Theophylline + Pyrantel

A single case report describes increased serum theophylline levels when a child was also given pyrantel.

Clinical evidence

An 8-year-old boy with status asthmaticus was treated firstly with intravenous aminophylline and then switched to sustained-release oral theophylline on day 3, at which point his serum theophylline level was 15 mg/L. On day 4 he was given a single 160-mg dose of pyrantel (for an *Ascaris lumbricoides* infection) at the same time as his second theophylline dose. About 2.5 hours later his serum theophylline level was 24 mg/L, and a further 1.5 hours later it had risen to 30 mg/L. No further theophylline was given and no symptoms of theophylline toxicity occurred. The patient was discharged later in the day without theophylline.¹

Mechanism

Not understood. One suggestion is that the pyrantel inhibited the liver enzymes concerned with the metabolism of the theophylline, thereby increasing its levels. However, this is unlikely as the interaction occurred so rapidly. Another suggestion was that pyrantel may have increased drug release from the sustained-release theophylline preparation.

Importance and management

Information is limited to this single case report. No general conclusions can be based on such slim evidence, but concurrent use should be well monitored because, in this case, the serum theophylline concentration increase was very rapid. More study is needed.

- Hecht L, Murray WE, Rubenstein S. Theophylline-pyranterol pamoate interaction. *DICP Ann Pharmacother* (1989) 23, 258.

Theophylline + Pyridoxal

There is no evidence of an adverse interaction if pyridoxal (a vitamin B₆ substance) and theophylline are taken concurrently. There may be some reduction in theophylline-induced hand tremor.

Clinical evidence, mechanism, importance and management

In a crossover study, 15 young healthy adults were given theophylline (*Theo-Dur*) for 4 weeks, with the dose adjusted to give plasma levels of 10 mg/L, combined with daily doses of either a placebo or a vitamin B₆ supplement containing pyridoxal hydrochloride 15 mg. A variety of psychomotor and electrophysiological tests and self-report questionnaires failed to distinguish between the effects of the placebo or the vitamin B₆ supplement, except that the hand tremor induced by the theophylline tended to be reduced.¹ In another study by the same research group, 15 healthy subjects (smoking status not indicated) took pyridoxal 15 mg daily for 2 weeks prior to starting, and when also taking, sustained-release theophylline (*Theo-Dur*), 5 mg/kg daily for one week increased to 8 mg/kg daily for the next 3 weeks. Theophylline levels were subtherapeutic and ranged from 7.6 to 9.9 [mg/L]. Supplementation with pyridoxal did not prevent theophylline-induced reductions in pyridoxine 5-phosphate levels, as an indicator of vitamin B₆ status, although these did not drop below the normal reference range.²

There would seem to be no reason for avoiding concurrent use and it may even have some advantage.

Theophylline + Quinolones

Theophylline serum levels can be markedly increased in most patients by enoxacin. Pipemidic acid and cinafloxacin probably interact similarly. Theophylline levels can also be markedly increased in some patients by ciprofloxacin, and possibly pefloxacin. Norfloxacin, ofloxacin, pazufloxacin, or prulifloxacin normally cause a much smaller rise in theophylline levels. However, serious toxicity has been seen in few patients given norfloxacin. Fleroxacin, flumequine, gatifloxacin, gemifloxacin, levofloxacin, lomefloxacin, moxifloxacin, nalidixic acid, rufloxacin, sparfloxacin and trovafloxacin appear not to interact.

Table 33.4 Effect of quinolones on theophylline pharmacokinetics in order of magnitude of the potential interaction

Quinolone (daily dose)	Increase in theophylline level	Increase in AUC	Decrease in clearance	Refs
Enoxacin 600 to 1200 mg	72 to 243%	84 to 248%	42 to 74%	1–8
Pipemidic acid 800 to 1500 mg	71%	76 to 79%	49%	3, 9
Clinafloxacin 400 to 800 mg			46 to 69%	10
Grepafloxacin 200 to 600 mg	28 to 82%	93 to 113%	33 to 54%	11, 12
Ciprofloxacin 600 to 1500 mg	17 to 50%	22 to 52%	18 to 31%	2, 3, 13–18
Pazufloxacin 500 mg	up to 27%	up to 33%	25%	19
Pefloxacin 400 to 800 mg	17 to 20%	19 to 53%	29%	2, 3
Norfloxacin 600 to 800 mg	up to 22%	up to 17%	up to 15%	7, 16, 20–23
Prulifloxacin 600 mg		16%	15%	24
Ofloxacin 400 to 600 mg	up to 10%	up to 10%	up to 12%	2, 3, 7, 22, 25–27
Trovafloxacin 200 to 300 mg		up to 8%		28, 29
Fleroxacin 400 mg	No significant change	up to 8%	up to 6%	30–33
Flumequine 1200 mg	No significant change	No significant change	No significant change	34
Gatifloxacin 400 mg	No significant change	No significant change		35
Gemifloxacin 400 to 600 mg	No significant change	No significant change		36
Levofloxacin 300 to 1000 mg	No significant change	No significant change	No significant change	11, 37, 38
Lomefloxacin 400 to 800 mg	No significant change	No significant change	No significant change	9, 15, 39–42
Moxifloxacin 200 mg to 400 mg	No significant change	No significant change	No significant change	43
Nalidixic acid 400 to 600 mg		No significant change	No significant change	2, 16
Rufloxacin 200 to 400 mg	No significant change	No significant change	No significant change	44, 45
Sparfloxacin 200 to 400 mg	No significant change	No significant change	No significant change	46–49

Clinical evidence

A. Pharmacokinetic studies

The effects of the quinolones on the pharmacokinetics of theophylline in clinical studies in healthy subjects or patients are listed in 'Table 33.4', (p.1193).

B. Case reports

(a) Ciprofloxacin

There are numerous cases that describe the interaction between ciprofloxacin and theophylline or aminophylline, which commonly report large increases in serum theophylline levels (32 to 478% or 1.3 to 5.6-fold increases), often associated with toxicity.¹⁻¹¹ From 1987 to 1988, the CSM in the UK had received 8 reports of clinically important adverse interactions between these two drugs, with one fatal case.¹ By 1991, the FDA in the US had received 39 reports of the interaction, with three deaths.⁹

An elderly woman taking theophylline developed toxic serum levels and died shortly after starting to take ciprofloxacin.⁷ Seizures, associated with toxic levels of theophylline, were described in a number of the case reports.^{5,9-11} Seizures have also occurred when ciprofloxacin was used with theophylline or aminophylline, even when theophylline levels were within the therapeutic range (10 to 20 mg/L).^{9,12,13} Ciprofloxacin and toxic levels of theophylline are both known to cause seizures independently. It was suggested that, in the case of seizures, there may be a pharmacodynamic interaction between theophylline and the fluoroquinolones as well as a pharmacokinetic interaction.⁹ In each case seizures began within 1 to 7 days of starting the combination and were reported as being either partial or grand mal. The addition of clarithromycin does not appear to increase the effects of ciprofloxacin on theophylline.¹⁴

(b) Clinafloxacin

The apparently stable serum theophylline levels of a 78-year-old man with steroid-dependent chronic obstructive pulmonary disease were approximately doubled after he received intravenous clinafloxacin 200 mg every 12 hours for 5 days. Two theophylline doses were withheld, and then the dosage was reduced from 300 mg every 8 hours to 200 mg every 8 hours. Within another 5 days his serum theophylline levels had returned to his previous steady-state level.¹⁵

(c) Enoxacin

Some patients in early studies of enoxacin experienced adverse effects (serious nausea and vomiting, tachycardia, seizures)^{16,17} and this was found to be associated with unexpectedly high plasma theophylline levels.^{16,18}

(d) Levofloxacin

Levofloxacin has not significantly altered the pharmacokinetics of theophylline in studies, see 'Table 33.4', (p.1193). However, a 59-year-old man developed theophylline toxicity 7 and 5 days after starting clarithromycin and levofloxacin, respectively. His theophylline clearance decreased by about 40% when compared to the value before starting these drugs and so the theophylline dosage was reduced. After stopping the levofloxacin, the theophylline level fell, and the theophylline clearance returned to the initial value, even though clarithromycin was continued.¹⁹

(e) Norfloxacin

No clinically significant changes in theophylline levels occurred in a patient given norfloxacin who subsequently had marked changes when given ciprofloxacin.³ This report and the studies in 'Table 33.4', (p.1193) contrast with the records of the FDA in the US, which describe 3 patients (up to 1989)²⁰ and 9 patients (up to 1991)⁹ who experienced marked increases in theophylline levels ranging from 64 to 171% (mean 103%). Three patients developed seizures, and one died.⁹

(f) Pefloxacin

An isolated report describes convulsions in a patient, which were attributed to the use of theophylline with pefloxacin.²¹

Mechanism

The interacting quinolones appear to inhibit the metabolism (*N*-demethylation) of theophylline to different extents (some hardly at all), so that it is cleared from the body more slowly and its serum levels rise. The quinolones are known to inhibit the cytochrome P450 isoenzyme CYP1A2 by which theophylline is metabolised. Although neither levofloxacin and clarithromycin alone usually interact, the case report suggests that togeth-

er they may.¹⁹ There is some evidence that combined use of theophyllines and quinolones may amplify the epileptogenic activity of the quinolones.^{9,22}

Importance and management

The interactions of enoxacin and ciprofloxacin with theophylline are well documented, well established and of clinical importance. The effect of enoxacin is marked and occurs in most patients, whereas the incidence with ciprofloxacin is uncertain and problems do not develop in all patients. The risk seems greatest in the elderly²³ and those with theophylline levels already towards the top end of the therapeutic range. Toxicity may develop rapidly (within 2 to 3 days) unless the theophylline dosage is reduced.

With enoxacin, it has been suggested that the dose of theophylline should be reduced by 50%,^{18,24-26} although reductions of 75% may possibly be necessary for those with high theophylline clearances.²⁶ Alterations in the theophylline dose should be based on careful monitoring of theophylline levels. New steady-state serum theophylline levels are achieved within about 2 to 3 days of starting and stopping enoxacin.^{26,27}

Although problems do not develop in all patients taking theophylline and ciprofloxacin it would be prudent to be alert for this interaction in any patient. Some recommend an initial reduction in theophylline dose, in the order of 30 to 50% when ciprofloxacin is started.^{9,28,29} However, since a proportion of patients will not require a dose reduction, others suggest that the dose should be modified based on the theophylline level on day 2 of ciprofloxacin use.^{11,24,30-32}

Direct information about clinafloxacin and pipemidic acid is more limited, but they also appear to cause a considerable rise in serum theophylline levels, similar to enoxacin, and therefore it would seem prudent to anticipate the need for a dosage reduction and monitor theophylline levels closely.

Keep a check on the effects if norfloxacin, ofloxacin, pazufloxacin, or pefloxacin are used because theophylline serum levels may possibly rise to a small extent (10 to 22%), but these antibacterials normally appear to be much safer. However, be aware that norfloxacin has caused a much larger rise on occasions.^{9,20} Fleroxacin, flumequine, gatifloxacin, gemifloxacin, levofloxacin, lomefloxacin, moxifloxacin, nalidixic acid, rufloxacin, sparfloxacin and trovafloxacin appear not to interact significantly, and no special precautions seem necessary with these drugs. However, note that acute infection *per se* can alter theophylline pharmacokinetics. The manufacturers of some quinolones include a warning in their product literature about the risk of combining theophylline with quinolones because of their potential additive effects on reducing the seizure threshold. Convulsions have been reported with theophylline and ciprofloxacin, norfloxacin, or pefloxacin. With some of these cases it is difficult to know whether what happened was due to increased theophylline levels, to patient pre-disposition, to potential additive effects on the seizure threshold, or to all three factors combined. However, the literature suggests that seizures attributed to concurrent use are relatively rare, so that the general warning about the risks with all quinolones may possibly be an overstatement.

Theophylline + Repaglinide

Repaglinide 2 mg three times a day for 4 days did not significantly affect the steady-state pharmacokinetics of theophylline in 14 healthy subjects, although the peak plasma concentration was slightly reduced.¹ No special precautions would appear to be necessary during concurrent use.

1. Hartop V, Thomsen MS. Drug interaction studies with repaglinide: repaglinide on digoxin or theophylline pharmacokinetics and cimetidine on repaglinide pharmacokinetics. *J Clin Pharmacol* (2000) 40, 184–92.

Theophylline + Ribavirin

Ribavirin does not alter theophylline levels.

Clinical evidence, mechanism, importance and management

Oral ribavirin 200 mg every 6 hours had no effect on the plasma theophylline levels of 13 healthy subjects given immediate or sustained-release aminophylline. Similarly, ribavirin 10 mg/kg daily did not affect the plasma theophylline levels in 6 children with influenza and asthma.¹ No special precautions seem necessary on concurrent use.

Theophylline + Rifamycins and/or Isoniazid

Rifampicin (rifampin) lowers the serum levels of theophylline, but rifabutin appears to have little effect. Isoniazid may decrease or increase theophylline clearance and may increase theophylline levels. An isolated report describes theophylline toxicity one month after a patient started to take theophylline with isoniazid. Isoniazid and rifampicin increased theophylline clearance during the initial few days of tuberculosis treatment in one study, but there is some evidence that it decreases it within 4 weeks in another.

Clinical evidence

A. Effects of the individual antimycobacterial drugs on theophylline

(a) Isoniazid alone

Theophylline toxicity has been described in one patient receiving isoniazid 5 mg/kg daily and theophylline, and this subsequently recurred on rechallenge.¹ In 7 healthy subjects, high-dose isoniazid (10 mg/kg daily) for 10 days increased the AUC₀₋₆ of theophylline by only 8%. The theophylline was given as an intravenous infusion of aminophylline and the plasma levels after 6 hours were 22% higher (about 10.5 mg/L compared with 8.7 mg/L). Five subjects also had an increase in the half-life and AUC of isoniazid, but these changes were not statistically significant.² Another study, in 13 healthy subjects, found that isoniazid 400 mg daily for 2 weeks reduced the mean clearance of theophylline (given as intravenous aminophylline) by 21%.³

However, another study in 4 healthy subjects given isoniazid 300 mg daily for 6 days found that the clearance of oral theophylline was increased by 16%, but no consistent changes were seen in any of the other pharmacokinetic parameters measured.⁴

(b) Rifabutin

The AUC of a single 5-mg/kg dose of theophylline was reduced by 6% in 11 healthy subjects who took rifabutin 300 mg daily for 12 days. The half-life and clearance of theophylline were not affected.⁵

(c) Rifampicin (Rifampin)

The AUC of theophylline (given as sustained-release aminophylline 450 mg) was reduced by 18% in 7 healthy subjects who took rifampicin 600 mg daily for one week. A parallel study in another 8 healthy subjects given the same dosage of rifampicin showed that the metabolic clearance of theophylline (given as intravenous aminophylline 5 mg/kg) was increased by 45%.⁶

Similarly, other studies in healthy subjects given oral or intravenous theophylline or intravenous aminophylline and rifampicin 300 to 600 mg daily for 6 to 14 days found 25 to 82% rises in theophylline clearance, and 19 to 31% decreases in its half-life.^{5,7-12} A 61% fall in the 5-hour post-dose serum levels of theophylline (given as choline theophyllinate) occurred in a 15-month-old boy when he was given a 4-day course of rifampicin 20 mg/kg daily as meningitis prophylaxis.¹³

B. Effects of combined antimycobacterial drugs on theophylline

A study in patients taking a combination of **isoniazid, rifampicin, ethambutol and pyrazinamide** for pulmonary tuberculosis with intravenous aminophylline 7.35 mg/kg daily for 7 days found that the clearance of theophylline progressively increased, and was 53% faster on day seven.¹⁴ In contrast, in an earlier study by the same authors, after 4 weeks of the same antimycobacterials (isoniazid, rifampicin, ethambutol with or without pyrazinamide) the theophylline clearance in patients receiving long-term theophylline was about 35% slower than in a control group of similar patients not taking antimycobacterials.¹⁵ A single report describes unexpectedly *high* serum theophylline levels 4 days after theophylline 300 mg twice daily was started in an alcoholic patient with hepatic impairment who had started to take **rifampicin** and **isoniazid** 2 weeks previously.¹⁶

Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism of the theophylline, thereby increasing its clearance and reducing its serum levels.⁸ It has been suggested that isoniazid inhibits the metabolism of theophylline by the liver, thereby reducing its clearance and increasing its plasma levels. Rifabutin is a much less potent liver enzyme inducer than rifampicin, and consequently has less of an effect on theophylline metabolism.

With combined therapy, it was suggested that the effects of rifampicin might be more apparent during the initial 7 days, but that by week 4 the effect of isoniazid might predominate, because of its reduced inactivation by rifampicin combined with a reduction in the effect of rifampicin by auto-induction of its own metabolism.¹⁵ High theophylline levels in the isolated case above may have been due to liver impairment brought about by the combined use of rifampicin and isoniazid, or alcoholism.¹³

Importance and management

The interaction between theophylline and **rifampicin** is established. The levels and therapeutic effects of theophylline are likely to be reduced during concurrent treatment, and this effect can usually be detected within

36 hours.¹³ The wide range of increases in clearance that have been reported (25 to 82%) and the large inter-subject variation make it difficult to predict the increase in theophylline dosage required, but in some instances a twofold increase may be needed.⁸ Monitor theophylline levels if rifampicin is started or stopped and adjust the theophylline dose accordingly.

The effects of **rifabutin** are considerably less than those of rifampicin, with the one available study showing no significant interaction. On the basis of this, no special precautions appear to be necessary, but it may be prudent to monitor the efficacy of theophylline on concurrent use.

The reason for the inconsistent results with **isoniazid** alone is not understood, nor is this interaction well established. It has been suggested that it may take 3 to 4 weeks for any significant increase in theophylline levels to occur.¹ However, if enzyme inhibition was the cause, the effects would be expected more rapidly than this. All of the studies cited covered a period of only 6 to 14 days, whereas the case report describes the effects over a period up to 55 days.¹ It has also been suggested that the dose of isoniazid may be important, with the clearance of theophylline being unaffected by 'usual doses' of isoniazid, but reduced by larger doses.¹⁷ The outcome of concurrent isoniazid and theophylline use is uncertain and may be affected by other antimycobacterials, but it would clearly be prudent to be alert for any evidence of changes in theophylline levels and toxicity if isoniazid is given.

Isoniazid and rifampicin are usually taken as part of a combination chemotherapy regimen in the treatment of tuberculosis. There is some evidence that, in the short-term, combined use of these drugs will decrease theophylline levels, but that theophylline levels may increase during long-term therapy. However this requires confirmation. Patients taking theophylline with a combined anti-tubercular regimen including isoniazid and rifampicin should have their theophylline levels closely monitored and the dose adjusted according to the response, bearing in mind that these changes may occur over a longer period of time as reported in the case with isoniazid.

Theophylline + Ropinirole

Theophylline and ropinirole do not appear to interact.

Clinical evidence, mechanism, importance and management

In one study, 12 patients with parkinsonism were given ropinirole, increased from 0.5 mg to 2 mg three times daily over 28 days, then continued for a further 19 days. The pharmacokinetics of theophylline, given as a single intravenous dose of aminophylline, were assessed before ropinirole was started and on day 27. The pharmacokinetics of ropinirole were then assessed before, during and after, the use of oral controlled-release theophylline twice daily for 13 days (dose titrated to achieve plasma

levels in the range 8 to 15 micrograms/mL). In both cases it was found that concurrent use did not alter the pharmacokinetics of either drug, and concurrent use was well tolerated.¹ There would therefore appear to be no reason to take special precautions if both drugs are used, and no need to adjust the dosage of either drug. An interaction had originally been suspected because both drugs are metabolised by the cytochrome P450 isoenzyme CYP1A2.

Theophylline + SSRIs

Theophylline serum levels can be markedly and rapidly increased by fluvoxamine. Toxicity will develop if the theophylline dosage is not suitably reduced. Some preliminary clinical evidence suggests that fluoxetine and citalopram may not interact, and *in vitro* evidence suggests that paroxetine and sertraline are also unlikely to interact.

Clinical evidence

(a) Citalopram

In a study in 13 healthy subjects citalopram 40 mg daily for 21 days (to achieve steady-state) did not affect the pharmacokinetics of a single 300-mg oral dose of theophylline.¹

(b) Fluoxetine

The pharmacokinetics of theophylline were unchanged in 8 healthy subjects when they were given a 6-mg/kg infusion of aminophylline over 30 minutes, 8 hours after a single 40-mg dose of fluoxetine.²

(c) Fluvoxamine

The effect of fluvoxamine on theophylline pharmacokinetics has been characterised in two studies in healthy subjects. In the first study the AUC of theophylline (given as a single 442-mg oral dose of aminophylline) was increased almost threefold, the clearance was reduced by 62% and the half-life was prolonged from 7.4 to 32.1 hours by fluvoxamine 50 mg daily for 3 days then 100 mg daily for 13 days.³ In the second study, the clearance of theophylline (given as a single 300-mg oral dose of aminophylline) was reduced by about 70% and the half-life was increased from 6.6 to 22 hours by fluvoxamine 50 to 100 mg daily for 7 days.⁴ This interaction was shown to be reduced in patients with mild and severe liver cirrhosis (Child class A and C, respectively), whereas the clearance of a single 4-mg/kg dose of theophylline elixir was reduced by 62%, 52%, and 10.5% in healthy subjects, patients with mild cirrhosis, and patients with severe cirrhosis, respectively. The half-life of theophylline was increased by 13.6 hours in healthy subjects compared with 10.5 hours in patients with mild cirrhosis and 1 hour in patients with severe cirrhosis, demonstrating the reduced metabolic capabilities of the cirrhotic liver.⁵

A number of case reports have described fluvoxamine-induced theophylline toxicity. Agitation and tachycardia (120 bpm) developed in an 83-year-old man taking theophylline 600 mg daily (*Theostat*) about a week after he started to take fluvoxamine 100 mg daily. His serum theophylline levels were found to have risen from under 15 mg/L to 40 mg/L.⁶ A 70-year-old man similarly developed theophylline toxicity, with theophylline levels of about 32 mg/L (reference range 10 to 20 mg/L), when fluvoxamine was added. Subsequently the theophylline concentrations were found to parallel a number of changes in the fluvoxamine dosage.⁷ The clearance of theophylline in an 84-year-old man was approximately halved while he was taking fluvoxamine.⁸ An 11-year-old boy complained of headaches, tiredness and vomiting within a week of starting to take fluvoxamine. His serum theophylline levels were found to have doubled, from 14.2 to 27.4 mg/L.⁹ A 78-year-old woman became nauseous within 2 days of starting to take fluvoxamine 50 mg daily, and by day 6, when the fluvoxamine was stopped, her serum theophylline levels were found to have increased about threefold. She experienced a seizure, became comatose, and had supraventricular tachycardia (200 bpm) requiring intravenous digoxin and verapamil. She recovered uneventfully.¹⁰ A patient taking fluvoxamine 100 mg daily developed nausea, vomiting, confusion, reduced sleep and a poor appetite 5 days after she began to take theophylline 300 mg twice daily for COPD. Her theophylline level was found to be 25.9 mg/L.¹¹

Mechanism

In vitro studies with human liver microsomes have shown that fluvoxamine inhibits the cytochrome P450 isoenzyme CYP1A2, the principal enzyme responsible for the metabolism of theophylline.^{12,13} This results in raised theophylline levels and toxicity. This metabolic function, and hence interaction, appears to be severely reduced in patients with severe cirrhosis, probably due to reduced hepatic expression of CYP1A2 and reduced uptake of fluvoxamine.⁵ The other SSRIs, citalopram, fluoxetine, **paroxetine** and **sertraline** only weakly inhibited CYP1A2 *in vitro*, and consequently would not be expected to interact.^{12,13}

Importance and management

The interaction between fluvoxamine and theophylline is established and clinically important. The CSM in the UK advise that concurrent use should usually be avoided, but that if this is not possible, reduce the theophylline dosage by half when fluvoxamine is added and monitor theophylline levels.¹⁴ There is evidence to suggest that the extent of this interaction is markedly reduced in patients with liver cirrhosis, particularly severe Child class C, despite higher levels of fluvoxamine,⁵ although caution should still be applied with concurrent use in this patient group as they are more likely to have high levels of theophylline due to reduced metabolism. There is good *in vitro* evidence to suggest that fluvoxamine is the only SSRI likely to interact (because it is the only one that significantly affects CYP1A2). This would seem to be borne out by the lack of studies and case reports in the literature describing problems with any of the other SSRIs.

Theophylline + St John's wort (*Hypericum perforatum*)

A patient needed a marked increase in the dosage of theophylline while taking St John's wort, but no pharmacokinetic interaction was found in a 2-week study in healthy subjects.

Clinical evidence

A woman, who had previously been stable for several months taking theophylline 300 mg twice daily, was found to need a markedly increased theophylline dosage of 800 mg twice daily to achieve serum levels of 9.2 mg/L. It turned out that 2 months previously she had started to take 300 mg of a St John's wort supplement (hypericin 0.3%) each day. When she stopped taking the St John's wort, her serum theophylline levels doubled within a week to 19.6 mg/L and her theophylline dosage was consequently reduced. This patient was also taking a whole spectrum of other drugs (amitriptyline, furosemide, ibuprofen, inhaled triamcinolone, morphine, potassium, prednisone, salbutamol (albuterol), valproic acid, zolpidem and zafirlukast) and was also a smoker. No changes in the use of these drugs or altered compliance were identified that might have offered an alternative explanation for the changed theophylline requirements.¹

However, a study in 12 healthy subjects found that a standardised preparation of St John's wort 300 mg (hypericin 0.27%) three times daily for 15 days had no significant effects on the plasma level of a single 400-mg oral dose of theophylline.²

Mechanism

Uncertain. *In vitro* data suggest one component of St John's wort (hypericin) can act as an inducer of the cytochrome P450 isoenzyme CYP1A2.¹ It has also been suggested that treatment with St John's wort for 15 days was unlikely to induce the isoenzymes sufficiently to cause changes in plasma theophylline.² The patient in the case report had been taking St John's wort for 2 months, although at a lower dose, therefore differences in duration of treatment may account for the discrepancy. This is supported by studies in which 4-week³ but not 2-week treatment⁴ with St John's wort modestly increased the paraxanthine/cafeine ratio, used as a measure of CYP1A2 activity.

Importance and management

Direct information about this apparent interaction between theophylline and St John's wort appears to be limited. No pharmacokinetic interaction was noted in healthy subjects, but the case report describes a marked decrease in theophylline levels. Mechanistic studies suggest a modest interaction at most. Furthermore most clinically significant interactions with St John's wort are mediated by the cytochrome P450 isoenzyme CYP3A4. However, it would be prudent to monitor the effects and serum levels of theophylline if St John's wort is started or stopped, and patients should be warned of the possible effects of concurrent use. In 2000, the CSM in the UK recommended that patients taking theophylline should not take St John's wort. In those patients already taking the combination, the St John's wort should be stopped and the theophylline dosage monitored and adjusted if necessary.^{5,6} More study is needed, as this interaction is potentially of little clinical significance.

Theophylline + Succimer

A single case report describes a 36% reduction in the serum theophylline levels of a man treated with succimer.

Clinical evidence, mechanism, importance and management

A 65-year old man with chronic obstructive airways disease and chronic lead intoxication was given a 19-day course of lead chelation with succimer. His theophylline level was found to be reduced from about 11 mg/L to 7 mg/L on day 6 and remained at this level until about 9 days after the course of succimer was completed, when it returned to pretreatment levels. His clinical status did not alter despite these changes; possibly because he was also taking prednisone.¹ The reason for these alterations is not understood.

The general importance of this interaction is not known, but it would now be prudent to monitor the situation closely if succimer is added to established treatment with theophylline.

1. Harchelroad R. Pharmacokinetic interaction between dimercaptosuccinic acid (DMSA) and theophylline (THEO). *Vet Hum Toxicol* (1994) 36, 376.

Theophylline + Sucralfate

Two studies found that sucralfate caused only minor changes in theophylline pharmacokinetics, but another suggests that the ab-

sorption of sustained-release theophylline is significantly reduced by sucralfate.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects no clinically important changes occurred in the absorption of a single 5-mg/kg dose of an oral non-sustained release theophylline preparation given at the same time as sucralfate 1 g four times daily. A slight 5% decrease in the AUC was detected.¹ Another study found that sucralfate 1 g four times daily reduced the AUC of a single dose of a sustained-release theophylline preparation (*Theodur*) by 9% (timing of the theophylline dose in relation to the sucralfate dose not noted).² In contrast, another group of workers found that when sucralfate 1 g was given 30 minutes before a 350 mg dose of sustained-release theophylline (*PEG capsules*), the theophylline AUC was reduced by 40%.³ Many patients are given sustained-release theophylline preparations, but neither of these studies clearly shows what is likely to happen in clinical practice, so be alert for any evidence of a reduced response to theophylline. Usually, separating the administration of sucralfate from other drugs by 2 hours is considered sufficient to avoid interactions that occur by reduced absorption.⁴ However, the study showing decreased theophylline absorption did not examine the effect of separating the doses. Further study is needed.

Theophylline + Sulfinpyrazone

Sulfinpyrazone can cause a small increase in theophylline clearance.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects the total clearance of theophylline 125 mg every 8 hours for 4 days was increased by 22% (range 8.5 to 42%) when they were given sulfinpyrazone 200 mg every 6 hours.¹ This appeared to be the sum of an increase in the metabolism of theophylline by the liver and a decrease in its renal clearance.

Information seems to be limited to this study. The resulting fall in serum theophylline levels is unlikely to be clinically relevant.

Theophylline + Tadalafil

Tadalafil does not alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

A double-blind, placebo-controlled, randomised, crossover study in 17 healthy subjects given enough oral theophylline (a non-selective phosphodiesterase inhibitor) to achieve steady-state levels of about 12 mg/L found that the concurrent use of tadalafil 10 mg daily for 7 days did not affect the pharmacokinetics of either drug. There was a small increase of 3.5 bpm in the heart rate, which was not considered to be clinically relevant in the healthy subjects,¹ but the UK manufacturers advise that this should be considered when both drugs are used concurrently.²

2. Cialis (Tadalafil). Eli Lilly and Company Ltd. UK Summary of product characteristics, July 2006.

Theophylline + Tamsulosin

No clinically relevant pharmacokinetic interaction occurs between theophylline and tamsulosin.

Clinical evidence, mechanism, importance and management

In a double-blind study 10 healthy subjects were given tamsulosin 400 micrograms 30 minutes after breakfast for 2 days then 800 micrograms on the following 5 days with a single 5-mg/kg dose of intravenous theophylline one hour after the last dose of tamsulosin. The pharmacokinetics of theophylline and tamsulosin were not affected by concurrent use. Theophylline is mainly metabolised by the cytochrome isoenzyme CYP1A2, while tamsulosin is metabolised by CYP3A4 and CYP2D6, and therefore a pharmacokinetic interaction would not be expected.¹ The safety of combined use was considered acceptable and dose adjustments were not considered necessary during concurrent use.¹

1. Miyazawa Y, Starkey LP, Forrest A, Schentag JJ, Kamimura H, Swarz H, Ito Y. Effects of the concomitant administration of tamsulosin (0.8 mg/day) on the pharmacokinetics and safety profile of theophylline (5 mg/kg): a placebo-controlled evaluation. *J Int Med Res* (2002) 30, 34–43.

Theophylline + Tegaserod

Tegaserod does not appear to alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

In 18 healthy subjects, the pharmacokinetics of a single 600-mg dose of controlled-release theophylline were unchanged when it was given with three doses of tegaserod 6 mg (the first was given about 24 hours before the theophylline, the second simultaneously, and the third 12 hours later).¹ It was suggested that tegaserod would not be expected to affect the pharmacokinetics of other drugs that are (like theophylline) substrates for the cytochrome P450 isoenzyme CYP1A2, see 'Table 1.2', (p.4).

1. Zhou H, Khalilieh S, Svendsen K, Pommier F, Osborne S, Appel-Dingemans S, Lasseter K, McLeod JF. Tegaserod coadministration does not alter the pharmacokinetics of theophylline in healthy subjects. *J Clin Pharmacol* (2001) 41, 987–93.

Theophylline + Teicoplanin

Clinical studies in 20 patients with chronic obstructive pulmonary disease found that teicoplanin 200 mg twice daily and aminophylline 240 mg twice daily (both given as intravenous infusions) had no significant effect on the steady-state pharmacokinetics of either drug.¹ No special precautions would seem necessary during concurrent use.

1. Angrisani M, Cazzola M, Loffreda A, Losasso C, Lucarelli C, Rossi F. Clinical pharmacokinetics of teicoplanin and aminophylline during cotreatment with both medicaments. *Int J Clin Pharmacol Res* (1992) 12, 165–71.

Theophylline + Terbinafine

Preliminary evidence indicates that terbinafine can increase the serum levels of theophylline to some extent, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

In an open-label, randomised, crossover study 12 healthy subjects were given a single 5-mg/kg oral dose of aminophylline before and after taking terbinafine 250 mg daily for 3 days. The AUC and half-life of theophylline were increased by 16% and 23%, respectively, and the theophylline clearance was reduced by 14%. It was suggested¹ that this is due to the inhibitory effect of terbinafine on the activity of the cytochrome P450 isoenzyme CYP1A2, which is the main isoenzyme involved in the metabolism of theophylline. The changes seen were only relatively small, but the study periods only lasted 3 days so that the effects of longer concurrent use are uncertain, but a clinically significant interaction seems unlikely. More study is needed.

1. Trépanier EF, Nafziger AN, Amsden GW. Effect of terbinafine on theophylline pharmacokinetics in healthy volunteers. *Antimicrob Agents Chemother* (1998) 42, 695–7.

Theophylline + Tetracyclines

Serum theophylline levels increased in two patients who were also given minocycline or tetracycline. Some controlled studies have shown both increases and decreases in theophylline clearance with doxycycline and tetracycline, with no significant changes overall.

Clinical evidence

(a) Doxycycline

A study in 10 asthmatic subjects given doxycycline 100 mg twice daily on day 1 and then 100 mg daily for 4 days found that the mean serum theophylline level was not significantly altered. However, there was large inter-individual variation, with 4 subjects showing rises of more than 20% (range 24 to 31%) and 2 having decreases of 22% and 33%.¹ Fluctuations of this size are not unusual with theophylline. Another study in 8 healthy subjects given doxycycline 100 mg daily for 7 days with theophylline 350 mg twice daily failed to find any significant changes in theophylline pharmacokinetics.²

(b) Minocycline

The serum theophylline levels of a 70-year-old woman with normal liver function increased from 9.8 to 15.5 mg/L after she was given minocycline 100 mg twice daily by infusion for 6 days. Her serum theophylline level was 10.9 mg/L 14 days after the minocycline was stopped.³

(c) Tetracycline

After taking tetracycline hydrochloride 250 mg four times daily for 8 days a patient with chronic obstructive pulmonary disease (COPD) showed evidence of theophylline toxicity. After 10 days of tetracycline her serum theophylline levels had risen from about 13 mg/L to 30.8 mg/L. Both drugs were stopped, and after 24 hours her theophylline level was 12.4 mg/L. A later rechallenge in this patient confirmed that the tetracycline was responsible for the raised theophylline levels.⁴

In an earlier study in 8 healthy subjects tetracycline 250 mg four times daily for 7 days did not affect the mean pharmacokinetics of theophylline (given as a single intravenous dose of aminophylline), although there was large inter-individual variation. Four subjects had a decrease in clearance of over 15%, (32% in one subject), and conversely, one subject had a 21% increase in clearance.⁵ Other studies in subjects and patients given tetracycline for shorter periods have not found evidence of an important interaction. A study in 9 healthy adults given single 5-mg/kg intravenous doses of aminophylline found that tetracycline 250 mg every 6 hours for 48 hours had no significant effect on theophylline pharmacokinetics.⁶ Five non-smoking patients with COPD or asthma had an average rise in serum theophylline levels of 14% after 5 days of treatment with tetracycline 250 mg four times daily, and an 11% decrease in clearance. However, when a sixth patient was included (a smoker) the results were no longer statistically significant.⁷

Mechanism

Not understood. Inhibition of theophylline metabolism and clearance by the tetracyclines has been suggested.⁴

Importance and management

Information seems to be limited. There are two isolated cases of increased theophylline levels with minocycline and tetracycline, but controlled studies have not shown any significant changes in overall theophylline pharmacokinetics. It has been suggested that a clinically important interaction may possibly only occur in a few patients.^{1,4} Further study is needed. There seems to be no evidence of adverse interactions with any of the other tetracyclines. However, note that acute infections *per se* can alter theophylline pharmacokinetics.

Theophylline + Thyroid and Antithyroid compounds

Thyroid dysfunction may modestly affect theophylline requirements. There are two isolated cases of theophylline toxicity in patients being treated for hypothyroidism.

Clinical evidence

The theophylline elimination rate constant after a single intravenous dose of aminophylline was found to be greater in hyperthyroid patients (0.155 h⁻¹) than in euthyroid (0.107 h⁻¹) or hypothyroid patients (0.060 h⁻¹); some other pharmacokinetic parameters were also changed.¹ The authors concluded that thyroid dysfunction may modestly alter theophylline requirements. It is therefore also likely that drug-induced changes in the thyroid status, such as those caused by amiodarone, may also alter the amount of theophylline needed to maintain therapeutic levels.

(a) Antithyroid compounds

The serum theophylline level of an asthmatic patient was found to have doubled, from 15.2 to 30.9 mg/L, accompanied by toxicity, 3 months after treatment for hyperthyroidism with **radioactive iodine** (¹³¹I). At this point the patient was hypothyroid, and after treatment with levothyroxine was started, his serum theophylline returned to approximately the same level as before radioactive iodine treatment (13.9 mg/L).² Another patient with Graves' disease treated with a combination of **thiamazole** (**methimazole**) 10 mg three times daily and Lugol's solution (**iodine** and **potassium iodide**) and taking theophylline 500 mg twice daily (*TheoDur*), had a theophylline level of 4.7 mg/L before radioactive iodine therapy. His level increased to 13.6 mg/L 7 months after thyroid ablation.³ Five hyperthyroid patients had a 20% reduction in theophylline clearance and an increase in their theophylline half-life, from 4.6 to 5.9 hours, when they were given **carbimazole** 45 mg and propranolol 60 mg daily. In this study, a single intravenous dose of aminophylline was given before the treatment of thyrotoxicosis and after the euthyroid state had been achieved.⁴ Note that propranolol can reduce the clearance of theophylline but should be avoided in patients with respiratory disease, see 'beta blockers', (p.1175), for more information.

(b) Thyroid hormones

One week after starting to take theophylline 1 g daily, a patient who was hypothyroid (serum thyroxine 1.4 micrograms/dL, reference range 4 to 11 micrograms/dL) developed severe theophylline toxicity, with serum theophylline levels of 34.7 mg/L, manifested by ventricular fibrillation (from which he was successfully resuscitated) and repeated seizures over 24 hours. After 2 months treatment with **thyroid hormones**, which increased his serum thyroxine levels to 4.3 micrograms/dL, his serum theophylline level was 13.2 mg/L, 10 days after reinstatement of the same theophylline dosage.⁵

Mechanism

Thyroid status may affect the rate at which theophylline is metabolised. In hyperthyroidism it is increased, whereas in hypothyroidism it is decreased.

Importance and management

It is established that changes in thyroid status may affect how the body handles theophylline. Monitor the effects and anticipate the possible need to begin to reduce the theophylline dosage if treatment for hyperthyroidism is started (e.g. with radioactive iodine, carbimazole, **thiamazole**, **propylthiouracil**, etc.). Similarly, anticipate the possible need to increase the theophylline dosage if treatment is started for hypothyroidism (e.g. with levothyroxine). Stabilisation of the thyroid status may take weeks or even months to achieve so that if monitoring of the theophylline dosage is considered necessary, it will need to extend over the whole of this period.

This monitoring would also apply to drugs that may cause thyroid dysfunction such as amiodarone.

Theophylline + Tobacco

Tobacco smokers, and non-smokers heavily exposed to tobacco smoke, may need more theophylline than non-smokers to achieve the same therapeutic benefits, because the theophylline is cleared from the body more quickly. This may also occur in those who chew tobacco or take snuff but not if they chew nicotine gum.

Clinical evidence

A study found that the mean half-life of theophylline (given as a single oral dose of aminophylline) was 4.3 hours in a group of tobacco smokers (20 to 40 cigarettes a day) compared with 7 hours in a group of non-smokers, and that theophylline clearance was higher (mean 126%) and more variable in the smokers.¹ Almost identical results were found in an earlier study,² and a number of later studies in subjects given oral or intravenous theophylline or aminophylline confirm these findings.^{3–7} The ability of smoking to increase theophylline clearance occurs irrespective of gender,^{3,6} and in the presence of congestive heart failure or liver impairment.⁷ The effects of ageing on the induction of theophylline metabolism by tobacco smoking is less clear. One study has found that in both young subjects (less than 30-years-old) and elderly subjects (more than 67-years-old) smoking decreased the half-life and increased the clearance of theophylline, when compared with non-smokers. The effect was greater in the young subjects.⁴ However, another study found no difference in the pharmacokinetics of theophylline between asthmatic and healthy smokers and non-smokers aged over 65 years.⁸ A similar high clearance of theophylline (given as intravenous aminophylline) has been seen in a patient who chewed tobacco (1.11 mL/kg per minute compared with the more usual 0.59 mL/kg per minute).⁹ The half-life of theophylline (given as intravenous aminophylline) in passive smokers (non-smokers regularly exposed to tobacco smoke in the air they breathe, for 4 hours a day in this study) is reported to be shorter than in non-smokers (6.93 hours compared with 8.69 hours).¹⁰ The clearance of theophylline (given as intravenous aminophylline) in asthmatic children exposed to passive tobacco smoke was also found to be greater (1.36 mL/kg per minute compared with 0.09 mL/kg per minute) and their steady-state serum theophylline levels were lower than in similar children not exposed to passive smoking.¹¹

In one study, 3 of 4 patients who stopped smoking for 3 months (confirmed by serum thiocyanate levels) had a longer theophylline half-life, but only 2 had a slight decrease in theophylline clearance.¹ In another study, ex-smokers who had stopped heavy smoking 2 years previously had values for theophylline clearance and half-life that were intermediate between non-smokers and current heavy smokers.³ In another study, 7 hospitalised smokers who abstained from smoking for 7 days had a 35.8% increase in theophylline half-life and a 37.6% decrease in clearance (although clearance after abstinence was still higher than values usually found in non-smokers).¹²

Mechanism

Tobacco smoke contains polycyclic hydrocarbons, which act as inducers of the cytochrome P450 isoenzyme CYP1A2, and this results in a more rapid clearance of theophylline from the body. Both the *N*-demethylation and 8-hydroxylation of theophylline is induced.¹³ Ageing appears to offset the effects of smoking on theophylline metabolism.⁸

Importance and management

An established interaction of clinical importance. Heavy smokers (20 to 40 cigarettes daily) may need much greater theophylline dosage than non-smokers,¹ and increased doses are likely for those who chew tobacco or

take snuff,⁹ but not for those who chew nicotine gum.^{12,14} In patients who stop smoking, a reduction in the theophylline dosage of up to 25 to 33% may be needed after one week,¹² but full normalisation of hepatic function appears to take many months or even years.^{1,3} Investigators of the possible interactions of theophylline with other drugs should take smoking habits into account when selecting their subjects.^{6,10,11} Note that the effects of ‘cannabis’, (p.1177), may be additive with those of tobacco smoking.

Theophylline + Trimetazidine

Trimetazidine does not appear to alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

In a study in 13 healthy subjects trimetazidine 20 mg twice daily for at least 14 days did not alter the pharmacokinetics of a single 375-mg dose of theophylline.¹ These results suggest that treatment with theophylline is unlikely to be altered in patients concurrently treated with trimetazidine, but this needs confirmation in multiple-dose studies.

Theophylline + Vidarabine

A single case report describes a woman who had a rise in serum theophylline levels when she took aminophylline oral liquid with vidarabine.

Clinical evidence, mechanism, importance and management

A woman taking aminophylline oral liquid developed elevated serum theophylline levels (an increase from 14 mg/L to 24 mg/L) four days after starting to take vidarabine 400 mg daily for herpes zoster.¹ She was also being treated with ampicillin, gentamicin, clindamycin and digoxin, for congestive heart failure, chronic pulmonary disease and suspected sepsis. It was suggested that the vidarabine inhibited the metabolism of the theophylline resulting in the raised levels seen. The general significance of this case is uncertain, but it would now seem prudent to bear this interaction in mind if vidarabine is given with aminophylline or theophylline.

