during which he was also treated with **potassium iodide**, the hypothyroidism became even more marked, but resolved completely within 2 weeks of the withdrawal of both drugs. This patient was studied before the potential risk of hypothyroidism with iodine was well-recognised.¹

In another study of the possible effects of iodide intake on thyroid function in 10 patients on lithium therapy, 3 to 5 weeks of **potassium iodide** caused hypothyroidism in 2 patients and hyperthyroidism in one. Little effect on thyroid function was seen in 5 control patients given **potassium iodide** without lithium.² A case of hypothyroidism involving lithium and a product containing **isopropamide iodide** plus haloperidol (*Vesalium*) has also been reported.^{3,4}

Mechanism

Lithium accumulates in the thyroid gland and blocks the release of the thyroid hormones by thyroid-stimulating hormone, and can therefore cause clinical hypothyroidism.^{1,5-12} The prevalence of hypothyroidism may be higher in women, in middle-age,¹² and in countries with a higher level of nutritional iodine.¹³ Potassium iodide temporarily prevents the production of thyroid hormones but, as time goes on, synthesis recommences. Thus, both lithium and iodide ions can depress the production or release of the hormones and therefore have additive hypothyroid effects.

Importance and management

The pharmacological interaction of altered thyroid function with lithium and iodides would appear to be established. However, the clinical use of iodides is now very limited (mostly to the pre-operative treatment of thyrotoxicosis). It is therefore unlikely that iodides will be used in patients on lithium. Where countries are adopting iodization programmes to prevent iodine deficiency, there may be an increased risk of clinical hypothy-

roidism in patients taking lithium.¹³ Lithium-induced hypothyroidism can be treated with thyroxine replacement.

Lithium + Ispaghula (Psyllium)

In an isolated case, the withdrawal of ispaghula husk resulted in an increase in lithium levels. Psyllium slightly reduced the absorption of lithium in a study in healthy subjects.

Clinical evidence

A 47-year-old woman recently started on lithium was found to have blood-lithium levels of 0.4 mmol/L five days after an increment in her lithium dose and whilst also taking one teaspoonful of ispaghula husk twice daily. The ispaghula husk was stopped 3 days later and lithium levels measured 4 days later were found to be 0.76 mmol/L.¹

A study in 6 healthy subjects similarly showed that the absorption of lithium (as measured by the urinary excretion) was reduced by about 14% by psyllium.²

Mechanism

Not understood. One idea is that the absorption of the lithium from the gut is reduced.^{1,2}

Importance and management

Information is very limited and the general importance of this interaction is uncertain, but it would now seem prudent to bear this interaction in mind in patients given ispaghula or psyllium preparations. If an interaction is suspected consider monitoring lithium levels and separating the administration of the two drugs by at least an hour, or use an alternative laxative.

Lithium + Mazindol

An isolated report describes a case of lithium toxicity, which was attributed to the concurrent use of mazindol.

Clinical evidence, mechanism, importance and management

A bipolar depressive woman, stabilised on lithium carbonate, showed signs of lithium toxicity (sluggishness, ataxia) within 3 days of starting to take mazindol 2 mg daily. After 9 days she developed twitching, limb rigidity and muscle fasciculation, and was both dehydrated and stuporose. Her serum-lithium levels were found to have risen from a range of 0.4 to 1.3 mmol/L up to 3.2 mmol/L. The mazindol was stopped, and she recovered over the next 48 hours whilst being rehydrated.¹ It is not known whether this was a direct interaction between the two drugs, but the authors suggest that the anorectic effect of mazindol led to this toxicity [i.e. the reduced intake of sodium and water caused a reduction in the renal excretion of lithium]. There seem to be no other reports of interactions be-

tween lithium and other anorectic drugs confirming this possibility.

This is an isolated case and its general importance is uncertain, but bear it in mind in the case of an unexpected response to treatment. Note that stimulants such as mazindol are no longer generally recommended as appetite suppressants.²

Lithium + Methyldopa

Symptoms of lithium toxicity, not always associated with raised lithium levels, have been described in four patients and four healthy subjects when they were also given methyldopa.

Clinical evidence

A manic-depressive woman, taking lithium carbonate 900 mg daily was hospitalised for signs of manic decompensation and her lithium dose was increased to 1.8 g daily. When she was also given methyldopa 1 g daily for hypertension, she developed signs of lithium toxicity (blurred vision, hand tremors, mild diarrhoea, confusion, and slurred speech), even though her serum-lithium levels were within the range of 0.5 to 0.7 mmol/L. The methyldopa was then stopped and the lithium carbonate dose reduced to 1.5 g daily. Ten days later the lithium level was 1.4 mmol/L, and the lithium dose was decreased to 900 mg daily.¹ Later the author of this report demonstrated this interaction on himself.² He took lithium carbonate 150 mg four times daily for a week (lithium level 0.5 mmol/L), and then added methyldopa 250 mg every 8 hours. Within 2 days, signs of lithium toxicity had clearly developed, and the following day his lithium level had increased to 0.8 mmol/L. He then stopped the methyldopa, and about 36 hours later his lithium level was 0.7 mmol/L.

There are 3 other cases of patients who took methyldopa with lithium, and developed symptoms of lithium toxicity. In one of these cases the patient had lithium levels within the normal therapeutic range,³ but in the other two the lithium levels increased to 1.5 and 1.87 mmol/L.^{4,5} A small study in 3 healthy subjects also found that the combination of lithium and methyldopa resulted in increased confusion, sedation and dysphoria.⁶

Mechanism

Not understood. Both a central effect and an effect on renal excretion have been proposed.^{3–5}

Importance and management

Information appears to be limited to the reports cited, but the interaction would seem to be established. Avoid concurrent use whenever possible, but if this is not workable then the effects should be closely monitored. Serum-lithium measurements may be unreliable because symptoms of toxicity can occur even though the levels remain within the normally accepted therapeutic range.

Lithium + NSAIDs

NSAIDs may increase serum-lithium levels leading to toxicity, but there is great variability between different NSAIDs and also between individuals taking the same NSAID. For example, studies have found that celecoxib causes a modest 17% increase in lithium levels, yet case reports describe increases of up to 344%. Similar effects occur with other NSAIDs, and it seems likely that all NSAIDs will interact similarly. However, note that sulindac seems unique in that it is the only NSAID that has also been reported to cause a decrease in lithium levels.

Clinical evidence

A retrospective analysis of 10 615 elderly patients receiving lithium found that 413 (3.9%) were admitted to hospital at least once for lithium toxicity during a 10-year study period. The prescriptions for any NSAID were compared between these 413 hospitalised patients and 1651 control patients. For any use of an NSAID (63 cases and 187 controls) there was no increased relative risk of hospitalisation for lithium toxicity (relative risk 1.1). Similarly, when patients who were newly started on an NSAID were analysed (4 cases and 17 controls), there was still no increased risk (relative risk 0.6). The authors considered that these findings suggest that the use of NSAIDs and lithium may not be as hazardous as previously thought, although they do suggest that another explanation could be that clinicians were aware of the potential interaction, and so adjusted doses or observed patients more closely in the outpatient setting, thereby avoiding any hospitalisations for toxicity.¹

Case reports and studies about individual, named NSAIDs are outlined in the following subsections, and 'Table 31.1', (p.1127) summarises the effects of NSAIDs on lithium concentrations.

(a) Celecoxib

A 58-year-old woman, with a stable serum-lithium level of between 0.5 and 0.9 mmol/L, developed renal impairment associated with severe lithium toxicity, within 5 days of starting to take celecoxib 400 mg twice daily. Her lithium level was 4 mmol/L. Of note, and a possible contributory factor, was the presence of ibuprofen, which she had taken with her lithium for several years without incident.²

In addition to 3 of the cases in 'Table 31.1', (p.1127), a review of the FDA's Adverse Event Reporting System database in January 2003 found 2 cases of increased lithium levels and symptoms of lithium toxicity in patients who also took celecoxib.³

(b) Ibuprofen

Three patients stabilised on lithium, with plasma levels of 0.7 to 0.9 mmol/L, were given ibuprofen 1.2 or 2.4 g daily for 7 days. The serum-lithium levels of one patient rose from 0.8 to 1 mmol/L and he experienced nausea and drowsiness. The 2 other patients, including the one on the 1.2-g ibuprofen dose, did not show this interaction.⁴

Three other case reports describe patients with symptoms of lithium toxicity that occurred within 1 to 7 days of them starting to take ibuprofen 1.2 g daily.⁵⁻⁷ In another case, episodes of unsteadiness and tremor associated with raised lithium levels were attributed to varying use of prescribed ibuprofen 400 mg three times daily.⁸

(c) Indometacin

A case report describes lithium toxicity in a man given indometacin 50 mg every 6 hours. Three days after he started the indometacin his serum creatinine was raised, and 9 days later he had symptoms of lithium toxicity and was found to have a lithium levels of 3.5 mmol/L. It was suggested that the indometacin caused renal impairment, which led to lithium retention and toxicity.⁹

(d) Ketorolac

An 80-year-old man taking haloperidol, procyclidine, clonazepam, aspirin, digoxin and lithium (serum levels between 0.5 and 0.7 mmol/L) was additionally given indometacin 100 mg daily for arthritis, which was replaced, after 13 days, by ketorolac 30 mg daily. The next day his serum-lithium level was 0.9 mmol/L and 6 days later 1.1 mmol/L. Subsequently the patient developed severe nausea and vomiting, and both drugs were stopped.¹⁰

(e) Mefenamic acid

Acute lithium toxicity, accompanied by a sharp deterioration in renal function, was seen in a patient taking lithium carbonate with mefenamic acid 500 mg three times daily for 2 weeks. Withdrawal of the drugs and subsequent rechallenge confirmed this interaction.¹¹ Another case of toxicity was seen in a patient on lithium given mefenamic acid. Her renal function was impaired when the lithium was started, but it had been stable for about 6 months before the NSAID was added.¹² A brief report also mentions another case of this interaction.¹³

(f) Niflumic acid

An isolated report describes lithium toxicity in a woman who took niflumic acid (said to be three capsules daily) for 7 days with the addition of aspirin 1.5 g daily after 5 days. Her serum-lithium levels rose from 0.8 to 1.6 mmol/L.¹⁴

(g) Nimesulide

A 42-year-old woman taking lithium was given nimesulide 100 mg and ciprofloxacin 250 mg, both twice daily, for flank pain and dysuria. After 72 hours, she developed symptoms of lithium toxicity and the dose of lithium was reduced. After 98 hours she had vomiting, ataxia, and oliguria, and lithium levels were found to be 3.23 mmol/L (previous level 1.08 mmol/L) and her serum creatinine was raised.¹⁵

(h) Oxyphenbutazone

In an apparently isolated case, a 49-year-old woman is reported to have developed nausea and vomiting associated with a rise in lithium levels following the addition of oxyphenbutazone suppositories 500 mg daily. She responded well to a reduction in the lithium dosage.¹⁶

(i) Parecoxib

The manufacturers of parecoxib say that valdecoxib, the main active metabolite of parecoxib, has been shown to cause decreases in the clearance of lithium (serum clearance reduced by 25%, renal clearance reduced by 30%), resulting in a 34% increase in its serum levels. Valdecoxib pharmacokinetics were unchanged by lithium.¹⁷

(j) Piroxicam

A 56-year-old woman, stabilised for over 9 years on lithium, with levels usually between 0.8 and 1 mmol/L, experienced lithium toxicity (unsteadiness, trembling, confusion) and was admitted to hospital on three occasions after taking piroxicam. Her serum levels on two occasions had risen to 2.7 and 1.6 mmol/L, although in the latter instance the lithium had been withdrawn the day before the levels were taken. In a subsequent study her serum-lithium levels rose from 1 to 1.5 mmol/L after she took piroxicam 20 mg daily.¹⁸ Two other case reports describe lithium toxicity, which occurred 4 weeks and 4 months after piroxicam was started.^{19,20}

(k) Rofecoxib

A 73-year-old man, with lithium levels of between 0.6 and 0.9 mmol/L for the past 13 years, developed symptoms of lithium toxicity (serum-lithium level 1.5 mmol/L) within 9 days of starting to take rofecoxib 12.5 mg daily. An interaction was strongly suspected. However, it should be noted that the patient had required his lithium dose to be successively decreased over the 13 years to maintain his lithium levels within the desired range. Captopril 6.25 mg daily had also been started during this time,²¹ although it is unclear whether it had a part to play either in the lithium dose reduction or the development of an interaction.

In addition to 6 of the cases in 'Table 31.1', (p.1127), a review of the FDA's Adverse Event Reporting System database in January 2003 found 7 cases of increased serum-lithium concentrations after the addition of rofecoxib.³

(l) Sulindac

1. *Lithium levels reduced.* A patient stabilised on lithium had a marked fall in serum-lithium levels from 0.65 to 0.39 mmol/L after 2 weeks of concurrent treatment with sulindac 100 mg twice daily. Her serum-lithium levels gradually climbed over the next 6 weeks to 0.71 mmol/L and restabilised without any change in the dosage of either lithium or sulindac. She needed amitriptyline for depression while the lithium levels were low, but bouts of depression had not been uncommon, even when lithium levels were stable.²² The serum-lithium levels of another patient were approximately halved a week after his dosage of sulindac was doubled to 200 mg twice daily. He remained on both drugs, but a higher dose of lithium was needed.²²

2. *Lithium levels unaffected.* Two small studies (in a total of 10 patients)^{23,24} and a case report²⁵ found that serum-lithium levels were unaffected by the use of sulindac.

3. *Lithium levels increased.* Two patients developed increased serum-lithium levels apparently due to the use of sulindac.²⁶ In one case the lithium levels rose from 1 to 2 mmol/L after 19 days of treatment with sulindac 150 mg twice daily, and symptoms of toxicity were seen. The levels fell to 0.8 mmol/L within 5 days of stopping the sulindac. The other patient had a rise from 0.9 to 1.7 mmol/L within a week of adding sulindac 150 mg twice daily. The sulindac was continued and the lithium dosage was reduced from 1.8 to 1.5 g daily. The serum-lithium levels fell and were 1.2 mmol/L at 37 days and 1 mmol/L at 70 days. No symptoms of lithium toxicity occurred.²⁶

(m) Tiaprofenic acid

A 79-year-old woman on lithium (as well as fosinopril, nifedipine, oxazepam and haloperidol) had a rise in her trough serum-lithium levels

Table 31.1 Summary of the effects of NSAIDs on lithium levels

NSAID	Dose	Subjects	Increase in lithium levels	Time to symptoms or increase in levels	Refs
Celecoxib	200 to 800 mg daily	4 cases	56 to 248%	10 days to 10 weeks	1, 2
	200 mg twice daily	Study in healthy subjects	17%		3, 4
Diclofenac	75 mg daily	Case	86%	25 days	5
	50 mg three times daily	Study in 5 healthy subjects	26%	7 to 10 days	6
Flurbiprofen	100 mg twice daily	Placebo-controlled study in 11 otherwise healthy subjects with bipolar disorder	19%	7 days	7
Ibuprofen	1.6 to 1.8 g daily in divided doses	Studies in 11 healthy subjects and 9 subjects with bipolar disorder	12 to 67%	6 to 9 days	8, 9
Indometacin	150 mg daily	Studies in 9 healthy subjects and 6 subjects with bipolar disorder	30 to 61%	6 to 10 days	10-12
Ketoprofen	400 mg daily	Case	About 90%	3 weeks	13
Ketorolac	60 mg daily	Case	50%	3 weeks	14
	40 mg daily	Study in 5 healthy subjects	29%	5 days	15
Lornoxicam	4 mg twice daily	Study in 12 healthy subjects	20% (61% in one subject)	7 days	16
Meloxicam	15 mg daily	Study in 16 healthy subjects	21%	14 days	17
Naproxen	220 or 250 mg three times daily	Study in 9 healthy subjects and 7 bipolar or schizoaffective disorder	0 to 42%	5 to 6 days	18, 19
Phenylbutazone	750 mg daily (suppositories)	Case	106%	36 hours	20
	100 mg three times daily	Study in 5 subjects with bipolar disorder	0 to 15%	6 days	21
Piroxicam	20 mg daily	2 cases	130 to 235%	1 to 2 months	22, 23
Rofecoxib	Not stated or 25 mg once or twice daily	7 cases	58 to 448%	6 days to about 3 months	2, 24
	50 mg [daily]	Study in 10 healthy subjects	Unstated rise in 9 subjects, of these 3 were withdrawn early with levels of 1.26 mmol/L or more	Up to 5 days	25

from 0.36 to 0.57 mmol/L within 3 days of starting to take tiaprofenic acid 200 mg three times daily. The serum-lithium levels had risen to 0.65 mmol/L by the next day and, despite halving the lithium dosage, were found to be 0.69 mmol/L five days later. These rises were attributed to an interaction with the tiaprofenic acid exacerbated by the fosinopril,²⁷ see 'Lithium + ACE inhibitors', p.1112.

Mechanism

Not understood. It has been suggested that the interacting NSAIDs inhibit the synthesis of the renal prostaglandins (PGE₂) so that the renal blood flow is reduced, thereby reducing the renal excretion of the lithium. In addition, reduced renal PGE₂ levels may be associated with increased reabsorption of sodium and lithium. However, this fails to explain why aspirin, which blocks renal prostaglandin synthesis by 65 to 70%, does not usually affect serum-lithium levels, see 'Lithium + Aspirin or other Salicylates', p.1119.

Importance and management

The interaction between NSAIDs and lithium is well established, although the incidence is unknown. The increase in serum-lithium levels appears to vary between the different NSAIDs and also between individuals taking the same NSAID (see 'Table 31.1', (p.1127)). Factors such as advanced age, impaired renal function, decreased sodium intake, volume depletion, renal artery stenosis, and heart failure increase the risk.

The documentation of these interactions is variable and limited, and although only some NSAIDs have been shown to interact, it seems likely that they will all interact to a greater or lesser extent. What is known indicates that most NSAIDs should be avoided, especially if other risk factors are present, unless serum-lithium levels can be very well monitored (initially every few days) and the dosage reduced appropriately. The effects of sulindac appear to be unpredictable (serum levels raised, lowered or unchanged) so that good monitoring is still necessary.

Patients on lithium should be aware of the symptoms of lithium toxicity and told to report them immediately should they occur. This should be reinforced when they are given an NSAID.

Lithium + Paracetamol (Acetaminophen)

Paracetamol appears not to alter lithium levels.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects given lithium carbonate 300 mg every 12 hours to achieve steady state, followed by the addition of 650 mg of paracetamol every 6 hours for 5 days, found no evidence that paracetamol increased serum-lithium levels. Six subjects had no change in lithium levels, one subject had a 0.1 mmol/L decrease, and two had a 0.1 mmol/L increase.¹ One patient whose serum lithium level doubled while taking rofecoxib was later given paracetamol without any problems.² No precautions seem necessary on concurrent use.

Lithium + Propranolol

One study suggests that propranolol may decrease the clearance of lithium, but the significance of this is unclear. An isolated report describes a patient taking lithium who developed marked bradycardia after he took propranolol 30 mg daily.

Clinical evidence, mechanism, importance and management

A study in lithium-treated manic-depressive patients found that the clearance of lithium was about 20% lower in 23 patients also taking propranolol than in 292 similar patients on lithium alone.¹ However, the clinical effects of this difference were not evaluated, so the significance of this finding is unclear. A 70-year-old man who had been stable on lithium for 16 years was additionally started on propranolol 30 mg daily for lithium-induced tremor. Six weeks later he was hospitalised because of vomiting, dizziness, headache and a fainting episode. His pulse rate was 35 to 40 bpm and his serum-lithium level was 0.3 mmol/L. When later discharged on lithium without propranolol his pulse rate had risen to a range of 64 to 80 bpm.²

The authors attribute the bradycardia to an interaction with lithium as the low dose of propranolol was considered unlikely to cause bradycardia alone. They also point out that both drugs affect the movement of calcium across cell membranes, which could account for the decreased contraction rate of the heart muscle, and thus bradycardia in this patient. They suggest careful monitoring in elderly patients with atherosclerotic cardiovascular problems.²

The general importance of this interaction, if it is such, is uncertain, but it seems possible with all beta blockers because they can all cause bradycardia. However, as beta blockers are used to treat lithium-induced tremor, any serious problem would be expected to have come to light by now.

Lithium + Sodium compounds

The ingestion of marked amounts of sodium can prevent the establishment or maintenance of adequate serum-lithium levels. Conversely, dietary salt restriction can cause serum-lithium levels to rise to toxic concentrations if the lithium dosage is not reduced appropriately.

Clinical evidence

(a) *Lithium response reduced by the ingestion of sodium*

A 35-year-old man, started on lithium carbonate 250 mg four times a day, had a serum-lithium level of 0.5 mmol/L by the following morning. When the dosage frequency was progressively increased to five, and later six times a day, his serum-lithium levels did not exceed 0.6 mmol/L because, unknown to his doctor, he was also taking **sodium bicarbonate**.

The patient's wife said he had been taking "Soda Bic" for years but since he started on lithium he had been "shovelling it in." When the **sodium bicarbonate** was stopped, relatively stable serum-lithium levels of 0.8 mmol/L were achieved on the initial dosage of lithium carbonate.¹

An investigation to find out why a number of inpatients failed either to reach or maintain adequate therapeutic serum-lithium levels over a period of 2 months, revealed that a clinic nurse had been giving the patients *Efferdax*, a product containing about 50% **sodium bicarbonate**, because the patients complained of nausea. The reduction in the expected serum-lithium levels was as much as 40% in some cases.²

Other studies confirm that the serum-lithium levels can fall, and the effectiveness of treatment can lessen, if the intake of sodium is increased.³⁻⁵

(b) *Lithium response increased by sodium restriction*

The serum-lithium levels of 4 patients rose more rapidly and achieved a higher peak when salt was restricted to less than 10 mmol of sodium per day compared with the situation when the patients took a **dietary salt supplement**.⁶

Mechanism

The situation is complex and not fully established, but the mechanism can be broadly described in simplistic terms.

Sodium balance is controlled by the kidney; if the serum sodium is low the kidney can reabsorb more sodium to maintain the balance. The kidney excretes and reabsorbs both lithium and sodium, but it does not appear to clearly distinguish between lithium and sodium ions. Therefore, if a patient taking lithium restricts sodium intake, the kidney may reabsorb both sodium and lithium, causing a rise in serum-lithium levels. A corresponding decrease in lithium levels can occur when sodium intake is supplemented.^{7,8}

Importance and management

Well established and clinically important interactions. The establishment and maintenance of therapeutic serum-lithium levels can be jeopardised if the intake of sodium is altered. Warn patients not to take non-prescription antacids or urinary alkalinisers without first seeking informed advice. Sodium bicarbonate comes in various guises and disguises e.g. *Alka-Seltzer* (55.8%), *Andrews Salts* (22.6%), *Eno* (46.4%), *Jaap's Health Salts* (21.3%), *Peptac* (28.8%). Substantial amounts of sodium also occur in some **urinary alkalinising agents** (e.g. *Citralka*, *Citravescent*).⁹ There are many similar preparations available throughout the world. An antacid containing **aluminium/magnesium hydroxide** with simeticone has been found to have no effect on the bioavailability of lithium carbonate,¹⁰ so that antacids of this type would appear to be safer alternatives.

Patients already stabilised on lithium should not begin to limit their intake of salt unless their serum-lithium levels can be monitored and suitable dosage adjustments made, because their lithium levels can rise quite rapidly.

Lithium + Theophylline

Serum-lithium levels are moderately reduced by 20 to 30% by the concurrent use of theophylline, which may cause patients to relapse.

Clinical evidence

The serum-lithium levels of 10 healthy subjects taking lithium carbonate 900 mg daily fell by 20 to 30%, and the urinary clearance increased by 30%, when they were given theophylline (*Theo-dur*). Steady-state theophylline levels of 5.4 to 12.7 micrograms/mL were achieved, and it was noted that higher theophylline levels were strongly correlated with increased lithium clearance.¹ This study has been reported in brief elsewhere.²

A man taking theophylline was diagnosed with a bipolar disorder and started on lithium while in hospital for an exacerbation of COPD. When the dose of theophylline was raised, because of a worsening in his condition, his lithium dose also had to be increased to control the emergence of manic symptoms. He received a maximum theophylline dose of 1.5 g daily, during which time he needed 2.7 g of lithium daily. When the theophylline was stopped, he only needed around 1.5 g of lithium daily to control his manic symptoms.³ Two studies support the evidence from these cases with the finding that lithium excretion is increased by about 50% by **aminophylline** or theophylline.^{4,5}

Mechanism

Uncertain. Theophylline has an effect on the renal clearance of lithium.

Importance and management

Information is very limited but the interaction appears to be established. Depressive and manic relapses may occur if the dosage of lithium is not raised appropriately when theophylline is given. Serum-lithium levels should be monitored if theophylline or aminophylline is stopped, started, or if the dosage is altered.

Other xanthines e.g. caffeine appear to have a similar effect, see 'Lithium + Caffeine', p.1120.

Lithium + Triptans

In two cases patients on lithium developed symptoms suggestive of the serotonin syndrome after taking sumatriptan.

Clinical evidence, mechanism, importance and management

A comprehensive literature search published in 1998 identified several cases of adverse events reported with **sumatriptan** and lithium, although in most cases other medications were also being taken. Two patients taking **sumatriptan** and lithium concurrently were identified with symptoms suggestive of the serotonin syndrome, but these were mild to moderate and self-limiting. The number of patients taking lithium and **sumatriptan** was not stated, so the incidence is unknown.¹ The conclusion was reached that **sumatriptan** can be used cautiously in patients receiving lithium.¹ The manufacturers of **sumatriptan** and other triptans (e.g. **almotriptan**)² do not appear to have studied the effects of these drugs on lithium and there seem to be no other reports of problems with lithium and triptans. More study is needed.

MAOIs

The intended target of the MAOIs (monoamine oxidase inhibitors) is MAO within the brain, but MAO is also found in other parts of the body. Particularly high concentrations occur in the gut and liver, where it acts as a protective detoxifying enzyme against tyramine and possibly other potentially hazardous amines, which exist in foods that have undergone bacterial degradation. There are at least two forms of MAO: MAO-A metabolises (deaminates) noradrenaline (norepinephrine) and serotonin (5-HT), while MAO-B metabolises phenylethylamine. Substances like tyramine and dopamine are metabolised by both forms of MAO.

The older MAOIs (see 'Table 32.1', (below)) are non-selective or non-specific, and inhibit both isoenzymes A and B. They are irreversible and long-acting, because the return of MAO activity depends upon the regeneration of new enzymes. As a result their effects (both beneficial and adverse) can last for 2 to 3 weeks after they have been withdrawn. Tranylcypromine differs in being a more reversible inhibitor of MAO, so the onset and disappearance of its actions are quicker than the other non-selective MAOIs. However, its effects still last for a number of weeks after withdrawal (e.g. see 'MAOIs or RIMAs + Tyramine-rich foods', p.1153), so it is still effectively an irreversible inhibitor, and is usually classified as such. These non-selective MAOIs cause serious and potentially life-threatening hypertensive interactions with the sympathomimetics found in some proprietary 'cough and cold remedies', (p.1147), and with 'tyramine-rich foods', (p.1153), and 'drinks', (p.1151).

Some of the newer and more recently developed drugs with MAO inhibitory activity (see 'Table 32.1', (below)) interact to a lesser extent than the older MAOIs. This is because they are largely selective. One group of these selective inhibitors targets MAO-A, and are relatively rapidly reversible; inhibition of this enzyme is responsible for the antidepressant effect. These selective MAO-A inhibitors (moclobemide, toloxatone) have been given the acronym RIMAs (Reversible Inhibitors of Monoamine oxidase A). They leave MAO-B largely uninhibited so that there is still a metabolic pathway available for the breakdown of amines, such as

tyramine, that can cause a rise in blood pressure. In practical terms this means that the amount of tyramine needed to cause a hypertensive crisis is about tenfold greater than with the non-selective MAOIs (see 'tyramine-rich foods', (p.1153)).

The other newer selective MAOIs that specifically inhibit MAO-B are ineffective for the treatment of depression and are mainly used for Parkinson's disease, and so are covered elsewhere, see 'Antiparkinsonian and related drugs', (p.672). In low doses they inhibit MAO-B, leaving MAO-A largely uninhibited. However, selegiline loses some of its selectivity at doses of more than 10 mg daily and will therefore be subject to the same interactions as the non-selective MAOIs. Rasagiline is another irreversible selective inhibitor of MAO-B used for Parkinson's disease.

Some other drugs covered elsewhere also have MAOI activity. Furazolidone is an antiprotozoal with MAOI activity. Linezolid is an oxazolidinone antibacterial with reversible nonselective MAOI activity. Interactions typical of MAOI inhibitors might therefore occur with furazolidone and linezolid.

If you look at the product information issued by manufacturers, you will frequently see warnings about real and alleged interactions with MAOIs. Blackwell,¹ who has done much work on the interactions of the MAOIs, has rightly pointed out that the MAOIs are among the drugs that accumulate much myth and misinformation. He notes that the MAOIs have developed such a sinister reputation that manufacturers often issue a reflexive admonition to avoid co-administration with new drugs.

This means that many of the warnings about potential interactions with the MAOIs may lack a sound scientific basis. However, equally this does not mean that the proven serious life-threatening interactions that are associated with the MAOIs should be dismissed, and it should be noted that any drug with indirectly-acting sympathomimetic activity is likely to interact.

MAOIs + Antihistamines

The alleged interaction between the MAOIs and antihistamines appears to be based on a single *animal* study, and is probably more theoretical than real. The exception seems to be cyproheptadine, which can reduce the effect of MAOIs because of its serotonin antagonist effect, see 'MAOIs or RIMAs + Antihistamines; Cyproheptadine', below.

Clinical evidence, mechanism, importance and management

A number of lists, charts and books about adverse interactions suggest that potentially serious interactions can occur between the MAOIs and the antihistamines. This appears to be based on a study in *rabbits* from 1972, which showed that some antihistamines (notably alkylamine antihistamines such as **chlorphenamine**, **brompheniramine**, and also **diphenhydramine**) produced a fatal hyperpyrexia, thought to be due to serotonin potentiation, when given intravenously to **phenelzine** pretreated *rabbits*.¹ This reaction was considered to be similar to that seen with 'pethidine', (p.1140), or the 'tricyclics', (p.1149). However, in over 20 years since the publication of this data, the manufacturers of various antihistamines did not identify any clinical reports of adverse interactions attributed to the use of any antihistamine with an MAOI.²⁻⁶ Nevertheless, the UK manufacturers of most of the sedating antihistamines (**alimemazine**, **brompheniramine**, **chlorphenamine**, **diphenhydramine**, **promethazine**) state that MAOIs may intensify the antimuscarinic effect of antihistamines, and many contraindicate or caution concurrent use⁷⁻¹¹ (see also 'MAOIs + Antimuscarinics', p.1132). No such warning is given for non-sedating antihistamines. There would appear to be no good reason to avoid the concurrent use of sedating or non-sedating antihistamines and MAOIs. Note that cyproheptadine is an exception, because of its specific serotonin antagonist properties, see 'MAOIs or RIMAs + Antihistamines; Cyproheptadine', below.

MAOIs or RIMAs + Antihistamines; Cyproheptadine

Isolated reports describe delayed hallucinations in a patient on phenelzine and cyproheptadine, and the rapid re-emergence of depression in two other patients on brofaromine or phenelzine when given cyproheptadine.

Clinical evidence

A woman who had responded well to **brofaromine** rapidly became depressed again when she took cyproheptadine. She had to be hospitalised due to suicidal ideation, but eventually she responded to treatment and she then took **brofaromine** and cyproheptadine for 6 months.¹ A man whose depression responded well to **phenelzine** 75 mg daily was given cyproheptadine 4 mg to treat associated sexual dysfunction and anorgasmia. Within 3 days of adding the cyproheptadine his depression returned, but the anorgasmia did not improve. When the cyproheptadine was stopped his depression was relieved.² Hallucinations developed in a woman taking **phenelzine** 2 months after cyproheptadine was started.³

Mechanism

Cyproheptadine is a serotonin antagonist. The reversal of the effects of the brofaromine was therefore attributed by the authors of one report¹ to the

blockage of 5-HT (serotonin) receptors by cyproheptadine (brofaromine has both MAO-A inhibitory and 5-HT uptake inhibitory properties).

Cyproheptadine has also been observed to block the activity of serotonin reuptake inhibitors (see 'SSRIs + Cyproheptadine', p.1216).

Importance and management

Information seems to be limited to these reports but it would now be prudent to be alert for a reduction in efficacy or an adverse response if cyproheptadine is given with any MAOI or RIMA. The manufacturer of cyproheptadine actually contraindicates concurrent use with MAOIs.⁴ However, there appears to be no reason why cyproheptadine cannot be used to treat the serotonin syndrome occurring in a patient on an MAOI.

As with other sedative antihistamines (see 'MAOIs + Antihistamines', above), the UK manufacturers of cyproheptadine also say that MAOIs prolong and intensify the antimuscarinic effects of antihistamines,⁴ but there seems to be no clinical data to support this.

MAOIs or RIMAs + Antihypertensives

Bradycardia has been reported in two patients taking nadolol or metoprolol with phenelzine. MAOIs commonly cause hypotension, and might reasonably be expected to have additive hypotensive effects with antihypertensive drugs, although this was not seen with phenelzine and atenolol in a study in normotensive patients. In one small study, the RIMA, moclobemide increased the hypotensive effect of metoprolol, but did not alter the effect of nifedipine or hydrochlorothiazide on blood pressure.

Clinical evidence, mechanism, importance and management

(a) MAOIs

It had been claimed¹ that MAOIs should be discontinued at least 2 weeks before starting **propranolol**, but studies in *animals*² using **mebanazine** as a representative MAOI failed to show any undesirable property of **propranolol** following the use of an MAOI. Bradycardia of 46 to 53 bpm has been described in two patients taking **nadolol** 40 mg or **metoprolol** 150 mg daily for hypertension within 8 to 11 days of starting **phenelzine** 60 mg daily. No noticeable adverse effects were seen, but the authors recommend careful monitoring, particularly in the elderly, who may tolerate bradycardia poorly.³ MAOIs can cause symptomatic hypotension, and therefore additive blood pressure lowering effects with antihypertensive drugs might occur. However, in one small study in normotensive patients with migraine, 11 (33%) of patients had orthostatic hypotension when they were given **phenelzine** alone, but none of these had orthostatic hypotension when they were also given **atenolol**.⁴ Nevertheless, it would be prudent to monitor blood pressure more closely in patients taking antihypertensives with MAOIs.

(b) RIMAs

A study in 5 hypertensive subjects taking **metoprolol** found that **moclobemide** 200 mg three times daily for 2 weeks increased the hypotensive effect of **metoprolol** (systolic 10 to 15 mmHg lower, diastolic 5 to 10 mmHg lower). However, no comparable effects were seen when **moclobemide** was given to 7 subjects taking **hydrochlorothiazide** or 6 subjects taking **nifedipine**. No orthostatic hypotension occurred with any of the drug combinations.⁵ The reason for the differing effect with **metoprolol** is unknown, and further study is needed. Be aware that **moclobemide** may add to the effect of **metoprolol**, and consider increased monitoring if either drug is started or stopped.

MAOIs + Antimuscarinics

No adverse interactions between the MAOIs and antimuscarinics have been reported, although the possibility has been suggested.

Clinical evidence, mechanism, importance and management

A hyperthermic reaction has been reported in some *animals* given **tranylcypromine** or **nialamide** with **procyclidine** or **benzotropine**. It was considered that this might be due to an exaggerated dopamine response.¹ However, there do not appear to be any reports of such an interaction occurring clinically. Nevertheless, some manufacturers of irreversible non-selective MAOIs^{2,3} and antimuscarinics⁴ issue cautions about the possibility of increased effects of antimuscarinics when given with MAOIs. This is presumably because, in theory, inhibition of drug-metabolising enzymes by MAOIs may possibly enhance the effects of antimuscarinics.

MAOIs + Barbiturates

Although the MAOIs can enhance and prolong the activity of barbiturates in animals, only a few isolated cases of adverse responses attributed to an interaction have been described.

Clinical evidence

One reviewer¹ briefly mentions that on three or four occasions patients taking an MAOI continued, without the prescriber's knowledge, to take their usual barbiturate hypnotic and thereby "... unknowingly raised their dose of barbiturate by five to ten times, and as a consequence barely managed to stagger through the day." No details are given, so it is not known whether the serum barbiturate levels of these patients were measured, or whether the raised levels are only a surmise.

A patient taking **tranylcypromine** 10 mg three times daily was inadvertently given intramuscular **amobarbital sodium** 250 mg for sedation. Within an hour she became ataxic, and fell to the floor, repeatedly hitting her head. After complaining of nausea and dizziness the patient became semicomatose and remained in that state for a further 36 hours. To what extent the head trauma played a part is uncertain.²

A man taking **amobarbital sodium** 195 mg at night suffered severe headache, and became confused after also taking **phenelzine** 15 mg three times daily for 4 weeks. On admission to hospital he was comatose, and he had a temperature of 40°C, blood pressure of 150/90 mmHg, tachycardia, stertorous respiration, fixed dilated pupils, exaggerated tendon reflexes and extensor plantar responses. His condition deteriorated and he died 2 hours after admission.³ Pathology suggested a rise in intracranial pressure was responsible. The authors attribute this response to the drugs, but do not rule out a possible contribution of alcohol.³

Mechanism

Not known. *Animal* studies^{2,4} show that MAOIs prolong the activity of barbiturates, and that this is possibly because they inhibit the metabolism of barbiturates by a mechanism independent of MAO inhibition. Whether this occurs in man as well is uncertain.

Importance and management

The evidence for these interactions seem to be confined to a few unconfirmed anecdotal reports. There is no well-documented evidence showing that concurrent use should be avoided, although some caution is clearly appropriate. For mention of successful anaesthesia including the use of

thiopental in patients on MAOIs, see 'Anaesthetics, general + MAOIs', p.100.

MAOIs or RIMAs + Benzodiazepines

Isolated cases of adverse reactions (chorea, severe headache, facial flushing, massive oedema, and prolonged coma) attributed to interactions between phenelzine and chlordiazepoxide, clonazepam or nitrazepam, and between isocarboxazid and chlordiazepoxide have been described. Evidence from clinical trials suggests that there is no interaction between moclobemide and benzodiazepines, although one study found a slight progressive worsening in driving performance.

Clinical evidence and mechanism

(a) MAOIs (non-selective, irreversible)

A patient who had been taking **phenelzine** 45 mg daily for 9 years developed a severe occipital headache after taking 500 micrograms of clonazepam. A similar but milder headache occurred the next night when she took the same dose. No blood pressure measurements were taken.¹ Another report describes facial flushing in a patient taking clonazepam, which occurred after **phenelzine** was started, and which responded to a reduction in the clonazepam dose.²

A patient with depression responded well when given **phenelzine** 15 mg and chlordiazepoxide 10 mg three times a day, but 4 to 5 months later developed choreiform movements of moderate severity, and slight dysarthria. These symptoms subsided when both drugs were withdrawn.³

Two patients taking chlordiazepoxide and either **phenelzine** or **isocarboxazid** developed severe oedema, which was attributed to the use of the combination.^{4,5}

A patient became unconscious and hyperreflexic, with a low blood pressure (100/60 mmHg), increased heart rate (100 bpm), and increased temperature (38.4°C) about 29 hours after taking an overdose of **phenelzine** and chlordiazepoxide.⁶ Another report briefly mentions a case of prolonged coma lasting 3 days in a patient who overdosed with **phenelzine** and chlordiazepoxide.⁷

A patient taking **phenelzine** 30 mg twice daily was started on nitrazepam 5 mg at night and the dose was gradually increased to 15 mg at night over 2 months. He developed MAOI toxicity (excessive sweating, postural hypotension) within 10 days of increasing his dose of nitrazepam to 15 mg daily. Both drugs were stopped and he recovered after 3 days. The **phenelzine** was restarted 2 weeks later without problems. It was suggested that since the patient was a slow acetylator, metabolism of nitrazepam by *N*-acetyl transferase would have been decreased, which may have affected the metabolism of **phenelzine**, thereby increasing its levels.⁸

(b) RIMAs

A meta-analysis of 879 patients taking **moclobemide** is reported to have found that insomnia, restlessness, agitation and anxiety occurred twice as often in the 467 patients taking one or more benzodiazepines than in those not taking concurrent benzodiazepines. However, these adverse events were often already present when **moclobemide** was started, so it is suggested that the patient groups were probably different. Apart from this difference between the patient groups, there was no evidence of any relevant pharmacokinetic or pharmacodynamic interaction.⁹ Another review briefly reported that no clinically relevant interaction was noted between **moclobemide** and benzodiazepines in clinical studies.¹⁰

Driving performance gradually worsened over 6 weeks in a double-blind study in depressed patients given **moclobemide** (22 subjects) or fluoxetine (19 subjects). Thirty-one patients were taking long-term benzodiazepines, and at the start of the study their driving was no different to the patients not taking benzodiazepines. In an attempt to suggest a possible reason for the worsening performance, various variables were assessed in a regression analysis. It was found that patients taking **moclobemide** who were also taking a benzodiazepine with nordiazepam among its metabolites (**clorazepate**, **prazepam**, **diazepam**, **cloxazolam**, **clotiazepam**) ex-

perenced a progressive worsening in their driving, whereas patients on other benzodiazepines (**bromazepam**, **alprazolam**, **oxazepam**, **lorazepam**) tended to have no change in driving ability. It was tentatively suggested that **moclobemide** may have inhibited the metabolism of nordiazepam by the cytochrome P450 isoenzyme CYP2C19, so increasing the effect of the benzodiazepine, and worsening driving performance.¹¹

Importance and management

The case reports of adverse interactions cited here appear to be isolated, and it is by no means certain that all the responses were in fact due to drug interactions. However, bear them in mind in the event of unexpected responses to treatment. No special precautions would normally be required during concurrent use, although a reminder that benzodiazepines may affect the performance of skilled tasks, such as driving, may be appropriate when a patient's medication is changed. Note that the manufacturer of moclobemide says that if depressed patients with excitation or agitation are first treated with moclobemide, a sedative such as a benzodiazepine should also be given for up to 2 to 3 weeks.¹² Further study is required to find out if there are any clinically important pharmacokinetic interactions between moclobemide and any of the benzodiazepines.

MAOIs or RIMAs + Buspirone

Elevated blood pressure has been reported in four patients taking buspirone and either phenelzine or tranlycypromine. Buspirone may have contributed to a case of the serotonin syndrome in a patient who overdosed on moclobemide and clomipramine.

Clinical evidence, mechanism, importance and management

(a) MAOIs

Four cases of significant blood pressure elevation, which occurred during the use of buspirone and either **phenelzine** or **tranlycypromine**, have been reported to the FDA's Spontaneous Reporting System. One patient was a 75-year-old woman and the other 3 patients were men aged between 30 and 42 years. The report does not say how much the blood pressure rose, or how quickly, and no other details are given.¹ On the basis of this rather sparse information the manufacturers of buspirone^{2,3} recommend that it should not be used concurrently with an MAOI.

(b) RIMAs

A severe case⁴ of the serotonin syndrome (including hyperthermia and muscle rigidity requiring mechanical ventilation) has been reported in a patient who took an overdose of '**moclobemide**, **clomipramine** and **buspirone**', (p.1149). Concurrent use of more than one serotonergic drug is thought to be a risk factor for the development of 'the serotonin syndrome', (p.9).

MAOIs + Caffeine or Choline theophyllinate

Isolated reports suggest that the CNS stimulant effects of caffeine may possibly be increased by the MAOIs. Another isolated report describes the development of tachycardia and apprehension in a patient taking phenelzine after she also took a cough syrup, containing choline theophyllinate.

Clinical evidence

(a) Caffeine

One reviewer briefly mentions that a patient who normally drank 10 or 12 cups of **coffee** daily, without adverse effects, experienced extreme jitteriness during treatment with an MAOI, which subsided when the **coffee** consumption was reduced to 2 or 3 cups a day. The same reaction was also said to have occurred in other patients taking MAOIs who drank **tea** or some of the '**Cola** drinks, which contain caffeine.¹ This reviewer also mentions another patient taking an MAOI who claimed that a single cup of **coffee** taken in the morning kept him jittery all day and up the entire night as well, a reaction that occurred on three separate occasions.¹ In another report, a woman taking **phenelzine** experienced a severe headache with a slight blood pressure rise on two occasions after drinking **cola** containing 35 to 55 mg of caffeine.² Similarly, a brief mention is made of 2 patients taking **phenelzine** who experienced extreme restlessness, agitation, tremor, and insomnia after starting to drink large quantities of **diet cola**. This was attributed to an interaction between **phenelzine** and **aspartame**,³ but could equally well be attributed to an interaction with caffeine, or indeed a reaction to caffeine alone. Caffeine and **theophylline** may have contributed to the serious reaction that occurred in a woman the day after discontinuing **phenelzine**, who took a *Do-Do* tablet (containing ephedrine, caffeine, theophylline),⁴ see also 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1147.

(b) Choline theophyllinate

A woman with agoraphobia, being treated with **phenelzine** 45 mg daily, developed tachycardia, palpitations and apprehension lasting for about 4 hours after she had taken a cough syrup containing choline theophyllinate and guaifenesin. The symptoms recurred when she was again given the cough syrup, and yet again when given choline theophyllinate alone, but not when given guaifenesin alone.⁵

Mechanism

Unknown. Caffeine alone can cause headache, tachycardia, and jitteriness, and individuals vary in their susceptibility to these effects. The effects of caffeine, theophylline, and theobromine in *rats* were enhanced by MAOIs.⁶

Importance and management

Apart from these few reports, the literature appears to be otherwise silent about an interaction between the MAOIs and xanthines. Whether this reflects their mildness and unimportance, or their rarity, is not clear. There would seem to be no need for any special precautions in patients taking MAOIs who are given xanthine bronchodilators or consuming caffeine-containing beverages or pharmaceuticals, but bear these adverse reports in mind in the event of any unexpected response. Nevertheless, some manufacturers of MAOIs recommend the avoidance of excessive amounts of tea and coffee,⁷ or caffeine in any form.^{8–10}

MAOIs + Cloral hydrate

A case of fatal hyperpyrexia and another case of serious hypertension have been linked to interactions between cloral hydrate and phenelzine, but in both cases there are other plausible explanations for the reactions seen.

Clinical evidence, mechanism, importance and management

A woman taking **phenelzine** 15 mg three times daily was found in bed deeply comatose with marked muscular rigidity, twitching down one side and a temperature of 41°C. She died without regaining consciousness. A postmortem failed to establish the cause of death, but it subsequently came to light that she had started drinking whisky, and she had access to cloral hydrate, of which she may have taken a fatal dose.¹ Another patient, also taking **phenelzine** 15 mg three times daily and cloral hydrate to aid sleep, developed an excruciating headache followed by nausea, photophobia and a substantial rise in blood pressure.² This latter reaction is similar to the 'cheese reaction', see 'tyramine-rich foods', (p.1153), but at the time the authors of the report were unaware of this type of reaction so that they failed to find out if any tyramine-rich foods had been eaten on the day of the attack.²

There is no clear evidence that either of these adverse reactions was due to an interaction between **phenelzine** and cloral hydrate, and there do not seem to be any other reports to suggest that an interaction between these drugs is likely.

MAOIs + Cocaine

Some reports suggest that patients on MAOIs may experience a severe headache if they abuse cocaine. Two isolated reports describe the delayed development of hyperpyrexia, and other symptoms including coma, agitation, muscle tremors and rigidity after patients taking phenelzine or iproniazid were given a cocaine spray during surgery.

Clinical evidence, mechanism, importance and management

The use of cocaine is generally contraindicated in patients taking MAOIs¹⁻³ because it is expected to interact like 'indirectly-acting sympathomimetics', (p.1147). This is supported by a report of hypertensive reactions in 2 patients taking **phenelzine** who became drunk and used cocaine. Both experienced frightening reactions including headache, a rise in blood pressure, palpitations, and chest tightness. One required no treatment, and the other was treated with propranolol and diazepam.⁴ Because this reaction was not considered as dangerous as expected, **phenelzine** has been tried as a deterrent to the abuse of cocaine: one uncontrolled study reports its use in 26 patients without mentioning any adverse reactions.⁴ Another report mentions a man given **phenelzine** for cocaine abuse who experienced no reaction to the use of cocaine. He was then given **tranylcypromine**, and after 10 weeks risked sniffing cocaine, which did produce a severe occipital headache and nausea. However, after abstaining for another 10 weeks he again used cocaine, this time without any reaction.⁵

A man taking **phenelzine** 15 mg twice daily underwent vocal chord surgery. He was anaesthetised with thiopental, and later nitrous oxide and isoflurane 0.5% in oxygen. Muscle paralysis was produced with suxamethonium and gallamine. During the operation his vocal chords were sprayed with 1 mL of a 10% cocaine spray. He regained consciousness 30 minutes after the surgery and was returned to the ward, but a further 30 minutes later he was found unconscious, with generalised coarse tremors and marked muscle rigidity. His rectal temperature was 41.5°C. He was initially thought to have malignant hyperpyrexia and was treated accordingly with wet blankets, as well as with intravenous fluids and oxygen, and he largely recovered within 7 hours. However, later it seemed more likely that the reaction had been due to an adverse interaction between the **phenelzine** and cocaine, because he had been similarly and uneventfully treated with cocaine in the absence of **phenelzine** on two pre-

vious occasions.⁶ A similar case was described in a woman taking **iproniazid** who had her trachea sprayed with 1 mL of 10% cocaine before intubation during surgery. She was also given pethidine 20 mg, and shortly after surgery became pyrexial, flushed, agitated and sweated profusely. She was treated with intravenous chlorpromazine.⁷ In this case, the reaction could have been due to the pethidine alone (see 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1140), or both the cocaine and the pethidine. The reasons for these adverse reactions are not understood, but a delayed excitatory reaction due to increased 5-HT (serotonin) concentrations has been suggested.⁶ The general importance of these cases is not known, but bear them in mind if cocaine is used in a patient on an MAOI.

MAOIs or RIMAs + Dextromethorphan

Two fatal cases of hyperpyrexia and coma (symptoms similar to the serotonin syndrome) have occurred in patients taking phenelzine with dextromethorphan (in overdose in one case). Three other serious but non-fatal reactions occurred in patients taking dextromethorphan with isocarboxazid or phenelzine. MAOIs should not be used with dextromethorphan. Moclobemide inhibits the metabolism of dextromethorphan, and isolated cases of severe CNS reactions have occurred with the combination, which is also contraindicated.

Clinical evidence

(a) MAOIs

A woman taking **phenelzine** 15 mg four times daily complained of nausea and dizziness before collapsing, 30 minutes after drinking about 55 mL of a cough mixture containing dextromethorphan. She remained hyperpyrexial (42°C), hypotensive (systolic blood pressure below 70 mmHg) and unconscious for 4 hours, before dying after a cardiac arrest.¹

A 15-year-old girl taking **phenelzine** 15 mg three times daily (as well as thioridazine, procyclidine and metronidazole) took 13 capsules of *Romilar CF* (containing dextromethorphan hydrobromide 15 mg, phenindamine tartrate 6.25 mg, phenylephrine hydrochloride 5 mg and paracetamol (acetaminophen) 120 mg in each capsule). She became comatose, hyperpyrexial (103°F), had a blood pressure of 100/60 mmHg, a pulse of 160 bpm and later died of a cardiac arrest.² This case is complicated by the overdose and multiplicity of drugs present, particularly the phenylephrine. See 'MAOIs or RIMAs + Sympathomimetics; Phenylephrine', p.1148.

A 28-year-old woman developed severe myoclonus and rigidity, and became largely unresponsive after taking **phenelzine** and *Robitussin DM* (dextromethorphan hydrobromide 15 mg with guaifenesin 100 mg).³ Yet another patient taking **phenelzine** developed muscular rigidity, uncontrollable shaking, generalised hyperreflexia and sweating when given *Robitussin DM*. Within 2 hours he had responded to 10 mg of intravenous diazepam and oral activated charcoal.⁴

A woman taking **isocarboxazid** 30 mg daily took diazepam 1 mg and 10 mL of *Robitussin DM*. Within 20 minutes she was nauseated and dizzy, and within 45 minutes she began to have fine bilateral leg tremor and muscle spasms of the abdomen and lower back. These were followed by bilateral and persistent myoclonic jerks of legs, occasional choreoathetoid movements and marked urinary retention. These adverse effects persisted for about 19 hours, gradually becoming less severe.⁵

The US manufacturer of **tranylcypromine** notes that the concurrent use of MAOIs and dextromethorphan has resulted in brief episodes of psychosis or bizarre behaviour.⁶ Similarly, the US manufacturer of **phenelzine** mentions one case of drowsiness and bizarre behaviour when dextromethorphan lozenges were used by a patient taking phenelzine. They also note that concurrent use of dextromethorphan may cause a reaction similar to

that seen with pethidine (meperidine),⁷ as described in some of the cases above.

(b) RIMAs

Moclobemide 300 mg twice daily for 9 days markedly reduced the *O*-demethylation of dextromethorphan (seven 20-mg doses given every 4 hours over 2 days), in 4 healthy subjects.⁸ The manufacturer notes that isolated cases of severe CNS adverse reactions have been seen with the combination.⁹ Concurrent use of dextromethorphan may have contributed to a fatality involving the illicit use of **moclobemide** and 'ecstasy', (p.1144).

Mechanism

(a) The authors of three of the reports³⁻⁵ suggest that these effects may have been due to an increase in serotonin activity in the CNS 'the serotonin syndrome', (p.9). Symptoms similar to the serotonin syndrome (hyperpyrexia, dilated pupils, hyperexcitability and motor restlessness) have been seen in *rabbits* treated with dextromethorphan and **nialamide**, **phenelzine** or **pargyline**,¹⁰ and also with MAOIs and 'pethidine', (p.1140).

(b) Moclobemide appears to inhibit the metabolism of dextromethorphan by the cytochrome P450 isoenzyme CYP2D6, and the combination may also cause adverse CNS effects.

Importance and management

Despite the very limited information available, the severity of the reactions indicates that patients taking MAOIs should avoid taking dextromethorphan. The manufacturer of moclobemide also contraindicates the concurrent use of dextromethorphan.⁹ Patients should be warned that many cough preparations contain dextromethorphan.

MAOIs + Disulfiram

An isolated report describes delirium in a man taking lithium and disulfiram when the moclobemide he was also taking was replaced by tranlycypromine.

Clinical evidence, mechanism, importance and management

A man with disulfiram implants taking long-term lithium had his MAOI changed from **moclobemide** [dosage not stated] to **tranlycypromine** 10 mg twice daily. Within 2 days he became acutely delirious (agitated, disoriented, incoherent, visual hallucinations) and later subcomatose, with nystagmus and a downward gaze. He was successfully treated with haloperidol and promethazine, and recovered within 24 hours. No alcohol was detected in his blood, and serum **tranlycypromine** levels were below 50 micrograms/L, which was considered normal.¹

The authors of this report attribute the reaction to an interaction between **tranlycypromine** and disulfiram. However, there would seem to be other possible explanations for this reaction. MAOIs have rarely been seen to interact adversely with 'lithium', (p.1136), and there also seems potential for an interaction between the two 'MAOIs', (p.1137).

This seems to be the only report of an adverse reaction between disulfiram and an MAOI, so it is possible that this is just an idiosyncratic reaction. However, warnings about this drug combination, based on theoretical considerations and studies in *animals*, have previously been

given, and **tranlycypromine** was considered to be the MAOI that presented the greatest risk.² Consequently, the US manufacturers of **tranlycypromine**³ and **isocarboxazid**⁴ recommend caution with the concurrent use of disulfiram. It seems that this particular patient had no problems while taking **moclobemide**, which is a RIMA.

4. Marplan (Isocarboxazid). Oxford Pharmaceutical Services Inc. US Prescribing information, January 2000.

MAOIs + Dopa-rich foods

A few reports describe a rapid, serious and potentially life-threatening hypertensive reaction in patients taking MAOIs if they eat young broad bean pods, which contain dopa. No serious hypertensive reaction is likely to occur with moclobemide.

Clinical evidence

A 65-year-old hypertensive man taking **pargyline** had a severe headache and palpitations on two occasions after eating "whole, cooked, broad beans" (young broad bean pods). A controlled study in this man found that he had a rise in systolic blood pressure from 165 to 262 mmHg about 20 minutes after eating whole broad bean pods. The pods alone had the same effect, but the beans on their own had little effect. This rise in blood pressure was also seen in two other patients on **pargyline**, and was reversed by intravenous phentolamine. Two normotensive subjects taking **pargyline** 50 mg daily also had an increase in blood pressure (over 70 mmHg systolic in one subject) following the ingestion of bean pods.¹ Another case report describes a man taking **phenelzine** 15 mg three times daily who had a very severe headache after eating a meal including fresh, young, sliced, broad bean pods from his garden.² One other case has been briefly mentioned, although it was not known whether the broad beans were eaten with or without the pods.³

Mechanism

Broad bean (*Vicia faba*) pods contain dopa,¹ which is enzymatically converted in the body, firstly to dopamine and then to noradrenaline, both of which are normally broken down by monoamine oxidase. In the presence of an MAOI this breakdown is suppressed, which means that the total levels of dopamine and noradrenaline are increased. Precisely how this then leads to a sharp rise in blood pressure is not clear, but either dopamine or noradrenaline, or both, directly or indirectly stimulate the alpha-receptors of the cardiovascular system.

Importance and management

Although there are only a few cases of the interaction between the non-selective MAOIs (listed in 'Table 32.1', (p.1130)) and broad bean pods, the interaction would appear to be established and is serious and potentially life-threatening. Patients should not eat young broad bean pods during treatment with any of these MAOIs, nor for a period of 2 to 3 weeks after their withdrawal. It should be noted that this prohibition does not apply to 'mature' broad beans (the seeds) removed from their pods, which is the more common way of eating broad beans.

MAOIs + Doxapram

No adverse interactions have been reported between the MAOIs and doxapram, although animal studies suggest that an increased pressor effect is theoretically possible.

Clinical evidence, mechanism, importance and management

The manufacturers note that *animal* studies have shown that the actions of doxapram may be potentiated by pretreatment with an MAOI,¹ and that

the pressor effects of MAOIs and doxapram may be additive.² Based on this, they advise that concurrent use should be undertaken with great care.^{1,2} To date, there appear to be no clinical reports of this interaction.

2. Dopram (Doxapram hydrochloride). Baxter Healthcare Corporation. US Prescribing information, March 2004.

MAOIs + Erythromycin

An isolated case report describes severe hypotension and fainting in a woman taking phenelzine, which occurred shortly after she started a course of erythromycin.

Clinical evidence, mechanism, importance and management

A woman taking **phenelzine** 15 mg daily experienced three syncopal episodes 4 days after starting to take erythromycin 250 mg four times daily for pneumonia. When admitted to hospital her supine systolic blood pressure was only 70 mmHg. When she sat up, it was unrecordable. Although she was not dehydrated, she was given 4 litres of sodium chloride 0.9%, without any effect on her blood pressure. Within 24 hours of stopping the **phenelzine** her blood pressure had returned to normal.¹ The reasons for this severe hypotensive reaction are not known, but it was suggested that the erythromycin may have caused rapid gastric emptying, which resulted in a very rapid absorption of the **phenelzine** (described by the author as rapid dumping into the blood stream), which resulted in the adverse effect of hypotension.¹ This seems to be the first and only report of this interaction, and so its general importance is uncertain.

1. Bernstein AE. Drug interaction. *Hosp Community Psychiatry* (1990) 41, 806–7.

MAOIs + Ginseng

Isolated reports describe two patients taking phenelzine who developed adverse effects (including headache and insomnia) after taking ginseng.

Clinical evidence, mechanism, importance and management

A 64-year-old woman taking **phenelzine** developed headache, insomnia, and tremulousness on two occasions after taking ginseng.¹ Three years later, she experienced the same symptoms and an increase in depression 72 hours after starting to take ginseng capsules.² Another depressed woman taking ginseng and bee pollen experienced a relief of her depression and became active and extremely optimistic when she was started on **phenelzine** 45 mg daily, but this was accompanied by insomnia, irritability, headaches and vague visual hallucinations. When the **phenelzine** was stopped and then re-started in the absence of the ginseng and bee pollen, her depression was not relieved.³ It seems unlikely that the bee pollen had any part to play in these reactions and suspicion therefore falls on the ginseng. It would seem that the psychoactive effects of the ginsenosides from the ginseng and the MAOI were somehow additive. Ginseng has stimulant effects, but its adverse effects include insomnia, nervousness, hypertension and euphoria. These two cases once again illustrate that herbal medicines are not necessarily problem-free if combined with orthodox drugs.

MAOIs or RIMAs + Levodopa

A rapid, serious and potentially life-threatening hypertensive reaction can occur in patients taking MAOIs if they are also given levodopa. An interaction with levodopa given with carbidopa or benserazide is unlikely. No serious hypertensive reaction has been

reported to occur with moclobemide. See also ‘MAOIs + Dopamine-rich foods’, p.1135.

Clinical evidence

(a) MAOIs

A patient who had been taking **phenelzine** daily for 10 days was given 50 mg of oral levodopa. In just over an hour his blood pressure had risen from 135/90 mmHg to about 190/130 mmHg, and despite a 5 mg intravenous injection of phentolamine it continued to rise over the next 10 minutes to 200/135 mmHg, before falling after a further 4 mg injection of phentolamine. The following day the experiment was repeated with levodopa 25 mg, but no blood pressure changes were seen. Three weeks after withdrawal of the **phenelzine** even 500 mg of levodopa had no hypertensive effect.¹

Similar cases of severe, acute hypertension, accompanied in most instances by flushing, throbbing and pounding in the head, neck and chest, and light-headedness have been described in other case reports and studies involving the concurrent use of levodopa with **pargyline**,² **nialamide**,³ **tranylcypromine**,^{4,5} **phenelzine**⁶ and **isocarboxazid**.¹

(b) RIMAs

A study in 12 healthy subjects given a single dose of levodopa/benserazide with **moclobemide** 200 mg twice daily found that nausea, vomiting and dizziness were increased, but no significant hypertensive reaction was seen.⁷

Mechanism

Not fully understood. Levodopa is enzymatically converted in the body, firstly to dopamine and then to noradrenaline, both of which are normally broken down by monoamine oxidase. But in the presence of an MAOI this breakdown is suppressed, which means that the total levels of dopamine and noradrenaline are increased. Precisely how this then leads to a sharp rise in blood pressure is not clear, but either dopamine or noradrenaline, or both, directly or indirectly stimulate the alpha-receptors of the cardiovascular system.

Importance and management

The interaction between the non-selective MAOIs (listed in ‘Table 32.1’, (p.1130)) and levodopa on its own is well documented, serious and potentially life-threatening. Patients should not be given levodopa on its own during treatment with any of these MAOIs, nor for a period of 2 to 3 weeks after their withdrawal. Note that this interaction is inhibited by the presence of dopa-decarboxylase inhibitors⁴ such as carbidopa and benserazide (as in *Sinemet* and *Madopar*) so that a serious interaction is unlikely to occur with these preparations. Even so, the manufacturers continue to list the MAOIs among their contraindications.

No important acute adverse interaction appears to occur between levodopa/benserazide and moclobemide, but some adverse effects can apparently occur.

MAOIs or RIMAs + Lithium

Two cases of tardive dyskinesia have been described following the long-term use of tranylcypromine and lithium, which did not resolve when the MAOI was stopped. Limited evidence suggests that no problems occur when moclobemide is given with lithium.

Clinical evidence, mechanism, importance and management

(a) MAOIs

One report describes 2 patients with bipolar affective disorder who developed a buccolingual-masticatory syndrome after taking **tranylcypromine** 30 or 40 mg daily and lithium carbonate 900 or 1200 mg daily for 1.5 or 3 years. These symptoms did not resolve when the **tranylcypromine** was stopped. This reaction was attributed to dopamine receptor hypersensitivity.¹

There appear to be no other reports suggesting that the combination of MAOIs and lithium is unsafe. However, there are a few reports of patients taking MAOIs and lithium who developed hyperpyrexia when given 'tryptophan', (p.1151). The role (if any) of lithium in these cases is unknown. Note that lithium has been used to augment antidepressants although most of the data relate to tricyclics or SSRIs.² Bear these cases in mind in the event of any unexpected response to treatment with MAOIs and lithium.

(b) RIMAs

There was no evidence of any adverse interaction when **moclobemide** 150 to 675 mg daily was given for 3 to 52 weeks to 50 patients taking lithium.³ Similarly, lithium augmentation was used in a small uncontrolled study in patients on high-dose **moclobemide** without any evidence of important adverse effects.⁴

MAOIs + MAOIs or RIMAs

Strokes, fatal reactions (possibly including the serotonin syndrome), hypertensive reactions and CNS disturbances have been seen, either when one MAOI was abruptly replaced by another, when the two MAOIs were given together, or when there was an insufficient MAOI-free interval. A case of serotonin syndrome occurred in a patient who overdosed on moclobemide and tranylcypromine.

Clinical evidence, mechanism, importance and management

(a) MAOIs + MAOIs

A patient who had been taking **isocarboxazid** for 3.5 weeks (starting at 10 mg daily and gradually increased to 30 mg daily) was switched to **tranylcypromine** 10 mg, starting the same day, followed by 10 mg three times daily on the following day. Later that night she complained of feeling 'funny', had difficulty in talking, developed a headache, was restless, flushed, sweating, had an elevated temperature of 39.5°C, and a pulse rate of 130 bpm. She died the following day.¹ Another patient, switched without a drug-free period, from **phenelzine** 75 mg daily (by tapering the dose by 15 mg daily until discontinued) to **tranylcypromine** (starting at 10 mg daily, increasing by 10 mg daily, until a dose of 20 mg twice daily was reached), suffered a subcortical cerebral haemorrhage on the fourth day following the morning 20-mg dose of **tranylcypromine**, which resulted in total right-sided hemiplegia.^{2,3} The patient remained significantly disabled from the sequelae of her stroke.⁴ A third patient experienced a mild cerebral haemorrhage, without residual problems, when she took **phenelzine** 45 mg and **tranylcypromine** 20 mg at bedtime; the MAOIs were being switched by reducing the dose of phenelzine and gradually increasing the dose of **tranylcypromine**. Consumption of 'soy sauce', (p.1153), may have contributed to this reaction.⁵ In a fourth case, **phenelzine** 45 mg daily was stopped, and then after a two-day drug-free period **tranylcypromine** 20 mg was given, with a further 30-mg dose the next day. The patient experienced a rise in blood pressure to 240/130 mmHg, but recovered uneventfully, and a year later was successfully switched from **phenelzine** to **tranylcypromine** with a 2-week drug-free interval.² In another case, hypertension with severe headache, inability to walk and slurred speech, but without permanent sequelae, resulted from starting **tranylcypromine** 30 mg seven days after discontinuing **phenelzine**. **Tranylcypromine**

10 mg daily was restarted 3 days later (10 days after discontinuing the **phenelzine**) with no adverse effects, but when the dose was increased to 20 mg daily (14 days after discontinuing **phenelzine**) the patient experienced a milder version of the same symptoms.⁶

Acute CNS toxicity, hypertension, tachycardia, tremor and urinary retention occurred in a woman 48 hours after **phenelzine** was abruptly stopped and **isocarboxazid** started. In this patient, **phenelzine** was poorly tolerated causing hypertension and headache.⁷

Switching from **iproniazid** to **tranylcypromine**/trifluoperazine may have been the cause of a fatal reaction (fever, shivering, sweating, cyanosis) in a patient also given ephedrine^{8,9} (see also 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1147).

In contrast, one woman was switched directly from **phenelzine** 60 mg daily to **tranylcypromine** 20 mg daily without any obvious problems (blood pressure was on the high side, but within the usual range for this patient). She was abruptly switched directly back to **phenelzine**, again without any adverse effect.^{10,11} Similarly, a review of 8 cases of patients who were switched rapidly from **tranylcypromine** to **phenelzine** (3 cases) or *vice versa* (5 cases) found that 7 patients tolerated the switch well with minimal or no adverse effects. However the eighth patient experienced anxiety, nausea, hyperventilation, flushing, sense of doom, and increased insomnia, which may have been a mild form of the serotonin syndrome.¹²

The reasons for these reactions are not understood, but one idea is that the amphetamine-like properties of **tranylcypromine** may have had some part to play. Certainly there are cases of spontaneous rises in blood pressure and intracranial bleeding in patients given **tranylcypromine**.¹³ Not all patients experience adverse reactions when switched from one MAOI to another,^{10,12} but because of the sometimes severe reactions, it would seem prudent to have a drug-free wash-out interval when doing so, and to start dosing in a conservative and step-wise manner.

(b) RIMAs + MAOIs

The serotonin syndrome occurred in a patient who took an overdose of **moclobemide** and **tranylcypromine**. In this analysis of moclobemide overdoses, the risk of developing serotonin toxicity was increased 35-fold in patients who also took another serotonergic drug, of which this case with **tranylcypromine** was one of 11 mentioned.¹⁴

MAOIs + Mazindol

An isolated report describes a patient taking phenelzine who had a marked rise in blood pressure when given a single dose of mazindol.

Clinical evidence, mechanism, importance and management

A woman taking **phenelzine** 30 mg three times daily had a rise in blood pressure from 110/60 to 200/100 mmHg within 2 hours of receiving a 10-mg test dose of mazindol. The blood pressure remained elevated for another hour, but had fallen again after another 3 hours. The patient experienced no subjective symptoms.¹ It is uncertain whether this hypertensive reaction was the result of an interaction, or simply a direct response to the mazindol alone (the dose was large compared with the manufacturer's recommended dosage of 2 to 3 mg daily). The general importance is uncertain. The manufacturer advises avoiding the combination, and say that

mazindol should not be used until 14 days after MAOIs have been stopped.²

MAOIs + Methyldopa

Theoretically hypertension may occur when non-selective MAOIs are taken with methyldopa, although additive blood-pressure lowering effects are also a possibility. The concurrent use of anti-depressant MAOIs and methyldopa may not be desirable because methyldopa can sometimes cause depression.

Clinical evidence, mechanism, importance and management

Theoretically, methyldopa might cause hypertension in patients treated with non-selective MAOIs, by releasing catecholamines into the circulation^{1,2} On the basis of this the manufacturers of some MAOIs^{3,4} and methyldopa⁵ contraindicate concurrent use. Nevertheless, there do not appear to be any reports of hypertension occurring as a result of concurrent use. Conversely, the UK manufacturer of **isocarboxazid**⁶ mentions that it may potentiate the hypotensive effect of methyldopa. MAOIs alone have hypotensive effects and additional blood pressure lowering effects have been reported in a few patients given **pargyline** (an MAOI formerly used in the treatment of hypertension) with methyldopa.^{7,8} Note that the potential depressant adverse effects of methyldopa may make it an unsuitable drug for patients with depression.

MAOIs + Monosodium glutamate

Hypertension in patients taking MAOIs who had eaten certain foods (soy sauce, chicken nuggets) has been attributed, in anecdotal reports, to an interaction with monosodium glutamate. However, a small controlled study found no evidence to support this idea, and the reaction was probably related to 'tyramine', (p.1153).

Clinical evidence

Five healthy subjects were given monosodium glutamate 400 to 1600 mg or a placebo with or without **tranlycypromine** for at least 2 weeks. Episodes of hypertension were seen in 2 subjects taking **tranlycypromine** with both placebo and monosodium glutamate, but no changes in blood pressure or heart rate occurred that could be attributed to an interaction while taking monosodium glutamate. The largest dose of monosodium glutamate used was about twice the amount usually found in meals containing large amounts of monosodium glutamate.¹

There have been anecdotal reports of hypertensive reactions in patients taking MAOIs that were attributed to interactions with the monosodium glutamate contained in **soy sauce**² and **chicken nuggets**.³

Mechanism

Monosodium glutamate alone can cause a small rise in blood pressure, and MAOIs alone very occasionally cause hypertensive episodes. However, the reactions reported with soy sauce and chicken nuggets were probably due to a high tyramine content, as a high tyramine content has subsequently been detected in some soy sauces,⁴ (see also 'MAOIs or RIMAs + Tyramine-rich foods', p.1153).

Importance and management

No interaction between monosodium glutamate *per se* and MAOIs has been established, although it should be pointed out that the number of subjects studied was very small. It is quite possible that the anecdotal reports were due to the tyramine content of the foods, and not to monosodium glutamate. In Hong Kong, patients on MAOIs are not advised to avoid monosodium glutamate, but are instructed to avoid excessive soy sauce because of its possible high tyramine content.⁴

MAOIs + Opioids; Fentanyl and related drugs

Fentanyl has been used without problems in a few reports, but one fatal case of hyperthermia has occurred, and also a case of hypertension and tachycardia. Case reports describe the uneventful use of alfentanil, remifentanil and sufentanil in patients taking MAOIs.

Clinical evidence

(a) Alfentanil

A 54-year-old woman taking **tranlycypromine** with trifluoperazine underwent general anaesthesia with no problems. She received temazepam as premedication, and propofol induction. Supplementary alfentanil was given in increments of 250 micrograms to a total of 2.5 mg. Atracurium was given for neuromuscular block with 100% oxygen for ventilation.¹ Similarly, another report describes successful anaesthesia using propofol, alfentanil 25 micrograms/kg, and succinylcholine during ECT therapy in two patients taking a variety of drugs including **phenelzine**.²

(b) Fentanyl

A 71-year-old woman taking **Parstelin (tranlycypromine)** with trifluoperazine was given an intravenous test dose of fentanyl 20 micrograms and diazepam before surgery, without problems. She was then given another 20-microgram intravenous dose of fentanyl during surgery, followed by an epidural bolus infusion of fentanyl 50 micrograms 15 minutes before the end of the surgery. After surgery she was given a continuous epidural infusion of fentanyl 50 to 70 micrograms/hour for 4 days to control postoperative pain, also without problems.³ Similarly, another report describes 2 patients who had stopped taking **phenelzine** 36 hours and 10 days before undergoing uneventful cardiac surgery using fentanyl, pancuronium and 100% oxygen.⁴ Four further patients taking **tranlycypromine, isocarboxazid, or pargyline** had no adverse reactions to fentanyl given during surgery (3 cases) or for postoperative pain relief (3 cases).⁵

In contrast, a man taking **tranlycypromine** who received fentanyl during and after surgery developed postoperative hypertension, hyperthermia, and severe shivering followed by resistant hypotension, and finally died.⁶ Another patient taking **phenelzine** who underwent cardiac surgery, with anaesthesia maintained by fentanyl and midazolam, developed hypertension and supraventricular tachycardia, which did not respond to digoxin and esmolol. About 15 minutes after stopping the fentanyl/midazolam and starting enflurane, the haemodynamics gradually improved, and analgesia was subsequently managed with ketorolac without problems.⁷

(c) Remifentanil

A patient taking **phenelzine** was given remifentanil for the maintenance of anaesthesia without adverse effect. An adverse interaction was considered unlikely with this combination.⁸

(d) Sufentanil

A 43-year-old woman taking **tranlycypromine** 60 mg daily underwent general anaesthesia with sufentanil, isoflurane, and nitrous oxide without problem.⁹

Mechanism, importance and management

Fentanyl has been used safely in a number of patients receiving MAOIs. However, a fatality due to a serotonin-like syndrome has occurred in a patient taking an MAOI given fentanyl, and another case of hypertension and tachycardia has occurred. The authors of one of these reports, considered that there was insufficient evidence to conclude that patients on MAOIs can be given fentanyl safely, and call for all cases of combined use to be reported.⁶ Case reports also describe the safe use of alfentanil, remifentanyl, and sufentanil. However, one UK manufacturer of fentanyl patches recommends that they should not be used during the use of, or within 14 days of stopping, an MAOI.¹⁰

Note that fentanyl and related drugs are frequently used during surgery, and it is generally considered that MAOIs should be discontinued 2 weeks before surgery, see 'Anaesthetics, general + MAOIs', p.100.

MAOIs or RIMAs + Opioids; Dextropropoxyphene (Propoxyphene)

An isolated report describes 'leg shakes', diaphoresis and severe hypotension in a woman taking phenelzine when she was given dextropropoxyphene. Another isolated report describes a marked increase in sedation when a woman was given phenelzine and dextropropoxyphene. Animal data show moclobemide potentiates dextropropoxyphene.

Clinical evidence, mechanism, importance and management

(a) MAOIs

A woman taking phenelzine 15 mg three times daily, sodium valproate, lithium and trazodone, was given dextropropoxyphene 100 mg and paracetamol (acetaminophen) 650 mg for back pain and headache. Some 12 hours later she was admitted to hospital for leg shakes, discomfort and weakness. She was confused and anxious, and intensely diaphoretic. The next day she became severely hypotensive (systolic BP 55 to 60 mmHg) and needed large fluid volume resuscitation in intensive care. She later recovered fully.¹ Another woman taking propranolol, oestrogen-replacement therapy and phenelzine became very sedated and groggy, causing her to have to lie down on two occasions, both within 2 hours of taking dextropropoxyphene 100 mg and paracetamol 650 mg. She had experienced no problems with either paracetamol or dextropropoxyphene/paracetamol before starting the phenelzine, and subsequently had no problems with paracetamol alone while continuing the phenelzine.² The mechanisms of these interactions are not understood but some of the symptoms in the first case were not unlike those seen in the serotonin syndrome.

Apart from these two isolated reports, there seems to be no other clinical evidence of adverse interactions between MAOIs and dextropropoxyphene. For reports of the serotonin syndrome seen with pethidine (meperidine) and MAOIs, see 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1140.

(b) RIMAs

In animals, the effects of dextropropoxyphene were increased by moclobemide.³ A brief mention is made of 3 patients, taking moclobemide and codeine (2 patients) or dextropropoxyphene (1 patient): one of these patients developed moderate agitation.³

MAOIs + Opioids; Miscellaneous

Hypotension (profound in one case) has been seen in a few patients given morphine and an MAOI. One case of hypotension and stupor has occurred with papaveretum. Single cases of the safe use of methadone and hydromorphone have also been described.

Clinical evidence

(a) Hydromorphone

No problems were encountered when a patient taking **tranylcypromine** was given hydromorphone via a patient-controlled device for postoperative pain.¹ This patient also received sufentanil during surgery without problem.

(b) Methadone

A patient receiving methadone maintenance therapy (30 mg daily) was successfully and uneventfully treated for depression with **tranylcypromine**, initially 10 mg daily gradually increased to 30 mg daily.²

(c) Morphine

A study in 15 patients who had been taking either **phenelzine**, **isocarboxazid**, **iproniazid** or **Parstelin** (**tranylcypromine** with trifluoperazine) for 3 to 8 weeks, had no changes in blood pressure, pulse rate or state of awareness when given test doses of up to 4 mg of intramuscular morphine. However, note that none of these patients showed an interaction with test doses of up to 40 mg of **pethidine** (meperidine).³ One other study reported no adverse interaction in 3 patients taking **isocarboxazid** when they were given morphine premedication,⁴ and a further study revealed no problems in 9 patients taking **tranylcypromine** who were given morphine for postoperative pain relief.⁵ Another patient taking **phenelzine** was uneventfully treated with morphine postoperatively.⁶ Two further patients taking MAOIs, who reacted adversely to **pethidine** (meperidine),^{7,8} had not previously done so when given morphine. In an early report, intramuscular morphine was given without apparent problem to 5 patients who had developed severe headache while taking **tranylcypromine**.⁹ Another author briefly noted that he knew of about 10 cases where morphine had been used in patients taking MAOIs with no adverse effects except a more prolonged morphine action.¹⁰

However, a patient taking **tranylcypromine** 40 mg and trifluoperazine 20 mg daily and undergoing a preoperative test with morphine, developed pin point pupils, became unconscious and unresponsive to stimuli, and had a systolic blood pressure fall from 160 to 40 mmHg after receiving a total of 6 mg of morphine intravenously. Within 2 minutes of being given naloxone 4 mg intravenously, the patient was awake and rational with a systolic blood pressure fully restored.¹¹ A moderate fall in blood pressure (from 140/90 to 90/60 mmHg) was seen in another patient taking an MAOI given morphine,¹² and a brief episode of hypotension treated with phenylephrine occurred in a patient taking **phenelzine** receiving continuous epidural morphine during surgery.⁵

(d) Papaveretum

A 54-year-old woman taking **phenelzine** was given papaveretum 10 mg as premedication, and 50 minutes later she was found to be unrousable, sweating and hypotensive.¹³

Mechanism, importance and management

This serious MAOI/pethidine interaction also casts a shadow over morphine, which probably accounts for its inclusion in a number of lists and charts of drugs said to interact with the MAOIs. However, there is some limited evidence that patients on MAOIs who had reacted adversely with pethidine did not do so when given morphine,^{7,8} and quite a number of reports of its safe use. The few hypotensive reactions cited here^{5,11,12} are of a different character and appear to be rare. There would therefore seem to be no good reason for avoiding morphine in patients taking MAOIs, but be alert for the rare adverse response. However, several manufacturers have contraindicated concurrent use of morphine in patients taking MAOIs or within 2 weeks of stopping an MAOI,^{14–16} because they can cause CNS adverse effects with hyper- or hypotension.^{14,15} A similar sit-

uation exists with codeine: one UK manufacturer of a codeine/paracetamol product states that concurrent use of codeine with an MAOI may increase the effects of both drugs;¹⁷ however another contraindicates the use of codeine, both with and within 14 days of stopping an MAOI.¹⁸ Some recommend lower initial dosages of morphine or oxycodone, frequent monitoring, and gradual upward dose titration.¹⁹ One case report suggests that MAOIs can be given to patients on methadone, but the evidence is clearly limited.

MAOIs or RIMAs + Opioids; Pethidine (Meperidine)

The concurrent use of pethidine and MAOIs has resulted in a serious and potentially life-threatening reaction in several patients, and one possible case has been reported with moclobemide. Excitement, muscle rigidity, hyperpyrexia, flushing, sweating and unconsciousness can occur very rapidly. Respiratory depression and hypertension or hypotension have also been seen. Pethidine should not be given to patients taking any MAOI or RIMA.

Clinical evidence

(a) MAOIs

Severe, rapid and potentially fatal toxic reactions, both excitatory and depressant can occur:

A woman stopped taking **iproniazid** 50 mg twice daily and about a day and a half later became restless and incoherent almost immediately after being given pethidine 100 mg for chest pain. She was comatose within 20 minutes. An hour after receiving the injection she was flushed, sweating and showed Cheyne-Stokes respiration. Her pupils were dilated and unreactive. Deep reflexes could not be initiated and plantar reflexes were extensor. Her pulse rate was 82 bpm and blood pressure 156/110 mmHg. She was rousable within 10 minutes of receiving an intravenous injection of prednisolone hemisuccinate 25 mg. A very similar reaction was described in another patient.¹

A woman who, unknown to her doctor, was taking **tranlycypromine**, was given pethidine 100 mg. Within minutes she became unconscious, noisy and restless, having to be held down by 3 people. Her breathing was stertorous and the pulse impalpable. Generalised tonic spasm developed, with ankle clonus, extensor plantar reflexes, shallow respiration and cyanosis. On admission to hospital she had a pulse rate of 160 bpm, a blood pressure of 90/60 mmHg and was sweating profusely (temperature 38.3°C). Her condition gradually improved and 4 hours after admission she was conscious but drowsy. Recovery was complete the next day.²

Other cases of this interaction have been reported in patients treated with **iproniazid**,^{3–5} **pargyline**,^{6,7} **phenelzine**,^{8–13} and **mebanazine**.¹⁴ Fatalities have occurred. One of 8 patients taking an MAOI and given test doses of

pethidine experienced a drop in systolic blood pressure of 30 mmHg and a rise in pulse rate of 20 bpm after the first 5-mg dose of pethidine.¹⁵ However, a study in 15 patients who had been taking either **phenelzine**, **isocarboxazid**, **iproniazid** or **Parstelin** (**tranlycypromine** with trifluoperazine) for 3 to 8 weeks, found no changes in blood pressure, pulse rate or state of awareness with test doses of up to 40 mg of pethidine.¹⁶ Similarly, no major problems were noted in a retrospective review of 45 episodes of anaesthesia in patients taking **isocarboxazid** who were given pethidine as part of premedication.¹⁷

(b) RIMAs

One report suggests that on the basis of *animal* studies the combination of **moclobemide** and pethidine should be avoided or used with caution.¹⁸ A report of suspected serotonin syndrome in a 73-year-old woman, given pethidine in addition to her usual treatment with **moclobemide** 750 mg daily, nortriptyline 100 mg daily and lithium 750 mg daily, adds some weight to this suggestion.¹⁹

Mechanism

Not understood, despite the extensive studies undertaken.^{20–22} The reaction has proved difficult to study in *animals*, since mice appear to be more sensitive to the reaction than humans. There is some evidence that the reactions may be due to an increase in levels of 5-HT within the brain, causing 'the serotonin syndrome', (p.9). Tramadol, an opioid with additional noradrenergic and serotonergic properties, has clearly caused the serotonin syndrome when used with MAOIs, see 'tramadol', (p.1141).

Importance and management

The interaction between pethidine and the MAOIs, which was first observed in the mid-1950s, is based on case reports. One case has been reported with RIMA moclobemide. It is serious and potentially fatal. Its incidence is unknown, but it is probably quite low, because one study that attempted to produce the interaction by giving increasing test doses of pethidine to 15 patients taking various MAOIs did not show the interaction.¹⁶ It may therefore be an idiosyncratic reaction. Nevertheless, it would be imprudent to give pethidine to any patients on an MAOI or RIMA. Bear in mind that the older MAOIs are all essentially irreversible so that an interaction is possible for many days after their withdrawal (at least 2 weeks is the official advice), whereas the newer RIMAs (e.g. moclobemide) are reversible and unlikely still to interact 48 hours after they have been stopped.

Sensitivity test

A sensitivity test has been suggested,¹⁵ but given the fact that there are many alternatives to pethidine and MAOIs readily available, and given that a drop in systolic blood pressure of 30 mmHg has been reported even with the first step of the test dose (5 mg of pethidine)¹⁵ it would seem prudent to avoid the combination. Also, the test dose procedure is unlikely to be suitable when opioids are required in an emergency situation.