1. Gannon R, Sullman S, Levy RM, Grober J. Possible interaction between vidarabine and theophylline. *Ann Intern Med* (1984) 101, 148–9.

Theophylline + Viloxazine

Viloxazine increases serum theophylline levels and toxicity may occur.

Clinical evidence

A study in 8 healthy subjects given a single 200-mg dose of theophylline suggested that pretreatment with viloxazine 100 mg three times daily for 3 days increased the AUC₀₋₂₄ of theophylline by 47%, increased its maximum serum concentration, and reduced its clearance.¹ An elderly woman hospitalised for respiratory failure and treated with a variety of drugs including theophylline, developed acute theophylline toxicity (a grand mal seizure) 2 days after starting to take viloxazine 200 mg daily. Her serum theophylline levels had increased threefold, from about 10 to 28 mg/L, but the levels were reduced when the viloxazine was withdrawn.² Nausea and vomiting, associated with raised serum theophylline levels, occurred in another patient treated with viloxazine. Theophylline was stopped, and then reintroduced at one quarter of the original dose. The theophylline level subsequently became subtherapeutic when the viloxazine was stopped.³ A further case report in an elderly man describes a marked rise in serum theophylline levels to toxic concentrations (55.3 mg/L) when viloxazine, 100 mg then 300 mg daily, was started.⁴

Mechanism

It is suggested that the viloxazine competitively antagonises the metabolism of the theophylline by the liver, thereby reducing its clearance and resulting in an increase in its serum levels.

Importance and management

Information seems to be limited to these reports but it would appear to be a clinically important interaction. Theophylline serum levels should be well monitored if viloxazine is added, anticipating the need to reduce the dosage.

Theophylline + Zileuton

Zileuton raises theophylline levels and increases the incidence of adverse effects.

Clinical evidence

In a double-blind, crossover study, 13 healthy subjects were given 200 mg of theophylline (*Slo-Phyllin*) four times daily for 5 days and either zileuton 800 mg twice daily or a placebo. Zileuton caused a 73% rise in the mean steady-state peak serum levels of theophylline (from 12 to 21 mg/L), a 92% increase in its AUC, and halved its apparent plasma clearance. During the use of zileuton the incidence of adverse effects increased (headache, gastrointestinal effects), which was attributed to theophylline toxicity, and this caused 3 of the original 16 subjects to withdraw from the study.¹

Mechanism

Not fully established but it seems highly likely that zileuton inhibits the metabolism of the theophylline by the cytochrome P450 enzymes (probably the isoenzymes CYP1A2 and CYP3A) so that its serum levels rise.

Importance and management

Information is limited but the interaction appears to be established and of clinical importance. Concurrent use need not be avoided but monitor theophylline levels and reduce the dosage of theophylline as necessary. The report quoted above suggests that a typical asthma patient may initially need the theophylline dosage to be halved, and this dose reduction is recommended by the US manufacturers.² Similarly, the dose of theophylline should be reduced if it is given to a patient already taking zileuton, and adjusted according to theophylline levels.² This is based on the results of a study in over 1000 patients taking zileuton 600 mg four times daily without apparent problems when this course of action was followed.¹

2. Zylflo (Zileuton). Critical Therapeutics Inc. US Prescribing information, November 2005.

Zafirlukast + Aspirin

Aspirin 650 mg four times daily is reported to have resulted in a mean increase in the plasma levels of zafirlukast 40 mg daily of 45%. No further details are available.^{1,2} The clinical importance of this interaction awaits assessment but the manufacturers do not suggest any alteration in the zafirlukast dosage.³

2. Accolate (Zafirlukast). AstraZeneca UK Ltd. UK Summary of product characteristics, December 2004.
3. Zeneca Pharmaceuticals, Personal communication, July 1997.

Zafirlukast + Macrolides

Zafirlukast plasma levels are decreased by erythromycin, but this does not appear to be clinically important. No interaction has been found between zafirlukast and azithromycin or clarithromycin.

Clinical evidence, mechanism, importance and management

A study in 11 asthmatic patients found that erythromycin 500 mg three times daily for 5 days reduced the mean plasma level of zafirlukast 40 mg by about 40%.^{1,2} This reduction in levels would be expected to reduce its antiasthmatic effects. If these drugs are given concurrently, be alert for a reduced response. However, note that the manufacturers do not suggest any alteration in the zafirlukast dosage.³

Zafirlukast is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 *in vitro*. However, a study in 12 healthy subjects found that zafirlukast 20 mg twice daily for 12 days did not significantly affect the pharmacokinetics of a single 500-mg dose of azithromycin or clarithromycin.⁴ No precaution would seem necessary if zafirlukast is given with azithromycin or clarithromycin.

Zafirlukast + Terfenadine

Zafirlukast plasma levels are decreased by terfenadine but the clinical significance of this is unclear. Zafirlukast does not increase the levels of terfenadine, and concurrent use does not prolong the QTc interval.

Clinical evidence, mechanism, importance and management

A study in 16 healthy men given zafirlukast 160 mg twice daily for 16 days with terfenadine 60 mg twice daily on days 8 to 16 found that the mean maximum serum levels and AUC of zafirlukast were reduced by 70% and 60%, respectively. There was a small, non-significant reduction in the terfenadine AUC and serum levels.¹ A study in 8 healthy subjects given zafirlukast 160 mg twice daily with terfenadine 60 mg twice daily for 8 days found that the AUC of terfenadine and the QTc interval were not significantly increased with concurrent use, despite the fact that zafirlukast appears to inhibit CYP3A4 *in vitro*, the major enzyme involved in terfenadine metabolism.² The reduction in zafirlukast serum levels would be expected to reduce its antiasthmatic effects, but this needs assessment. If both drugs are given be alert for a reduced response to zafirlukast.

SSRIs, Tricyclics and related antidepressants

The development of the tricyclic antidepressants arose out of work carried out on phenothiazine compounds related to chlorpromazine. The earlier molecules possessed two benzene rings joined by a third ring of carbon atoms, with sometimes a nitrogen, and had antidepressant activity, hence their name. Some of the later antidepressants have one, two or even four rings. 'Table 34.1', (see below) lists the common tricyclic antidepressants, the selective serotonin reuptake inhibitors (SSRIs) and a number of other drugs that are also used for depression.

SSRIs

These antidepressants act on neurones in a similar way to the tricyclics (see below) but they selectively inhibit the reuptake of serotonin (5-hydroxytryptamine or 5-HT). They have fewer antimuscarinic effects and are also less sedative and cardiotoxic.

Tricyclic antidepressants

The tricyclic antidepressants inhibit the activity of the 'uptake' mechanism by which some chemical transmitters (serotonin (5-HT) or noradrenaline (norepinephrine)) re-enter nerve endings in the CNS. In this way they raise the concentrations of the chemical transmitter in the receptor area. If depression represents some inadequacy in transmission between the nerves in the brain, increasing the amount of transmitter may go some way towards reversing this by improving transmission.

The tricyclics also have antimuscarinic (sometimes referred to as anticholinergic or atropine-like) activity and can cause dry mouth, blurred vision, constipation, urinary retention and an increase in ocular pressure. Postural hypotension and cardiotoxic effects may also occur, but they are less frequent. CNS adverse effects include sedation, the precipitation of seizures in certain individuals, and extrapyramidal reactions.

Other antidepressant drugs

(a) Nefazodone and Trazodone

Nefazodone is a phenylpiperazine structurally related to trazodone. Both nefazodone and trazodone block the reuptake of serotonin at presynaptic neurones and block α_1 -adrenoceptors, but have no apparent effect on dopamine. Unlike trazodone, nefazodone blocks the reuptake of noradrenaline. Compared to the tricyclics, neither drug has very significant antimuscarinic effects, but trazodone also has marked sedative properties. Nefazodone is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and therefore it will inhibit the metabolism of drugs by this route. For a list of CYP3A4 substrates see 'Table 1.4', (p.6). Note that, nefazodone has largely been withdrawn due to adverse hepatic effects.

(b) Reboxetine

Reboxetine is a potent inhibitor of noradrenaline reuptake. It has a weak effect on serotonin reuptake and no significant affinity for muscarinic receptors.

(c) Serotonin and noradrenaline reuptake inhibitors (SNRIs)

Antidepressants in this group include duloxetine, milnacipran and venlafaxine. They inhibit both serotonin and noradrenaline reuptake but with differing selectivity. Milnacipran blocks serotonin and noradrenaline reuptake approximately equally, but duloxetine and to a greater extent venlafaxine have selectivity for serotonin. Duloxetine and venlafaxine are reported to weakly inhibit dopamine reuptake. They are also reported to have no significant affinity for histaminergic, muscarinic or adrenergic receptors, and, compared with the tricyclics, appear to lack significant sedative and antimuscarinic effects.

(d) Tetracyclic antidepressants and related drugs

Mianserin and maprotiline are tetracyclic antidepressants, which have actions similar to those of the tricyclic antidepressants. However, while the tetracyclics are more sedating, their antimuscarinic effects are less marked. Maprotiline inhibits the reuptake of noradrenaline (norepinephrine) and has weak affinity for central adrenergic (α_1) receptors. Mianserin does not prevent the peripheral reuptake of noradrenaline; it blocks presynaptic adrenergic (α_2) receptors and increases the turnover of brain noradrenaline. It is also an antagonist of serotonin receptors in some parts of the brain.

Mirtazapine is a piperazinoazepine and an analogue of mianserin. It is a presynaptic adrenergic α_2 -antagonist that increases central noradrenergic and serotonergic transmission. It is a potent inhibitor of histamine (H_1) receptors and this accounts for its sedative properties. It has little antimuscarinic activity.

Table 34.1 SSRIs, Tricyclics and related antidepressants

Group	Drugs
SSRIs (Selective serotonin reuptake inhibitors)	Citalopram, Escitalopram, Femoxetine, Fluoxetine, Fluvoxamine, Paroxetine, Sertraline
Tetracyclic antidepressants	Maprotiline, Mianserin
Tricyclic antidepressants	Amineptine, Amitriptyline, Amoxapine, Butriptyline, Clomipramine, Desipramine, Dibenzepin, Dosulepin, Doxepin, Imipramine, Lofepramine, Melitracen, Nortriptyline, Opipramol, Protriptyline, Trimipramine
Other antidepressants	Duloxetine, Iprindole, Mirtazapine, Milnacipran, Nefazodone, Reboxetine, Trazodone, Venlafaxine, Viloxazine

Bupropion + Antiepileptics

Carbamazepine decreases bupropion levels and increases the levels of its active metabolite hydroxybupropion. Phenobarbital and phenytoin are predicted to interact similarly. The concurrent use of bupropion and valproate has led to increased levels of valproate and hydroxybupropion, and hallucinations have been reported in patients taking both drugs. Hypomania has been reported in a patient taking bupropion and lamotrigine.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine, Phenobarbital, Phenytoin

One study found that carbamazepine at steady-state decreased the maximum plasma levels and AUC of bupropion and two of its metabolites (threohydrobupropion and erythrohydrobupropion) by about 81 to 96%. These two metabolites have only weak potential antidepressant activities. However, the AUC of another metabolite, hydroxybupropion (which has similar potency to the parent compound) was increased by 50% and its maximum plasma levels by 71%.¹ Two patients with bipolar illness have been described who were initially given bupropion 450 mg daily, later increased up to 600 mg daily. They had undetectable bupropion plasma levels while taking carbamazepine but their plasma levels of hydroxybupropion were markedly increased.²

What the sum of all these changes is likely to mean is uncertain, but good monitoring for any evidence of reduced efficacy and/or increased toxicity (due to the raised hydroxybupropion) is clearly needed. The same good monitoring would also be appropriate with phenytoin and phenobarbital, which would be expected to interact similarly, but clinical studies appear to be lacking.

(b) Lamotrigine

A study in 12 healthy subjects found that bupropion 150 mg twice daily did not affect the pharmacokinetics of a single 100-mg dose of lamotrigine.³ A 23-year-old patient with a DSM-IV diagnosis of major depression taking bupropion 400 mg daily had an improvement in mood when she was also given lamotrigine 25 mg at night, and there was further improvement in mood, decreased anxiety and increased energy when lamotrigine was increased to 50 mg daily for 3 weeks. However, when the dose of lamotrigine was increased to 75 mg daily she reported decreased sleep, increased energy, mood lability and increased spending, which was diagnosed as hypomania. The symptoms resolved over about 2 weeks when the lamotrigine dose was reduced to 50 mg at bedtime. Antidepressants in high doses or in combination can induce hypomania and in this case the effect was attributed to a potentiation of the effects of bupropion, caused by lamotrigine.⁴

(c) Sodium valproate

A study found that the AUC of hydroxybupropion, an active metabolite of bupropion, almost doubled when bupropion was given with valproate at steady-state, but the pharmacokinetics of the parent compound and the two other less active metabolites were unaffected.¹ An increase in valproate levels of almost 30% was seen in another report in one patient.² Visual and auditory hallucinations were reported in a patient given bupropion and valproate.⁵ The UK manufacturer recommends caution when using drugs which may inhibit bupropion metabolism, such as valproate.⁶ As valproate levels may also be increased by bupropion, good monitoring for evidence of increased adverse effects of both drugs would seem appropriate.

Bupropion + Antiretrovirals

Ritonavir, efavirenz and nelfinavir inhibit the cytochrome P450 isoenzyme CYP2B6 *in vitro* and may, theoretically, increase bupropion levels. However, an *in vivo* study suggests that ritonavir may decrease bupropion levels.

Clinical evidence, mechanism, importance and management

In vitro data¹ indicate that the antiretroviral drugs **efavirenz**, **nelfinavir** and **ritonavir** are capable of inhibiting the cytochrome P450 isoenzyme CYP2B6, which is the isoenzyme primarily involved in bupropion metabolism. The potential therefore exists for a drug interaction causing an increase in bupropion concentrations, which may lead to an increased risk of seizures. The US manufacturer of **ritonavir** predicts that the metabolism of bupropion might possibly be inhibited, leading to increased plasma levels and toxicity,² and they recommend caution with a possible decrease in bupropion dose.² However, a retrospective study identified 10 HIV-positive patients who had taken bupropion 150 mg once or twice daily together with **nelfinavir**, **ritonavir** or **efavirenz** for 3 weeks to 2 years (median 8 months) without having seizures, but note that the number of patients was small and the 2 patients who received **ritonavir** were only given 100 mg twice daily.³

In contrast, the manufacturers of bupropion report a study in healthy subjects, in which **ritonavir** 600 mg twice daily for 20 days decreased the AUC and maximum serum levels of bupropion by about 65% and 60%, respectively. The plasma levels of the active metabolites of bupropion were also decreased.⁴ This contrasting information suggests that further study is needed. In the meantime, patients given bupropion with **ritonavir** should be monitored for increased bupropion effects and decreased bupropion effects. It would seem prudent to start bupropion at the lowest recommended dose and titrate to effect.

Bupropion + Benzodiazepines and related drugs

Visual hallucinations have been seen in one patient given zolpidem with bupropion. Bupropion is contraindicated during the abrupt withdrawal from any drug known to be associated with seizures on withdrawal, particularly benzodiazepines and related drugs.

Clinical evidence, mechanism, importance and management

Visual hallucinations lasting 3 to 4 hours occurred in a 17-year-old boy who had been taking bupropion 450 mg daily for one month and **zolpidem** 5 to 10 mg daily for about 6 months, when he increased the **zolpidem** dose to 60 mg.¹ Note that the recommended dose of **zolpidem** is 10 mg daily and that **zolpidem** itself can cause psychiatric adverse effects such as hallucinations. Therefore an interaction is not established. Bupropion is contraindicated during abrupt withdrawal from any drug known to be associated with seizures on withdrawal, particularly benzodiazepines and benzodiazepine-like drugs.^{2,3}

3. Zyban (Bupropion hydrochloride). GlaxoSmithKline. US Prescribing information, August 2007.

Bupropion + Carbimazole

An isolated report describes acute liver failure in a patient taking bupropion and carbimazole.

Clinical evidence, mechanism, importance and management

A 41-year-old man treated for hyperthyroidism with carbimazole 15 mg daily and propranolol 10 mg daily for 5 years received a 10-day course of bupropion 150 mg daily to aid smoking cessation. Ten weeks after completing the course of bupropion he was admitted to hospital with severe jaundice, nausea, dyspepsia, lethargy, and epigastric discomfort persisting for 5 days. The only other medication he had taken was paracetamol (acetaminophen) 500 mg to 1 g daily for up to 2 days, about 2 weeks before admission. Both carbimazole and propranolol were discontinued. He developed acute liver failure and a rapid deterioration of renal function, complicated by sepsis and coagulopathy. Liver biopsy showed evidence of non-specific drug-induced acute liver injury. The patient died 19 days after the onset of symptoms. Both bupropion and carbimazole may cause liver damage. In this case the hepatotoxicity was attributed to bupropion or a combined toxic effect of bupropion and carbimazole. The potential for serious hepatotoxicity should be borne in mind if bupropion is given with other hepatotoxic drugs.¹

1. Khoo A-L, Tham L-S, Lee K-H, Lim G-K. Acute liver failure with concurrent bupropion and carbimazole therapy. *Ann Pharmacother* (2003) 37, 220–3.

Bupropion + Cimetidine

A randomised, open-label, crossover study in 24 healthy subjects found no evidence of any significant pharmacokinetic interaction between a single 300-mg dose of bupropion (sustained release preparation) and a single 800-mg dose of cimetidine.¹ No special precautions would seem to be necessary on concurrent use.

1. Kustra R, Corrigan B, Dunn J, Duncan B, Hsyu P-H. Lack of effect of cimetidine on the pharmacokinetics of sustained-release bupropion. *J Clin Pharmacol* (1999) 39, 1184–8.

Bupropion + Corticosteroids

A patient taking bupropion had a seizure after being given an intra-articular injection of methylprednisolone.

Clinical evidence, mechanism, importance and management

A case report describes a patient taking bupropion, who experienced a severe, prolonged seizure 24 hours after receiving **methylprednisolone** 30 mg for subacromial bursitis.¹ The author notes that there could be a risk of seizures in patients taking bupropion who are given prophylactic oral steroids.¹ This is in line with the manufacturers' suggestion that systemic steroids could increase the risk of seizures, see 'Bupropion + Miscellaneous', p.1206.

1. White P. Interaction of intra-articular steroids and bupropion. *Clin Radiol* (2002) 57, 235.

Bupropion + Guanfacine

A grand mal seizure in a child, which was attributed to an interaction between bupropion and guanfacine, was later identified as being more probably due to a bupropion overdose.

Clinical evidence, mechanism, importance and management

A 10-year-old girl, being treated for attention deficit hyperactivity disorder, was prescribed increasing doses of bupropion up to 100 mg three times daily, to which guanfacine, initially 500 micrograms twice daily then 500 micrograms three times daily, was added. Ten days later she had a grand mal seizure, which the author of the report attributed to an interaction between the two drugs.^{1,2} This was challenged in subsequent correspondence.³ Furthermore, 2 years later the author of the original report wrote to say that he had now discovered that the girl had in fact taken 500 mg of bupropion and 5 mg of guanfacine before the seizure took place, so that what happened was much more likely to have been due to an overdose of the bupropion than to an interaction with guanfacine.⁴ Bupropion is associated with seizures at high doses (see 'Bupropion + Miscella-

neous', p.1206). There is insufficient evidence to suggest that the concurrent use of these two drugs should be avoided.

4. Tilton P. Seizure after guanfacine plus bupropion: correction. *J Am Acad Child Adolesc Psychiatry* (2000) 39, 1341.

Bupropion + MAOIs and related drugs

Bupropion is contraindicated with MAOIs, although there is little clinical evidence of serious problems. Orthostatic hypotension occurred in a patient given bupropion and selegiline, and an isolated report describes hypertension in a patient receiving bupropion and the antibacterial linezolid, which has weak MAO inhibitory activity.

Clinical evidence, mechanism, importance and management

In an uncontrolled study, 10 patients were treated for major affective disorder (8 unipolar, 2 bipolar) with bupropion in daily doses of 225 to 450 mg and an MAOI: **isocarboxazid** (1 patient), **phenelzine** (5), **tranylcypromine** (2), and the MAO-B inhibitor **selegiline** (2). Four were transferred from the MAOI to bupropion without any washout period, and the other 6 were given both drugs concurrently. No untoward cardiovascular events occurred, except for one patient taking bupropion and **selegiline**, who experienced orthostatic hypotension. Notable weight loss occurred in two others when transferred from the MAOI to bupropion.¹ A Medline search (1962 to 2003) and review of published literature found no documented reports of hypertensive crises or fatalities when a stimulant drug (including bupropion) was cautiously added to an MAOI, although orthostatic hypotension and elevated blood pressure were reported.²

Despite very limited clinical evidence, the manufacturers of bupropion are apparently wary of a possible interaction with MAOIs because of the toxicity seen in studies in *animals* when **phenelzine** and bupropion were given concurrently.³ They contraindicate bupropion with MAOIs and recommend that at least 14 days should elapse between stopping irreversible MAOIs and starting bupropion.^{3,4} This precaution would therefore apply particularly to the older MAOIs (**phenelzine**, **tranylcypromine**, **isocarboxazid** etc). For reversible MAOIs such as **moclobemide**, the manufacturers advise that a 24-hour period is sufficient.⁴ Note also, that an isolated report describes severe intermittent intraoperative hypertension possibly due to an interaction between maintenance bupropion and **linezolid**, which had been started 24 hours previously for treatment of a resistant gram-positive infection.⁵ Linezolid is known to have weak MAOI properties, and, although concurrent use need not be avoided, this report therefore introduces a note of caution if both drugs are given together.

Bupropion + Methylphenidate

Isolated reports describe grand mal seizures in one patient and myocardial infarction in another, associated with bupropion and methylphenidate.

Clinical evidence, mechanism, importance and management

A 14-year-old boy taking methylphenidate 60 mg daily was additionally given bupropion 200 mg increased to 300 mg daily. The patient experienced grand mal seizures 4 weeks after the dosage increase, but remained seizure-free once the bupropion was discontinued.¹ Another report describes acute myocardial infarction in a 16-year-old boy associated with methylphenidate, bupropion and erythromycin. It was proposed that the erythromycin might have caused elevated levels of bupropion leading to a

hyperadrenergic state and this, together with the sympathetic effects of the methylphenidate, resulted in excessive vasospasm, leading to myocardial damage.²

The report of the myocardial infarction is isolated and of uncertain general significance. Note that the manufacturers of bupropion list stimulants as drugs that increase the risk of seizures with bupropion (see 'Bupropion + Miscellaneous', below) and this case adds weight to that warning.

1. Ickowicz A. Bupropion-methylphenidate combination and grand mal seizures. *Can J Psychiatry* (2002) 47, 790–1.
2. George AK, Kunwar AR, Awasthi A. Acute myocardial infarction in a young male on methylphenidate, bupropion, and erythromycin. *J Child Adolesc Psychopharmacol* (2005) 15, 693–5.

Bupropion + Miscellaneous

The manufacturers issue warnings about the concurrent use of bupropion with alcohol, amantadine, levodopa, drugs that can lower the convulsive threshold, drugs metabolised by the cytochrome P450 isoenzyme CYP2D6, drugs which affect CYP2B6, and also the use of nicotine.

Clinical evidence, mechanism, importance and management

(a) Alcohol

The manufacturers report rare adverse neuropsychiatric events or reduced alcohol tolerance in patients drinking alcohol during bupropion treatment. They recommend that the consumption of alcohol should be minimised or avoided.^{1,2} For comment on the increased risk of seizures with alcohol see (d), below.

(b) Antiparkinsonian drugs

The manufacturers say that the concurrent use of bupropion and **levodopa** or **amantadine** should be undertaken with caution because limited clinical data suggest a higher incidence of undesirable effects (nausea, vomiting, excitement, restlessness, postural tremor) in patients given bupropion with either drug. Good monitoring is therefore appropriate and patients should be given small initial bupropion doses, which are increased gradually.^{1,2}

(c) CYP2B6 substrates

The manufacturers advise caution if bupropion is used with drugs such as **clopidogrel**, **cyclophosphamide**, **ifosfamide**, **orphenadrine**, and **ticlopidine** as bupropion is metabolised to its major metabolite hydroxybupropion by CYP2B6 and these drugs are also metabolised by this isoenzyme.^{1,2} However, there is no evidence to suggest that this is a problem in practice.

(d) CYP2D6 substrates

The manufacturers of bupropion predict that it may inhibit the metabolism of drugs by the cytochrome P450 isoenzyme CYP2D6, which might result in a rise in their plasma levels. They name **haloperidol**, **risperidone**, **thioridazine**, **flecainide**, **propafenone**. The recommendation is that if any of these drugs is added to treatment with bupropion, doses at the lower end of the range should be used. If bupropion is added to existing treatment, decreased dosages should be considered.^{1,2} This seems a prudent precaution as bupropion raises the levels of 'desipramine', (p.1232), 'dextromethorphan', (p.1255), 'metoprolol', (p.838), all of which are metabolised by this isoenzyme.

(e) Drugs and circumstances that can lower the convulsive threshold

There is a small dose-related risk of seizures with bupropion. At a daily dose of 300 mg of the sustained-release formulation the risk is 0.1%, which increases to 0.4% at a dose of 450 mg of the immediate-release formulation, and increases tenfold between doses of 450 and 600 mg daily.² The manufacturers caution the use of other drugs that lower the convulsive threshold, the concern being that these drugs might further increase the risk of seizures. The UK¹ and US² manufacturers list **antipsychotics**, antidepressants (see 'SSRIs', (p.1215) and 'tricyclics', (p.1232)), 'systemic steroids', (p.1205), and **theophylline**. The UK manufacturers additionally list **antimalarials**, **tramadol**, **quinolones** and **sedating antihistamines**. A maximum dose of 150 mg of bupropion should be considered for patients prescribed such drugs.¹ Caution is also urged with regard to circumstances that may lower the convulsive threshold, including the use of **anorectics** or 'stimulants', (p.1205), excessive use of **alcohol** or **sedatives**, addiction to **cocaine** or **opiates**. Bupropion is contraindicated during abrupt withdrawal from **alcohol** or any drug known to be associated with seizures on withdrawal.^{1,2}

(f) Nicotine

Nicotine transdermal patches are reported not to affect the pharmacokinetics of bupropion or its metabolites.¹ The manufacturers of bupropion say that limited data suggest that giving up smoking is more easily achieved if bupropion is taken while using a nicotine transdermal system, but a higher rate of treatment-emergent hypertension has been noted with the combined treatment.^{1,2} They recommend weekly monitoring to check for any evidence of a blood pressure increase.¹ The same warning would also seem to be applicable to the use of nicotine in any other form (oral or nasal).

For a report of acute myocardial ischaemia attributed to combined use of bupropion, nicotine (from smoking) and pseudoephedrine, see 'Bupropion + Pseudoephedrine', below.

1. Zyban (Bupropion hydrochloride). GlaxoSmithKline UK. UK Summary of product characteristics, October 2006.
2. Zyban (Bupropion hydrochloride). GlaxoSmithKline. US Prescribing information, August 2007.

Bupropion + Pseudoephedrine

An isolated report describes acute myocardial ischaemia associated with bupropion, nicotine and pseudoephedrine.

Clinical evidence, mechanism, importance and management

A 21-year-old man presented in a hospital emergency department with severe chest pain, radiating pain into both arms and between the shoulder blades, diaphoresis and shortness of breath. Initially this was diagnosed as an acute myocardial infarction, but a later angiogram showed normal coronary arteries and it was concluded that these symptoms were due to acute myocardial ischaemia apparently brought on by the combined use of pseudoephedrine (9 tablets of 30 mg taken over the previous 3 days), bupropion for smoking cessation and **nicotine** (he smoked 25 cigarettes daily). The authors of the report postulate that all these drugs acted on the alpha receptors of the coronary arteries to cause vasospasm and acute ischaemia. He had been taking both drugs and erythromycin for 3 days, and had taken pseudoephedrine on numerous previous occasions without problems. He recovered fully.¹

This is an isolated case from which no general conclusions can be drawn, but some warning might be appropriate for patients who are at risk of coronary ischaemia. For comment on the use of **nicotine** with bupropion, see 'Bupropion + Miscellaneous', above.

Bupropion + St John's wort (*Hypericum perforatum*)

A brief report describes the development of mania in one patient, which was associated with the concurrent use of St John's wort and bupropion.¹ No general conclusions can be drawn from this isolated report.

Maprotiline + Hormonal contraceptives or Tobacco

Neither tobacco smoking nor the use of oral contraceptives affect the levels of maprotiline.

Clinical evidence, mechanism, importance and management

A study in women showed that, over a 28-day period, the use of oral contraceptives did not significantly affect the steady-state blood levels of maprotiline 75 mg given at night, nor was its therapeutic effectiveness

changed.¹ Smoking also has no effect on maprotiline efficacy and blood levels.^{1,2}

2. Holman RM. Maprotiline and cigarette smoking: an interaction study: clinical findings. In 'Depressive Illness — Far Horizons?' McIntyre JNM (ed), Cambridge Med Publ, Northampton 1982, p 66–7.

Maprotiline + Propranolol

Maprotiline toxicity, attributed to the concurrent use of propranolol, has been described in three patients.

Clinical evidence

A patient experienced maprotiline toxicity (dizziness, hypotension, dry mouth, blurred vision, etc.) after taking propranolol 120 mg daily for 2 weeks. His trough maprotiline levels had risen by 40%. The levels fell and the adverse effects disappeared when the propranolol was withdrawn.¹ Another patient taking propranolol 120 mg daily began to experience visual hallucinations and psychomotor agitation within a few days of starting to take maprotiline 200 mg daily.² Another man taking haloperidol, benzatropine, triamterene, hydrochlorothiazide and propranolol became disorientated, agitated and uncooperative, with visual hallucinations and incoherent speech, within a week of starting to take maprotiline 150 mg daily. These symptoms disappeared when all the drugs were withdrawn. Reintroduction of the antihypertensive drugs with haloperidol and desipramine proved effective and uneventful.³

Mechanism

Not understood. A suggested reason is that the propranolol reduces the blood flow to the liver so that the metabolism of the maprotiline is reduced, leading to its accumulation in the body.

Importance and management

Information seems to be limited to the cases cited. The general importance of this interaction is uncertain. The authors of one of the reports² say that simultaneous use is inadvisable, but on the basis of just three cases, and with no further information, this seems over-cautious.

Maprotiline + Risperidone

Risperidone appears to increase the plasma levels of maprotiline.

Clinical evidence, mechanism, importance and management

A 39-year-old patient with a schizodepressive disorder taking pipamperone and lorazepam, and taking maprotiline 175 mg daily for a severe depressive episode had plasma levels of maprotiline of 145 and 166 nanograms/mL after 4 and 6 weeks, respectively. After 8 weeks, she was given risperidone to treat acute psychotic symptoms. The dose of risperidone was titrated over 5 days up to 5 mg daily and the dose of pipamperone was increased from 40 to 80 mg at night. She had a rapid remission of the psychotic symptoms and almost complete remission of the depression, but gradually developed antimuscarinic adverse effects. Ten days after starting risperidone and with maprotiline at a dose of 150 mg daily, maprotiline plasma levels had increased to 266 nanograms/mL. The doses of maprotiline and risperidone were reduced to 100 mg and 3 mg daily, respectively, and this reduced the severity of the adverse effects.¹

Gradual increases in maprotiline levels over 6 to 7 weeks during concurrent risperidone therapy have been found in 2 other patients. One of the patients was also taking **nortriptyline**, but its levels were unaltered.¹

Maprotiline is mainly metabolised by the cytochrome P450 isoenzyme CYP2D6. The increased levels of maprotiline may be due to an inhibition of CYP2D6-mediated metabolism by risperidone.¹ This interaction is

unconfirmed but be aware of the possibility of an interaction if maprotiline adverse effects are troublesome.

1. Normann C, Lieb K, Walden J. Increased plasma concentration of maprotiline by coadministration of risperidone. *J Clin Psychopharmacol* (2002) 22, 92–4.

Maprotiline or Mianserin + Sympathomimetics

No adverse interaction would usually be expected in patients taking maprotiline or mianserin who are also given sympathomimetics (commonly used as vasopressors or in cough and cold remedies).

Clinical evidence, mechanism, importance and management

The pressor (increased blood pressure) responses to **tyramine** and **noradrenaline (norepinephrine)** in depressed patients remained virtually unchanged after 14 days of treatment with mianserin 60 mg daily.^{1–4} In 5 healthy subjects taking maprotiline the pressor response to **tyramine** was reduced threefold while the **noradrenaline** response remained unchanged.⁵

The practical importance of these observations is that, unlike the tricyclic antidepressants, no special precautions normally seem necessary if patients taking maprotiline or mianserin are given **noradrenaline** or other directly-acting sympathomimetics. Similarly, none of the dietary precautions against eating **tyramine**-rich foods or drinks, or any precautions against the administration of indirectly-acting sympathomimetics such as **phenylpropanolamine** in cough and cold remedies, would appear to be necessary.

Mianserin + Antiepileptics

Plasma levels of mianserin can be markedly reduced by the concurrent use of carbamazepine, phenobarbital or phenytoin.

Clinical evidence

A comparative study in 6 epileptics and 6 healthy subjects showed that **phenytoin** with either **phenobarbital** or **carbamazepine** markedly reduced the plasma levels of a single dose of mianserin.^{1,2} The mean half-life of mianserin was reduced by 75% (from 16.9 to 4.8 hours) and the AUC was reduced by 86%. Another study in 4 patients found that **carbamazepine** reduced serum mianserin levels by 70%.³ In another study 12 patients taking mianserin 60 mg daily were also given **carbamazepine** 400 mg daily for 4 weeks. Average plasma levels of total *S*-mianserin (the more potent enantiomer) and total *R*-mianserin were reduced by about 45% in the presence of **carbamazepine**.⁴

Mechanism

It seems probable that these antiepileptics increase the metabolism of mianserin by the liver, thereby increasing its loss from the body. Carbamazepine may increase the metabolism of mianserin by cytochrome P450 isoenzyme CYP3A4.⁴

Importance and management

Information seems to be limited to these studies, but the interaction appears to be established and of clinical importance. Monitor concurrent use and increase the dosage of mianserin as necessary. One study suggests that the dose of mianserin may need to be approximately doubled if carbamazepine 400 mg daily is added.⁴

Mirtazapine + Antidepressants

The manufacturers say that two weeks should elapse between taking an MAOI and mirtazapine. Mirtazapine combined with other serotonergic antidepressants may possibly increase the risk of bleeding and/or the serotonin syndrome. SSRIs may increase plasma levels of mirtazapine and there is a report of hypomania associated with combined use. The concurrent use of mirtazapine with amitriptyline may have a minor effect on the levels of both drugs.

Clinical evidence

(a) MAOIs

No adverse interactions have been reported between mirtazapine and the MAOIs^{1,2} but, to be on the safe side, the manufacturers say that the concurrent use of mirtazapine and MAOIs should be avoided both during and within two weeks of stopping treatment.^{2,3}

(b) SNRIs

For mention of the serotonin syndrome and an increased risk of bleeding in patients given mirtazapine and **venlafaxine**, see ‘SNRIs; Venlafaxine + Antidepressants’, p.1212.

(c) SSRIs

1. **Escitalopram**. For a report of bleeding associated with the combined use of escitalopram, mirtazapine and venlafaxine, see ‘SNRIs; Venlafaxine + Antidepressants’, p.1212.

2. **Fluoxetine**. There is an isolated report⁴ of the serotonin syndrome in a 75-year-old woman when fluoxetine 20 mg daily was discontinued and mirtazapine 30 mg daily started soon afterwards (exact interval not stated). Symptoms including dizziness, headache, nausea, dry mouth, anxiety, agitation, suicidal ideas and difficulty in walking occurred within hours of the first dose of mirtazapine. Symptoms worsened until mirtazapine was discontinued on day 5, after which an improvement was noticed. Fluoxetine was restarted on day 7.

3. **Fluvoxamine**. A 26-year-old woman with a 12-year history of anorexia nervosa, taking fluvoxamine 200 mg daily, developed symptoms consistent with the serotonin syndrome (tremors, restlessness, twitching, flushing, diaphoresis, nausea) about 4 days after starting mirtazapine 30 mg daily.⁵ A 17-year-old boy taking mirtazapine 30 mg daily experienced increased anxiety when fluvoxamine 100 mg daily was also given. Mirtazapine serum levels were increased threefold. In a second patient taking mirtazapine 15 mg daily, the addition of fluvoxamine 50 mg daily resulted in a fourfold increase in serum mirtazapine concentrations, accompanied by mood improvements.⁶

4. **Paroxetine**. A study in 21 healthy subjects given mirtazapine 30 mg, paroxetine 40 mg or a combination of both, daily for 9 days, found that paroxetine inhibited the metabolism of mirtazapine (AUC of mirtazapine increased by about 17%). Mirtazapine did not alter the pharmacokinetics of paroxetine. The results of psychometric assessments suggested that concurrent use of mirtazapine and paroxetine did not alter cognitive function, or cause major changes in mood or sleep, compared with the use of either drug alone.⁷

5. **Sertraline**. A woman taking sertraline 250 mg daily was also given mirtazapine 15 mg daily because of inadequately controlled depression. Within 4 days she developed hypomanic symptoms and she stopped taking the mirtazapine. The hypomania resolved within 3 days but her depression then recurred.⁸

(d) Tricyclic antidepressants

In a single-blind, crossover study involving 24 healthy subjects, mirtazapine 15 to 30 mg daily, **amitriptyline** 25 to 75 mg daily or both drugs were given for periods of 9 days and in addition, 8 subjects received placebo. **Amitriptyline** increased the maximum plasma levels of mirtazapine, in male subjects only, by 36%. Mirtazapine increased the maximum

plasma levels of **amitriptyline** in male subjects by 23% but in female subjects the maximum plasma levels were *decreased* by 23%. Other pharmacokinetic parameters and tolerability were not affected by concurrent use.⁹

Mechanism

The cytochrome P450 isoenzyme CYP2D6 is inhibited by fluoxetine and paroxetine and CYP1A2 is inhibited by fluvoxamine. Both of these isoenzymes are involved in the metabolism of mirtazapine, which may explain the raised mirtazapine levels reported.

SNRIs, SSRIs and mirtazapine affect serotonin transmission, which may lead to increased serotonin levels^{4,5} and therefore cause the symptoms described as the serotonin syndrome. For more about the serotonin syndrome see ‘Additive or synergistic interactions’, (p.9).

Importance and management

These isolated reports would seem to suggest that the combined use of mirtazapine and the SSRIs can lead to the serotonin syndrome. However, whether these are cases of the serotonin syndrome has been disputed.¹⁰ Low body weight and a decrease in total body fat may also have contributed in one case.⁵ This and other reports of anxiety and hypomania highlight the need for some caution during concurrent use. One manufacturer reported that, from postmarketing experience, it appears that the serotonin syndrome occurs very rarely in patients taking mirtazapine alone or in combination with SSRIs. They recommend that if the combination is required, dosage alterations should be made with caution and patients closely monitored for any signs of excessive serotonin stimulation.¹¹ Similar caution would also seem appropriate with SNRIs.

Mirtazapine + Antiepileptics

Carbamazepine and phenytoin can decrease the plasma levels of mirtazapine.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, healthy subjects were given **carbamazepine** (at steady state) with mirtazapine for 7 days. It was found that **carbamazepine** (an inducer of cytochrome P450 isoenzyme CYP3A4) decreased the AUC and maximum plasma levels of mirtazapine, by 63% and 44%, respectively, and increased the peak levels of demethylmirtazapine. Another related study found that mirtazapine did not affect the pharmacokinetics of **carbamazepine** (also a CYP3A4 substrate).¹

A study in 9 healthy subjects given **phenytoin** 200 mg daily for 17 days, and from day 11, mirtazapine 15 mg daily for 2 days then 30 mg daily for 5 days, found that mirtazapine had no effect on the steady-state pharmacokinetics of **phenytoin**.² In a second associated study, 8 healthy subjects were given mirtazapine 15 mg daily for 2 days then 30 mg daily for 15 days with **phenytoin** 200 mg daily on days 8 to 17. It was found that **phenytoin** (an inducer of CYP3A4) decreased the AUC and maximum plasma levels of mirtazapine by 47% and 33%, respectively.²

The manufacturers advise that if **carbamazepine** or other drugs that induce drug metabolism (such as **phenytoin**) are given with mirtazapine, the mirtazapine dose may have to be increased. Further, if treatment with an inducer is stopped, the mirtazapine dosage may have to be reduced.^{3,4} Although not specifically named, **phenobarbital** and **primidone** can also induce CYP3A4, and they therefore may interact similarly. Note that,

mirtazapine can lower the seizure threshold, and therefore its use should be carefully considered in patients taking these drugs for epilepsy.

Mirtazapine + Antipsychotics

Limited evidence suggests that risperidone does not appear to affect mirtazapine pharmacokinetics. Mirtazapine does not appear to interact to a clinically relevant extent with clozapine, olanzapine or risperidone.

Clinical evidence, mechanism, importance and management

A pilot study in 6 psychiatric patients taking **risperidone** 1 to 3 mg twice a day for 1 to 4 weeks followed by 2 to 4 weeks of combined treatment with mirtazapine 15 to 30 mg at night, found that mirtazapine did not affect the plasma levels of **risperidone** or its 9-hydroxy metabolite. Data from another patient suggest that giving **risperidone** with mirtazapine does not result in clinically relevant changes in the plasma levels of mirtazapine. Concurrent use did not appear to increase the incidence of adverse effects, but the number of patients was limited.¹

Another study in 24 schizophrenic patients investigated the effect of adding mirtazapine 30 mg at bedtime, for 6 weeks, to treatment with **clozapine** (9 patients), **risperidone** (8), or **olanzapine** (7). Mirtazapine had a negligible effect on the metabolism of all three drugs and the combination was well tolerated.²

Mirtazapine + Benzodiazepines

The sedative effects of mirtazapine may be increased by the benzodiazepines.

Clinical evidence, mechanism, importance and management

A single-dose study in 12 healthy subjects found that the pharmacokinetics of mirtazapine and **diazepam** were not affected by concurrent use, but **diazepam** further impaired the action of mirtazapine on objectively measured skill performance; the combined actions were mostly additive.¹ The impairment of psychomotor performance and learning caused by **diazepam** is increased by mirtazapine and therefore the manufacturers warn that the sedative effects of benzodiazepines in general may be potentiated by concurrent use with mirtazapine.^{2,3}

3. Remeron (Mirtazapine). Organon USA Inc. US Prescribing information, June 2005.

Mirtazapine + Cimetidine

Cimetidine increases the bioavailability of mirtazapine.

Clinical evidence, mechanism, importance and management

In a double-blind, crossover study in 12 healthy subjects, placebo or cimetidine 800 mg twice daily were given for 14 days. Mirtazapine 30 mg was given at night on days 6 to 12. Concurrent administration of cimetidine with mirtazapine increased the AUC and peak plasma levels of mirtazapine by 54% and 22%, respectively. Trough and average mirtazapine plasma levels, at steady state, were increased by 61% and 54%, respectively,

by cimetidine. Mirtazapine did not affect the pharmacokinetics of cimetidine.¹ The manufacturers advise that mirtazapine dosage may need to be reduced during concurrent treatment and increased when cimetidine treatment is stopped.^{2,3}

1. Sitsen JMA, Maris FA, Timmer CJ. Concomitant use of mirtazapine and cimetidine: a drug-drug interaction study in healthy male subjects. *Eur J Clin Pharmacol* (2000) 56, 389–94.
2. Zispin (Mirtazapine). Organon Laboratories Ltd. UK Summary of product characteristics, September 2005.
3. Mirtazapine. Genus Pharmaceuticals. UK Summary of product characteristics, May 2005.

Mirtazapine + Miscellaneous

Pharmacokinetic interactions may occur between mirtazapine and inhibitors or inducers of the cytochrome P450 isoenzyme CYP3A4.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inhibitors

Ketoconazole is reported to increase the peak plasma levels and AUC of mirtazapine by about 30% and 45%, respectively.¹ Mirtazapine is extensively metabolised and the cytochrome P450 isoenzyme CYP3A4 is thought to be responsible for the formation of the N-demethyl and N-oxide metabolites.² The manufacturers advise caution when potent inhibitors of CYP3A4 such as **azole antifungals**, **protease inhibitors**, **erythromycin**, or **nefazodone** are given with mirtazapine.^{1,2}

(b) Rifampicin (Rifampin)

The manufacturers advise that if drugs such as rifampicin, that induce drug metabolism, are given with mirtazapine, the mirtazapine dose may have to be increased. Further, if treatment with an inducer is stopped, mirtazapine dosage may have to be reduced.^{1,2}

1. Zispin (Mirtazapine). Organon Laboratories Ltd. UK Summary of product characteristics, September 2005.
2. Mirtazapine. Genus Pharmaceuticals. UK Summary of product characteristics, May 2005.