MAOIs + Opioids; Tramadol

The serotonin syndrome developed in one patient on iproniazid and tramadol, and delirium in another given tramadol shortly after stopping phenelzine. A fatal case of possible serotonin syndrome has been seen with tramadol, moclobemide and clomipramine.

Clinical evidence, mechanism, importance and management

The manufacturers of tramadol contraindicated its use with the MAOIs^{1,2} on the basis that it is an opioid agonist, like pethidine (meperidine). This may mean the serotonin syndrome could develop (see ‘MAOIs or RIMAs + Opioids; Pethidine (Meperidine)’, p.1140). This prediction was confirmed by a report³ of the development of the serotonin syndrome (myoclonus, tremor, sweating, hyperreflexia, tachycardia) in a patient on **iproniazid** when tramadol was added to his drug regimen. When the tramadol was stopped the patient recovered within 48 hours. Another single case report describes the development of severe delirium in a patient within 3 days of stopping long term treatment with **phenelzine** 45 mg daily and starting intramuscular tramadol 100 mg three times daily. The patient became anxious and confused, and developed visual hallucinations and persecutory ideation. The symptoms disappeared within 48 hours of stopping the tramadol.⁴ Another report suggests that tramadol may have contributed to the development of a fatal serotonin syndrome in a patient abusing tramadol, **moclobemide** and clomipramine.⁵

This demonstrates that there are sound practical and theoretical reasons for patients on MAOIs to avoid tramadol. Note that the serotonin syndrome has also occurred with ‘tramadol and SSRIs’, (p.1222).

MAOIs or RIMAs + Phenothiazines

The concurrent use of MAOIs and phenothiazines is usually safe and effective. However, rarely, cases of possible neuroleptic malignant syndrome or hyperpyrexia have been reported with MAOIs and chlorpromazine, levomepromazine or trifluoperazine. Some of these cases were fatal. Chlorpromazine has been successfully used for treatment of the serotonin syndrome occurring with MAOIs and other drugs. Moclobemide has been used with various phenothiazines without problem, but one case of fatal overdose is attributed to an interaction between moclobemide and perazine.

Clinical evidence

(a) MAOIs

MAOIs and phenothiazines have been safe and effective when used together in the treatment of psychiatric conditions, particularly in the form of a preparation containing both **tranlycypromine** and **trifluoperazine**,^{1–3} which is still marketed in some countries. There is also a report of the beneficial use of **tranlycypromine** with **chlorpromazine**.⁴

However, rarely, cases suggestive of the neuroleptic malignant syndrome or similar have been reported. In one case, a 70-year-old woman taking **isocarboxazid** 10 mg daily and **chlorpromazine** 25 mg three times daily, suddenly developed dyspnoea, tachycardia, pyrexia, muscular rigidity, hypotension, and became comatose. Her condition initially improved over 24 hours, but she later died from acute renal failure as a result of rhab-

domyolysis. Throughout the previous 2 years of inpatient care, the patient had received neuroleptics intermittently and had developed an unexplained toxic confusional state on 6 occasions, which suggested that the neuroleptic malignant syndrome had a milder chronic course in this patient before the full acute syndrome developed.⁵ In another case, a woman presented with symptoms of the neuroleptic malignant syndrome one week after starting **tranlycypromine/trifluoperazine** 10/1 mg and immediately after doubling the dose. She was intubated and treated with dantrolene and intravenous sodium bicarbonate, and made a full recovery.⁶ Interpretation of her case is complicated by the fact she had been previously taking imipramine, and was switched to tranlycypromine/trifluoperazine without a break (see also ‘MAOIs or RIMAs + Tricyclic and related antidepressants’, p.1149). One study mentions an unexplained fatality in a woman who suddenly developed hyperthermia and coma while taking **levomepromazine** and **pargyline**.⁷ Another report briefly mentions a woman who developed fatal hyperthermia while taking **levomepromazine** and **tranlycypromine**,⁸ and a fatality following the use of an unnamed MAOI/phenothiazine combination.⁸ Note that **chlorpromazine**⁹ has 5-HT antagonist activity, and has been successfully used in the treatment of severe serotonin syndrome occurring with ‘MAOIs and tricyclic antidepressants’, (p.1149).

One early reviewer stated that MAOIs increase the potency of phenothiazine derivatives such that their initial dose should be reduced by three-quarters. He briefly mentions a case of a patient taking long-term **perphenazine** who developed a Parkinson-like syndrome with extrapyramidal symptoms a few hours after starting an MAOI.¹⁰ The US manufacturers note that, based on the increased incidence of extrapyramidal effects reported with concurrent use of some MAOIs and phenothiazines, this possibility should be considered with **promethazine**.¹¹

A report attributes 2 cases of fatal fulminant hepatitis to an interaction between **iproniazid** and **prochlorperazine**.¹²

A single report¹³ describes a woman taking an MAOI who developed a severe occipital headache after taking 30 mL of a paediatric cough linctus. Initially this interaction was attributed to **promethazine**, but it is now known that the linctus in question contained phenylpropanolamine, which is much more likely to have been the cause.¹⁴ See ‘MAOIs or RIMAs + Sympathomimetics; Indirectly-acting’, p.1147 for the interaction with phenylpropanolamine.

(b) RIMAs

Clinically relevant interactions were not noted when **moclobemide** was given with one or more neuroleptics (including phenothiazines such as **chlorpromazine**, **levomepromazine**, **thioridazine**). Adverse effects such as hypotension, tachycardia, drowsiness, tremor, and constipation were somewhat more frequent, probably due to additive effects.¹⁵ A fatal case of overdose with **moclobemide** and **perazine** was attributed to synergistic effects resulting in functional cardiovascular disorder.¹⁶

Mechanism

Neuroleptic malignant syndrome (NMS) is a rare condition associated with a reduction in dopamine activity in the brain, which has occurred with a wide variety of dopamine antagonists including the phenothiazines. It is unclear what role, if any, is played by the MAOIs in the few possible cases cited here. Note that MAOIs can cause the similar serotonin syndrome, and it is important to differentiate between the two conditions, especially since phenothiazines would aggravate NMS, but can successfully treat the serotonin syndrome.

Importance and management

No special precautions would normally seem to be necessary during the concurrent use of MAOIs and phenothiazines. However, bear in mind that serious, sometimes fatal, cases of the neuroleptic malignant syndrome or hyperpyrexia have rarely occurred with combinations of MAOIs and **chlorpromazine**, **levomepromazine** and **trifluoperazine**. The role of the MAOI in these cases is unclear. Chlorpromazine has been used successfully to treat the serotonin syndrome occurring with MAOIs and other serotonergic drugs, but note that it should be avoided if neuroleptic malignant syndrome is a possible diagnosis, or if the patient is hypotensive, see ‘MAOIs or RIMAs + Tricyclic and related antidepressants’, p.1149.

MAOIs + Rauwolfia alkaloids or Tetrabenazine

Central excitation and possibly hypertension can occur if rauwolfia alkaloids are given to patients already taking an MAOI, but is less likely if the rauwolfia alkaloid is given first. Theoretically additive blood-pressure lowering effects are also a possibility. The use of drugs that have the potential to cause depression, such as the rauwolfia alkaloids or tetrabenazine, is generally contraindicated in patients needing treatment for depression.

Clinical evidence

A woman with a history of manic depression who had been in a depressed phase for 5 years was given **nialamide** 100 mg three times daily. Two days later, **reserpine** 500 micrograms three times daily was also started. The following day she became frankly hypomanic and almost immediately went into mania.¹

In another report,² a patient, who was started on **tetrabenazine** 10 mg three times daily, 2 days after stopping a week of treatment with **nialamide** 25 mg daily, collapsed 6 hours after the first dose, and demonstrated epileptiform convulsions, partial unconsciousness, rapid respiration and tachycardia. He recovered within 15 minutes, but 3 days later he had a similar attack and the **tetrabenazine** was stopped.

Another author states that the use of **reserpine** or **tetrabenazine** after pretreatment with **iproniazid** can lead to a temporary disturbance of affect and memory, associated with autonomic excitation, delirious agitation, disorientation and illusions of experience and recognition, which lasts for up to 3 days.^{3,4}

A prolonged period of increased motor activity after starting **reserpine** ('reserpine-reversal') possibly occurred in 3 patients with schizophrenia treated firstly with **phenelzine** for 12 weeks, then a placebo for 16 to 33 weeks, and lastly **reserpine** for 12 weeks, when compared with patients receiving **reserpine** who had not received an MAOI. Their blood pressures rose slightly and persistently, and their psychomotor activity was considerably increased, lasting in two cases throughout the 12-week period of treatment.⁵

Theoretically, **reserpine** might cause hypertension in patients treated with non-selective MAOIs (see Mechanism). On the basis of this the US manufacturer of **tranylcypromine**⁶ contraindicates concurrent use. Conversely, the UK manufacturer of **isocarboxazid**⁷ mentions that it may potentiate the hypotensive effect of **reserpine** (MAOIs alone can have hypotensive effects).

Mechanism

Rauwolfia alkaloids such as reserpine cause adrenergic neurones to become depleted of their normal stores of noradrenaline (norepinephrine). In this way they prevent or reduce the normal transmission of impulses at the adrenergic nerve endings of the sympathetic nervous system and thereby act as antihypertensives. Since the brain also possesses adrenergic neu-

rones, failure of transmission in the CNS could account for the sedation and depression observed with these drugs. If rauwolfia alkaloids are given to patients already taking an MAOI, large amounts of accumulated noradrenaline can be released throughout the body. In the brain, 5-HT is also released. The release of these substances results in marked central excitation and hypertension. This would account for the case reports cited and the effects seen in *animals*.^{8–10} These stimulant effects are sometimes called 'reserpine-reversal' because instead of the expected sedation or depression, excitation or delayed depression is seen. It depends upon the order in which the drugs are given.

Importance and management

The use of drugs that have the potential to cause depression is generally contraindicated in patients needing treatment for depression. However, one report suggests that if concurrent use is considered desirable, the MAOIs should be given after, and not before the rauwolfia alkaloid, so that sedation rather than excitation will occur.¹¹ Bear in mind the possibility of hypo- or hypertension.

MAOIs or RIMAs + SSRIs

A number of case reports describe the serotonin syndrome in patients given SSRIs with MAOIs: some have been fatal. Concurrent use is contraindicated. Some studies suggest that moclobemide may not interact with the SSRIs, but there have also been case reports of the serotonin syndrome and concurrent use is contraindicated. A suitable washout interval is needed when switching between MAOIs or RIMAs and SSRIs.

Clinical evidence, mechanism, importance and management

A. MAOIs

(a) Fluoxetine

A very high incidence (25 to 50%) of adverse effects occurred in 12 patients taking fluoxetine 10 to 100 mg daily with either **phenelzine** 30 to 60 mg daily or **tranylcypromine** 10 to 140 mg daily, and in 6 other patients started on either of these MAOIs 10 days or more after stopping fluoxetine. There were mental changes such as hypomania, racing thoughts, agitation, restlessness and confusion. The physical symptoms included myoclonus, hypertension, tremor, teeth chattering and diarrhoea.¹

A detailed review of cases reported to the manufacturers described 8 acute cases, 7 of them fatal, in patients given fluoxetine with either **tranylcypromine** or **phenelzine**.² Uncontrollable shivering, teeth chattering, double vision, nausea, confusion, and anxiety developed in a woman given **tranylcypromine** after stopping fluoxetine. The problem resolved within a day of stopping the **tranylcypromine**, and did not recur when fluoxetine was tried again 6 weeks later.³

A number of other reports describe similar reactions in patients given fluoxetine and **tranylcypromine**,^{3–8} some occurring up to 6 weeks after the SSRI was stopped,⁶ and several resulting in fatalities.^{3,7}

(b) Sertraline

A man taking **tranylcypromine** and clonazepam was additionally given sertraline 25 to 50 mg daily. Within 4 days he began to experience chills, increasing confusion, sedation, exhaustion, unsteadiness and incoordination. Other symptoms included impotence, urinary hesitancy and consti-

pation. These problems rapidly resolved when the sertraline was stopped and the **tranylcypromine** dosage reduced from 30 to 20 mg daily.⁹

A woman with a major depressive disorder taking lithium, thioridazine, doxepin and **phenelzine** was also given sertraline 100 mg daily for worsening depression. Within 3 hours she became semi-comatose, with a temperature of 41°C, a heart rate of 154 bpm and symptoms of rigidity and shivering. She was treated with diazepam, midazolam, ice-packs and dantrolene.¹⁰ Two other similar cases, involving the use of sertraline with **isocarboxazid**¹¹ and **phenelzine**¹² have been reported. The latter case was fatal.¹² Another case of mild serotonin syndrome (managed with cyproheptadine) occurred in a woman who took a single dose of sertraline 11 days after stopping **isocarboxazid**.¹³

B. RIMAs

(a) Citalopram

A 34-year-old man who had been taking **moclobemide** 100 mg every 8 hours for several months was switched to citalopram 20 mg daily without a break. An hour later he started getting agitated and had involuntary movements of the legs, which progressed to generalised rigidity. Apart from a heart rate of 100 bpm all other vital signs were normal. He was treated with benzodiazepines and recovered uneventfully.¹⁴ Three patients developed the serotonin syndrome (tremor, convulsions, hyperthermia, unconsciousness) and died 3 to 16 hours after taking overdoses of **moclobemide** and citalopram.¹⁵ Other cases of the serotonin syndrome after overdose of **moclobemide** and citalopram have been reported:^{16,17} one also included **sertraline** and sumatriptan.¹⁶

(b) Fluoxetine

A placebo-controlled trial in 18 healthy subjects found that the use of fluoxetine 20 mg with **moclobemide** 100 to 600 mg daily for 9 days gave no evidence of an adverse interaction.¹⁸ Other studies in healthy subjects and patients similarly found no evidence of the serotonin syndrome.^{19,20}

A post-marketing analysis found that at least 30 patients switched from fluoxetine to **moclobemide** within a week had experienced no adverse effects.^{18,21}

However, 3 patients have developed the serotonin syndrome²²⁻²⁴ and one developed agitation and confusion²⁵ following the use of **moclobemide** and fluoxetine. A fatal case of the serotonin syndrome occurred in a patient who took an overdose of **moclobemide**, fluoxetine, and clomipramine,²⁶ and another patient taking **moclobemide** developed the serotonin syndrome after taking an overdose of fluoxetine.²⁷ A study suggests that the combination may cause a high rate of adverse effects (insomnia, dizziness, nausea and headache).²²

A double-blind study in 41 healthy subjects found that when they were given fluoxetine 40 mg daily for 7 days, then 20 mg for 9 days, immediately followed by **befloxatone** (2.5, 5, 10 or 20 mg daily) for 5 days, no unusual adverse reactions occurred and no changes in body temperature, haemodynamics or ECGs were seen.²⁸

(c) Fluvoxamine

When 13 of 22 healthy subjects given fluvoxamine 100 mg daily for 9 days were also given **moclobemide** in increasing doses of 50 to 400 mg daily for 4 days from day 7, no serious adverse reactions occurred. Any adverse events were mild to moderate (some increase in headaches, fatigue, dizziness, all of which may occur with both drugs alone) and there was no evidence of the serious serotonin syndrome.^{18,29} An open study in 6 depressed patients given **moclobemide** 225 to 800 mg daily and fluvoxamine 50 to 200 mg daily found a marked improvement in depression. Insomnia was the commonest adverse effect (treated with trazodone) but none of the patients showed any evidence of the serotonin syndrome.³⁰ Similar results were found in other studies.^{20,31} However, a fatal case of the serotonin syndrome occurred in a woman who took an overdose of **moclobemide** and fluvoxamine, and another fatal overdose was attributed to the same combination.³²

(d) Paroxetine

An open 6-week study in 19 patients with major depression taking paroxetine (or fluoxetine) 20 mg daily to which **moclobemide** up to 600 mg daily was added, indicated that these combinations were possibly effective.³³ An extension of this study with 50 patients is reported elsewhere.²² However, a range of adverse effects occurred in some patients, the clearest one being insomnia, and the serotonin syndrome was seen in one patient.^{22,33} Conversely, the serotonin syndrome was not seen in another study, where low initial doses and gradual up-titration of both paroxetine and **moclobemide** was used.²⁰ Two possible cases of mild serotonin syndrome

occurred in women on **moclobemide** within 2 to 24 hours of starting additional paroxetine.³⁴ Similarly, cases of severe serotonin syndrome have been reported with overdoses of **moclobemide** and paroxetine.^{35,36}

(e) Sertraline

In one study, 31 severely ill patients were given **moclobemide** 35 to 800 mg daily with SSRIs including sertraline 25 to 100 mg daily, initially using lower than usual starting doses of both drugs and then gradually titrating them slowly upwards. The other SSRIs used were fluoxetine, fluvoxamine and paroxetine. There was no evidence of the serotonin syndrome.²⁰ An open study in 5 depressed patients given **moclobemide** 150 to 600 mg daily and sertraline 25 to 200 mg daily found improvements ranging from minimal to complete remission. Insomnia was the commonest adverse effect (treated with trazodone) but none of the patients showed any evidence of the serotonin syndrome.³⁰ However, one case of possible serotonin syndrome occurred in a woman who took an overdose of **moclobemide** and sertraline,³⁴ and another after an overdose of **moclobemide**, citalopram, sertraline and sumatriptan.¹⁶ Similarly, a fatality has been reported with an overdose of **moclobemide**, sertraline and pimozide, with blood levels suggesting that none of the drugs individually would have been fatal.³⁷

(f) Unspecified SSRIs

Serotonin toxicity (the serotonin syndrome) occurred in 5 patients who took an overdose of **moclobemide** with an SSRI [specific drugs not mentioned]. In this analysis of **moclobemide** overdoses, the risk of developing serotonin toxicity was increased 35 times in patients who also took another serotonergic drug. Of the 11 cases mentioned 5 patients were taking SSRIs.³⁸

Mechanism

MAO-A is involved in the metabolism of serotonin, so combined use of MAOIs or RIMAs with SSRIs may lead to excessive serotonin levels, which can result in the serotonin syndrome. For more information see 'the serotonin syndrome', (p.9).

Importance and management

Direct information about the interaction between MAOIs and SSRIs is limited. However, it is clear that severe, sometimes fatal interactions (the serotonin syndrome or similar) have occurred with MAOIs and fluoxetine or sertraline, so these reports should certainly be taken seriously. The incidence appears to be low, possibly as the combined use of any MAOI and any SSRI is contraindicated. In addition, at least 2 weeks should elapse between stopping any MAOI and starting any SSRI to allow for the effects of the MAOI to diminish. Moreover, the manufacturers of each SSRI give guidance on the appropriate intervals that should be left between stopping the SSRI and starting an MAOI, that is, 14 days for sertraline,^{39,40} seven days for citalopram,⁴¹ **escitalopram**,⁴² fluvoxamine⁴³ or paroxetine⁴⁴ (14 days in the US),⁴⁵⁻⁴⁷ and at least 5 weeks for fluoxetine, with an even longer interval if long-term or high-dose fluoxetine has been used.^{48,49}

The RIMAs (e.g. moclobemide) also have serotonergic effects, and so they are unlikely to be any safer than the non-selective MAOIs in regard to interactions with SSRIs. The few cases of serotonin syndrome cited with therapeutic doses of this combination confirm that it is not necessarily safe. The combination may be particularly problematic in overdose, and negates the generally benign course of moclobemide overdose alone. It should be noted that the manufacturer of moclobemide contraindicates its use with SSRIs.⁵⁰ Because the effects of moclobemide are readily reversible, only one day need elapse between stopping moclobemide and starting an SSRI. However, if stopping an SSRI and starting moclobemide, the same intervals are required as for the irreversible MAOIs.

For the management of serotonin syndrome, see Importance and management under 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1149.

MAOIs + Sulfafurazole (Sulfisoxazole)

An isolated report describes a patient taking phenelzine who developed weakness and ataxia after also taking sulfafurazole.

Clinical evidence, mechanism, importance and management

A woman who had been taking **phenelzine** 15 mg three times daily for about 3 weeks complained of weakness, ataxia, vertigo, tinnitus, muscle pains and paraesthesia within 7 days of starting to take sulfafurazole 1 g four times daily. These adverse effects continued until the 10-day sulfonamide course was completed, and did not occur again in the following 8 weeks.¹ The reasons are not understood, but as these adverse effects are a combination of the adverse effects of both drugs, it seems possible that a mutual interaction (perhaps saturation of the acetylating mechanisms in the liver) was responsible. This appears to be an isolated report, but bear it in mind in the event of an unexpected response to treatment.

MAOIs or RIMAs + Sympathomimetics; Amfetamines and related drugs

The concurrent use of non-selective MAOIs and amfetamines and related drugs can result in a potentially fatal hypertensive crisis and/or serotonin syndrome. Interactions have been reported for amfetamine, dexamfetamine, metamphetamine, and methylphenidate. Interactions have also been reported with the illicit drug ecstasy (MDMA, methylenedioxyamfetamine) when taken with phenelzine or moclobemide. The manufacturers of fenfluramine and dexfenfluramine contraindicated their use with MAOIs.

Clinical evidence

A. MAOIs

(a) Amfetamines

A 30-year-old depressed woman who was taking **phenelzine** 15 mg three times daily and trifluoperazine 2 mg at night, acquired some **dexamfetamine sulfate** tablets from a friend and took 20 mg. Within 15 minutes she complained of severe headache, which she described as if "her head was bursting". An hour later her blood pressure was 150/100 mmHg. Later she became comatose with a blood pressure of 170/100 mmHg and died. A postmortem examination revealed a haemorrhage in the left cerebral hemisphere, disrupting the internal capsule and adjacent areas of the corpus striatum.¹

This interaction has been reported with single oral doses of **amfetamine**,^{2,3} single intravenous doses of **amfetamine**,⁴ single doses of illicit **amfetamine/dexamfetamine**,^{5,6} or single doses of intravenous **metamphetamine**,⁷⁻¹⁰ in patients taking **tranylcypromine**,^{2,7,8} **phenelzine**,^{3,5,6,8,9} and **isocarboxazid**.^{8,10} A woman who had been addicted to high-dose **dexamfetamine/amobarbital** was hospitalised and had the **dexamfetamine/amobarbital** withdrawn. Five days later she was given a single dose of **tranylcypromine** and within an hour had a 20 minute episode of hypertension, tachycardia, headache, sweating, lacrimation and altered consciousness, which abated without treatment. She had similar attacks at 2-hourly intervals over about 5 days when they gradually became milder and shorter.¹¹

Extreme hyperpyrexia, apparently without hypertension, has been described in a woman who took **tranylcypromine** with **dexamfetamine/amobarbital**. She developed progressive agitation, diaphoresis, hyperkinesia, opisthotonus, coma and convulsions, but recovered following the use of an ice bath and other supportive measures.^{12,13}

(b) Dexfenfluramine or fenfluramine

The manufacturer recommended that fenfluramine should not be used in patients with a history of depression, or during treatment with antidepressants (especially the MAOIs), and there should be an interval of 3 weeks between stopping the MAOIs and starting fenfluramine.¹⁴ A woman taking **phenelzine** developed severe headache, neck stiffness and nausea within an hour of taking fenfluramine 20 mg, and then collapsed and re-

mained stuporous for about 4 hours. This reaction was considered similar to that seen with MAOIs and amfetamines.¹⁵

The manufacturer of dexfenfluramine similarly contraindicated its use with or within 2 weeks of stopping an MAOI,¹⁶ and advised waiting 3 weeks between stopping dexfenfluramine and starting an MAOI. This is due to the potential risk of the serotonin syndrome,^{17,18} which has rarely occurred with the concurrent use of two or more serotonergic drugs (see 'the serotonin syndrome', (p.9)). The manufacturer of dexfenfluramine and fenfluramine had found no clinical evidence of serious problems with either of these drugs when taken with MAOIs,¹⁹ so that the published warnings about possible interactions would appear to be based on theoretical considerations.

Note that dexfenfluramine and fenfluramine have generally been withdrawn because their use was found to be associated with a high incidence of abnormal echocardiograms indicating abnormal functioning of heart valves.

(c) Ecstasy (MDMA, methylenedioxyamfetamine)

Marked hypertension, diaphoresis, altered mental status and hypertonicity (slow forceful twisting and arching movements) occurred in one patient taking **phenelzine** with ecstasy.²⁰ Increased muscle tension, decorticate-like posturing, fever, tachycardia and coma occurred in another patient taking **phenelzine**, 15 minutes after drinking juice containing ecstasy.²¹ Both patients recovered.^{20,21}

(d) Methylphenidate

A patient started treatment with **tranlycypromine**, then 4 days later methylphenidate was added. After 15 days of concurrent use he had a hypertensive crisis and both drugs were stopped.²² In a study of the use of **phenelzine** as an antagonist to stimulants, 3 patients took oral or intravenous methylphenidate and all three experienced moderate to severe headache.⁶ An episode of symptoms consistent with the serotonin syndrome occurred in a man taking **isocarboxazid** and trazodone, 2 months after the dose of these drugs was increased and methylphenidate was added. He had experienced two similar episodes 4 and 8 weeks previously, which had each resolved spontaneously over 12 hours. All three drugs have serotonergic properties and were thought to have contributed to the reaction.²³ Conversely, a man taking **tranlycypromine** for depression was successfully treated with methylphenidate for attention deficit/hyperactivity disorder (ADHD). He was given methylphenidate 2.5 mg daily, which was very gradually increased over a number of months to 45 mg daily. He was successfully treated with the combination for 6 months and periodic blood pressure measurements did not change significantly from baseline.²⁴ Another similar case has been described with **phenelzine** and methylphenidate.²⁵ No cases of hypertensive crisis were seen in 4 patients taking **tranlycypromine** or **phenelzine** when treated concurrently with methylphenidate for periods of 6 to 30 months.²⁶

B. RIMAs

Four patients died after taking **moclobemide** and **ecstasy** (MDMA, methylenedioxyamfetamine). The clinical evidence is limited, but in each case the forensic pathologist concluded that the cause of death was the combined use of these drugs. It was suggested that what happened is consistent with the serotonin syndrome, although the evidence is fairly slim. Two patients had taken maximum therapeutic doses and two moderate overdoses of **moclobemide**. Note that **moclobemide** had not been prescribed to any of them. Post-mortem analysis also found the presence of **dextromethorphan** in one patient, which was thought to have contributed,²⁷ see also 'MAOIs or RIMAs + Dextromethorphan', p.1134.

Mechanism

The hypertensive reaction can be attributed to overstimulation of the adrenergic receptors of the cardiovascular system.²⁸ During treatment with non-selective MAOIs, large amounts of noradrenaline (norepinephrine) accumulate at adrenergic nerve endings not only in the brain, but also within the sympathetic nerve endings, which innervate arterial blood vessels. Stimulation of these latter nerve endings by sympathomimetic amines with indirect actions causes the release of the accumulated noradrenaline and results in the massive stimulation of the receptors. An exaggerated blood vessel constriction occurs and the blood pressure rise is proportionately excessive. Intracranial haemorrhage can occur if the pressure is so high that a blood vessel ruptures.¹

Some of the reactions may also possibly be related to the serotonin syndrome. Amfetamines act by releasing serotonin (and possibly also

dopamine) from neurones in the brain, so that increased stimulation of the serotonin receptors occurs. This possibly explains their mood-modifying effects. MAOIs prevent the breakdown of serotonin within neurones so that more serotonin is available for release, and in excess this can apparently result in the toxic and even fatal serotonin syndrome. The RIMAs (such as moclobemide) appear to behave like the older non-selective MAOIs in this context.

Importance and management

The hypertensive reaction is a very well-documented, serious, and potentially fatal interaction, whereas the serotonin syndrome appears to be rarer. Patients taking any of the non-selective MAOIs should not normally take amfetamines, or related drugs such as methylphenidate. A possible exception to this prohibition is that under very well controlled conditions dexamfetamine and methylphenidate may sometimes be effectively (and apparently safely) used with MAOIs for refractory depression,^{25,26,29} or ADHD.²⁴ Direct evidence implicating central stimulants such as **diethylpropion**, **mazindol**, **pemoline**, **phendimetrazine**, and **phenmetrazine** seems not to have been documented, but on the basis of their known pharmacology their concurrent use with the MAOIs should be avoided. Patients on MAOIs should also be warned to avoid the illicit use of amfetamines and ecstasy. It would also be prudent to avoid moclobemide with amfetamines and related drugs, although the incidence of the interactions with moclobemide is unlikely to be as great as that seen with the non-selective MAOIs. In the cases with ecstasy, it seems likely that high doses of moclobemide were used to try to enhance the actions of the ecstasy, but these cases, nevertheless, show that combined use is potentially life threatening.

Treatment

For a brief mention of the treatment of hypertensive crisis, see Importance and Management under 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1147. For the management of fever and other symptoms of the serotonin syndrome, see Importance and management under 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1149.

MAOIs or RIMAs + Sympathomimetics; Beta-agonist bronchodilators

An isolated case of tachycardia and apprehension has been described in an asthmatic taking phenelzine after salbutamol (albuterol) was added. Hypomania was seen in another asthmatic taking phenelzine when inhaled isoetarine was added. Hypertensive crisis occurred in a woman taking toloxatone and phenylephrine when given [oral] terbutaline.

Clinical evidence

(a) MAOIs

A report briefly describes a case of tachycardia and apprehension in a patient taking phenelzine when salbutamol (albuterol) was started [route of administration not stated].¹ Hypomania has been described in a patient taking phenelzine in the few weeks after starting inhaled isoetarine 680 micrograms up to every 4 hours.²

(b) RIMAs

A 72-year old woman taking long-term levothyroxine, toloxatone 400 mg daily (for 2 months), and phenylephrine (for 3 weeks) developed episodes of hypertension, sweating, tachycardia, and headache within 3 days after starting [oral] terbutaline 10 mg daily. She had extremely high plasma catecholamine levels. All drugs were stopped on admission to hospital and she recovered over 2 to 3 days.³

Mechanism

Note that drugs with directly-acting sympathomimetic effects (of which beta agonists are an example) do not normally interact to cause hypertension with MAOIs, see 'sympathomimetics; directly-acting', (below). However, phenylephrine (which has some indirect actions, see 'sympathomimetics; phenylephrine', (p.1148)) may have contributed to the reaction between toloxatone and terbutaline, and the fact that terbutaline seems to have been given orally would also have contributed. The hypomania reaction is not understood.

Importance and management

These appear to be isolated cases, and are possibly not of general importance. Bear them in mind in the event of an unexpected response to treatment.

MAOIs or RIMAs + Sympathomimetics; Directly-acting

The pressor effects of adrenaline (epinephrine), isoprenaline (isoproterenol), noradrenaline (norepinephrine) and methoxamine may be unchanged or only moderately increased in patients taking MAOIs. There is limited evidence that the increase may be somewhat greater in those who show a significant hypotensive response to the MAOI. Moclobemide does not appear to interact.

Clinical evidence

(a) MAOIs

In a randomised, double-blind, placebo-controlled study in 12 healthy subjects, phenelzine 15 mg three times daily for 7 days had no effect on the dose of intravenous noradrenaline (norepinephrine) required to raise the systolic blood pressure by 25 mmHg. In addition, phenelzine had no effect on the diastolic blood pressure rises and heart rate reductions seen with noradrenaline. In this study, phenelzine itself had no effect on blood pressure or heart rate.¹ Similarly, in an earlier study in two healthy subjects given phenelzine 15 mg three times daily and two given tranlycpromine 10 mg three times daily for 7 days, there was no significant

change in pressor response to intravenous adrenaline (epinephrine) or isoprenaline (isoproterenol) after treatment with the MAOI. However, the tachycardia caused by isoprenaline was antagonised by the MAOIs (109 bpm with the MAOI versus 127 bpm without). No clinically significant potentiation of the pressor effect of noradrenaline was seen, although one of the subjects taking tranlycpromine had a twofold increase in the pressor response in the mid-range of noradrenaline concentrations infused, but not in the upper or lower ranges. None of these 4 subjects had a change in blood pressure or heart rate caused by the MAOI alone.² In yet another study in 3 healthy subjects given tranlycpromine for 8 to 14 days, the effects of intravenous noradrenaline were slightly increased, while with intravenous adrenaline a moderate two to fourfold increase in the effects on heart rate and diastolic pressure took place, but a less marked increase in systolic pressure. Intravenous isoprenaline behaved very much like adrenaline, but there was no enhancement of systolic pressure. This study did not state the effect of the MAOI alone on blood pressure.³

A patient using 1% adrenaline eye drops twice daily had no increase in blood pressure or heart rate when treated with tranlycpromine 20 mg, rising to 50 mg daily.⁴ Another patient taking phenelzine presented with severe anaphylaxis after taking two doses of flucloxacillin, and was initially treated unsuccessfully with hydrocortisone, chlorpheniramine and ranitidine because of concerns about using adrenaline with MAOIs. However, as her condition worsened she was given two 100-microgram boluses of intravenous adrenaline, with rapid improvement. No adverse reaction was noted.⁵ In another study, one healthy subject given phenelzine for 8 days experienced a marked reduction in blood pressure, but showed no significant changes in pressor response to noradrenaline.⁶

In contrast, in a study in hypertensive patients who had postural hypotension after being given either pheniprazine (a formerly investigational older MAOI) (6 patients) or tranlycpromine (one patient), the dose of noradrenaline required to produce a 25 mmHg rise in systolic pressure was reduced by 62 to 87%. In three of these patients on pheniprazine the dose of methoxamine was reduced by 61 to 70% compared with that required in the absence of an MAOI. Three patients were later given nialamide: augmentation of the pressor response of noradrenaline or methoxamine only occurred in the one patient who had developed postural hypotension.⁷

(b) RIMAs

In a randomised, double-blind, placebo-controlled study in 12 healthy subjects, moclobemide 100 mg three times daily for 7 days had no effect on the dose of intravenous noradrenaline required to raise the systolic blood pressure by 25 mmHg. In addition, moclobemide had no effect on the diastolic blood pressure rises and heart rate reductions seen with noradrenaline. In this study, moclobemide itself had no effect on blood pressure or heart rate.¹ A review paper also briefly mentions that moclobemide 600 mg daily for 3 weeks had no relevant effect on the heart rate response to intravenous isoprenaline.⁸

Mechanism

These sympathomimetic amines act directly on the receptors at the nerve endings, which innervate arterial blood vessels, so that the presence of the MAOI-induced accumulation of noradrenaline within these nerve endings would not be expected to alter the extent of direct stimulation (contrast 'Sympathomimetics; Indirectly-acting', (p.1147)). The enhancement seen in those patients whose blood pressure was lowered by the MAOI might possibly be due to an increased sensitivity of the receptors, which is seen if the nerves are cut, and is also seen during temporary 'pharmacological severance'.

Importance and management

The overall picture is that no clinically relevant enhancement of the effects of noradrenaline or adrenaline occurs in patients taking MAOIs, although some uncertainty remains about those who show MAOI-induced hypotension. The authors of three of the reports cited^{2–4} are in broad agreement that problems are unlikely to occur, and others consider that intravenous adrenaline may be used in life-threatening situations in patients on MAOIs, albeit with caution.⁵ Others also consider that the use of adrenaline in eye drops or as a component of local anaesthesia in dental and other procedures may be used in patients receiving MAOIs,^{4,9} and that there is no justification for the continued listing of an interaction between MAOIs and local anaesthetics with vasoconstrictors in US prescribing informa-

tion.⁹ It is worth noting that there are no case reports of interactions with these drugs.

Direct evidence about methoxamine is even more limited, but it seems to behave similarly. None of the studies demonstrated any marked changes in the effects of isoprenaline.

The situation in patients who show a reduced blood pressure due to the use of an MAOI is less clear. One early study⁷ found an increase in the pressor effects of noradrenaline and methoxamine in hypertensive patients who had developed orthostatic hypotension on pheniprazine or tranlycypromine. Bear this possibility in mind.

Moclobemide does not appear to alter the pressor response to noradrenaline.

The interaction between phenylephrine and the MAOIs is dealt with elsewhere (see 'MAOIs or RIMAs + Sympathomimetics; Phenylephrine', p.1148). Consider also 'MAOIs or RIMAs + Sympathomimetics; Beta-agonist bronchodilators', p.1146 and 'Inotropes and Vasopressors; Dopamine + Selegiline', p.893, for dosing advice with when dopamine is given to patients taking MAOIs.

MAOIs or RIMAs + Sympathomimetics; Indirectly-acting

The use of indirectly-acting sympathomimetic amines concurrently with, and for 2 weeks after stopping, non-selective MAOIs can result in a potentially fatal hypertensive crisis and should be avoided. Note that these amines are commonly used as vasoconstrictor decongestants (e.g. ephedrine, phenylpropanolamine and pseudoephedrine) in many proprietary cough, cold and influenza preparations, or for their vasoconstrictor effects in migraine (e.g. isometheptene). Indirectly-acting amines are also used parenterally for treating hypotension occurring during spinal anaesthesia (e.g. ephedrine, mephentermine, metaraminol). Potentially serious interactions have also been seen with moclobemide and indirectly-acting sympathomimetics.

Clinical evidence

(a) MAOIs

A study in 3 healthy subjects, given phenelzine 45 mg or tranlycypromine 30 mg daily for 5 to 14 days, found that the blood pressure rise following oral ephedrine 30 mg was enhanced. The maximal increase in mean arterial pressure was 22 mmHg (compared with 4 to 6 mmHg without the MAOI). A similar increase was seen up to 10 days after discontinuation of the MAOI. A similar increase in blood pressure was also seen in one of the subjects given intravenous ephedrine 2 mg per minute for 6 minutes.¹ In another subject given tranlycypromine 30 mg daily for 20 to 30 days, phenylpropanolamine in capsules or a linctus preparation caused a rapid and marked rise in blood pressure to 210/140 mmHg within 2 hours, necessitating the use of phentolamine to reverse the effect.² Slow-release phenylpropanolamine caused a smaller and more gradual rise to 160/100 mmHg over 2 hours.² Similarly, the pressor effect of intravenous phenylpropanolamine was potentiated about four to fivefold (systolic) and three to tenfold (diastolic) in 3 subjects given tranlycypromine 30 mg daily for 8 to 14 days, and the reflex bradycardia was potentiated about 2.5- to 6-fold.³

Numerous case reports describe similar rapid and serious rises in blood pressure, accompanied by tachycardia, chest pains and severe occipital

headache with concurrent use of MAOIs and indirectly-acting sympathomimetics. Other symptoms that have occurred include neck stiffness, flushing, sweating, nausea, vomiting, hypertonicity of the limbs, and sometimes epileptiform convulsions, and fatal intracranial haemorrhage, cardiac arrhythmias and cardiac arrest have resulted.

This interaction has been reported with oral ephedrine,⁴ oral isometheptene mucate,⁵ intravenous mephentermine,⁶ intramuscular metaraminol,⁷ oral phenylpropanolamine,⁸⁻¹³ and oral pseudoephedrine,^{12,14,15} in patients taking nialamide,⁴ phenelzine,^{5,6,9-13} iproniazid,¹⁵ mebanazine,⁹ and pargyline.^{7,8}

Tachycardia and hypotension, then pyrexia has been described in a woman who took a single Do-Do tablet (ephedrine, caffeine, theophylline) the day after stopping phenelzine.¹⁶ Similarly, fatal hyperpyrexia without hypertension occurred in a man taking tranlycypromine/trifluoperazine given oral ephedrine,¹⁷ although switching his MAOI without a full washout period may have caused, or contributed to, this reaction¹⁸ (see 'MAOIs + MAOIs or RIMAs', p.1137). A woman taking phenelzine developed bradycardia (40 bpm) after taking one tablet of Sinutab (without codeine),¹⁹ which probably contained pseudoephedrine.

(b) RIMAs

No interaction was seen in subjects taking brofaromine 75 mg twice daily for 10 days when given 75 mg of slow-release phenylpropanolamine (Acutrim Late Day), but immediate-release phenylpropanolamine in gelatin capsules caused a 3.3-fold increase in pressor sensitivity.²⁰ The pressor effects of high-dose oral ephedrine (two doses of 50 mg with a 4-hour interval) in 11 healthy subjects taking moclobemide 300 mg twice daily were increased about three to fourfold, and this resulted in an increase in palpitations and headache.^{21,22}

Mechanism

The reaction can be attributed to overstimulation of the adrenergic receptors of the cardiovascular system. During treatment with non-selective MAOIs, large amounts of noradrenaline (norepinephrine) accumulate at adrenergic nerve endings not only in the brain, but also within the sympathetic nerve endings, which innervate arterial blood vessels. Stimulation of these latter nerve endings by sympathomimetic amines with indirect action causes the release of the accumulated noradrenaline and results in the massive stimulation of the receptors. An exaggerated blood vessel constriction occurs and the blood pressure rise is proportionately excessive. Intracranial haemorrhage can occur if the pressure is so high that a blood vessel ruptures. Directly-acting sympathomimetics do not cause this effect, see 'MAOIs or RIMAs + Sympathomimetics; Directly-acting', p.1146.

Importance and management

(a) MAOIs

A very well-documented, serious, and potentially fatal interaction. Patients taking any of the MAOIs should not normally take any sympathomimetic amine with indirect activity. These include ephedrine, isometheptene mucate, mephentermine, metaraminol, phenylpropanolamine and pseudoephedrine. Direct evidence implicating methylephedrine and pholedrine seems not to have been documented, but on the basis of their known pharmacology their concurrent use with the MAOIs should be avoided.

Note that some of the indirectly-acting amines, including ephedrine, phenylpropanolamine and pseudoephedrine, are used as vasoconstrictor decongestants in numerous oral non-prescription cough, cold and influenza preparations. Isometheptene is used in non-prescription analgesic preparations for migraine. Patients on MAOIs should be strongly warned not to take any of these drugs concurrently or for 2 weeks after stopping their MAOI. Also, note that serious interactions have occurred because of confusion between non-prescription products with very similar names that contain different active ingredients.¹²

Physicians should also avoid the use of indirectly-acting vasoconstrictor amines such as ephedrine, mephentermine and metaraminol for reversing hypotension during spinal anaesthesia in patients taking MAOIs or who have recently stopped these (within the previous 2 weeks).

(b) RIMAs

The data with high-dose ephedrine show that moclobemide is not free of this interaction, and the manufacturers of moclobemide²³ advise avoiding sympathomimetics such as ephedrine, pseudoephedrine and phenylpropanolamine.

nolamine. It would also be prudent to avoid moclobemide with any of the other indirectly-acting sympathomimetics cited here, although the severity of the interactions with moclobemide is unlikely to be as great as that seen with the MAOIs. For example, ephedrine and phenylephrine have been successfully and uneventfully used in the presence of moclobemide (omitted on the day of surgery) during anaesthesia to control hypotension.²⁴

(c) Treatment

Hypertensive reactions have been controlled by intravenous phenolamine, phenoxybenzamine, intramuscular chlorpromazine, labetalol or sublingual nifedipine. The manufacturers of phenelzine state that on the basis of present evidence, slow intravenous injection of phenolamine is recommended.^{25,26} However, it is advisable to refer to current guidelines on the management of hypertensive crises for up-to-date advice. MAOIs or RIMAs + Sympathomimetics; Phenylephrine

The concurrent use of oral phenylephrine and the non-selective MAOIs can result in a potentially life-threatening hypertensive crisis. Phenylephrine is commonly found in proprietary cough, cold and influenza preparations. The effects of parenteral phenylephrine may be approximately doubled by MAOIs. Some interaction occurs between phenylephrine and the RIMAs moclobemide or brofaromine, but the blood pressure response appears to be much smaller than that seen with the non-selective MAOIs.