Nefazodone + Antidepressants

An isolated report describes a woman who developed marked and acute hypotension and weakness when desipramine, fluoxetine and venlafaxine were replaced by nefazodone. Isolated cases describe the serotonin syndrome in patients given nefazodone together, or sequentially, with another serotonergic drug (amitriptyline, paroxetine, St John's wort, or trazodone). The manufacturer recommended that nefazodone should not be used with an MAOI or within 14 days of discontinuing an MAOI. Note that, due to adverse hepatic effects nefazodone was widely withdrawn from the market.

Clinical evidence, mechanism, importance and management

(a) MAOIs

The manufacturer stated that nefazodone should not be used with an MAOI or within 2 weeks of discontinuing treatment with an MAOI. Conversely at least one week should be allowed after stopping nefazodone before starting an MAOI.¹ There appears to be no direct clinical evidence that an adverse interaction occurs.

(b) Reboxetine

Nefazodone may increase the plasma concentrations of reboxetine, see 'Reboxetine + Antidepressants', p.1210.

(c) SSRIs

Anecdotal evidence has suggested that patients who are switched from an SSRI to nefazodone may tolerate nefazodone poorly. Nevertheless, in a 12-week, open study involving 26 depressed patients, nefazodone 100 to 600 mg daily was equally well tolerated in the 13 patients who had discontinued an SSRI within 1 to 4 weeks compared with the other 13 patients who had received no antidepressant treatment for the previous 6 months. However, the patients who had recent exposure to an SSRI (within the previous 4 weeks) were given a washout period of 4 to 5 days for short half-life SSRIs or a full week washout period for **fluoxetine** prior to initiating

nefazodone.² Cases with specific SSRIs are discussed in the subsections below.

1. *Fluoxetine*. A woman with a one-year history of DSM-IV major depressive disorder and panic disorder was given daily doses of **desipramine** 75 mg, fluoxetine 20 mg, **venlafaxine** 37.5 mg, **clonazepam** 3 mg and **valproate** 400 mg with no adverse effects, except a dry mouth and sexual difficulties.³ The first three drugs were stopped and replaced by nefazodone 100 mg twice daily, started about 12 hours later. Within an hour of the first dose she felt very weak and her blood pressure was found to have fallen to only 90/60 mmHg (normally 120/90 mmHg). On waking the next day she had severe weakness, unsteady gait, pale, cool and sweaty skin, and paraesthesia. During the day she took two further 100-mg doses of nefazodone and her condition persisted and worsened with continuing hypotension. The nefazodone was discontinued and by the following day the weakness had improved, disappearing over the next few days. Within a week nefazodone 200 mg daily was reintroduced without problems.

The US manufacturer of nefazodone noted that nefazodone did not alter the pharmacokinetics of fluoxetine, but fluoxetine increased the AUC of the metabolites of nefazodone by up to 6-fold.¹ When nefazodone 200 mg twice was given to patients who had been taking fluoxetine for 7 days adverse effects (including headache and nausea) were increased. The manufacturers advised allowing a washout period of at least one week (more may be needed depending on dose and individual patient characteristics) to minimise these effects.¹ It therefore seems likely that fluoxetine was the interacting drug, but it is impossible to rule out a contribution from the other drugs.

2. *Paroxetine*. A woman was withdrawn from nefazodone after about 6 months of treatment, tapering over the last fortnight to 75 mg every 12 hours. Within a day she started taking paroxetine 20 mg daily and valproic acid, and was admitted the next day with muscle rigidity, uncoordinated muscle tremors, flailing arms and twitching legs, diaphoresis and agitation. This was identified as the serotonin syndrome. Rechallenge with paroxetine 7 days later was uneventful.⁴

(d) *St John's wort*

An elderly patient taking nefazodone 100 mg twice daily, developed symptoms similar to the serotonin syndrome within 3 days of starting to take St John's wort 300 mg three times daily. The symptoms included nausea, vomiting, and restlessness. She was asked to stop both medications, but continued the St John's wort and her symptoms gradually improved over a 1-week period.⁵

(e) *Trazodone*

A woman taking irbesartan for hypertension was also given nefazodone at an initial dosage of 200 mg daily, followed by 400 mg daily for about 5 weeks. Four days after the dose was increased to 500 mg daily, and trazodone 25 to 50 mg daily was also added as a hypnotic, she was admitted to hospital with a blood pressure of 240/120 mmHg. She was confused, had difficulty concentrating and had numbness on the right side of her lips, nose and right-hand fingers, flushed pruritic skin, nausea, and loose stools. On examination she was restless, hyperreflexic, and diaphoretic. Nefazodone and trazodone were discontinued. She recovered after treatment with labetalol, clonidine, amlodipine and increased irbesartan dosage.⁶ Although trazodone is used with other serotonergic drugs, it is important to be aware that this may lead to the potentially fatal 'serotonin syndrome', (p.9).

The manufacturers of trazodone say that *in vitro* drug metabolism studies suggest that there is a potential for drug interactions when trazodone is given with a potent CYP3A4 inhibitor such as nefazodone. There may be substantial increases in trazodone levels, with the potential for adverse effects, and a lower dose of trazodone should be considered.^{7,8} The UK manufacturer suggests avoidance of the combination where possible.⁷

(f) *Tricyclic antidepressants*

1. *Amitriptyline*. A woman who had been taking amitriptyline 10 mg at night and thioridazine developed the serotonin syndrome after taking half a tablet of nefazodone (dosage unspecified).⁹

2. *Desipramine*. The manufacturer of nefazodone reported that desipramine 75 mg daily did not change the pharmacokinetics of nefazodone 150 mg twice daily, but levels of the nefazodone metabolite, meta-chlorophenylpiperazine, were increased by up to 50%. There was no change in the pharmacokinetics of desipramine or its metabolite. No specific dosage adjustments were said to be required on concurrent use.¹

Nefazodone + Cimetidine

No changes in the steady-state pharmacokinetics of either cimetidine or nefazodone were seen in a week long study in 18 healthy subjects given cimetidine 300 mg four times daily and nefazodone 200 mg every 12 hours. No special precautions would seem to be necessary if both drugs are used concurrently.¹

- Barbhuiya RH, Shukla UA, Greene DS. Lack of interaction between nefazodone and cimetidine: a steady state pharmacokinetic study in humans. *Br J Clin Pharmacol* (1995) 40, 161–5.

Reboxetine + Antidepressants

The manufacturer of reboxetine recommends avoiding the concurrent use of potent CYP3A4 inhibitors as reboxetine levels may be increased. They also recommend avoiding the concurrent use of MAOIs, because of the possible risk of hypertensive crises. The concurrent use of fluoxetine and reboxetine does not appear to alter the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

A study in 30 healthy subjects given reboxetine 4 mg twice daily and fluoxetine 20 mg daily found no significant changes in the pharmacokinetics of either drug.¹

The manufacturer of reboxetine suggests that because **fluvoxamine** is a potent inhibitor of CYP3A4 it may increase plasma concentrations of reboxetine, and, because of the narrow therapeutic margin of reboxetine, concurrent use should be avoided.² However, note that **fluvoxamine** is more usually considered a potent inhibitor of CYP1A2 and is generally considered a weak inhibitor of CYP3A4.

No data seem to be available about the concurrent use of reboxetine with MAOIs and the manufacturer currently advises the avoidance of MAOIs because of the potential risk of a tyramine-like effect [hypertensive crisis].²

- Edronax (Reboxetine methanesulphonate). Pharmacia Ltd. UK Summary of product characteristics, May 2006.

Reboxetine + CYP3A4 inhibitors

Ketoconazole may inhibit the metabolism of reboxetine. The manufacturer therefore advises avoiding the concurrent use of azoles, macrolides and nefazodone.

Clinical evidence, mechanism, importance and management

A study in 11 healthy subjects found that **ketoconazole** 200 mg daily for 5 days increased the plasma concentrations of a single 4-mg dose of reboxetine, taken on the second day, by about 50%. Although the adverse effect profile of reboxetine was not altered, because reboxetine has a narrow therapeutic index it was concluded that caution should be used and a reduction in reboxetine dosage considered if it is given with **ketoconazole**.¹ The manufacturer recommends that potent inhibitors of CYP3A4, including **azoles, macrolides (erythromycin)** and **nefazodone** should not

be given with reboxetine.² For a list of clinically significant CYP3A4 inhibitors see 'Table 1.4', (p.6).

2. Edronax (Reboxetine methanesulphonate). Pharmacia Ltd. UK Summary of product characteristics, May 2006.

Reboxetine + Dextromethorphan

A study in 10 healthy subjects who were of the CYP2D6 extensive metaboliser phenotype (the most commonly found phenotype) found that the pharmacokinetics of reboxetine 8 mg daily were not affected by a single 30-mg dose of dextromethorphan.¹

1. Avenoso A, Facciola G, Scordo MG, Spina E. No effect of the new antidepressant reboxetine on CYP2D6 activity in healthy volunteers. *Ther Drug Monit* (1999) 21, 577–9.

Reboxetine + Miscellaneous

The manufacturer points out the possibility of hypokalaemia if reboxetine is used with potassium-depleting diuretics. Experience with reboxetine in elderly patients suggests it reduces potassium by up to 0.8 mmol/L, starting after 14 weeks of use. They also suggest that the concurrent use of reboxetine and ergot derivatives might result in increased blood pressure although no clinical data are quoted, and the concurrent use of lorazepam results in mild to moderate drowsiness and an orthostatic increase in heart rate, but no pharmacokinetic interaction occurs.¹

1. Edronax (Reboxetine methanesulphonate). Pharmacia Ltd. UK Summary of product characteristics, May 2006.

SNRIs + H₂-receptor antagonists

Cimetidine may increase duloxetine and venlafaxine plasma levels, which may lead to an increase in their adverse effects. Famotidine does not appear to interact with duloxetine.

Clinical evidence, mechanism, importance and management

(a) Duloxetine

The metabolism of duloxetine is reduced by cytochrome P450 isoenzyme CYP1A2 inhibitors and it has been suggested that drugs with this effect should be avoided (see 'fluvoxamine', (p.1212)). The US manufacturer of duloxetine specifically mentions **cimetidine** as an inhibitor of this enzyme¹ and therefore if duloxetine is given with **cimetidine** it would seem prudent to monitor duloxetine plasma levels and adverse effects. **Famotidine** has no effect on the rate or extent of absorption of a single 40-mg dose of duloxetine,¹ and it may therefore be a suitable alternative to **cimetidine** in patients taking duloxetine.

(b) Venlafaxine

Cimetidine 800 mg daily for 5 days was found to reduce the oral clearance of venlafaxine 50 mg every 8 hours by 40%, and to increase the AUC by 62% in 18 healthy subjects. It had no effect on the formation or elimination of the major active metabolite of venlafaxine, *O*-desmethylvenlafaxine (ODV). The total level of venlafaxine with ODV was found to be increased by only 13%. Thus the overall pharmacological activity of the two was only slightly increased by **cimetidine**² and no special precautions would seem to be necessary on concurrent use. However, the manufacturers of venlafaxine suggest that the elderly and those with hepatic impairment may possibly show a more pronounced effect, and such patients should be monitored more closely,^{3,4} for venlafaxine adverse effects.

4. Effexor XR (Venlafaxine hydrochloride). Wyeth Pharmaceuticals Inc. US Prescribing information, June 2007.

SNRIs + Propafenone

An isolated report describes psychosis, which occurred when a patient took venlafaxine with propafenone. Duloxetine may increase propafenone levels.

Clinical evidence, mechanism, importance and management

(a) Duloxetine

Duloxetine is a moderate inhibitor of the cytochrome P450 isoenzyme CYP2D6 and may increase the levels of drugs metabolised by CYP2D6 such as propafenone. The US manufacturer recommends that the concurrent use of duloxetine and propafenone should be approached with caution.¹

(b) Venlafaxine

A 67-year-old woman with bipolar disorder taking venlafaxine 300 mg daily experienced symptoms of paranoia, visual hallucinations and marked confusion, about 2 weeks after starting propafenone 600 mg daily for intermittent atrial fibrillation. Serum levels of venlafaxine had increased from 85 nanograms/mL to 520 nanograms/mL (upper level of normal range 150 nanograms/mL) and levels of the metabolite *O*-desmethylvenlafaxine had increased but were still within normal ranges. Venlafaxine was stopped for a few days then restarted at the lower dose of 75 mg daily and her mental condition (diagnosed as organic psychosis) improved. However, as she also had orthostatic hypotension her propafenone dosage was subsequently reduced to 300 mg daily, which necessitated dosage adjustments of venlafaxine because of a marked drop in serum level. When propafenone was again increased to 600 mg daily the venlafaxine had to be reduced to 50 mg daily.² The reasons for the interaction are not known, but venlafaxine is partly metabolised by CYP2D6 and propafenone may compete for this metabolic pathway. Information is limited to this single case report, and therefore its general significance is unclear..

2. Pfeffer F, Grube M. An organic psychosis due to a venlafaxine-propafenone interaction. *Int J Psychiatry Med* (2001) 31, 427–32.

SNRIs + St John's wort (*Hypericum perforatum*)

The serotonin syndrome has been reported in one patient taking venlafaxine and St John's wort.

Clinical evidence, mechanism, importance and management

An interaction between **venlafaxine** and St John's wort (*Hypericum perforatum*) was reported to the Centre Régional de Pharmacovigilance de Marseille involving a 32-year-old man who had been taking **venlafaxine** 250 mg daily for several months. He started taking St John's wort at a dose of 200 drops 3 times daily (usual dose up to 160 drops daily) and on the third day felt faint and anxious, and had symptoms of diaphoresis, shivering and tachycardia. The St John's wort was stopped and his symptoms resolved in 3 days without altering the dose of **venlafaxine**.¹ A search of Health Canada's database of spontaneous adverse reactions for the period 1998 to 2003 also found one case of suspected serotonin syndrome as a result of an interaction between **venlafaxine** and St John's wort.² **Duloxetine** would be expected to interact similarly. The manufacturers of both **duloxetine** and **venlafaxine** generally advise caution if they are given with drugs that affect the serotonergic neurotransmitter systems,^{3–5}

4. Effexor XR (Venlafaxine hydrochloride). Wyeth Pharmaceuticals Inc. US Prescribing information, June 2007.
5. Cymbalta (Duloxetine hydrochloride). Eli Lilly and Company Ltd. UK Summary of product characteristics, November 2006.

SNRIs; Duloxetine + Antidepressants

The manufacturers of duloxetine contraindicate the concurrent use of MAOIs because of the theoretical risk of the serotonin syndrome. Similarly they recommend caution with other serotonergic drugs, including the SSRIs, venlafaxine, and tryptophan. Fluvoxamine should not be used with duloxetine, because it markedly increases duloxetine levels. Low-dose paroxetine caused a modest increase in the duloxetine AUC, and fluoxetine is predicted to interact similarly.

Clinical evidence, mechanism, importance and management

The manufacturer advises caution if duloxetine is used with **SSRIs** (see below), 'tricyclic antidepressants', (p.1240), 'St John's wort', (p.1224), **venlafaxine**, or **tryptophan**, because the concurrent use of more than one serotonergic drug has rarely resulted in 'the serotonin syndrome', (p.9).^{1,2}

(a) SSRIs

1. *Fluvoxamine*. Fluvoxamine 100 mg daily increased the AUC of duloxetine five- to sixfold, and decreased its clearance by about 77% in 14 healthy subjects.¹⁻³ Similar increases in duloxetine plasma levels were found in 15 healthy subjects who were given fluvoxamine 50 to 100 mg daily and duloxetine 40 mg twice daily.⁴

Fluvoxamine is a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2, by which duloxetine is, in part, metabolised.³ Therefore concurrent use raises duloxetine levels. Although the clinical relevance of the increases in duloxetine levels have not been assessed, the manufacturer considers that the rise with fluvoxamine is so marked that the combination should be avoided.¹⁻³ The UK manufacturers specifically contraindicate concurrent use.^{1,2} Other SSRIs have minimal effects on this isoenzyme, and would therefore not be expected to interact by *this* route, but see also paroxetine, below.

2. *Paroxetine*. The concurrent use of paroxetine 20 mg daily and duloxetine 40 mg daily increased the AUC of duloxetine at steady state by about 60% in healthy subjects.³ Paroxetine is an inhibitor of CYP2D6, which has a role in duloxetine metabolism. Therefore concurrent use raises duloxetine levels. The rise in duloxetine levels with paroxetine 20 mg daily is probably not clinically relevant, but the manufacturer notes that greater increases would be expected with higher doses.³ Caution is warranted. Other SSRIs (notably **fluoxetine**) also inhibit this isoenzyme, and would therefore be expected to interact similarly.

(b) MAOIs

The manufacturers contraindicate the use of duloxetine with non-selective irreversible MAOIs, and for 14 days after discontinuing an MAOI, and at least 5 days should be allowed after stopping duloxetine before starting an MAOI. This is because of the possible risk of serotonin syndrome.¹⁻³ Although the risk would be lower with selective, reversible MAOIs such as **moclobemide**, the manufacturer still says concurrent use is not recommended.^{1,2}

5. Skinner MH, Kuan H-Y, Pan A, Sathirakul K, Knadler MP, Gonzales CR, Yeo KP, Reddy S, Lim M, Ayan-Oshodi M, Wise SD. Duloxetine is both an inhibitor and a substrate of cytochrome P4502D6 in healthy volunteers. *Clin Pharmacol Ther* (2003) 73, 170-7.

SNRIs; Duloxetine + Miscellaneous

Ciprofloxacin, enoxacin and quinidine are predicted to raise duloxetine levels. Duloxetine is predicted to raise the levels of flecainide and thioridazine. Due to the theoretical risk of serotonin syndrome, the manufacturers of duloxetine recommend caution

with other serotonergic drugs or other CNS depressants. The pharmacokinetics of duloxetine were not affected by antacids.

Clinical evidence, mechanism, importance and management

(a) Antacids

Aluminium/magnesium-containing antacids had no effect on the rate or extent of absorption of a single 40-mg dose of duloxetine.¹⁻³ No special precautions appear to be necessary on concurrent use.

(b) CYP1A2

1. *Inducers*. Population pharmacokinetic studies have shown that **smokers** have almost 50% lower plasma concentrations of duloxetine, when compared with **non-smokers**.¹ The clinical significance of this finding is unclear.

2. *Inhibitors*. 'Fluvoxamine', (above), a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2, markedly increases duloxetine levels. The manufacturers predict that some **quinolones** (they name **ciprofloxacin** and **enoxacin**) will have the same effect and suggest that their concurrent use with duloxetine should be avoided.¹⁻³ For a list of clinically significant CYP1A2 inhibitors, see 'Table 1.2', (p.4).

(c) CYP2D6

1. *Inhibitors*. Paroxetine, an inhibitor of the cytochrome P450 isoenzyme CYP2D6, increases duloxetine levels. The manufacturer suggests that other CYP2D6 inhibitors will interact similarly, and specifically names **quinidine**.³ For a list of clinically significant CYP2D6 inhibitors, see 'Table 1.3', (p.6).

2. *Substrates*. Duloxetine is a moderate inhibitor of the cytochrome P450 isoenzyme CYP2D6. The manufacturers advise caution if duloxetine is given with drugs that are predominantly metabolised by CYP2D6 and have a narrow therapeutic index,¹⁻³ including **flecainide**, and **thioridazine** which is contraindicated in the US because of the risk of arrhythmias with elevated levels of this drug.³ This seems prudent as the CYP2D6 inhibitory effects of duloxetine have been shown to be modest (see 'tolterodine', (p.1289) and 'desipramine', (p.1240)), and changes of this size may be clinically significant with narrow therapeutic index drugs.

(d) Serotonergic drugs

Because the concurrent use of more than one serotonergic drug has rarely resulted in 'the serotonin syndrome', (p.9), the manufacturer advises caution if duloxetine is used with 'tricyclic antidepressants', (p.1240), or other 'antidepressants', (above), **triptans**, **tramadol**, and **pethidine**.^{1,2}

1. Cymbalta (Duloxetine hydrochloride). Eli Lilly and Company Ltd. UK Summary of product characteristics, November 2006.
2. Yentreve (Duloxetine hydrochloride). Eli Lilly and Company Ltd. UK Summary of product characteristics, November 2006.
3. Cymbalta (Duloxetine hydrochloride). Eli Lilly and Company. US Prescribing information, May 2007.

SNRIs; Venlafaxine + Antidepressants

Bupropion may increase venlafaxine plasma levels. Antimuscarinic adverse effects can develop in patients taking fluoxetine and venlafaxine. Venlafaxine combined with other serotonergic antidepressants may increase the risk of bleeding and/or the serotonin syndrome. The serotonin syndrome has also been reported in patients taking venlafaxine with mirtazapine or trazodone; some of these patients were also taking other serotonergic drugs.

Clinical evidence and mechanism

(a) Bupropion

Bupropion was found to increase venlafaxine plasma levels and decrease the levels of the metabolite, O-desmethylvenlafaxine, in 7 patients who had been given venlafaxine alone for a minimum of 6 weeks and then with bupropion SR 150 mg daily for a further 8 weeks.¹

For a report of worsening symptoms of the serotonin syndrome when venlafaxine was given with bupropion and sertraline, see 'SSRIs + Bupropion', p.1215.

(b) MAOIs

For reports of the serotonin syndrome with venlafaxine and MAOIs, see 'MAOIs or RIMAs + Venlafaxine', p.1156.

(c) *Mirtazapine*

The serotonin syndrome occurred in a patient given extended-release venlafaxine 75 mg daily and mirtazapine 30 mg daily, during cross-tapering of the two drugs (reducing mirtazapine dose and starting venlafaxine).² Another case occurred when tramadol was given to a patient taking venlafaxine and mirtazapine.³

For a report of haemorrhages associated with the use of mirtazapine, venlafaxine and escitalopram, see (d) below.

(d) *SSRIs*

1. *Antimuscarinic adverse effects.* A woman taking **fluoxetine** 20 mg and clonazepam 1 mg daily developed blurred vision, dry mouth, constipation, dizziness, insomnia and a hand tremor within a week of starting to take venlafaxine 37.5 mg daily. These symptoms worsened by the second week and persisted until the venlafaxine was stopped.^{4,5} Four patients (aged 21, 24, 51 and 70) taking **fluoxetine** developed antimuscarinic adverse effects (constipation, blurred vision, urinary retention and dry mouth) within a week of starting venlafaxine, which persisted until the venlafaxine was stopped.⁶ A 61-year-old man taking **fluoxetine** 20 mg daily had extreme difficulty in urinating within 2 days of starting to take venlafaxine 37.5 mg daily. The effect became intolerable after 10 days but no other obvious antimuscarinic adverse effects (blurred vision, constipation, dry mouth, tachycardia) were seen. This patient had some prostate enlargement and had previously had some moderate urinary problems while taking **fluoxetine** and nortriptyline.^{5,7}

One possible explanation is that **fluoxetine** inhibits the cytochrome P450 isoenzyme CYP2D6, which is concerned with the metabolism of venlafaxine, leading to an increase in its serum levels and in its usually minimal antimuscarinic adverse effects.^{4,7} An alternative explanation is that these adverse effects are due to an adrenergic mechanism.⁷

2. *Haemorrhages.* A 60-year-old man experienced haemorrhages from his nose and rectum one week after venlafaxine 150 mg daily and **mirtazapine** 15 mg daily were added to treatment with **escitalopram** 20 mg daily. The bleeding progressively worsened during the following 3 weeks and then the patient reduced the dosages to **escitalopram** 15 mg, **mirtazapine** 7.5 mg and venlafaxine 100 mg daily, and the bleeding decreased over the following week. He continued weekly tapering of the medications and the bleeding progressively decreased until it stopped when the doses were **escitalopram** 5 mg, **mirtazapine** 7.5 mg and venlafaxine 37.5 mg daily. Previous treatments with these three drugs used alone had not caused haemorrhages and it was suggested that the bleeding was due to the combined drugs causing high levels of serotonin.⁸

3. *Serotonin syndrome.* A 39-year-old woman with depression and panic attacks was taking cimetidine, trazodone, clonazepam and **fluoxetine**. Within 24 hours of abruptly stopping clonazepam and **fluoxetine** and starting lorazepam and venlafaxine, she developed the serotonin syndrome (diaphoresis, tremors, slurred speech, myoclonus, restlessness and diarrhoea).⁹

A 21-year-old woman whose long-term treatment with **paroxetine** was stopped a week before starting venlafaxine (37.5 mg daily for 5 days then 75 mg daily for 2 days) developed vomiting, dizziness, incoordination, anxiety and electric shock sensations in her arms and legs within 3 days of starting venlafaxine. She stopped venlafaxine after 7 days of treatment, but symptoms persisted for 5 days until she was treated with cyproheptadine.¹⁰

A 75-year-old man developed the serotonin syndrome after discontinuing **sertraline** and starting venlafaxine 48 hours later, although the onset of symptoms did not develop until after 14 days of therapy with venlafaxine. The venlafaxine was discontinued and the symptoms subsided over a 6-day period. However, 2 weeks later **amitriptyline** was introduced and a recurrence of symptoms was seen over the following 48 hours. The author commented that any drug with serotonergic activity might potentially cause a serotonin syndrome when serotonin transmission has been enhanced by concomitant or recently withdrawn serotonergic drugs.¹¹ Other reports of the serotonin syndrome have been described with venlafaxine and 'amitriptyline', (p.1240), and 'sertraline and bupropion', (p.1215).

(e) *Trazodone*

A 50-year-old HIV-positive man, who was receiving methadone for opioid dependence, developed signs of the serotonin syndrome 18 days after starting to take extended-release venlafaxine (dose increased to 225 mg

daily over 7 days) and trazodone 100 mg at bedtime. His clinical status improved rapidly over 24 hours when all medications were discontinued. The serotonin syndrome was thought to have been precipitated by the combination of venlafaxine and trazodone, both of which inhibit the re-uptake of serotonin, but methadone may have also been a contributing factor. He was not taking any concurrent medication for his HIV infection.¹²

(f) *Tricyclic antidepressants*

For reports of increased antimuscarinic effects and the serotonin syndrome, see 'Tricyclic antidepressants + SNRIs; Venlafaxine', p.1240.

Importance and management

Information about the adverse antimuscarinic adverse effects due to an interaction between fluoxetine and venlafaxine seems to be limited to the reports cited, all by the same author. The incidence is not known, but if venlafaxine and fluoxetine are given concurrently, be alert for any evidence of increased antimuscarinic adverse effects (such as dry mouth, blurred vision and urinary retention). It may be necessary to withdraw one or other of the two drugs.

Also note that the development of the serotonin syndrome has been attributed to the sequential use of an SSRI (fluoxetine, paroxetine, or sertraline) and venlafaxine. It has also occurred with concurrent use of venlafaxine and mirtazapine or trazodone. The manufacturers of venlafaxine caution its use with other drugs that affect serotonergic transmission, such as the SSRIs^{13,14} because of the potential risks of the serotonin syndrome. For more about the serotonin syndrome see 'Additive or synergistic interactions', (p.9).

SNRIs; Venlafaxine + Antihypertensives

No important interactions normally appear to occur with venlafaxine and ACE inhibitors, beta blockers or diuretics, but an isolated report suggests that propranolol, particularly if it is given with other CYP2D6 substrates, may affect the metabolism of venlafaxine.

Clinical evidence, mechanism, importance and management

During the phase II and III clinical studies of venlafaxine, 267 patients were also taking antihypertensive medications, including **beta blockers**, **diuretics**, **ACE inhibitors** (specific drugs were not named in the report) without any reported adverse interactions, but note that no specific pharmacokinetic studies were undertaken.¹ A case study reports high trough plasma levels of venlafaxine and low levels of O-desmethylvenlafaxine in a patient also taking **propranolol** and mianserin.² It was thought that these drugs competitively inhibited the metabolism of venlafaxine by the cyto-

chrome P450 isoenzyme CYP2D6. The general significance of this report is unclear.

SNRIs; Venlafaxine + Co-amoxiclav

An isolated case of the serotonin syndrome has been attributed to the concurrent use of venlafaxine and co-amoxiclav.

Clinical evidence, mechanism, importance and management

A 56-year-old man taking venlafaxine 37.5 mg twice daily for 10 months was given a course of co-amoxiclav (**amoxicillin** with **clavulanate**) 375 mg three times daily to treat gingivitis and a dental abscess. Within 3 hours of a dose of co-amoxiclav he developed tingling in the tip of his tongue, intense paraesthesia in the fingers, severe abdominal cramps, profuse diarrhoea, cold sweats, tremor and uncontrollable shivering. He was also agitated and frightened, but not confused. The symptoms lasted for 6 hours and were initially assumed to be due to gastroenteritis. However, 2 months later while still taking venlafaxine, he developed identical symptoms after a single dose of co-amoxiclav, which was then diagnosed as the serotonin syndrome. The patient had taken co-amoxiclav without problem when not taking venlafaxine and after the second episode continued venlafaxine without further episodes of the serotonin syndrome. Venlafaxine is metabolised mainly by the cytochrome P450 isoenzyme CYP2D6, but co-amoxiclav is not a substrate for this isoenzyme and its ability to inhibit CYP2D6 is not known. It is probable that many patients have received both venlafaxine and co-amoxiclav without adverse effects, so the general importance of this isolated report is unknown, but it seems likely to be small.¹

1. Connor H. Serotonin syndrome after single doses of co-amoxiclav during treatment with venlafaxine. *J R Soc Med* (2003) 96, 233–4.

SNRIs; Venlafaxine + Dexamfetamine

An isolated case of the serotonin syndrome has been attributed to the concurrent use of dexamfetamine and venlafaxine.

Clinical evidence, mechanism, importance and management

A 32-year-old patient taking dexamfetamine 5 mg three times daily for adult attention deficit hyperactivity disorder (ADHD) presented with marked agitation, anxiety, shivering and tremor 2 weeks after also starting to take venlafaxine 75 mg to 150 mg daily. Other symptoms included generalised hypertonia, hyperreflexia, frequent myoclonic jerking, tonic spasm of the orbicularis oris muscle, and sinus tachycardia. His symptoms resolved completely when both drugs were withdrawn and cyproheptadine, to a total dose of 32 mg over 3 hours, was given. Dexamfetamine was restarted after 3 days. It was suggested that the combination of serotonin re-uptake blockade and either presynaptic release of serotonin or monoamine oxidase inhibition by dexamfetamine could cause increased serotonin in the CNS. Caution is advised when dexamfetamine is given with venlafaxine.¹ For more information about the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

SNRIs; Venlafaxine + Jujube (*Ziziphus jujuba*)

An isolated report describes an acute serotonin reaction when venlafaxine was given with a Chinese herbal remedy, jujube (sour date nut).

Clinical evidence, mechanism, importance and management

A 40-year-old woman with intermittent depression took jujube 500 mg daily (**sour date nut**; **suanzaoren**; *Ziziphus jujuba*), prescribed by a traditional Chinese healer, for several weeks, with minor improvement. She

was then prescribed venlafaxine 37.5 mg daily by a psychiatrist, but approximately one hour after taking the first dose of venlafaxine together with the jujube she became agitated, restless, nauseated, dizzy and ataxic, and subsequently collapsed. She showed symptoms of a severe acute serotonin reaction with some anaphylactic features, which improved over the following 8 hours. She stopped taking the jujube and subsequently took venlafaxine 150 mg daily for 1 month without adverse effects.¹ This highlights the need for physicians to ask patients about the use of herbal remedies and to advise their discontinuation before prescribing antidepressant drugs if there is any possibility of an interaction.

1. Stewart DE. Venlafaxine and sour date nut. *Am J Psychiatry* (2004) 161, 1129–30.

SNRIs; Venlafaxine + Metoclopramide

An isolated case of the serotonin syndrome has been attributed to the concurrent use of metoclopramide and venlafaxine.

Clinical evidence, mechanism, importance and management

A 32-year-old woman with depression who had been taking venlafaxine 225 mg daily in divided doses for 3 years was admitted to hospital after a fall. She developed a movement disorder and a period of unresponsiveness after being given a 10-mg intravenous dose of metoclopramide. After a second dose of metoclopramide the symptoms recurred and were associated with confusion, agitation, fever, diaphoresis, tachypnoea, tachycardia, and hypertension. The symptoms were consistent with the serotonin syndrome, with a serious extrapyramidal movement disorder. The venlafaxine was withheld and she was given diazepam. The symptoms resolved over the next two days, after which she continued to take venlafaxine.¹ Information seems to be limited to this report, and the general significance of this interaction is unclear.

SNRIs; Venlafaxine + Miscellaneous

Theoretically the metabolism of venlafaxine may be inhibited by CYP2D6 inhibitors or substrates such as diphenhydramine, melperone, quinidine or thioridazine. CYP3A4 inhibitors such as ketoconazole may also have some effect. An isolated case describes a hypertensive crisis associated with venlafaxine and disulfiram. The manufacturers predict that the use of triptans with venlafaxine may have additive effects on serotonin, which could lead to the serotonin syndrome.

Clinical evidence, mechanism, importance and management

(a) CYP2D6 inhibitors or substrates

Venlafaxine is primarily metabolised to its active metabolite *O*-desmethylvenlafaxine by CYP2D6.^{1,2} Some studies suggest that the metabolism of venlafaxine may be inhibited by inhibitors or substrates of CYP2D6 such as **diphenhydramine**,³ **melperone**,⁴ **quinidine**,⁵ or **thioridazine**,⁶ especially in patients who are extensive metabolisers (i.e. have normal levels) of this isoenzyme.^{3,6} However, the US manufacturer says that the concurrent use of these drugs would produce plasma levels of venlafaxine similar to those seen in patients who are genetically CYP2D6 poor metabolisers (about 5 to 10% of general population) and therefore no dosage adjustment is necessary.² However, the UK manufacturer suggests caution particularly if venlafaxine, another drug that inhibits CYP3A4, is also given to patients who are poor metabolisers of CYP2D6, see below under CYP3A4 inhibitors.¹

(b) CYP3A4 inhibitors

CYP3A4 plays a minor role in the metabolism of venlafaxine to the inactive metabolite *N*-desmethylvenlafaxine.⁷ However, the manufacturers suggest that in poor CYP2D6 metabolisers, CYP3A4 could become more important, and clinically significant drug interactions with CYP3A4 inhibitors may then occur.¹ In one study involving CYP2D6 extensive and poor metabolisers, **ketoconazole** (a potent CYP3A4 inhibitor) increased the plasma levels of venlafaxine and *O*-desmethylvenlafaxine (AUCs increased 36% and 26%, respectively). However, the response in poor

metabolisers was erratic with 3 out of 6 displaying marked increases in AUC (81%, 126% and 206%, respectively) whilst the other 3 showed little or no change.⁷

(c) Disulfiram

An isolated report describes a hypertensive crisis associated with a low dose of venlafaxine (75 mg daily). It was thought that the concurrent use of disulfiram might have increased the toxicity of venlafaxine by interfering with its metabolism via CYP3A4. However disulfiram predominantly inhibits CYP2E1 and has not been reported to significantly affect CYP3A4. Note that disulfiram may provoke hypertension through its interaction with alcohol; however the authors state they found no evidence of a reaction with alcohol in this patient.⁸ This is an isolated and unexplained case, which is of unknown general significance.

(d) Triptans

The manufacturers caution the use of drugs that affect serotonergic transmission, such as the triptans.^{1,2} This is because of the possible risks of the serotonin syndrome. For more about the serotonin syndrome see 'Additive or synergistic interactions', (p.9). This interaction has been seen, rarely, to occur with a number of other serotonergic drugs and venlafaxine, which gives weight to this prediction.

SNRIs; Venlafaxine + Tramadol

Two cases of the serotonin syndrome have been reported when tramadol was given with venlafaxine; one patient was also receiving mirtazapine. Fatal seizures occurred in an alcoholic man receiving tramadol, venlafaxine, quetiapine and trazodone.

Clinical evidence, mechanism, importance and management

A 47-year-old man who had been stable taking venlafaxine 300 mg daily and mirtazapine 30 mg daily for 4 months was given tramadol, titrated to 300 mg daily over 4 weeks, without adverse effects. However, approximately 7 weeks after increasing the dose of tramadol to 400 mg daily he experienced agitation, confusion, severe shivering, diaphoresis, myoclonus, hyperreflexia, mydriasis, and tachycardia. His symptoms resolved over 36 hours after all medications were discontinued and did not recur when venlafaxine and mirtazapine were restarted without tramadol.¹ A 65-year-old woman who had been taking venlafaxine 100 mg daily for 3 weeks, developed symptoms of the serotonin syndrome 3 days after tramadol 300 mg daily was added. The symptoms resolved completely 3 days after venlafaxine withdrawal, when tramadol was also withdrawn. No symptoms occurred on rechallenge with venlafaxine alone, 2 weeks later.² A 36-year-old alcoholic died after developing seizures while taking tramadol several drugs, including venlafaxine, trazodone and quetiapine, all of which interact with the neurotransmitter serotonin. It was thought that the combination of these drugs and alcohol withdrawal lowered the seizure threshold.³

SSRIs + Azoles

Anorexia developed in a patient taking fluoxetine when itraconazole was started, and it disappeared when the itraconazole was stopped. The pharmacokinetics of citalopram in healthy subjects were not affected by ketoconazole. The clearance of escitalopram was not affected by ketoconazole in an *in vitro* study.

Clinical evidence, mechanism, importance and management

(a) Citalopram or Escitalopram

In a double-blind, placebo-controlled, crossover study in 18 healthy subjects, a single 200-mg dose of **ketoconazole** did not affect the pharmacokinetics of citalopram 40 mg.¹ **Ketoconazole** is a potent inhibitor of cytochrome P450 isoenzyme CYP3A4, which, in part, metabolises citalopram, but as several other cytochrome P450 isoenzymes are also involved in citalopram metabolism it would seem that inhibition of only one pathway does not result in clinically significant effects. Similarly, escitalopram is metabolised by CYP3A4, CYP2C19, and CYP2D6, and it has been suggested that its clearance is also unlikely to be affected by impaired activity of only one CYP isoform.²

(b) Fluoxetine

A man taking fluoxetine 20 mg daily, diazepam and several anti-asthma drugs (salbutamol (albuterol), salmeterol, budesonide, theophylline) was given **itraconazole** 200 mg daily for allergic bronchopulmonary aspergillosis. Within 1 to 2 days he developed anorexia without nausea. He stopped the **itraconazole** after a week, and the anorexia resolved 1 to 2 days later. The author of the report suggested that **itraconazole**, a potent enzyme inhibitor, increased the levels of the fluoxetine metabolite, nor-fluoxetine, which resulted in the anorexia.³ Anorexia is a recognised adverse effect of fluoxetine. However, drug levels were not taken, so this suggestion has not been confirmed.

This report and the conclusions reached are uncertain, but they draw attention to the possibility of an interaction between fluoxetine and **itraconazole**. Consider this interaction if fluoxetine adverse effects are troublesome.

SSRIs + Bupropion

There are isolated reports of psychosis, mania and seizures associated with the use of bupropion and fluoxetine and an isolated report of the serotonin syndrome with bupropion and sertraline. Hypersexuality has also been reported with bupropion and fluoxetine or sertraline.

Clinical evidence

(a) Fluoxetine

The day after stopping fluoxetine 60 mg daily, a 41-year-old man was started taking 75 mg and later 100 mg of bupropion three times daily. After 10 days he became edgy and anxious and after 12 days he developed myoclonus. After 14 days he became severely agitated and psychotic, with delirium and hallucinations. His behaviour returned to normal 6 days after the bupropion was stopped.¹ Another patient taking lithium carbonate for bipolar disorder developed anxiety, panic and eventually mania a little over a week after stopping fluoxetine and starting bupropion.²

A further patient developed a grand mal seizure after being given fluoxetine and bupropion 300 mg daily.³

A 35-year old woman taking fluoxetine 40 mg daily was given low-dose bupropion (100 mg daily) to treat fluoxetine-induced sexual dysfunction. Despite a good initial response, hypersexuality developed leading to discontinuation of bupropion.⁴

(b) Sertraline

A 62-year-old woman treated with therapeutic doses of bupropion and sertraline experienced upper extremity tremor, clumsiness and gait difficulties, with fluctuating symptoms of confusion, forgetfulness, and alternating agitation and lethargy, which started after a few days on this regimen. Venlafaxine was then added and the clinical picture worsened with deterioration of mental status, hallucinations, insomnia, myoclonic jerks, postural and balance difficulties, incoordination and incontinence. The medications were discontinued and the symptoms, which were indicative of the serotonin syndrome, gradually resolved.⁵

An isolated case describes spontaneous orgasm with the combined use of bupropion and sertraline. Bupropion had been successfully used to treat SSRI-induced impaired sexual function, but after 6 weeks of combined therapy she experienced a sudden-onset, spontaneous orgasm; this occurred again on rechallenge with bupropion.⁶

Mechanism

Several mechanisms have been proposed. Bupropion inhibits the cytochrome P450 isoenzyme CYP2D6, which may interfere with the metabolism of some SSRIs, causing an increase in plasma levels and increased toxicity. However, a small study found no statistically significant changes in plasma levels of fluoxetine or paroxetine when combined with bupropion.⁷ An *in vitro* study demonstrated that several SSRIs (paroxetine, sertraline, norfluoxetine, and fluvoxamine) could inhibit CYP2B6, the isoenzyme involved in bupropion hydroxylation,⁸ and in one of the cases described above it was suggested that residual fluoxetine may have inhibited the metabolism of bupropion, leading to toxic levels.¹ A pharmacodynamic mechanism has also been proposed. Bupropion can cause seizures and antidepressants may further lower the seizure threshold, see 'Bupropion + Miscellaneous', p.1206.

Importance and management

Information is very limited but these reports suggest that if concurrent or sequential use is thought appropriate, the outcome should be well monitored and reduced doses should be considered. The UK and US manufacturers recommend that drugs that are metabolised by CYP2D6 should be given with bupropion with caution and initiated at the lower end of the dose range. If bupropion is added to the treatment of a patient already taking a drug metabolised by CYP2D6, the need to decrease the dose of this drug should be considered.^{9,10} The UK manufacturers specifically name paroxetine and the US manufacturers additionally name fluoxetine and sertraline. In addition, the manufacturers advise extreme caution if bupropion is given with antidepressants that lower seizure threshold¹⁰ and recommend reducing the dose of bupropion to a maximum of 150 mg daily.⁹

SSRIs + Cocaine

An isolated report describes a fatal multiple drug intoxication involving citalopram and cocaine. Animal studies have suggested that SSRIs may potentiate the pro-convulsive effects of cocaine.

Clinical evidence, mechanism, importance and management

An isolated report describes a fatal multiple drug intoxication involving citalopram and cocaine. It was suggested that SSRIs and cocaine bind to the same receptor site and their concurrent use may have an additive effect through inhibition of serotonin reuptake. The patient also took other drugs including omeprazole, which may have further potentiated the effects of citalopram.¹

A study in *animals* suggested that most SSRIs potentiate cocaine-induced convulsions, although sertraline appeared to have no effect on convulsions or lethality.²

- O'Dell LE, George FR, Ritz MC. Antidepressant drugs appear to enhance cocaine-induced toxicity. *Exp Clin Psychopharmacol* (2000) 8, 133–41.

SSRIs + Cyproheptadine

Several reports suggest that cyproheptadine can oppose the anti-depressant effects of fluoxetine, and another describes the same effect with paroxetine.