Clinical evidence

(a) MAOIs

A study in 3 healthy subjects, given phenelzine 45 mg or tranlycypromine 30 mg daily for 7 days, found that the blood pressure rise following oral phenylephrine was markedly enhanced. On 2 of 3 occasions when 45 mg of phenylephrine was given orally, the rise in blood pressure be-

came potentially disastrous and had to be reversed with phenolamine. On these two occasions the maximal increase in mean arterial pressure was 67 mmHg (compared with 1 or 11 mmHg without the MAOI). On the other occasion, the maximal increase in mean arterial pressure was 48 mmHg. The rise in blood pressure was accompanied by a severe headache. With 3 and 10 mg of phenylephrine, the maximal increase was 7 and 20 mmHg, respectively. After intravenous phenylephrine 3 mg was given over 20 minutes, the maximal increase in mean arterial pressure was 45 mmHg, compared with 23 mmHg without an MAOI.¹

Another study describes a similar 2- to 2.5-fold increase in the pressor effects of intravenous phenylephrine following the use of phenelzine or tranlycypromine.² A patient taking tranlycypromine who developed hypotension (40/0 mmHg) during surgery had an exaggerated pressor response (250/140 mmHg) when an intravenous infusion of phenylephrine 4 mg/500 mL was started.³ However, in another report repeated 100-microgram doses of intravenous phenylephrine were successfully used to treat hypotension in a patient on an MAOI, without any hypertensive reaction.⁴

A case report of hypertension that was initially attributed to phenylephrine was later corrected to pseudoephedrine.⁵

(b) RIMAs

No clinically important interaction occurred in healthy subjects taking brofaromine 75 mg twice daily when they were given a single 2.5-mg dose of phenylephrine as nasal drops.⁶ However, higher doses [exact amount not stated] did produce a blood pressure response,⁶ with a maximum recorded diastolic blood pressure of 100 mmHg.

A study in 7 healthy subjects found that moclobemide 100 mg three times daily for one week had no effect on the increase in blood pressure induced by intravenous phenylephrine.⁷ Another study reported similar results.⁸ However, when moclobemide was given in a dose of 200 mg three times daily for up to 3 weeks the blood pressure response to infusions of phenylephrine was increased by up to 1.8-fold.⁷ In one patient taking moclobemide (dose withheld on the morning of surgery), ephedrine and phenylephrine were used successfully and uneventfully to control hypotension during anaesthesia.⁹

A case of life-threatening hypertension¹⁰ occurred in a patient taking toloxatone, non-prescription phenylephrine and 'terbutaline', (p.1146).

Mechanism

If given by mouth phenylephrine is used in large doses because much of it is destroyed by MAO in the gut and liver, and only a small amount gets into the general circulation. If MAO is inhibited, most of the oral dose escapes destruction and passes freely into circulation, hence the gross enhancement of the pressor effects. Phenylephrine has mainly direct sympathomimetic activity, but it may also have some minor indirect activity as well, which would be expected to result in the release of some of the MAOI-accumulated noradrenaline (norepinephrine) at adrenergic nerve endings (see also 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1147). This might account for the increased response to phenylephrine given parenterally.

Importance and management

The interaction between the MAOIs and oral phenylephrine is established, serious and potentially life-threatening. Phenylephrine commonly occurs in oral non-prescription cough, cold and influenza preparations, so patients should be strongly warned about them. Whether the effects of nasal drops and sprays and eye drops are also enhanced is uncertain, but it would be prudent to avoid them until they have been shown to be safe. The response to parenteral administration is also approximately doubled, so that a dosage reduction is necessary.

The few studies that are available suggest that any interaction with RIMAs is less severe than that with MAOIs, but this needs confirmation.

Treatment

These hypertensive reactions have been controlled by intravenous phenolamine,¹ chlorpromazine, or nifedipine.¹¹ However, it is advisable to refer to current guidelines on the management of hypertensive crises for up-to-date advice. In the US, the manufacturers of phenelzine advise intravenous phenolamine 5 mg, given slowly to avoid excessive hypotension.¹² See also Importance and management under 'MAOIs or RIMAs + Tyramine-rich foods', p.1153.

MAOIs or RIMAs + Tricyclic and related antidepressants

Because of the very toxic and sometimes fatal reactions (the serotonin syndrome or similar) that have occurred in patients taking either MAOIs or RIMAs with tricyclic antidepressants, concurrent use is regarded as contraindicated in all but rare circumstances, and a suitable washout interval is needed when switching between MAOIs or RIMAs and tricyclics. Of the tricyclics, clomipramine and imipramine have been most frequently implicated in adverse reactions with the MAOIs.

Clinical evidence

A. MAOIs

The toxic reactions that occur when the tricyclics are given with MAOIs have included (with variations) sweating, flushing, hyperpyrexia, restlessness, excitement, tremor, muscle twitching and rigidity, convulsions and coma. Two illustrative examples:

A woman who had been taking **tranylcypromine** 10 mg twice daily for about 3 weeks, stopped taking it 3 days before she took a single tablet of **imipramine**. Within a few hours she complained of an excruciating headache, and soon afterwards lost consciousness and started to convulse. The toxic reactions manifested were a temperature of 40.6°C, pulse rate of 120 bpm, severe extensor rigidity, carpal spasm, opisthotonos and cyanosis. She was treated with amobarbital and phenytoin, and her temperature was reduced with alcohol-ice-soaked towels. The treatment was effective and she recovered.¹

In a recent case, a patient was treated with **imipramine** 75 mg daily for 7 weeks with lithium as well for the last 3 weeks. These drugs were discontinued and after one week of washout he started **tranylcypromine**, which was gradually increased to 50 mg twice daily. After 2 weeks at this dose, he received a single 225-mg dose of **imipramine** in error. Four hours later his condition deteriorated rapidly. He was agitated, confused, with severe rigidity, myoclonic jerks, hyperthermia, hypertension and tachycardia, and 2 hours later had a cardiac and respiratory arrest. He was resuscitated and treated with midazolam, pancuronium, dantrolene sodium, and a cooling mattress. The following day he had a sudden fall in blood pressure, and was eventually pronounced brain dead, and artificial respiration was terminated.²

Similar reactions have been recorded with oral therapeutic doses of:

- **amitriptyline** with **phenelzine**^{3,4}
- **clomipramine** with **phenelzine**⁵⁻⁷ or **tranylcypromine** (with or without trifluoperazine)⁸⁻¹⁰
- **desipramine** with **phenelzine**¹¹
- **imipramine** with **iproniazid**,¹² **isocarboxazid**,¹² **pargyline**,¹³ **phenelzine**¹⁴⁻¹⁶ or **tranylcypromine**.^{12,17}

There have been a number of fatalities.^{8,9,11,18} Reactions have also occurred when intramuscular **imipramine** was given with **phenelzine**.¹⁹⁻²¹ In some instances the drugs were not taken together, but were substituted without a washout period in between.^{6,17} In some other reports there was an overdose of one or both drugs,²²⁻²⁵ and/or the presence of other poten-

tially interacting drugs.^{23,24} There are many more reports of these interactions than are listed here: those published prior to 1977 have been extensively reviewed elsewhere.^{16,26,27}

Three patients with bipolar disorder developed mania when treated with **isocarboxazid** and **amitriptyline**.²⁸

In contrast, there are a number of other uncontrolled studies²⁹⁻³¹ and reviews^{26,27} describing the beneficial use of an MAOI with a tricyclic antidepressant. In addition, one study has reported switching 178 patients from tricyclics to MAOIs within 4 days or less. Of these patients, 63 were given the MAOI while still being tapered from the tricyclic, all without any apparent problems.³² Nevertheless, in a 6-week randomised double-blind trial, the combinations of **phenelzine** or **isocarboxazid** plus **trimipramine** were less effective than **trimipramine** alone in patients with mild to moderate depression.³³ Similarly, in a smaller randomised open study, the combination of **amitriptyline** and **tranylcypromine** was no more effective than either drug alone.³⁴

B. RIMAs

(a) Amitriptyline

Two small studies in healthy subjects and patients found no problems when **moclobemide** was given with, or 24 hours after, amitriptyline.^{35,36} or when amitriptyline was given immediately after **moclobemide**.³⁵ However, a patient taking amitriptyline and **clomipramine** developed the serotonin syndrome after taking a dose of **moclobemide** and died³⁷ (see also **clomipramine** below).

Only a minor and clinically unimportant change in the pharmacokinetics of amitriptyline occurs in patients given **toloxatone**.³⁸

(b) Clomipramine

A small study in healthy subjects found no problems when **moclobemide** was given 24 hours after clomipramine.³⁶ However, the serotonin syndrome occurred in 3 patients when clomipramine was replaced by **moclobemide** without a washout period^{39,40} or with only a 24-hour washout period,⁴¹ and in another patient when **moclobemide** was replaced by clomipramine after only 12 hours.⁴² A fatal case of the serotonin syndrome occurred in a patient taking clomipramine and **amitriptyline**, with symptoms manifesting within 30 minutes of a 300-mg dose of **moclobemide**.³⁷ Two other patients developed fatal serotonin syndrome after taking moderate overdoses of **moclobemide** and clomipramine.⁴³ The serotonin syndrome has been reported in at least 8 other cases of **moclobemide** and clomipramine overdose,⁴⁴⁻⁵⁰ one of which also involved tramadol⁴⁵ (see also 'MAOIs + Opioids; Tramadol', p.1141), another fluoxetine⁴⁶ (see also 'MAOIs or RIMAs + SSRIs', p.1142), and yet another buspirone⁵⁰ (see also 'MAOIs or RIMAs + Buspirone', p.1133). Conversely, a case of an overdose of moclobemide and clomipramine resulted in no adverse effects except sinus tachycardia.⁵¹

(c) Desipramine

A small single dose study in healthy subjects found no problems when **moclobemide** was given with desipramine.³⁵

(d) Doxepin

Serotonin toxicity (the serotonin syndrome) occurred in a patient who took an overdose of **moclobemide** and doxepin. In this analysis of **moclobemide** overdoses, the risk of developing serotonin toxicity was increased 35 times in patients who also took another serotonergic drug, of which this case with doxepin was one of 11 mentioned.⁵²

(e) Imipramine

The serotonin syndrome occurred in a patient who had been taking **moclobemide** for about a month and imipramine (50 mg at night increased to 200 mg at night) for about 17 days.⁵³

(f) Maprotiline

One study found a nonsignificant 25% rise in serum levels of maprotiline (a tetracyclic antidepressant) in 6 patients also taking **moclobemide**. No serious toxic reactions were reported.⁵⁴

(g) Trimipramine

One study found a 39% rise in serum trimipramine levels in 15 patients also taking **moclobemide**. No serious toxic reactions were reported.⁵⁴

Mechanism

Not understood. One idea is that both drugs cause grossly elevated monoamine levels (5-HT, noradrenaline (norepinephrine)) in the brain,

which 'spill-over' into areas not concerned with mood elevation. It may be related to, or the same as 'the serotonin syndrome', (p.9). Of the tricyclics, clomipramine in particular is a potent inhibitor of serotonin uptake. Less likely suggestions are that the MAOIs inhibit the metabolism of the tricyclic antidepressants, or that active and unusual metabolites of the tricyclic antidepressants are produced.²⁶

Importance and management

An established and fairly common interaction, but serious and life-threatening occurrences seem rare. If concurrent use is to be avoided, the following guidelines⁵⁵ are recommended:

- Tricyclic antidepressants should *not* be started for 2 weeks after treatment with MAOIs has been stopped (3 weeks if starting clomipramine or imipramine).
- An MAOI should *not* be started until at least 7 to 14 days after a tricyclic or related antidepressant has been stopped (3 weeks in the case of clomipramine or imipramine).
- Moclobemide has a short duration of action so no treatment-free period is required after it has been stopped before starting a tricyclic antidepressant. [Note however that some recommend waiting 24 hours.⁴²]
- Moclobemide should *not* be started until at least a week after a tricyclic antidepressant has been stopped.

No detailed clinical work has been done to find out precisely what sets the scene when the interaction does occur, but some general empirical guidelines have been suggested so that it can, as far as possible, be avoided when concurrent treatment is thought appropriate:^{15,16,26,27,56}

- Treatment with both types of drug should only be undertaken by those well aware of the problems and who can undertake adequate supervision.
- Only patients refractory to all other types of treatment should be considered.
- Tranlycypromine, phenelzine, clomipramine and imipramine appear to be high on the list of drugs that have interacted adversely. Combination of clomipramine with tranlycypromine is particularly dangerous. Amitriptyline, trimipramine and isocarboxazid are possibly safer.
- Absence of information documenting unsuitability or hazard does not necessarily imply that the two drugs may be used safely together, but may merely reflect an untried combination.⁵⁶
- Drugs should be given orally, not parenterally.
- It seems safer to give the tricyclic antidepressants first, or together with the MAOI, than to give the MAOI first. If the patient is already taking an MAOI, it may not be safe to start the tricyclic antidepressant until recovery from MAO-inhibition is complete.
- Small doses should be given initially, increasing the levels of each drug, one at a time, over a period of 2 to 3 weeks to levels generally about half⁵⁶ those used for each one individually.

Treatment of the serotonin syndrome

In the management of serotonin syndrome, it is important to recognise the possibility of the syndrome early, as the patient's condition can rapidly deteriorate. Potentially precipitating drugs should be stopped and agitation should be managed with benzodiazepines. The intensity of therapy depends on the severity of the condition. Moderately ill patients may benefit from the administration of 5-HT antagonists such as cyproheptadine. The 5-HT antagonist, chlorpromazine has also been used and can be beneficial, but should not be given if the patient is hypotensive or if the neurological malignant syndrome is a possible diagnosis. Hyperthermic patients should be immediately sedated, given neuromuscular blockers and intubated, since the rise in temperature is due to muscular activity. MAOI-induced hypotension should be managed with low doses of direct-acting sympathomimetics. Propranolol, bromocriptine, and dantrolene have been used, but these are no longer recommended. Because of the potential severity of the condition, a poison-control centre, clinical pharmacology service or medical toxicologist should be consulted for up-to-date advice.⁵⁷

MAOIs + Tryptophan

A number of patients have developed severe behavioural and neurological signs of toxicity (some similar to the serotonin syndrome) after taking MAOIs with tryptophan, and fatalities have occurred.

Clinical evidence

A man taking **phenelzine** 90 mg daily developed behavioural and neurological toxicity within 2 hours of being given 6 g of tryptophan.¹ He had shivering and diaphoresis, his psychomotor retardation disappeared and he became jocular, fearful, and moderately labile. His neurological signs included bilateral Babinski signs, hyperreflexia, rapid horizontal ocular oscillations, shivering of the jaw, trunk and limbs, mild dysmetria and ataxia. The situation resolved on withdrawal of the drugs.¹

Similar symptoms have been reported in other studies and cases. In an early study, giving tryptophan 20 to 50 mg/kg to 7 patients with hypertension taking an unknown MAOI produced neurological effects including alcohol-like intoxication, drowsiness, hyperreflexia and clonus.² Similar symptoms with the addition of sweating, flushing and paraesthesias were described in 5 patients in an experimental study of tryptophan 30 mg/kg orally combined with **pargyline** or **isocarboxazid**.³ In another study in 14 depressed patients taking various MAOIs, 4 patients had muscular jactitation and hyperreflexia when also given tryptophan 2.5 to 5 g three times daily, and in 2 patients this was severe enough to discontinue the tryptophan.⁴ Other reports describe similar symptoms in patients taking **phenelzine**^{5,6} or **tranylcypromine**⁷ when they were given tryptophan.

One patient taking **tranylcypromine** and lithium had transient episodes of toxicity with hyperthermia (and other symptoms of neurological toxicity) when the dose of tryptophan was increased to 2 g at night. He had a total of about 12 of these episodes over several weeks before tryptophan was stopped and the episodes ceased.⁸ Malignant hyperpyrexia occurred in a patient taking **phenelzine** and tryptophan,⁹ and fatal cases have occurred in two patients on **phenelzine**, tryptophan and lithium.^{10,11} Another patient who had been taking **tranylcypromine** for 2 weeks developed serious hyperpyrexia and muscular rigidity 2 days after starting tryptophan 6 g daily: she had discontinued levodopa-carbidopa one month previously.¹² Tryptophan may have contributed to a fatal case of the serotonin syndrome in a patient switched from fluoxetine to **tranylcypromine**.¹³

Hypomania without neurological symptoms has occurred in 2 patients when tryptophan was added to **phenelzine** or **tranylcypromine**,¹⁴ and delirium or disorientation, (sometimes with neurological symptoms) has occurred in 8 patients on **tranylcypromine** within 2 to 4 days of starting tryptophan, or within 1 day of increasing the dose of tryptophan.¹⁵ A further patient also experienced delirium within hours of tryptophan being added to her **phenelzine** treatment.¹⁶

In contrast, concurrent use has been reported as both safe and effective.¹⁷

Mechanism

Not understood. The reactions appear to be related to the serotonin syndrome, which can occur with two or more serotonergic drugs (see 'The serotonin syndrome', (p.9)). MAOIs may inhibit the metabolism of 5-hydroxytryptamine (serotonin), formed from tryptophan, so resulting in its accumulation.^{3,9}

Importance and management

Information seems to be confined to the reports listed. Concurrent use can be effective in the treatment of depression,¹⁷ but occasionally and unpredictably severe and even life-threatening toxicity occurs. The authors of one of the reports detailed above¹ recommend that patients on MAOIs should be started on a low dose of tryptophan (0.5 g). This should be gradually increased while monitoring the mental status of the patient for

changes suggesting hypomania, and neurological changes, including ocular oscillations and upper motor neurone signs.

Note that products containing tryptophan for the treatment of depression were withdrawn in the USA, UK, and many other countries because of a possible association with the development of an eosinophilia-myalgia syndrome. However, since the syndrome appeared to have been associated with tryptophan from one manufacturer, tryptophan preparations were reintroduced in the UK in 1994 for restricted use.^{18,19}

MAOIs or RIMAs + Tyramine-rich drinks

Patients taking the non-selective MAOIs (e.g. tranylcypromine, phenelzine) can suffer a serious hypertensive reaction if they drink tyramine-rich drinks (some beers or lagers, including low-alcohol brands, or wines), but no serious interaction is likely with the RIMAs (e.g. moclobemide). The hypotensive adverse effects of the MAOIs may be exaggerated in a few patients by alcohol, and they may experience dizziness and faintness after drinking relatively modest amounts. Moclobemide does not appear to alter the psychomotor effects of alcohol to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

A. Hypertensive reactions

A severe and potentially life-threatening hypertensive reaction can occur in patients taking MAOIs if they consume alcoholic drinks containing significant amounts of tyramine. The details of the tyramine/MAOI reaction, its mechanism, the names of the non-selective MAOIs that interact, and the RIMAs that are unlikely to do so are described in the monograph 'MAOIs or RIMAs + Tyramine-rich foods', p.1153. The specific case reports for various tyramine-containing drinks are outlined in the sub-sections below. Note that an 8 to 20-mg dose of tyramine is required before an important rise in blood pressure takes place in a patient taking **tranylcypromine**, and this dose may be higher for other MAOIs (see under 'tyramine-rich foods', (p.1153)). 'Table 32.2', (p.1152) summarises the reported tyramine-content of some drinks,^{1–7} and more extensive lists have been published elsewhere.^{6–8} These can be used as a broad general guide when advising patients, but they cannot be an absolute guide because alcoholic drinks are the end-product of a biological fermentation process and no two batches are ever absolutely identical. For example there may be a 50-fold difference even between wines from the same grape stock.⁵ There is no way of knowing for certain the tyramine-content of a particular drink without a detailed analysis.

Table 32.2 The tyramine-content of some drinks

	Tyramine content (mg/L)	Refs
<i>Ales, beers and lagers</i>		
Beer (Canada)	0 to 11.2, 27.1, 29.5, 112.9	1,2
Beer (Former Czechoslovakia)	10.4, 47 to 60	3
Beer (Germany)	1	3
Beer (Ireland)	0.5 to 4, 54	2,3
Beer (Netherlands)	1	3
Beer (UK)	0.3 to 1.34	2-4
Beer (USA)	0.7 to 4.4	2,3,5
Low-alcohol beers	0 to 10	2,6
<i>Wines</i>		
<i>Chianti (Italy)</i>		
Governo process	1.8 to 10.4, 25.4	1, 5
Newer process	0.0 to 4.7	3,4,7,8
Champagne	1, 13.7 to 18	3,9
Wine, red (Canada, France, Italy, Spain, USA)	0 to 8.6 (mean 5.2)	9
Wine, white (France, Germany, Italy, Portugal, Spain, Former Yugoslavia)	0.4 to 6.5	4,5,9
<i>Fortified wines and spirits</i>		
Gin	0	8
Port	Less than 0.2 (undetectable)	5
Sherry	0.2 to 3.6	1,3,5,8
Vodka	0	8
Whiskey	0	8

(a) Ales, Beers and Lagers

Some ales, beers and lagers in 'social' amounts contain enough tyramine to reach the 8 to 20 mg dose needed to provoke a reaction; for example a litre (a little under two pints) of some samples of **Canadian ale or beer** (see 'Table 32.3', (p.1154)). Case reports of reactions have been published. A man taking **phenelzine** 60 mg daily developed a typical hypertensive reaction after drinking only 14 oz. (about 400 mL) of **Upper Canada lager beer on tap** (containing about 113 mg of tyramine/litre).⁸

In addition, **alcohol-free beer** and **lager** may have a tyramine-content that is equal to ordinary beer and lager.^{9,10} One patient taking **tranylcypromine** suffered an acute cerebral haemorrhage after drinking a **de-alcoholised Irish beer**.⁹ Hypertensive reactions occurred in three other patients taking **tranylcypromine** or **phenelzine** after drinking no more than about 375 mL of **alcohol-free beer or lager**¹⁰ and a further patient taking **tranylcypromine** developed a vascular headache after drinking 3 bottles of non-alcoholic beer.¹¹ A very extensive study of 79 different brands of beer (from Canada, England, France, Germany, Holland, Ireland, Scotland, USA) found that the tyramine content of the **bottled** and **canned beers** examined was generally too low to matter (less than 10 mg/L), but four of 37 **beers on tap** (all 4 were lagers) contained more than enough tyramine (27 to 113 mg/L) to cause a hypertensive reaction.⁸ It was concluded in this report that the consumption of **canned** or **bottled beer**, including **de-alcoholised beer**, in moderation (fewer than four bottles, 1.5 litres in a 4-hour period) was safe in patients on MAOIs, but, to be on the cautious side, all **beers on tap**, including **lagers** should be avoided.⁸ The RIMAs are less likely to interact, see 'MAOIs or RIMAs + Tyramine-rich foods', p.1153.

(b) Spirits

Gin, whisky, vodka and **other spirits** do not contain significant amounts of tyramine because they are distilled, and the volumes drunk are relatively small.⁷ There seem to be no reports of hypertensive reactions in patients taking MAOIs after drinking spirits and none would be expected. One author¹² anecdotally noted that "bottles of whisky have been drunk by some patients on the MAOIs, the only result being that they got drunk more easily and cheaply." However, a 38-year-old man collapsed with tachycardia the morning after taking an overdose of **moclobemide** and drinking half a bottle of **whisky** (more than 350 mL). He then suffered a cardiac arrest, and resuscitation was unsuccessful. Blood pressure was not recorded. The authors attributed this case to an interaction between moclobemide and tyramine,¹³ although the tyramine content of the whisky was not assessed, so any interaction is not established, especially since whisky does not usually contain tyramine.

(c) Wines

In the context of adverse interactions with MAOIs, **Chianti** has developed a sinister reputation, because 400 mL of one early sample of **Italian Chianti** wine (see 'Table 32.2', (above)) contained enough tyramine to reach the 8 to 20 mg threshold for causing important hypertensive reactions. However, it is claimed by the **Chianti** producers¹⁴ and others¹⁵ that the newer methods that have replaced the ancient 'governo alla toscana' process result in negligible amounts of tyramine in today's **Chianti**. This seems to be borne out by the results of analyses,^{3,5-7} two of which failed to find any tyramine at all in some samples.^{3,7} Some of the other wines listed in 'Table 32.2', (above) also contain tyramine, but patients would have to drink as much as 2 litres or more before reaching what is believed to be the threshold dosage. This suggests that small or moderate amounts (1 or 2 glasses) are unlikely to be hazardous in patients taking MAOIs.

B. Hypotensive reactions

Some degree of hypotension can occur in patients taking MAOIs and this may be exaggerated by the vasodilation and reduced cardiac output caused by alcohol. In one report, a patient on an MAOI describes having a **gin** and **orange** and then becoming unsteady when standing up and hitting her head on the wall.¹⁶ Patients should therefore be warned of the possibility of orthostatic hypotension and syncope if they drink. They should be advised not to stand up too quickly, and to remain sitting or lying if they feel faint or begin to 'black out'.

C. Psychomotor performance

The possibility that **alcohol**-induced deterioration in psychomotor skills (i.e. those associated with safe driving) might be increased by the RIMAs has been studied. Moclobemide appears to have only a minor and clinically unimportant effect.^{17,18}

MAOIs or RIMAs + Tyramine-rich foods

A potentially life-threatening hypertensive reaction can develop in patients on the non-selective MAOIs (tranylcypromine, phenelzine etc.) who eat tyramine-rich foods. Deaths from intracranial haemorrhage have occurred. Significant amounts of tyramine occur in some aged cheeses, yeast extracts (e.g. *Marmite*) and some types of salami. Caviar, pickled herrings, soy sauce, avocados and other foods have been implicated in this interaction. Note that any food high in aromatic amino acids can become high in tyramine if spoilage occurs or after storage. The RIMAs (moclobemide, toloxatone) interact with tyramine to a lesser extent, such that dietary restrictions are generally unnecessary.

Clinical evidence

A. Reactions to foods

(a) MAOIs

A rapid, serious, and potentially fatal rise in blood pressure can occur in patients taking MAOIs who ingest tyramine-rich foods or drinks. A violent occipital headache, pounding heart, neck stiffness, flushing, sweating, nausea and vomiting may be experienced. One of the earliest recorded observations specifically linking this reaction to **cheese** was in 1963 by a pharmacist called Rowe, who wrote to Blackwell¹ after seeing the reaction in his wife who was taking *Parstelin* (tranylcypromine with trifluoperazine).

“After **cheese on toast**; within a few minutes face flushed, felt very ill; head and heart pounded most violently, and perspiration was running down her neck. She vomited several times, and her condition looked so severe that I dashed over the road to consult her GP. He diagnosed ‘palpitations’ and agreed to call if the symptoms had not subsided in an hour. In fact the severity diminished and after about 3 hours she was normal, other than a severe headache — but ‘not of the throbbing kind’. She described the early part of the attack ‘as though her head must burst’.”

Blackwell and his colleagues¹ discuss a series of 25 early cases, and the information that led to this interaction becoming established. **Tranylcypromine** was the most frequently implicated MAOI: of 25 cases, 17 were with **tranylcypromine**, 6 with **phenelzine** and one each with **pargyline** and **mebanazine**. In addition, **cheese** was the most frequently implicated food, in 18 of 25 cases, with **Marmite** (yeast extract) in 3 and **pickled herrings** in one. Four patients had intracranial haemorrhages and one died.¹ From 1961 up to February 1964 the US FDA found about 500 cases of induced hypertension with **tranylcypromine** and 38 cases of cerebral vascular accidents with 21 deaths. As a result, **tranylcypromine** was withdrawn in the US, although it was later reintroduced with many restrictions, including the need to avoid **cheese** while taking the drug.²

In addition to reactions to **cheese**, cases of hypertensive reactions have been reported with **avocados**,³ **beef livers**⁴ and **chicken livers**,⁵ **caviar**,⁶ **pickled herrings**,⁷ **soused herrings**,⁸ **tinned fish**,⁸ **tinned milk**,¹ **peanuts**,⁸ **soy sauce**,⁹ **miso**,¹⁰ **a powdered protein diet supplement** (*Ever-so-slim*¹¹ or *Complan*¹) **packet soup** (containing hydrolysed yeast),¹² **sour cream** in coffee,⁸ and **New Zealand prickly spinach**¹³ (*Tetragonia tetragonoides*). [Note this is not a true spinach as found in the USA or Europe.] These reactions occurred with **tranylcypromine**,^{3,5-9} **phenelzine**^{4,10,11,13} or unspecified MAOIs.^{8,12}

(b) Moclobemide

There do not appear to be any published reports of the ‘**cheese reaction**’ with moclobemide. The combination of **Bovril** (yeast extract) 12 g and moclobemide 150 mg, both three times daily, was used to normalise blood pressure in a patient with severe postural hypotension as a result of central autonomic failure.¹⁴

B. Tyramine studies

Pharmacodynamic studies comparing RIMAs with MAOIs using oral tyramine sensitivity tests have revealed that only 20 to 50 mg of oral tyramine (given with a meal) is required to raise the systolic BP by 30 mmHg in subjects taking **tranylcypromine** 10 mg twice daily.¹⁵ In another study, the pressor tyramine dose was only 8 mg in those given **tranylcypromine**, but higher (33 mg) in those taking **phenelzine**.¹⁶ These pharmacodynamic studies confirm the clinical evidence that the **cheese reaction** is more likely with **tranylcypromine**.

The mean dose of oral tyramine (added to a meal) required to raise systolic BP by 30 mmHg (the tyramine 30 dose) was decreased fivefold (from 1450 mg to 306 mg, range 150 to 500 mg) by moclobemide 200 mg three times daily, in a double-blind, parallel group, placebo-controlled study in healthy subjects. In comparison, **tranylcypromine** 10 mg twice daily decreased the tyramine 30 dose by about 38-fold.¹⁵ In another study, the reduction in the tyramine 30 dose for **moclobemide** 150 mg three times daily was sevenfold; for **phenelzine** 60 mg daily, 13-fold; and for **tranylcypromine** 20 mg daily, 55-fold. After stopping the drugs, the pressor effect to tyramine normalised within 3 days for **moclobemide**, and 30 days for **tranylcypromine**. However, the pressor response had normalised in only 2 subjects 2 to 4 weeks after they stopped **phenelzine**, and had not normalised during the 11-week study period in the other 4 subjects.¹⁶ In a further study the tyramine 30 dose was reduced by about 4-fold by **moclobemide** 100 mg three times daily and 10.3-fold by **phenelzine** 15 mg three times daily.¹⁷ Numerous other pharmacological studies have confirmed the low increase in pressor response to tyramine with **moclobemide**.¹⁸⁻²¹

The pressor response to oral tyramine 200 mg was not altered by pretreatment with **toloxatone** 200 mg or 400 mg three times daily in healthy subjects, although the effect of higher doses of tyramine was increased.²² Similar results were reported in an earlier study.²³

Mechanism

Tyramine is formed in foods such as cheese by the bacterial degradation of milk and other proteins, firstly to tyrosine and other amino acids, and the subsequent decarboxylation of the tyrosine to tyramine. This interaction is therefore not associated with fresh foods, but with those which have been allowed to over-ripen or ‘mature’ in some way,³ or if spoilage occurs. Tyramine is an indirectly-acting sympathomimetic amine, one of its actions being to release noradrenaline (norepinephrine) from the adrenergic neurones associated with blood vessels, which causes a rise in blood pressure by stimulating their constriction.³

Normally any ingested tyramine is rapidly metabolised by the enzyme monoamine oxidase in the gut wall and liver before it reaches the general circulation. However, if the activity of the enzyme at these sites is inhibited (by the presence of an MAOI), any tyramine passes freely into the circulation, causing not just a rise in blood pressure, but a highly exaggerated rise due to the release from the adrenergic neurones of the large amounts of noradrenaline that accumulate there during inhibition of MAO.³ This final step in the interaction is identical to that which occurs with any other indirectly-acting sympathomimetic amine in the presence of an MAOI (see ‘MAOIs or RIMAs + Sympathomimetics; Indirectly-acting’, p.1147).

RIMAs such as moclobemide and toloxatone selectively inhibit MAO-A, which leaves MAO-B still available to metabolise tyramine. This means that they have less effect on the tyramine pressor response than non-selective MAOIs.

Importance and management

An extremely well-documented, well-established, serious interaction. A potentially fatal hypertensive reaction can occur between the irreversible, non-selective MAOIs (see ‘Table 32.1’, (p.1130)) and tyramine-rich foods. Tranylcypromine is more likely to cause the reaction than phenelzine. The incidence is uncertain, but early estimates of hypertensive reactions to tranylcypromine (before restrictions in its use with indirectly-acting sympathomimetics and foods) range from 0.03% to 20%.^{2,24,25} Patients taking any of the non-selective MAOIs (**isocarboxazid**, **nialamide**,

phenelzine, pargyline, tranylcypromine, and **iproniazid**) should not eat foods reported to contain substantial amounts of tyramine (see 'Table 32.3', (above) and 'Table 32.4', (p.1155)). As little as 8 to 20 mg of tyramine can raise the blood pressure in patients taking tranylcypromine, and this may be present in usual portions of hard cheeses.¹⁶ In addition, avoidance of the prohibited foods should be continued for 2 to 3 weeks after stopping the MAOI to allow full recovery of the enzymes. However, note that in one study some patients took over 11 weeks to recover from the effects of phenelzine.¹⁶

Because tyramine levels vary so much it is impossible to guess the amount present in any food or drink. Old, over-ripe strong smelling cheeses with a salty, biting taste or those with characteristic holes due to fermentation should be avoided as they generally contain high levels of tyramine. Fresh cheeses made from pasteurised milk tend to have lower levels of tyramine.²⁶ The tyramine-content can even differ significantly within a single cheese: the centre having the lowest levels of tyramine, and the rind, containing the most.^{26,27} There is no guarantee that patients who have uneventfully eaten these hazardous foodstuffs on many occasions may not eventually experience a full-scale hypertensive crisis, if all the many variables conspire together.²⁸

The need to plan a sensible and safe diet for those taking MAOIs is clear, and over the years attempts have been made to produce simplified, practical diets for those taking MAOIs.²⁹⁻³⁵ A total prohibition should be imposed on the following: **aged cheese** and **yeast extracts** such as *Marmite*, and possibly also *Bovril* and **pickled herrings** (see 'Table 32.3', (above)). A number of other foods should also be viewed with suspicion such as **sauerkraut**, **fermented bologna** and **salami**, **pepperoni**, and **summer sausage** because some of them may contain significant amounts of tyramine (see 'Table 32.3', (above)). Some preserved and fermented Far Eastern foods such as **fermented soya beans**, **soya bean paste** and **soya bean curd (Tofu)** can also contain relatively high tyramine levels.^{33,36} However, **yoghurt**, **fresh cream** and possibly **chocolate** are often viewed with unjustifiable suspicion. It also seems very doubtful if either **cream cheese** or **cottage cheese** represent a hazard, or **processed cheese** slices.³² **Whole green bananas** contain up to 65 micrograms of tyramine per gram, but this is mostly in the skin as the **pulp** contains relatively small amounts. Although case reports have occurred with a variety of other foods, it is generally acknowledged that widespread restrictions should not be imposed on a food based solely on an unsubstantiated isolated report,^{29,30,32} and that some reports could equally be attributed to spoilage.^{30,37} Therefore, of perhaps more importance is the advice to only eat protein-based foods (particularly meat, fish and liver) when fresh (within their sell-by date and after correct storage).^{30,32} Note that cooking does not inactivate tyramine. For the need to avoid broad-bean pods because of their dopamine content, see 'MAOIs + Dopa-rich foods', p.1135. The RIMAs are safer (in the context of interactions with tyramine-rich foods and drinks) than the older MAOIs, because they are more readily reversible and selective. Therefore the risk of a serious hypertensive reaction with moclobemide is very much reduced. The authors of one study calculate

Table 32.4 The tyramine content of some cheeses

that the lowest amount of tyramine (150 mg) found to cause a 30 mmHg rise in systolic BP with moclobemide is equivalent to that found in about 200 g of Stilton cheese or 300 g of Gorgonzola cheese, which are really excessive amounts of cheese to be eaten in a few minutes.¹⁵ Moreover, no 'cheese reactions' appear to have been published for moclobemide. Most patients therefore do not need to follow the special dietary restrictions required with the older MAOIs, but, to be on the safe side, the manufacturers of moclobemide advise all patients to avoid large amounts of tyramine-rich foods, because a few individuals may be particularly sensitive to tyramine.³⁸ This warning would also seem appropriate for all of the other RIMAs. Note that if moclobemide were given with an MAO-B inhibitor such as selegiline, it would essentially be the same as giving a non-selective MAOI, and dietary tyramine restrictions would then be required, see 'MAO-B inhibitors + Tyramine-rich foods', p.693.

Treatment

Severe hypertensive reactions require urgent immediate treatment. The drug most commonly used to control hypertensive reactions with MAOIs is phentolamine, given as a slow intravenous injection. However, the need for the patient to get to an emergency treatment centre delays treatment, and as a consequence, providing the patient with a drug they could self administer has been suggested. Sublingual nifedipine has been advocated,³⁹ but does not appear to have been widely adopted, perhaps because the possibility of a sudden dramatic drop in blood pressure is just as dangerous. Another similar option is a small dose of chlorpromazine.⁴⁰

It is advisable to refer to current guidelines on the management of hypertensive crises for up-to-date advice.

MAOIs or RIMAs + Venlafaxine

Serious and potentially life-threatening reactions (the serotonin syndrome) can develop if venlafaxine and non-selective MAOIs (isocarboxazid, phenelzine, tranlycypromine) are given concurrently, or even sequentially if insufficient time is left in between. The situation with moclobemide, in therapeutic doses, is uncertain.

Clinical evidence

(a) MAOIs

1. *Isocarboxazid*. A man with recurrent depression taking isocarboxazid 30 mg daily was additionally given venlafaxine 75 mg. After the second dose he developed agitation, hypomania, diaphoresis, shivering and dilated pupils. These symptoms subsided when the venlafaxine was stopped. He subsequently developed myoclonic jerks and diaphoresis when given both drugs.¹

2. *Phenelzine*. A woman who had stopped taking phenelzine 45 mg daily 7 days previously, developed sweating, lightheadedness and dizziness within 45 minutes of taking a single 37.5-mg dose of venlafaxine. In the emergency department she was found to be lethargic, agitated and extremely diaphoretic. The agitation was treated with lorazepam. A week later, after she had recovered, she was again started on the same regimen of venlafaxine without problems.² A man similarly developed the serotonin syndrome when he started venlafaxine the day after he stopped taking phenelzine.³ A woman developed the serotonin syndrome within less than an hour of taking phenelzine and venlafaxine together,⁴ and 4 other patients similarly developed the reaction when phenelzine was replaced by venlafaxine.⁵

Twelve days after an overdose of phenelzine (53 tablets of 15 mg), benzotropine, haloperidol and lorazepam, a 31-year-old man was given venla-

faxine 75 mg every 12 hours in addition to existing treatment with olanzapine and diazepam. About an hour after the first dose, he developed leg shakiness and stiffness, diaphoresis, blurred vision, difficulty breathing, chills, nausea and palpitations. Venlafaxine and olanzapine were discontinued and the man recovered within 24 hours, after treatment with intravenous fluids, propranolol and paracetamol.⁶

3. *Tranlycypromine*. A woman who had been taking tranlycypromine for 3 weeks developed a serious case of the serotonin syndrome within 4 hours of inadvertently taking a single tablet of venlafaxine. She recovered within 24 hours, when treated with ice packs, a cooling blanket, diazepam and dantrolene.⁷ The serotonin syndrome developed in a man taking tranlycypromine within 2 hours of taking half a venlafaxine tablet.⁸ Another case of the serotonin syndrome has been described in a man taking tranlycypromine 60 mg daily who accidentally took venlafaxine 300 mg.⁹

(b) RIMAs

A 32-year-old man taking **moclobemide** 20 mg twice daily and diazepam developed the serotonin syndrome 40 minutes after taking a single 150-mg dose of venlafaxine.¹⁰ Serotonin toxicity (the serotonin syndrome) occurred in 4 patients who took an overdose of **moclobemide** with venlafaxine (just 150 mg in one case and 750 mg in another). In this analysis of **moclobemide** overdoses, the risk of developing serotonin toxicity was increased 35 times in patients who also took another serotonergic drug. Venlafaxine was taken in 4 of the 11 cases mentioned.¹¹ Another man very rapidly developed the serotonin syndrome after taking considerable overdoses of **moclobemide** (3 g) and venlafaxine (2.625 g).¹²

Mechanism

The serotonin syndrome is thought to occur because venlafaxine can inhibit serotonin re-uptake (its antidepressant effect is related to this activity), and MAOIs and RIMAs inhibit the metabolism of serotonin. The result is an increase in the concentrations of serotonin apparently causing overstimulation of the 5-HT_{1A} receptors in the brain and spinal cord. See also 'the serotonin syndrome', (p.9).

Importance and management

An established, serious and potentially life-threatening interaction. The manufacturers of venlafaxine say that adverse reactions, some serious, have been seen in patients who had recently stopped taking an MAOI and started venlafaxine, or who had stopped venlafaxine and then started an MAOI. Some have been fatal.^{13,14} They recommend that venlafaxine should not be used in combination with an MAOI or within 14 days of stopping treatment with the MAOI.^{13,14} Based on the half-life of venlafaxine they say that at least 7 days should elapse between stopping venlafaxine and starting an MAOI. The manufacturers do not distinguish in this recommendation between the irreversible older non-selective MAOIs and the RIMAs such as moclobemide. In one of the studies it was suggested that a wash-out period of several weeks is required between stopping MAOIs such as phenelzine and initiating a second serotonergic drug such as venlafaxine.⁶

RIMAs; Moclobemide + Antipsychotics

The manufacturer of moclobemide noted that in 1992 there were data available from 110 patients given moclobemide 150 to 400 mg daily with various antipsychotics, namely acepromazine, aceprometazine, alimemazine, bromperidol, chlorpromazine, chlorprothixene, clothiapine, clozapine, cyamemazine, flupenthixol, fluphenazine, fluspirilene, haloperidol, levomepromazine, penfluridol, pipamperone, prothipendyl, sulpiride, thioridazine, or zuclopenthixol. There was no evidence of any clinically relevant interactions. There was, however, some evidence that hypotension, tachycardia, sleepiness, tremor and constipation were more common, suggesting synergistic adverse effects.¹

RIMAs; Moclobemide + Cimetidine

Cimetidine increases the plasma levels of moclobemide. Moclobemide dosage reductions are recommended.

Clinical evidence, mechanism, importance and management

After taking cimetidine 200 mg five times daily for 2 weeks the maximum plasma levels of a single 100-mg dose of moclobemide in 8 healthy subjects was increased by 39% and the clearance was reduced by 52%.¹ The probable reason is that the cimetidine (a well-recognised enzyme inhibitor) reduces the first-pass metabolism of the moclobemide.