Clinical evidence

(a) Fluoxetine

Three depressed men complained of anorgasmia when taking fluoxetine. When this was treated with cyproheptadine their depressive symptoms returned, decreasing again when cyproheptadine was stopped.¹ Two women also complained of anorgasmia within 1 to 3 months of starting to take fluoxetine 40 to 60 mg daily for bulimia nervosa. When cyproheptadine was added to treat this sexual dysfunction, the urge to binge on food returned in both of them and one experienced increased depression. These symptoms resolved 4 to 7 days after stopping cyproheptadine.² A woman successfully treated with fluoxetine 40 mg daily showed a re-emergence of her depressive symptoms on two occasions within 36 hours of starting to take cyproheptadine.³ In a further case, a woman who responded well to fluoxetine 20 mg daily for depression had a recurrence of her depression after she began to take cyproheptadine for migraine. Increasing the dose of fluoxetine to 40 mg daily controlled the depressive symptoms while cyproheptadine was continued for migraine.⁴ In contrast, no exacerbation of depression was seen in a study in which both cyproheptadine and fluoxetine were used in 2 patients.⁵

(b) Paroxetine

A woman taking paroxetine 20 mg daily for depression relapsed and worsened, and developed confusion and psychotic symptoms, within 2 days of starting to take cyproheptadine 2 mg twice daily for the treatment of anorgasmia.⁶ Psychotic symptoms resolved 2 days after stopping cyproheptadine. However, cyproheptadine (8 mg followed by 12 mg in 3 divided doses over 24 hours) seemed to have little effect on the course of the serotonin syndrome caused by a massive overdose of paroxetine (3.6 g) taken with alcohol. It was thought that the dosing of cyproheptadine might have been insufficient for such a large overdose. The patient recovered over the next 6 days with supportive measures.⁷

Mechanism

Although the mechanism is not fully understood, it has been suggested that because cyproheptadine is a serotonin antagonist it blocks or opposes the serotonergic effects of these SSRIs.^{1-3,6,7}

Importance and management

Direct information about this interaction appears to be limited to these studies although cyproheptadine has also been found to oppose the antidepressant effects of MAOIs (see 'MAOIs or RIMAs + Antihistamines; Cyproheptadine', p.1131). One study suggests that not every patient is affected.⁵ If concurrent use is thought appropriate, the outcome should be very well monitored for evidence of a reduced antidepressant response.

SSRIs and related antidepressants + Dextromethorphan

Three reports describe the development of a serotonin-like syndrome in two patients taking paroxetine and one taking citalopram and nefazodone, when they were given dextromethorphan. Another report describes hallucinations in a woman taking fluoxetine and dextromethorphan.

Clinical evidence

(a) Citalopram

A man who had been taking citalopram 30 mg, nefazodone 600 mg and long-acting oxycodone 10 mg at bedtime without problems, started taking a cough syrup containing dextromethorphan and within a day he began to experience fatigue, lethargy, jitteriness and headache. He stopped taking the dextromethorphan and his symptoms gradually disappeared over several hours.¹

(b) Fluoxetine

A woman who had been taking fluoxetine 20 mg daily for 17 days took about 10 mL of a cough syrup containing dextromethorphan, and a further dose the next morning, with the next dose of fluoxetine. Within 2 hours vivid hallucinations developed (bright colours, distortions of shapes and sizes), which lasted 6 to 8 hours. The patient said they were similar to her past experience with LSD 12 years earlier.² However, in a report of an extensive metabolic study³ in which depressed patients taking fluoxetine were given a single 30-mg dose of dextromethorphan, no mention was made of adverse effects.³

(c) Paroxetine

A man with multiple medical problems was admitted to hospital as an emergency, mainly because he was vomiting blood. He was taking diazepam, diltiazem, glyceryl trinitrate, paroxetine, piroxicam, ranitidine and ticlopidine. Four days previously he had begun to take *Nyquil*, a non-prescription remedy for colds, containing dextromethorphan, pseudoephedrine, paracetamol (acetaminophen) and doxylamine. After two days he developed shortness of breath, nausea, headache and confusion, and on admission he was also diaphoretic, tremulous, tachycardic and hypertensive. Later he became rigid. The eventual diagnosis was that he was suffering from the serotonin syndrome, attributed to an interaction between paroxetine and dextromethorphan in the presence of vascular disease. He was successfully treated with lorazepam 16 mg intravenously over 1 hour. The bleeding was thought to be from a small prepyloric ulcer.⁴

The authors of this report very briefly describe another patient taking paroxetine who developed symptoms consistent with the serotonin syndrome within a few hours of taking a non-prescription cough remedy containing dextromethorphan and guaifenesin. She needed intensive care treatment.⁵

Mechanism

Not understood. The symptoms that developed with citalopram or paroxetine and dextromethorphan were attributed by the authors of the reports to the serotonin syndrome, caused by the additive effects of the SSRIs and dextromethorphan on serotonin transmission. It has also been suggested that paroxetine inhibited the cytochrome P450 isoenzyme CYP2D6, by which dextromethorphan is metabolised, resulting in increased dextromethorphan levels.^{5,6} Fluoxetine also inhibits CYP2D6.³

Importance and management

These seem to be, so far, the only reports of the serotonin syndrome being attributed to an interaction between an SSRI and dextromethorphan. However, it has been suggested that the incidence of mild serotonin excess (as seen in with citalopram) may be more common than is known.¹ The general importance of this apparent interaction is therefore very uncertain. The SSRIs are now very widely prescribed and dextromethorphan is a rel-

atively common ingredient of non-prescription medicines. More study is therefore needed to establish this apparent interaction, but in the meantime it would seem prudent for patients taking citalopram, fluoxetine, or paroxetine to be cautious using dextromethorphan-containing products because of the risks of the serotonin syndrome, which, if it occurs, can be serious. Concurrent use should be well monitored. It is not clear whether other SSRIs would interact with dextromethorphan similarly, but it has been predicted that **sertraline** and **fluvoxamine** are less likely to do so.⁶ This prediction has been challenged.⁵ The outcome will largely depend on the mechanism of this interaction, as **sertraline** and **fluvoxamine** do not usually have clinically significant effects on CYP2D6. For more information about the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

SSRIs + Grapefruit juice

Excessive consumption of grapefruit caused symptoms similar to the serotonin syndrome in a patient taking fluoxetine and trazodone.

Grapefruit juice appears to raise fluvoxamine levels, which resulted in adverse effects in one patient. Sertraline plasma levels are also increased by grapefruit juice.

Clinical evidence

A 57-year-old HIV-positive man had been receiving indinavir, stavudine and lamivudine, as well as other medications including **fluoxetine** 20 mg daily and trazodone 200 mg daily. He complained of dizziness, mild confusion, diarrhoea, visual changes, and a general feeling of being "out of sorts" for approximately one month. On further questioning it was found that the patient had been having one grapefruit each morning but had increased his consumption to 3 per day. His symptoms resolved when he stopped eating grapefruit.¹

A randomised, placebo-controlled, crossover study in 10 healthy subjects found that 250 mL of grapefruit juice three times daily for 6 days increased the AUC of a single 75-mg dose of **fluvoxamine** by 60% and increased the maximum plasma levels by 33%.² A 75-year-old woman taking **fluvoxamine** 150 mg at night experienced palpitations when on holiday in Florida, which stopped when she returned home. The only change identified was that she drank grapefruit juice daily while in Florida. She had previously experienced palpitations when taking a higher dose of **fluvoxamine** (200 mg at night).³

A study in 5 patients taking **sertraline** 50 to 75 mg daily found that the concurrent use of grapefruit juice for one week increased serum trough levels by almost 50%.⁴

Mechanism

Grapefruit juice is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and sertraline is partially metabolised by this enzyme. Therefore grapefruit juice would be expected to reduce the metabolism of sertraline. This has been demonstrated *in vitro*; grapefruit juice inhibited the formation of desmethylsertraline in a dose-dependent manner.⁴ The other SSRIs mentioned above are not significantly affected by CYP3A4, but grapefruit juice also inhibits other isoenzymes that could affect the metabolism of SSRIs especially if the patient is also a poor metaboliser of CYP2D6.^{2,3}

Importance and management

There are very few reports of clinically significant interaction between grapefruit and SSRIs, but the possibility of an interaction should be borne in mind especially if unusual amounts of grapefruit have been consumed.

SSRIs + H₂-receptor antagonists

Citalopram, escitalopram, paroxetine and sertraline levels are moderately increased by cimetidine but the only clinically relevant effect appears to be a slight increase in adverse effects with sertraline.

Clinical evidence

(a) Citalopram

Twelve healthy subjects were given citalopram 40 mg daily for 21 days and then for the next 8 days they were also given **cimetidine** 400 mg twice daily. The **cimetidine** caused a 29% decrease in the oral clearance of the citalopram, a 39% rise in its maximum serum levels and a 43% increase in its AUC. Some changes in the renal clearance of the citalopram metabolites were also seen.¹

(b) Escitalopram

Cimetidine 400 mg twice daily increased the mean plasma level of escitalopram by about 70%. There was also a 22% increase in the maximum plasma level of citalopram, but this was not considered to be clinically significant.²

(c) Paroxetine

Cimetidine 200 mg four times daily for 8 days did not affect the mean pharmacokinetic values or bioavailability of a single 30-mg dose of paroxetine in 10 healthy subjects. However, 2 subjects had AUC increases of 55% and 81%, respectively, while taking **cimetidine** and 4 others also had some minor increases.³ Another study in 11 healthy subjects found that **cimetidine** 300 mg three times a day increased the AUC of paroxetine 30 mg daily by 50% after 1 week of concurrent use.⁴

(d) Sertraline

In a randomised, two-way, crossover study, 12 healthy subjects were given a single 100-mg oral dose of sertraline after taking either **cimetidine** 800 mg or a placebo at bedtime for 7 days. **Cimetidine** increased the AUC of sertraline by 50%, the maximum serum levels of sertraline by 24%, and the half-life by 26%.^{5,6} There was a small increase in sertraline adverse effects (not specified) while taking the **cimetidine**.⁵

Mechanism

The apparent reason for all these changes is that cimetidine inhibits the activity of cytochrome P450 so that the metabolism of the SSRIs is reduced, and as a result their serum levels rise.

Importance and management

The authors of the citalopram study say that while cimetidine certainly causes an increase in the serum levels of citalopram, the extent is only moderate and because the drug is well tolerated and there are very considerable pharmacokinetic variations between individual subjects, they consider that there is no need to reduce the citalopram dosage.¹ This advice is most likely applicable to escitalopram, the *S*-isomer of citalopram. However, the manufacturer of escitalopram suggests caution, and advises that a reduction in the dose of escitalopram may be necessary (based on monitoring of adverse effects) during concurrent treatment.⁷

Information on the concurrent use of cimetidine and paroxetine or sertraline seems to be limited and the clinical significance of the changes in clearance is not known. However, it would be prudent to monitor the outcome for excessive adverse effects (dry mouth, nausea, diarrhoea, dyspepsia, tremor, ejaculatory delay, sweating) if cimetidine is used with either of these SSRIs and reduce the sertraline or paroxetine dosage if necessary.

If the suggested mechanism of interaction is true, one of the other H₂-re-

ceptor antagonists that lack enzyme inhibitory activity, such as **ranitidine** or **famotidine**, might be a non-interacting alternative for cimetidine. This needs confirmation.

SSRIs + Herbal medicines

A man taking fluoxetine experienced symptoms of the serotonin syndrome after ingesting the psychoactive beverage ayahuasca, which contains monoamine oxidase-inhibiting harmala alkaloids. The Japanese herbal medicine *Gorei-san* does not appear to interact with fluvoxamine or paroxetine.

Clinical evidence, mechanism, importance and management

A 36-year-old man who was receiving **fluoxetine** 20 mg daily for mild depression participated in a religious ceremony using **ayahuasca** (also known as **caapi**, **daime**, **hoasca**, **natema**, **yage**) which is a psychoactive beverage characteristically containing harmala alkaloids (primarily **harmine** and **harmaline**) derived from the vine *Banisteriopsis caapi*. One hour after ingesting 100 mL of **ayahuasca** he experienced tremors, sweating, shivering and confusion. His condition deteriorated over the next few hours with gross motor tremors and severe nausea and vomiting, but he rapidly recovered four hours after ingestion of the **ayahuasca**, with no treatment. The harmala alkaloids are capable of blocking the enzymatic activity of MAO for several hours, and consequently inhibit the metabolic breakdown of neurotransmitters. There is, therefore, the potential for the serotonin syndrome with SSRIs and **ayahuasca**.¹

For reports of the serotonin syndrome and other adverse effects when St John's wort was taken together with SSRIs, see 'SSRIs + St John's wort (*Hypericum perforatum*)', p.1224.

An efficacy study in 20 patients taking **fluvoxamine** (19 patients) or **paroxetine** (1 patient) reported that the addition of the Japanese herbal medicine **Gorei-san** (TJ-17), which is composed of 5 herbs (*Alismatis rhizoma*, *Atractylodis lanceae rhizoma*, *Polyporus*, *Hoelen*, and *Cinnamomi cortex*), caused no additional adverse events.² However, note that this study was not specifically looking at drug interactions and therefore only gives a broad indication that concurrent use is safe and effective.

SSRIs + 5-HT₃-receptor antagonists

Symptoms similar to the serotonin syndrome have been reported in two patients receiving paroxetine and ondansetron or sertraline and dolasetron.

Clinical evidence, mechanism, importance and management

A possible case of the serotonin syndrome (or possibly neuroleptic malignant syndrome) was reported in a 49-year-old woman who developed postoperative delirium. She had been taking **paroxetine** 30 mg daily up to 2 days before surgery and was given **ondansetron** 4 mg during surgery and morphine during and after surgery. Approximately one hour after leaving theatre she became agitated and confused. She also displayed uncontrolled limb movements, brisk reflexes, ankle clonus, abnormal ocular function, hypertension, pyrexia, and raised creatinine kinase levels. The delirium did not respond to naloxone, diazepam or flumazenil and lasted for nearly 2 days. Several explanations involving the disruption of

serotonergic and/or dopaminergic transmission were suggested.¹ There has been some debate about whether inhibition of CYP2D6 was another possible mechanism, but this seems unlikely.^{1,2}

Similarly, a 49-year-old woman, who had been receiving **sertraline** for some time without incident was premedicated with **dolasetron** 100 mg before receiving her first cycle of adjuvant chemotherapy for breast cancer. Shortly afterwards she developed symptoms of profound agitation and elation, but with an overwhelming desire to commit suicide and was disoriented. The symptoms resolved within hours without pharmacological intervention. Three weeks later she received the same medications except **ondansetron** was substituted for **dolasetron** and she experienced no adverse effects. The author concluded that a variant of the serotonin syndrome may rarely be seen when 5-HT₃-receptor antagonists and SSRIs are given together, and clinicians should consider this possibility if these adverse effects occur.³

SSRIs + Interferons

The antidepressant effects of paroxetine and trazodone may be reversed by interferon.

Clinical evidence, mechanism, importance and management

A 31-year-old woman, whose mood and other depressive symptoms improved during treatment with **paroxetine** 50 mg daily and trazodone 50 mg at night, was later found to have essential thrombocythaemia. After unsuccessful treatment with dipyridamole, she was given **interferon alfa**, stabilised at 3 million units 3 times weekly. After 3 months her depressive symptoms returned, and worsened over a period of 6 months, despite increased doses of trazodone and cognitive therapy. **Interferon alfa** was discontinued and replaced by hydroxycarbamide, and then anagrelide. After a good response to a course of ECT, her depressive symptoms were controlled by **paroxetine** 50 mg daily and trazodone 150 mg at night.¹

Interferon is associated with a risk of depression, but in this case it appeared to reverse the antidepressant response. It was suggested that this might have been due to the capacity of interferon to impair serotonin synthesis, by inducing enzymes that degrade the serotonin precursor tryptophan. If this mechanism is true then all SSRIs have the potential to interact. Bear the possibility of an interaction in mind if the response to an SSRI is poor in a patient given interferon.

1. McAllister-Williams RH, Young AH, Menkes DB. Antidepressant response reversed by interferon. *Br J Psychiatry* (2000) 176, 93.

SSRIs + Lysergide (LSD)

Three patients with a history of lysergide (LSD) abuse experienced the new onset or worsening of the LSD flashback syndrome when given fluoxetine, paroxetine or sertraline. Grand mal convulsions occurred when one patient taking LSD was given fluoxetine. In contrast, one study found that SSRIs reduced or eliminated the subjective responses to LSD.

Clinical evidence

An 18-year-old girl with depression, panic and anxiety disorders, and with a long history of illicit drug abuse experienced a 15-hour LSD flashback within 2 days of starting to take **sertraline** 50 mg daily. Another flashback lasting a day occurred when the **sertraline** was replaced by **paroxetine**. No further flashbacks occurred when the SSRIs were stopped. A 17-year-old boy with depression, also with a long history of illicit drug abuse (including LSD), began to experience LSD flashbacks 2 weeks after starting to take **paroxetine**. His father, a chronic drug abuser, had taken both **fluoxetine** and **paroxetine** for depression and had also reported new onset of a flashback syndrome.¹ An isolated report describes grand mal convul-

sions in a patient while taking **fluoxetine**, tentatively attributed to the concurrent abuse of LSD.² In contrast, a retrospective study found that 28 of 32 subjects (88%) who took LSD and who had taken an SSRI (**fluoxetine**, **paroxetine** or **sertraline**) or trazodone for more than 3 weeks had a subjective decrease or virtual elimination of their responses to LSD. However, another subject who had taken **fluoxetine** for only one week had an increased response to LSD.³

Mechanism

Not understood. Lysergide increases serotonin in the brain, and one suggestion is that when the serotonin re-uptake is blocked in the brain, there is an increased stimulation of 5-HT₁ and 5-HT₂ receptors.¹ Changes in brain catecholamine systems may also be involved.³

Importance and management

Information is very limited and conflicting. The authors of the first report suggest that patients who are given SSRIs should be warned about the possibility of flashback or hallucinations if they have a known history of LSD abuse.

SSRIs + Macrolides

An isolated case report describes apparent acute fluoxetine toxicity in a man brought about by the use of clarithromycin. Another isolated report describes the development of what is thought to be the serotonin syndrome in a 12-year-old boy taking sertraline and erythromycin.

Clinical evidence

(a) Fluoxetine

A 53-year-old-man taking fluoxetine 80 mg and nitrazepam 10 mg at bedtime for depression and insomnia, was given **clarithromycin** 250 mg twice daily for a respiratory infection. Within a day he started to become increasingly confused and after 3 days was admitted to hospital with a diagnosis of psychosis and delirium. When no organic cause for the delirium could be found, all his medications were stopped, and **erythromycin** was started. His mental state returned to normal after 36 hours. Once the antibacterial course had finished, the fluoxetine and nitrazepam were restarted and no further problems occurred.¹

(b) Sertraline

A 12-year-old boy with severe obsessive-compulsive disorder and simple phobia, responded to sertraline 12.5 mg daily, titrated over 12 weeks to 37.5 mg daily. He began to feel mildly nervous within 4 days of starting to take **erythromycin** 400 mg daily for an infection. Over the next 10 days his nervousness grew, culminating in panic, restlessness, irritability, agitation, paraesthesias, tremulousness, decreased concentration and confusion. The symptoms abated within 72 hours of stopping both drugs.²

Mechanism

The authors attribute what was seen to fluoxetine toxicity in the first case, and to the serotonin syndrome in the second case. They postulated that erythromycin (a known and potent inhibitor of cytochrome P450 isoenzyme CYP3A4) and the related macrolide clarithromycin, reduced the metabolism of the SSRIs, thereby raising their serum levels and precipitating the observed toxicity.^{1,2}

Importance and management

These are isolated reports and their general importance is unknown. Nor is it unequivocally established that the second case was the serotonin syn-

drome and not an idiosyncratic reaction. Nevertheless, be aware of these cases when using macrolides with fluoxetine or sertraline.

2. Lee DO, Lee CD. Serotonin syndrome in a child associated with erythromycin and sertraline. *Pharmacotherapy* (1999) 19, 894–6.

SSRIs + Metoclopramide

There are two reports of the serotonin syndrome in patients taking sertraline when metoclopramide was added. Extrapyramidal symptoms have occurred in patients given fluoxetine, fluvoxamine or sertraline with metoclopramide.

Clinical evidence

(a) Extrapyramidal symptoms

Two patients developed extrapyramidal symptoms while taking **fluoxetine** and metoclopramide.^{1,2}

A 14-year-old boy receiving **fluvoxamine** 50 mg daily for anorexia nervosa was, after day 7, given metoclopramide 10 mg three times daily. On the third day of concurrent use he developed acute movement disorders including acute dystonia, jaw rigidity, horizontal nystagmus, uncontrolled tongue movements and dysarthria. The boy had taken the same dose of metoclopramide alone on other occasions without experiencing extrapyramidal reactions. A pharmacokinetic interaction was considered unlikely since both drugs use different metabolic pathways.³

In another report a woman with gastro-oesophageal reflux, controlled with metoclopramide 15 mg four times daily, developed symptoms consistent with a mandibular dystonia (periauricular pain, jaw tightness, the sensation of her teeth clenching and grinding) 2 days after starting **sertraline** 50 mg daily. A 50-mg dose of diphenhydramine resolved the problem within 30 minutes, but the same symptoms recurred the next day, 8 hours after taking **sertraline**. The symptoms were relieved by 2 mg of oral benzatropine.⁴

A regional pharmacovigilance centre in France reported 37 cases of extrapyramidal adverse effects linked to concurrent use of an SSRI and a neuroleptic (said to be metoclopramide in 4 cases).⁵

(b) Serotonin syndrome

A patient who had been taking **sertraline** 100 mg daily started taking metoclopramide 10 mg four times daily for nausea. After 24 hours his symptoms had worsened and he developed malaise, cardiac arrhythmia, visual hallucinations, diaphoresis, sialosis, hyperreflexia, and tremor. The serotonin syndrome was diagnosed and his symptoms improved with cyproheptadine.⁶ Another patient taking **sertraline** 100 mg daily for depression over an 18-month period developed agitation, dysarthria, diaphoresis, and a movement disorder within 2 hours of receiving a single 10-mg intravenous dose of metoclopramide. The symptoms, diagnosed as the serotonin syndrome with serious extrapyramidal movement disorder, resolved within 6 hours of treatment with diazepam.⁷

Mechanism

Both SSRIs and metoclopramide can cause extrapyramidal reactions; metoclopramide by blocking dopamine D₂ receptors in the basal ganglia, and SSRIs by inhibition of dopamine neurotransmission.^{3,4} Metoclopramide has also been reported to have intermediate affinity to certain serotonin receptors.⁷

Importance and management

Information seems to be limited to these reports, but they highlight the fact that care should be taken if two drugs with the potential to cause the same adverse effects are used together.

SSRIs + NNRTIs

A case of the serotonin syndrome occurred in a woman taking fluoxetine when efavirenz was added. Nevirapine decreased fluoxetine plasma levels, but fluvoxamine increased nevirapine levels.

Clinical evidence, mechanism, importance and management

(a) Efavirenz

A case of serotonin syndrome in a woman taking **fluoxetine** coincided with the start of a new antiretroviral regimen including efavirenz. Symptoms resolved when the **fluoxetine** dose was halved. It was suggested that efavirenz inhibited the metabolism of **fluoxetine**.¹ Until further information is available, caution may be warranted if both drugs are given.

(b) Nevirapine

A study involving 60 HIV-positive patients taking a nevirapine-containing regimen found that **fluoxetine** had no influence on the pharmacokinetics of nevirapine, but nevirapine significantly lowered the combined plasma levels of **fluoxetine** and norfluoxetine.² If nevirapine is given with **fluoxetine**, the clinical response to **fluoxetine** should be monitored and the dosage increased if necessary. In the same study the concurrent use of **fluvoxamine** resulted in a significant 34% reduction in the apparent clearance of nevirapine, and this appeared to be dependent on the dose of **fluvoxamine**. The pharmacokinetics of **fluvoxamine** were not affected.² If both drugs are given be aware that **fluvoxamine** could be a cause of increased nevirapine adverse effects.

2. De Maat MMR, Huitema ADR, Mulder JW, Meenhorst PL, van Gorp ECM, Mairuhu ATA, Beijnen JH. Drug interaction of fluvoxamine and fluoxetine with nevirapine in HIV-1-infected individuals. *Clin Drug Invest* (2003) 23, 629–37.

SSRIs + Opioids

Symptoms of the serotonin syndrome have been reported with opioids including hydromorphone, oxycodone, pentazocine, pethidine and tramadol and possibly morphine when given with various SSRIs. Seizures have been seen when dextropropoxyphene was given with an SSRI.

Fluoxetine has slightly reduced the analgesic effects of morphine and oxycodone. Buprenorphine metabolism is inhibited by fluvoxamine *in vitro*, but this is probably not clinically relevant.

Clinical evidence

(a) Buprenorphine

Fluvoxamine inhibited the metabolism of buprenorphine *in vitro*, but the inhibition was not thought sufficient to be clinically significant.¹

Fluoxetine did not inhibit buprenorphine dealkylation *in vitro*, although norfluoxetine did so, but this was also thought unlikely to be significant *in vivo*.¹

(b) Dextropropoxyphene

Ten of 32 cases of seizures or myoclonus associated with antidepressant treatment reported to the Swedish Adverse Drug Reactions Advisory Committee involved SSRIs (**fluvoxamine** 6, **citalopram** 2, **paroxetine** 2). An important risk factor appeared to be concurrent treatment with other drugs, such as dextropropoxyphene (2 cases), that decrease the seizure threshold.²

(c) Hydrocodone

Visual hallucinations occurred in a 90-year-old woman taking hydrocodone when her antidepressant was changed from **citalopram** 10 mg daily to **escitalopram** 10 mg daily. The hallucinations stopped after her hydrocodone was discontinued because of improvement in pain control. The patient had previously taken **paroxetine** and the same dose of hydrocodone, without experiencing hallucinations or other serotonin-related symptoms.³

(d) *Hydromorphone*

An 81-year-old woman who had been taking **fluoxetine** 20 mg daily along with other medication for several years, developed abnormal movements, confusion, incoherent speech, sweating, facial redness, tremor, hyper-reflexia and muscle spasm 2 days after starting to take hydromorphone 12 mg daily. The symptoms resolved within 2 weeks of stopping the **fluoxetine** (the hydromorphone was continued).⁴

(e) *Methadone*

The SSRIs, particularly fluvoxamine, can raise methadone levels. See 'SSRIs + Opioids; Methadone', below.

(f) *Morphine*

A double-blind, placebo-controlled study in 35 patients found that the preoperative use of **fluoxetine** 10 mg daily for 7 days reduced the analgesic effect of intravenous morphine given for postoperative dental pain.⁵ In contrast, a double-blind, crossover study in 15 healthy subjects found that a single 60-mg dose of **fluoxetine** slightly improved (by 3 to 8%) the analgesic effect (as assessed by dental electrical stimulation) of morphine sulfate in doses tailored to produce and maintain steady-state plasma levels of 15, 30 and 60 nanograms/mL for 60 minutes. Plasma levels of morphine were not affected by **fluoxetine**, and morphine was found not to affect plasma levels of **fluoxetine** or norfluoxetine. The subjects experienced less nausea and drowsiness, but the psychomotor and respiratory depressant effects of morphine were not altered.⁶

A patient experienced postoperative delirium which lasted for nearly 2 days and included agitation, confusion, uncontrolled limb movements, abnormal ocular function, hypertension, pyrexia, brisk reflexes, ankle clonus and raised creatinine kinase. She had been taking **paroxetine** before surgery and during surgery she was given morphine and ondansetron.⁷

(g) *Oxycodone*

A man with advanced multiple sclerosis found that when he began to take **fluoxetine** 20 mg daily for depression he needed to increase his analgesic dosage of oxycodone (for painful muscle spasms) about fourfold, from 65 to 75 mg daily to about 250 to 275 mg daily.⁸

A bone-marrow transplant recipient taking, amongst other drugs, **sertraline** 50 mg daily, ciclosporin 75 mg daily, and oxycodone 10 mg as needed, developed severe tremors and visual hallucinations. This coincided with him taking oxycodone 200 mg over 48 hours for severe pain. An adverse reaction to ciclosporin was initially suspected (although serum levels were not high), and this was temporarily discontinued along with the oxycodone. The visual hallucinations decreased but the tremors continued, and did not lessen until **sertraline** was discontinued and cyproheptadine given. It was concluded that the patient was experiencing a form of the serotonin syndrome as a result of markedly increased opioid use while taking an SSRI.⁹ Two other cases describe probable serotonin syndrome in elderly patients receiving either **sertraline** or **escitalopram** together with extended-release oxycodone. In both cases symptoms of the serotonin syndrome (agitation, increased muscle tone, ataxia, tremor and/or myoclonic jerks) occurred after increasing the opioid dose.³ Another case of severe serotonergic symptoms including confusion, nausea, fever, shivering, agitation, clonus, hyperreflexia, hypertonia, and tachycardia occurred in a 70-year-old woman taking **fluvoxamine** 200 mg daily when she started taking oxycodone 40 mg twice daily. Discontinuation of these two drugs resulted in resolution of her symptoms over 48 hours.¹⁰

(h) *Pentazocine*

A double-blind, placebo-controlled study in 35 patients has shown that oral **fluoxetine** 10 mg daily for 7 days preoperatively did not to reduce the analgesic effects of pentazocine 45 mg given intravenously for postoperative dental pain.⁵

A man who had been taking **fluoxetine** 20 mg daily, later increased to 40 mg daily, was given a single 100-mg oral dose of pentazocine (*Talwin Nx* containing pentazocine 50 mg and naloxone 500 micrograms) for a severe headache. Within 30 minutes he complained of lightheadedness, anxiety, nausea and paraesthesias of the hands. He was diaphoretic, flushed, and ataxic, and had a mild tremor of his arms. His blood pressure was 178/114 mmHg, pulse 62 bpm and respiration 16 breaths per minute. He was given intramuscular diphenhydramine 50 mg and recovered over the following 4 hours.¹¹

(i) *Pethidine (Meperidine)*

A 43-year-old man who had been taking **fluoxetine** approximately every other day experienced symptoms of the serotonin syndrome immediately after receiving pethidine 50 mg intravenously for an endoscopic procedure.¹²

(j) *Tramadol*

The serotonin syndrome has occurred in a number of patients taking SSRIs with tramadol. See 'SSRIs + Opioids; Tramadol', p.1222.

Mechanism

Fluoxetine inhibits the activity of the cytochrome P450 isoenzyme CYP2D6 within the liver so that the metabolism of oxycodone to an active metabolite oxymorphone is reduced. The metabolism of hydrocodone and similar opioids may also be affected by CYP2D6 inhibitors, see 'Opioids; Codeine and related drugs + Quinidine', p.184. Buprenorphine and morphine are not metabolised by CYP2D6, so their metabolism would not be expected to be affected by fluoxetine. Buprenorphine is metabolised by CYP3A4 and so fluvoxamine might be expected to inhibit its metabolism to some extent.

Dextropropoxyphene may have inhibited the metabolism of the SSRIs leading to an increase in seizures.

It has been suggested that the reason for the reduced morphine analgesia may have something to do with the initial effects of SSRIs on serotonergic neurotransmission.⁶ The serotonin syndrome seems to develop unpredictably in some patients given two or more serotonergic drugs, in this case, opioids and SSRIs.

Importance and management

Adverse interactions between SSRIs and opioids seem rare (although see 'methadone', (below)) and there is little to suggest that they cannot be used together safely and effectively. The evidence suggesting that fluoxetine may decrease morphine or oxycodone analgesia is limited and insufficient to suggest any change in practice. However, if a patient does not seem to respond well to either of these opioids consider an interaction as a possible cause. Buprenorphine metabolism might be slightly reduced by fluvoxamine, but this does not appear to be clinically relevant.

The incidence of serotonin syndrome-like reactions with opioids and SSRIs is fairly rare (although see 'tramadol', (p.1222)); however, the possibility of 'the serotonin syndrome', (p.9), should be considered in patients experiencing altered mental status, autonomic dysfunction and neuromuscular adverse effects while receiving these drugs.

SSRIs + Opioids; Methadone

Methadone serum levels may rise if fluvoxamine is added, sometimes resulting in increased adverse effects. Sertraline, paroxetine, and possibly fluoxetine, may also modestly increase methadone levels.

Clinical evidence

(a) Fluoxetine

Methadone 30 to 100 mg daily, and fluoxetine 20 mg daily were given to 9 patients (two of them were also taking fluvoxamine). Although there were possible compliance problems with some of the patients, the methadone plasma/dose ratio of the group as a whole was not altered by the addition of the fluoxetine.¹ This is consistent with the results of two other studies, which found that fluoxetine did not appear to alter the plasma methadone levels of patients treated for cocaine dependence.^{2,3} However, the plasma samples for 7 of the 9 patients in the first study¹ were subsequently analysed again to measure the *S*- and *R*-enantiomers of methadone separately. This analysis revealed that fluoxetine 20 mg daily modestly increased the levels-to-dose ratio of the active *R*-methadone (by 33%) without significantly changing either the total or inactive *S*-methadone level-to-dose ratios.⁴ Moreover, a patient taking methadone developed opioid toxicity when given ciprofloxacin and fluoxetine, see 'Opioids; Methadone + Ciprofloxacin', p.189.

(b) Fluvoxamine

Five patients taking maintenance doses of methadone were given fluvoxamine. Two of them had an increase of about 20% in the methadone plasma/dose ratio, while the other 3 showed 40 to 100% rises (suggesting increased methadone levels). One of them developed asthenia, marked drowsiness and nausea, which disappeared when both drug dosages were reduced.⁵ A subsequent analysis of the enantiomers of methadone revealed that fluvoxamine increased the levels of both *R*- and *S*-methadone.⁴ A report describes one patient who was unable to maintain adequate methadone levels, despite a daily dosage of 200 mg, and experienced withdrawal symptoms until fluvoxamine was added.⁶ Another patient taking methadone 70 mg daily and diazepam 2 mg twice daily was admitted to hospital with an acute exacerbation of asthma and intractable cough 3 weeks after starting fluvoxamine 100 mg daily. Blood gas measurements indicated severe hypoxaemia and hypercapnia. The symptoms resolved when the methadone dose was reduced to 50 mg daily and diazepam was gradually withdrawn, at which point methadone levels fell by about 23% (from 262 to 202 nanograms/mL).⁷

(c) Paroxetine

Paroxetine 20 mg daily increased steady-state methadone levels by 35% in 10 patients taking maintenance doses of methadone. Both *R*- and *S*-methadone levels were increased in the 8 patients who were extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6 (see 'Genetic factors', (p.4)), but in the 2 patients who were poor metabolisers, only the *S*-methadone levels were increased. Apart from one patient who reported feeling high during the first night after starting paroxetine, no symptoms of over-medication or toxicity were noted.⁸

(d) Sertraline

A placebo-controlled study in 31 depressed methadone-maintained patients found that sertraline significantly increased the methadone plasma level/dose ratio by 26% while patients on placebo had a 16% decrease after 6 weeks treatment, but by 12 weeks ratios had shifted towards baseline values. Adverse effects were similar in both groups.⁹ A 31-year-old woman taking methadone 230 mg daily was found to have a prolonged QT interval after taking sertraline 50 mg daily was added to her medications, although she was asymptomatic. The QT interval returned to normal when the methadone and sertraline were stopped and her methadone was replaced with morphine.¹⁰

Mechanism

Fluvoxamine, and to a lesser extent fluoxetine, paroxetine, and sertraline, can inhibit the liver metabolism of the methadone (possibly by the cytochrome P450 isoenzymes CYP3A4,¹¹ CYP2D6,^{11,12} and/or CYP1A2⁴) thereby allowing it to accumulate in the body.

Importance and management

Information is limited, but it indicates that the effects of starting or stopping fluvoxamine should be monitored in patients taking methadone, being alert for the need to adjust the methadone dosage. Although the increase in methadone levels with sertraline and paroxetine, and possibly also fluoxetine, is unlikely to have clinical effects in most patients, the possibility should be borne in mind, especially if high doses of methadone

are being used. Note that methadone can prolong the QT-interval in high doses, see 'drugs that prolong the QT-interval', (p.257).

SSRIs + Opioids; Tramadol

Tramadol should be used with caution with SSRIs because of the increased risk of seizures. Several reports describe the development of the serotonin syndrome in patients taking SSRIs with tramadol. Another patient developed hallucinations with tramadol and paroxetine.

Clinical evidence

(a) Seizures

The CSM in the UK has publicised 27 reports of convulsions and one of worsening epilepsy with tramadol, a reporting rate of 1 in 7000 patients. Some of the patients were given doses well in excess of those recommended, and some were taking SSRIs (5 patients) or 'tricyclic antidepressants', (p.187), both of which are known to reduce the convulsive threshold.¹ Similarly, of 124 seizure cases associated with tramadol reported to the FDA in the US, 20 included the concurrent use of SSRIs.²

(b) Serotonin syndrome

The Australian Adverse Drug Reaction Advisory Committee has stated that tramadol may cause the serotonin syndrome, particularly when it is used at high doses or in combination with other drugs increasing serotonin levels; of 20 reported cases of the serotonin syndrome associated with tramadol, 16 were taking potentially interacting medicines including SSRIs.³ Cases of the serotonin syndrome with specific SSRIs are discussed below.

1. *Citalopram*. A 70-year-old woman who had been taking citalopram 10 mg daily for 3 years developed tremors, restlessness, fever, confusion, and visual hallucinations after starting to take tramadol 50 mg daily for pain relief following an operation. Her symptoms stopped after tramadol was stopped. However, she continued to take citalopram and one year later she developed identical symptoms after taking tramadol 20 mg daily. Citalopram is metabolised by the cytochrome P450 enzyme CYP2C19 and tramadol is *O*-demethylated by CYP2D6 and the patient was found to be deficient in both CYP2C19 and CYP2D6, suggesting that her metabolising capacity of both pathways was reduced.⁴

2. *Fluoxetine*. A woman who had been taking fluoxetine 20 mg daily for 3 years developed what was eventually diagnosed as the serotonin syndrome. A month previously she had started to take tramadol 50 mg four times daily, increased after a fortnight to 100 mg four times daily. Ten days before hospitalisation she had developed a tremor of the right hand and face, and in hospital she showed agitation, marked facial blepharospasm, some sweating and pyrexia, and stuttering. The symptoms began to subside 7 days after both drugs were stopped, and after 2 months she had recovered fully.⁵

3. *Paroxetine*. A man who had been taking paroxetine 20 mg daily for 4 months without problems developed shivering, diaphoresis and myoclonus and became subcomatose within 12 hours of taking tramadol 100 mg. This was diagnosed as the serotonin syndrome. Tramadol was stopped, the paroxetine dosage halved and he became conscious within a day. The other symptoms gradually disappeared over the next week.⁶ A 78-year-old woman taking paroxetine 20 mg daily developed nausea, diaphoresis and irritability 3 days after starting tramadol 50 mg three times a day. The next day she developed muscular weakness and confusion, and was found to have a temperature of about 38.2°C and a pulse rate of 110 bpm. She recovered when the drugs were withdrawn. Similar symptoms occurred in another elderly woman taking paroxetine 10 mg daily within 2 days of starting tramadol 50 mg four times daily. Both women were later able to continue taking paroxetine alone without problems.⁷

A tetraparetic patient with chronic pain developed nightmares and hallucinations 56 days after starting to take tramadol, paroxetine and dosulepin, which only stopped when the drugs were withdrawn.⁸

4. *Sertraline*. A 42-year-old woman was admitted to intensive care with atypical chest pain, sinus tachycardia, confusion, psychosis, sundowning [increased agitation, activity and negative behaviours, which happen late in the day or evening], agitation, diaphoresis and tremor. She was taking a large number of drugs, including sertraline and tramadol. She was diagnosed as having the serotonin syndrome, attributed to an increase in the dosage of tramadol (from 150 mg daily to 300 mg daily in increments of 50 mg every 2 to 3 days), and an increased sertraline dosage [original amounts not stated but 100 mg daily when the adverse events developed]. The tramadol had been started 3 weeks previously and she had been taking the sertraline for a year.⁹

An 88-year-old woman taking sertraline 50 mg daily (later increased to 100 mg daily), as well as several other medications was given dextropropoxyphene with paracetamol and tramadol 200 mg daily increased to 400 mg daily for pain relief after a fracture. Ten days after starting tramadol she became confused, with alterations in cognitive function, tremor, problems with co-ordination and muscle weakness. The serotonin syndrome was suspected and therefore sertraline was withdrawn over a period of 2 days, the dose of tramadol was reduced from 400 to 200 mg daily, and the patient recovered over a period of about 2 weeks.¹⁰

In another report, the serotonin syndrome occurred after the first dose of sertraline 50 mg in a 75-year-old woman who had been taking tramadol 50 mg daily for 3 days. The concentration of serotonin (5-hydroxytryptamine) in her CSF was found to be elevated to 38.5 nanograms/mL (normal value less than 10 picograms/mL).¹¹

(c) Pharmacokinetic effect

A double-blind, placebo-controlled, crossover study in 16 healthy extensive metabolisers found that pretreatment with paroxetine 20 mg daily for 3 days increased the AUC of (+)- and (-)-tramadol by 37% and 32%, respectively and decreased the AUCs of the *O*-demethylated metabolites of tramadol by 67% and 40%, respectively. The analgesic effect of tramadol was reduced, but not abolished.¹²

Mechanism

Tramadol may cause seizures and SSRIs can reduce the seizure threshold, thus if both are taken together the risk is increased. 'The serotonin syndrome', (p.9), seems to develop unpredictably in some patients given two or more serotonergic drugs (in this case, tramadol and SSRIs).

Paroxetine is a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6 and inhibits the CYP2D6 mediated formation of the *O*-demethylated metabolites of tramadol. The reduction in these metabolites may result in reduced analgesia as the opioid effect of tramadol is thought to be mediated mainly by (+)-*O*-desmethyltramadol.¹²

Importance and management

Because of the possible increased risk of seizures, tramadol should be used with caution in patients taking drugs such as the SSRIs, which can lower the seizure threshold. The concurrent use of tramadol and SSRIs may also lead to an increase in serotonin-associated effects, which can include the serotonin syndrome. However, the relatively few reported cases of the serotonin syndrome or other reactions due to an interaction between an SSRI and tramadol need to be set in the wider context of apparently uneventful and advantageous use in other patients,¹²⁻¹⁴ although some workers have suggested that the incidence of serotonin syndrome may be underreported.¹⁵ There would seem to be little reason for totally avoiding the concur-

rent use of the SSRIs and tramadol but it would clearly be prudent to monitor the outcome closely.

Tramadol analgesia may possibly be altered by paroxetine and potentially by other drugs that inhibit CYP2D6, such as fluoxetine.¹²

SSRIs + Protease inhibitors

Fluoxetine modestly raised the levels of ritonavir, and ritonavir is predicted to raise levels of fluoxetine, paroxetine and sertraline. A few cases of the serotonin syndrome have been attributed to the use of fluoxetine and ritonavir. The concurrent use of escitalopram and ritonavir do not appear to affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

In a single-dose study involving 18 healthy subjects, no significant pharmacokinetic interaction was seen when ritonavir was given with escitalopram.¹

Ritonavir 600 mg was given to 16 healthy subjects before and after 8 days of treatment with fluoxetine 30 mg twice daily. The maximum plasma levels of ritonavir were unaffected, but its AUC rose by 19%. These changes were not considered large enough to warrant changing the dose of ritonavir.² The study was criticised for not achieving steady state before assessing the pharmacokinetics and thus possibly underestimating the interaction.³ However, the authors point out that fluoxetine levels were equivalent to those seen at steady state, and multiple dosing of ritonavir is likely to induce its own metabolism, so if anything, the interaction would be lessened at steady state.⁴

The UK manufacturers of ritonavir predict that it may raise the levels of SSRIs (fluoxetine, paroxetine, sertraline) due to the inhibitory effect of ritonavir on the cytochrome P450 isoenzymes CYP2D6.⁵ The US manufacturers do not mention any specific SSRIs.⁶ Both manufacturers suggest careful monitoring of adverse effects when these drugs are used with ritonavir; a dose reduction of the SSRI may be required.^{5,6}

Two cases of serotonin syndrome were attributed to adding ritonavir to established fluoxetine treatment. In one patient this was managed by halving the fluoxetine dose, and in the other ritonavir was withdrawn. Other cases of the serotonin syndrome have been seen in patients taking ritonavir or indinavir with fluoxetine. One involved the additional use of 'trazodone', (p.1229), and the other involved large quantities of 'grapefruit', (p.1217).

SSRIs + Rifampicin (Rifampin)

In two isolated cases rifampicin decreased the efficacy of citalopram and sertraline.

Clinical evidence

A 34-year-old man, with a long-standing history of anxiety disorder being treated with **sertraline** 200 mg at bedtime, reported that the medication was no longer working well. He was experiencing a significant amount of anxiety, excessive worry, and poor energy. He additionally reported feeling “spaced out,” and having dizziness exacerbated by movement, lethargy, and insomnia. He had started taking rifampicin 300 mg twice daily and co-trimoxazole 7 days earlier and it was found that his **sertraline** and *N*-desmethylsertraline levels were only 39% and 46%, respectively, of the levels achieved when he was not taking rifampicin and co-trimoxazole. He later experienced similar symptoms when the **sertraline** dose was tapered so that paroxetine could be substituted.¹ Similarly, a 55-year-old man taking **citalopram** 40 to 60 mg daily reported a decrease in therapeutic efficacy (increased crying and panic attacks) after starting rifampicin 600 mg twice daily. His condition improved when the rifampicin was stopped.²

Mechanism

Both sertraline and citalopram are metabolised by cytochrome P450 isoenzymes including CYP3A4 and rifampicin is a potent inducer of the hepatic CYP450 system, particularly CYP3A4. It would therefore appear that rifampicin induced the metabolism of these two drugs resulting in decreased plasma levels.

Importance and management

There seem to be very few reports of this interaction, but rifampicin is a potent enzyme inducer and so clinicians should be aware that rifampicin may reduce citalopram or sertraline plasma levels leading to decreased efficacy or symptoms of SSRI withdrawal. In theory, rifampicin could affect other SSRIs metabolised via other cytochrome P450 isoenzymes, but there appear to be no reports of this. The UK manufacturer of **paroxetine** suggests that no initial dosage adjustment is considered necessary when **paroxetine** is given with enzyme inducing drugs such as rifampicin. Any subsequent dosage adjustment should be guided by clinical effect (tolerability and efficacy).³ Until more is known this would seem to be a sensible approach with rifampicin and any SSRI.

SSRIs + SSRIs

An isolated report describes an adverse reaction (hypertension, tachycardia, fever, auditory hallucinations and confusion) in a man when he started sertraline within a day of stopping fluoxetine. A small study found that the concurrent use of citalopram and fluvoxamine increased citalopram plasma levels with beneficial effects and the manufacturers of escitalopram predict that it may be similarly affected.

Clinical evidence, mechanism, importance and management

(a) Citalopram or Escitalopram with Fluvoxamine

A study in 7 depressed patients who had not responded to treatment with citalopram 40 mg daily for 3 weeks, found that the addition of fluvoxamine 50 to 100 mg daily for another 3 weeks improved the control of the depression. Plasma *S*- and *R*-citalopram levels rose two- to threefold. None

of the patients developed the serotonin syndrome, and no changes in vital signs or ECGs were seen.¹ The manufacturers of escitalopram, the *S*-isomer of citalopram therefore suggest that its levels may similarly be raised by fluvoxamine.²

(b) Fluoxetine with Sertraline

One of 16 healthy subjects who began to take sertraline 50 mg daily on the day after stopping a 2-week trial of fluoxetine 20 mg daily, rapidly developed hypertension, tachycardia, fever, auditory hallucinations and confusion. Most of these symptoms disappeared 48 hours after stopping the sertraline, but the confusion took a week to subside.³ The other 15 subjects had no clinically significant adverse effects. This subject was later found to have a history of psychosis so that the picture is a little confused, but the rapid abatement of the symptoms when the sertraline was stopped suggests that they were due either to the sertraline alone, or to an interaction with the residual fluoxetine.

It is therefore not clear whether a washout period is needed between these two drugs, but a decision on this will depend on the severity of the depression in the particular patient being treated. The manufacturers of sertraline imply caution when they say that the duration of a washout period when switching from one SSRI to another has not yet been established.^{4,5}

SSRIs + St John's wort (*Hypericum perforatum*)

Several patients taking sertraline developed symptoms diagnosed as the serotonin syndrome after also taking St John's wort. Another patient taking St John's wort developed severe sedation after taking a single dose of paroxetine. Isolated cases of mania have also been reported when SSRIs were taken with St John's wort.

Clinical evidence

(a) Fluoxetine

For a report of hypomania when St John's wort and Ginkgo biloba were added to treatment with fluoxetine and buspirone, see 'Buspirone + Herbal medicines', p.741.

(b) Paroxetine

In one report, a woman stopped taking paroxetine 40 mg daily after 8 months, and 10 days later started to take 600 mg of St John's wort powder daily. No problems occurred until the next night when she took a single 20-mg dose of paroxetine because she thought it might help her sleep. The following day at noon she was found still to be in bed, rousable but incoherent, groggy and slow moving and almost unable to get out of bed. Two hours later she still complained of nausea, weakness and fatigue, but her vital signs and mental status were normal. Within 24 hours all symptoms had resolved.¹

(c) Sertraline

Four elderly patients taking sertraline developed symptoms characteristic of the serotonin syndrome within 2 to 4 days of also taking St John's wort 300 mg, either two or three times daily. The symptoms included dizziness, nausea, vomiting, headache, anxiety, confusion, restlessness, and irritability. Two of them were treated with oral cyproheptadine 4 mg either two or three times daily, and the symptoms of all of them resolved within a week. They later resumed treatment with sertraline without problems.² A search of Health Canada's database of spontaneous adverse reactions from 1998 to 2003 found 2 cases of suspected serotonin syndrome as a result of an interaction between sertraline and St John's wort.³

Mania developed in a 28-year-old man, who continued to take St John's wort against medical advice whilst also receiving sertraline 50 mg daily for depression; he was also receiving testosterone replacement post-orchidectomy.⁴

Mechanism

A pharmacodynamic interaction may occur between St John's wort and SSRIs because they can both inhibit the reuptake of 5-hydroxytryptamine (serotonin).⁵ The serotonin syndrome has been seen with St John's wort alone,⁶ and so additive serotonergic effects appear to be the explanation for what occurred in the cases described here.

Importance and management

Information appears to be limited to these reports, but interactions between SSRIs and St John's wort would seem to be established. The incidence is not known but it is probably small, nevertheless because of the potential severity of the reaction it would seem prudent to avoid concurrent use. The advice of the CSM in the UK is that St John's wort should be stopped if patients are taking any SSRI because of the risk of increased serotonergic effects and an increased incidence of adverse reactions.⁷

SSRIs + Sympathomimetics

Isolated reports describe delirium in one patient and a seizure in another when methylphenidate was taken with sertraline. Schizophrenia and symptoms of amphetamine toxicity have also been reported in two patients taking amphetamine and fluoxetine. There is an isolated report of the serotonin syndrome associated with concurrent citalopram and dexamfetamine and another associated with sertraline and etilefrine. There is also a report of adverse effects associated with fluoxetine and phenylpropranolamine.

Clinical evidence, mechanism, importance and management

(a) Amfetamines

1. *Amfetamine*. A man who had taken a small, unspecified, but previously tolerated dose of amphetamine developed signs of amphetamine overdose (restlessness, agitation, hyperventilation, etc.) while taking **fluoxetine** 60 mg daily. Another man taking **fluoxetine** 20 mg daily developed symptoms of schizophrenia after taking two unspecified doses of amphetamine.¹ It was suggested that this occurred because **fluoxetine** inhibits the cytochrome P450 isoenzyme CYP2D6, which is involved in the metabolism of amphetamine, thereby increasing amphetamine levels.² The general importance of these apparent interactions is uncertain.

2. *Dexamfetamine*. A patient who experienced the serotonin syndrome with concurrent 'venlafaxine', (p.1214) and dexamfetamine had a second episode when **citalopram** was given with the dexamfetamine.³

3. *Ecstasy (MDMA, methylenedioxymethamphetamine)*. For comments on the effects of SSRIs on the metabolism of ecstasy and the possibility of increased serotonin effects, see 'Amfetamines and related drugs + SSRIs', p.201.

(b) Etilefrine

A case of the serotonin syndrome was reported due to an interaction between **sertraline** and etilefrine.⁴

(c) Methylphenidate

A 61-year-old man with major depression was prescribed **sertraline** 50 mg daily without response. Three months later the dose was increased to 100 mg daily and methylphenidate 2.5 mg daily was started. His symptoms improved and the dose of methylphenidate was increased to 2.5 mg twice daily and then 5 mg twice daily. After several days at the higher dose, the patient experienced visual hallucinations and confusion. The methylphenidate was discontinued and a day later the psychosis resolved. He was maintained on **sertraline** 100 mg daily and his mood and motivation remained good.⁵

An isolated report describes a tonic-clonic seizure in a 13-year-old boy after he had been taking **sertraline** 25 to 50 mg daily and methylphenidate 80 mg daily for about 2 weeks. He had been receiving methylphenidate without significant adverse effects for about 10 months before the seizure and following discontinuation of the **sertraline** experienced no further seizures.⁶

In contrast, beneficial augmentation of effects has been reported with methylphenidate and SSRIs (**fluoxetine**, **paroxetine**, **sertraline**) without significant adverse effects.^{7,8}

(d) Phenylpropranolamine

A 16-year-old girl with an eating disorder, taking **fluoxetine** 20 mg daily, developed vague medical complaints of dizziness, 'hyper' feelings, diarrhoea, palpitations and a reported weight loss of 14 lbs within 2 weeks. The author of the report suggested that these effects might have been the result of an interaction with phenylpropranolamine (1 to 2 capsules of *Dexatrim* once daily), which the patient was surreptitiously taking, associated with a restricted food and fluid intake.⁹

SSRIs + Tobacco

Smoking does not appear to alter citalopram pharmacokinetics, and has only modest effects on fluvoxamine pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Citalopram

In a pharmacokinetic study involving 44 adolescent patients (under 21 years of age), there was considerable inter-individual variation in serum levels of citalopram and its metabolites at all doses studied. However, smoking did appear to influence the disposition of citalopram.¹ The clinical significance of this is unknown and more study is required.

(b) Fluvoxamine

A comparative study in 12 smokers and 12 non-smokers given single 50-mg oral doses of fluvoxamine found that smoking reduced the fluvoxamine AUC and the maximum serum levels by about 30%.² However, a study in Japanese patients found no significant difference in steady-state plasma levels of fluvoxamine and its metabolite (fluvoxamino acid) between 34 non-smokers and 15 smokers.³ This suggests that the overall pharmacokinetic effect of smoking is probably minimal, although the effects of a sudden withdrawal from heavy smoking has not been investigated.

SSRIs + Tryptophan

Central and peripheral toxicity developed in five patients taking fluoxetine when they were given tryptophan. On theoretical grounds an adverse reaction seems possible between fluvoxamine (and probably other SSRIs) and tryptophan or oxitriptan.

Clinical evidence*(a) Fluoxetine*

The concurrent use of tryptophan with fluoxetine 20 mg daily has been reported to be tolerated.¹ A more recent placebo-controlled, double-blind study involving 30 patients with depression found that the use of tryptophan 2 g daily during the initial phase of treatment with fluoxetine 20 mg daily was beneficial and well-tolerated,² but problems have been seen when higher doses of both drugs have been given together. Five patients taking fluoxetine 50 to 100 mg daily for at least 3 months developed a number of reactions including central toxicity (agitation, restlessness, aggressive behaviour, worsening of obsessive-compulsive disorders) and peripheral toxicity (abdominal cramps, nausea, diarrhoea) within a few days of starting tryptophan 1 to 4 g daily. These symptoms disappeared when the tryptophan was stopped. Some of the patients had taken tryptophan in the absence of fluoxetine without problems.³

(b) Fluvoxamine

A warning by the CSM in the UK about the risks of giving fluvoxamine with tryptophan appears to be an extrapolation from the serious reaction (the serotonin syndrome) which has been seen with fluoxetine⁴ (see above).

Mechanism, importance and management

Tryptophan is a precursor of serotonin (5-hydroxytryptamine) and the authors point out that the symptoms resemble the serotonin syndrome, which occurs when serotonin levels are increased. They warn against the concurrent use of tryptophan with fluoxetine or other serotonin reuptake inhibitors.³ This caution is echoed by most of the manufacturers of the SSRIs; the UK manufacturer of paroxetine additionally mentions **oxitriptan** [L-5-hydroxytryptophan].⁵

SSRIs; Citalopram + Irinotecan

An isolated report describes rhabdomyolysis in a patient receiving citalopram and irinotecan. However, an interaction is by no means established.

Clinical evidence, mechanism, importance and management

A 74-year-old man who had been taking citalopram for 2 months developed rhabdomyolysis after undergoing initial treatment for gastrointestinal cancer with irinotecan. All medications were discontinued, but the rhabdomyolysis was exacerbated upon restarting the citalopram for depression. The citalopram was discontinued and he improved over the next 5 days. It was thought that levels of citalopram might have increased because citalopram and irinotecan share at least one metabolic pathway (CYP3A4), and the cytochrome system may also have been compromised in the cancer patient.¹ However, the patient was also taking **simvastatin**, which is known to be associated with rhabdomyolysis and which is also metabolised by CYP3A4; however the authors make no mention of this. An interaction between citalopram and irinotecan is therefore by no means established, and speculatively, this could perhaps be an interaction between irinotecan and simvastatin, which was exacerbated by citalopram.

SSRIs; Fluoxetine + Alosetron

Alosetron had no clinically significant effect on fluoxetine pharmacokinetics in healthy subjects.

Clinical evidence, mechanism, importance and management

An open study in 12 healthy subjects found that alosetron 1 mg twice daily for 15 days had no clinically significant effect on the pharmacokinetics of a single 20-mg dose of fluoxetine. There was a median 3-hour delay in time to reach peak levels of both *S*- and *R*-fluoxetine, but this was thought unlikely to be clinically relevant for a drug that requires several weeks to achieve its full therapeutic effect.¹

1. D'Souza DL, Dimmitt DC, Robbins DK, Nezamis J, Simms L, Koch KM. Effect of alosetron on the pharmacokinetics of fluoxetine. *J Clin Pharmacol* (2001) 41, 455–8.

SSRIs; Fluoxetine + Aminoglutethimide

Limited evidence suggests that the effects of fluoxetine are increased by aminoglutethimide.

Clinical evidence, mechanism, importance and management

A patient with severe obsessive-compulsive disorder, resistant to clomipramine combined with SSRIs, improved when given fluoxetine 40 mg daily and aminoglutethimide 250 mg four times daily. Over a four-and-a-half year period, whenever attempts were made to reduce the dosage of either drug, the patient started to relapse.¹ Thus at least one patient has taken both drugs together without problems, and the evidence suggests that the aminoglutethimide has a potentiating effect on the fluoxetine. However, more study is needed to confirm the efficacy and safety of this drug combination in other patients.

SSRIs; Fluoxetine + Cannabis

An isolated report describes mania when a patient taking fluoxetine smoked cannabis.

Clinical evidence, mechanism, importance and management

A 21-year-old woman with a 9-year history of bulimia and depression was taking fluoxetine 20 mg daily. A month later, about 2 days after smoking two 'joints' of cannabis (**marijuana**), she experienced a persistent sense of well-being, increased energy, hypersexuality and pressured speech. These symptoms progressed into grandiose delusions, for which she was hospitalised. Her mania and excitement were controlled with lorazepam and perphenazine, and she largely recovered after about 8 days. The reasons for this reaction are not understood but the authors of the report point out that one of the active components of cannabis, **dronabinol** (Δ^9 -**tetrahydrocannabinol**) is, like fluoxetine, a potent inhibitor of serotonin uptake. Thus a synergistic effect on central serotonergic neurones might have occurred.¹ This seems to be the first and only report of an apparent adverse interaction between cannabis and fluoxetine, but it emphasises the risks of concurrent use.

1. Stoll AL, Cole JO, Lukas SE. A case of mania as a result of fluoxetine-marijuana interaction. *J Clin Psychiatry* (1991) 52, 280–1.

SSRIs; Fluoxetine + Chlorothiazide

Fluoxetine is reported not to affect the pharmacokinetics of chlorothiazide.¹ No special precautions would seem necessary on concurrent use.

1. Lemberger L, Bergstrom RF, Wolen RL, Farid NA, Enas GG, Aronoff GR. Fluoxetine: clinical pharmacology and physiologic disposition. *J Clin Psychiatry* (1985) 46, 14–19.

SSRIs; Fluoxetine + CYP2D6 substrates

There is *in vitro* evidence that the effects of flecainide and mexiletine may possibly be increased by fluoxetine. The plasma levels of other drugs predominantly metabolised by CYP2D6 (such as encaïnide and thioridazine) may also be increased by fluoxetine. The

US manufacturer of fluoxetine contraindicates its use with thioridazine due to the risk of ventricular arrhythmias.

Clinical evidence, mechanism, importance and management

Studies in patients and *in vitro* investigations using human liver microsomes have shown that fluoxetine and its metabolite, norfluoxetine have a strong inhibitory effect on the activity of the cytochrome P450 isoenzyme CYP2D6 in the liver.^{1,2} This means that in practice, fluoxetine may increase and prolong the effects of drugs metabolised by this isoenzyme.

Flecainide and **mexiletine** are predominantly or partly metabolised by CYP2D6 but there appear to be no clinical cases of interactions between these drugs and fluoxetine. However, fluoxetine does interact with 'propafenone', (p.275), which is also metabolised by CYP2D6 so it would seem prudent to be alert for increased and prolonged effects of these drugs if fluoxetine is added.

The manufacturers of fluoxetine warn that drugs predominantly metabolised by CYP2D6, and which have a narrow therapeutic index, should be initiated at or adjusted to the low end of their dose range in patients taking fluoxetine. This will also apply if fluoxetine has been taken in the previous 5 weeks because of its long elimination half-life.^{3,4} The UK manufacturer³ specifically mentions **flecainide**, **encainide**, and 'tricyclic antidepressants', (p.1241)). For a list of CYP2D6 substrates, see 'Table 1.3', (p.6). Of interest, the US manufacturer also lists vinblastine as a CYP2D6 substrate, and therefore cautions its use, but note that vinblastine is more usually considered to be a CYP3A4 substrate.

- Prozac (Fluoxetine). Eli Lilly and Company. US Prescribing information, May 2007.

SSRIs; Fluoxetine + Orlistat

The pharmacokinetics of a single 40-mg oral dose of fluoxetine (a lipophilic drug) were not affected by orlistat 120 mg three times daily in healthy subjects.¹

- Zhi J, Moore R, Kanitra L, Mulligan TE. Effects of orlistat, a lipase inhibitor, on the pharmacokinetics of three highly lipophilic drugs (amiodarone, fluoxetine, and simvastatin) in healthy volunteers. *J Clin Pharmacol* (2003) 43, 428–35.

SSRIs; Fluvoxamine + Enoxacin

A study in healthy subjects suggested that enoxacin slightly inhibits the metabolism of fluvoxamine.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 10 healthy subjects given enoxacin 200 mg daily for 11 days and a single 50-mg dose of fluvoxamine on the eighth day, found that enoxacin increased the plasma levels of fluvoxamine at 2 and 3 hours and the maximum plasma level was increased from 10.2 to 11.6 nanograms/mL. The scores of the Stanford sleepiness scale were also increased. Enoxacin appears to slightly inhibit the metabolism of fluvoxamine, presumably by interfering with cytochrome P450 isoenzyme CYP1A2-mediated pathways, although the exact pathway was not clear.¹

- Kunii T, Fukasawa T, Yasui-Furukori N, Aoshima T, Suzuki A, Tateishi T, Inoue Y, Otani K. Interaction study between enoxacin and fluvoxamine. *Ther Drug Monit* (2005) 27, 349–53.

SSRIs; Paroxetine + Barbiturates

Paroxetine appears not to interact to a clinically important extent with amobarbital, but phenobarbital may reduce the AUC of paroxetine. Two cases of hepatotoxicity have been reported when paroxetine was given with a barbiturate.

Clinical evidence, mechanism, importance and management

Phenobarbital 100 mg once daily given to 10 healthy subjects for 14 days caused reductions of 10 to 86% in the AUC of paroxetine in 6 subjects, but the mean AUC values were unaltered. One subject showed a 56% increase in AUC.¹ The sedative effects and impairment of psychomotor performance caused by **amobarbital** 100 mg were not increased by paroxetine 30 mg.² Two cases of hepatitis in young women were considered to be caused by the concurrent use of **Atrium** (a barbiturate complex) and paroxetine, which are both hepatotoxic.³

For an isolated report of a tonic clonic seizure in a woman taking paroxetine who was anaesthetised with methohexital, see 'Anaesthetics, general + SSRIs', p.105.

SSRIs; Paroxetine + Miscellaneous

Paroxetine appears not to interact to a clinically important extent with aluminium hydroxide or food, although absorption may be reduced by large quantities of milk. Concurrent use of paroxetine and aprepitant may slightly reduce the plasma levels of both drugs, but this is probably not clinically significant.

Clinical evidence, mechanism, importance and management

(a) Aluminium hydroxide

Aludrox (aluminium hydroxide) 15 mL twice daily increased the absorption of a single 30-mg dose of paroxetine in healthy subjects by about 12%, and increased the maximum plasma concentration by 14%.¹ This is unlikely to be clinically important. No particular precautions would seem to be necessary on concurrent use.

(b) Aprepitant

The US manufacturer of aprepitant notes that the concurrent use of paroxetine 20 mg daily and aprepitant 85 or 170 mg daily reduced the AUC of both drugs by about 25%, and reduced the maximum serum levels by about 20%.² These changes are unlikely to be clinically important.

(c) Food or drink

A study in healthy subjects found that the absorption of paroxetine was not markedly changed by food. A 40% reduction in absorption was seen when paroxetine was taken with one litre of **milk**,¹ but few people are likely to drink such a large amount regularly, and so this interaction is unlikely to be clinically significant.

- Greb WH, Brett MA, Buscher G, Dierdorf H-D, von Schrader HW, Wolf D, Mellows G, Zussman BD. Absorption of paroxetine under various dietary conditions and following antacid intake. *Acta Psychiatr Scand* (1989) 80 (Suppl 350), 99–101.
- Emend (Aprepitant). Merck & Co., Inc. US Prescribing information, June 2006.

Tianeptine + Oxazepam

A study in healthy subjects given tianeptine 12.5 mg and oxazepam 10 mg both three times daily found no significant changes in the pharmacokinetics of either drug.¹

- Toon S, Holt BL, Langley SJ, Mullins FGP, Rowland M, Halliday MS, Salvadori C, Delalleau B. Pharmacokinetic and pharmacodynamic interaction between the antidepressant tianeptine and oxazepam at steady-state. *Psychopharmacology (Berl)* (1990) 101, 226–32.

Trazodone + Antidepressants

Trazodone and fluoxetine have been used concurrently with advantage, but some patients develop increased adverse effects. There have been isolated reports of the serotonin syndrome in patients receiving trazodone and MAOIs, usually in association with

other serotonergic drugs. A single case report describes the development of anorexia, psychosis and hypomania in a patient receiving trazodone and tryptophan.

Clinical evidence, mechanism, importance and management

(a) MAOIs

A case report describes a patient treated with trazodone, **isocarboxazid** and methylphenidate who developed symptoms of the serotonin syndrome.¹ The US manufacturer says due to the absence of clinical experience, if MAOIs are discontinued shortly before or are to be given concurrently with trazodone, therapy should be initiated cautiously with a gradual increase in dosage until optimum response is achieved.² However, the UK manufacturer of trazodone says possible interactions with MAOIs have occasionally been reported; they do not recommend concurrent use, nor should trazodone be given within 2 weeks of stopping an MAOI. MAOIs should not be taken within one week of stopping trazodone.³

(b) SSRIs

A patient taking trazodone showed a 31% increase in the antidepressant/dose ratio (suggesting increased trazodone levels) when **fluoxetine** 40 mg daily was added. She became sedated and developed an unstable gait.⁴ A study involving 27 patients also found that **fluoxetine** increases plasma trazodone levels.⁵ However, another study reported **citalopram** and **fluoxetine** had no significant impact on trazodone serum levels, even though the mean concentration/dose ratios were nearly 30% higher with the combined therapy than with trazodone monotherapy.⁶

A man with traumatic brain injury showed new-onset dysarthria and speech blocking when **fluoxetine** was added to trazodone. His speech returned to normal when the **fluoxetine** was stopped.⁷ A 39-year-old HIV-positive man taking multiple antiviral and antibacterial drugs experienced bilateral hand tremor while receiving trazodone 50 mg at bedtime, which worsened when the dose of trazodone was increased to 100 mg and **fluoxetine** 20 mg daily was added. The trazodone and **fluoxetine** were discontinued and the tremor completely disappeared after 7 days without specific treatment for myoclonus.⁸

Five out of 16 patients receiving **fluoxetine** stopped taking trazodone 25 to 75 mg, which was given for insomnia, because of excessive sedation the next day.⁹ Three out of 8 patients had improvement in sleep and depression when given both drugs but the other 5 were either unaffected or had intolerable adverse effects (headaches, dizziness, daytime sedation, fatigue).¹⁰ However, another report described advantageous concurrent use in 6 patients without an increase in adverse effects.¹¹

It appears that the plasma levels of trazodone may be increased by **fluoxetine** due to inhibition of cytochrome P450 isoenzymes by **fluoxetine** and/or norfluoxetine.⁵ Trazodone is a substrate for CYP3A4 and, although **fluoxetine** is a weak inhibitor, its metabolite norfluoxetine is a moderate inhibitor of this enzyme.⁸ *In vitro* data suggest **citalopram** has little inhibitory effect on CYP3A4.^{6,12}

These cases and studies suggest that the concurrent use of trazodone and **fluoxetine** can be useful and uneventful but it would seem prudent to monitor the outcome for any evidence of increased adverse effects. **Citalopram** would not be expected to have a pharmacokinetic interaction. However, the cases with **fluoxetine** suggest that a pharmacodynamic interaction may be possible, and therefore a degree of caution would be prudent if trazodone is given with any SSRI.

(c) Tryptophan

A single report describes the effective use of trazodone 100 mg and tryptophan 500 mg, both three times weekly with clonazepam in a patient with schizophrenia and congenital defects. However, the patient stopped eating, lost 4.5 kg in weight over 3 weeks, developed signs of psychosis or hypomania, and soon afterwards she became drowsy and withdrawn. When the drugs were withdrawn the aggressive behaviour restarted, but she responded again to lower doses of trazodone and tryptophan although the signs of psychosis re-emerged.¹³

(d) Venlafaxine

Trazodone + Azoles

Ketoconazole or itraconazole may inhibit the metabolism of trazodone.

Clinical evidence, mechanism, importance and management

An *in vitro* study demonstrated that **ketoconazole** inhibited the metabolism of trazodone to its principal metabolite, meta-chlorophenylpiperazine.¹ Trazodone is a substrate for the cytochrome P450 isoenzyme CYP3A4 and inhibitors of this enzyme such as **ketoconazole** or **itraconazole** may inhibit its metabolism, leading to substantial increases in trazodone plasma concentrations with the potential for adverse effects.^{2–4} The FDA in the US and the manufacturers of trazodone recommend that a lower dose of trazodone should be considered if it is given with a potent CYP3A4 inhibitor such as **ketoconazole** or **itraconazole**.^{2–4} However, the UK manufacturer also suggests that the combination should be avoided where possible.⁴

Trazodone + Ginkgo biloba

Coma developed in an elderly patient with Alzheimer's disease after she took trazodone with ginkgo biloba.

Clinical evidence, mechanism, importance and management

An 80-year-old woman with Alzheimer's disease developed coma a few days after starting low-dose trazodone 20 mg twice daily and ginkgo biloba. The patient woke immediately after being given flumazenil 1 mg intravenously. It was suggested that the flavonoids in the ginkgo had a subclinical direct effect on the benzodiazepine receptor. In addition, increased CYP3A4 metabolism of trazodone to its active metabolite, 1-(m-chlorophenyl)piperazine (mCPP), was thought to have enhanced the release of GABA (gamma-amino butyric acid). Flumazenil may have blocked the direct effect of the flavonoids, thus causing the GABA activity to fall below the level required to have a clinical effect.¹ This appears to be an isolated case, from which no general conclusions can be drawn.

1. Galluzzi S, Zanetti O, Binetti G, Trabucchi M, Frisoni GB. Coma in a patient with Alzheimer's disease taking low dose trazodone and ginkgo biloba. *J Neurol Neurosurg Psychiatry* (2000) 68, 679–80.

Trazodone + Haloperidol

Low-dose haloperidol is reported not to interact to a clinically relevant extent with trazodone.

Clinical evidence, mechanism, importance and management

Nine depressed patients who had been taking trazodone 150 to 300 mg at bedtime for 2 to 19 weeks were given haloperidol 4 mg daily for a week. Plasma trazodone levels were not significantly changed but levels of its metabolite (*m*-chlorophenylpiperazine) were slightly raised (from 78 to 92 nanograms/mL). This study¹ was carried out to investigate the way trazodone is metabolised, but it also demonstrated that no clinically relevant pharmacokinetic interaction occurs between these two drugs at these dosages.

1. Mihara K, Otani K, Ishida M, Yasui N, Suzuki A, Ohkubo T, Osanai T, Kaneko S, Sugawara K. Increases in plasma concentration of *m*-chlorophenylpiperazine, but not trazodone, with low-dose haloperidol. *Ther Drug Monit* (1997) 19, 43–5.

Trazodone + Lysergide (LSD)

A retrospective study found that 28 of 32 subjects (88%) who took LSD and who had taken an SSRI or trazodone for more than 3 weeks had a subjective decrease or virtual elimination of their responses to LSD.¹

1. Bonson KR, Buckholtz JW, Murphy DL. Chronic administration of serotonergic antidepressants attenuates the subjective effects of LSD in humans. *Neuropsychopharmacology* (1996) 14, 425–36.

Trazodone + Macrolides

Clarithromycin impaired the clearance of trazodone and enhanced its sedative effects in healthy subjects. Erythromycin is also likely to increase trazodone plasma levels.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in healthy subjects, clarithromycin impaired the clearance and enhanced the sedative effects of a 50-mg dose of trazodone.¹ The manufacturers comment that trazodone is a substrate for the cytochrome P450 isoenzyme CYP3A4 and inhibitors of this enzyme may inhibit its metabolism leading to substantial increases in trazodone plasma levels, with the potential for adverse effects.^{2,3} The UK manufacturer of trazodone recommends that a lower dose of trazodone should be considered if it is given with a CYP3A4 inhibitor such as erythromycin, but that concurrent use should be avoided where possible.³ It seems likely that all macrolides that inhibit CYP3A4 will interact to some extent. As azithromycin does not significantly affect CYP3A4 it would not be expected to interact.

2. Desyrel (Trazodone hydrochloride). Bristol-Myers Squibb Company. US Prescribing information, January 2005.
3. Molipaxin (Trazodone hydrochloride). Sanofi-Aventis. UK Summary of product characteristics, July 2005.

Trazodone + Protease inhibitors

Ritonavir impairs the clearance of trazodone with an increased potential for adverse effects. Other protease inhibitors may interact similarly.

Clinical evidence

A randomised, placebo-controlled, crossover study in 10 healthy subjects found that short-term exposure to low-dose ritonavir (200 mg twice daily for 2 days) impaired the clearance of a single 50-mg dose of trazodone by 52%. Mean peak plasma levels of trazodone were increased by 34%, and the AUC increased more than twofold. In addition, ritonavir enhanced the adverse effects of trazodone with increased sedation, fatigue and performance impairment.¹ Symptoms of the serotonin syndrome occurred in an HIV-positive patient taking antiretrovirals and other drugs, including fluoxetine and trazodone, when ritonavir was added. The symptoms resolved on discontinuing the trazodone and halving the ritonavir dose.² The serotonin syndrome has also been seen in a patient taking trazodone, indinavir and excessive amounts of 'grapefruit', (p.1217).

An *in vitro* study demonstrated that the metabolism of trazodone to its principal metabolite, meta-chlorophenylpiperazine (mCPP), was inhibited by ritonavir, which is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4. Indinavir was also a strong inhibitor of mCPP formation, whereas saquinavir and nelfinavir were considerably less potent inhibitors.³

Mechanism

Trazodone is a substrate for CYP3A4 and inhibitors of this enzyme such as ritonavir and indinavir may inhibit its metabolism, leading to substantial increases in trazodone plasma concentrations with the potential for adverse effects.⁴⁻⁶

Importance and management

The FDA in the US and the manufacturers of trazodone recommend that a lower dose of trazodone should be considered if it is given with potent CYP3A4 inhibitors such as the protease inhibitors ritonavir and indinavir.⁴⁻⁶ However, the UK manufacturer also suggests that the combination should be avoided where possible.⁵

Trazodone + Pseudoephedrine

A single report describes toxicity in a woman treated with trazodone when she took pseudoephedrine.

Clinical evidence, mechanism, importance and management

An isolated report describes a woman who had been taking trazodone 250 mg daily for 2 years who took two doses of a non-prescription medicine containing pseudoephedrine. Within 6 hours she experienced dread, anxiety, panic, confusion, depersonalisation and the sensation that parts of her body were separating. None of these symptoms had been experienced in the past when she was taking either preparation alone.¹ The reasons for this reaction are not understood. This appears to be an isolated case, and therefore no general conclusions can be drawn.

1. Weddige RL. Possible trazodone-pseudoephedrine toxicity: a case report. *Neurobehav Toxicol Teratol* (1985) 7, 204.

Tricyclic antidepressants + ACE inhibitors

Preliminary evidence from two patients suggests that enalapril may increase the effects of clomipramine, resulting in toxicity.

Clinical evidence

Two patients taking enalapril (one taking 20 mg daily and the other taking 20 mg five times weekly) were given clomipramine for depression. The clomipramine dosage of one of them was increased from 25 to 50 mg, and 10 days later he became euphoric and exalted. The problem resolved when the clomipramine dosage was reduced to 25 mg again. The other patient had been stable taking enalapril for over a year when clomipramine and disulfiram 400 mg daily were added. Within 2 weeks he developed confusion, irritability and insomnia. These adverse effects diminished when the clomipramine dosage was reduced to 50 mg daily.¹

Mechanism

The ratio of clomipramine to its metabolite (desmethylclomipramine) is normally less than 1, but both of these patients demonstrated a ratio of more than 1. This suggests that the normal metabolism (demethylation) of

the clomipramine was inhibited, thus allowing the clomipramine to accumulate and its toxic effects to manifest themselves. In the second patient the disulfiram may also have had a minor additional enzyme inhibitory effect.¹

Importance and management

Information is limited to these two cases and the interaction is not firmly established. More study is needed. There seems to be nothing documented about adverse effects from the concurrent use of the other ACE inhibitors and tricyclic antidepressants, although postural hypotension is a possibility.

1. Toutoungi M. Potential effect of enalapril on clomipramine metabolism. *Hum Psychopharmacol* (1992) 7, 347–9.

Tricyclic antidepressants + Amfetamines and related drugs

Methylphenidate can increase the levels and rate of response to tricyclic antidepressants. This has led to both increased beneficial and adverse effects. No significant pharmacokinetic interaction has been reported between desipramine and dexamfetamine or methylphenidate. An isolated report describes a blood dyscrasia in a child given methylphenidate and imipramine.

Clinical evidence

A study in 'several patients' demonstrated a dramatic increase in the plasma levels of **imipramine** and its active metabolite desipramine when they took **methylphenidate**. In one patient taking **imipramine** 150 mg daily, methylphenidate 20 mg daily increased the plasma levels of **imipramine** from 100 to 700 micrograms/L and of the metabolite desipramine from 200 to 850 micrograms/L over a period of 16 days. Clinical improvement occurred in several of the patients.¹ Similar effects have been described in other reports.^{2–5} It seems that elevation of drug levels takes several days to occur, and several days to wear off.³

A study of the combined use of tricyclic antidepressants (**desipramine**, **imipramine**, **nortriptyline**, **doxepin**) with **methylphenidate** 5 to 15 mg twice daily was undertaken in 20 of 41 patients with depression who responded to a test dose of **methylphenidate**. Combined use accelerated the antidepressant response to tricyclics with 6 of 20 patients responding after 1 week and 10 of 16 patients responding after 2 weeks. Adverse effects included insomnia, dizziness, hypotension and dry mouth. **Methylphenidate** was discontinued after less than 2 weeks concurrent use in 3 patients because of increased anxiety, irritability and hypomania.⁶ There is also a report of a 9-year-old boy and a 15-year-old boy who exhibited severe behavioural problems until the **imipramine** and **methylphenidate** they were taking were stopped.⁷ Another report describes more frequent adverse effects in 10 paediatric patients taking **methylphenidate** with **desipramine** than with **methylphenidate** alone.⁸ Three patients taking tricyclic antidepressants and with labile blood pressure experienced hypertensive episodes when **methylphenidate** was also given. They responded to withdrawal of **methylphenidate** and two patients had further hypertensive episodes when rechallenged with **methylphenidate**.⁹ An isolated report describes leucopenia, anaemia, eosinophilia and thrombocytosis in a child of 10 when given **imipramine** and **methylphenidate**.¹⁰ In one patient taking **desipramine** 250 mg daily, concurrent **methylphenidate** 40 mg daily resulted in a small decrease in serum **desipramine** levels, but a marked improvement in mood.¹¹

In contrast, a retrospective review in 142 children and adolescents taking either **desipramine** alone, or **desipramine** with **dexamfetamine** or **methylphenidate**, indicated the absence of a clinically significant interaction between **desipramine** and either stimulant. Pharmacokinetic parameters were similar in each group.¹²

Mechanism

In vitro experiments with human liver slices indicate that methylphenidate inhibits the metabolism of imipramine, resulting in raised blood levels.³ The accelerated response to tricyclic antidepressants may also be partly due to increased serum levels in the presence of methylphenidate, although the adverse effects observed were not entirely consistent with elevated levels of tricyclics.⁶ There are also reports suggesting that

methylphenidate does not significantly affect desipramine levels.^{8,11} The blood dyscrasia may have been due to the rare additive effects of both drugs.¹⁰

Importance and management

Information is limited. Some therapeutic improvement including accelerated response is seen in some patients. This may be partially because of the very marked rise in the blood levels of the antidepressant due to methylphenidate, but may also be due to an additional effect on mood attributable to methylphenidate. Concurrent use may cause adverse effects sufficiently severe to necessitate withdrawal of methylphenidate, but it is not certain whether this can solely be attributed to increases in serum levels of tricyclic antidepressants. Information about other tricyclic antidepressants is lacking. However, it has been suggested that concurrent use in children and adolescents may be undesirable, due to case reports of adverse behavioural effects.⁷ If concurrent use is deemed necessary it would seem prudent to monitor concurrent use for adverse tricyclic effects (e.g. dry mouth, blurred vision, urinary retention) and adjust the dose as necessary.

Tricyclic antidepressants + Azoles; Fluconazole

Markedly increased serum amitriptyline levels developed in five patients and increased serum nortriptyline levels in another patient when they took fluconazole. Mental changes, syncope, and prolonged QTc interval occurred in some of these patients and there is also a report of prolonged QT interval and torsades de pointes associated with the concurrent use of amitriptyline and fluconazole in a further patient.

Clinical evidence

(a) Amitriptyline

A man with AIDS given fluconazole 200 mg daily and amitriptyline 25 mg then 50 mg three times a day developed mental changes and visual hallucinations within 3 days. His serum amitriptyline levels were found to be 724 nanograms/mL (therapeutic levels 150 to 250 nanograms/mL). The confusion resolved within 4 days of stopping the amitriptyline when the levels had fallen to 270 nanograms/mL. Two similar cases were described in this report, in one case in a patient with renal impairment.¹ A woman taking amitriptyline 100 mg twice daily, isosorbide mononitrate and metoprolol became lethargic, drowsy and confused 4 days after starting fluconazole 100 mg daily. She was found to have elevated serum levels of amitriptyline plus nortriptyline of 956 nanograms/mL (patient's usual range 150 to 250 nanograms/mL) and a prolonged QTc interval. At first, amitriptyline overdose was suspected. The patient was intubated but became delirious, agitated and disorientated. She recovered over the next 24 hours and the amitriptyline level had fallen to 190 nanograms/mL after 4 days. It was concluded that the amitriptyline toxicity was due to an interaction with fluconazole.²

Other reports similarly describe increased amitriptyline levels when fluconazole was given; in a child who developed syncope as a result³ and in

a 57-year-old woman who developed QT-interval prolongation (although hypokalaemia and the use of sertraline, which can increase serum tricyclic levels, may have contributed to this effect).⁴

(b) Nortriptyline

An elderly woman taking nortriptyline 75 mg daily and other drugs (ciclosporin, morphine, metoclopramide, bumetanide as well as an unnamed antibacterial) was given fluconazole (loading dose of 200 mg, followed by 100 mg daily). After concurrent use for 13 days her trough serum nortriptyline levels had risen by 70% (from 149 to 252 nanograms/mL).⁵

Mechanism

Not understood, but it has been suggested that the fluconazole inhibits the cytochrome P450 isoenzymes CYP2C9, CYP2C19, CYP3A4 and possibly CYP2D6, which are concerned with the metabolism of these tricyclics, and as a result their serum levels rise.^{1,3}

Importance and management

Information about an interaction between tricyclics and fluconazole seems to be limited to these reports, which, bearing in mind the widespread use of these drugs, would suggest that these interactions are uncommon. The evidence suggests that other factors (such as renal impairment and other potentially interacting medications) may be necessary before this interaction occurs. Bear this possible interaction in mind if tricyclic adverse effects become troublesome.

Tricyclic antidepressants + Azoles; Ketoconazole

Ketoconazole appears not to interact with desipramine, and only interacts to a small and clinically irrelevant extent with imipramine.

Clinical evidence, mechanism, importance and management

Two groups of 6 healthy subjects were given a single 100-mg dose of either **imipramine** or **desipramine** alone, and then again on day 10 of a 14-day course of ketoconazole 200 mg once daily. It was found that the ketoconazole caused the oral clearance of the **imipramine** to fall by 17%, its half-life to rise by 15% and the AUC of **desipramine**, derived from the **imipramine**, to fall by 9%. No significant changes in the pharmacokinetics of the **desipramine** were seen.¹

These findings show that ketoconazole inhibits the demethylation of **imipramine** without affecting the 2-hydroxylation of **imipramine** and **desipramine**, and confirms that cytochrome P450 isoenzyme CYP3A4 has a role in the metabolism of these tricyclic antidepressants.¹ However, in practical terms it would seem that any changes are small and unlikely to be of any clinical significance. No special precautions would appear necessary if ketoconazole is used with either of these two drugs. Information about other tricyclics seems to be lacking.

1. Spina E, Avenoso A, Campo GM, Scordo MG, Caputi AP, Perucca E. Effect of ketoconazole on the pharmacokinetics of imipramine and desipramine in healthy subjects. *Br J Clin Pharmacol* (1997) 43, 315–8.

Tricyclic antidepressants + Baclofen

An isolated report describes a patient with multiple sclerosis taking baclofen who was unable to stand within a few days of starting to take nortriptyline, and later imipramine.

Clinical evidence, mechanism, importance and management

A man with multiple sclerosis, who was taking baclofen 10 mg four times a day to relieve spasticity, complained of leg weakness and was unable to stand within 6 days of starting to take **nortriptyline** 50 mg at bedtime. His muscle tone returned 48 hours after stopping the **nortriptyline**. Two weeks later he was given **imipramine** 75 mg daily and once again his muscle tone was lost.¹ The reason is not understood. There seems to be nothing documented about any other tricyclic antidepressant and baclofen. Prescribers should be aware of this report if considering the use of both drugs, but its general importance is not known. It is probably small.

1. Silverglat MJ. Baclofen and tricyclic antidepressants: possible interaction. *JAMA* (1981) 246, 1659.

Tricyclic antidepressants + Barbiturates

The plasma levels of amitriptyline, imipramine and nortriptyline can be reduced by the barbiturates. A reduced therapeutic response would be expected. The tricyclics also lower the convulsive threshold and may be inappropriate for patients with convulsive disorders.

Clinical evidence

A comparative study in 5 pairs of twins given **nortriptyline** found that the twins also taking unnamed barbiturates had considerably lower steady-state plasma **nortriptyline** levels.¹

Similar observations have been made in patients and healthy subjects taking **nortriptyline** with **amobarbital**^{2,3} or **pentobarbital**,⁴ and **protriptyline** with **amobarbital sodium**.⁵ Another patient had a reduction in blood **imipramine** levels of about 50% (and loss of antidepressant control) within 2 weeks of starting to take about 400 mg of **butalbital** daily.⁶

Mechanism

The barbiturates are potent liver enzyme inducers and may therefore increase the metabolism and clearance of the tricyclic antidepressants from the body.

Importance and management

The interaction between tricyclic antidepressants and barbiturates is established. By no means every drug pair has been studied but since the barbiturates as a whole are potent liver enzyme inducers one should be alert for this interaction with any of them. Some reduction in the effects of the tricyclic would be expected, but the general clinical importance is uncertain.

Note that the tricyclics lower the convulsive threshold and may therefore be inappropriate for patients with convulsive disorders.

6. Garey KW, Amsden GW, Johns CA. Possible interaction between imipramine and butalbital. *Pharmacotherapy* (1997) 17, 1041–2.

Tricyclic antidepressants + Benzodiazepines and related drugs

Concurrent use is not uncommon and normally appears to be uneventful. However, three patients became drowsy, forgetful and appeared uncoordinated and drunk while taking amitriptyline and chlorthalidoxepoxide. A combined preparation of amitriptyline and chlorthalidoxepoxide (*Limbtirol*) is available but its advantages have been questioned: adverse effects have been seen in four patients. Diazepam may increase the risks of carrying out complex tasks (e.g. driving) if added to amitriptyline, as may other combinations of benzodiazepines and tricyclics.