It has been recommended that if moclobemide is added to treatment with cimetidine it should be started at the lowest therapeutic dose, and titrated as required. If cimetidine is added to treatment with moclobemide, the dosage of the moclobemide should initially be reduced by 50% and later adjusted as necessary.^{2,3}

3. Manerix (Moclobemide). Roche Products Ltd. UK Summary of product characteristics, September 2005.

RIMAs; Moclobemide + Omeprazole

Omeprazole doubled the AUC of moclobemide in extensive metabolisers of CYP2C19, effectively making them poor metabolisers. The clinical relevance of this is uncertain.

Clinical evidence

Omeprazole 40 mg daily for 7 days increased the AUC of a single 300-mg dose of moclobemide by about twofold in 8 healthy subjects who were extensive metabolisers of CYP2C19.¹ After this increase, the AUC of moclobemide in these subjects was still lower than that seen in 8 healthy subjects who were poor metabolisers of CYP2C19 (without omeprazole). Omeprazole had no appreciable effect on the pharmacokinetics of moclobemide in the 8 subjects who were poor metabolisers of CYP2C19.

Mechanism

Omeprazole is an inhibitor of cytochrome P450 isoenzyme CYP2C19, by which moclobemide is extensively metabolised. Activity of this enzyme is genetically determined with about 5% of Caucasians and up to 20% of Asians being poor metabolisers. Consider also 'Genetic factors', (p.4).

Importance and management

The pharmacokinetic interaction is established, but its clinical relevance is unclear. Omeprazole effectively makes extensive metabolisers of moclobemide into poor metabolisers. Moclobemide is a fairly safe drug, and metaboliser status is usually unknown. Bear in mind the possibility of an interaction if adverse effects are seen in a patient on moclobemide given omeprazole.

Respiratory drugs

This section includes the diverse drugs that are principally used in the management of asthma and chronic obstructive pulmonary disease (COPD), with the exception of corticosteroids, which are covered elsewhere.

(a) Antimuscarinic bronchodilators

The parasympathetic nervous system is involved in the regulation of bronchomotor tone and antimuscarinic drugs have bronchodilator properties. Ipratropium bromide and other antimuscarinic bronchodilators used in COPD are listed in 'Table 33.1', (p.1159). A wide range of drugs have antimuscarinic (anticholinergic) adverse effects. Enhanced antimuscarinic effects occur when drugs with these properties are given concurrently, see 'Antimuscarinics + Antimuscarinics', p.674. However, these interactions do not usually occur with drugs such as ipratropium, given by inhalation.

(b) Beta₂-agonist bronchodilators

Salbutamol and terbutaline are examples of short-acting beta agonists that selectively stimulate the beta₂ receptors in the bronchi causing bronchodilation. They are used in the treatment of asthma and the management of COPD. Long-acting beta₂ agonists such as salmeterol are used in patients with asthma who also require anti-inflammatory therapy. 'Table 33.1', (p.1159) lists the beta₂ agonists available. The beta₂ agonists represent a significant improvement on isoprenaline (isoproterenol), which also stimulates beta₁ receptors in the heart, and on ephedrine, which also stimulates alpha receptors. The beta₂ agonists can cause hypokalaemia, which can be increased by the concurrent use of other 'potassium-depleting drugs', (p.1162).

(c) Leukotriene antagonists

Montelukast and zafirlukast block the effects of cysteinyl leukotrienes, which cause effects such as airways oedema, bronchoconstriction and inflammation. The leukotriene antagonists are used in the treatment of asthma, either alone, or with inhaled corticosteroids. They should not be used to relieve an acute asthma attack. Both drugs are metabolised in the liver by the cytochrome P450 isoenzymes such as CYP3A4 and CYP2C9 (montelukast) and CYP2C9 (zafirlukast). Zafirlukast is thought to inhibit CYP2C9 and CYP3A4, and this is thought to be the mechanism for its interaction with 'warfarin', (p.423). There is therefore a possibility that in-

teractions could occur with other drugs that undergo metabolism by these isoenzymes but clinical evidence of this varies.

(d) Xanthines

The main xanthines used in medicine are theophylline and aminophylline, the latter generally being preferred when greater water solubility is needed (e.g. in the formulation of injections). Xanthines are given in the treatment of asthma because they relax the bronchial smooth muscle. In an attempt to improve upon theophylline, various different derivatives have been made, such as diprophylline and enprofylline. 'Table 33.1', (p.1159) lists these xanthines. Theophylline is metabolised by the cytochrome P450 isoenzymes in the liver, principally CYP1A2, to demethylated and hydroxylated products. Many drugs interact with theophylline by inhibition or potentiation of its metabolism. Theophylline has a narrow therapeutic range, and small increases in serum levels can result in toxicity. Moreover, symptoms of serious toxicity such as convulsions and arrhythmias can occur before minor symptoms suggestive of toxicity. Within the context of interactions, aminophylline generally behaves like theophylline, because it is a complex of theophylline with ethylenediamine.

Caffeine is also a xanthine and it is principally used as a central nervous system stimulant, increasing wakefulness, and mental and physical activity. It is most commonly taken in the form of tea, coffee, cola drinks ('Coke') and cocoa. 'Table 33.2', (p.1159) lists the usual caffeine content of these drinks. Caffeine is also included in hundreds of non-prescription analgesic preparations with aspirin, codeine and/or paracetamol, but whether it enhances the analgesic effect is debatable. Caffeine is also used to assess the activity of hepatic enzyme systems (particularly the cytochrome P450 isoenzyme CYP1A2) and can usefully demonstrate altered liver function, notably from drugs, as well as disease states.

Caffeine, like theophylline, also undergoes extensive hepatic metabolism, principally by CYP1A2, and interacts with many drugs, but it has a wider therapeutic range. However, other xanthines may act differently (e.g. diprophylline does not undergo hepatic metabolism), so it should not be assumed that they all share common interactions.

Note though, that all xanthines can potentiate hypokalaemia caused by other drugs and that the toxic effects of different xanthines are additive.

Table 33.1 Respiratory drugs

Group	Route	Drugs
Antimuscarinics (Anticholinergics)	Inhaled	Ipratropium bromide, Oxitropium, Tiotropium
Beta-2 adrenoceptor agonists	Oral	Bambuterol, Clenbuterol, Reproterol, Salbutamol (Albuterol), Terbutaline
	Inhaled	Short-acting: Bitolterol, Clenbuterol, Fenoterol, Levosalbutamol, Pirbuterol, Procaterol, Reproterol, Salbutamol (Albuterol), Terbutaline, Tolubuterol Long-acting: Arformoterol, Formoterol, Salmeterol
	Intravenous	Reproterol, Salbutamol (Albuterol), Terbutaline
Leukotriene antagonists and inhibitors	Oral	Amlexanox, Ibudilast, Montelukast, Pemirolast, Pranlukast, Zafirlukast
Lipoxygenase inhibitors	Oral	Zileuton
Mast cell stabilisers	Inhaled	Nedocromil sodium, Sodium cromoglicate
	Oral	Amlexanox, Ketotifen, Pemirolast, Tranilast
Sympathomimetics	Oral	Ephedrine, Hexoprenaline, Orciprenaline
Xanthine derivatives	Oral	Aminophylline, Bamifylline, Bufylline, Choline theophyllinate, Diprophylline, Doxofylline, Etofylline, Etamiphylline camsilate, Heptaminol acefyllinate, Proxiphylline, Theophylline
	Intravenous	Aminophylline, Bamifylline

Table 33.2 Caffeine-containing herbs and caffeine-containing drinks

Source	Caffeine-content	Caffeine-content of drink
Cocoa ¹		about 5 mg/100 mL
Coffee beans ²	1 to 2%	up to 100 mg/100 mL, decaffeinated up to about 3 mg/100 mL
Guarana ^{3*}	2.5 to 7%	
Kola (Cola) ²	1.5 to 2.5%	up to 20 mg/100 mL in 'cola' drinks
Maté (Paraguay tea) ²	0.2 to 2%	
Tea ²	1 to 5%	up to 60 mg/100 mL

*Note that guarana contains guaranine (which is known to be identical to caffeine) as well as small quantities of other xanthines.

Anti-asthma drugs + Areca (Betel nuts)

The chewing of betel nuts may worsen the symptoms of asthma.

Clinical evidence

A study of a possible interaction with betel nuts was prompted by the observation of two Bangladeshi patients with severe asthma that appeared to have been considerably worsened by chewing betel nuts. One out of 4 other asthmatic patients who regularly chewed betel nuts developed severe bronchoconstriction (a 30% fall in FEV₁) on two occasions when given betel nuts to chew, and all 4 patients said that prolonged betel nut chewing induced coughing and wheezing. A double-blind study found that the inhalation of **arecoline** (the major constituent of the nut) caused bronchoconstriction in 6 of 7 asthmatics, and 1 of 6 healthy control subjects.¹ A study in asthmatic patients who regularly chewed betel nuts found that 4 patients had a mean increase in their FEV₁ of 10 to 25%, whereas 11 patients had significant falls in their FEV₁ of 11 to 25%. Interestingly, 5 of the patients who did not think chewing betel nut affected their asthma experienced a reduction in their FEV₁.²

A survey in 61 asthmatic patients found that 22 of the 34 patients who still chewed betel nut, either for occasional use or regularly, reported that it worsened their asthma.³

Mechanism

Betel nut 'quids' consist of areca nut (*Areca catechu*) wrapped in betel vine leaf (*Piper betle*) and smeared with a paste of burnt (slaked) lime. It is chewed for the euphoric effects of the major constituent, arecoline, a cholinergic alkaloid, which appears to be absorbed through the mucous membrane of the mouth. Arecoline has identical properties to pilocarpine and normally has only mild systemic cholinergic properties; however asthmatic subjects seem to be particularly sensitive to the bronchoconstrictor effects of this alkaloid and possibly other substances contained in the nut.

Importance and management

Direct evidence appears to be limited to the above reports, but the interaction seems to be established. It would not normally appear to be a serious interaction, but asthmatics should be encouraged to avoid betel nuts. This is a drug-disease interaction rather than a drug-drug interaction.

Anti-asthma drugs + Beta blockers

Non-cardioselective beta blockers (e.g. propranolol, timolol) should not be used in asthmatic subjects because they may cause serious bronchoconstriction, even if given as eye drops. Non-cardioselective beta blockers oppose the bronchodilator effects of beta-agonist bronchodilators, and higher doses may be required to reverse bronchospasm. Even cardioselective blockers (e.g. atenolol) can sometimes cause acute bronchospasm in asthmatics. However, cardioselective beta blockers do not generally inhibit the bronchodilator effect of beta-agonist bronchodilators.

Clinical evidence

(a) Cardioselective beta blockers

A review of 29 studies (including 19 single-dose studies) on the use of cardioselective beta blockers in patients with reversible airway disease indicated that in patients with mild to moderate disease, the short-term use of cardioselective beta blockers does not cause significant adverse respiratory effects. Information on the effects in patients with more severe or less reversible disease, or on the frequency or severity of acute exacerbations was not available.¹ Another review indicated that when low doses of cardioselective beta blockers are given to patients with mild, intermittent or persistent asthma, or moderate persistent asthma, and heart failure or myocardial infarction, the benefits of treatment outweigh the risks. However,

it was considered that further study is required to establish long-term safety, and also that beta blockers should be avoided in severe persistent asthma.²

The cardioselective beta blockers would not be expected to affect the beta receptors in the bronchi, but bronchospasm can sometimes occur following their use by asthmatics and others with obstructive airways diseases, particularly if high doses are used. Deterioration of asthma was reported in a patient taking oral **betaxolol** with **theophylline** and **pranlukast**, although **betaxolol** is considered to be highly cardioselective and less likely to cause pulmonary adverse effects than other cardioselective beta blockers.³

No adverse pharmacodynamic interaction normally occurs between beta-agonist bronchodilators and cardioselective beta blockers. This has been demonstrated in studies with:

- **Atenolol** with **salbutamol (albuterol)** inhalation.^{4,5}
- **Celiprolol** in asthmatic patients with **isoprenaline (isoproterenol)**, or **salbutamol**,^{4,6,7} or **terbutaline** infusion or inhalation⁸
- **Metoprolol** in asthmatic patients at rest with **isoprenaline** infusion.^{9,10}

In contrast, another study found that the increase in forced expiratory volume (FEV) with a **terbutaline** inhalation and infusion was reduced by about 300 mL by **atenolol** and **metoprolol**. The authors considered that this would be clinically relevant in severe asthma.¹¹ Another study in 12 patients with mild asthma found that single doses of **celiprolol** 200 mg or **nebivolol** 5 mg reduced the FEV₁ by 272 mL and 193 mL, respectively, when compared with placebo. Increasing inhalation of **salbutamol** to a total dose of 800 micrograms reversed these reductions but did not restore the FEV₁ back to its initial value. None of these changes was considered to be clinically significant by the authors.¹²

Fifteen patients with mild to moderate COPD and airways hyperresponsiveness were given **celiprolol** 200 mg daily, **metoprolol** 100 mg daily or **propranolol** 80 mg daily for 4 days. Propranolol significantly reduced the FEV₁ and increased airways hyper-responsiveness compared with placebo whereas metoprolol only increased airways hyper-responsiveness. Celiprolol had no significant effects on pulmonary function. The bronchodilating effects of a single 12-microgram dose of **formoterol** were significantly reduced by propranolol, but not by metoprolol or celiprolol.⁷

(b) Non-selective beta blockers

Non-selective beta blockers (e.g. **propranolol**) are contraindicated in asthmatic subjects because they can cause bronchospasm, reduce lung ventilation and may possibly precipitate a severe asthmatic attack in some subjects. An example of the danger is illustrated by an asthmatic patient who developed fatal status asthmaticus after taking just one dose of **propranolol**.¹³ Another case report describes a patient with bronchial asthma receiving **salbutamol** who collapsed and died after taking three 20-mg **propranolol** tablets, which had been supplied in error instead of 20-mg prednisone tablets.¹⁴ The manufacturers of **propranolol** note that from 1965 to 1996, the CSM in the UK had received 51 reports of bronchospasm due to **propranolol**, 13 of them fatal, and 5 of them in patients who had a history of asthma, bronchospasm or wheeze.¹⁵ The non-cardioselective beta blockers **oxprenolol**⁵ and **propranolol**^{4,5,8-10} oppose the effects of bronchodilators such as **isoprenaline (isoproterenol)**,^{4,9,10} **salbutamol (albuterol)**,^{4,5} and **terbutaline**.⁸ Even eye drops containing the non-selective beta blockers **timolol**^{16,17} and **metipranolol**¹⁸ have been reported to precipitate acute bronchospasm. In patients with heart failure treated with **carvedilol**, 3 of 12 with concurrent asthma had wheezing requiring **carvedilol** withdrawal. In contrast, only 1 of 31 patients with COPD had wheezing.¹⁹

Mechanism

Non-selective beta blockers such as propranolol also block the beta₂ receptors in the bronchi so that the normal bronchodilation, which is under the control of the sympathetic nervous system, is reduced or abolished. As a result the bronchoconstriction of asthma can be made worse. Cardioselective beta blockers on the other hand, preferentially block beta₁ receptors in the heart, with less effect on the beta₂ receptors, so that beta₂ stimulating bronchodilators, such as isoprenaline, salbutamol and terbutaline, continue to have bronchodilator effects.

Importance and management

A well established drug-disease interaction. In 1996, the CSM in the UK²⁰ re-issued the following advice: "Beta blockers, including those considered to be cardioselective, should not be given to patients with a history of asth-

ma/bronchospasm." Non-cardioselective beta blockers (indicated in 'Table 22.1', (p.833)) should certainly be avoided in asthmatics and those with chronic obstructive pulmonary disease, whether given systemically or in eye drops, because serious and life-threatening bronchospasm may occur. The cardioselective beta blockers are generally safer but not entirely free from risk in some patients, particularly in high dosage. In contrast to the 1996 recommendations of the CSM on cardioselective beta blockers, one recent review from 2002/3^{1,21} recommends that "cardioselective beta blockers should not be withheld from patients with mild to moderate reversible airway disease". However, some concern has been expressed that this conclusion was based on results from short-term studies and state that the question of safety in asthmatics over the long term has not been answered.²² Further, there are no studies to suggest the safety of cardioselective beta blockers in patients with exacerbations of asthma,²³ and even a highly cardioselective drug such as betaxolol may cause bronchospasm.³ In 2004, the American College of Cardiology and American Heart Association guidelines for management of ST-elevation myocardial infarction stated that the benefits of using beta blockers strongly outweigh the risk of adverse events in patients with COPD or mild asthma (non-active), and noted that most patients with asthma are able to tolerate cardioselective beta blockers. Therefore if a beta blocker is required a cardioselective beta blocker should be used, and the patient's pulmonary function monitored.²⁴ A recent Cochrane review concluded that cardioselective beta blockers did not produce any significant adverse respiratory effects or reduction in the response to beta₂ agonists, and it recommended that cardioselective beta blockers should not be withheld from patients with COPD.²⁵

Celiprolol (a cardioselective beta blocker) appears to be exceptional in causing mild bronchodilatation in asthmatics and not bronchoconstriction, although it may still produce a reduction in expiratory volume, as seen in the study above,¹² but some caution is still necessary as this requires confirmation.⁶

The bronchoconstrictive effects of the beta blockers can be opposed by beta₂ agonist bronchodilators such as salbutamol, but as the manufacturers point out, large doses may be needed and they suggest that ipratropium and intravenous aminophylline may also be needed.¹⁵

Anti-asthma drugs + NSAIDs

Aspirin and many other NSAIDs can cause bronchoconstriction in some asthmatic patients. Celecoxib, etoricoxib and meloxicam do not usually cause bronchospasm in aspirin or NSAID-sensitive patients. Aspirin, nimesulide and piroxicam appear not to alter theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) NSAIDs in asthma

About 10% of asthmatics are hypersensitive to aspirin, and in some individuals life-threatening bronchoconstriction can occur. This is not a drug-drug interaction but an adverse response of asthmatic patients to aspirin, whether taking an anti-asthmatic drug or not. The reasons are not fully understood. Those known to be sensitive to aspirin may also possibly react to other NSAIDs, in particular the acetylated salicylates, the indole and indene acetic acids, and the propionic acid derivatives (see 'Table 6.1', (p.134)). The fenamates, oxicams, pyrazolones and pyrazolidinediones are better tolerated.¹ The nonacetylated salicylates (sodium salicylate, salicylamide, choline magnesium trisalicylate) are normally well tolerated. Aspirin-sensitive individuals are also less likely to react to nimesulide.^{1,2}

In 60 patients with proven aspirin-sensitivity, celecoxib 100 mg on day one and 200 mg on day two caused no decline in forced expiratory volume.³ Two more studies found similar results.^{4,5} Celecoxib is a selective inhibitor of cyclo-oxygenase-2 and this supports the suggestion that inhibition of cyclo-oxygenase-1 may be critical factor in the precipitation of respiratory reactions in aspirin-exacerbated respiratory disease.³ This suggests that celecoxib may be an alternative in patients who are known to be aspirin sensitive. Nevertheless, the manufacturer of celecoxib contraindicates its use in patients who are sensitive to aspirin or NSAIDs.⁶ In a study in 21 patients with either asthma, nasal polyps, allergic rhinitis or a combination of these, challenged with meloxicam 7.5 mg, only one patient with a history of aspirin allergy developed bronchospasm and erythema with meloxicam.⁷ Another study found no reaction in 24 patients with a history of NSAID-induced respiratory hypersensitivity given meloxicam 7.5 to 15 mg daily.⁴

However, the manufacturer of meloxicam contraindicates its use in patients who are sensitive to aspirin or NSAIDs.⁸ Seventy-seven rheumatology patients with a history of asthma caused by aspirin or a NSAID and given ascending doses of etoricoxib 60 to 120 mg daily for 3 days had no respiratory or cutaneous reaction to etoricoxib even after rechallenge 5 days later.⁹

(b) NSAIDs with theophylline

Piroxicam 20 mg daily for 7 days had no effect on the pharmacokinetics of theophylline (given as a single 6-mg/kg intravenous dose of aminophylline) in 6 healthy subjects.¹⁰ Enteric-coated aspirin 650 mg daily for 4 weeks had no effect on the steady-state serum levels of theophylline in 8 elderly patients (aged 60 to 81) with chronic obstructive pulmonary disease.¹¹ Nimesulide 100 mg twice daily for 7 days did not affect lung function in 10 patients with chronic obstructive airways disease taking slow-release theophylline 200 mg twice daily, although there was a slight, clinically insignificant fall in theophylline levels, possibly due to enzyme induction. The pharmacokinetics of the nimesulide were unchanged.¹²

Apart from checking that the patient is not sensitive to aspirin or any other NSAID (see (a) above), there would seem to be no reason for avoiding aspirin or piroxicam in patients taking theophylline.

Beta-agonist bronchodilators + Potassium-depleting drugs

Beta agonists (e.g. fenoterol, salbutamol (albuterol), terbutaline) can cause hypokalaemia. This can be increased by other potassium-depleting drugs such as the corticosteroids, diuretics (e.g. bendroflumethiazide, furosemide) and theophylline. The risk of serious cardiac arrhythmias in asthmatic patients may be increased.

Clinical evidence

(a) Corticosteroids

1. *Hypokalaemia.* The hypokalaemic effects of beta₂ agonists may be increased by corticosteroids. Twenty-four healthy subjects had a fall in their serum potassium levels when they were given either **salbutamol (albuterol)** 5 mg or **fenoterol** 5 mg by nebuliser over 30 minutes. The fall in potassium levels was increased after they took **prednisone** 30 mg daily for a week. The greatest fall (from 3.75 to 2.78 mmol/L) was found 90 minutes after **fenoterol** and **prednisone** were taken. The ECG effects observed included ectopic beats and transient T wave inversion, but no significant ECG disturbances were noted in these healthy subjects.¹

2. *Anti-inflammatory/bronchodilator effects.* A marked rise in asthma deaths was noted in New Zealand in the 1980s. A case-control study found that the risk of death was increased in oral corticosteroid-dependent asthmatics (severe asthma) who were also taking inhaled **fenoterol**.² This, and other data, suggested the possibility that combined use of short-acting beta₂ agonists and corticosteroids might be deleterious in some situations, prompting numerous studies, which were reviewed in 2000.³ The overall findings were, that although inhaled corticosteroids do not prevent the pro-inflammatory effects of short-acting beta₂ agonists, the combination is beneficial in the treatment of asthma at usual therapeutic doses of both drugs. The authors caution that this might not apply with excessive use of short-acting beta₂ agonists.³

The addition of a long-acting beta₂ agonist (e.g. **salmeterol**) to treatment in patients with chronic asthma inadequately controlled by inhaled corticosteroids and 'as required' short-acting beta₂ agonists is beneficial.^{3,4}

(b) Diuretics

The serum potassium level of 15 healthy subjects was measured after they were given inhaled **terbutaline** 5 mg with either a placebo, **furosemide** 40 mg daily, or **furosemide** 40 mg with **triamterene** 50 mg daily for 4 days. With **terbutaline** alone the potassium levels fell by 0.53 mmol/L; after taking **furosemide** as well they fell by 0.75 mmol/L; and after **furosemide** and **triamterene** they fell by 0.59 mmol/L. These falls were reflected in some ECG (T wave) changes.⁵

After 7 days of treatment with **bendroflumethiazide** 5 mg daily the serum potassium levels of 10 healthy subjects had fallen by 0.71 mmol/L. After taking 100 micrograms to 2 mg of inhaled **salbutamol (albuterol)** as well, the levels fell by 1.06 mmol/L, to 2.72 mmol/L. ECG changes consistent with hypokalaemia and hypomagnesaemia were seen.⁶ In an-

other study the same authors found that the addition of **bendroflumethiazide** 5 mg daily to inhaled **salbutamol** 2 mg further reduced serum potassium levels by 0.4 mmol/L, to 2.92 mmol/L. This reduction was abolished by the addition of **triamterene** 200 mg (serum potassium increased to 3.43 mmol/L) or **spironolactone** 100 mg (serum potassium increased to 3.53 mmol/L) but **triamterene** 50 mg only attenuated the effect of **bendroflumethiazide** (serum potassium 3.1 mmol/L). ECG effects with this combination were also reduced by the addition of triamterene or spironolactone.⁷

Other diuretics that can cause potassium loss include **bumetanide, furosemide, etacrynic acid, the thiazides**, and many other related diuretics, see 'Table 26.1', (p.944).

(c) Theophylline

The concurrent use of **salbutamol (albuterol)** or **terbutaline** and theophylline can cause an additional fall in serum potassium levels, and other beta₂ agonists will interact similarly. See 'Theophylline + Beta-agonist bronchodilators', p.1174.

Mechanism

Additive potassium-depleting effects.

Importance and management

Established interactions. The CSM in the UK⁸ advises that, as potentially serious hypokalaemia may result from beta₂ agonist therapy, particular caution is required in severe asthma, as this effect may be potentiated by theophylline and its derivatives, corticosteroids, diuretics, and by hypoxia. Hypokalaemia with concurrent use of thiazide and loop diuretics may be reduced or even abolished by the addition of spironolactone or high-dose triamterene. Plasma potassium levels should therefore be monitored in patients with severe asthma. Hypokalaemia may result in cardiac arrhythmias in patients with ischaemic heart disease and may also affect the response of patients to drugs such as the digitalis glycosides and antiarrhythmics.

Note that the combined use of beta₂ agonists and corticosteroids in asthma is usually beneficial.

Caffeine + Allopurinol

Allopurinol may invalidate the results of studies using caffeine as a probe drug for determining acetylase status or activity of CYP1A2.

Clinical evidence, mechanism, importance and management

In 21 healthy subjects, allopurinol 300 mg daily for 8 days altered the levels of urinary caffeine metabolites of a single 200-mg dose of caffeine. In particular, the metabolic ratio used to determine whether people are fast or slow acetylators was substantially changed. Thus, allopurinol may invalidate the results of phenotyping with the urinary caffeine test. In addition, the caffeine metabolite ratio used to express the activity of the cytochrome P450 isoenzyme CYP1A2 was not stable when allopurinol was used.¹ This interaction is of relevance to research rather than clinical practice.

1. Fuchs P, Haefeli WE, Ledermann HR, Wenk M. Xanthine oxidase inhibition by allopurinol affects the reliability of urinary caffeine metabolic ratios as markers for N-acetyltransferase 2 and CYP1A2 activities. *Eur J Clin Pharmacol* (1999) 54, 869–76.

Caffeine + Antiepileptics

Phenytoin can increase the clearance of caffeine, and possibly invalidates the caffeine breath test. Whether carbamazepine increases caffeine metabolism is unclear. Valproate appears not to have any effect on caffeine.

Clinical evidence

The clearance of caffeine was about twofold higher and its half-life was reduced by about 50% in patients with epilepsy taking **phenytoin**, when compared with healthy subjects not taking any medications. In the same study, there were no significant differences in caffeine pharmacokinetics between healthy subjects and patients receiving **carbamazepine** or **sodium valproate**.¹ Conversely, **carbamazepine** was considered to have induced the metabolism of caffeine in 5 children with epilepsy, as assessed by the caffeine breath test.² In another study in healthy subjects, there was a reduction in the AUC of **carbamazepine** when it was given with caffeine, but caffeine had no effect on the pharmacokinetics of **sodium valproate**.³

Mechanism

Phenytoin acts as an enzyme inducer, thereby increasing the metabolism of caffeine, lowering its levels. Carbamazepine possibly has the same effect.

Importance and management

Phenytoin may possibly invalidate the caffeine breath test, but normally no special precautions are needed if both drugs are taken. The interaction between carbamazepine and caffeine requires further study.

Caffeine + Antifungals

Fluconazole and terbinafine cause a modest rise in serum caffeine levels. Ketoconazole appears to have less effect.

Clinical evidence, mechanism, importance and management

A study in 6 young subjects (average age 24) given **fluconazole** 400 mg daily and 5 elderly subjects (average age 69) given **fluconazole** 200 mg daily for 10 days found that fluconazole reduced the plasma clearance of caffeine by an average of 25% (32% in the young and 17% in the old).¹ In a single-dose study in 8 healthy subjects, **terbinafine** 500 mg and **ketoconazole** 400 mg decreased caffeine clearance by 21% and 10%, respectively, and increased its half-life by 31% and 16%, respectively.²

It seems unlikely that these moderately increased serum caffeine levels will have a clinically important effect, but this needs confirmation.

Caffeine + Artemisinin

Artemisinin reduces the metabolism of caffeine.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects found that a single 500-mg dose of artemisinin reduced clearance of a single 136.5-mg dose of caffeine by 35%. The metabolism of caffeine to one of its major metabolites, paraxanthine, was reduced by 66%.¹ It was suggested that artemisinin inhibits the metabo-

lism of caffeine by the cytochrome P450 isoenzyme CYP1A2 in the liver.¹

There is too little information to advise patients taking artemisinin to completely avoid caffeine-containing beverages, foods or medication, but bear this interaction in mind if the adverse effects of caffeine (insomnia, jitteriness etc) become troublesome.

1. Bapiro TE, Sayi J, Hasler JA, Jande M, Rimoy G, Masselle A, Masimirembwa CM. Artemisinin and thiaabendazole are potent inhibitors of cytochrome P450 1A2 (CYP1A2) activity in humans. *Eur J Clin Pharmacol* (2005) 61, 755–61.

Caffeine + Cimetidine

The clearance of caffeine is decreased by cimetidine but this seems unlikely to be clinically significant.

Clinical evidence, mechanism, importance and management

In 5 subjects cimetidine 1 g daily for 6 days increased the half-life of a single 300-mg dose of caffeine by about 70% and reduced caffeine clearance.¹ In another study, cimetidine 1.2 g daily for 4 days increased the caffeine half-life by 45% in 6 smokers and by 96% in 6 non-smokers. The caffeine clearance was reduced by 31% in the smokers and by 42% in the non-smokers.² A further study found that the caffeine half-life was increased by 59% and the clearance decreased by 40% by cimetidine.³ Conversely, in a further study in children, cimetidine was not found to affect caffeine metabolism as assessed by the caffeine breath test.⁴

The changes seen in some studies probably occurred because cimetidine, a well-known non-specific enzyme inhibitor reduced the metabolism of caffeine by the liver, resulting in its accumulation in the body.

Any increased caffeine effects are normally unlikely to be of much importance in most people, but they might have a small part to play in exaggerating the undesirable effects of caffeine from food, drinks (e.g. tea, coffee, cola drinks, chocolate) and analgesics, which are sometimes formulated with caffeine.

Caffeine + Class I antiarrhythmics

Caffeine clearance is reduced by 30 to 60% by mexiletine, resulting in raised serum caffeine levels. Whether this might result in caffeine toxicity is uncertain. Lidocaine, flecainide and tocainide do not appear to affect caffeine clearance. Caffeine does not significantly alter mexiletine levels.

Clinical evidence

(a) Mexiletine

In a study in 7 patients with cardiac arrhythmias taking long-term mexiletine 600 mg daily the clearance of caffeine was found to be reduced by 48%.¹ In 5 healthy subjects given a single 200-mg dose of mexiletine, the clearance of a single 366-mg dose of caffeine was reduced by 57%, from 126 to 54 mL/minute, and the elimination half-life rose from approximately 4 to 7 hours.¹ The clearance of mexiletine was not affected by caffeine. A preliminary report of this study also noted that fasting caffeine levels were almost sixfold higher during the mexiletine treatment period (1.99 compared with 0.35 micrograms/mL).²

Another study in 14 healthy subjects found that caffeine 100 mg four times daily, for 2 days before and 2 days after mexiletine, did not cause any significant changes in the plasma levels of a single 200-mg dose of mexiletine. Caffeine levels tended to be increased 24 hours after taking mexiletine.³

(b) Other antiarrhythmics

Single doses of **lidocaine** 200 mg, **flecainide** 100 mg and **tocainide** 500 mg had no effect on caffeine clearance in 7 healthy subjects given a single 366-mg dose of caffeine.²

Mechanism

It is likely that, as with theophylline (see 'Theophylline + Mexiletine or Tocainide', p.1188), mexiletine inhibits the hepatic metabolism of caffeine by the cytochrome P450 isoenzyme CYP1A2.

Importance and management

The interaction between caffeine and mexiletine appears to be established, but its clinical importance is uncertain. Some of the adverse effects of mexiletine might be partially due to caffeine-retention (from drinking tea, coffee, cola drinks, etc.).¹ In excess, caffeine can cause jitteriness, tremor and insomnia. It has also been suggested that the caffeine test for liver function might be impaired by mexiletine.¹ Be alert for these possible effects.

Caffeine + Disulfiram

Disulfiram reduces the clearance of caffeine, which might complicate the withdrawal from alcohol.

Clinical evidence, mechanism, importance and management

A study in healthy subjects and recovering alcoholics found that disulfiram 250 or 500 mg daily reduced the clearance of caffeine by about 30%, but a few of the alcoholics had a more than 50% reduction.¹ As a result the levels of caffeine in the body increased. Raised levels of caffeine can cause irritability, insomnia and anxiety, similar to the symptoms of alcohol withdrawal. As coffee consumption is often particularly high among recovering alcoholics, there is the risk that they may turn to alcohol to calm themselves down. To avoid this possible complication it might be wise for recovering alcoholics not to drink too much tea or coffee. Decaffeinated coffee and tea are widely available.

1. Beach CA, Mays DC, Guiler RC, Jacober CH, Gerber N. Inhibition of elimination of caffeine by disulfiram in normal subjects and recovering alcoholics. *Clin Pharmacol Ther* (1986) 39, 265–70.

Caffeine + Echinacea

Echinacea appears to have a variable effect on the pharmacokinetics of caffeine.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 12 healthy subjects were given an 8-day course of *Echinacea purpurea* root 400 mg four times daily, with a single 200-mg oral dose of caffeine on day 6. The maximum serum concentration and AUC of caffeine were increased by about 30%. There was a large variation between subjects, with some having a 50% increase in caffeine clearance, and some a 90% decrease. The paraxanthine-to-caffeine ratio (a measure of CYP1A2 activity) was reduced by just 10%.¹ In another study in 12 healthy subjects given *Echinacea purpurea* 800 mg twice daily for 28 days, the paraxanthine-to-caffeine ratio was not significantly affected when a single 100-mg dose of caffeine was given at the end of the treatment with *Echinacea purpurea*.²

It is possible that drugs that are metabolised by the cytochrome P450 isoenzyme CYP1A2 and have a narrow therapeutic index may be adversely affected by the concurrent use of Echinacea-containing products. For a list of drugs that are substrates of this enzyme, see 'Table 1.2', (p.4). Further study is required.

Caffeine + Fluvoxamine

The clearance of caffeine is considerably reduced by fluvoxamine. An increase in the stimulant and adverse effects of caffeine would be expected, however this was not demonstrated in one study. Caffeine may cause a reduction in the bioavailability of fluvoxamine.

Clinical evidence

In a randomised, crossover study, fluvoxamine 50 mg daily for 4 days and then 100 mg daily for a further 8 days was given to 8 healthy subjects, with a single 200-mg oral dose of caffeine before and on day 8 of fluvoxamine use. Fluvoxamine reduced the total clearance of caffeine by about 80% (from 107 to 21 mL/minute) and increased its half-life from 5 to 31 hours. Specifically, the clearance of caffeine by N3-, N1- and N7-demethylation was decreased.¹ Another study in 30 patients found a positive correlation between plasma fluvoxamine and plasma caffeine levels, suggesting that the interaction is dose-related.² A further study found that low, sub-therapeutic doses of fluvoxamine 10 or 20 mg daily were sufficient to markedly inhibit caffeine metabolism.³ A study in 7 subjects found that fluvoxamine 100 mg twice daily for 4 doses significantly increased the maximum levels of a single 250-mg dose of caffeine by 40%, and increased the AUC and half-life of caffeine by 12.7-fold and 10-fold, respectively. However, this did not result in an increase in caffeine-related adverse effects, and none of the subjects felt they were more alert with the combination than with either drug alone.⁴

A study in 12 healthy subjects (6 smokers and 6 non-smokers, none were poor metabolisers of CYP2D6) found that caffeine 150 mg twice daily for 11 days reduced the AUC of a single 50-mg dose of fluvoxamine taken on day 8, by approximately 24%. The plasma concentration of fluvoxamine was also decreased by 12% but this was not significant.⁵

Mechanism

Fluvoxamine is a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2, which is the principal enzyme concerned with the metabolism of caffeine. As a result the caffeine is cleared from the body much more slowly and accumulates.¹⁻³

Importance and management

The increase in caffeine levels with concurrent use would seem to be established. There are no reports of caffeine toxicity arising from this interaction and one study⁴ found no increase in the pharmacodynamic or adverse effects of caffeine despite a large increase in the levels. However, an increase in the stimulant and adverse effects of caffeine (headache, jitteriness, restlessness, insomnia) may be possible in susceptible patients if they continue to consume large amounts of caffeine-containing food or drinks (tea, coffee, cola drinks, chocolate, etc.) or take caffeine-containing medications. They should be warned to reduce their caffeine intake if problems develop. It has been suggested that some of the adverse effects of fluvoxamine (i.e. nervousness, restlessness and insomnia) could in fact be caused by caffeine toxicity. However, a preliminary study, as well as the study reported above,⁴ found that caffeine intake had a limited effect on the frequency of adverse effects of fluvoxamine.⁶

The clinical significance of the change in the AUC of fluvoxamine with caffeine intake is unclear. This slight decrease is unlikely to be important in most patients.

Caffeine + Grapefruit juice

Grapefruit juice does not interact with caffeine to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects grapefruit juice, at a dose of 1.2 litres, decreased the clearance of caffeine from coffee by 23% and prolonged its half-life by 31%, but these changes were not considered clinically relevant.¹ A crossover study in 6 healthy subjects given caffeine 3.3 mg/kg found that multiple doses of grapefruit juice (equivalent to 6 glasses) caused a non-significant increase in the AUC of caffeine. No changes in ambulatory systolic or diastolic blood pressure or heart rate were seen.²

Caffeine + Hormonal contraceptives or HRT

The half-life of caffeine is prolonged to some extent in women taking combined oral contraceptives or HRT.

Clinical evidence

(a) Contraceptives

The clearance of a single 162-mg dose of caffeine was reduced, the half-life prolonged (7.9 compared with 5.4 hours), and the plasma levels were raised in 9 women taking low-dose combined oral contraceptives for at least 3 months, when compared with 9 other women not taking an oral contraceptive.¹ This finding was confirmed in three other studies,^{2–4} which found that caffeine elimination was prolonged, from 4 to 6 hours before the use of combined oral contraceptives, to about 9 hours by the end of the first cycle, and to about 11 hours by the end of the third cycle.^{3,4} A further study found that there was little difference between the effects of two oral contraceptives (ethinylestradiol 30 micrograms with gestodene 75 micrograms or levonorgestrel 125 micrograms) on caffeine: both increased the half-life of caffeine by a little over 50%, but the maximum serum levels were unchanged.⁵

(b) HRT

In one study, 12 healthy postmenopausal women were given a single 200-mg dose of caffeine after taking estradiol (*Estrace*) for 8 weeks, titrated to give estradiol plasma concentrations of 50 to 150 picograms/mL. The metabolism of caffeine was reduced by 29% overall. If the data for 2 subjects who were found to have taken extra caffeine during the study period are excluded, the caffeine metabolism showed an even greater average reduction of 38%.⁶

Mechanism

Uncertain. Estrogens can inhibit the cytochrome P450 isoenzyme CYP1A2, by which caffeine is metabolised, which may explain its accumulation in the body.

Importance and management

An established interaction that is probably of limited clinical importance. Women taking oral contraceptives containing estrogens or HRT who take caffeine-containing analgesics or drink caffeine-containing drinks (tea, coffee, cola drinks, etc.) may find the effects of caffeine, such as jitteriness and insomnia, increased and prolonged.

Caffeine + Idrocilamide

Oral idrocilamide reduces the clearance of caffeine, which can lead to caffeine toxicity.

Clinical evidence, mechanism, importance and management

The possibility that caffeine ingestion might have had some part to play in the development of psychiatric disorders seen in patients taking idrocilamide, prompted a pharmacokinetic study in 4 healthy subjects. While taking oral idrocilamide 400 mg three times a day the half-life of caffeine (150 to 200 mg of caffeine from one cup of coffee) was prolonged from about 7 to 59 hours. The overall clearance of caffeine was decreased by about 90%.^{1,2}

Idrocilamide can inhibit the cytochrome P450 isoenzyme CYP1A2 by which caffeine is metabolised, leading to its accumulation.

Evidence is limited but the interaction appears to be established. Patients taking oral idrocilamide should probably avoid or minimise their intake of caffeine, including caffeine-containing drinks (tea, coffee, cola drinks, etc.), otherwise caffeine toxicity may develop. Decaffeinated teas and coffee are widely available. Some medicines may contain caffeine, so these should also be used with care.

Caffeine + Kava

There are conflicting results from studies of the interaction of kava and caffeine. It appears that kava is unlikely to affect the pharmacokinetics of caffeine, although further study is required to confirm this.

Clinical evidence, mechanism, importance and management

In a study in 6 subjects (3 of whom smoked tobacco) who regularly took 7 to 27 g of kavalactones weekly as an aqueous kava extract, the metabolic ratio of caffeine was increased twofold when kava was withheld for 30 days, which suggested that kava inhibits the cytochrome P450 isoenzyme CYP1A2, which is involved in the metabolism of caffeine.¹

However, in a study in 12 non-smoking healthy subjects given kava kava root extract 1 g twice daily for 28 days before receiving a single 100-mg dose of oral caffeine, no significant change in the metabolic ratio of caffeine was noted.² It is possible that the inhibitory effect of tobacco smoke on CYP1A2, and the lack of standardisation of kava intake may have influenced the results.

1. Russman S, Lauterburg BH, Barguil Y, Choblet E, Cabalion P, Rentsch K, Wenk M. Traditional aqueous kava extracts inhibit cytochrome P450 1A2 in humans: protective effect against environmental carcinogens? *Clin Pharmacol Ther* (2005) 77, 451–4.

Caffeine + Menthol

A crossover study in 11 healthy subjects found that a single 100-mg dose of menthol taken with coffee containing 200 mg caffeine increased the time to maximum caffeine concentration by about 30 minutes. The increase in the actual maximum concentration was not significant, and there were no significant effects on caffeine half-life. It was thought that menthol reduced the rate of caf-

caffeine absorption.¹ The clinical importance of this is not clear but it seems likely to be small.

1. Gelal A, Guven H, Balkan D, Artok L, Benowitz NL. Influence of menthol on caffeine disposition and pharmacodynamics in healthy female volunteers. *Eur J Clin Pharmacol* (2003) 59, 417–22.

Caffeine + Psoralens

Oral methoxsalen and 5-methoxypsoralen markedly reduce caffeine clearance but the clinical significance of this is uncertain. Topical methoxsalen does not interact with caffeine.

Clinical evidence

A single 1.2-mg/kg oral dose of **methoxsalen** (8-methoxypsoralen), given to 5 subjects with psoriasis 1 hour before a single 200-mg oral dose of caffeine, reduced the clearance of caffeine by 69%. The elimination half-life of caffeine over the period from 2 to 16 hours after taking the **methoxsalen** increased tenfold (from 5.6 to 57 hours).¹ In a similar study, 8 patients with psoriasis were given caffeine 200 mg with or without **5-methoxypsoralen** 1.2 mg/kg. The AUC of caffeine increased by about threefold and there was a threefold decrease in its clearance.²

A study in patients receiving PUVA therapy (**methoxsalen** either orally, in 4 patients, or topically as a bath in 7 patients, plus UVA) found that the clearance of a single 150-mg dose of caffeine was markedly reduced in the patients given oral **methoxsalen** but not altered in those given topical **methoxsalen**.³

Mechanism

Both methoxsalen and 5-methoxypsoralen inhibit the hepatic metabolism of caffeine by the cytochrome P450 isoenzyme CYP1A2, thereby markedly increasing caffeine levels.^{2,3}

Importance and management

The practical consequences of this interaction are as yet uncertain, but it seems possible that the toxic effects of caffeine will be increased. In excess, caffeine (including that from tea, coffee and cola drinks) can cause jitteriness, headache and insomnia. The interaction does not appear to occur with topical methoxsalen.

3. Tancheva-PoGr I, Servera-Llaneras M, Scharffetter-Kochanek K, Fuhr U. Liver cytochrome P450 CYP1A2 is markedly inhibited by systemic but not by bath PUVA in dermatological patients. *Br J Dermatol* (2001) 144, 1127–32.

Caffeine + Quinolones

Enoxacin markedly increases caffeine levels. The effects of caffeine derived from drinks such as tea, coffee or cola, would be expected to be increased. Pipemidic acid interacts to a lesser extent, and ciprofloxacin, norfloxacin and pefloxacin interact less still. Fleroxacin, lomefloxacin, ofloxacin, rufloxacin, and trovafloxacin appear not to interact.

Clinical evidence

The effects of various quinolones on the pharmacokinetics of caffeine^{1–13} are summarised in 'Table 33.3', (p.1167). In one study ciprofloxacin and fleroxacin increased caffeine levels more in women than men, but this difference in effect was not significant when the results were normalised for body weight.¹³

Mechanism

It would seem that the metabolism (*N*-demethylation) of caffeine is markedly reduced by some quinolones (notably pipemidic acid and enoxacin) resulting in greater levels and possibly greater effects. Other quinolones

have either a much smaller effect or no effect at all. The quinolones that interact appear to inhibit the cytochrome P450 isoenzyme CYP1A2¹⁴ by which caffeine is metabolised.

Importance and management

Established interactions. Based on the results of two studies, on a scale of 100 to 0, the relative potencies of these quinolones as inhibitors of caffeine elimination have been determined as follows: enoxacin 100, pipemidic acid 29, ciprofloxacin 11, norfloxacin 9 and ofloxacin 0.¹⁵ From further studies, clinafloxacin appears to be similar to enoxacin (profound effect), pefloxacin to norfloxacin (to which it is metabolised; modest effect), and fleroxacin, lomefloxacin, rufloxacin, and trovafloxacin appear to behave like ofloxacin (no effect). Patients taking enoxacin might be expected to experience an increase in the effects of caffeine (such as headache, jitteriness, restlessness, insomnia) if, for example, they continue to drink their usual amounts of caffeine-containing drinks (tea, coffee, cola drinks, etc.). They should be warned to cut out or reduce their intake of caffeine if this occurs. The authors of one report¹ suggest that patients with hepatic disorders, cardiac arrhythmias or latent epilepsy should avoid caffeine if they take enoxacin for one week or more. The effects of pipemidic acid are less, and those of ciprofloxacin, norfloxacin and pefloxacin are probably of little or no clinical importance. Fleroxacin, lomefloxacin, ofloxacin, rufloxacin, and trovafloxacin do not interact.

Caffeine + Saw palmetto

Saw palmetto does not appear to affect the pharmacokinetics of caffeine.

Clinical evidence, mechanism, importance and management

Saw palmetto 160 mg twice daily was given to 12 healthy subjects for 28 days with a single 100-mg dose of caffeine at the end of treatment with saw palmetto. The metabolism of caffeine was not affected by the concurrent use of saw palmetto, which suggests that saw palmetto does not significantly affect the cytochrome P450 isoenzyme CYP1A2. Therefore the metabolism of other drugs that are substrates of CYP1A2 would not be expected to be affected by saw palmetto.¹ For a list of drugs that are substrates of this isoenzyme, see 'Table 1.2', (p.4).

Caffeine + Sho-saiko-to

Sho-saiko-to slightly reduces the metabolism of caffeine, but this is not expected to be clinically important.

Clinical evidence, mechanism, importance and management

In a study, 26 healthy subjects were given sho-saiko-to 2.5 g twice daily for 5 days, with a single 150-mg dose of caffeine on days 1 and 5. By assessing the metabolites of caffeine, it was estimated that sho-saiko-to caused a 16% inhibition of the cytochrome P450 isoenzyme CYP1A2. The clinical significance of this finding is unclear, but is likely to be small, although further studies will help clarify this.¹

Caffeine + St John's wort (*Hypericum perforatum*)

St John's wort appears to increase the metabolism of caffeine in women, but not men.

Clinical evidence, mechanism, importance and management

A study in 16 healthy subjects given a single 200-mg dose of caffeine before and after St John's wort 300 mg (containing 900 micrograms of hypericin) three times daily for 14 days, found no overall change in the pharmacokinetics of caffeine. However, when the subset of 8 female patients was considered, it was found that there was an induction of CYP1A2 in this group of patients resulting in an increase in the production of caffeine metabolites.¹ More study is needed, as this may have important implications for other CYP1A2 substrates.

1. Wenk M, Todesco L, Krähenbühl S. Effect of St John's wort on the activities of CYP1A2, CYP3A4, CYP2D6, N-acetyltransferase 2, and xanthine oxidase in healthy males and females. *Br J Clin Pharmacol* (2004) 57, 494-9.

Caffeine + Tiabendazole

Tiabendazole reduces the metabolism of caffeine.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects found that a single 500-mg dose of tiabendazole reduced the clearance of caffeine by 66% and increased the half-life and AUC by 140% and 57%, respectively. The metabolism of caffeine to one of its major metabolites, paraxanthine, was reduced by 92%.¹ It was suggested that tiabendazole inhibits the metabolism of caffeine by the cytochrome P450 isoenzyme CYP1A2 in the liver.

Tiabendazole is known to have clinically significant inhibitory effects on the metabolism of 'theophylline', (p.1171), and therefore would also be expected to affect caffeine metabolism. There is too little information to suggest that patients taking tiabendazole should avoid caffeine-containing

beverages, foods or medication, but bear this interaction in mind if the adverse effects of caffeine (e.g. insomnia, jitteriness) become troublesome.

1. Bapiro TE, Sayi J, Hasler JA, Jande M, Rimoy G, Masselle A, Masimirembwa CM. Artemisinin and thiabendazole are potent inhibitors of cytochrome P450 1A2 (CYP1A2) activity in humans. *Eur J Clin Pharmacol* (2005) 61, 755-61.

Caffeine + Venlafaxine

Venlafaxine does not affect the pharmacokinetics of caffeine.

Clinical evidence, mechanism, importance and management

In 15 healthy subjects venlafaxine 37.5 mg twice daily for 3 days then 75 mg twice daily for 4 days did not affect the AUC or clearance of caffeine 200 mg daily (equivalent to about 3 cups of coffee). A slight but significant decrease in the half-life from 6.1 to 5.5 hours was noted.¹ On the basis of this study, no special precautions are needed if both drugs are taken together.

1. Amchin J, Zarycranski W, Taylor KP, Albano D, Klockowski PM. Effect of venlafaxine on CYP1A2-dependent pharmacokinetics and metabolism of caffeine. *J Clin Pharmacol* (1999) 39, 252-9.

Caffeine + Verapamil

A small and relatively unimportant decrease in the clearance of caffeine may occur in patients given verapamil.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects verapamil 80 mg three times daily for 2 days decreased the total clearance of a single 200-mg dose of caffeine by 25%, and increased its half-life by 25% (from 4.6 to 5.8 hours).¹ These changes are small, and unlikely to be of much importance in most patients.

1. Nawoot S, Wong D, Mays DC, Gerber N. Inhibition of caffeine elimination by verapamil. *Clin Pharmacol Ther* (1988) 43, 148.

Doxofylline + Miscellaneous

There is some limited evidence to suggest that erythromycin may increase the effects of doxofylline, but the clinical importance of this is uncertain. Digoxin initially raises, then lowers serum doxofylline levels, but the bronchodilator effects do not appear to be significantly affected. Allopurinol and lithium carbonate appear to have no significant effects on doxofylline.

Clinical evidence, mechanism, importance and management

Healthy subjects were given doxofylline 400 mg three times daily, either alone, or with **allopurinol** 100 mg once daily, **erythromycin** 400 mg three times daily or **lithium carbonate** 300 mg three times daily. None of the pharmacokinetic parameters measured, including the maximum serum levels, were significantly altered by any of these drugs apart from the AUC of doxofylline, which was raised by about 40% by **allopurinol**, 70% by **erythromycin**, and 35% by **lithium carbonate**. Only the **erythromycin** result was statistically significant.¹ The clinical significance of these changes is uncertain, and their mechanism is not understood. Until the sit-

uation is much clearer it would be prudent to check the outcome of adding **erythromycin** to established treatment with doxofylline, being alert for evidence of increased effects.

In a comparative study in 9 patients taking doxofylline 800 mg daily, **digoxin** 500 micrograms daily was given to 5 patients. It was found that **digoxin** increased the serum levels of doxofylline by 50% on the first day of treatment, 3 hours after administration but then reduced doxofylline levels by about 30% at steady-state (day 30). Nevertheless, the bronchodilating effects of the doxofylline were little different between the two groups. It was concluded that concurrent use is normally safe and effective, but the initial doxofylline dose should be chosen to avoid too high a serum level on the first day, and pulmonary function should be well monitored.²

Ipratropium bromide + Salbutamol (Albuterol)

Acute angle-closure glaucoma developed rapidly in eight patients given nebulised ipratropium and salbutamol. Increased intra-ocular pressure has been reported in others, including one patient using an ipratropium metered-dose inhaler with nebulised salbutamol.

Clinical evidence

Five patients with an acute exacerbation of chronic obstructive airways disease given nebulised ipratropium and salbutamol, developed acute angle-closure glaucoma, four of them within 1 to 36 hours of starting treatment. Two of the patients had a history of angle-closure glaucoma.¹ Three other similar cases of acute angle-closure glaucoma due to the concurrent use of salbutamol and ipratropium are reported elsewhere.^{2,3} An increase in intra-ocular pressure has also been reported in other patients given both drugs by nebuliser.⁴ One case of acute angle-closure glaucoma has been reported in a patient treated with inhaled ipratropium, via a metered-dose inhaler, and nebulised salbutamol.⁵

Mechanism

This reaction appears to occur because the antimuscarinic action of the ipratropium causes semi-dilatation of the pupil, partially blocking the flow of aqueous humour from the posterior to the anterior chamber, thereby bowing the iris anteriorly and obstructing the drainage angle. The salbutamol increases the production of aqueous humour and makes things worse. Additional factors are that higher levels of both drugs are achieved by using a nebuliser, and that some drug may escape round the edge of the mask and have a direct action on the eye.¹

Importance and management

An established but uncommon interaction, which appears to occur mainly in patients receiving these drugs by nebuliser and those already predisposed to angle-closure glaucoma. The authors of the first report¹ advise care in the placing of the mask to avoid the escape of droplets (the use of goggles and continuing the application of any glaucoma treatment is also effective⁴) and, if possible, the avoidance of their concurrent use by nebuliser in patients predisposed to angle-closure glaucoma.

Montelukast + Anti-asthma drugs

There is an isolated report of severe oedema in a patient taking oral prednisone and montelukast, but studies suggest that the

concurrent use of montelukast and prednisolone or prednisone are useful and well-tolerated. Montelukast in normal doses does not interact to a clinically relevant extent with salbutamol (albuterol)

Clinical evidence, mechanism, importance and management

(a) Beta agonists

A study in patients with moderately severe asthma found no adverse interactions when **salbutamol (albuterol)** was given with montelukast 100 mg or 250 mg, with or without inhaled corticosteroids.¹ The British Thoracic Society guidelines recommend that a leukotriene antagonist is used as an add-on therapy in patients using short-acting inhaled beta₂ agonists.²

(b) Corticosteroids

A study in healthy subjects (55 taking montelukast and 36 taking a placebo) found that the plasma profiles of oral **prednisone** 20 mg and of intravenous **prednisolone** 250 mg were unaffected by montelukast 200 mg daily for 6 weeks.³ The manufacturers also report that licensed doses of montelukast do not have any clinically significant effect on the pharmacokinetics of prednisone and prednisolone.⁴ Other studies in patients using inhaled and/or oral corticosteroids have found that concurrent use is beneficial and well tolerated.^{5–7}

However, an isolated report describes a case of marked peripheral oedema possibly linked to the use of **prednisone** and montelukast. A 23-year-old patient with severe allergic and exercise-induced asthma and rhinconjunctivitis treated with salmeterol and fluticasone by inhalation and oral cetirizine was given **prednisone** 40 mg daily for one week then 20 mg daily for a further week. When **prednisone** was stopped, severe asthma reoccurred and he was given **prednisone** 60 mg daily for one week then 40 mg daily for a further week with montelukast 10 mg daily. After 10 days of treatment he developed severe peripheral oedema, gaining 13 kg in weight. Renal and cardiovascular function were normal. **Prednisone** was stopped and the asthma was controlled by continued montelukast and the excess weight was lost as the oedema resolved. The patient had good tolerance of both **prednisone** and montelukast alone. Corticosteroid-induced renal tubular sodium and fluid retention may have occurred when montelukast was also given.⁸

This isolated report is of uncertain general relevance. Usually, no special precautions appear to be needed if these drugs are used concurrently, and the British Thoracic Society guidelines recommend that a leukotriene antagonist is used as an add-on therapy to inhaled steroids in adults and children over five years of age.²

Montelukast + Antiepileptics

Phenobarbital modestly reduces montelukast levels, but this is not thought to be clinically significant. Phenytoin is predicted to interact similarly.

Clinical evidence, mechanism, importance and management

Montelukast 10 mg was given to 14 healthy subjects before and after they took **phenobarbital** 100 mg daily for 14 days. It was found that the geo-

metric mean AUC and the maximum serum levels of the montelukast were reduced by 38% and 20%, respectively, but it was concluded that no montelukast dosage adjustment is needed.¹ The reason for these reductions is almost certainly because phenobarbital induces the cytochrome P450 isoenzyme CYP3A4 so that montelukast metabolism is increased. The manufacturers therefore caution the use of montelukast with inducers of CYP3A4, such as **phenytoin** and **phenobarbital**, especially in children.² However, there is so far no clinical evidence that the montelukast dosage needs adjustment in the presence of any of these drugs.

- Holland S, Shahane A, Rogers JD, Porras A, Grasing K, Lasseter K, Pinto M, Freeman A, Gertz B, Amin R. Metabolism of montelukast (M) is increased by multiple doses of phenobarbital (P). *Clin Pharmacol Ther* (1998) 63, 231.
- Singulair (Montelukast sodium). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, November 2006.

Montelukast + Antihistamines

Montelukast does not interact to a clinically relevant extent with loratadine or terfenadine.

Clinical evidence, mechanism, importance and management

Healthy subjects were given terfenadine 60 mg every 12 hours for 14 days, with montelukast 10 mg daily from day 8 to day 14. It was found that the **terfenadine** pharmacokinetics and the QTc interval were unaltered by concurrent use.¹ No adverse interactions were seen in large numbers of patients given montelukast 10 or 20 mg and **loratadine** 10 mg, and the combination was found to be beneficial in the treatment of allergic rhinitis and conjunctivitis.² No special precautions are therefore needed if these drugs are given concurrently.

- Holland S, Gertz B, DeSmet M, Michiels N, Larson P, Freeman A, Keymeulen B. Montelukast (MON) has no effect on terfenadine (T) pharmacokinetics (PK) or QTc. *Clin Pharmacol Ther* (1998) 63, 232.
- Malstrom K, Meltzer E, Prenner B, Lu S, Weinstein S, Wolfe J, Wei LX, Reiss TF. Effects of montelukast (a leukotriene receptor antagonist), loratadine, montelukast + loratadine and placebo in seasonal allergic rhinitis and conjunctivitis. *J Allergy Clin Immunol* (1998) 101, S97.

Montelukast + Rifampicin (Rifampin)

The manufacturers of montelukast caution its use with inducers of the cytochrome P450 isoenzyme CYP3A4, such as rifampicin, especially in children.¹ This is because phenobarbital (an inducer of CYP3A4) has been found to reduce the AUC and serum levels of montelukast.¹ However, there is currently no clinical evidence that the montelukast dosage needs adjustment in patients taking rifampicin.

- Singulair (Montelukast sodium). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, November 2006.

Terbutaline + Magnesium sulfate

Subcutaneous terbutaline and intravenous magnesium sulfate appear not to interact adversely.

Clinical evidence, mechanism, importance and management

Eight healthy adults were given two subcutaneous doses of terbutaline 250 micrograms 30 minutes apart, with and without intravenous magnesium sulfate 4 g in 250 mL of sodium chloride 0.9%, given over the same 30-minute period.¹ Most of the effects of terbutaline, such as those on respiratory rate, blood pressure, glucose and calcium levels, were found to be moderately increased by magnesium sulfate at 60 minutes but these changes were all considered to be small. It was concluded that there appear to be no good reasons for avoiding their concurrent use, for example in the emergency treatment of asthma and other conditions.

- Skorodin MS, Freebeck PC, Yetter B, Nelson JE, Van de Graaff WB, Walsh JM. Magnesium sulfate potentiates several cardiovascular and metabolic actions of terbutaline. *Chest* (1994) 105, 701–5.

Theophylline + Aciclovir

Preliminary evidence suggests that aciclovir can increase the serum levels of theophylline.

Clinical evidence

Prompted by a case of increased theophylline adverse effects in a patient given aciclovir, a study was carried out in 5 healthy subjects who were given single 320-mg doses of theophylline (as 400 mg of aminophylline) before and with the sixth dose of aciclovir 800 mg five times daily for 2 days. The AUC of the theophylline was increased by 45% and its total body clearance was reduced by 30% by the aciclovir.¹

Mechanism

Uncertain, but the evidence suggests that aciclovir inhibits the oxidative metabolism of theophylline, resulting in accumulation.¹

Importance and management

Evidence appears to be limited to this report. However, be alert for an increase in adverse effects of theophylline (nausea, headache, tremor) if aciclovir is added to established treatment, and consider monitoring levels. More study is needed.

- Maeda Y, Konishi T, Omoda K, Takeda Y, Fukuhara S, Fukuzawa M, Ohune T, Tsuya T, Tsukikai S. Inhibition of theophylline metabolism by aciclovir. *Biol Pharm Bull* (1996) 19, 1591–5.

Theophylline + Allopurinol

Evidence from clinical studies and a single case report indicate that the effects of theophylline may be increased by allopurinol.

Clinical evidence

The peak plasma levels of theophylline 450 mg daily rose by 38% in a patient who took allopurinol for 3 days.¹ In a study in 12 healthy subjects, allopurinol 300 mg twice daily for 14 days increased the half-life of a single 5-mg/kg oral dose of theophylline by 25%, and increased its AUC by 27%.² Similar increases were seen when a second dose of theophylline was given 28 days after starting the allopurinol.²

However, in two other studies allopurinol 300 mg daily for 7 days did not have any effect on the pharmacokinetics of theophylline, following a single 5-mg/kg intravenous dose of aminophylline.^{3,4} Similarly, steady-state theophylline levels were not affected by allopurinol 100 mg three times daily in 4 subjects. However, there was an alteration in the proportion of different urinary theophylline metabolites: methyluric acid decreased and methylxanthine increased.⁴

Mechanism

Uncertain. Allopurinol, a xanthine oxidase inhibitor, can block the conversion of methylxanthine to methyluric acid, but this had no effect on theophylline levels in two studies. One suggestion is that allopurinol inhibits the oxidative metabolism of theophylline by the liver.¹

Importance and management

Evidence appears to be limited to a single case report and the studies in healthy subjects. The interaction only appears to be of moderate importance. Nevertheless, it would seem prudent to check for any signs of theophylline adverse effects (headache, nausea, tremor) during concurrent use, particularly in situations where the metabolism of the theophylline may already be reduced (other drugs or diseases), or where high doses of allopurinol are used. For mention that allopurinol may invalidate the results of phenotyping tests using caffeine, see 'Caffeine + Allopurinol', p.1162.

Theophylline + Alosetron

Alosetron does not alter theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 10 healthy women were given alosetron 1 mg twice daily for 16 days with oral theophylline 200 mg twice daily from day 8 to day 16. No clinically relevant changes in the pharmacokinetics of theophylline were seen, and concurrent use was well tolerated. The effect of theophylline on alosetron pharmacokinetics was not measured but the authors of the report say that no metabolic interaction seems likely.¹ No special precautions would therefore appear to be needed if these drugs are used together.

1. Koch KM, Ricci BM, Hedayetullah NS, Jewell D, Kersey KE. Effect of alosetron on theophylline pharmacokinetics. *Br J Clin Pharmacol* (2001) 52, 596–600.

Theophylline + Aminoglutethimide

Theophylline clearance is increased by aminoglutethimide, which may result in a moderate reduction in the serum levels and therapeutic effects of theophylline.

Clinical evidence, mechanism, importance and management

Aminoglutethimide 250 mg four times a day increased the clearance of sustained-release theophylline 200 mg twice daily by 18 to 43% in 3 patients.¹ Theophylline clearance was assessed before starting aminoglutethimide as well as during weeks 2 to 12 of concurrent use.

It seems probable that aminoglutethimide, a known enzyme inducer, increases the metabolism of theophylline by the liver, thereby decreasing its levels. The clinical importance is uncertain, but it seems likely that the effects of theophylline would be reduced to some extent. Monitor the effects and if necessary take theophylline levels. Increase the theophylline dosage accordingly.

Theophylline + Amiodarone

An isolated case report describes an elderly man who developed raised theophylline levels and toxicity when he was given amiodarone.

Clinical evidence, mechanism, importance and management

An 86-year-old man taking furosemide, digoxin, domperidone and sustained-release theophylline developed signs of theophylline toxicity when amiodarone 600 mg daily was given. After 9 days his serum theophylline levels had doubled, from about 16.8 to 35 mg/L. The toxicity disappeared when the theophylline was stopped.¹ The reason for this adverse reaction is not understood but it has been suggested that amiodarone may reduce the metabolism of the theophylline by the liver.¹ This is an isolated case and its general importance is uncertain. More study is needed.

Amiodarone may cause thyroid dysfunction, which may affect theophylline requirements, see also 'Theophylline + Thyroid and Antithyroid compounds', p.1200.

1. Soto J, Sacristán JA, Arellano F, Hazas J. Possible theophylline-amiodarone interaction. *DICP Ann Pharmacother* (1990) 24, 1115.

Theophylline + Antacids

The extent of absorption of theophylline from the gut does not appear to be significantly affected by aluminium or magnesium hydroxide antacids. However, an increase in the rate of absorption of some sustained-release theophylline preparations may occur.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, there was no difference in the steady-state maximum serum concentrations or AUC of theophylline given as *Nuelin-Depot* or *Theodur* when an antacid (*Novalucid*, containing **aluminium/magnesium hydroxide** and **magnesium carbonate**) was given. However, the antacid caused a faster absorption of theophylline from *Nuelin-Depot*, which resulted in greater fluctuations in the serum levels. It was considered that the adverse effects of theophylline might be increased in those patients with serum levels at the top of the range.¹ Similar results have been found in single-dose studies when aminophylline,² *Slo-Phyllin Gyrocaps*,³ *Somophyllin CRT*,⁴ and *Theo-Dur*⁵ were given with **aluminium/magnesium hydroxide** antacids, and in multiple dose studies in patients when *Armophylline*,⁶ *Aminophyllin*⁷ or *Theodur*⁷ were given with **aluminium/magnesium hydroxide** antacids. Administration of 30 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox*) four times daily did not affect the trough levels of theophylline in a patient taking *Theo-Dur* 400 mg three times daily.⁸ Care should be taken extrapolating this information to other sustained-release preparations of theophylline, but generally speaking no special precautions seem to be necessary if antacids are given with theophylline.

Theophylline + Anthelmintics; Benzimidazoles

Theophylline serum levels can be markedly increased by tiabendazole and toxicity may develop. Neither albendazole nor mebendazole appear to interact with theophylline.

Clinical evidence

(a) Albendazole

A study in 6 healthy subjects found that the pharmacokinetics of a single dose of theophylline were unaffected by a single 400-mg dose of albendazole.¹

(b) Mebendazole

A study in 6 healthy subjects found that the pharmacokinetics of a single dose of intravenous aminophylline were unaffected by mebendazole 100 mg twice daily for 3 days.¹ The absence of a significant interaction was reported in another similar study using the same mebendazole dosage.²

(c) Tiabendazole

An elderly man taking prednisone, furosemide, terbutaline and orciprenaline was switched from oral to intravenous aminophylline, giving a stable serum level of 21 mg/L after 48 hours. When he was also given tiabendazole 4 g daily for 5 days, for persistence of a *Strongyloides stercoralis* infestation, he developed theophylline toxicity (severe nausea) and his serum levels were found to be 46 mg/L. Three months previously, he had been treated with tiabendazole 3 g daily for 3 days without any symptoms of toxicity (no theophylline levels were measured).³ The theophylline levels of another patient rose from 15 to 22 mg/L when he was given tiabendazole 1.8 g twice daily for 3 days, despite a theophylline dosage reduction of one-third, made in anticipation of the interaction. Theophylline levels were still elevated 2 days after the tiabendazole was stopped, and the theophylline dose was further reduced. Levels returned to normal after 5 days, and the theophylline dose was eventually increased again.⁴

A retrospective study of patients given theophylline and tiabendazole found that 9 out of 40 (23%) had developed elevated serum theophylline levels and of those 9 patients, 5 experienced significant toxicity, with 3 re-

quiring hospitalisation. The other 31 patients did not have theophylline levels taken.⁵ A further report describes a patient receiving intravenous aminophylline who had an increase in theophylline levels from 18 to 26 mg/L within 2 days of starting tiabendazole 1.5 g twice daily.² The authors of this report then studied 6 healthy subjects who received a single dose of aminophylline before and while taking tiabendazole 1.5 g twice daily for 3 days. Three of the subjects had to discontinue the study because of severe nausea, vomiting or dizziness. In the remaining three, tiabendazole markedly affected the pharmacokinetics of aminophylline; the half-life increased from 6.7 to 18.6 hours, the clearance fell by 66% and the elimination rate constant decreased by 65%.²

Mechanism

Uncertain. It is suggested that tiabendazole inhibits the metabolism of theophylline, probably by the cytochrome P450 isoenzyme CYP1A2 in the liver, thereby prolonging its stay in the body and raising its serum levels. The nausea and vomiting may have been due to the adverse effects of both theophylline and tiabendazole.

Importance and management

The interaction between theophylline and tiabendazole is established and of clinical importance. Monitor theophylline levels and reduce the theophylline dosage accordingly. A 50% reduction in the theophylline dosage has been suggested,⁴ or, where practical, stopping theophylline for 2 to 3 days while giving the tiabendazole.⁵ Albendazole and mebendazole do not appear to interact with theophylline, and therefore may be suitable alternative anthelmintics depending on the condition being treated.

Theophylline + Anticholinesterases; Centrally acting

The serum levels of theophylline are increased by tacrine. Donepezil has no effect on theophylline levels.

Clinical evidence, mechanism, importance and management

(a) Donepezil

An open-label, crossover study in 12 healthy subjects found that donepezil 5 mg daily for 10 days had no significant effects on the pharmacokinetics of theophylline. Dose modification or additional monitoring is not required during concurrent use.¹

(b) Tacrine

Healthy subjects were given theophylline 158 mg alone or while taking tacrine 20 mg every 6 hours. The clearance of the theophylline was reduced by 50%, probably because the tacrine inhibits its metabolism by the cytochrome P450 isoenzyme CYP1A2 in the liver.² Be alert for the need to reduce the theophylline dosage to avoid toxicity if tacrine is added. More study of this interaction is needed in patients given multiple doses of both drugs.

Theophylline + Antihistamines and related drugs

Azelastine, cetirizine, ketotifen, mequitazine, mizolastine, pemirolast, repirinast, and terfenadine do not appear to alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

Azelastine 2 mg twice daily had no significant effect on the clearance of theophylline 300 mg twice daily in 10 subjects with bronchial asthma. However, one patient had a 20.8% increase and another a 25.3% decrease in clearance.¹

A single 240-mg dose of *intravenous* theophylline was given to 6 healthy subjects after they had taken **cetirizine** 10 mg twice daily for 3.5 days. There was no change in theophylline pharmacokinetics, but the half-life of cetirizine was decreased by 19%. This change in cetirizine pharmacokinetics was not considered to be clinically relevant.²

Two studies, one in healthy adults³ and one in asthmatic children,⁴ showed that **ketotifen** did not affect the pharmacokinetics of a single oral dose of either theophylline³ or aminophylline.⁴ It was suggested that concurrent use might actually decrease the CNS adverse effects of each drug.³

In 7 asthmatic patients the steady-state pharmacokinetics of theophylline were not significantly affected when **mequitazine** 6 mg daily was given for 3 weeks.⁵

Mizolastine 10 mg daily had virtually no effect on the steady-state pharmacokinetics of theophylline in 17 healthy subjects, although a 13% increase in mean trough level and an 8% increase in the AUC was seen. These changes were not considered clinically relevant.⁶

Pemirolast 10 mg daily for 4 days was found to have no significant effect on the steady-state serum levels or clearance of theophylline in 7 healthy subjects.⁷

Repirinast 300 mg daily had no effect on the pharmacokinetics of theophylline in 10 asthmatics given a single dose of aminophylline.⁸ Another study in 7 asthmatics found that **repirinast** (dosage unclear) for 3 weeks had no effect on the pharmacokinetics of theophylline 400 to 800 mg, given in two divided doses.⁹

In 10 healthy subjects the pharmacokinetics of a single 250-mg dose of theophylline were unchanged by **terfenadine** 120 mg twice daily for 16 days.¹⁰ Similarly, **terfenadine** 60 mg twice daily did not affect the steady-state pharmacokinetics of theophylline 4 mg/kg daily.¹¹ Another study in 17 healthy, male subjects found no change in the pharmacokinetics of a single 4-mg/kg oral dose of theophylline (rounded to nearest 50 mg) when taken with a single 60-mg dose of **terfenadine**.¹²

No special precautions seem to be necessary if any of these drugs is given with theophylline.

Theophylline + Azoles

Theophylline levels are normally unaffected or only minimally affected by fluconazole and ketoconazole. An isolated report describes a rise in serum theophylline levels due to fluconazole, and another describes falls in theophylline levels in three patients taking ketoconazole.

Clinical evidence

(a) Fluconazole

A crossover study in 5 healthy subjects found that fluconazole 100 mg given every 12 hours for 7 doses caused only a non-significant 16% decrease in the clearance of a single 300-mg oral dose of aminophylline.¹ Another study in 10 healthy subjects found that fluconazole 100 mg daily for one week had no significant effect on the serum levels of theophylline 150 mg twice daily.² The clearance of a single 6-mg/kg oral dose of theophylline was reduced by 13.4% in 9 subjects who took fluconazole 400 mg daily for 10 days.³ In contrast, an isolated and brief report says that one of 2 patients given theophylline and fluconazole had a rise (amount not specified) in serum theophylline levels.⁴

(b) Ketoconazole

No significant changes in the pharmacokinetics of a single 3-mg/kg intravenous dose of theophylline (given as aminophylline) were seen in 12 healthy subjects who took a single 400-mg dose of ketoconazole, or in 4 subjects who took ketoconazole 400 mg daily for 5 days.⁵ Similar results were found in another study in 10 healthy subjects who took ketoconazole 200 mg daily for 7 days.⁶ Ketoconazole 400 mg daily for 6 days increased the half-life of a single 250-mg oral dose of theophylline by 21.7% in 6 healthy subjects, but had no effect on its clearance.⁷ In contrast, a case report describes a man whose serum theophylline levels fell sharply from about 16.5 to 9 mg/L (reference range 10 to 20 mg/L) over the 2 hours immediately after taking 200 mg of ketoconazole. A less striking fall was seen in 2 other patients.⁸

Mechanism

These antifungals appear to have minimal effects on the cytochrome P450 isoenzyme CYP1A2, which is concerned with the oxidative metabolism of theophylline.^{1,7} It is not clear why a few individuals show some changes in theophylline levels.

Importance and management

Information seems to be limited to these reports. Neither fluconazole nor ketoconazole normally appears to interact to a relevant extent in most patients. However, it seems that very occasionally some changes occur so bear this interaction in mind in the case of unexpected changes in theophylline levels, adverse effects or uncontrolled symptoms. Other azole antifungals such as itraconazole, posaconazole and voriconazole, which are substrates for and inhibitors of CYP2C19, CYP2C9, and/or CYP3A4, are also unlikely to interact with theophylline.

Theophylline + Barbiturates

Theophylline serum levels can be reduced by phenobarbital or pentobarbital. A single report describes a similar interaction with

secobarbital and it would be expected to occur with other barbiturates.

Clinical evidence

(a) Pentobarbital

A single case report describes a man receiving intravenous aminophylline who had a 95% rise in the clearance of theophylline after he was given high-dose intravenous pentobarbital.¹ In healthy subjects pentobarbital 100 mg daily for 10 days increased the clearance of oral theophylline by a mean of 40% and reduced the AUC by 26%, although there were marked intersubject differences.²

(b) Phenobarbital

After taking phenobarbital (2 mg/kg daily to a maximum of 60 mg) for 19 days the mean steady-state serum theophylline levels in 7 asthmatic children aged 6 to 12 years were reduced by 30%, and the clearance was increased by 35% (range 12 to 71%).³ In contrast, two earlier studies (one by the same group of authors) found no significant change in the pharmacokinetics of theophylline, in asthmatic children given phenobarbital 2 mg/kg daily, or 16 or 32 mg three times daily.^{4,5}

The mean theophylline clearance, from a single intravenous dose of aminophylline, was increased by 34% in healthy adult subjects given phenobarbital.⁶ In another study the clearance of theophylline was increased by 17% when phenobarbital was given for 2 weeks, although this was not significant.⁷ The effects of phenobarbital can be additive with the effects of phenytoin and smoking; one patient required 4 g of theophylline daily to maintain therapeutic serum levels and to control her asthma.⁸

One retrospective study found that premature infants needed a higher dose of intravenous aminophylline for neonatal apnoea when they were given phenobarbital,⁹ but a later prospective study failed to confirm this.¹⁰ A study in one set of newborn twins given intravenous aminophylline found that the serum theophylline levels of the twin given phenobarbital were about half those of the twin not given phenobarbital.¹¹

(c) Secobarbital

The clearance of theophylline increased by 337% over a 4-week period in a child treated with periodic doses of secobarbital and regular doses of phenobarbital.¹²

Mechanism

The barbiturates are potent liver enzyme inducers, which possibly increase the metabolism of theophylline by the liver, thereby hastening its removal from the body. This has been shown in *animal* studies, although *N*-demethylation (the main metabolic route for theophylline) was not affected.¹³

Importance and management

A moderately well documented, established and clinically important interaction. Patients given phenobarbital or pentobarbital may need above-average doses of theophylline to achieve and maintain adequate serum levels. Concurrent use should be monitored and appropriate theophylline dosage increases made. All of the barbiturates can cause enzyme induction and may, to a greater or lesser extent, be expected to behave similarly. This is illustrated by the single report involving secobarbital. However, direct information about other barbiturates seems to be lacking. Note that theophylline itself can cause seizures, although mostly in overdose, and should be used with caution in patients with epilepsy.

Theophylline + BCG vaccine

BCG vaccine can increase the half-life of theophylline, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

Two weeks after 12 healthy subjects were vaccinated with 0.1 mL of BCG vaccine, the clearance of a single 128-mg dose of theophylline (as choline theophyllinate) was reduced by 21% and the theophylline half-life was prolonged by 14% (range: 10% reduction to 47% increase).¹ It therefore seems possible that the occasional patient may develop some signs of theophylline toxicity if their serum levels are already towards the top end of the therapeutic range but theophylline levels are unlikely to be affected in most patients given BCG vaccine.

1. Gray JD, Renton KW, Hung OR. Depression of theophylline elimination following BCG vaccination. *Br J Clin Pharmacol* (1983) 16, 735–7.

Theophylline + Beta-agonist bronchodilators

The concurrent use of xanthines such as theophylline and beta-agonist bronchodilators is a useful option in the management of asthma and chronic obstructive pulmonary disease, but potentiation of some adverse reactions can occur, the most serious being hypokalaemia and tachycardia, particularly with high-dose theophylline. Some patients may have a significant fall in serum theophylline levels if given oral or intravenous salbutamol (albuterol) or intravenous isoprenaline (isoproterenol).

Clinical evidence

(a) Fenoterol

A study in 12 patients with chronic airways disease found that oral fenoterol 2.5 mg three times daily did not affect the steady-state level of sustained-release theophylline 10.1 mg/kg twice daily.¹

Another study in 8 healthy subjects found that the addition of sustained-release theophylline to inhaled fenoterol 600 and 800 micrograms increased the heart rate and systolic blood pressure. Theophylline levels were not affected.²

(b) Formoterol

In a single-dose study, 8 healthy subjects were given oral doses of theophylline 375 mg and formoterol 144 micrograms. Combined use caused no significant pharmacokinetic interaction, but a significantly greater drop in the potassium level was seen, when compared with either drug given alone.³

(c) Isoprenaline (Isoproterenol)

An infusion of isoprenaline increased the clearance of theophylline (given as intravenous aminophylline) by a mean of 19% in 6 children with status asthmaticus and respiratory failure. Two of them had increases in clearance of greater than 30%.⁴ Another study in 12 patients with status asthmaticus found that an isoprenaline infusion (mean maximum rate 0.77 micrograms/kg per minute) caused a mean fall in serum theophylline levels of almost 6 micrograms/mL.⁵ The levels rose again when isoprenaline was stopped.⁵ A critically ill patient receiving intravenous aminophylline, phenytoin and nebulised terbutaline had a marked 4.5-fold increase in theophylline clearance when an isoprenaline infusion and intravenous methylprednisolone were added to the regimen.⁶

(d) Orciprenaline (Metaproterenol)

In 6 healthy subjects orciprenaline 20 mg given every 8 hours by mouth or 1.95 mg given every 6 hours by inhalation for 3 days had no effect on the pharmacokinetics of theophylline (given as a single intravenous dose of aminophylline).⁷ This confirms a previous finding in asthmatic children,

in whom it was shown that oral orciprenaline did not alter steady-state serum theophylline levels.⁸

(e) Salbutamol (Albuterol)

1. *Effects on heart rate or potassium levels.* Pretreatment with oral theophylline for 9 days significantly increased the hypokalaemia and tachycardia caused by an infusion of salbutamol (4 micrograms/kg loading dose then 8 micrograms/kg for an hour) in healthy subjects.⁹ A potentially dangerous additive increase in heart rate of about 35 to 40% was seen in one study in 9 patients with COPD given infusions of aminophylline and salbutamol.¹⁰ Similarly, heart rate was significantly higher in 15 asthmatic children given single doses of oral theophylline and salbutamol (109 bpm) when compared with a control group given oral theophylline alone (91 bpm).¹¹ However, another study in 18 patients with COPD and heart disease found that neither the occurrence nor the severity of arrhythmias seemed to be changed when oral theophylline was given with inhaled salbutamol.¹² A 10-year-old girl given theophylline and salbutamol had a respiratory arrest, possibly related to hypokalaemia.¹³

2. *Effects on theophylline levels.* Theophylline clearance was increased by a mean of 14%, and in 3 cases by greater than 30%, when salbutamol was given orally to 10 healthy subjects, but no changes in clearance were seen when salbutamol was given by inhalation.¹⁴ Another study reported a 25% reduction in serum theophylline levels in 10 patients who took oral salbutamol 16 mg.¹⁵ A child of 19 months given intravenous theophylline was also given an infusion of salbutamol: theophylline clearance was increased and the theophylline dose needed to be increased threefold to compensate.¹⁶ Peak flow readings were decreased in 15 children (aged 5 to 13 years) given single doses of oral salbutamol and theophylline, but theophylline levels were not significantly decreased.¹¹ These reports contrast with another study in 8 healthy subjects, which found no change in the steady-state pharmacokinetics of oral theophylline given with oral salbutamol.¹⁷

(f) Terbutaline

In 7 healthy subjects pretreatment with oral theophylline for at least 4 days significantly increased the fall in serum potassium levels and rises in blood glucose, pulse rate, and systolic blood pressure caused by an infusion of terbutaline.¹⁸ A study in children given slow-release formulations of both theophylline and terbutaline found no increases in reported adverse effects and simple additive effects on the control of their asthma.¹⁹

Oral terbutaline decreased serum theophylline levels by about 10% in 6 asthmatics, but the control of asthma was improved.²⁰ Another study in asthmatic children, found that terbutaline elixir 75 micrograms/kg three times daily reduced steady-state serum levels of theophylline by 22%, but the symptoms of cough and wheeze improved.²¹ Yet another study found no changes in the pharmacokinetics of aminophylline in asthmatic children given terbutaline.²²

(g) Unspecified beta₂ agonists

In 1990, the CSM in the UK noted that, of 26 reports they had on record of hypokalaemia with unnamed xanthines or beta₂ agonists, 9 occurred in patients receiving both groups of drugs. In 5 of these 9 cases, the hypokalaemia had no clinical consequence. However, in 2 cases it resulted in cardiorespiratory arrest, in another case confusion, and in a further case intestinal pseudo-obstruction.²³

Mechanism

Beta₂ agonists can cause hypokalaemia, particularly when they are given parenterally or by nebulisation. Xanthines such as theophylline can also cause hypokalaemia, and this is a common feature of theophylline toxicity. The potassium-lowering effects of both these groups of drugs are additive. Why some beta agonists lower serum theophylline levels is not known.

Importance and management

Concurrent use is beneficial, but the reports outlined above illustrate some of the disadvantages and adverse effects that have been identified. In particular, it has been suggested that the use of intravenous beta agonists in acutely ill patients receiving theophylline may be hazardous because of the risk of profound hypokalaemia and cardiac arrhythmias.^{9,18} Monitoring of serum potassium in these situations was suggested.¹⁸ Moreover, the CSM in the UK particularly recommends monitoring potassium levels in those with severe asthma as the hypokalaemic effects of beta₂ agonists can

be potentiated by theophylline and its derivatives, corticosteroids, diuretics and hypoxia.²³

Theophylline + Beta blockers

Propranolol reduces the clearance of theophylline. More importantly, non-cardioselective beta blockers such as nadolol and propranolol, should not be given to asthmatic patients because they can cause bronchospasm. The concurrent use of theophylline and cardioselective beta blockers such as atenolol, bisoprolol or metoprolol is not contraindicated, but some caution is still appropriate. Atenolol and bisoprolol do not affect the pharmacokinetics of theophylline.