Clinical evidence

(a) Amitriptyline

1. *Chlordiazepoxide*. Clinical studies in large numbers of patients have shown that the incidence of adverse reactions while taking amitriptyline and chlordiazepoxide was no greater than might have been expected with either of the drugs used alone,¹⁻³ but a few adverse reports have been documented. A depressed patient taking amitriptyline 150 mg and chlordiazepoxide 40 mg daily became confused, forgetful and uncoordinated. He acted as though he was drunk.⁴ Two other patients taking amitriptyline and chlordiazepoxide experienced drowsiness, memory impairment, slurring of the speech and an inability to concentrate. Both were unable to work and one described himself as feeling drunk.⁵ Four patients taking *Limbitrol* are reported to have experienced some manifestations of toxicity (delusions, confusion, agitation, disorientation, dry mouth, blurred vision).⁶ Some of these effects seem to arise from increased CNS depression (possibly additive) and/or an increase in the antimuscarinic adverse effects of the tricyclic.

2. *Diazepam*. A study demonstrated an increase in amitriptyline levels when diazepam was given,⁷ and two others found that the addition of diazepam to amitriptyline 50 to 75 mg further reduced attention and the performance of a number of psychomotor tests.^{8,9} In contrast, two studies suggested that diazepam did not affect amitriptyline levels.^{3,10}

3. *Nitrazepam* or *Oxazepam*. Studies on the effects of nitrazepam and oxazepam on the steady-state plasma levels of amitriptyline;³ did not find any interactions.

(b) Clomipramine

One study suggested that alprazolam does not affect clomipramine levels.¹¹

(c) Desipramine

1. *Alprazolam*. An *in vitro* study in human liver microsomes found that alprazolam does not affect the metabolism (hydroxylation) of desipramine.¹²

2. *Clonazepam*. An isolated report describes a patient taking desipramine 300 mg daily whose serum desipramine levels were halved when he was given clonazepam 3 mg daily and rose again when it was withdrawn.¹³

3. *Zolpidem*. Visual hallucinations have been seen in one patient given zolpidem and desipramine.¹⁴

(d) Imipramine

1. *Alprazolam*. Alprazolam seems to raise imipramine levels by about 20 to 30%.¹⁵

2. *Triazolam*. Triazolam is effective in treating insomnia in depressed patients taking imipramine, and does not reduce the effects of the antidepressant.^{16,17}

3. *Zaleplon*. A single 75-mg dose of imipramine had no effect on the pharmacokinetics of zaleplon 20 mg, and psychomotor tests showed only short term additive effects lasting 1 to 2 hours.¹⁸

4. *Zolpidem*. A single-dose study using zolpidem 20 mg and imipramine 75 mg found no effect on the pharmacokinetics of either drug. However, imipramine increased the sedative effects of zolpidem, and anterograde amnesia was seen.¹⁹

(e) Nortriptyline

Lorazepam may be useful for anxiety or insomnia in elderly depressed patients without impairing the response to treatment with nortriptyline.²⁰

Studies on the effects of alprazolam, chlordiazepoxide, diazepam, nitrazepam and oxazepam on the steady-state plasma levels of nortriptyline^{3,12,21} found no interactions.

(f) Trimipramine

In a study in 10 healthy subjects, when zopiclone and trimipramine were given concurrently for a week, the bioavailability of zopiclone was reduced by almost 14% and the bioavailability of the trimipramine by almost 27%, but neither of these changes were statistically significant.²²

Mechanism

Uncertain. Additive CNS depression and increased antimuscarinic effects are a possibility with some combinations.

Importance and management

There seems to be no reason for avoiding the concurrent use of benzodiazepines and tricyclics although the advantages and disadvantages remain the subject of debate. Other combinations of tricyclic antidepressants and benzodiazepines would not be expected to behave differently from those described here. Some patients will possibly experience increased drowsiness and inattention with the more sedative antidepressants such as amitriptyline, particularly during the first few days, and this may be exaggerated by benzodiazepines such as diazepam. Driving risks may therefore be increased.

Tricyclic antidepressants + Bupropion

Bupropion may increase the levels of tricyclic antidepressants that are metabolised by CYP2D6, including desipramine, imipramine, and nortriptyline. Adverse effects including confusion, lethargy and unsteadiness have been reported with nortriptyline and bupropion. A seizure occurred in a patient given trimipramine and bupropion.

Clinical evidence

A pharmacokinetic study in healthy subjects known to be extensive metabolisers of CYP2D6 found that bupropion doubled the maximum plasma levels of **desipramine** and increased its AUC fivefold.^{1,2} Another study in a 64-year-old woman taking **imipramine** 150 to 200 mg daily found that when bupropion 225 mg daily was added, there was a fourfold rise in the plasma levels of **imipramine** and its metabolite desipramine, but no problems were reported. A comparison of the estimated clearances were: without bupropion, **imipramine** 1.7 mL/minute and **desipramine** 1.7 mL/minute; with bupropion, **imipramine** 0.73 mL/minute and **desipramine** 0.31 mL/minute.³

Nortriptyline toxicity occurred in an 83-year-old woman when sustained-release bupropion was also given. **Nortriptyline** 75 mg at night produced a plasma level of 96 nanograms/mL, but when bupropion

150 mg twice daily was added she became unsteady, confused and lethargic and her plasma **nortriptyline** level increased by about 200% (to 274 nanograms/mL). The increased plasma **nortriptyline** level and toxicity occurred again when she was rechallenged with bupropion.⁴ An isolated report describes a seizure when **trimipramine** 100 mg daily was taken with bupropion 150 mg twice daily. The addition of bupropion resulted in a substantial increase in her plasma levels of **trimipramine** into the 'toxic' range. She was later successfully treated with lower doses of both drugs (**trimipramine** 50 mg at night and bupropion 150 mg daily).⁵

Mechanism

In vitro studies^{1,2} have shown that both bupropion and its active metabolite, hydroxybupropion, are inhibitors of CYP2D6, the isoenzyme involved with the metabolism of these tricyclics, which would explain why their levels rose.

Importance and management

Although clinical evidence is limited it is supported by *in vitro* data, and so an interaction would seem to be established. It would seem prudent to be alert for increased tricyclic adverse effects if any of these drugs listed here is given with bupropion, and reduce the tricyclic dose as necessary. Note that bupropion is predicted to increase the risk of seizures with tricyclics, and this effect is dose-related. See 'Bupropion + Miscellaneous', p.1206.

Tricyclic antidepressants + Butyrophenones

Serum desipramine levels can be considerably increased in a few patients by haloperidol. This may have caused a grand mal seizure in one case but toxic reactions appear to be uncommon. Desipramine and bromperidol appear not to interact.

Clinical evidence

(a) Bromperidol

When 13 schizophrenics taking bromperidol 12 to 24 mg daily for 1 to 20 weeks were additionally given **desipramine** 50 mg daily for a week, bromperidol plasma levels remained unchanged and no adverse clinical events were seen.¹

(b) Haloperidol

1. *Desipramine*. A comparative study in patients taking similar doses of desipramine (2.5 to 2.55 mg/kg) showed that the two patients also taking haloperidol had steady-state plasma desipramine levels that were more than double those of 15 others not taking haloperidol (255 nanograms/mL compared with 110 nanograms/mL).²

A case report describes a patient who had a grand mal seizure when taking desipramine with haloperidol. Her serum desipramine levels were unusually high at 610 nanograms/mL.³

2. *Imipramine*. The urinary excretion of a test dose of ¹⁴C-imipramine given to two schizophrenic patients was reduced by about 35 to 40% when they took haloperidol 12 to 20 mg daily.⁴ The plasma metabolite levels of ¹⁴C-nortriptyline of another schizophrenic fell while taking haloperidol 16 mg daily, whereas plasma levels of unchanged nortriptyline rose.⁵

Mechanism

Haloperidol reduces the metabolism of the tricyclic antidepressants, thereby reducing their clearance, which results in a rise in their plasma levels.

Importance and management

The interaction between the tricyclic antidepressants and haloperidol is established though its documentation is sparse. Concurrent use is common

whereas adverse reactions are not, but be aware that serum desipramine levels may be elevated. This may have been the cause of the grand mal seizure in the case cited.³ Imipramine appears to interact similarly. Monitor the outcome if haloperidol is added to established treatment with tricyclic antidepressants.

Note that bromperidol and haloperidol prolong the QT-interval, and this effect has been seen with tricyclics, usually in overdose, see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Tricyclic antidepressants + Calcium-channel blockers

Diltiazem and verapamil can increase plasma imipramine levels, possibly accompanied by undesirable ECG changes. Two isolated reports describe increased nortriptyline and trimipramine levels in two patients given diltiazem.

Clinical evidence

(a) Imipramine

Twelve healthy subjects were given a 7-day course of **verapamil** 120 mg every 8 hours and 13 healthy subjects were given a 7-day course of **diltiazem** 90 mg every 8 hours. The AUCs of a single 100-mg dose of imipramine given on day 4 were increased by 15% by **verapamil**, and 30% by **diltiazem**. One hour after taking imipramine (2 hours after taking the calcium-channel blockers), the average PR interval was greater than 200 milliseconds, which represented first-degree heart block. Two subjects developed second-degree heart block after taking imipramine with **verapamil**.¹

(b) Nortriptyline

A diabetic patient taking glipizide and aspirin started taking nortriptyline, and, at the same time, his treatment with **nifedipine** was replaced by **diltiazem** 180 mg daily initially, raised to 240 mg daily after a week. Several changes in the nortriptyline dosage were made over a 4-week period because its plasma levels became unexpectedly high (the ratio of plasma nortriptyline to its dosage were approximately doubled).²

(c) Trimipramine

A depressed woman taking trimipramine 125 mg daily developed high plasma levels of 546 micrograms/L while taking **diltiazem** 60 mg three times daily. Two weeks later they reached 708 micrograms/L, despite a reduction in the trimipramine dosage to 75 mg daily. She showed no toxicity and her ECG was normal.³

Mechanism

It has been suggested that diltiazem and verapamil increase the bioavailability of imipramine by decreasing its clearance. The ECG changes appear to result from the increased imipramine levels and the additive effects of both drugs on the atrioventricular conduction time. Diltiazem may similarly affect nortriptyline and trimipramine.

Importance and management

Information appears to be limited to these reports so that the general clinical importance of each of these interactions is uncertain. However it would now seem prudent to be alert for evidence of increases in the levels of tricyclic antidepressants if diltiazem or verapamil is added. The evidence of heart block with imipramine and diltiazem is of particular concern.

Tricyclic antidepressants + Cannabis

Tachycardia has been described when patients taking tricyclic antidepressants smoked cannabis.

Clinical evidence, mechanism, importance and management

A 21-year-old woman taking **nortriptyline** 30 mg daily experienced marked tachycardia (an increase from 90 to 160 bpm) after smoking a cannabis cigarette. It was controlled with propranolol.¹ A 26-year-old complained of restlessness, dizziness and tachycardia (120 bpm) after smoking cannabis while taking **imipramine** 50 mg daily.² Four adolescents aged 15 to 18 taking tricyclic antidepressants for attention-deficit hyperactivity disorder had transient cognitive changes, delirium and tachycardia after smoking cannabis.³

Increased heart rates are well-documented adverse effects of both the tricyclic antidepressants and cannabis, and what occurred was probably due to the additive beta-adrenergic and antimuscarinic effects of the tricyclics, with the beta-adrenergic effect of the cannabis. Direct information is limited but it has been suggested that concurrent use should be avoided.¹

Tricyclic antidepressants + Carbamazepine

The serum levels of amitriptyline, desipramine, doxepin, imipramine and nortriptyline can be reduced (halved or more) by carbamazepine but there is evidence that this is not necessarily clinically important. In contrast raised clomipramine levels have been seen in patients taking carbamazepine. An isolated report describes carbamazepine toxicity in a patient shortly after she started to take desipramine.

Clinical evidence

(a) Carbamazepine levels increased

A woman receiving long-term treatment with carbamazepine developed toxicity (nausea, vomiting, blurred vision with visual hallucinations, slurred speech, ataxia) within 6 days of starting to take **desipramine** daily (3 days at 150 mg daily). Her carbamazepine levels were found to have doubled from 7.7 to 15 micrograms/mL.¹

(b) Tricyclic levels increased

A study confirming the value of carbamazepine and **clomipramine** in the treatment of post-herpetic neuralgia found that carbamazepine appeared to raise both **clomipramine** plasma levels and those of its major metabolite (desmethylclomipramine).²

(c) Tricyclic levels reduced

A study found that carbamazepine reduced the serum levels of **nortriptyline** by 58% and of **amitriptyline** plus its metabolite, **nortriptyline**, by 60% in 8 psychiatric patients. In 17 other patients carbamazepine reduced serum **doxepin** levels by 54% and **doxepin** plus its metabolite, **nordoxepin**, by 55%.³ A retrospective study of very large numbers of patients confirmed that carbamazepine approximately halves the serum levels of **amitriptyline** and **nortriptyline**.⁴ An elderly woman needed her **nortriptyline** dosage to be increased from 75 to 150 mg daily to achieve effective antidepressant serum levels when carbamazepine 500 to 600 mg daily was added.⁵

In a study in 36 children (aged 5 to 16 years) with attention-deficit disorder taking **imipramine**, or **imipramine** and carbamazepine for 1 to 6 months, found that even though the **imipramine** dosage was significantly higher in the combined treatment group, the plasma levels were significantly lower; and the total plasma antidepressant levels were approximately half of those found in the children not taking carbamazepine.⁶ A study⁷ in 6 healthy subjects found that carbamazepine

200 mg twice daily for a month increased the apparent oral clearance of a single 100-mg dose of **desipramine** (given on day 24) by 31% and shortened its half-life from 22.1 to 17.8 hours. A patient given **desipramine** and carbamazepine is reported to have had exceptionally low serum **desipramine** levels and cardiac complaints, which may have been due to the presence of increased levels of the hydroxy metabolite of **desipramine**.⁸

A study in 13 patients with endogenous depression (DSM-III-R) taking **imipramine**, which confirmed that carbamazepine reduced the total serum levels of **imipramine** and desipramine, found that levels of the pharmacologically active free drugs remained unchanged.^{9,10} Moreover 10 of the patients demonstrated a positive therapeutic response (greater than a 50% decrease in the Hamilton Depression Rating Scale) and a reduction in adverse drug reactions.⁹

Mechanism

It seems likely that the carbamazepine (a recognised enzyme-inducing drug) increases the metabolism and loss of these tricyclics from the body, thereby reducing their serum levels. The reason for the increased serum carbamazepine and clomipramine levels is not understood.

Importance and management

The reduction in the serum levels of amitriptyline, desipramine, doxepin, imipramine and nortriptyline caused by the interaction with carbamazepine appears to be established but the clinical importance is very much less certain. Evidence from one study,⁹ that achieved a beneficial response in patients taking tricyclics and carbamazepine suggests that it is possibly not necessary to increase the tricyclic dosage to accommodate this interaction. The fact that a retrospective study found that increased imipramine doses were being given to those taking carbamazepine suggests that this interaction will be naturally accounted for. If carbamazepine is added to treatment with any of these tricyclics, be aware that the dose of the tricyclic may need to be titrated up to achieve the desired therapeutic response. Remember too that the tricyclics can lower the convulsive threshold and should therefore be used with caution in patients with epilepsy.

Tricyclic antidepressants + Colestyramine

Colestyramine causes a moderate fall in the plasma levels of imipramine. *In vitro* evidence suggests that amitriptyline, desipramine and nortriptyline are likely to be similarly affected. One patient who had an unusual gut pathology and depression controlled by doxepin became depressed again when colestyramine was added.

Clinical evidence

Six depressed patients taking **imipramine** 75 to 150 mg, usually twice daily, were given colestyramine 4 g three times daily for 5 days. The plasma levels of **imipramine** fell by an average of 23% (range 11 to 30%) and the plasma levels of desipramine (the major metabolite) fell, although this was less consistent and said not to be statistically significant.

The effect of these reduced levels on the control of the depression was not assessed.¹

A man whose depression was controlled with **doxepin** relapsed within a week of starting to take colestyramine 6 g twice daily. Within 3 weeks of increasing the dosage separation levels of the two drugs from 4 to 6 hours his combined serum antidepressant levels (i.e. **doxepin** plus *n*-desmethyldoxepin) had risen from 39 to 81 nanograms/mL and his depression had improved. Reducing the colestyramine dosage to a single 6-g dose daily, separated from the **doxepin** by 15 hours, resulted in a further rise in his serum antidepressant levels to 117 nanograms/mL accompanied by relief of his depression.²

Mechanism

It seems almost certain that these tricyclics become bound to the colestyramine (an anion-exchange resin) within the gut, thereby reducing their absorption. An *in vitro* study³ with simulated gastric fluid found that, at pH 1, **amitriptyline**, **desipramine**, **doxepin**, **imipramine** and **nortriptyline** were approximately 79 to 90% bound by colestyramine: at pH 4 they were 36 to 48% bound and at pH 6.5 they were 62 to 76% bound. In an earlier study,⁴ binding of these tricyclics at pH 1 had ranged from 76 to 100%.

Importance and management

The interaction between imipramine and colestyramine is established but of uncertain clinical importance because the fall in the plasma imipramine levels quoted above was only moderate (23%) and the effects were not measured. The single case involving doxepin² was unusual because the patient had an abnormal gastrointestinal tract (hemigastrectomy with pyloroplasty and chronic diarrhoea). Nevertheless it would now be prudent to be alert for any evidence of a reduced antidepressant response if colestyramine is given concurrently. A simple way of minimising the admixture of the drugs in the gut is to separate their administration. It is usually suggested that these drugs should be given 1 hour before or 4 to 6 hours after colestyramine. There seems to be no direct clinical information about other tricyclics but *in vitro* studies suggest that amitriptyline, desipramine and nortriptyline probably interact like imipramine.

Tricyclic and related antidepressants + Co-trimoxazole

Four patients taking tricyclic antidepressants and one taking viloxazine relapsed when they took co-trimoxazole. Recurrence of panic attacks occurred in another patient taking imipramine when she also took co-trimoxazole.

Clinical evidence, mechanism, importance and management

Four patients taking tricyclic antidepressants (**imipramine**, **clomipramine**, **dibenzepin**) and one taking **viloxazine** relapsed into depression when they took co-trimoxazole (trimethoprim with sulfamethoxazole) for 2 to 9 days.¹ The reasons are not known. Another patient treated for 5 years with alprazolam and **imipramine** for panic disorder and who had not had panic attacks for several months developed insomnia, anxiety and panic attacks within 6 days of starting to take co-trimoxazole. The panic

attacks stopped when she stopped taking co-trimoxazole. It is not known whether co-trimoxazole interacted with alprazolam and **imipramine** to reduce their effects or whether co-trimoxazole, which may cause nervousness, had exacerbated the panic disorder.² These seem to be the only reports of a possible interaction between these drugs so that the general importance is very uncertain.

2. Zealberg JJ, Lydiard RB, Christie S. Exacerbation of panic disorder in a woman treated with trimethoprim-sulfamethoxazole. *J Clin Psychopharmacol* (1991) 11, 144–5.

Tricyclic antidepressants + Disulfiram

Disulfiram reduces the clearance of imipramine and desipramine. The concurrent use of amitriptyline and disulfiram has been reported to cause a therapeutically useful increase in the effects of disulfiram but 'organic brain syndrome' has been seen in two patients.

Clinical evidence, mechanism, importance and management

It has been noted that **amitriptyline** increases the effects of both disulfiram and citrated **calcium carbimide** without any increase in adverse effects.¹ However, there is also some evidence that an adverse interaction can occur. A study in two men found that disulfiram 500 mg daily increased the AUC of **imipramine** (12.5 mg given intravenously after an overnight fast) by about 30%, and of **desipramine** 12.5 mg given intravenously in one subject by a similar amount.² Peak plasma levels were also increased. The suggested reason is that the disulfiram inhibits the metabolism of the antidepressants by the liver. There is also a report of a man taking disulfiram who, when given **amitriptyline**, complained of dizziness, visual and auditory hallucinations, and who became disorientated to person, place and time. A similar reaction was seen in another patient.³ Concurrent use should therefore be well monitored for any evidence of toxicity.

3. Maany I, Hayashida M, Pfeffer SL, Kron RE. Possible toxic interaction between disulfiram and amitriptyline. *Arch Gen Psychiatry* (1982) 39, 743–4.

Tricyclic antidepressants + Fenfluramine

It has been said that the concurrent use of tricyclics and fenfluramine is safe and effective; however, others have suggested that as fenfluramine can cause depression, concurrent use should be avoided if the tricyclic is given for depression.

Clinical evidence, mechanism, importance and management

Exacerbation of depression has been seen in some patients given fenfluramine¹ and several cases of withdrawal depression have been observed in patients taking amitriptyline and fenfluramine, following episodes of severe depression.² The manufacturers have advised that fenfluramine should not be used in patients with a history of depression or in those being treated with antidepressants.³ On the other hand it has also been claimed that fenfluramine can be used safely and effectively with tricyclic antidepressants.^{4,5} One report describes a rise in the plasma levels of amitriptyline when fenfluramine 60 mg daily was given to patients taking amitriptyline 150 mg daily.⁶

Note that fenfluramine was widely withdrawn in 1997 because its use was found to be associated with a high incidence of abnormal echocardiograms indicating abnormal functioning of heart valves.

Tricyclic antidepressants + Flupentixol

Flupentixol did not inhibit the metabolism of imipramine in two patients but high levels of imipramine and its metabolite, desipramine, were found in another patient.

Clinical evidence, mechanism, importance and management

A study using ¹⁴C-imipramine showed that, unlike the situation with the 'phenothiazines', (p.760), flupentixol 3 to 6 mg daily did not inhibit the metabolism of imipramine in 2 patients.¹ However, there is an isolated report of very high plasma levels of imipramine and its metabolite desipramine in a patient with schizophrenia who was given flupentixol decanoate 40 mg intramuscularly once every 2 weeks and imipramine 150 mg daily. It was suggested that this may have resulted from competitive inhibition of liver enzymes.² This is an isolated case and its general significance is unknown.

Tricyclic antidepressants + Food

Limited evidence suggests that very high fibre diets can reduce the serum levels of doxepin and desipramine, and therefore decrease their effects. The bioavailability of amitriptyline may be affected by food.

Clinical evidence, mechanism, importance and management

Three patients showed no response to doxepin or desipramine and had reduced serum tricyclic antidepressant levels while taking very high fibre diets (wheat bran, wheat germ, oat bran, rolled oats, sunflower seeds, coconut shreds, raisins, bran muffins). When the diet was changed or stopped, the serum tricyclic antidepressant levels rose and the depression was relieved.¹ The reasons for this effect are not known. This interaction may possibly provide an explanation for otherwise unaccountable relapses or inadequate responses to tricyclic antidepressant treatment. Another study in 12 healthy subjects found that breakfast had no effect on the bioavailability of a 50-mg dose of imipramine, or on its peak levels or the time to peak levels.² A study in 9 healthy subjects given a single 25-mg dose of amitriptyline in the fasting state and with a standardised breakfast found that there were no consistent significant changes in the bioavailability of amitriptyline or its main metabolite nortriptyline. Similar results were found in a parallel study in which the same subjects were given a single 25-mg dose of nortriptyline. However, there were large inter-individual changes in the AUC of amitriptyline after food, ranging from an increase of 94% to a decrease of about 40%. The largest food-related amitriptyline AUC increases occurred among the subjects with the lowest fasting AUC values and the only major food-related decrease occurred in the subject with the largest fasting AUC. It was concluded that for an individual patient, the timing of amitriptyline administration in relation to food intake should be standardised to avoid large variations in drug levels.³

Tricyclic antidepressants + Grapefruit juice

Grapefruit juice does not appear to have a clinically significant affect on amitriptyline or clomipramine levels or imipramine absorption.

Clinical evidence, mechanism, importance and management

A study in 6 patients given clomipramine 112.5 to 225 mg daily found that grapefruit juice 250 mL increased the mean plasma levels of clomipramine and desmethylclomipramine by 4.5% and 10.5%, respectively. In another 7 patients taking amitriptyline 100 to 150 mg daily grapefruit juice did not affect tricyclic plasma levels.¹

Tricyclic antidepressants + H₂-receptor antagonists

Cimetidine can raise the plasma levels of amitriptyline, desipramine, doxepin, imipramine and nortriptyline. Other tricyclic antidepressants are expected to interact similarly. Ranitidine does not appear to interact with the tricyclics.

Clinical evidence

(a) Amitriptyline

After a group of healthy subjects took cimetidine 300 mg every 6 hours for two days, the peak plasma levels and the AUC of a single 25-mg dose of amitriptyline were raised by 37% and 80%, respectively.¹

Another study by the same authors found that ranitidine does not interact with amitriptyline.²

(b) Desipramine

In a study in 8 patients cimetidine 1 g daily for 4 days raised the plasma levels of desipramine 100 to 250 mg daily by 51%, and its hydroxylated metabolite (2-hydroxydesipramine) was raised by 46%.³ Another study showed that this interaction only occurs in those individuals who are [CYP2D6 extensive metabolisers].⁴

(c) Doxepin

A study in 10 healthy subjects given a single 100-mg oral dose of doxepin 12 hours after starting to take cimetidine 300 mg every 6 hours found that the peak plasma level and AUC of doxepin were raised by 28% and 31%, respectively.⁵

In another study cimetidine 600 mg twice daily was found to double the steady-state plasma levels of doxepin 50 mg daily, whereas ranitidine 300 mg daily had no effect.⁶ A patient taking doxepin complained that the normally mild adverse effects (urinary hesitancy, dry mouth and decreased visual acuity) became incapacitating when he also took cimetidine. His serum doxepin levels were found to be elevated.⁷

(d) Imipramine

In 12 healthy subjects cimetidine 300 mg every 6 hours for 3 days raised the peak plasma levels and the AUC of a single 100-mg dose of imipramine by 65% and 172%, respectively. After taking ranitidine 150 mg twice daily for 3 days the pharmacokinetics of imipramine were unaltered.⁸ These findings with cimetidine confirm those of previous studies.^{9,10}

There are case reports of patients taking imipramine who developed severe antimuscarinic adverse effects (dry mouth, urine retention, blurred vision) associated with very marked rises in serum imipramine levels when they also took cimetidine.^{11,12}

(e) Nortriptyline

After taking cimetidine 300 mg four times daily for 2 days, the peak plasma nortriptyline levels of 6 healthy subjects were not significantly raised, but the AUC was increased by 20%.⁹

A case report describes a patient whose serum nortriptyline levels were raised about one-third while taking cimetidine.¹³ Another patient complained of abdominal pain and distention (but no other antimuscarinic adverse effects) when treated with nortriptyline and cimetidine.¹⁴

Mechanism

Cimetidine is a potent liver enzyme inhibitor, which reduces the metabolism of the tricyclic antidepressants, and may also reduce the hepatic clearance of these drugs. This results in a rise in their serum levels. Ranitidine does not interact because it is not an enzyme inhibitor.

Importance and management

The interactions with cimetidine are well established, well documented and of clinical importance. The incidence is uncertain but most patients could be affected. Those taking amitriptyline, desipramine, doxepin, imipramine or nortriptyline who are given cimetidine should be warned that adverse effects such as mouth dryness, urine retention, blurred vision, constipation, tachycardia, postural hypotension may be more likely to occur. Other tricyclic antidepressants would be expected to be similarly affected. If symptoms are troublesome reduce the dosage of the antidepressant (33 to 50% has been suggested) or replace the cimetidine with ranitidine, which does not appear to interact. Other H₂-receptor antagonists that do not cause enzyme inhibition (e.g. **famotidine** and **nizatidine**) would also not be expected to interact.

Tricyclic antidepressants + Inotropes and Vasopressors

Patients taking tricyclic antidepressants show a grossly exaggerated response (hypertension, cardiac arrhythmias, etc.) to parenteral noradrenaline (norepinephrine), adrenaline (epinephrine) and to a lesser extent to phenylephrine. Case reports suggest that this interaction only occurs rarely with local anaesthetics containing these vasoconstrictors.

Clinical evidence

The effects of intravenous infusions of **noradrenaline (norepinephrine)** were increased approximately ninefold, and of **adrenaline (epinephrine)** approximately threefold, in 6 healthy subjects who had been taking **protriptyline** 60 mg daily for 4 days.^{1,2}

The pressor effects of intravenous infusions of **noradrenaline** were increased four to eightfold, of **adrenaline** two to fourfold, and of **phenylephrine** two to threefold in 4 healthy subjects who had been taking **imipramine** 75 mg daily for 5 days. There were no noticeable or consistent changes in their response to **isoprenaline (isoproterenol)**.³ However, in a study of possible adverse interactions between **imipramine** and **isoprenaline**, although no abnormalities of heart rhythm were seen, one out of the 4 healthy subjects studied showed potentiation of **isoprenaline**-induced tachycardia.⁴

Five patients taking **nortriptyline**, **desipramine** or other unnamed tricyclic antidepressants experienced adverse reactions, some of them severe (throbbing headache, chest pain) following the injection of **Xylestesin** (lidocaine with 1:25 000 **noradrenaline**) during dental treatment.⁵ Several episodes of marked increases in blood pressure, dilated pupils, intense malaise, violent but transitory tremor, and palpitations have been reported in patients taking unnamed tricyclic antidepressants when they were given

local anaesthetics containing **adrenaline** or **noradrenaline** for dental treatment.⁶

There are other reports describing this interaction of:

- **noradrenaline** with **imipramine**,^{7–9} **clomipramine**,⁹ **desipramine**,^{8,10} **nortriptyline**,¹¹ **protriptyline**¹⁰ and **amitriptyline**,^{8,10}
- **adrenaline** with **amitriptyline**,¹²
- **corbadrine** with **desipramine** (in dogs).¹³

Mechanism

The tricyclics and some related antidepressants block or inhibit the uptake of noradrenaline (norepinephrine) into adrenergic neurones. Thus the most important means by which noradrenaline is removed from the adrenoceptor area is inactivated and the concentration of noradrenaline outside the neurone can rise. If more noradrenaline (or one of the other directly acting alpha or alpha/beta agonists) is then given, the adrenoceptors of the cardiovascular system concerned with raising blood pressure become grossly stimulated by this superabundance of amines, and the normal response becomes exaggerated.

Importance and management

A well documented, well established and potentially serious interaction. The parenteral use of noradrenaline (norepinephrine), adrenaline (epinephrine), phenylephrine or any other sympathomimetic amines with predominantly direct activity should be avoided in patients taking tricyclic antidepressants. If these inotropes must be used, the rate and amount injected must be very much reduced to accommodate the exaggerated responses that will occur. However, the situation where adrenaline or noradrenaline are used with a local anaesthetic for surface or infiltration anaesthesia, or nerve block is less clear. The cases cited are all from the 1960s or 1970s, and the preparations concerned contained concentrations of adrenaline or noradrenaline several times greater than those used currently. However, it should be noted that preparations such as **Xylocaine** with adrenaline still carry a caution about their use with tricyclic antidepressants.¹⁴ Anecdotal evidence suggests that local anaesthetics containing sympathomimetics are, in practice, commonly used in patients receiving tricyclic antidepressants,¹⁵ so the sparsity of reports, especially recent ones, would add weight to the argument that the interaction is only rarely significant. However, it would still seem advisable to be aware of the potential for interaction. Aspiration has been recommended to avoid inadvertent intravenous administration. **Felypressin** has been shown to be a safe alternative.^{16–18} If an adverse interaction occurs it can be controlled by the use of an alpha-receptor blocker, such as phentolamine.

Doxepin in doses of less than 150 to 200 mg daily blocks neuronal uptake much less than other tricyclic antidepressants and so is unlikely to show this interaction to the same degree, but in larger doses it will interact like other tricyclics.^{19,20} It does not seem to have been established whether the response to oral doses or nasal drops containing phenylephrine is enhanced by the presence of a tricyclic, but there seem to be no reports of problems.

Tricyclic antidepressants + Macrolides

Troleandomycin increases the plasma levels of imipramine, and an isolated report suggests that josamycin may possibly increase amitriptyline serum levels. Erythromycin may possibly raise clomipramine levels, but was not found to interact with other tricyclic antidepressants in one study.

Clinical evidence, mechanism, importance and management

(a) Erythromycin

Erythromycin 250 mg four times daily for 6 days was found not to affect the tricyclic antidepressant levels of 8 patients taking **desipramine**, **imipramine**, **doxepin**, or **nortriptyline**.¹ Behavioural changes have been reported in a 15-year-old patient when erythromycin was added to a regimen of **clomipramine** and risperidone,² resulting in symptoms compatible with the serotonin syndrome, although mental confusion and autonomic instability were absent.³ It was suggested that erythromycin increased **clomipramine** levels by inhibiting its metabolism by the cytochrome P450 isoenzyme CYP3A4.⁴ **Clomipramine** levels may also have been raised by competition with risperidone for metabolism by CYP2D6.

(b) Josamycin

A patient taking **amitriptyline** had a marked increase in the total serum levels of **amitriptyline** and its metabolite, nortriptyline, after taking josamycin but no toxicity was reported. It was suggested that josamycin had inhibited **amitriptyline** metabolism.⁵ This is only an isolated case and its general significance is unknown.

(c) Troleandomycin

A study in 9 healthy Chinese men found that when they were given troleandomycin 250 mg daily for 2 days before a single 100-mg oral dose of **imipramine**, the AUC of the **imipramine** was increased by 59% and its oral clearance was reduced by 30%. It is thought that troleandomycin inhibits the *N*-demethylation of **imipramine** by inhibiting the cytochrome P450 isoenzyme subfamily CYP3A.⁶ The clinical importance of this interaction is uncertain, but it may be prudent to be alert for increased antimuscarinic adverse effects (e.g. dry mouth, blurred vision, urinary retention).

Tricyclic antidepressants + Modafinil

Clomipramine serum levels were reported to be increased by modafinil in one patient. However, a study found no pharmacokinetic interaction.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study, 18 patients were given a single 50-mg dose of **clomipramine** on day 1 and modafinil 200 mg daily on days 1 to 3. No pharmacokinetic changes were found to have occurred with either of the two drugs.¹ However, a single case report describes a patient taking **clomipramine** 75 mg daily who had a rise in serum **clomipramine** and desmethylclomipramine levels when modafinil 200 mg was added.² It was suggested that she had low levels of the cytochrome P450 isoenzyme CYP2D6 (a 'poor metaboliser') so that the additional inhibition of CYP2C19 by modafinil resulted in elevated serum levels.

Information about other tricyclic antidepressants is lacking, but the manufacturers of modafinil point out that other poor metabolisers (about 7 to 10% of the Caucasian population) may possibly also show increased serum tricyclic antidepressant levels in the presence of modafinil.^{3,4} Therefore monitoring concurrent use would seem to be a prudent precaution.

Tricyclic antidepressants + Nasal decongestants

The effects of phenylpropanolamine, pseudoephedrine and other related drugs would be expected to be reduced by the tricyclic antidepressants, but so far only one case, involving ephedrine and amitriptyline, seems to have been reported.

Clinical evidence, mechanism, importance and management

Drugs such as **phenylpropanolamine** and **pseudoephedrine** exert their effects by causing the release of noradrenaline (norepinephrine) from adrenergic neurones. In the presence of a tricyclic antidepressant, the uptake of these amines into adrenergic neurones is partially or totally prevented and the noradrenaline-releasing effects are therefore blocked. Consequently the effects of drugs such as **phenylpropanolamine** would be expected to be reduced by tricyclic antidepressants. This predicted interaction has been listed by the manufacturers in some data sheets. However, the almost total lack of evidence in the literature suggests that this is no more than a theoretical interaction. The only report found describes an elderly woman taking **amitriptyline** 75 mg daily, who developed hypotension (70 mmHg systolic) during subarachnoid anaesthesia. Her blood pressure rose only minimally when she was given intravenous boluses of **ephedrine** totalling 90 mg.¹

Bearing in mind how long and how widely both groups of drugs have been in use, the absence of any other reports would suggest that any interaction between them is rarely of practical importance.

- Serle DG. Amitriptyline and ephedrine in subarachnoid anaesthesia. *Anaesth Intensive Care* (1985) 13, 214.

Tricyclic antidepressants + Oestrogens

There is evidence that oestrogens can sometimes reduce the effects of imipramine, yet at the same time paradoxically cause imipramine toxicity. The general clinical importance of this interaction has yet to be evaluated.

Clinical evidence

A study in women taking **imipramine** 150 mg daily for primary depression found that those given **ethinylestradiol** 25 or 50 micrograms [daily] for one week showed greater improvement than those given **imipramine** alone. However, after 2 weeks, those given **ethinylestradiol** 50 micrograms daily showed less improvement than other women given only 25 micrograms of **ethinylestradiol** [daily] or a placebo.¹ In an earlier associated study 5 patients taking **imipramine** 150 mg and **ethinylestradiol** 50 micrograms daily developed signs of **imipramine** toxicity (severe lethargy (4 patients), hypotension (4), coarse tremor (2), mild depersonalisation (2)) that was dealt with by halving the **imipramine** dose.¹ Another study found that oral contraceptives increased the absolute bioavailability

of imipramine by 60%.²

Long-standing imipramine toxicity was relieved in a woman taking imipramine 100 mg daily when her dosage of conjugated oestrogen was reduced to 25%.³ However, although several studies have shown that serum clomipramine levels were raised or remained unaffected by the concurrent use of oestrogen-containing contraceptives, they failed to confirm that tricyclic antidepressant toxicity occurs more often in those taking oral contraceptives than those who are not.⁴⁻⁷ Akathisia in 3 patients has been attributed to an interaction between conjugated oestrogens and amitriptyline or clomipramine.⁸

Mechanism

Among the possible reasons for these effects are that the oestrogens increase the bioavailability of imipramine,² or inhibit its metabolism.⁹

Importance and management

These interactions are inadequately established. There is no obvious reason for avoiding concurrent use, but it would seem reasonable to be alert for any evidence of toxicity and/or lack of response to tricyclic antidepressant treatment in those taking oestrogens in any form. One study suggested that the imipramine dosage should be reduced by about one-third.² More study is needed.

Tricyclic antidepressants + Orlistat

Orlistat appears not to affect the plasma levels of clomipramine or desipramine in patients, or the pharmacokinetics of amitriptyline in healthy subjects.

Clinical evidence, mechanism, importance and management

A preliminary study in patients who had been taking psychotropic drugs long-term found no clinically relevant changes in plasma levels of clomipramine (3 patients) or desipramine (1 patient) when they were given orlistat over an 8-week period.¹ A study in 20 healthy subjects found that orlistat 120 mg three times daily for 6 days did not affect the pharmacokinetics of amitriptyline 25 mg three times daily.²

Although evidence is limited no particular precautions seem likely to be necessary on concurrent use.

Tricyclic antidepressants + Protease inhibitors

Ritonavir raises desipramine levels and is predicted to also raise the levels of other tricyclic antidepressants.

Clinical evidence, mechanism, importance and management

A single 100-mg dose of desipramine was given to 14 healthy subjects before and after they took ritonavir 500 mg twice daily for 10 days. The AUC and half-life of desipramine increased nearly 2.5-fold and 2-fold, respectively. The maximum plasma levels were also increased by about

22%. These changes are considered to be clinically significant, so the authors suggest that a lower initial dose of desipramine should be used if it is to be started in patients taking ritonavir, and careful monitoring should be carried out in the first few weeks of treatment.¹ These effects are likely to be due to the inhibitory effects of ritonavir on the cytochrome P450 isoenzyme CYP2D6.² Because of this, the manufacturers of ritonavir also predict that the levels of other tricyclic antidepressants (e.g. amitriptyline, imipramine, nortriptyline) will also be raised, and they suggest careful monitoring of adverse effects if any tricyclic is used with ritonavir. A dose reduction of the tricyclic may be required.^{3,4} *In vitro* data show that other protease inhibitors also inhibit desipramine hydroxylation (in order of potency; indinavir, saquinavir, and then nelfinavir), but all of these drugs have less of an effect than ritonavir.²

Tricyclic antidepressants + Quinidine or Quinine

Quinidine can reduce the clearance of desipramine, imipramine, nortriptyline and trimipramine, and quinine can reduce the clearance of desipramine, thereby increasing their serum levels.

Clinical evidence

(a) Quinidine

In a study in 5 healthy subjects quinidine 50 mg given 1 hour before a single 50-mg dose of nortriptyline increased the nortriptyline AUC fourfold, and the half-life threefold (from 14.2 to 44.7 hours).¹ The clearance fell from 5.4 to 1.9 mL/minute.

A single-dose study in healthy subjects found that quinidine 200 mg daily reduced the clearance of imipramine 100 mg by 30% and desipramine 100 mg by 85%.² A further study in 2 healthy subjects similarly found that quinidine 50 mg almost doubled the half-life of a single 75-mg dose of trimipramine, which was reflected in some waking EEG changes.³

In healthy subjects given quinidine 800 mg daily for 2 days, the urinary excretion of 2-hydroxydesipramine from a single 25-mg dose of desipramine was reduced by 97% and 68% in rapid and slow hydroxylators, respectively.⁴

(b) Quinine

Quinine 750 mg daily for 2 days reduced the urinary excretion of 2-hydroxydesipramine from a single 25-mg dose of desipramine in rapid hydroxylators by 56% but had no significant effect on the clearance in slow hydroxylators.⁴

Mechanism

Quinidine reduces the metabolism (hydroxylation) of these tricyclic antidepressants, by inhibiting the cytochrome P450 isoenzyme CYP2D6, and thereby reduces their loss from the body.^{5,6} Quinine inhibits the metabolism of desipramine to a lesser extent than quinidine.

Importance and management

The clinical importance of these interactions awaits assessment, but be alert for evidence of increased tricyclic antidepressant effects and possibly toxicity if quinidine is added. One report suggested steady-state increases of 30% with imipramine and more than 500% with desipramine in extensive metabolisers.² More study is needed. There seems to be no information about the effect of quinidine on other tricyclics. Information about the effect of quinine on tricyclics is very limited, but the effects are smaller than those of quinidine and therefore less likely to result in clinically significant adverse effects. Note that quinidine, possibly quinine, and the tricyclics (notably in overdose) may prolong the QT interval, see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Tricyclic antidepressants + Rifampicin (Rifampin)

In three patients a marked reduction in nortriptyline or amitriptyline levels occurred when rifampicin was given.

Clinical evidence

A man with tuberculosis needed to take 175-mg doses of **nortriptyline** to achieve therapeutic serum levels while taking isoniazid 300 mg, rifampicin 600 mg, pyrazinamide 1.5 g and pyridoxine 25 mg daily. Three weeks after stopping the antitubercular drugs, the patient suddenly became drowsy and his **nortriptyline** serum levels were found to have risen from 193 nanomol/L to 562 nanomol/L, and later to 671 nanomol/L. It was then found possible to maintain his **nortriptyline** serum levels in the range of 150 to 500 nanomol/L with only 75 mg of **nortriptyline** daily.¹ A woman taking **amitriptyline** and fluoxetine had a marked fall in her plasma **amitriptyline** levels when she took rifampicin 600 mg, isoniazid 200 mg and ethambutol 1.2 g daily. When these antitubercular drugs were stopped, her **amitriptyline** plasma levels rose once again.² In a further case in a 43-year-old woman taking **nortriptyline** 50 mg daily, serum levels were not detectable when rifampicin 600 mg daily was given. Increasing the dose of **nortriptyline** to 75 mg daily failed to produce detectable serum levels. Two weeks after discontinuation of rifampicin, **nortriptyline** levels increased significantly.³

Mechanism

It seems highly probable that rifampicin (a well recognised and potent enzyme inducer) increased the metabolism of nortriptyline and amitriptyline by the liver thereby reducing their levels.

Importance and management

Information about the interaction between tricyclic antidepressants and rifampicin seems to be limited to just these three reports, which is a little surprising since both have been widely used for a considerable time. This suggests that generally this interaction may have limited clinical importance. However, bear this interaction in mind if patients taking rifampicin seem unresponsive to treatment with tricyclics. Increase the tricyclic dosage if necessary, and remember to readjust the dose if rifampicin is stopped.

Tricyclic antidepressants + SNRIs; Duloxetine

Duloxetine markedly increased the AUC of desipramine; other tricyclics metabolised by CYP2D6 are expected to interact similarly. Note that the use of duloxetine with other serotonergic drugs such as the tricyclics should be undertaken with caution or avoided because of the theoretical increased risk of serotonin syndrome.