Clinical evidence

(a) Pharmacokinetics

A study in 8 healthy subjects (5 of whom smoked 10 to 30 cigarettes daily) found that the clearance of a single 5.7 to 6.4 mg/kg dose of theophylline (as intravenous aminophylline) was reduced by 37% by **propranolol** 40 mg every 6 hours, when compared with theophylline alone. **Metoprolol** 50 mg every 6 hours did not alter the clearance in the group as a whole, but the smokers had an 11% reduction in clearance.¹ Another study, in 7 healthy subjects, found that the steady-state plasma clearance of theophylline was reduced by 30% by **propranolol** 40 mg every 8 hours, and by 52% by **propranolol** 240 mg every 8 hours.² However, a further study found no significant pharmacokinetic interaction between theophylline and **propranolol**.³ Three other studies found that the cardioselective beta blockers **atenolol** 50 to 150 mg,^{4,5} and **bisoprolol** 10 mg,⁶ and the non-se-

lective beta blocker **nadolol** 80 mg⁴ did not affect the pharmacokinetics of theophylline.

(b) Pharmacodynamics

Beta blockers, particularly those that are not cardioselective, can cause bronchoconstriction, which opposes the bronchodilatory effects of theophylline. See 'betaxolol with theophylline and pranlukast', (p.1160), for mention of a patient who had a deterioration of asthma with this combination.

In a study in 8 healthy subjects both **propranolol** 40 mg every 6 hours and **metoprolol** 50 mg every 6 hours prevented the mild inotropic effect seen with theophylline alone.⁷

An infusion of **propranolol** reduced the hypokalaemia and tachycardia that occurred after a theophylline overdose.^{8,9} **Esmolol** has been used similarly.¹⁰

Mechanism

Propranolol possibly affects the clearance of theophylline by inhibiting its metabolism (demethylation and hydroxylation).^{2,11}

Importance and management

The risk of severe, possibly even fatal bronchospasm when beta blockers are taken by asthmatics would seem to be far more important than any pharmacokinetic interaction with theophylline. See the warning in 'Anti-asthma drugs + Beta blockers', p.1160. Therefore the non-cardioselective beta blockers, such as propranolol, are contraindicated in patients with asthma or chronic obstructive pulmonary disease (COPD). Bronchospasm can occur with beta blockers given by any route of administration, even topically as eye drops. Cardioselective beta blockers have less effect on the airways, but can still cause bronchoconstriction. See 'Table 22.1', (p.833), for details of the selectivity of beta blockers.

Theophylline + Caffeine

Consumption of caffeine-containing beverages can raise serum theophylline levels, but the clinical relevance of this is unclear.

Clinical evidence, mechanism, importance and management

Caffeine can decrease the clearance of theophylline by 18 to 29%, prolong its half-life by up to 44% and increase its average serum levels by as much as 23%.^{1–3} In addition, caffeine plasma levels were increased about twofold when theophylline was given.² In these studies, caffeine was given in the form of tablets^{1,2} or as 2 to 7 cups of instant coffee.³ In one study, 2 of the subjects who did not normally drink coffee experienced headaches and nausea.² The probable mechanism of the interaction is that the two drugs compete for the same metabolic pathway resulting in a reduction in their metabolism and accumulation. In addition, when caffeine levels are high, a small percentage of it is converted to theophylline. There would, however, seem to be no good reason for patients taking theophylline to avoid caffeine (in **coffee, tea, cola drinks**, medications, etc.), but if otherwise unexplained adverse effects occur it might be worth checking if caf-

feine is responsible. In addition, caffeine intake could have an impact on the interaction of theophylline with other drugs.

Theophylline + Calcium-channel blockers

Giving calcium-channel blockers to patients taking theophylline normally has no adverse effect on the control of asthma, despite the small or modest alteration that may occur in serum theophylline levels with diltiazem, felodipine, nifedipine and verapamil. However, there are isolated case reports of unexplained theophylline toxicity in two patients given nifedipine and two patients given verapamil. Isradipine appears not to interact.

Clinical evidence

(a) Diltiazem

In 9 healthy subjects diltiazem 90 mg twice daily for 10 days reduced the clearance of theophylline (given as a single 6-mg/kg dose of aminophylline) by 21%, and increased its half-life from 6.1 to 7.5 hours.¹ A 12% fall in the clearance of a single 5-mg/kg oral dose of theophylline was found when healthy subjects were given diltiazem 90 mg three times daily.² In 8 patients with asthma or chronic obstructive pulmonary disease (COPD), diltiazem 60 mg three times daily for 5 days reduced the clearance of steady-state theophylline (given as a continuous infusion of aminophylline 12 mg/kg/day) by 22% and increased its half-life from 5.7 to 7.5 hours.³

Conversely, other studies found no significant changes in peak steady-state theophylline levels in 18 patients with asthma given diltiazem 240 to 480 mg daily for 7 days,⁴ or in 7 healthy subjects given diltiazem 120 mg twice daily for 7 days.⁵ Similarly, there was no significant change in the half-life or clearance of theophylline (given as a single 250-mg intravenous dose of aminophylline) in healthy subjects given diltiazem 120 mg three times daily for 6 days.⁶

(b) Felodipine

In 10 healthy subjects felodipine 5 mg every 8 hours for 4 days reduced the plasma AUC of theophylline (given as theophylline aminopropanol; *Oxyphylline*) by 18.3%, but had no effect on metabolic or renal clearance.⁷

(c) Isradipine

A three-way, crossover study in 11 healthy subjects found that isradipine 2.5 or 5 mg every 12 hours for 6 days had no significant effect on the pharmacokinetics of a single 5-mg/kg dose of aminophylline oral solution.⁸

(d) Nifedipine

In one study, slow-release nifedipine 20 mg twice daily reduced the mean steady-state theophylline levels of 8 asthmatics by 30%, from 9.7 to 6.8 mg/L. Levels fell by 50%, 56%, and 64% in three of the patients, but no changes in the control of the asthma (as measured by peak flow determinations and symptom scores) were seen.⁹ However, many other studies have found no changes, or only small to modest changes, in the pharmacokinetics of theophylline (given as oral theophylline or as intravenous lysine theophylline¹⁰ or aminophylline¹¹) in healthy subjects^{5,10-12} or asthmatic patients^{4,13,14} given nifedipine. The control of the asthma was unchanged by nifedipine.^{13,14} Yet another study found that the combined use of slow-release theophylline and nifedipine improved pulmonary function and blood pressure control.¹⁵

In contrast, there are 2 case reports of patients who developed theophylline toxicity (theophylline levels raised to 30 mg/L and 41 mg/L), apparently due to the addition of nifedipine.^{16,17} In one case, the toxicity recurred on rechallenge, and resolved when the theophylline dosage was reduced by 60%.¹⁷ During a Swan Ganz catheter study of patient response to nifedipine for pulmonary hypertension, 2 patients developed serious nifedipine adverse effects, which responded to intravenous aminophylline.¹⁸

(e) Verapamil

In one study, verapamil 80 mg every 6 hours for 2 days had no effect on the pharmacokinetics of theophylline (200 mg aminophylline every

6 hours) given to 5 asthmatics, and no effect on their spirometry (FVC, FEV₁, FEF₂₅₋₇₅).¹⁹ Similarly, another study found that verapamil 80 mg every 8 hours had no effect on the steady-state levels of sustained-release theophylline 3 mg/kg per day in healthy subjects.²⁰ In contrast, numerous other studies in healthy subjects (given intravenous or oral aminophylline or theophylline) have found modest reductions in theophylline clearance of between 8 and 23% with verapamil 40 to 120 mg taken every 6 to 8 hours.^{2,6,12,21-23} One study showed that the extent of reduction in clearance depended on the verapamil dosage.²³ An isolated report describes a woman taking digoxin and sustained-release theophylline who developed signs of toxicity (tachycardia, nausea, vomiting) after starting to take verapamil 80 mg, increased to 120 mg every 8 hours. Her theophylline serum levels doubled over a 6-day period. Theophylline was later successfully reintroduced at one-third of the original dosage.²⁴ Another isolated report describes a patient who needed a 50% reduction in their theophylline dose while taking verapamil 120 mg daily.²⁵

Mechanism

It is believed that diltiazem and verapamil can, to a limited extent, decrease the metabolism of theophylline by the liver, possibly by inhibiting the cytochrome P450 isoenzyme CYP1A2.²⁶ Similarly, nifedipine may alter hepatic theophylline metabolism,¹² or it may increase the volume of distribution of theophylline.^{10,11} Felodipine possibly reduces theophylline absorption.⁷

Importance and management

The evidence for this interaction is adequately documented but the results are not entirely consistent. However, the overall picture is that the concurrent use of theophylline and these calcium-channel blockers is normally safe. Despite the small or modest decreases in the clearance or absorption of theophylline seen with diltiazem, felodipine and verapamil, and the quite large reductions in serum levels seen in one study with nifedipine, no adverse changes in the control of the asthma were seen in any of the studies. However, very occasionally and unpredictably theophylline levels have risen enough to cause toxicity in patients given nifedipine (2 case reports) or verapamil (2 case reports), so that it would be prudent to be aware of the possibility of an interaction when these drugs are given.

Theophylline + Cannabis

Cannabis smokers may need more theophylline than non-smokers to achieve the same therapeutic benefits, because the theophylline is cleared from the body more quickly.

Clinical evidence, mechanism, importance and management

One study found that tobacco or cannabis smoking similarly caused higher total clearances of theophylline (given as oral aminophylline) than in non-smokers (about 74 mL/kg per hour compared with 52 mL/kg per hour), and that clearance was even higher (93 mL/kg per hour) in those who smoked both.¹ A later analysis by the same authors, of factors affecting theophylline clearance, found that smoking 2 or more joints of cannabis weekly was associated with a higher total clearance of theophylline than non-use (82.9 mL/kg per hour versus 56.1 mL/kg per hour).²

Tobacco and cannabis smoke contain polycyclic hydrocarbons, which act as inducers of the cytochrome P450 isoenzyme CYP1A2, and this results in a more rapid clearance of theophylline from the body.

Little is known about the effects of smoking cannabis on theophylline levels, but be alert for the need to increase the theophylline dosage in regular users.

Theophylline + Carbamazepine

Two case reports describe a marked fall in serum theophylline levels when carbamazepine was given. Another single case report and a pharmacokinetic study describe a fall in serum carbamazepine levels when theophylline was given.

Clinical evidence

(a) Theophylline serum levels reduced

An 11-year-old girl with asthma was stable for 2 months taking theophylline, and phenobarbital until the phenobarbital was replaced by carbamazepine. The asthma worsened, her theophylline serum levels became subtherapeutic and the half-life of the theophylline was reduced from 5.25 to 2.75 hours. Asthmatic control was restored, and the half-life returned to pre-treatment levels 3 weeks after the carbamazepine was replaced by ethotoin.¹ The clearance of theophylline in an adult patient was doubled by carbamazepine 600 mg daily.²

(b) Carbamazepine serum levels reduced

The trough carbamazepine levels of a 10-year-old girl were roughly halved when she was given theophylline for 2 days, and she experienced a grand mal seizure. Her serum theophylline levels were also unusually high at 26 mg/L for the 5 mg/kg dosage she was taking, so it may be that the convulsions were as much due to this as to the fall in carbamazepine levels.³

A single-dose pharmacokinetic study in healthy subjects found that the AUC and maximum serum levels of carbamazepine were reduced by 31% and 45%, respectively, by oral aminophylline.⁴

Mechanism

Not established, but it seems probable that each drug increases the liver metabolism and clearance of the other drug, resulting in a reduction in their effects.^{1,3} It is also possible that aminophylline interferes with the absorption of carbamazepine.⁴

Importance and management

Information seems to be limited to the reports cited so that the general importance is uncertain. Concurrent use need not be avoided, but it would be prudent to check that the serum concentrations of each drug (and their effects) do not become subtherapeutic. Note that theophylline should be used with caution in patients with epilepsy as it can cause seizures, although this is usually a sign of toxicity.

Theophylline + Cephalosporins

Ceftibuten and cefalexin appear not to interact with theophylline. Cefaclor has been implicated in two cases of theophylline toxicity in children, but studies in adult subjects found no pharmacokinetic interaction.

Clinical evidence, mechanism, importance and management

Ceftibuten 200 mg twice daily for 7 days was found to have no significant effect on the pharmacokinetics of a single intravenous dose of theophylline given to 12 healthy subjects.¹ A study in 9 healthy adults given a single 5-mg/kg intravenous dose of aminophylline found that **cefalexin** 500 mg, then 250 mg every 6 hours for 48 hours, had no significant effect on the pharmacokinetics of theophylline.²

A case report³ suggested that **cefaclor** might have been responsible for the development of theophylline toxicity in 2 children. However, a single-dose study⁴ and a steady-state study⁵ in healthy adults found that **cefaclor** 250 mg three times daily for 8 and 9 days, respectively, had no effect on the pharmacokinetics of oral or intravenous theophylline. Although the pharmacokinetics of theophylline differ in adults and children a significant interaction with **cefaclor** seems unlikely.

No special precautions seem to be necessary with any of these antibiotics. Note that acute infections *per se* can alter theophylline pharmacokinetics.

Theophylline + Clopidogrel or Ticlopidine

Ticlopidine reduces the clearance of theophylline and is expected to raise its serum levels. Clopidogrel, an analogue of ticlopidine, appears not to interact.

Clinical evidence, mechanism, importance and management

(a) Clopidogrel

Clopidogrel 75 mg daily for 10 days did not alter the steady-state pharmacokinetics of theophylline given to 12 healthy subjects.¹ No problems are therefore anticipated with the concurrent use of these two drugs.

(b) Ticlopidine

In 10 healthy subjects ticlopidine 250 mg twice daily for 10 days reduced the clearance of a single 5-mg/kg oral dose of theophylline by 37% and increased the half-life by 44%, from about 8.5 hours to 12 hours.² The reason for these effects is not known but it seems possible that ticlopidine inhibits the metabolism of theophylline by the liver. Information is limited, but it would seem prudent to monitor the effects of concurrent use: it may

be necessary to reduce the dosage of theophylline, particularly when serum levels are already at the top end of the range.

1. Caplain H, Thebault J-J, Necciari J. Clopidogrel does not affect the pharmacokinetics of theophylline. *Semin Thromb Hemost* (1999) 24, 65–8.
2. Colli A, Buccino G, Cocciolo M, Parravicini R, Elli GM, Scaltrini G. Ticlopidine-theophylline interaction. *Clin Pharmacol Ther* (1987) 41, 358–62.

Theophylline + Codeine

A study in 6 healthy subjects found that codeine 30 mg prolonged the oral to caecal transit time of a single 500-mg dose of sustained-release theophylline (*Theo-Dur*). The mean amount left to be absorbed from the colon was reduced from 58% to 33%, but the time to 90% absorption of theophylline was not significantly affected (7.1 hours compared with 8.5 hours). Therefore codeine does not appear to significantly affect the rate or extent of absorption of theophylline, and concurrent use need not be avoided.¹

1. Sommers DK, Meyer EC, Van Wyk M, Moncrieff J, Snyman JR, Grimbeek RJ. The influence of codeine, propantheline and metoclopramide on small bowel transit and theophylline absorption from a sustained-release formulation. *Br J Clin Pharmacol* (1992) 33, 305–8.

Theophylline + Corticosteroids

Theophylline and corticosteroids have established roles in the management of asthma and their concurrent use is not uncommon. There are isolated reports of increases in serum theophylline levels (sometimes associated with toxicity) when oral or parenteral corticosteroids are given, but other reports show no changes. The general clinical importance of these findings is uncertain. Both theophylline and corticosteroids can cause hypokalaemia, which may be additive.

Clinical evidence

(a) *Betamethasone*

The elimination half-life of theophylline (given as intravenous aminophylline) was no different in premature infants who had been exposed to betamethasone *in utero* than in those who had not, although the exposed neonates had a wider range of theophylline metabolites indicating greater hepatic metabolism.^{1,2}

(b) *Dexamethasone*

In one study it was briefly mentioned that theophylline did not appear to affect dexamethasone metabolism.³

(c) *Hydrocortisone*

Three patients in status asthmaticus with relatively stable serum concentrations of theophylline were given a 500-mg intravenous bolus of hydrocortisone followed 6 hours later by 200 mg of hydrocortisone given every 2 hours for 3 doses. In each case the serum theophylline levels rose from about 20 mg/L to between 30 and 50 mg/L. At least 2 of the patients complained of nausea and headache.⁴ In contrast, 7 healthy subjects given sustained-release theophylline had no significant change in steady-state theophylline clearance when they were given a single 33-mg/kg dose of intravenous hydrocortisone, although there was a trend towards increased clearance.⁵ Intravenous bolus doses of hydrocortisone 500 mg or 1 g did not affect theophylline levels in patients taking choline theophyllinate 400 mg every 12 hours for 8 days.⁶

(d) *Methylprednisolone*

An 88% increase in the clearance of a single dose of intravenous aminophylline was seen in one of 3 healthy subjects pretreated with oral methylprednisolone.⁷ There was no significant change in clearance in the other 2 subjects. Another study in 10 children (aged 2 to 6) with status asthmaticus found that intramuscular methylprednisolone tended to increase the half-life of theophylline (given as oral aminophylline or theophylline).⁸ A further study also reported that when intravenous aminophylline was given to 16 children taking corticosteroids (route and type not specified) the theophylline half-life was prolonged from 5 to 6.2 hours, and the clearance was reduced by about one-third, when compared with 10 children not taking corticosteroids.⁹ Similarly, 7 healthy subjects given sustained-release theophylline had no significant change in steady-state theophylline clear-

ance when they were given a single 1.6-mg/kg dose of intravenous methylprednisolone, although there was a trend towards increased clearance.⁵

(e) *Prednisone or Prednisolone*

A study in 6 healthy subjects showed that a single 20-mg oral dose of prednisone had no significant effect on the pharmacokinetics of a single 200-mg oral dose of aminophylline.¹⁰ The pharmacokinetics of a single 5.6-mg/kg intravenous dose of aminophylline was unchanged in 9 patients with chronic airflow obstruction when they were given prednisolone 20 mg daily for 3 weeks.¹¹

Mechanism

Not understood.

Importance and management

The concurrent use of theophylline and corticosteroids is common and therapeutically valuable, whereas the few reported interactions of theophylline with oral or parenteral corticosteroids are poorly documented and their clinical importance is difficult to assess because both increases, small decreases and no changes in the serum levels of theophylline have been seen. It is also questionable whether the results of studies in healthy subjects can validly be extrapolated to patients with status asthmaticus. There do not appear to be any data on the effect of *inhaled* corticosteroids on the clearance of theophylline. Both theophylline and corticosteroids can cause hypokalaemia, and the possibility that this may be potentiated by concurrent use should be considered.

Theophylline + Co-trimoxazole

Co-trimoxazole (trimethoprim/sulfamethoxazole) does not alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects co-trimoxazole 960 mg twice daily for 8 days had no effect on the pharmacokinetics of theophylline, given as a single 341-mg intravenous dose of aminophylline.¹ Another study, in 8 healthy subjects, found that co-trimoxazole 960 mg twice daily for 5 days had no effect on the pharmacokinetics of a single 267-mg oral dose of theophylline.² No special precautions would seem necessary if these drugs are given concurrently. However, note that acute infections *per se* can alter theophylline pharmacokinetics.

2. Lo KF, Nation RL, Sansom LN. Lack of effect of co-trimoxazole on the pharmacokinetics of orally administered theophylline. *Biopharm Drug Dispos* (1989) 10, 573–80.

Theophylline + Dextropropoxyphene (Propoxyphene)

Dextropropoxyphene does not significantly alter steady-state theophylline levels.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects pre-treatment with dextropropoxyphene 65 mg every 8 hours for 5 days did not significantly change the total plasma clearance of steady-state theophylline 125 mg every 8 hours.¹ There was a small reduction in the formation of the hydroxylated metabolite of theophylline. There would seem to be no need to avoid concurrent use or to take particular precautions.

Theophylline + Disulfiram

Theophylline clearance is decreased by disulfiram.

Clinical evidence

After taking disulfiram 250 mg daily for one week, the clearance of a 5-mg/kg intravenous dose of theophylline was decreased by a mean of about 21% (range 14.6 to 29.6%) in 20 recovering alcoholics. Those taking disulfiram 500 mg daily had a mean decrease of 32.5% (range 21.6 to 49.6%).¹ Smoking appeared to have no important effects on the extent of this interaction. None of the patients were reported to have any significant liver disease, such as cirrhosis, which may also affect theophylline metabolism.

Mechanism

Disulfiram inhibits the liver enzymes concerned with the both the hydroxylation and demethylation of theophylline, thereby reducing its clearance from the body.

Importance and management

Information appears to be limited to this study but it would seem to be a clinically important interaction. Monitor the serum levels of theophylline and its effects if disulfiram is added, anticipating the need to reduce the theophylline dosage. Note that the extent of this interaction appears to depend upon the dosage of disulfiram used.

Theophylline + Dobutamine

A man taking theophylline developed marked tachycardia when he was given dobutamine.

Clinical evidence, mechanism, importance and management

An asthmatic patient taking sustained-release theophylline 150 mg twice daily, digoxin and spironolactone was anaesthetised for an aortic valve replacement with fentanyl, midazolam and pipecuronium. Following induction, intubation, and ventilation with 100% oxygen, his systolic blood pressure fell from 120 to 80 mmHg, and his heart rate slowed from 70 to 50 bpm. Dobutamine was given at a dose of 5 micrograms/kg per minute, and after 2 to 3 minutes his heart rate rose to 150 bpm and his systolic pressure rose to 190 mmHg. The authors of the report¹ attribute the tachycardia to an interaction between dobutamine and theophylline. They suggested that the interaction was possibly as a result of a synergistic increase in cyclic AMP levels in cardiac muscle and/or theophylline-induced potentiation of catecholamine action. They advise the careful titration of dobutamine in any asthmatic taking theophylline, particularly if a slow-release preparation is being used. However, more study of this apparent interaction is needed as this appears to be the only report, and so its general importance is unknown.

1. Baraka A, Darwish R, Rizkallah P. Excessive dobutamine-induced tachycardia in the asthmatic cardiac patient: possible potentiation by theophylline therapy. *J Cardiothorac Vasc Anesth* (1993) 7, 641–2.

Theophylline + Doxapram

Doxapram pharmacokinetics are unchanged by theophylline in premature infants, but agitation and increased muscle activity may occur in adults.

Clinical evidence, mechanism, importance and management

Intravenous theophylline does not affect the pharmacokinetics of doxapram given to treat apnoea in premature infants. No adjustment of the dosage of doxapram is needed in the presence of theophylline.¹ However, the manufacturers of doxapram say that there may be an interaction between doxapram and aminophylline or theophylline, which is manifested by agitation and increased skeletal muscle activity. Care should therefore be taken if these drugs are used together.²

2. Dopram (Doxapram hydrochloride). Baxter Healthcare Corporation. US Prescribing information, March 2004.

Theophylline + Enoximone

Aminophylline possibly reduces the beneficial cardiovascular effects of enoximone. Theoretically, milrinone would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

An experimental study into the mechanism of action of enoximone in 14 patients with ischaemic or idiopathic dilative cardiomyopathy found that pretreatment with intravenous aminophylline 7 mg/kg given over 15 minutes reduced the beneficial haemodynamic effects of intravenous enoximone 1 mg/kg given over 15 minutes.¹ This appears to occur because each drug competes for inhibition of cAMP specific phosphodiesterases in cardiac and vascular smooth muscle. **Milrinone**, another phosphodiesterase inhibitor similar to enoximone, would be expected to interact in the same way. However, there are, at present, no published reports of a possible interaction with milrinone, and no case reports of a problem occurring with the concurrent use of either drug with theophylline. The clinical importance of this study therefore awaits evaluation.

1. Morgagni GL, Bugiardini R, Borghi A, Pozzati A, Ottani F, Puddu P. Aminophylline counteracts the hemodynamic effects of enoximone. *Clin Pharmacol Ther* (1990) 47, 140.

Theophylline + Ephedrine

Some data suggest that an increased frequency of adverse effects occurs when ephedrine is used with theophylline.

Clinical evidence, mechanism, importance and management

A double-blind, randomised study in 23 children aged 4 to 14 found that when ephedrine was given with theophylline (in a ratio of 25 mg ephedrine to 130 mg theophylline), the number of adverse reactions increased significantly, when compared with each drug taken separately. Moreover, the combination was no more effective than theophylline alone. The combination was associated with insomnia (14 patients), nervousness (13) and gastrointestinal complaints (18), including vomiting (12). The serum theophylline levels were unchanged by ephedrine.¹ A previous study by the same authors in 12 asthmatic children given ephedrine and aminophylline found similar results.² In contrast, a later study suggested that ephedrine 25 mg every 8 hours given with aminophylline did produce improvements in spirometry and no adverse effects were seen. However, it was calculated that the theophylline dosage used was about half that used in the previous study.³

In the treatment of asthma, ephedrine has been largely superseded by more selective sympathomimetics, which have fewer adverse effects. Ephedrine is still an ingredient of a number of non-prescription cough and cold remedies, when it may be combined with theophylline (e.g. *Franol*).

Patients taking theophylline requiring ephedrine should be advised report any adverse effects.

Theophylline + Food

The effect of food on theophylline bioavailability is unclear. In general it appears that fat or fibre in food has no effect, whereas high-protein and high-carbohydrate diets decrease and increase the theophylline half-life, respectively. Significant changes in theophylline bioavailability have been seen in patients given both enteral feeds and total parenteral nutrition.

Clinical evidence

(a) Food

The bioavailability of theophylline from sustained-release preparations has been shown to be reduced,^{1,2} increased,^{1,3} or unaffected^{4–8} when the theophylline was given immediately after **breakfast**. Dose dumping, leading to signs of theophylline toxicity, was seen in 3 children with asthma who were given a dose of *Uniphyllin* immediately after **breakfast**.⁶ The **fat** content^{9,10} or **fibre** content¹¹ of meals does not seem to significantly affect theophylline absorption. **High-protein** meals appear to decrease theophylline half-life,^{12,13} whereas **high-carbohydrate** meals seem to increase it.¹³ There was no difference in theophylline metabolism in one study when patients were changed from a **high-carbohydrate/low-protein** diet to a **high-protein/low-carbohydrate** diet.¹⁴ One study found that changing from a **high-protein** to a **high-carbohydrate** meal had an effect on the metabolism of theophylline similar to that of cimetidine, and that the effects of the meal change and cimetidine were additive.¹⁵ The effects of **spicy food** have been studied, but the clinical significance of the changes are uncertain.¹⁶

(b) Enteral feeds

A patient with chronic obstructive pulmonary disease had a 53% reduction in his serum theophylline levels accompanied by bronchospasm when he was fed continuously through a nasogastric tube with *Osmolite*. The interaction occurred with both theophylline tablets (*Theo-Dur*) and liquid theophylline, but not when the theophylline was given intravenously as aminophylline. It was also found that the interaction could be avoided by interrupting feeding 1 hour either side of the oral liquid theophylline dose.¹⁷ Conversely, hourly administration of 100 mL of *Osmolite* did not affect the extent of theophylline absorption from a slow-release preparation (*Slo-bid Gyrocaps*) in healthy subjects, although the rate of absorption was slowed.¹⁸ Similarly, in healthy subjects, hourly administration of 100 mL of *Ensure* for 10 hours did not affect the rate or extent of absorption of theophylline from *Theo-24* tablets.¹⁹

(c) Parenteral nutrition

An isolated report describes an elderly woman treated with aminophylline by intravenous infusion who had a marked fall in her serum theophylline levels (from 16.3 to 6.3 mg/L) when the amino acid concentration of her parenteral nutrition regimen was increased from 4.25 to 7%.²⁰ A study in 7 patients with malnutrition (marasmus-kwashiorkor) found only a small, probably clinically irrelevant increase in the elimination of a single intravenous dose of theophylline when they were fed intravenously.²¹

Mechanism

Not fully understood. As with any sustained-release formulation, the presence of food in the gut may alter the rate or extent of drug absorption by altering gastrointestinal transit time. It has been suggested that high-protein diets stimulate liver enzymes thereby increasing the metabolism of the theophylline and hastening its clearance from the body. High carbohydrate diets have the opposite effect. The cytochrome P450 isoenzyme CYP1A2 (the principal enzyme involved in the metabolism of theophylline) is known to be induced by chemicals contained in cruciferous vegetables²² or formed by the action of high temperatures or smoke on meat.²³ This suggestion is supported by a study in which charcoal-grilled (broiled) beef decreased the half-life of theophylline by an average of 22%.²⁴ Further,

high doses of daidzein, the principal isoflavone in soybeans, may inhibit CYP1A2 resulting in an increase in theophylline levels and half-life of about 33% and 41%, respectively.²⁵

Importance and management

Interactions between theophylline and food have been thoroughly studied but there seems to be no consistent pattern in the way the absorption of different theophylline preparations is affected. Be alert for any evidence of an inadequate response that can be related to food intake. Avoid switching between different preparations, and monitor the effects if this is necessary. Consult the product literature for any specific information on food and encourage patients to take their theophylline consistently in relation to meals where this is considered necessary. Advise patients not make major changes in their diet without consultation. Monitor the effects of both enteral and parenteral nutrition, since theophylline dosage adjustments may be required.

Theophylline + Furosemide

Furosemide is reported to increase, decrease or to have no effect on serum theophylline levels. Both theophylline and diuretics can cause hypokalaemia, which may be additive.

Clinical evidence

In 8 asthmatics the mean peak serum level of a 300-mg dose of sustained-release theophylline was reduced by 41%, from 12.14 to 7.16 mg/L by a

single 25-mg oral dose of furosemide.¹ Conversely, 10 patients with asthma, chronic bronchitis or emphysema, receiving a continuous maintenance infusion of aminophylline, had a 21% rise in their serum theophylline levels, from 13.7 to 16.6 mg/L, 4 hours after being given a 40-mg intravenous dose of furosemide over 2 minutes.² A crossover study in 12 healthy subjects failed to find any change in steady-state plasma theophylline levels when two 20-mg doses of oral furosemide were given 4 hours apart, although the overall renal clearance of theophylline was reduced.³

Four premature neonates, two given oral and two given intravenous theophylline with furosemide had a fall in steady-state serum theophylline levels from 8 mg/L down to 2 to 3 mg/L when furosemide was given within 30 minutes of the theophylline.⁴

A randomised, placebo-controlled study in 24 infants receiving ECMO (extracorporeal membrane oxygenation) found that theophylline 2 mg/kg enhanced the response to diuresis with furosemide 1 mg/kg. If the response were maintained over a 24-hour period an extra 110 mL/kg of fluid would have been lost.⁵

Mechanism

Not understood, although in theory furosemide may cause increased renal excretion of theophylline, which could explain the reduced levels.

Importance and management

Information is limited and the outcome of concurrent use is inconsistent and uncertain. If both drugs are used be aware of the potential for changes in serum theophylline levels. Consider measuring levels, and make appropriate dosage adjustments as necessary. Both theophylline and diuretics can cause hypokalaemia, and the possibility that this may additive on concurrent use should be considered. More study is needed to assess the clinical significance of the effects of theophylline and furosemide on diuresis.

Theophylline + Grapefruit juice

Grapefruit juice does not significantly alter theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

In one study, 12 healthy subjects were given a single 200-mg oral dose of theophylline solution (*Euphyllin*) diluted in either 100 mL of grapefruit juice or water, followed by another 900 mL of juice or water over the next 16 hours. The pharmacokinetics of the theophylline were found to be unchanged by the grapefruit juice.¹

The authors of this study had previously shown that grapefruit juice had a small effect on the pharmacokinetics of 'caffeine', (p.1165), and that one of the constituents of grapefruit juice (naringenin) inhibited the cytochrome P450 isoenzyme CYP1A2 (the principal enzyme in theophylline metabolism) *in vitro*. However, most clinically relevant interactions between drugs and grapefruit juice are considered to occur because grapefruit juice inhibits intestinal CYP3A4.

There would seem to be no reason why patients taking theophylline should avoid grapefruit juice.

Theophylline + Griseofulvin

Griseofulvin does not appear to alter the pharmacokinetics of theophylline to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

A study was initiated because it was suspected that griseofulvin might possibly interact with theophylline. In 12 healthy subjects griseofulvin 500 mg daily for 8 days reduced the half-life of theophylline from 6.6 to 5.7 hours, and increased the clearance of two of its metabolites, after a single oral dose of aminophylline (*Teofylamin*). However, these changes are far too small to usually have any clinical relevance.¹ There would appear to be no reason for avoiding concurrent use.

Theophylline + H₂-receptor antagonists

Cimetidine raises theophylline serum levels and toxicity may develop. However, the extent of the interaction is unlikely to be clinically relevant in most patients with low-dose cimetidine. Famotidine, nizatidine, ranitidine and roxatidine appear not to interact.

Clinical evidence

(a) Cimetidine

A number of case reports describe significantly increased theophylline levels, including many that were toxic, in patients (adults and children) given oral or intravenous aminophylline or theophylline with cimetidine.¹⁻⁶ A few cases describe serious adverse effects such as seizures.^{3,4}

In a large number of pharmacokinetic studies healthy subjects were given oral or intravenous aminophylline or theophylline⁷⁻¹⁵ and patients were given oral or intravenous theophylline¹⁶⁻²⁰ with oral cimetidine 800 mg to 1.2 g daily in divided doses for 4 to 10 days. It was clearly shown that cimetidine prolonged the theophylline half-life by about 30 to 65% and reduced the theophylline clearance by about 20 to 40%. Steady-state serum theophylline levels were raised about one-third.^{16,17,20} The effect of cimetidine was maximal in 3 days in the one study assessing this.¹⁶ The extent of the interaction did not differ between cimetidine 1.2 g daily and 2.4 g daily in one study,¹⁰ although two further studies found that cimetidine 800 mg daily had less effect than cimetidine 1.2 g daily.^{12,21} A study investigating low-dose cimetidine (200 mg twice daily; UK non-prescription dosage) found only a 12% decrease in theophylline clearance.²²

Two studies found that the effect of cimetidine did not differ between young and elderly subjects,^{12,23} whereas another found it was more pronounced in the elderly.²¹ The effects of cimetidine did not differ between smokers and non-smokers in one study,²⁴ but were more pronounced in smokers in another.²⁵ In a further study the effects of cimetidine were not affected by gender.²¹ Three studies found that the inhibitory effects of cimetidine and 'ciprofloxacin', (p.1192), were additive.^{23,26,27}

Three studies found that intravenous cimetidine also inhibited the clearance of theophylline (given as intravenous aminophylline or sustained-release theophylline).²⁸⁻³⁰ In one of these, oral and intravenous cimetidine reduced theophylline clearance to the same extent, but when clearance was corrected for the lower bioavailability of the oral cimetidine, oral cimetidine resulted in a greater inhibition than intravenous cimetidine.²⁸ Another study found that the effects of a continuous 50-mg/hour infusion of cimetidine were similar to those of an intermittent infusion of 300 mg every 6 hours.²⁹

In contrast, a further study³¹ in healthy subjects found no clinically important interaction between intravenous aminophylline and an intravenous cimetidine infusion, but the aminophylline was given only 12 hours after starting the cimetidine, which may be insufficient for cimetidine to have had an effect. Similarly, a more recent study in 18 critically ill patients given a continuous 50-mg/hour intravenous infusion of cimetidine and low-dose aminophylline 10.8 mg/hour for just 48 hours found no clinically important interaction.³²

(b) Famotidine

Famotidine 40 mg twice daily for 5 days had no effect on the pharmacokinetics of theophylline (given as intravenous aminophylline) in 10 healthy subjects.¹⁴ In another study, 16 patients with bronchial asthma or chronic obstructive pulmonary disease (COPD) found that famotidine 20 mg twice daily for at least 3 days did not affect the clearance of theophylline.³³ Two further studies also found no interaction between intravenous theophylline and famotidine 20 or 40 mg twice daily for 4 or 9 days in COPD

patients.^{19,34} In a post-marketing surveillance study it was noted that 4 asthmatics taking theophylline had also taken famotidine 40 mg daily for 4 to 8 weeks without any problems.³⁵ In contrast, in a patient with COPD and liver impairment, the AUC and serum levels of an intravenous dose of theophylline were raised by 78% and the clearance was halved by famotidine 40 mg daily for 8 days.³⁶ A later study by the same authors in 7 patients with COPD similarly treated, but with normal liver function, found that the AUC of theophylline was increased by 56% and its clearance was reduced by 35% by famotidine.³⁷

(c) Nizatidine

A study in 17 patients with chronic obstructive pulmonary disease found that nizatidine 150 mg twice daily for a month had no effect on the steady-state pharmacokinetics of theophylline.²⁰ However, there were 6 reports of apparent interactions in the Spontaneous Adverse Drug Reaction Database of the FDA in the US up to the end of August 1989. Four patients taking theophylline developed elevated serum theophylline levels, with symptoms of toxicity in at least one case, when given nizatidine. The problems resolved when either both drugs, or just nizatidine were stopped.³⁸

(d) Ranitidine

Many studies in healthy subjects (given intravenous aminophylline or oral theophylline)^{10,11,15,39-41} and patients (given sustained-release theophylline)^{17,20,42-45} have failed to find that ranitidine affects the pharmacokinetics of theophylline, even in daily doses far in excess of those used clinically (up to 4.2 g of ranitidine daily).³⁹ However, there are 7 reports describing a total of 10 patients, who developed theophylline toxicity when given ranitidine with sustained-release theophylline⁴⁶⁻⁵¹ or intravenous aminophylline.⁵² The validity of a number of these reports has been questioned,⁵³⁻⁵⁶ with the authors subsequently modifying some.^{57,58}

(e) Roxatidine

Roxatidine 150 mg daily did not affect the clearance of theophylline.⁵⁹ Similarly, in 9 healthy subjects, roxatidine 150 mg twice daily did not significantly change the pharmacokinetics of a single 250-mg intravenous dose of aminophylline.⁶⁰

Mechanism

Cimetidine is an enzyme inhibitor that reduces the metabolism (predominantly *N*-demethylation)⁶¹ of theophylline by the cytochrome P450 isoenzyme CYP1A2 in the liver, thereby raising its serum levels. Famotidine, nizatidine and ranitidine do not have enzyme-inhibiting effects so that it is not clear why they sometimes appear to behave like cimetidine.

Importance and management

The interaction between theophylline and cimetidine is very well documented (not all the references being listed here), very well established and clinically important. Theophylline serum levels normally rise by about one-third, but much greater increases have been seen in individual patients. Monitor theophylline levels closely. Note that in one study the peak effect was reached in 3 days. Initial theophylline dose reductions of 30 to 50% have been suggested to avoid toxicity.⁴ Alternatively, use one of the other H₂-receptor antagonists, or consider changing to a proton pump inhibitor, see 'Theophylline + Proton pump inhibitors', p.1191. The effect of low-dose (e.g. UK non-prescription dose) cimetidine is unlikely to be clinically relevant unless theophylline levels are at the higher end of the therapeutic range. The situation with famotidine, nizatidine and ranitidine is not totally clear. They would not be expected to interact because they are not enzyme inhibitors like cimetidine, but very occasionally and unpredictably they appear to do so. Nevertheless, current opinion is that normally no special precautions are needed with these H₂-receptor antagonists,⁵⁴ or roxatidine.

Note that some of the symptoms of theophylline toxicity, such as nausea, vomiting and abdominal pain, are similar to those of gastrointestinal ulceration. It is important to check the theophylline level should patients present with these symptoms, to prevent a misdiagnosis.

Theophylline + Hormonal contraceptives

Theophylline clearance is reduced to some extent in women taking a combined oral contraceptive, but no toxicity has been reported.

Clinical evidence

The total plasma clearance of a single 4-mg/kg oral dose of aminophylline was about 30% lower in 8 women taking a combined oral contraceptive (**ethinylestradiol/norgestrel**, *Ovral*) than in 8 other women not taking oral contraceptives.¹ The theophylline half-life was also prolonged by about 30%, from 7.34 to 9.79 hours. Similar results were found in other studies in subjects given intravenous or oral aminophylline and combined oral contraceptives (**ethinylestradiol/norgestrel**, *Ovral* and **mestranol/etynodiol diacetate**, *Ovulen* or unnamed products).^{2,3} In contrast, no significant differences were seen in the pharmacokinetics of theophylline (given as intravenous aminophylline) in 10 adolescent women (15 to 18 years) taking low-dose combined or sequential oral contraceptives (**ethinylestradiol/norethisterone**), when compared with age matched controls.⁴ However, in the same women the clearance of oral theophylline was found to be reduced by 33% after they took a triphasic combined oral contraceptive for 3 to 4 months.⁵ In a retrospective analysis of factors affecting theophylline clearance, the use of oral contraceptives was associated with a reduced theophylline clearance in women who smoked.⁶

Mechanism

Uncertain, but it seems possible that the oestrogenic component may inhibit the metabolism of the theophylline by the liver microsomal enzymes, thereby reducing its clearance.

Importance and management

An established interaction, but there seem to be no reports of theophylline toxicity resulting from concurrent use. Women taking combined oral contraceptives may need less theophylline than those not taking oral contraceptives. There is a small risk that patients with serum theophylline levels at the top end of the range may show some toxicity when oral contraceptives are added. It has been proposed that the effects may be more apparent with long-term, high-dose contraceptive use.^{1,4}

Theophylline + Idrocilamide

Idrocilamide given orally can increase serum theophylline levels.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects oral idrocilamide 600 mg daily for 3 days then 1.2 g for 4 days increased the half-life of a single dose of theophylline 2.5-fold, from 8.5 to 21.6 hours, and reduced the clearance by 67%.¹ This is due to a reduction in the liver metabolism caused by the idrocilamide (see also 'Caffeine + Idrocilamide', p.1165). Information is very limited but it indicates that concurrent use should be closely monitored. Anticipate the need to reduce the theophylline dosage with oral idrocilamide.

Theophylline + Imipenem

Seizures developed in three patients taking aminophylline or theophylline when they were given imipenem.

Clinical evidence, mechanism, importance and management

Two patients receiving intravenous aminophylline developed seizures within 11 to 56 hours of starting treatment with intravenous imipenem 500 mg every 6 to 8 hours. Seizures developed in a third patient taking theophylline after imipenem had been given for 6 days. In all 3, seizures occurred 2 to 3 hours after a dose of imipenem.¹ The reasons for this effect are not known. Theophylline serum levels appeared to be unchanged.¹ In an analysis of data from 1754 patients who had received imipenem in dose-ranging studies, 3% had seizures, and imipenem was judged to be associated with a third of these cases. However, the concurrent use of theophylline or aminophylline was not found to be a significant risk factor for the development of seizures with imipenem.² The general importance of these cases is therefore uncertain.

Theophylline + Influenza vaccines

Normally none of the influenza vaccines (whole-virion, split-virion and surface antigen) interact with theophylline, but there are three reports describing rises in serum theophylline levels in a few patients (some to toxic levels), which was attributed to the use of an influenza vaccine.

Clinical evidence

(a) Evidence of no interaction

Mean steady-state serum theophylline levels were not altered by a trivalent split-virion influenza vaccine (*Fluzone*) in 12 patients with asthma, although one patient had an increase in levels (see (b), below). Levels were measured before vaccination and 1, 3, 7 and 14 days after vaccination.¹ Theophylline levels were unchanged in 5 patients with COPD when they were given 0.5 mL of influenza vaccine (*Fluogen*).² Similarly, no evidence of a rise in theophylline levels was found in a number of other studies in healthy subjects, both adults and children, receiving maintenance theophylline or aminophylline, and given various trivalent split-virion vaccines^{3–6} including *Fluzone*,⁷ *Fluogen*,^{8–10} *Influvac*,¹¹ *Mutagrip*.¹² In addition, no change in the pharmacokinetics of theophylline (given as oral aminophylline) was found after use of a whole-virion vaccine in healthy adults.¹³ No evidence of serious theophylline toxicity was seen in 119 eld-

erly people taking maintenance theophylline and given an unspecified influenza vaccine.¹⁴

(b) Evidence of an interaction

Three patients who had been taking oral choline theophyllinate (oxtriphylline) 200 mg (equivalent to 128 mg of theophylline) every 6 hours for at least 7 days had a rise in their serum theophylline levels of 219%, 89%, and 85%, respectively, within 12 to 24 hours of receiving 0.5 mL of trivalent split-virion influenza vaccine (*Fluogen*, Parke Davis). In some cases effects persisted for up to 72 hours, and two patients showed signs of theophylline toxicity. A subsequent study in 4 healthy subjects found that the same dose of vaccine more than doubled the half-life of theophylline, from 3.3 to 7.3 hours, and halved its clearance.¹⁵

A girl had a rise in theophylline levels from 20 to 34 mg/L (with no sign of toxicity) within 5 hours of being given a trivalent split-virion vaccine.¹⁶ In a study where 11 of 12 patients had no increase in theophylline levels after vaccination with *Fluzone*, one woman showed a rise in levels (from 10 to 24.5 mg/L) accompanied by headaches and palpitations.¹

The clearance of theophylline (given as choline theophyllinate) was reduced by 25% one day after influenza vaccination (trivalent influenza vaccine, *Fluogen*, Parke Davis) in 8 healthy subjects, but this was of borderline significance. Theophylline metabolism had returned to pre-vaccination levels after 7 days.¹⁷

A patient with COPD treated with sustained-release theophylline 300 mg twice daily (theophylline levels between 7 and 12 mg/L) developed nausea and palpitations the day after he received a trivalent influenza vaccination (*Fluogen*). His theophylline level was increased to 26 [mg/L]. His dose was reduced to 200 mg twice daily and the adverse effects resolved. However, a few days later his COPD had become symptomatic and the theophylline level was found to be subtherapeutic, so the dose was raised to 300 mg twice daily, as before.¹⁸

Mechanism

Uncertain. If an interaction occurs, it has been suggested it is probably due to inhibition of the liver enzymes concerned with the metabolism of theophylline, possibly secondary to interferon production, resulting in theophylline accumulation in the body.^{15,17} One suggestion is that vaccine contaminants, which are potent interferon-inducing agents, may be responsible (rather than the vaccine itself), so that an interaction would seem to be less likely with modern highly-purified subunit vaccines.¹⁹ In one study where an interaction occurred, an increase in serum interferon levels was detected,¹⁷ whereas, in two of the studies showing no interaction, no interferon production was detected.^{10,13} Influenza infection *per se* can result in decreased theophylline clearance and theophylline toxicity.²⁰

Importance and management

A very thoroughly investigated interaction, the weight of evidence being that no adverse interaction normally occurs with any type of influenza vaccine in children, adults or the elderly. Even so, bearing in mind the occasional and unexplained reports of an interaction^{1,15,16,18} it would seem prudent to monitor the effects of concurrent use (for nausea headaches, palpitations), although problems are very unlikely to arise now that purer vaccines are available (see 'Mechanism'). Note that any rise in theophylline levels is likely to be transient.

Theophylline + Interferons

Theophylline clearance is reduced by up to 50% by interferon alfa and by about 25% by interferon beta.

Clinical evidence

A study in 5 patients with stable chronic active hepatitis B and 4 healthy subjects found that 20 hours after being given a single 9- or 18-million unit intramuscular injection of interferon (recombinant human interferon alfa A), the clearance of theophylline (given as intravenous aminophylline) was approximately halved (range 33 to 81%) in 8 of the 9 subjects. The mean theophylline elimination half-life was increased from 6.3 to 10.7 hours (1.5 to sixfold increases). In the healthy subjects the theophylline clearances were noted to have returned to their former values 4 weeks after the study.¹

Another study, in 11 healthy subjects given interferon alfa (*Roferon-A*) 3 million units daily for 3 days, found that the terminal half-life and AUC of theophylline (given as aminophylline) were only increased by 10 to 15%, with a similar decrease in clearance.² In 7 patients with cancer interferon alfa (*Intron-A*) 3 million units given 3 times a week for 2 weeks decreased the clearance of a single 150-mg oral dose of theophylline by 33%.³

Seven patients with chronic hepatitis C receiving interferon beta 3 to 9 million units daily for 8 weeks were given a single 250-mg dose of intravenous aminophylline. Interferon beta reduced the total body clearance of theophylline by 26% (range 5.8 to 57%) and increased the elimination half-life by 39% (range 27 to 139%), but had no significant effect on the volume of distribution, although there was wide inter-patient variability.⁴

Mechanism

Interferon alfa inhibits the liver enzymes⁵ concerned with the metabolism of some drugs, such as theophylline. Therefore the metabolism of theophylline is reduced, and it accumulates. Interferon beta also appears to inhibit liver enzymes.⁴

Importance and management

Direct information appears to be limited to these reports, only one of which found clear evidence of a clinically important interaction. So far there appear to be no reports of toxicity but it would seem prudent to monitor concurrent use closely (nausea, headaches, palpitations), taking theophylline levels if necessary. Patients with enhanced metabolism (e.g. smokers) are predicted to be most at risk.¹

Theophylline + Ipriflavone

An isolated report describes increased theophylline levels in a patient given ipriflavone.

Clinical evidence, mechanism, importance and management

The theophylline serum levels of a patient with chronic obstructive pulmonary disease, taking sustained-release theophylline 300 mg twice daily, rose from 9.5 to 17.3 mg/L when ipriflavone 600 mg daily for about 4 weeks was taken. No symptoms of toxicity occurred. The serum theophylline levels returned to roughly the initial level when the ipriflavone was stopped, and rose again when it was restarted.¹ *In vitro* studies with human liver microsomes suggest that ipriflavone can inhibit the cytochrome P450 isoenzyme CYP1A2 and the demethylation of theophylline,^{2,3} which would reduce the metabolism of theophylline and increase its levels.

Although so far only one case of this interaction has been reported, the *in vitro* studies suggest that it would be prudent to monitor the theophylline levels of any patient given ipriflavone, making any dosage reductions as necessary.

Theophylline + Leukotriene antagonists

Montelukast does not appear to alter theophylline levels. A single case report describes a rapid rise in theophylline levels in a patient given zafirlukast. Zafirlukast levels are modestly reduced by theophylline, but this does not appear to be clinically important.

Clinical evidence

(a) Montelukast

In a study in 16 healthy subjects, the pharmacokinetics of a single intravenous dose of theophylline were not significantly changed by montelukast 10 mg daily for 10 days, but when they were given montelukast 200 mg and 600 mg daily, the AUC of theophylline was reduced by 43% and 66%, respectively. These doses are 20 and 60-fold higher than the usual 10 mg daily dose,¹ and therefore the clinical relevance of these effects is unclear.

(b) Zafirlukast

When zafirlukast was given with theophylline, the mean serum levels of zafirlukast were reduced by 30%, but the serum theophylline levels remained unchanged.² In contrast, an isolated report describes a 15-year-old asthmatic taking sustained-release theophylline 300 mg twice daily (as well as inhaled fluticasone, salbutamol (albuterol) and salmeterol, and oral prednisolone) who became nauseous shortly after zafirlukast (dose not stated) was added to her treatment. An increase in her theophylline level from 11 to 24 mg/L was noted. The theophylline was stopped, and later attempts to reintroduce theophylline at lower doses resulted in the same dramatic increases in serum theophylline levels.³

Mechanism

Not understood.

Importance and management

Information about interactions between theophylline and montelukast seems to be limited. The study above indicates that when using normal clinical doses of montelukast no special precautions or dosage alterations are needed. Similarly, no adverse interaction would normally seem to occur with zafirlukast and theophylline; the isolated case is of doubtful general significance.

3. Katial RK, Stelzle RC, Bonner MW, Marino M, Cantilena LR, Smith LJ. A drug interaction between zafirlukast and theophylline. *Arch Intern Med* (1998) 158, 1713–5.

Theophylline + Loperamide

Loperamide delays the absorption of theophylline from a sustained-release preparation.

Clinical evidence, mechanism, importance and management

A study of the effects of altering the transit time of drugs through the small intestine found that when 12 healthy subjects were given high-dose loperamide (8 mg every 6 hours for a total of 8 doses), the rate, but not extent, of absorption of a single 600-mg dose of sustained-release theophylline (*Theo-24*) was decreased. The maximum serum theophylline levels were reduced from 4.6 to 3.2 micrograms/mL, and this peak level occurred at 20 hours instead of 11 hours. One suggested reason for these effects is that loperamide inhibits the movement of the gut, thereby decreasing the dissolution rate of the *Theo-24* pellets.¹ More study is needed to establish the clinical significance of the interaction in patients receiving long-term theophylline.

1. Bryson JC, Dukes GE, Kirby MG, Heizer WD, Powell JR. Effect of altering small bowel transit time on sustained release theophylline absorption. *J Clin Pharmacol* (1989) 29, 733–8.

Theophylline + Macrolides

Troleandomycin can increase serum theophylline levels, causing toxicity if the dosage is not reduced. Azithromycin, clarithromycin, dirithromycin, josamycin, midecamycin, rokitamycin, spiramycin, and telithromycin normally only cause modest changes in theophylline levels or do not interact at all. There are unexplained and isolated case reports of theophylline toxicity with josamycin and clarithromycin. Roxithromycin usually has no relevant interaction but a significant increase in theophylline levels was seen in one study. See also 'Theophylline + Macrolides; Erythromycin', p.1187.

Clinical evidence

(a) Azithromycin

In an analysis of the safety data from clinical studies of azithromycin, there was no evidence that the plasma levels of theophylline were affected in patients given both drugs.¹ Similarly, no adverse effects were reported in another clinical study of patients taking azithromycin and theophylline.² Azithromycin 250 mg twice daily did not affect the clearance or serum levels of theophylline in patients with asthma.³ However, a 68-year-old man had a marked but transient fall in his serum theophylline level when azithromycin was withdrawn, and this was confirmed on rechallenge.⁴ The same authors conducted a study in 4 healthy subjects given azithromycin 500 mg on day 1 then 250 mg daily for 4 days and sustained-release theophylline 200 mg twice daily. Theophylline levels were slightly elevated during the use of azithromycin, and a transient drop occurred 5 days after azithromycin was stopped.⁵

(b) Clarithromycin

Clarithromycin 250 mg twice daily for 7 days had no effect on the steady-state serum theophylline levels of 10 elderly patients with COPD.⁶ Similarly, two other studies found that clarithromycin had little or no effect on theophylline pharmacokinetics.^{3,7} Another study in healthy subjects given clarithromycin 500 mg twice daily for 4 days found a 17% increase in the AUC and an 18% increase in the maximum plasma levels of theophylline, but this was considered clinically unimportant.⁸ In two clinical studies in patients with an acute bacterial exacerbation of chronic bronchitis the number of patients requiring an adjustment in theophylline dosage was similar when those who took clarithromycin were compared with those who took ampicillin.^{9,10} However, there are isolated reports of possible theophylline toxicity, including a case that resulted in rhabdomyolysis with renal failure requiring haemodialysis.^{11,12} For a report of theophylline toxicity in a patient also taking clarithromycin and levofloxacin, see 'Theophylline + Quinolones', p.1192.

(c) *Dirithromycin*

In one study, 13 healthy subjects had a fall in their steady-state trough theophylline level of 18%, and a fall in their peak serum level of 26% while taking dirithromycin 500 mg daily for 10 days, although this was not considered clinically relevant.¹⁵ No significant changes in theophylline pharmacokinetics were seen in 14 patients with COPD who were given dirithromycin 500 mg daily for 10 days.¹⁴ This is supported by a similar single-dose study in 12 healthy subjects.¹⁵

(d) *Josamycin*

No clinically significant changes in serum theophylline levels were seen in 5 studies in patients (both adults and children)^{16–18} or healthy subjects¹⁹ given josamycin, but a modest rise in theophylline levels was described in one study in children.²⁰ Another study reported a 23% reduction in the levels of theophylline (given as intravenous aminophylline) in 5 patients with particularly severe respiratory impairment, but no significant effect in 5 other patients with less severe disease.²¹ However, an isolated report describes theophylline toxicity in a 80-year-old man who was given josamycin.²²

(e) *Midecamycin/Midecamycin diacetate*

In one study, 18 asthmatic children had a slight decrease in serum theophylline levels when they were given midecamycin 40 mg/kg daily for 10 days for a bronchopulmonary infection, but no changes were seen in 5 healthy adult subjects.²³

Similarly, no significant changes in serum theophylline levels were seen in 20 patients taking slow-release theophylline (*Theo-dur*) 300 mg twice daily, or intravenous theophylline 4 mg/kg three times daily, when they were given midecamycin diacetate (miocamycin; ponsinomycin) 1.2 g daily for 10 days.²⁴ A number of other studies confirm the absence of a clinically important interaction between oral or intravenous theophylline or intravenous aminophylline and midecamycin diacetate in children and adults.^{25–28}

(f) *Rokitamycin*

Two studies in 12 adults with COPD and 11 elderly patients taking theophylline found no significant changes in serum theophylline levels when they were given rokitamycin 600 to 800 mg daily for a week.^{29,30}

(g) *Roxithromycin*

One study in 12 healthy subjects and another in 16 patients with chronic obstructive pulmonary disease found only minor increases in steady-state theophylline levels, which were not considered clinically relevant, when they were given roxithromycin 150 mg twice daily.^{31,32} Another study in 5 healthy subjects similarly showed that roxithromycin 300 mg twice daily did not affect the pharmacokinetics of theophylline.³³ However, further study reported a significant increase in serum theophylline levels in 14 patients with asthma who were given roxithromycin 150 mg twice daily, but since the rise was not quantified it is difficult to assess the clinical relevance of this finding.³

(h) *Spiramycin*

A study in 15 asthmatic patients taking theophylline found that spiramycin 1 g twice daily for at least 5 days had no significant effect on their steady-state serum theophylline levels.³⁴

(i) *Telithromycin*

A study in 24 healthy subjects given theophylline found that telithromycin 800 mg daily for 4 days did not have a clinically relevant effect on theophylline exposure.³⁵

(j) *Troleandomycin*

A series of 8 patients with severe chronic asthma found that troleandomycin 250 mg four times daily caused an average reduction in the clearance of theophylline (given as intravenous aminophylline) of 50%. One patient had a theophylline-induced seizure after 10 days, with a serum theophylline level of 43 mg/mL (reference range 10 to 20 mg/L). The theophylline half-life in this patient had increased from 4.6 to 11.3 hours.³⁶ Other studies in healthy subjects^{23,37} and patients¹⁸ given oral theophylline with troleandomycin have also found reductions in theophylline clearance and marked rises in serum theophylline levels and half-life, even at low troleandomycin doses.³⁸

Mechanism

It is believed that troleandomycin forms inactive cytochrome P450-metabolite complexes within the liver, the effect of which is to reduce the metabolism (*N*-demethylation and 8-hydroxylation)³⁷ of theophylline, thereby reducing its clearance and increasing its levels. Clarithromycin, josamycin, midecamycin, and roxithromycin are thought to rarely form complexes, and azithromycin, dirithromycin, rokitamycin and spiramycin are not thought to inactivate cytochrome P450.³⁹

Importance and management

The interaction between theophylline and troleandomycin is established and well documented. If troleandomycin is given, monitor the levels of theophylline closely and adjust the dose as necessary. Reductions of 25 to 50% may be needed.^{38,40} The situation with roxithromycin is uncertain since only 1 of 4 studies suggested an interaction, but it would be prudent to be alert for the need to reduce the theophylline dosage. Alternative macrolides that usually interact only moderately, or not at all are azithromycin, clarithromycin, dirithromycin, josamycin, midecamycin, rokitamycin and spiramycin. Telithromycin may also be a suitable alternative. However, even with these macrolides it would still be prudent to monitor the outcome because a few patients, especially those with theophylline levels at the high end of the range, may need some small theophylline dosage adjustments. In the case of azithromycin, care should be taken in adjusting the dose based on theophylline levels taken after about 5 days of concurrent use, as they may only be a reflection of a transient drop. In addition, acute infection *per se* may alter theophylline pharmacokinetics.

Theophylline + Macrolides; Erythromycin

Theophylline serum levels can be increased by erythromycin. Toxicity may develop in those patients whose serum levels are at the higher end of the therapeutic range unless the dosage is reduced. The onset may be delayed for several days, and not all patients demonstrate this interaction. Erythromycin levels may possibly fall to subtherapeutic concentrations.

Clinical evidence

(a) Effect on theophylline

The peak serum theophylline levels of 12 patients with COPD given aminophylline 4 mg/kg orally every 6 hours were raised by 28% by erythromycin stearate 500 mg every 6 hours for 2 days. The clearance was reduced by 22%. Only one patient developed clinical signs of toxicity, although the authors suggest this may be because the other patients had low theophylline levels (11 mg/L) to start with and they may not have been studied for long enough to detect the full effect of the erythromycin.¹ Several single-dose studies in healthy or asthmatic adults given aminophylline or theophylline have demonstrated this interaction^{2–6} and multiple-dose studies with aminophylline have also shown that erythromycin alters theophylline pharmacokinetics.^{7,8} A multiple-dose study in asthmatic children showed a 40% rise in the levels of theophylline (given as intravenous aminophylline).⁹ There was often wide inter-subject variability, and not all patients demonstrated the interaction.^{1,4,6–9} In addition to the studies, there are several case reports where erythromycin was thought to have caused previously therapeutic theophylline levels to rise to become toxic. In 3 cases the level rose twofold, with accompanying symptoms of toxicity,^{10–12} and in one case the patient developed a fatal cardiac arrhythmia.¹³ Toxic theophylline levels of 41 mg/L have also been reported in one patient 3 days after a 6-day course of erythromycin was finished, although this patient did not have any clinical signs or symptoms or theophylline toxicity.¹⁴

Several studies in both healthy adults,^{15–18} and adults with COPD^{5,19} did not demonstrate any clinically significant interaction, although two of these studies did find a reduction in the clearance of theophylline in some subjects.^{15,19}

(b) Effect on erythromycin

The peak serum levels of erythromycin 500 mg every 8 hours were almost halved and the AUC_{0–8h} was reduced by 38% when 6 healthy subjects were given a single 250-mg intravenous dose of theophylline.⁶ Another pharmacokinetic study found that serum erythromycin levels fell by more than 30% when intravenous theophylline was given with oral erythromycin.⁸ Other studies using intravenous erythromycin found no significant pharmacokinetic changes. The renal clearance was increased, but this did not affect the overall clearance.^{18,20}

Mechanism

The mechanism for the effects of erythromycin on theophylline levels is not fully understood. It seems most likely that erythromycin inhibits the metabolism of theophylline by the liver resulting in a reduction in its clearance and a rise in its serum levels. The human organic anion transporter 2 (hOat2) found in the liver may also be involved in this interaction.²¹ The reduction in erythromycin levels may be caused by theophylline affecting the absorption of oral erythromycin.¹⁸

Importance and management

The effects of erythromycin on theophylline are established (but still debated) and well documented. Not all the reports are referenced here. It does not seem to matter which erythromycin salt is used. Monitor theophylline levels and anticipate the need to reduce the theophylline dosage to avoid toxicity. Not all patients will show this interaction but remember it may take several days (most commonly 2 to 7 days) to manifest itself. Some patients may have a high theophylline level but no clinical signs or symptoms, therefore do not rely on symptoms alone to monitor for toxicity.¹⁴ Limited evidence suggests that levels may return to normal 2 to 7 days after stopping erythromycin.^{10–12,14} There are many factors, such as smoking,^{3,19} which also affect theophylline kinetics, and which may play a role in altering the significance of the interaction in different patients. Those particularly at risk are patients with already high serum theophylline levels and/or taking high dosages (20 mg/kg or more). Ideally, use a non-interacting antibacterial if possible. However, where concurrent treatment cannot be avoided, a 25% reduction in theophylline dose has been recommended for patients with levels in the 15 to 20 mg/L range,^{1,2,22} but little dosage adjustment is probably needed for those at the lower end of the range, (below 15 mg/L) unless toxic symptoms appear.^{1,4} In practice erythromycin can probably be safely started with theophylline, with the levels monitored after 48 hours and appropriate dosage adjustments then made.

The fall in erythromycin levels caused by theophylline is not well documented, but what is known suggests that it may be clinically important. Be alert for any evidence of an inadequate response to the erythromycin and increase the dosage or change the antibacterial if necessary. Intravenous erythromycin appears not to be affected.

Theophylline + Methoxsalen

Oral methoxsalen markedly increases theophylline levels. Topical methoxsalen would not be expected to interact.

Clinical evidence, mechanism, importance and management

In a single-dose study in 3 healthy subjects a 1.2-mg/kg oral dose of methoxsalen increased the AUC of a single 600-mg dose of theophylline (given 1 hour later) 1.7-fold, 2.1-fold and 2.7-fold, in the 3 subjects, respectively.¹ Methoxsalen probably inhibits the metabolism of theophylline² by the cytochrome P450 isoenzyme CYP1A2. Although information is limited, the findings support what is known about caffeine and 'psoralens', (p.1166). Theophylline dose reductions are likely to be required during concurrent use with systemic methoxsalen but seem unlikely to be necessary with topical treatment such as PUVA therapy.

Theophylline + Metoclopramide

Metoclopramide does not appear to interact with slow-release theophylline.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects a single 10-mg dose of metoclopramide taken 20 minutes before a 600-mg dose of slow-release theophylline (*Theo-Dur*), caused a small but insignificant 14.5% reduction in the bioavailability of theophylline. However, adverse effects (nausea, headache, tremors, CNS stimulation) were seen more often in those taking metoclopramide than in those taking placebo, possibly because metoclopramide caused an earlier rise in theophylline levels, and because some of the adverse effects of these two drugs may be additive.¹ A later study in 12 healthy subjects found that metoclopramide 15 mg every 6 hours had no effect on the rate or extent of absorption of a 600-mg dose of sustained-release theophylline (*Theo-24*).² A similar lack of interaction was found in another study using *Theo-Dur*.³ There would seem to be no reason for avoiding concurrent use.

Theophylline + Metronidazole

No interaction of clinical importance normally takes place if metronidazole is given to patients taking theophylline, but an isolated report describes seizures in one patient also taking ciprofloxacin.

Clinical evidence, mechanism, importance and management

There were no significant changes in the pharmacokinetics of theophylline given as a single intravenous dose of aminophylline to 5 women taking metronidazole 250 mg three times a day for trichomoniasis.¹ Another study in 10 healthy subjects confirmed this finding.² However, an acutely ill elderly woman taking theophylline had a generalised seizure while being treated with metronidazole and ciprofloxacin, despite her theophylline level being within the therapeutic range (10 to 20 mg/L).³ Both ciprofloxacin and, more rarely, metronidazole are associated with seizures.³ Although the evidence is limited, no special precautions would seem to be necessary during concurrent use.

Theophylline + Mexiletine or Tocainide

Serum theophylline levels are increased by mexiletine and toxicity may occur. Tocainide has only a small and probably clinically unimportant effect on theophylline pharmacokinetics.

Clinical evidence

(a) Mexiletine

A man developed theophylline toxicity within a few days of starting to take mexiletine 200 mg three times daily. His serum theophylline level rose from 15.3 to 25 mg/L, but fell to 14.2 mg/L, and the symptoms of toxicity resolved, when the theophylline dosage was reduced by two-thirds.¹

Other case reports describe 1.5 to threefold increases in theophylline serum levels (accompanied by clear signs of toxicity in some instances) in a total of 10 patients who were given mexiletine.^{2–7} Theophylline dose reductions of 50% were required in 3 cases,^{2,6} although 2 of the patients that did not require dose reductions had initial theophylline levels below the therapeutic range.³ The arrhythmia of one patient was aggravated even at therapeutic serum theophylline levels, and mexiletine was discontinued.⁴

In 15 healthy subjects, mexiletine 200 mg three times a day for 5 days reduced the clearance of a single 5-mg/kg intravenous dose of theophylline by 46% in women and 40% in men. The theophylline half-life was prolonged by 96% (from 7.4 to 14.5 hours) in women and 71% (from 8.7 to 14.9 hours) in men.⁸ Two further studies in healthy subjects given theophylline with mexiletine for 5 days found a reduction in steady-state theophylline clearance of about 45%, and an increase in the AUC of about 60%.^{9,10}

(b) Tocainide

After taking tocainide 400 mg every 8 hours for 5 days, the pharmacokinetics of a single 5-mg/kg intravenous dose of theophylline was measured in 8 healthy subjects. The clearance was decreased by about 10% and the half-life slightly prolonged (from 9.7 to 10.4 hours), but these changes were not thought to be large enough to warrant altering theophylline doses.¹¹

Mechanism

Mexiletine inhibits the metabolism (demethylation) of theophylline by the liver, thereby increasing its effects.^{8,10,12} It is possible that the interaction is due to competitive inhibition of the cytochrome P450 isoenzyme CYP1A2.¹³

Importance and management

The interaction between theophylline and mexiletine is established and of clinical importance. Monitor concurrent use and reduce the theophylline dosage as necessary to prevent the development of theophylline toxicity. It has been suggested that 50% dose reductions may be necessary.⁸ It seems doubtful if the interaction between theophylline and tocainide is clinically important but this needs confirmation.

Theophylline + Moracizine

Moracizine modestly increases theophylline clearance, although conversely animal data suggest that moracizine inhibits theophylline metabolism.

Clinical evidence

Single oral doses of aminophylline and a sustained-release theophylline preparation (*TheoDur*) were given to 12 healthy subjects. After they took moracizine 250 mg three times daily for 2 weeks, the AUC of theophylline was reduced by 32% and 36%, its clearance was increased by 44% and 66%, and the elimination half-life decreased by 33% and 20%, for aminophylline and theophylline respectively.¹

Mechanism

Uncertain. Moracizine is an enzyme inducer and appears to increase the metabolism of theophylline.¹ In contrast, *in vitro* and *animal* data show moracizine to be an inhibitor of the cytochrome P450 isoenzyme CYP1A2, which is the main isoenzyme involved in the metabolism of theophylline.² This would, in theory, be expected to lead to raised theophylline levels.

Importance and management

Information seems to be limited to this study. The clinical importance of this interaction has not been assessed, but monitor the effects of concurrent use and be alert for the need to adjust the theophylline dose. More study is needed.

Theophylline + Nefazodone

Nefazodone does not appear to interact adversely with theophylline.

Clinical evidence, mechanism, importance and management

Nefazodone 200 mg twice daily for 7 days had no effect on the pharmacokinetics or pharmacodynamics of theophylline 600 mg to 1.2 g daily in patients with chronic obstructive airways disease, nor was there any effect on their FEV₁ values.¹ No special precautions would seem necessary if both drugs are used.

1. Dockens RC, Rapoport D, Roberts D, Greene DS, Barbhayia RH. Lack of an effect of nefazodone on the pharmacokinetics and pharmacodynamics of theophylline during concurrent administration in patients with chronic obstructive airways disease. *Br J Clin Pharmacol* (1995) 40, 598–601.

Theophylline + Non-prescription theophylline products

Patients taking theophylline should not take other medications containing theophylline (some of which are non-prescription products) unless the total dosage of theophylline can be adjusted appropriately.

Clinical evidence, mechanism, importance and management

A patient taking theophylline developed elevated serum theophylline levels of 35.7 micrograms/mL while taking *Quinamm* for leg cramps (old formulation containing quinine 260 mg and aminophylline 195 mg). This case report highlights the need to avoid the inadvertent intake of additional doses of theophylline if toxicity is to be avoided. The newer formulation of *Quinamm* does not contain theophylline.¹ Note that non-prescription preparations containing theophylline are available in many countries. For

example, some cough and cold preparations in the UK contain theophylline (e.g. *Do-Do Chesteze*, *Franol Plus*). Patients should be warned.

Theophylline + Olanzapine

There appears to be no significant pharmacokinetic interaction between theophylline and olanzapine.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects given olanzapine 5 mg on day one, 7.5 mg on day 2 and then 10 mg daily for 7 days found no significant changes in the pharmacokinetics of theophylline (given as a single 350-mg intravenous dose of aminophylline). The pharmacokinetics of olanzapine also appeared to be unchanged when both drugs were given.¹ No special precautions would appear to be necessary on concurrent use. The authors also conclude that olanzapine would not be expected to affect the pharmacokinetics of other drugs that are (like theophylline) substrates for the cytochrome P450 isoenzyme CYP1A2, see 'Table 1.2', (p.4).

Theophylline + Ozagrel

Ozagrel does not appear to alter theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

Ozagrel 200 mg twice daily was given to 4 patients with asthma taking sustained-release theophylline. After 24 weeks the ozagrel was stopped without any significant effect on the pharmacokinetics of theophylline. Similarly, in another 8 patients with bronchial asthma, there were no significant differences in the pharmacokinetics of theophylline (given as a single infusion of aminophylline) before and after taking ozagrel 200 mg twice daily for 7 days.¹ No special precautions would seem to be needed during concurrent use.

Theophylline + Penicillins

Ampicillin, with or without sulbactam, and amoxicillin do not alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

A retrospective study in asthmatic children aged 3 months to 6 years found that the mean half-life of theophylline did not differ between those treated with ampicillin and those not.¹ The pharmacokinetics of theophylline 8.5 mg/kg daily were not altered in 12 adult patients with chronic obstructive pulmonary disease when they were given ampicillin 1 g plus sulbactam 500 mg every 12 hours for 7 days.²

A study in 9 healthy adult subjects showed that amoxicillin 750 mg daily for 9 days did not affect the pharmacokinetics of theophylline 540 mg twice daily.^{3,4}

No special precautions would seem to be necessary during concurrent use of these antibacterials and theophylline. However, note that acute infections *per se* can alter theophylline pharmacokinetics.

Theophylline + Pentoxifylline

Pentoxifylline can raise serum theophylline serum levels.

Clinical evidence, mechanism, importance and management

The mean trough steady-state theophylline serum levels of 9 healthy subjects given sustained-release theophylline (*TheoDur*) 200 or 300 mg twice daily for 7 days were increased by 30% by pentoxifylline 400 mg three times daily. However, the change in levels ranged from a 12.8% decrease to a 94.8% increase. The subjects complained of insomnia, nausea, diarrhoea and tachycardia more frequently while taking both drugs, but this did not reach statistical significance.¹ The mechanism of this interaction is not understood, although note, pentoxifylline is also a xanthine derivative. Patients should be well monitored for theophylline adverse effects (headache, nausea, palpitations) while taking both drugs. More study is needed to clarify this highly variable interaction.

1. Ellison MJ, Horner RD, Willis SE, Cummings DM. Influence of pentoxifylline on steady-state theophylline serum concentrations from sustained-release formulations. *Pharmacotherapy* (1990) 10, 383–6.

Theophylline + Phenylpropranolamine

Phenylpropranolamine reduces the clearance of theophylline.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects a single 150-mg oral dose of phenylpropranolamine decreased the clearance of theophylline (given as a single 4-mg/kg intravenous dose of aminophylline 1 hour after the phenylpropranolamine) by 50%.¹ Such a large reduction in clearance would be expected to result in some increase in serum theophylline levels, but so far no studies of this potentially clinically important interaction seem to have been carried out in patients. Be alert for evidence of toxicity if both drugs are used. More study is needed. See also 'Pseudoephedrine and related drugs + Caffeine', p.1276.

1. Wilson HA, Chin R, Adair NE, Zaloga GP. Phenylpropranolamine significantly reduces the clearance of theophylline. *Am Rev Respir Dis* (1991) 143, A629.

Theophylline + Phenytoin

The serum levels of theophylline can be markedly reduced by phenytoin. Some limited evidence suggests that theophylline may also reduce phenytoin levels.

Clinical evidence

(a) Reduced phenytoin serum levels

A preliminary report noted that the seizure frequency of an epileptic woman taking phenytoin 100 mg four times daily increased when she was given intravenous, and then later oral, theophylline. Her serum phenytoin levels had more than halved, from 15.7 mg/L to around 5 to 8 mg/L. An increase in the phenytoin dosage to 200 mg three times daily raised her serum phenytoin levels to only 7 to 11 mg/L until the drugs were given 1 to 2 hours apart. The patient then developed phenytoin toxicity with a serum level of 33 mg/L. A subsequent single-dose study in 4 healthy subjects confirmed that higher serum levels of both drugs were achieved when the theophylline and phenytoin were given 2 hours apart rather than simultaneously.¹ Another study in 7 healthy subjects found that the AUC of a single 400-mg dose of phenytoin was reduced by 21% when it was given at the same time as a single 7.5-mg/kg dose of theophylline compared with a reduction of 7% when the same doses were given 2 hours apart.²

A later preliminary study in 14 subjects (by some of the same authors) found that after 2 weeks of concurrent use, the mean serum phenytoin levels of 5 of the subjects rose by 40% and the mean levels of the group as a whole rose by about 27% when the theophylline was stopped. Urinary concentrations of a phenytoin metabolite were raised.³

(b) Reduced theophylline serum levels

The observation that a patient taking phenytoin had lower than expected theophylline levels prompted a study in 10 healthy subjects. After taking

phenytoin for 10 days the clearance of theophylline (after a single intravenous dose of aminophylline) was increased by 73%, and both its AUC and half-life were reduced by about 50%.⁴ Another study in 6 healthy subjects showed that after taking phenytoin 300 mg daily for 3 weeks the mean clearance of theophylline (after a single intravenous dose of aminophylline) was increased by 45% (range 31 to 65%).⁵ Similar results were found in a further study.⁶ Other reports on individual asthmatic patients have shown that phenytoin can increase the clearance of theophylline by about 1.3- to 3.5-fold.⁷⁻⁹ Another study¹⁰ and a case report¹¹ show that the reduction in theophylline levels caused by phenytoin can be additive with the effects of smoking. A subsequent study found that the extent of phenytoin-induced metabolism of theophylline was not affected by age, despite an age-related reduction in theophylline metabolism.¹² Consider also 'Theophylline + Tobacco', p.1201.

Mechanism

Uncertain. It has been suggested that theophylline either impairs phenytoin absorption or induces phenytoin metabolism, but neither suggestion seem likely.

It seems probable that phenytoin, a known enzyme inducer, increases the metabolism of theophylline by the cytochrome P450 isoenzyme CYP1A2 in the liver, thereby increasing its clearance.

Importance and management

The effect of phenytoin on theophylline is established and of clinical importance. Patients given both drugs should be monitored to confirm that theophylline remains effective. Ideally the serum levels should be measured to confirm that they remain within the therapeutic range. Theophylline dosage increases of up to 50% or more may be required.¹³ Conversely, patients should be monitored for signs of toxicity and theophylline levels should be checked in patients who stop phenytoin. The effect of theophylline on phenytoin is not established and the documentation is limited. It may be prudent to monitor phenytoin levels as well. Separating the doses appears to minimise any interaction. Note that theophylline itself can cause seizures, although mostly in overdose, and should be used with caution in patients with epilepsy.

Theophylline + Pirenzepine

Pirenzepine does not appear to alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

Pirenzepine 50 mg twice daily for 5 days had no effect on the pharmacokinetics of theophylline (given as aminophylline 6.5 mg/kg, intravenously) in 5 healthy subjects.¹ This would suggest that no special precautions are needed on concurrent use.

1. Sertl K, Rameis H, Meryn S. Pirenzepin does not alter the pharmacokinetics of theophylline. *Int J Clin Pharmacol Ther Toxicol* (1987) 25, 15–17.

Theophylline + Pneumococcal vaccine

Pneumococcal vaccination does not appear to affect theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of oral theophylline 250 mg three times daily for 10 days were unaltered in 6 healthy subjects both the day after and one week after they received 0.5 mL of a pneumococcal vaccine.¹ These findings need confirmation in patients, but what is known suggests that no special precautions are needed during concurrent use.

1. Cupit GC, Self TH, Bekemeyer WB. The effect of pneumococcal vaccine on the disposition of theophylline. *Eur J Clin Pharmacol* (1988) 34, 505–7.

Theophylline or Diprophylline + Probenecid

Theophylline levels are unaffected by probenecid, but diprophylline levels can be raised.

Clinical evidence

(a) Diprophylline

A study in 12 healthy subjects showed that the half-life of a single 20-mg/kg oral dose of diprophylline was doubled (from 2.6 to 4.9 hours) and the clearance approximately halved by probenecid 1 g, which resulted in raised serum diprophylline levels.¹

(b) Theophylline

A study in 7 healthy subjects found that probenecid 1 g given 30 minutes before a 5.6-mg/kg oral dose of aminophylline had no significant effect on the pharmacokinetics of theophylline.²

Mechanism

Diprophylline is largely excreted unchanged by the kidneys, and probenecid inhibits its renal tubular secretion.³ Theophylline is largely cleared from the body by hepatic metabolism, and would therefore not be expected to be affected by probenecid.

Importance and management

Based on the findings of this single-dose study, it would seem to be prudent to monitor serum diprophylline levels if probenecid is started or stopped. No special precautions are needed if theophylline and probenecid are given concurrently.

Theophylline + Propafenone

Two isolated reports describe raised serum theophylline levels, with symptoms of toxicity, when two patients were given propafenone.

Clinical evidence

In a 71-year-old man, propafenone 150 mg daily raised the levels of sustained-release theophylline 300 mg twice daily from a range of 10.2 to 12.8 mg/L to 19 mg/L, and signs of theophylline toxicity developed. The day after propafenone was withdrawn the level fell to 10.8 mg/L. When the propafenone was later restarted the theophylline levels rose again to 17.7 mg/L within one week, but fell when the theophylline dosage was reduced by one-third.¹

In another report, a 63-year-old man had a marked reduction in the clearance of sustained-release theophylline and a rise in theophylline levels from 10.8 mg/L to a maximum of 20.3 mg/L over 7 days when he took

propafenone 150 mg every 8 hours, increasing to 300 mg every 8 hours.² Theophylline was discontinued.

Mechanism

Uncertain. It has been suggested that propafenone may reduce the metabolism of theophylline by the liver, thereby increasing its levels.

Importance and management

Information is limited to these two reports, but it would seem prudent to monitor the effect of adding propafenone to established treatment with theophylline in any patient. Be alert for increased theophylline levels and signs of toxicity. Controlled studies are needed to further investigate this potential interaction.

2. Spinler SA, Gammaitoni A, Charland SL, Hurwitz J. Propafenone-theophylline interaction. *Pharmacotherapy* (1993) 13, 68–71.

Theophylline + Proprantheline

A study in 6 healthy subjects found that proprantheline 30 mg did not affect the rate or extent of absorption of a single 500-mg dose of theophylline (*Theo-Dur*). No special precautions would seem necessary on concurrent use.¹

1. Sommers DK, Meyer EC, Van Wyk M, Moncrieff J, Snyman JR, Grimbeck RJ. The influence of codeine, proprantheline and metoclopramide on small bowel transit and theophylline absorption from a sustained-release formulation. *Br J Clin Pharmacol* (1992) 33, 305–8.

Theophylline + Protease inhibitors

Ritonavir can reduce the serum levels of theophylline. Indinavir appears not to interact.

Clinical evidence, mechanism, importance and management

(a) Indinavir

A study in 12 healthy subjects given a single 250-mg oral dose of theophylline before and after 5 days of treatment with indinavir 800 mg three times daily found an 18% increase in the AUC of theophylline, which was not considered clinically significant.¹ There have been no further published studies or cases to date to confirm this result, and as indinavir does not inhibit CYP1A2 (see 'Table 21.2', (p.773)), the main isoenzyme that metabolises theophylline, it would seem unlikely that special precautions are necessary during concurrent use.

(b) Ritonavir

In a placebo-controlled study, 27 subjects taking theophylline 3 mg/kg every 8 hours were given ritonavir 300 mg increased to 500 mg twice daily for 10 days. Ritonavir reduced the AUC of theophylline by 43% and reduced the maximum and minimum steady-state theophylline levels by 32% and 57%, respectively. The interaction achieved its maximal effect 6 days after starting ritonavir.² Ritonavir induces the metabolism of theophylline by CYP1A2. Information is very limited but the interaction appears to be established. Consider monitoring theophylline levels if ritonavir is started and be alert for the need to increase the theophylline dose.

1. Mistry GC, Laurent A, Sterrett AT, Deutsch PJ. Effect of indinavir on the single-dose pharmacokinetics of theophylline in healthy subjects. *J Clin Pharmacol* (1999) 39, 636–42.
2. Hsu A, Granneman GR, Witt G, Cavanaugh JH, Leonard J. Assessment of multiple doses of ritonavir on the pharmacokinetics of theophylline. 11th Int Conf AIDS, Vancouver, 1996. Mo.B.1200.

Theophylline + Proton pump inhibitors

Omeprazole may cause a small increase in theophylline clearance, and lansoprazole may cause a small decrease in theophylline levels, neither of which are likely to be clinically relevant. Pantoprazole and rabeprazole do not appear to interact with theophylline.

Clinical evidence

(a) Lansoprazole

Lansoprazole 60 mg daily for 9 days caused only a very slight reduction in the steady-state theophylline levels of 14 healthy subjects.¹ Other studies have also shown little or no change in theophylline pharmacokinetics on concurrent use.²⁻⁶

(b) Omeprazole

The changes in the half-life and clearance of theophylline caused by omeprazole were found to be small and clinically unimportant in two studies.^{7,8} No changes in the steady-state pharmacokinetics of theophylline were found in other studies.^{5,9,10} However, one study found that omeprazole produced an 11% increase in the clearance of theophylline in poor metabolisers of omeprazole (i.e. those with low levels of the cytochrome P450 isoenzyme CYP2C19 and therefore higher levels of omeprazole),¹¹ but this seems unlikely to be clinically significant.

(c) Pantoprazole

A crossover study in 8 healthy subjects showed that intravenous pantoprazole 30 mg daily had no clinically important effect on the pharmacokinetics of theophylline given by infusion. No clinically relevant changes in blood pressure, heart rate, ECG and routine clinical laboratory parameters were seen.¹² Other studies have also found no significant change in theophylline pharmacokinetics when pantoprazole was given.^{4,5}

(d) Rabeprazole

A single 250-mg oral dose of theophylline was given to 25 patients before and after taking rabeprazole 20 mg or a placebo daily for 7 days. No significant changes in the pharmacokinetics of theophylline were seen.^{13,14}

Mechanism, importance and management

Lansoprazole possibly induces cytochrome P450 isoenzyme CYP1A2 (the enzyme by which theophylline is metabolised) to a small extent, but this is unlikely to be significant unless an individual is particularly sensitive to this effect.¹ Other proton pump inhibitors are unlikely to interact with theophylline, and so no special precautions would seem necessary on concurrent use.