Clinical evidence

Duloxetine 60 mg twice daily increased the AUC of a single 50-mg dose of **desipramine** by 2.9-fold in subjects who were extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6.¹

Mechanism

Desipramine is extensively metabolised by the cytochrome P450 isoenzyme CYP2D6, and can be used as a probe drug for assessment of the effect of drugs on this isoenzyme in extensive metabolisers (see 'Genetic factors', (p.4)).

Importance and management

The pharmacokinetic interaction with desipramine is established. Although the clinical relevance of the increased levels has not been assessed, the manufacturer recommends caution if duloxetine is given to patients taking desipramine and other similarly metabolised tricyclics, such as **nortriptyline**, **amitriptyline** and **imipramine**.^{2,3}

The manufacturers note that tricyclics like **clomipramine** or **amitriptyline** should be used with caution³ or avoided⁴ with duloxetine, because of the possible risks of 'the serotonin syndrome', (p.9).

Tricyclic antidepressants + SNRIs; Venlafaxine

Venlafaxine can cause a marked increase in the antimuscarinic adverse effects of clomipramine, desipramine and nortriptyline. There are isolated reports of seizures in a patient taking venlafaxine and trimipramine and the serotonin syndrome has been seen in patients taking venlafaxine with, or shortly before, the use of tricyclics.

Clinical evidence

A 74-year-old man taking venlafaxine 150 mg daily and thioridazine had his treatment changed to daily doses of venlafaxine 75 mg, **desipramine** 50 mg, haloperidol 500 micrograms and alprazolam 250 micrograms. Within 5 days he exhibited severe antimuscarinic adverse effects (acute confusion, delirium, stupor, urinary retention and paralytic ileus). This was attributed to an interaction between the venlafaxine and amitriptyline.¹ Similarly, a 75-year-old man taking haloperidol, alprazolam and venlafaxine developed urinary retention and became delirious when he also took **desipramine**.² A woman taking **nortriptyline** 20 mg and fluoxetine 20 mg daily with only mild antimuscarinic adverse effects developed much more severe effects (dry mouth, worsened constipation, blurred vision) over 4 weeks following the replacement of the fluoxetine by venlafaxine 75 mg daily.³ Similar effects were seen in a 73-year-old man taking venlafaxine with **nortriptyline** 20 mg daily and a 61-year-old man taking venlafaxine with **clomipramine** 150 mg daily.²

A 69-year-old man with bipolar disorder, who had been taking venlafaxine up to 337.5 mg daily, thioridazine 25 mg at night, and sodium valproate 1.2 g daily for several months with no adverse motor symptoms, experienced extrapyramidal effects 3 to 4 days after the venlafaxine had been gradually replaced by **nortriptyline** 50 mg daily. Symptoms persisted despite withdrawal of thioridazine, but improved on reduction of the **nortriptyline** dosage to 20 mg daily.⁴ The cause of the reaction was not known, but it was suggested that there may have been an interaction between venlafaxine and **nortriptyline** possibly modulated by thioridazine or sodium valproate.

A 25-year-old woman taking venlafaxine 150 mg daily and **trimipramine** 50 mg daily for depression developed seizures within 11 days of the **trimipramine** dose being increased to 100 mg daily. Both drugs were stopped and the patient had no further seizures.⁵

There is also a report of the serotonin syndrome occurring in a 21-year-old patient when **amitriptyline** 10 mg at night was added to the range of medications she was receiving, which included venlafaxine 37.5 mg daily, pethidine (meperidine) 400 mg daily and fluconazole 200 mg daily.⁶ There are two other reports of the serotonin syndrome in patients who had discontinued venlafaxine 3 days and 2 weeks, respectively, before starting **amitriptyline**.^{7,8}

Mechanism

Not fully established but it is suggested that venlafaxine can inhibit the metabolism of these tricyclics by the cytochrome P450 isoenzyme CYP2D6, leading to an increase in their serum levels and a marked increase in their antimuscarinic adverse effects.²

Both venlafaxine and trimipramine can cause seizures, although usually after overdose. Either a pharmacokinetic interaction involving inhibition of drug metabolism by the isoenzyme CYP2D6, or a pharmacodynamic interaction may have resulted in seizures.⁵

'The serotonin syndrome', (p.9), has been reported in patients taking venlafaxine and amitriptyline alone or with other serotonergic drugs. Both can increase serotonergic activity by inhibition of serotonin re-uptake at presynaptic neurones. In addition, one of the cases described above⁶ is complicated by the fact that pethidine also has serotonergic activity and the metabolism of amitriptyline can be inhibited by 'fluconazole', (p.1230).

Importance and management

Information appears to be limited to these reports, three of which are by the same author. The incidence is not known but if venlafaxine and any tricyclic antidepressant are given concurrently, be alert for any evidence of increased antimuscarinic adverse effects. Although there appears to be only one report, the possibility of an increased risk of seizures with concurrent use should be borne in mind. It may be necessary to withdraw one or other of the two drugs. The reports of the serotonin syndrome highlight the need for caution when one or more serotonergic drugs are given either concurrently or within a short period of each other.

Tricyclic and related antidepressants + SSRIs

The levels of the tricyclic antidepressants can be raised by the SSRIs, but the extent varies greatly, from 20% to tenfold: fluvoxamine, fluoxetine and paroxetine appear to have the greatest effects. Tricyclic toxicity has been seen in a number of cases. Tricyclics may increase the levels of citalopram and possibly fluvoxamine, but the significance of this is unclear. There are several case reports of the serotonin syndrome following concurrent and even sequential use of the SSRIs and tricyclics.

Clinical evidence

(a) Citalopram

In one study¹ citalopram caused an increase of about 50% in the AUC of desipramine (the primary metabolite of **imipramine**), and a reduction in the levels of the subsequently formed metabolite of desipramine (2-hydroxydesipramine) after a single 100-mg oral dose of **imipramine**. In contrast, 5 patients taking **amitriptyline**, **clomipramine** or **maprotiline** had no changes in their plasma tricyclic antidepressant levels when citalopram 20 to 60 mg daily was also given.² In another general study, in which 18 patients were given citalopram and tricyclic antidepressants, serum levels of citalopram were doubled in those receiving the tricyclic **clomipramine**; pooled results for all the tricyclics showed a 44% rise in serum citalopram levels.³ An increase of this size is of doubtful clinical importance with citalopram. In 2 patients the plasma levels of **clomipramine** 100 mg daily remained stable when the dose was reduced to 75 mg daily and citalopram 40 mg daily was started.^{4,5} One had elevated levels of desmethylclomipramine⁴ and the other had elevated levels of the active metabolite, 8-hydroxydesmethylclomipramine.⁵

A case report describes elevated **desipramine** levels in a patient taking paroxetine that resolved when the patient was switched to citalopram.⁶

(b) Escitalopram

Escitalopram 20 mg daily for 21 days increased the maximum serum levels and AUC of a single 50-mg dose of **desipramine** by 40% and 100%, respectively.⁷ The UK manufacturers predict that **clomipramine** and **nortriptyline** will be similarly affected.⁸

(c) Fluoxetine

Four patients given daily doses of **desipramine** 300 mg, **imipramine** 150 mg or **nortriptyline** 100 mg had two to fourfold increases in plasma tricyclic antidepressant levels within 1 to 2 weeks of starting fluoxetine 10 to 60 mg daily. Two of them developed antimuscarinic adverse effects (constipation, urinary hesitancy).⁹

A number of other reports and studies clearly confirm that marked increases occur in the levels of **amitriptyline**,¹⁰⁻¹³ **clomipramine**,^{11,14} **desipramine**,¹⁵⁻²⁴ **imipramine**^{11,19-21,25,26} and **nortriptyline**,^{17,18,27-29} accompanied by toxicity, if fluoxetine is added without reducing the dosage of the tricyclic antidepressant. Delirium and seizures have also been described,^{20,30} and a death has been attributed to chronic **amitriptyline** toxicity caused by fluoxetine.³¹ The pharmacokinetics of fluoxetine appear not to be affected by **amitriptyline**.¹³

A migraine-like stroke developed in a woman 48 hours after her long-standing treatment with fluoxetine 100 mg daily was abruptly changed to **clomipramine** 200 mg daily.³²

(d) Fluvoxamine

The **amitriptyline** plasma levels of 8 patients rose (range 15 to 233%) when they were also given fluvoxamine 100 to 300 mg daily. Even larger rises in plasma **clomipramine** levels occurred (up to eightfold) in four other patients given fluvoxamine 100 to 300 mg daily. The tricyclic dosages remained the same or were slightly lower. No toxicity was seen.³³⁻³⁵

A number of other reports and studies confirm that increases occur in the levels of **amitriptyline**,³⁶⁻³⁹ **clomipramine**,³⁶⁻⁴¹ **desipramine**,⁴²⁻⁴⁵ **imipramine**,^{36,37,42-46} **maprotiline**³⁶ and **trimipramine**⁴⁷ in the presence of fluvoxamine. This interaction seems severe with **clomipramine** (a 10-fold rise in one case)⁴¹ and mild with **desipramine**.^{44,45} One study also suggested that fluvoxamine levels may be raised.³⁶ An isolated report describes worsening depression in a patient taking **dosulepin** 75 mg daily and mianserin within 24 hours of replacing the **dosulepin** with fluvoxamine 75 mg daily. The symptoms continued during the next day but were reversed within a day of fluvoxamine being replaced with **dosulepin**.⁴⁸

(e) Paroxetine

A study in 17 healthy subjects who were extensive metabolisers and taking **desipramine** 50 mg daily found that when they were also given paroxetine 20 mg daily for 10 days the maximum plasma levels of the **desipramine** rose by 358%, the trough plasma levels rose by 511% and the AUC rose by 421%. An approximately tenfold increase in the maximum plasma levels and the AUC of the paroxetine also occurred.⁴⁹ Another study found a fivefold decrease in **desipramine** clearance in extensive metabolisers given paroxetine 20 mg daily.⁵⁰ Paroxetine has also been shown to increase the levels of **clomipramine**,⁵¹ **desipramine**,⁶ **imipramine**,^{52,53} and **trimipramine**.⁵⁴ This resulted in a variety of adverse effects including dizziness,⁵¹ confusion,⁶ sedation⁵⁴ and memory impairment.⁵⁴

A 21-year-old man developed the serotonin syndrome when he took one tablet of paroxetine only one day after stopping **desipramine**, which he had taken for 5 days. He recovered after treatment with cyproheptadine.⁵⁵ A woman taking paroxetine 30 mg daily developed the serotonin syndrome (tachycardia, delirium, bizarre movements, myoclonus) within 2 hours of taking a single 50-mg dose of **imipramine**. She recovered when treated with intravenous fluids, sedation and cyproheptadine.⁵⁶

(f) Sertraline

In 9 healthy subjects, sertraline 50 mg daily increased the maximum plasma levels of **desipramine** 50 mg daily by 31% at steady-state, and increased the AUC by 23%.²⁴ A later related study in 17 healthy subjects by the same group of workers found that, using the same drug dosages, sertraline increased the **desipramine** maximum plasma levels by 44%, the minimum levels by 19% and the AUC by 37%. The maximum plasma levels and AUC of the sertraline were increased about twofold.⁴⁹ Other studies have found that sertraline increases **desipramine**,⁵⁷⁻⁶⁰ **imipramine**,⁵⁷ and **nortriptyline**⁶¹ levels, but it has also been suggested that sertraline has no effect on **imipramine** levels.^{62,63}

A woman who had been taking sertraline 50 mg daily (as well as morphine sulfate and periciazine) developed the serotonin syndrome within 3 days of starting to take **amitriptyline** 75 mg daily. She recovered when all of the psychotropic drugs were withdrawn.⁶⁴

Mechanism

Fluoxetine, paroxetine, and to a lesser extent sertraline and citalopram, inhibit the cytochrome P450 isoenzyme CYP2D6, which is involved in the metabolism of the tricyclic antidepressants. Hence these SSRIs cause tricyclic levels to rise. Fluvoxamine causes a similar effect, possibly by inhibiting the latter stages of metabolism through CYP1A2 and CYP3A4. The elevated levels of 8-hydroxydesmethylclomipramine during concurrent clomipramine and citalopram administration in one patient may have been due to the inhibition of glucuronidation by citalopram.⁵

The serotonin syndrome possibly develops because both the tricyclics and SSRIs affect serotonin transmission, which may result in increased serotonin levels. For more on the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

Importance and management

The interactions of the SSRIs and tricyclic antidepressants are established and of clinical significance. The SSRIs increase tricyclic levels, with fluvoxamine, fluoxetine and paroxetine apparently having the greatest effects. The increased tricyclic levels can be beneficial.^{36,39,65} However, it has been suggested that patients given fluoxetine should have their tricyclic dose reduced to one-quarter.¹⁹ Similar recommendations have been made with fluvoxamine (reduction in tricyclic dose to one-third)⁴² and sertraline.⁶⁶ It would also seem prudent to consider a dosage reduction of the tricyclic if paroxetine is added. Some suggest that a small initial dose of the SSRI should also be used.⁶⁶

Patients taking any combination of tricyclic and SSRI should be monitored for adverse effects (e.g. dry mouth, sedation, confusion) with tricyclic levels monitored where possible. Remember that the active metabolite of fluoxetine has a half-life of 7 to 15 days, and so any interaction may persist for some time after the fluoxetine is withdrawn,⁶⁷⁻⁶⁹ and may occur on sequential use.

The serotonin syndrome seems to occur rarely but patients and prescribers should be aware of the symptoms so that prompt action can be taken if problems occur. For more about the serotonin syndrome see, 'Additive or synergistic interactions', (p.9).

Tricyclic antidepressants + St John's wort (*Hypericum perforatum*)

The plasma levels of amitriptyline can be reduced by St John's wort, but the clinical importance of this interaction is unknown.

Clinical evidence

Twelve depressed patients were given 75 mg of **amitriptyline** twice daily and 900 mg of St John's wort extract (*Lichtwer Pharma, Berlin*) daily for at least 14 days. The AUC₀₋₁₂ of the **amitriptyline** was reduced by about 22% and the AUC of nortriptyline (its metabolite) was reduced by about 41%.¹

Mechanism

Not fully understood, but there is evidence that St John's wort is an enzyme inducer, which can increase liver metabolism by cytochrome P450 isoenzymes, thereby reducing the plasma levels of both amitriptyline and its metabolite (nortriptyline). Induction of P-glycoprotein by St John's wort may also contribute.

Importance and management

The interaction appears to be established, but its clinical importance is uncertain. Both the tricyclics and St John's wort are antidepressants, but whether the final sum of this interaction is more or less antidepressant activity is not known. It was not assessed in this study.¹ Other tricyclics probably interact similarly because they too can be affected by enzyme-inducing drugs. Monitor for antidepressant efficacy and increased adverse effects if St John's wort is given with any tricyclic. More study is needed.

Tricyclic antidepressants + Terbinafine

Terbinafine markedly increased the AUC of desipramine in a pharmacokinetic study. Case reports describe increases in the serum levels of amitriptyline, desipramine, imipramine and nortriptyline, with associated toxicity, in patients additionally given oral terbinafine.

Clinical evidence

(a) Amitriptyline

A 37-year-old woman who had been taking amitriptyline 75 mg daily, valproate and olanzapine for 3 years, developed extreme dryness of the mouth, nausea and dizziness shortly after starting to take terbinafine 250 mg daily. Serum levels of amitriptyline and its metabolite nortriptyline rose from just under 400 nanomol/L to over 1800 nanomol/L. Terbinafine was stopped, and the amitriptyline dose reduced to 25 mg daily, but the amitriptyline and nortriptyline levels did not return to baseline for several months. The patient had normal CYP2D6 metaboliser status.¹

(b) Desipramine

In a pharmacokinetic study terbinafine 250 mg daily for 21 days markedly increased the AUC of a single 50-mg dose of desipramine by fivefold, and increased the maximum levels twofold. The AUC of desipramine was still

more than double the baseline levels 4 weeks after stopping desipramine. In this study, healthy subjects were extensive CYP2D6 metabolisers, which is the usual phenotype.²

A case report describes a 3.5-fold increase in desipramine levels, with associated toxicity (dizziness, ataxia, incoordination, and difficulty swallowing), in a 52-year-old man taking desipramine 350 mg daily, which occurred within 2 to 3 weeks of him starting terbinafine. The desipramine was stopped for a few days and restarted at a dose of just 50 mg daily, which gave similar serum levels to those seen before terbinafine was started. When the terbinafine was stopped, the dose of desipramine needed to be gradually titrated up to the initial amount.³

(c) Imipramine

A 51-year-old man who had been taking lithium carbonate and varying doses of imipramine 150 to 200 mg daily for 10 years was also given oral terbinafine 250 mg daily for onychomycosis. About a week later he complained of dizziness, muscle twitching and excessive mouth dryness. His serum imipramine levels, measured 5 days later, had risen from his usual range of 100 to 200 nanograms/mL up to 530 nanograms/mL. Within 10 days of reducing his daily imipramine dose from 200 to 75 mg daily, his serum levels had fallen to 229 nanograms/mL. His liver function was normal.⁴

(d) Nortriptyline

A report describes a marked increase in the serum levels of nortriptyline (about doubled) accompanied by evidence of toxicity (fatigue, vertigo, loss of energy and appetite, and falls) in a 74-year-old man taking nortriptyline 125 mg daily, roughly 14 days after he started to take terbinafine 250 mg daily. His symptoms responded to a dose reduction to 75 mg daily. His serum levels were similarly elevated when he was later re-challenged with terbinafine. His liver function was normal.⁵ The same authors reported a similar case in a woman who had been taking nortriptyline and terbinafine for one month before she showed signs of an interaction. A later re-challenge with terbinafine confirmed the interaction.⁶

Mechanism

Terbinafine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, which is the principal enzyme involved in the metabolism of many tricyclics. Terbinafine can have a very prolonged half-life, so an interaction may occur/continue for a number of weeks after stopping the drug.

Importance and management

Although there are only a few case reports, the increase in levels of tricyclic antidepressant in the presence of terbinafine appears to be clinically important. Caution is recommended if terbinafine is given to patients taking drugs metabolised by CYP2D6 such as tricyclic antidepressants.² It would seem prudent to monitor for tricyclic adverse effects (such as dry mouth, blurred vision and urinary retention). Tricyclic levels may return to normal only slowly after discontinuation of terbinafine.^{1,2,6} It is also suggested that there may be a risk of clinically significant interactions if these drugs are given within 3 months of stopping terbinafine.¹

Tricyclic antidepressants + Thyroid hormones

The antidepressant response to imipramine, amitriptyline and possibly other tricyclics can be accelerated by the use of thyroid hormones. However, isolated cases of paroxysmal atrial tachycardia, thyrotoxicosis and hypothyroidism have occurred on concurrent use.

Clinical evidence, mechanism, importance and management

The addition of **liothyronine** 25 micrograms daily was found to increase the speed and efficacy of **imipramine** in relieving depression.¹ Similar results have been described in other studies with **desipramine**² or **amitriptyline**³ but the reasons are not understood. One possible explanation is that the patients had overt or subclinical hypothyroidism, which after correction with **liothyronine** allowed them to overcome an impaired response to tricyclic antidepressants.⁴ However, adverse reactions have also been seen. A patient being treated for both hypothyroidism and depression with **thyroid** 60 mg and **imipramine** 150 mg daily complained of dizziness and nausea. She was found to have developed paroxysmal atrial tachycardia.⁵ A 10-year-old girl with congenital hypothyroidism, well controlled on desiccated **thyroid** 150 mg daily, developed severe thyrotoxicosis after taking **imipramine** 25 mg daily for 5 months for enuresis. The problem disappeared when the **imipramine** was withdrawn.⁶ In another patient the effect of **levothyroxine** was lost and hypothyroidism developed when **dosulepin** was started.⁷

This is normally an advantageous interaction,⁸ in which **liothyronine** appears to have a significantly greater antidepressant-potentiating effect than **levothyroxine**.⁹ These apparent interactions remain unexplained. There would seem to be no good reason, generally speaking, for avoiding concurrent use unless problems arise.

Tricyclic antidepressants + Tobacco

Smoking tobacco reduces the plasma levels of amitriptyline, clomipramine, desipramine, imipramine and nortriptyline, but this does not appear to result in a clinically significant interaction.

Clinical evidence

Two studies found no difference between the steady-state **nortriptyline** plasma levels of tobacco smokers and non-smokers,^{1,2} but others have found that smoking tobacco lowers the plasma levels of **amitriptyline**, **clomipramine**,³ **desipramine**, **imipramine**⁴ and **nortriptyline**.⁵ For example a 25% reduction in plasma **nortriptyline** levels was found in one study,⁵ and a 45% reduction in total levels of **imipramine** and its metabolite, **desipramine**, was found in another.⁴

Mechanism

The probable reason for the reduced tricyclic levels is that some of the components of tobacco smoke are enzyme inducers, which increase the metabolism of these antidepressants by the liver.

Importance and management

These interactions are established but it might wrongly be concluded from the figures quoted that smokers need larger doses to control their depression. Some evidence suggests that the plasma levels of free (and pharmacologically active) **nortriptyline** are greater in smokers than non-smokers (10.2% compared with 7.4%), which probably offsets the fall in total plasma levels.⁵ Thus the lower plasma levels in smokers may be as therapeutically effective as the higher levels in non-smokers, so that there is probably no need to raise the dosage to accommodate this interaction.

Tricyclic antidepressants + Urinary acidifiers or alkalinisers

The urinary excretion of desipramine, nortriptyline and other tricyclic antidepressants are not significantly affected by drugs that alter urinary pH.

Clinical evidence, mechanism, importance and management

Because the tricyclics are bases it might be expected that changes in the urinary pH would have an effect on their excretion, but in fact the excretion of unchanged drug is small (less than 5% with **nortriptyline** and **desipramine**) compared with the amounts metabolised by the liver.¹ Only in the case of hepatic impairment is simple urinary clearance likely to take on a more important role.

1. Sjöqvist F, Berglund F, Borgå O, Hammer W, Andersson S, Thorstrand C. The pH-dependent excretion of monomethylated tricyclic antidepressants. *Clin Pharmacol Ther* (1969) 10, 826–33.

Tricyclic antidepressants + Valproate

Amitriptyline and nortriptyline plasma levels can be increased by sodium valproate and valpromide, but in contrast, an isolated report attributes a paradoxical rise in serum desipramine levels to the withdrawal of valproic acid. Valproate pharmacokinetics may be moderately affected by amitriptyline. Status epilepticus has been attributed to elevated clomipramine levels in a patient taking valproic acid.

Clinical evidence

(a) Sodium or Semisodium valproate

In one study, 15 healthy subjects were given a single 50-mg dose of **amitriptyline** 2 hours after taking the ninth dose of semisodium valproate 500 mg every 12 hours. The maximum plasma levels and AUC of **amitriptyline** were raised by 19% and 30%, respectively. The corresponding values for the nortriptyline metabolite were 28% and 55%, respectively.¹ A study in 6 patients with depression found that **amitriptyline** 100 mg daily for 3 weeks produced a 43% increase in the volume of distribution and a 16% increase in the plasma half-life of a single 400-mg intravenous dose of sodium valproate. The AUC and total body clearance of valproate were not significantly changed.²

One patient developed delirium within 3 days, and another developed grossly elevated **nortriptyline** plasma levels (393 nanograms/mL, about threefold higher than the therapeutic range) and evidence of toxicity (tremulousness of hands and fingers) about one week after starting valproate 750 mg to 1 g daily. The toxicity rapidly disappeared when both drugs were stopped. Another patient also developed elevated **nortriptyline** plasma levels, attributed to the addition of valproate.³ A patient taking **clomipramine** 150 mg daily suffered feelings of numbness and sleep disturbances attributed to elevated serum levels of **clomipramine** and desmethylclomipramine, caused by valproate 1 to 1.4 g daily. Halving the dose of **clomipramine** restored serum concentrations to therapeutic levels.⁴

(b) Valproic acid

An epileptic patient who had been seizure-free for 3 years while taking valproic acid developed a prolonged episode of status epilepticus 12 days after starting to taking **clomipramine** 75 mg daily. The **clomipramine** serum level 7 hours after the last dose was 341.6 nanograms/mL (usual levels 68 to 272 nanograms/mL). The seizure was attributed to the elevated **clomipramine** levels.⁵ In contrast, a woman taking valproic acid, tiotixene and **desipramine** developed elevated and potentially toxic serum **desipramine** levels (a rise from 259 to 324 nanograms/mL) at the end of a 3-month period during which valproic acid was gradually withdrawn and

replaced by clorazepate. The authors of the report attributed this reaction to the valproic acid withdrawal.⁶

(c) Valpromide

In 10 patients valpromide 600 mg daily for 10 days caused a 65% rise in the plasma levels of **nortriptyline** (from 61 to 100.5 nanograms/mL) and a 50% rise in the levels of **amitriptyline** (from 70.5 to 105.5 nanograms/mL).^{7,8}

Mechanism

Uncertain. Inhibition of the metabolism of these tricyclics by valproate has been suggested.³⁻⁵

Importance and management

Information seems to be limited to these reports. It would seem prudent to monitor for tricyclic adverse effects (such as dry mouth, blurred vision and urinary retention) in patients given valproate and amitriptyline, clomipramine, or nortriptyline and to reduce the dosage of the tricyclic if necessary. Where possible consider monitoring tricyclic levels. Information about other tricyclic antidepressants seems to be lacking. The occurrence of status epilepticus in another patient reinforces the fact that the tricyclics can lower the convulsive threshold and should therefore be used with caution in patients with epilepsy.

Tricyclic antidepressants; Amitriptyline + Ethchlorvynol

Transient delirium has been attributed to the concurrent use of amitriptyline and ethchlorvynol,¹ but no details were given and there appear to be no other reports confirming this alleged interaction.

1. Hussar DA. Tabular compilation of drug interactions. *Am J Pharm* (1969) 141, 109–156.

Tricyclic antidepressants; Amitriptyline + Furazolidone

A report describes the development of toxic psychosis, hyperactivity, sweating and hot and cold flushes in a woman taking amitriptyline with furazolidone, and diphenoxylate with atropine.

Clinical evidence, mechanism, importance and management

A depressed woman taking daily doses of conjugated oestrogens 1.25 mg and amitriptyline 75 mg, was also given furazolidone 300 mg daily and diphenoxylate with atropine sulfate. Two days later she began to experience blurred vision, profuse perspiration followed by alternate chills and hot flushes, restlessness, motor activity, persecutory delusions, auditory hallucinations and visual illusions. The symptoms cleared within a day of stopping the furazolidone.¹ The reasons are not understood but the authors point out that furazolidone has MAO-inhibitory properties and that the symptoms were similar to those seen when the tricyclic antidepressants and MAOIs interact. However the MAO-inhibitory activity of furazolidone normally develops over several days. Whether the concurrent use of atropine and amitriptyline (both of which have antimuscarinic activity)

had some part to play in the reaction is uncertain. No firm conclusions can be drawn from this slim evidence, but clinicians should be aware of this case when considering the concurrent use of tricyclic antidepressants and furazolidone.

1. Aderhold RM and Muniz CE. Acute psychosis with amitriptyline and furazolidone. *JAMA* (1970) 213, 2080.

Tricyclic antidepressants; Amitriptyline + Sucralfate

Sucralfate causes a marked reduction in the absorption of amitriptyline.

Clinical evidence, mechanism, importance and management

When 6 healthy subjects took a single 75-mg dose of amitriptyline with a single 1-g dose of sucralfate, the AUC of the amitriptyline was reduced by 50%.¹ Concurrent use should be monitored to confirm that the therapeutic effects of the antidepressant are not lost. An increase in the dosage may be needed. There seems to be nothing documented about other tricyclics.

1. Ryan R, Carlson J, Farris F. Effect of sucralfate on the absorption and disposition of amitriptyline in humans. *Fedn Proc* (1986) 45, 205.

Tricyclic antidepressants; Clomipramine + Ademetionine

A severe reaction, diagnosed as the serotonin syndrome, developed in a woman taking ademetionine shortly after her clomipramine dosage was raised.

Clinical evidence, mechanism, importance and management

An elderly woman with a major affective disorder was treated with intramuscular ademetionine 100 mg daily and clomipramine 25 mg daily for 10 days. About 2 to 3 days after the clomipramine dosage was raised to 75 mg daily, she became progressively agitated, anxious and confused. On admission to hospital she was stuporous, with a pulse rate of 130 bpm, a respiratory rate of 30 breaths per minute, and she had diarrhoea, myoclonus, generalised tremors, rigidity, hyperreflexia, shivering, profound diaphoresis and dehydration. Her temperature rose from 40.5 to 43°C. She had no infection, and the diagnosis was of 'the serotonin syndrome', (p.9). The drugs were withdrawn and she was given dantrolene 50 mg intravenously every 6 hours for 48 hours. She made a complete recovery.¹ The reason for this severe adverse reaction is not understood.

1. Iruela LM, Minguez L, Merino J, Monedero G. Toxic interaction of S-adenosylmethionine and clomipramine. *Am J Psychiatry* (1993) 150, 522.

Tricyclic antidepressants; Clomipramine + Oxybutynin

Oxybutynin reduced the blood levels of clomipramine in one patient.

Clinical evidence, mechanism, importance and management

An elderly woman had clomipramine and desmethylclomipramine blood levels of 405 and 50 nanograms/mL, respectively, after taking clomipramine 25 mg daily and fluvoxamine 100 mg daily for 18 days. Within one week of starting oxybutynin 5 mg daily, the levels of clomipramine and desmethylclomipramine had fallen to 133 and less than 25 nanograms/mL, respectively, and remained low during a further week of concurrent treatment.¹

Clomipramine levels may be reduced because oxybutynin is an inducer of cytochrome P450 isoenzymes, which could increase the metabolism of clomipramine, and therefore reduce its levels.¹ This appears to be the only report of an interaction, the mechanism of which is not fully clear. It is therefore of unknown general significance. However, note that both tricyclic antidepressants and oxybutynin have antimuscarinic effects, which

may be additive on concurrent use. Consider 'Antimuscarinics + Antimuscarinics', p.674, for more on this potential interaction.

- Grozinger M, Hartter S, Hiemke C, Roschke J. Oxybutynin enhances the metabolism of clomipramine and dextrophan possibly by induction of a cytochrome P450 isoenzyme. *J Clin Psychopharmacol* (1999) 19, 287–9.

Tricyclic antidepressants; Desipramine + Propafenone

An isolated report describes markedly raised serum desipramine levels in a patient who also took propafenone.

Clinical evidence, mechanism, importance and management

A man with major depression responded well to desipramine 175 mg daily with serum desipramine levels in the range of 500 to 1000 nanomol/L. When he was treated for paroxysmal atrial fibrillation with digoxin 250 micrograms daily and propafenone 150 mg twice daily and 300 mg at night he developed markedly elevated serum desipramine levels (2092 nanomol/L) and toxicity (dry mouth, sedation, shakiness) while taking desipramine 150 mg daily. The adverse effects resolved when the desipramine was stopped for 5 days, but when it was restarted at 75 mg daily his serum desipramine levels were still raised (1130 nanomol/L).

The raised desipramine levels are thought to result from decreased metabolism and clearance, caused by propafenone.¹ The general importance of this case is uncertain, but be alert for signs of desipramine toxicity in any patient given propafenone concurrently. Adjust the desipramine dosage appropriately.

- Katz MR. Raised serum levels of desipramine with the antiarrhythmic propafenone. *J Clin Psychiatry* (1991) 52, 432–3.

Tricyclic antidepressants; Doxepin + Tamoxifen

An isolated report describes a reduction in doxepin serum levels attributed to the use of tamoxifen.

Clinical evidence, mechanism, importance and management

A 79-year-old woman with a long history of bipolar disorder, stabilised on lithium carbonate and doxepin 200 mg at bedtime and also taking propranolol, was given tamoxifen 20 mg daily after a mastectomy for breast cancer. It was noted that her total blood levels of doxepin and its major metabolite were reduced by about 25% over the next 11 months. The control of her depression remained unchanged. The reasons for this apparent interaction are not known.¹ The manufacturer of tamoxifen has another undetailed and isolated report of a possible interaction.²

This appears to be the first and only clear report of an interaction between a tricyclic antidepressant and tamoxifen so that its general importance is not known. It seems likely to be small.

- Zeneca, Personal communication. November 1995.

Tricyclic antidepressants; Imipramine + Beta blockers

Propranolol increased the imipramine levels in two children. Labetalol has been found to increase imipramine levels in adults. The clinical importance of these interactions is uncertain.

Clinical evidence

(a) Labetalol

In 13 healthy subjects labetalol 200 mg every 12 hours for 4 days, increased the AUC of a single 100-mg dose of imipramine by 53%, when compared with a placebo.¹ The maximum plasma level increased by 28%.

(b) Propranolol

A 9-year-old boy was given propranolol for the control of anger and aggression, and imipramine for stress and depression. When his imipramine dosage was raised from 60 to 80 mg daily and his propranolol dose was also raised, from 360 to 400 mg daily, his levels of imipramine plus metabolite (desipramine) rose sharply from a total of 139 nanograms/mL to 469 nanograms/mL. Reducing the imipramine to 60 mg and raising the propranolol to 440 mg daily only reduced the total imipramine/desipramine levels to 426 nanograms/mL. Another imipramine reduction to 40 mg and an increase in the propranolol dose to 480 mg daily resulted in a final total imipramine/desipramine level of 207 nanograms/mL. No significant adverse effects or heart block occurred.²

A 9-year-old girl taking imipramine 75 mg daily with a total imipramine/desipramine level of 260 nanograms/mL, had a marked rise to 408 nanograms/mL within 3 days of starting to take propranolol 10 mg three times daily. Two days after stopping the imipramine, her desipramine level (imipramine not measured) had fallen from 382 to 222 nanograms/mL.²

Mechanism

Uncertain. The suggestion is that these drugs compete for metabolism (hydroxylation) by the same cytochrome P450 isoenzymes (CYP2D6 and CYP2C8) in the liver, with imipramine being the 'loser', resulting in its accumulation in the body.²

Importance and management

Information seems to be limited to these two studies. The clinical importance of this interaction is uncertain, but it would now be prudent to monitor the outcome if propranolol or labetalol is added to treatment with imipramine. Tricyclic adverse effects include dry mouth, blurred vision and urinary retention. Where possible consider monitoring the plasma imipramine levels. There seems to be no information as yet about other beta blockers or tricyclic antidepressants.

- Gillette DW, Tannery LP. Beta blocker inhibits tricyclic metabolism. *J Am Acad Child Adolesc Psychiatry* (1994) 33, 223–4.

Tricyclic antidepressants; Imipramine + Vinpocetine

Vinpocetine does not appear to affect plasma imipramine levels.

Clinical evidence, mechanism, importance and management

In 18 healthy subjects the steady-state plasma levels of imipramine 25 mg three times daily were unaffected by vinpocetine 10 mg three times daily, taken concurrently for 10 days.¹ No special precautions would seem to be necessary. There seems to be nothing documented about any of the other tricyclic antidepressants.

- Hitzenberger G, Schmid R, Braun W, Grandt R. Vinpocetine therapy does not change imipramine pharmacokinetics in man. *Int J Clin Pharmacol Ther Toxicol* (1990) 28, 99–104.

Miscellaneous drugs

Acamprosate + Miscellaneous

Naltrexone modestly increases the rate and extent of acamprosate absorption. There is no pharmacokinetic interaction between acamprosate and alcohol or diazepam. Disulfiram does not alter the pharmacokinetics of acamprosate, and acamprosate does not alter the pharmacokinetics of imipramine. The combination of acamprosate and barbiturates, meprobamate, or oxazepam does not appear to increase the risk of adverse effects.

Clinical evidence, mechanism, importance and management*(a) Alcohol*

In studies in healthy subjects, the pharmacokinetics of both alcohol and acamprosate were unchanged by concurrent use.¹

(b) Antidepressants, anxiolytics and hypnotics

A 15-day study in 591 patients, to assess the effects of the concurrent use of acamprosate with other drugs commonly used in the management of alcohol withdrawal, found no evidence of additional adverse effects with **meprobamate, oxazepam**, or the barbiturate complex **tetrabamate** (that includes **phenobarbital**).² Other studies found that acamprosate caused no clinically relevant changes in **imipramine** pharmacokinetics, and the pharmacokinetics of both **diazepam** and acamprosate were unchanged by concurrent use.¹

No special precautions would therefore appear to be needed with any of these drugs.

(c) Disulfiram

In a study in 12 healthy subjects, disulfiram 500 mg once daily for 7 days did not alter the plasma levels of acamprosate 666 mg three times daily.¹

(d) Naltrexone

In a study in 24 healthy subjects, the concurrent use of naltrexone 50 mg daily and acamprosate 2 g daily for 7 days modestly increased the rate and extent of absorption of acamprosate, as indicated by a 33% increase in maximum level, a 33% reduction in time to maximum level, and a 25% increase in AUC. There was no change in naltrexone pharmacokinetics.³ Similarly, an increase in acamprosate levels was seen in a study of the use of acamprosate and naltrexone in alcohol-dependent subjects.⁴ No particular adverse events were identified on concurrent use,^{3,4} suggesting that the drugs may be used together.

Agalsidase + Miscellaneous

Agalsidase alfa and agalsidase beta should not be given with amiodarone, chloroquine, gentamicin, monobenzone due to a theoretical risk of inhibition of intra-cellular alpha-galactosidase activity.^{1,2} These enzymes are unlikely to interact via cytochrome p450-mediated mechanisms.¹

Allopurinol + Aluminium hydroxide

Three haemodialysis patients had a marked reduction in the effects of allopurinol while taking aluminium hydroxide. Separating the doses by 3 hours reduced the effects of this interaction.

Clinical evidence

Three patients receiving haemodialysis, taking 5.7 g of aluminium hydroxide daily and allopurinol 300 mg daily for high phosphate and uric acid levels, had no reduction in their hyperuricaemia until the aluminium hydroxide was given 3 hours before the allopurinol, whereupon their uric acid levels fell by 40 to 65%. When one patient returned to taking both preparations together, her uric acid levels began to rise.¹

Mechanism

Not understood, but it seems likely that aluminium and allopurinol may bind in the gut, resulting in impaired allopurinol absorption.

Importance and management

Information seems to be limited to this report. Renal patients taking large doses of aluminium should be advised to separate the administration of these two drugs by 3 hours or more to avoid admixture in the gut. The effects of lower doses of aluminium and the effects in patients with normal renal function do not appear to have been studied.

1. Weissman I, Krivoy N. Interaction of aluminum hydroxide and allopurinol in patients on chronic hemodialysis. *Ann Intern Med* (1987) 107, 787.

Allopurinol + Iron compounds

No adverse interaction occurs if iron and allopurinol are given concurrently.

Clinical evidence, mechanism, importance and management

Some early *animal* studies, where allopurinol was given in very large doses, suggested that allopurinol might have an inhibitory effect on the release of iron from hepatic stores. It was feared that this might result in hepatic iron overload. This led the manufacturers of allopurinol in some countries to issue a warning about their concurrent use.¹ However, subsequent research suggests that no special precautions are needed.¹⁻³

Allopurinol + Tamoxifen

A single case report describes allopurinol hepatotoxicity in a man given tamoxifen.

Clinical evidence, mechanism, importance and management

An elderly man who had been taking allopurinol 300 mg daily for 12 years developed fever and marked increases in his serum levels of lactic dehydrogenase and alkaline phosphatase within a day of starting to take tamoxifen 10 mg twice daily.¹ He rapidly recovered when the allopurinol was stopped. The reasons for the reaction are not understood, but the authors suggested that the increased hepatotoxic effect may have resulted from tamoxifen inhibiting allopurinol metabolism, thereby increasing the serum levels of allopurinol and its metabolite. The general importance of this isolated report is not known.

- Shah KA, Levin J, Rosen N, Greenwald E, Zumoff B. Allopurinol hepatotoxicity potentiated by tamoxifen. *N Y State J Med* (1982) 82, 1745–6.

Allopurinol + Thiazide diuretics

Severe allergic reactions to allopurinol have been seen in a few patients with renal impairment who were also taking thiazide diuretics.

Clinical evidence, mechanism, importance and management

Most patients tolerate allopurinol very well, but life-threatening hypersensitivity reactions (e.g. rash, vasculitis, hepatitis, eosinophilia, progressive renal impairment) develop very occasionally with doses of 200 to 400 mg of allopurinol daily.¹ A report of six such hypersensitivity reactions found that all of the reported cases were associated with pre-existing renal impairment, and in half of these, the patients were also taking thiazide diuretics.¹ Another report describes two patients who developed a hypersensitivity vasculitis while taking allopurinol and **hydrochlorothiazide**.² The excretion of oxipurinol (the major metabolite of allopurinol) is reduced in renal impairment, but studies indicate that in healthy subjects with normal renal function thiazide diuretics, such as **hydrochlorothiazide**, do not appear to affect either the plasma levels of oxipurinol or its excretion.^{3,4} However, other studies have shown that the effects of allopurinol on pyrimidine metabolism are enhanced by the use of thiazides (i.e. they potentially increase hyperuricaemia, which may lead to renal damage).⁵ Some caution is therefore appropriate if both drugs are used, particularly if renal function is impaired, but more study is needed to confirm this possible interaction.

Allopurinol + Uricosuric drugs

Probenecid and benzbromarone increase the renal excretion of oxipurinol, the active metabolite of allopurinol, but this probably does not alter clinical efficacy. Theoretically, the use of uricosuric drugs with allopurinol could lead to uric acid precipitation in the kidneys and therefore maintenance of a high urine output is recommended when allopurinol is given by injection. Probenecid markedly increases the serum levels of allopurinol riboside, which may be advantageous in some circumstances.

Clinical evidence, mechanism, importance and management

(a) Allopurinol

Probenecid appears to increase the renal excretion of the active metabolite of allopurinol, oxipurinol,¹ while allopurinol is thought to inhibit the metabolism of **probenecid**.² Allopurinol can increase the half-life and raise the serum levels of **probenecid** by about 50% and 20%, respectively.² In another study, **benzbromarone** lowered the AUC of oxipurinol by about 40%, but did not affect allopurinol levels.³

It has been suggested that the use of allopurinol and **probenecid** might lead to an increase in the excretion of uric acid, which could result in the precipitation of uric acid in the kidneys. Conversely, increased renal excretion of oxipurinol might decrease the efficacy of allopurinol. However, the clinical importance of these mutual interactions seems to be minimal. No problems were reported in two studies in patients given 100 to 600 mg of allopurinol and 500 mg to 2.5 g of **probenecid** daily for between 8 and 16 weeks.⁴ Similarly, combined use of allopurinol and **benzbromarone** was more effective in lowering serum uric acid than allopurinol alone.³ Nevertheless, the UK manufacturer recommends that the significance of any reduction in efficacy, which may occur when uricosuric drugs are given with allopurinol, should be assessed in each case.⁵ For allopurinol injection, the US manufacturer recommends that to help prevent renal precipitation of urates in patients receiving concurrent uricosuric drugs, a fluid intake sufficient to give a urinary output of at least 2 litres daily, and the maintenance of neutral or slightly alkaline urine, are desirable.⁶

(b) Allopurinol riboside

A study in 3 healthy subjects found that **probenecid** halved the clearance, increased the peak plasma levels and AUC, and extended the half life of allopurinol riboside.⁷ In some circumstances such an interaction may be advantageous as there is some evidence that the cure rate of American trypanosomiasis (Chagas' disease) and cutaneous leishmaniasis is better when the two drugs are used together.^{7,8}

Alprostadil + Miscellaneous

Some manufacturers advise that intracavernosal alprostadil and other drugs used for erectile dysfunction should not be given concurrently.

Clinical evidence, mechanism, importance and management

There appear to be no published reports of adverse interactions between intracavernous alprostadil (prostaglandin E₁) and other drugs used for erectile dysfunction, but some manufacturers say that smooth muscle relaxants such as **papaverine** and other drugs used to induce erections such as **alpha-blocking drugs** [e.g. intracavernosal **phentolamine**] should not be used concurrently because of the risks of priapism (painful prolonged abnormal erection).¹

Aluminium hydroxide + Ascorbic acid (Vitamin C) or Citrates

Patients with renal failure, given aluminium and oral citrate, can develop a potentially fatal encephalopathy due to a very marked rise in blood aluminium levels. There is evidence that aluminium and vitamin C may interact similarly. Some also suggest that

those with normal renal function should not take aluminium antiacids within 2 to 3 hours of foods and drinks that contain citrates. It is worth noting that formulations of a wide range of drugs (including many non-prescription preparations) contain citrates as the effervescent or dispersing agent.

Clinical evidence

(a) Ascorbic acid

A study in 13 healthy subjects given aluminium hydroxide 900 mg three times daily found that ascorbic acid (vitamin C) 2 g daily increased the urinary excretion of aluminium threefold.¹ Ascorbic acid significantly increases the concentration of aluminium in the liver, brain, and bones of rats given aluminium hydroxide.²

(b) Citrates

Four patients with advanced chronic renal impairment taking aluminium hydroxide and citrate (**Shohl's**) solution died due to hyperaluminemia.³ Comparison of these 4 patients with another 34 renal patients revealed that they had taken more aluminium hydroxide, more citrate, and were older. In the group as a whole, increased serum aluminium levels were correlated with increased citrate intake.⁴ Five healthy subjects were then given aluminium hydroxide with or without citrate solution: aluminium levels were 11 micrograms/L at baseline, rising to 44 micrograms/L when aluminium hydroxide was given, and rising to 98 micrograms/L when citrate was added. Aluminium clearance also dramatically increased in the presence of citrate.⁴ Another report describes this interaction in 2 patients with renal impairment, and in a possible further 6 patients, all of whom died.⁵ In a further single-dose study in 6 patients with end-stage renal disease, sodium citrate/citric acid 30 mL markedly increased the AUC of aluminium, from a 30-mL dose of aluminium hydroxide gel, by 4.6-fold.⁶ A number of other studies in healthy subjects have confirmed that citrate markedly increases aluminium absorption, see mechanism, below.

A tenfold rise in serum aluminium levels that occurred in a haemodialysis patient given **effervescent co-codamol**, was attributed to the presence of sodium citrate in the formulation, which is used to produce the effervescence.⁷

Mechanism

Studies in healthy subjects clearly demonstrate that citrate markedly increases the absorption of aluminium from the gut.^{4,8,9} The absorption is increased threefold if taken with **lemon juice**,¹⁰ eight to tenfold if taken with **orange juice**,^{11,12} and five to 50-fold if taken with citrate.^{4,8,9,11} but the reason is not understood. It could be that a highly soluble aluminium citrate complex is formed.^{5,8}

Importance and management

(a) Patients with renal impairment

The interaction between aluminium and citrates in patients with renal impairment is established and clinically important: it is potentially fatal. Concurrent use should be strictly avoided. The authors of one report emphasise the risks associated with any of the commonly used citrates (sodium, calcium or potassium citrates, citric acid, **Shohl's** solution (citric acid/sodium citrate), etc).⁸ Remember too that some effervescent and dispersible tablets (including many proprietary non-prescription analgesics, indigestion and hangover remedies such as *Alka-Seltzer*) contain citric acid or citrates,^{7,13} and they may also occur in soft drinks.¹³ Haemodialysis patients should be strongly warned about these. The interaction between aluminium and ascorbic acid is not yet well established, but the information available so far suggests that this combination should also be avoided. It is not clear whether orange juice is also unsafe but the available evidence suggests that concurrent administration is probably best avoided.

(b) Patients with normal renal function

The importance of the interaction between aluminium and citrates in subjects with normal renal function is by no means clear, because it is still not known whether increased aluminium absorption results in aluminium accumulation over the long term, in those with normal renal function.¹²

However, some authors have recommended that food or drinks containing citric acid (citrus fruits and fruit juices) should not be taken at the same time as aluminium-containing medicines, but that their ingestion should be separated by 2 to 3 hours.¹²

Aprepitant + CYP2C9 substrates

Aprepitant slightly reduces the plasma levels of 'warfarin', (p.385) and 'tolbutamide' (p.515), because it is an inducer of the cytochrome P450 isoenzyme CYP2C9. The manufacturers therefore recommend caution when aprepitant is given with other drugs that are known to be metabolised by CYP2C9, because of the possibility that their plasma levels may be reduced.^{1,2} They specifically mention phenytoin. They also note that, because phenytoin is a 'CYP3A4 inducer', (below), it is predicted to decrease levels of aprepitant and might reduce its efficacy.^{1,2} Consequently, the UK manufacturer advises avoiding the concurrent use of phenytoin.¹ Other CYP2C9 substrates are listed in 'Table 1.3', (p.6).

1. Emend (Aprepitant). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, February 2007.
2. Emend (Aprepitant). Merck & Co., Inc. US Prescribing information, June 2006.

Aprepitant + CYP3A4 inducers

Rifampicin markedly reduced the AUC of aprepitant, and reduced efficacy would be expected. In the UK, the manufacturer recommends that concurrent use of aprepitant and other strong inducers of CYP3A4 should be avoided.

Clinical evidence, mechanism, importance and management

The manufacturers note that when a single 375-mg dose of aprepitant was given on day 9 of a 14-day regimen of **rifampicin** 600 mg daily, the AUC of aprepitant was decreased about 11-fold (91%), and the half-life about threefold (68%).^{1,2}

Rifampicin is an inducer of the cytochrome P450 isoenzyme CYP3A4, by which aprepitant is metabolised. Concurrent use therefore decreases aprepitant levels

Although not assessed, this marked reduction in aprepitant levels could result in reduced efficacy. In the UK, the manufacturer recommends that concurrent use of aprepitant and strong inducers of CYP3A4, such as **rifampicin**, be avoided.¹ They also name **phenytoin** (see also 'Aprepitant + CYP2C9 substrates', above), **carbamazepine**, and **phenobarbital**, and

also recommend that concurrent use of **St John's wort** is avoided.¹ Other inducers of CYP3A4 are listed in 'Table 1.4', (p.6).

1. Emend (Aprepitant). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, February 2007.
2. Emend (Aprepitant). Merck & Co., Inc. US Prescribing information, June 2006.

Aprepitant + CYP3A4 inhibitors

Ketoconazole markedly increases aprepitant levels. The manufacturer recommends caution when aprepitant is used with ketoconazole or other strong inhibitors of CYP3A4.

Clinical evidence, mechanism, importance and management

The manufacturers note that when a single 125-mg dose of aprepitant was given on day 5 of a 10-day course of **ketoconazole** 400 mg daily, the AUC of aprepitant was increased by about fivefold, and the half-life by about threefold.^{1,2}

Ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which aprepitant is metabolised. Concurrent use therefore raises aprepitant levels.

Although the effect of these increases has not been assessed, such marked increases in levels could increase adverse effects. The manufacturers recommend caution when aprepitant is given with **ketoconazole** and other drugs that are strong inhibitors of CYP3A4. They specifically name **ritonavir**, **clarithromycin**,^{1,2} **telithromycin**,¹ **itraconazole**, **nefazodone**, **troleandomycin**, and **nelfinavir**.² For the effect of **diltiazem** (a moderate CYP3A4 inhibitor), see 'Calcium-channel blockers + Aprepitant', p.861. Other inhibitors of CYP3A4 are listed in 'Table 1.4', (p.6).

1. Emend (Aprepitant). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, February 2007.
2. Emend (Aprepitant). Merck & Co., Inc. US Prescribing information, June 2006.

Aprepitant + CYP3A4 substrates

Aprepitant can increase the levels of CYP3A4 substrates in the short-term, then reduce them within 2 weeks. Caution is advised. Note that the manufacturers of aprepitant specifically contraindicate its concurrent use with pimozone, terfenadine, astemizole or cisapride.

Clinical evidence, mechanism, importance and management

In the first few days of use, aprepitant 125/80 mg markedly increased levels of midazolam, a probe drug substrate for the cytochrome P450 isoenzyme CYP3A4. Then, within 2 weeks, a reduction in levels was seen, see 'Benzodiazepines + Aprepitant', p.721. This effect was not seen with the 40/25 mg dose regimen. Aprepitant is therefore both a dose-dependent inhibitor and an inducer of CYP3A4.

Because of this, aprepitant is expected to increase drug levels of other CYP3A4 substrates during treatment by up to about threefold, and the manufacturer recommends caution.^{1,2} They specifically recommend caution with **ergot derivatives**. Moreover, because of the risk of life-threatening torsade de pointes arrhythmias with increased levels of **pimozone**, **terfenadine**, **astemizole** or **cisapride**, they specifically contraindicate the concurrent use of aprepitant with these CYP3A4 substrates. For a list of CYP3A4 substrates, see 'Table 1.4', (p.6). Within 2 weeks of aprepitant therapy, a reduced level of CYP3A4 substrates might occur, and caution is also advised during this time.

1. Emend (Aprepitant). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, February 2007.
2. Emend (Aprepitant). Merck & Co., Inc. US Prescribing information, June 2006.

Ascorbic acid (Vitamin C) + Salicylates

Aspirin reduces the absorption of ascorbic acid by about one-third. Serum salicylate levels do not appear to be affected by ascorbic acid.

Clinical evidence, mechanism, importance and management

A study in healthy subjects found that the absorption of a single 500-mg dose of ascorbic acid was about one-third lower in those given **aspirin** 900 mg concurrently, and the urinary excretion was about 50% lower.¹ The clinical importance of this is uncertain. It has been suggested that the normal physiological requirement of 30 to 60 mg of ascorbic acid daily may need to be increased to 100 to 200 mg daily in the presence of **aspirin**.¹ Another study in 9 healthy subjects found that ascorbic acid 1 g three times daily did not significantly affect serum salicylate levels of **choline salicylate**.²

Baclofen + Ibuprofen

A man developed baclofen toxicity when given ibuprofen.

Clinical evidence, mechanism, importance and management

An isolated report describes a man taking baclofen 20 mg three times a day, who developed baclofen toxicity (confusion, disorientation, bradycardia, blurred vision, hypotension and hypothermia) after taking 8 doses of ibuprofen 600 mg three times daily. It appeared that the toxicity was caused by ibuprofen-induced acute renal impairment leading to baclofen accumulation.¹ Renal impairment is a relatively rare adverse effect of ibuprofen. The general importance of this interaction is likely to be very small. There appears to be no information about baclofen and other NSAIDs, and little reason for avoiding concurrent use.

1. Dahlin PA, George J. Baclofen toxicity associated with declining renal clearance after ibuprofen. *Drug Intell Clin Pharm* (1984) 18, 805-8.

Baclofen + Tizanidine

No clinically significant pharmacokinetic interaction appears to occur between baclofen and tizanidine.

Clinical evidence, mechanism, importance and management

In a randomised, three-period study, 15 healthy subjects were given baclofen 10 mg three times daily and tizanidine 4 mg three times daily, together and alone, for 7 consecutive doses. None of the pharmacokinetic parameters of either drug were changed by more than 30%, a figure calculated to indicate the presence of an interaction.¹ No changes in the dosages of either drug are therefore likely to be needed if they are taken concurrently.

Benzbromarone + Aspirin

Aspirin antagonises the uricosuric effects of benzbromarone.

Clinical evidence, mechanism, importance and management

A single 160-mg dose of benzbromarone increased the percent ratio of urate to creatinine clearance by 371% at its peak in 6 subjects with gout (i.e. benzbromarone increases urate clearance). However, when the same dose of benzbromarone was given with a single 600-mg dose of aspirin, the peak ratio of urate to creatinine clearance with benzbromarone 160 mg was reduced by about 75%¹ (i.e. aspirin reduces the effect of benzbromarone on urate clearance). In another study aspirin, in divided doses of 650 mg, up to a total of 5.2 g daily, was given to 29 healthy subjects taking benzbromarone 40 to 80 mg daily. The urate lowering effects of benzbromarone were most affected by aspirin 2.7 g; benzbromarone reduced the urate levels by 60%, but in the presence of aspirin 2.7 g the levels were only reduced by 48%.² Aspirin and other **salicylates** antagonise the effects of uricosuric drugs such as benzbromarone, and should generally be

avoided in those with hyperuricaemia or gout (see also 'Aspirin or other Salicylates + Probenecid', p.138).

Betahistine + Terfenadine

A single report describes the re-emergence of labyrinthine symptoms when a patient taking betahistine was given terfenadine.

Clinical evidence, mechanism, importance and management

An isolated and very brief report describes a patient whose labyrinthine symptoms (vertigo, dizziness, nausea and vomiting), controlled by betahistine, returned during the concurrent use of terfenadine and other unspecified drugs.¹ This interaction had been predicted on theoretical grounds because betahistine, is an analogue of histamine, and would therefore be expected to interact like this with any antihistamine.² The use of antihistamines should be carefully considered in patients taking betahistine.

2. Serc (Betahistine). Solvay Healthcare Ltd. UK Summary of product characteristics, October 2006.

Bisphosphonates + Aminoglycosides

Severe hypocalcaemia occurred in two patients taking sodium clodronate when they were given netilmicin or amikacin. Theoretically, additive calcium lowering effects could occur with any bisphosphonate aminoglycoside combination.

Clinical evidence

A 62-year-old woman with multiple myeloma was given **sodium clodronate** 2.4 g daily for osteolysis and bone pain. After 7 days she developed grand mal seizures, and her serum calcium was found to be 1.72 mmol/L (normal range 2.25 to 2.6 mmol/L). Despite daily calcium infusions her calcium remained low. The authors state that symptomatic hypocalcaemia with clodronate is rare, and attributed the dramatic response in this patient to an interaction with a course of **netilmicin** given 5 days earlier for septicaemia.¹

A 69-year-old man with prostate cancer had been taking **sodium clodronate** 2.4 g daily for bone pain for 13 months, and serum calcium levels had always remained within normal limits. After being admitted with febrile neutropenia following a course of chemotherapy, the clodronate was withdrawn and he was given intravenous **amikacin** and ceftazidime. After 7 days he became unconscious, and developed spontaneous twitching movements in his arms and legs. His calcium was found to be 1.39 mmol/L and he was diagnosed with hypocalcaemic tetany. He was given calcium infusions, and his serum calcium returned to normal over the next 12 hours.²

Mechanism

Not fully understood, but one suggestion is that any fall in blood calcium levels brought about by the use of clodronate is normally balanced to some extent by the excretion of parathyroid hormone, which raises blood calcium levels. However, the aminoglycoside antibacterials can damage the kidneys, not only causing the loss of calcium, but of magnesium as well.

Any hypomagnesaemia inhibits the activity of the parathyroid gland, so that the normal homeostatic response to hypocalcaemia is reduced or even abolished.^{1,2} Clodronate itself can sometimes be nephrotoxic.

Importance and management

Direct information seems to be limited to these two reports. Biochemical hypocalcaemia is believed to occur in about 10% of patients taking bisphosphonates,³ but symptomatic hypocalcaemia is said to be rare.² It seems therefore that the addition of the aminoglycoside in these two cases precipitated severe clinical hypocalcaemia. The authors of both reports therefore advise care if bisphosphonates are given with aminoglycosides, and recommend close monitoring of calcium and magnesium levels. They also point out that the renal loss of calcium and magnesium can continue for weeks after aminoglycosides are stopped, and that bisphosphonates can also persist in bone for weeks.^{1,2} This means that the interaction is potentially possible whether the drugs are given concurrently or sequentially.

Bisphosphonates + Aspirin or NSAIDs

The concurrent use of alendronate and naproxen increased the incidence of gastric mucosal damage in a small pharmacological study, and increased the risk of upper gastrointestinal disorders in a case-control study. However, two analyses of placebo-controlled studies found no increased risk of gastrointestinal damage with the combination. There was no increased risk of gastrointestinal adverse effects in NSAID users given risedronate.

Indometacin raises tiludronate bioavailability, whereas aspirin and diclofenac do not appear to affect the pharmacokinetics of tiludronate. NSAIDs may exacerbate the renal dysfunction sometimes seen with clodronate.

Clinical evidence, mechanism, importance and management

(a) Alendronate

In a short-term endoscopy study in 26 healthy subjects, gastric mucosal damage developed in 8% of those given alendronate alone, in 12% of those given **naproxen** alone, and 38% of those given both drugs.¹ In a case-control study,² the risk of having an acid-related upper gastrointestinal disorder with alendronate was increased by the concurrent use of NSAIDs (relative risk 1.7). However, retrospective analysis of data from a very large long-term placebo-controlled study found no evidence that the risk of upper gastrointestinal adverse effects with concurrent use of NSAIDs and alendronate was any greater than with NSAIDs and placebo.³ Note that this finding has been questioned,⁴ and some of the issues responded to.⁵ Similarly, in a retrospective analysis of a 12-week placebo-controlled study, in those taking regular NSAIDs (about half of the patients) there was no difference in incidence of upper gastrointestinal adverse events between those given alendronate and those given placebo. The most commonly used NSAIDs in this study were **aspirin**, **celecoxib**, **rofecoxib**, **ibuprofen** and **naproxen**.⁶

Alendronate is commonly known to be associated with oesophageal adverse effects, and there are strict dosing instructions to minimise this risk.⁷ It may also cause local irritation of the stomach, although its potential to cause gastric ulcers is not considered established.^{3,7}

The status of this interaction is currently controversial. Some consider that alendronate should not be given to patients receiving NSAIDs,⁴ while others urge caution in their use together.^{1,2} However, some consider that there is no evidence that alendronate adds to the known gastrointestinal toxicity of NSAIDs,⁵ and the manufacturer issues no caution about the concurrent use of NSAIDs.⁷ Until further evidence is available, it would seem sensible to monitor the concurrent use of alendronate and NSAIDs carefully.

(b) Clodronate

The manufacturer notes that patients receiving NSAIDs in addition to clodronate have developed renal impairment, although a synergistic action has not been established.⁸ Clodronate alone may cause renal impairment,

and the manufacturers suggest that renal function should be assessed before giving clodronate.⁸ This would seem particularly important in those taking NSAIDs.

(c) *Risedronate*

The manufacturer notes that in phase III osteoporosis studies of risedronate, no clinically relevant interactions were noted, even though aspirin and NSAIDs being used by 33% and 45% of patients, respectively.⁹ Similarly, in a retrospective analysis of a 2-year placebo-controlled study, in those using regular NSAIDs (about two-thirds of patients) there was no difference in incidence of upper gastrointestinal adverse events between those given risedronate and those given placebo.¹⁰

(d) *Tiludronate*

Single-dose studies in 12 healthy subjects found that **diclofenac** 25 mg and aspirin 600 mg had no significant effect on the pharmacokinetics of tiludronate. On the other hand, **indometacin** 50 mg increased the maximum serum concentration and the AUC of tiludronate about twofold when these drugs were taken together, but not when they were given 2 hours apart.¹¹ For this reason the manufacturers advise that **indometacin** and tiludronate should be given 2 hours apart.¹²

Bisphosphonates + Polyvalent cations

The oral absorption of bisphosphonates is reduced by **Maalox** and by other antacids, calcium-rich foods, calcium supplements, iron preparations, magnesium-containing laxatives or milk.

Clinical evidence

(a) *Clodronate*

In a randomised study in 31 healthy subjects the AUC of clodronate was reduced to 10% of the optimum level when it was taken with breakfast. Delaying administration until 2 hours after breakfast only slightly improved the AUC (34% of optimum). The best AUC was achieved when clodronate was given 2 hours before breakfast, although the AUC one hour before was similar (91% of optimum).¹

(b) *Tiludronate*

The maximum serum levels and AUC of tiludronate in 12 healthy subjects were halved when **Maalox (aluminium/magnesium hydroxide)** was taken one hour before tiludronate, but the bioavailability was only slightly affected when **Maalox** was taken 2 hours after the tiludronate.²

Mechanism

The bisphosphonates can form complexes with a number of polyvalent metallic ions (e.g. Al³⁺, Ca²⁺, Fe, Mg²⁺), which can impair their absorption.

Importance and management

Established and important interactions, although the documentation is limited. Bisphosphonates should be prevented from coming into contact

with a range of preparations such as **antacids** (containing **aluminium, bismuth, calcium, magnesium**), **laxatives** (containing magnesium), **iron preparations** and **calcium** or other **mineral supplements**. **Food, milk** and **dairy products** in particular, contain calcium, and may also impair absorption.

Recommendations on the timing of administration of bisphosphonates in relation to food and other drugs varies.

- The manufacturers of **alendronate**³ suggest that, in order to avoid absorption interactions, patients should wait at least 30 minutes after taking alendronate before taking any other drug or food, and that alendronate should be taken with plain water only.
- The manufacturers of **tiludronate**⁴ recommend that it is taken with water on an empty stomach (at least two hours before or after meals). In addition, they recommend administration of tiludronate and antacids or calcium compounds should be separated by 2 hours.
- The manufacturers of **clodronate**⁵ suggest leaving 1 hour between the administration of food and clodronate.
- The manufacturers of **risedronate**⁶ recommend it is taken with water at least 30 minutes before the first food or drink of the day. Alternatively, they say it should be given at least 2 hours from any food or drink at any other time of the day, at least 30 minutes before going to bed.
- Similarly, the manufacturers of **etidronate**⁷ recommend it is given on an empty stomach at least 2 hours from any food or medicines containing polyvalent cations (as listed above).

Bitter orange + Cytochrome P450 isoenzyme substrates

Bitter orange does not alter the metabolism of caffeine, chlorzoxazone, debrisoquine, or midazolam, and is therefore unlikely to interact with drugs that are metabolised by CYP1A2, CYP2E1, CYP2D6 or CYP3A4.

Clinical evidence, mechanism, importance and management

Bitter orange (*Citrus aurantium*) 350 mg, standardised to 4% synephrine, was given to 12 healthy subjects twice daily for 28 days. Single doses of **caffeine** 100 mg, **chlorzoxazone** 250 mg, **debrisoquine** 5 mg, and **midazolam** 8 mg were given before and at the end of the treatment with bitter orange. The metabolism of these drugs was not affected by the concurrent use of bitter orange, which suggests that bitter orange is unlikely to affect the metabolism of other drugs that are substrates of the cytochrome P450 isoenzymes CYP1A2, CYP2E1, CYP2D6 or CYP3A4.¹ For a list of drugs that are substrates of these enzymes, see 'Table 1.2', (p.4), 'Table 1.3', (p.6), and 'Table 1.4', (p.6).

- Gurley BJ, Gardner SF, Hubbard MA, Williams DK, Gentry WB, Carrier J, Khan IA, Edwards DJ, Shah A. In vivo assessment of botanical supplementation on human cytochrome P450 phenotypes: *Citrus aurantium*, *Echinacea purpurea*, milk thistle, and saw palmetto. *Clin Pharmacol Ther* (2004) 76, 428–40.

Black cohosh + Cytochrome P450 isoenzyme substrates

Black cohosh does not affect the metabolism of caffeine, chlorzoxazone and debrisoquine, and is therefore unlikely to affect the metabolism of drugs that are substrates for CYP1A2, CYP2E1 and CYP2D6.

Clinical evidence, mechanism, importance and management

In a study in 12 non-smoking healthy subjects given black cohosh root extract 1090 mg twice daily for 28 days before receiving single doses of **caffeine**, **chlorzoxazone** and **debrisoquine**, no clinically significant changes in the metabolism of these drugs were noted. It is therefore unlikely that other drugs metabolised by CYP1A2, CYP2E1, or CYP2D6 (see 'Table 1.2', (p.4), and 'Table 1.3', (p.6)) will be affected by the use of black cohosh (*cimicifuga*).¹ For the lack of effect of black cohosh on midazolam, see 'benzodiazepines', (p.724).

1. Gurley BJ, Gardner SF, Hubbard MA, Williams DK, Gentry WB, Khan IA, Shah A. In vivo effects of goldenseal, kava kava, black cohosh, and valerian on human cytochrome P450 1A2, 2D6, 2E1, and 3A4/5 phenotypes. *Clin Pharmacol Ther* (2005) 77, 415–26.

Charcoal, activated + Miscellaneous

Small doses of activated charcoal appear to have little effect on the absorption of ciprofloxacin and oral contraceptives (administration separated), and only modestly reduces nizatidine absorption. Case reports describe the lack of efficacy of mitobronitol and reduced serum phenobarbital levels in the presence of small doses of activated charcoal.

Clinical evidence, mechanism, importance and management

The use of activated charcoal, in a usual dose of 50 g, to reduce the absorption of drugs and poisons after acute overdose is well established, as is repeated doses of activated charcoal to enhance the elimination of some drugs taken in overdose after they have been absorbed (e.g. **carbamazepine**, **theophylline**). Studies and references supporting these therapeutic uses of activated charcoal are not reviewed here.

Activated charcoal is also included in various remedies used for gastrointestinal disorders such as flatulence or diarrhoea. Doses in these instances are very much lower (1 to 2 g daily) than those used in the treatment of poisoning, and there seems to be little reported about the effects of these doses on the absorption of other drugs. In one single-dose study in healthy subjects, **nizatidine** absorption was reduced by about 30% when it was taken one hour before activated charcoal 2 g.¹ In another single-dose study in 6 subjects, taking activated charcoal 1 g soon after ciprofloxacin 500 mg, had little effect on the pharmacokinetics of **ciprofloxacin** 500 mg (AUC reduced by 10%).²

In one case report, an antiemetic complementary remedy containing activated charcoal was thought to be the cause of a lack of effect of **mitobronitol** 125 mg used to treat primary thrombocythaemia in one patient.³ In another case report,⁴ activated charcoal 2 g three times daily was given with **phenobarbital** and enteral nutrition via a gastric fistula tube. The charcoal appeared to reduce the absorption of **phenobarbital** (serum level 4.3 mg/L compared with a previous level of 24.8 mg/L). Giving the activated charcoal at least one hour apart from the **phenobarbital** resulted in an increase in serum levels to about 16 to 18 mg/L.

Activated charcoal 5 g four times daily was taken for 3 days, mid-cycle, with the first daily dose taken 3 hours after the morning dose of a **combined oral contraceptive** (ethinylestradiol/norethisterone or ethinylestradiol/gestodene), had no effect on the pharmacokinetics of the contraceptive steroids in 9 healthy subjects,⁵ and ovulation (assessed by hormone measurements and ultrasonography) did not occur.⁶ The authors concluded that repeated charcoal treatment, given 3 hours after and at least 12 hours before a **combined oral contraceptive**, can be used to treat diarrhoea in women taking **combined oral contraceptives**.^{5,6}

Chlorzoxazone + Disulfiram

Disulfiram markedly increases the plasma levels of chlorzoxazone.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects to identify the activity of cytochrome P450 isoenzyme CYP2E1 found that a single 500-mg dose of disulfiram markedly inhibited the metabolism of a single 750-mg dose of chlorzoxazone (clearance reduced by 85%, half-life increased from 0.92 to 5.1 hours, and a two-fold increase in peak plasma levels).¹

No increased adverse effects were seen while using these single doses, but an increase in toxicity would be expected (sedation, headache, nausea) with multiple doses. Be alert for the need to reduce the chlorzoxazone dosage if disulfiram is given concurrently.

1. Kharasch ED, Thummel KE, Mhyre J, Lillibridge JH. Single-dose disulfiram inhibition of chlorzoxazone metabolism: a clinical probe for P450 2E1. *Clin Pharmacol Ther* (1993) 53, 643–50.

Chlorzoxazone + Isoniazid

The adverse effects of chlorzoxazone may be increased in some patients (particularly slow-acetylators of isoniazid) if they also take isoniazid.

Clinical evidence

Five out of 10 healthy slow acetylators of isoniazid experienced an increase in the adverse effects of a 750-mg dose of chlorzoxazone (sedation, headache, nausea) after taking isoniazid 300 mg daily for 7 days. These symptoms disappeared within 2 days of withdrawing the isoniazid.¹ Pharmacokinetic analysis showed that the clearance of chlorzoxazone was reduced by 56% when given on the last day of isoniazid administration, then increased by 56% when given 2 days after stopping isoniazid.¹ Similar findings were reported in another study in slow acetylators of isoniazid: chlorzoxazone clearance was reduced by 78% when subjects had taken isoniazid 300 mg daily for 14 days, at which point the isoniazid was stopped. Two days later chlorzoxazone clearance was increased by 58%, and it had returned to normal 2 weeks later.² Rapid acetylators of isoniazid also had a 60% reduction in chlorzoxazone clearance on the last day of isoniazid administration, but did not have any increase 2 days later.²

Mechanism

Isoniazid appears to cause a dual interaction. During administration, it inhibits the activity of cytochrome P450 isoenzyme CYP2E1, the enzyme involved in the metabolism of chlorzoxazone. Shortly after stopping isoniazid, the metabolism of chlorzoxazone is increased, possibly because of induction of CYP2E1, although this effect was only evident in the slow acetylators.^{1,2}

Importance and management

The increase in chlorzoxazone levels is established, and occurs in both slow and fast acetylators of isoniazid, although the increase in levels is slightly greater in slow acetylators. In practical terms this means that it may be necessary to reduce the chlorzoxazone dosage in some patients if they take isoniazid. Monitor concurrent use carefully. The rebound increase in chlorzoxazone clearance in slow acetylators on stopping isoniazid was short-lived and is probably of little clinical importance.

CNS depressants + CNS depressants

The concurrent use of two or more drugs that depress the CNS may be expected to result in increased CNS depression. This may have undesirable and even life-threatening consequences.

Clinical evidence, mechanism, importance and management

Many drugs have the propensity to cause depression of the central nervous system, resulting in drowsiness, sedation, respiratory depression and at the extreme, death. If more than one CNS depressant is taken, their effects may be additive. It is not uncommon for patients, particularly the elderly, to be taking numerous drugs (and possibly alcohol as well). Such patients are therefore at risk of cumulative CNS depression ranging from mild drowsiness through to a befuddled stupor, which can make the performance of the simplest everyday task more difficult or even impossible. The importance of this will depend on the context: it may considerably increase the risk of accident in the kitchen, at work, in a busy street, driving a car, or handling other potentially dangerous machinery where alertness is at a premium. It has been estimated that as many as 600 traffic accident fatalities each year in the UK can be attributed to the sedative effects of psychoactive drugs.¹ In a Spanish study of fatal road traffic accidents, blood samples were analysed from 9.7% of drivers killed in road accidents over a 10-year period. Of these drivers, medicines were detected in 4.7% (269 cases), and of these benzodiazepines were the most common (73%). Other drugs present in 6% to 12% of cases included antidepressants, analgesics, antiepileptics, barbiturates and antihistamines. Of the benzodiazepine cases, almost three quarters had another substance detected, mainly illicit drugs (cocaine, opiates, or cannabis) or alcohol. Only 7.7% had taken benzodiazepines or another medicinal drug alone.² **Alcohol** almost certainly makes things worse.

An example of the lethal effects of combining an **antihistamine**, a **benzodiazepine** and **alcohol** is briefly mentioned in the monograph 'Alcohol + Antihistamines', p.47. A less spectacular but socially distressing example is that of a woman accused of shop-lifting while in a confused state arising from the combined sedative effects of *Actifed*, a *Beechams Powder* and *Dolobid* (containing **triprolidine**, **salicylamide** and **diflunisal**, respectively).³

Few if any well-controlled studies have investigated the cumulative or additive detrimental effects of CNS depressants (except with **alcohol**), but the following is a list of some of the groups of drugs that to a greater or lesser extent possess CNS depressant activity and which might be expected to interact in this way: **alcohol**, **opioid analgesics**, **anticonvulsants**, **antidepressants**, **antihistamines**, **antiemetics**, **antipsychotics**, **anxiolytics** and **hypnotics**. Some of the interactions of **alcohol** with these drugs are dealt with in individual monographs.

Colchicine + Macrolides

Several case reports describe acute life-threatening colchicine toxicity caused by the addition of erythromycin or clarithromycin, and one retrospective study found that 9 of 88 patients who had received the combination of colchicine and clarithromycin died.

Clinical evidence

A 29-year-old woman with familial Mediterranean fever and amyloidosis, who was taking long-term colchicine 1 mg daily, developed acute and life-threatening colchicine toxicity (fever, diarrhoea, myalgia, pancytopenia and later alopecia) 16 days after starting to take **erythromycin** 2 g daily. This patient had both cholestasis and renal impairment, factors that would be expected to reduce colchicine clearance and therefore predispose her to colchicine toxicity.¹ Colchicine levels rose from below 12.6 nanograms/mL to 22 nanograms/mL after the addition of **erythromycin**.¹ In another patient, who had been taking colchicine 1.5 mg daily for 6 years, similar signs of acute colchicine toxicity developed 4 days after starting a 7-day course of **clarithromycin** 1 g daily, amoxicillin and omeprazole for *H. pylori* associated gastritis. The colchicine dose was reduced to 500 micrograms daily and then, after recovery, gradually increased slowly back to 1.5 mg daily.²

In another case, a 67-year-old man on CAPD taking colchicine 500 micrograms twice daily was admitted with symptoms of colchicine toxicity (including pancytopenia) 4 days after starting a course of **clari-**

thromycin 500 mg twice daily for an upper respiratory tract infection. All drugs were stopped and supportive treatment given, but he later died from multi-organ failure.³

These case reports led to a retrospective study of patients who had received the combination of colchicine and **clarithromycin** as inpatients. Of 116 patients given the drugs, 88 had received them concurrently and 28 received them sequentially. Nine of the concurrent group died (compared with only 1 of the sequential group), and of the nine, five had pancytopenia, and six had renal impairment. In the 88 patients receiving the drugs concurrently, longer overlapping therapy increased the relative risk of death 2.16-fold, the presence of renal impairment increased the risk 9.1-fold, and the development of pancytopenia increased the risk 23.4-fold.⁴

Two further cases of fatal agranulocytosis, presumed to result from use of colchicine with **clarithromycin**, have been reported,⁵ and 2 other cases describe colchicine toxicity during **clarithromycin** use in patients with renal impairment.⁶

Mechanism

Erythromycin and clarithromycin may inhibit the hepatic metabolism of colchicine via the cytochrome P450 isoenzyme CYP3A4, and/or might increase its bioavailability via effects on P-glycoprotein.^{2,4} These effects would be more marked in patients with renal impairment.

Importance and management

Information on this interaction is limited, but it appears that macrolide antibacterials can provoke acute colchicine toxicity, at the very least in pre-disposed individuals. If any patient is given colchicine and a macrolide (except probably azithromycin, which is not a notable CYP3A4 inhibitor), be aware of the potential for toxicity, especially in patients with pre-existing renal impairment.

Contrast media + Phenothiazines

Two isolated case reports describe epileptiform reactions in two patients when metrizamide was used for lumbar myelography in the presence of chlorpromazine or dixyrazine. No such cases appear to have been reported for intrathecal iohexol: nevertheless, the manufacturer of iohexol advises the avoidance of phenothiazines and other drugs that lower seizure threshold when iohexol is used intrathecally.

Clinical evidence

A patient receiving long-term treatment with **chlorpromazine** 75 mg daily had a grand mal seizure three-and-a-half hours after being given **metrizamide** (16 mL of 170 mg iodine per mL by the lumbar route). He had another seizure 5 hours later.¹ One out of 34 other patients demonstrated epileptogenic activity on an EEG when given **metrizamide** for lumbar myelography. The patient was taking **dixyrazine** 10 mg three times daily.² However, a clinical study in 26 patients given **levomepromazine** for the relief of lumbago-sciatic pain found no evidence of an increased risk of seizures after receiving **metrizamide** for myelography.³

Mechanism

Intrathecal metrizamide or iohexol alone are rarely associated with seizures. Theoretically, this risk might be increased in patients taking other drugs that lower the seizure threshold, such as the phenothiazines.

Importance and management

The case report with intrathecal metrizamide led to the advice to stop phenothiazines prior to giving this contrast agent.⁴ Intrathecal iohexol has also rarely been associated with seizures, and consequently, the US manufacturer recommends that drugs that lower seizure threshold, especially phenothiazines are not recommended for use with iohexol by this route.⁵ They should be stopped 48 hours before the procedure and not restarted until at least 24 hours after the procedure. This advice specifically includes phenothiazines used for their antiemetic properties. Although this risk is theoretical this would seem to be a prudent precaution. This advice does not apply to other routes of iohexol administration.⁵

Contrast media; Iopanoic acid + Colestyramine

A single report describes poor radiographic visualisation of the gall bladder in a man due to an interaction between iopanoic acid and colestyramine within the gut.

Clinical evidence, mechanism, importance and management

The cholecystogram of a man with post-gastrectomy syndrome taking colestyramine who was given oral iopanoic acid as an x-ray contrast medium, suggested that he had an abnormal and apparently collapsed gall bladder. A week after stopping the colestyramine a repeat cholecystogram gave excellent visualisation of a gall bladder of normal appearance.¹ The same effects have been observed experimentally in *dogs*.¹ The reason seems to be that the colestyramine binds with the iopanoic acid in the gut so that little is absorbed and little is available for secretion in the bile, hence the poor visualisation of the gall bladder.

On the basis of reports about other drugs that similarly bind to colestyramine, it seems probable that this interaction could be avoided if the administration of the iopanoic acid and the colestyramine were to be separated as much as possible (note that it is usually recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine). Whether other oral acidic x-ray contrast media bind in a similar way to colestyramine is uncertain, but this possibility should be considered.

Cyclobenzaprine + Fluoxetine and Droperidol

A patient taking cyclobenzaprine and fluoxetine developed torsade de pointes arrhythmia and ventricular fibrillation when droperidol was added.

Clinical evidence, mechanism, importance and management

A 59-year-old woman receiving long-term treatment with fluoxetine and cyclobenzaprine, who had a prolonged baseline QTc interval of 497 milliseconds, was given droperidol before surgery on her Achilles tendon. During the surgery she developed torsade de pointes arrhythmia, which progressed to ventricular fibrillation. On the first postoperative day after the cyclobenzaprine had been withdrawn, her QTc interval had decreased towards normal (440 milliseconds).¹

A likely explanation is that her cyclobenzaprine serum levels were already raised by fluoxetine (a known inhibitor of cytochrome P450 isoenzyme CYP2D6, an enzyme involved in the metabolism of cyclobenzaprine) and as a result her QTc interval was prolonged. Cyclobenzaprine is structurally like the tricyclic antidepressants and shares their ability to cause arrhythmias, particularly in high doses. Therefore the addition of the droperidol, also known to prolong the QT interval, simply further extended the QTc interval and precipitated the torsade de pointes. This case not only illustrates the existence of an interaction between cy-

clobenzaprine and fluoxetine, but also the life-threatening risks of taking multiple 'drugs that can further prolong the QT interval', (p.257).

1. Michalets EL, Smith LK, Van Tassel ED. Torsade de pointes resulting from the addition of droperidol to an existing cytochrome P450 drug interaction. *Ann Pharmacother* (1998) 32, 761–5.

Dantrolene + Metoclopramide

Metoclopramide increases the bioavailability of dantrolene.

Clinical evidence, mechanism, importance and management

A study in 7 paraplegics and 6 quadriplegics with spinal cord injuries found that a single 10-mg intravenous dose of metoclopramide increased the bioavailability of a single 100-mg oral dose of dantrolene by 57%. The reasons are not known, although it was suggested that absorption may have been affected. The clinical relevance of this interaction is uncertain but the authors of the study suggest that patients should be well monitored if metoclopramide is added or withdrawn from patients who are taking dantrolene.¹

1. Gilman TM, Segal JL, Brunnemann SR. Metoclopramide increases the bioavailability of dantrolene in spinal cord injury. *J Clin Pharmacol* (1996) 36, 64–71.

Dextromethorphan + Amiodarone

Amiodarone can reduce the clearance of dextromethorphan.

Clinical evidence

A study in 8 patients with cardiac arrhythmias found that amiodarone (1 g daily for 10 days followed by 200 to 400 mg daily for a mean duration of 76 days) changed their excretion of dextromethorphan 40 mg and its metabolite. The amount of unchanged dextromethorphan in the urine rose by nearly 150%, whereas the amount of its metabolite (dextrorphan) fell by about 25%.¹

Mechanism

In vitro studies using liver microsomes have shown that amiodarone inhibits the metabolism (*O*-demethylation) of dextromethorphan by inhibiting the cytochrome P450 isoenzyme CYP2D6 within the liver.¹ Thus the dextromethorphan is cleared more slowly.

Importance and management

Information seems to be limited to this study. The clinical implications are that amiodarone may interfere with the results of phenotyping if dextromethorphan is used to determine CYP2D6 activity, and that dextromethorphan toxicity (excitation, confusion) may possibly develop in patients taking amiodarone. Be alert for any signs of toxicity if both are used. As yet, too little is known about this interaction to say by how much the dextromethorphan dosage should be reduced. Remember that dextromethorphan occurs in a considerable number of proprietary cough preparations.

1. Funck-Brentano C, Jacqz-Aigrain E, Leenhardt A, Roux A, Poirier J-M, Jaillon P. Influence of amiodarone on genetically determined drug metabolism in humans. *Clin Pharmacol Ther* (1991) 50, 259–66.

Dextromethorphan + Bupropion

Bupropion may reduce the metabolism of dextromethorphan in some patients.

Clinical evidence, mechanism, importance and management

A study in 21 subjects who were quitting smoking and were CYP2D6 extensive metabolisers, found that 6 of 13 subjects who received bupropion 150 mg once daily for 3 days and then twice daily for 14 days had metabolic ratios of dextromethorphan 30 mg similar to those seen in poor metabolisers: the metabolism of dextromethorphan to dextrorphan was substantially reduced. No such change was seen in the 8 subjects who received placebo. It has been suggested that care should be taken when ini-

tiating or discontinuing bupropion in patients taking dextromethorphan, due to the possibility of raised dextromethorphan levels.¹ Patients should be warned that they may experience increased adverse effects to dextromethorphan and advised that this is found in non-prescription preparations such as cough suppressants.

1. Kotlyar M, Brauer LH, Tracy TS, Hatsukami DK, Harris J, Bronars CA, Adson DE. Inhibition of CYP2D6 activity by bupropion. *J Clin Psychopharmacol* (2005) 25, 226–9.

Dextromethorphan + Echinacea

Echinacea does not appear to have a clinically relevant effect on the pharmacokinetics of dextromethorphan.

Clinical evidence, mechanism, importance and management

In a study, 12 healthy subjects were given *Echinacea purpurea* root 400 mg four times daily for 8 days with a single 30-mg dose of **dextromethorphan** on day 6. In the 11 subjects who were of the cytochrome P450 isoenzyme CYP2D6 extensive metaboliser phenotype (see ‘Genetic factors in drug metabolism’, (p.4)), there were no changes in the pharmacokinetics of **dextromethorphan**. In contrast, the one subject who was a poor metaboliser had a 42% increase in the AUC of **dextromethorphan** and a 31% increase in its half-life.¹ In another study, in 12 healthy subjects given *Echinacea purpurea* 800 mg twice daily for 28 days, there was no change in the debrisoquine urinary ratio after a single dose of debrisoquine 5 mg, suggesting that *Echinacea purpurea* does not alter the activity of the cytochrome P450 isoenzyme CYP2D6.²

The findings of these studies suggest that echinacea is unlikely to have a clinically relevant effect on CYP2D6 substrates (see ‘Table 1.3’, (p.6), for a list).

In vivo assessment of botanical supplementation on human cytochrome P450 phenotypes: *Citrus aurantium*, *Echinacea purpurea*, milk thistle, and saw palmetto. *Clin Pharmacol Ther* (2004) 76, 428–40.

Dextromethorphan + Ginkgo biloba

Ginkgo biloba does not affect the metabolism of dextromethorphan.

Clinical evidence, mechanism, importance and management

Ginkgo biloba leaf extract 120 mg twice daily for 16 days was given to 12 healthy subjects with a single 30-mg dose of dextromethorphan on day 14 day. The *Ginkgo biloba* preparation (*Ginkgold*) contained ginkgo flavonol glycosides 24% and terpene lactones 6%. There was no change in the metabolism of dextromethorphan when it was taken after the *Ginkgo biloba*.¹ Dextromethorphan is a probe substrate for the cytochrome P450 isoenzyme CYP2D6, and the findings suggest that *Ginkgo biloba* is unlikely to interact with other drugs that are substrates of CYP2D6, see ‘Table 1.3’, (p.6).

1. Markowitz JS, Donovan JL, DeVane CL, Sipkes L, Chavin KD. Multiple-dose administration of *Ginkgo biloba* did not affect cytochrome P-450 2D6 or 3A4 activity in normal volunteers. *J Clin Psychopharmacol* (2003) 23, 576–81.

Dextromethorphan + Quinidine

Quinidine markedly increases the plasma levels of dextromethorphan in those who are of the extensive CYP2D6 metaboliser phenotype (the most common phenotype). This effect is maximal at low doses of quinidine (25 to 30 mg).

Clinical evidence

In a study in 6 extensive CYP2D6 metabolisers given dextromethorphan 60 mg twice daily, steady-state plasma dextromethorphan levels averaged only 12 nanograms/mL. However, after being given quinidine 75 mg twice daily for a week, then a single 60-mg dose of dextromethorphan, their plasma dextromethorphan levels were over threefold higher, at 38 nanograms/mL.¹ Some of the patients given the combination had an increase in dextromethorphan adverse effects (nervousness, tremors, restlessness, dizziness, shortness of breath, confusion etc).¹ Similarly, other pharmacokinetic studies have found increases in dextromethorphan levels in extensive CYP2D6 metabolisers, but not in poor CYP2D6 metabolisers.^{2–4} In a dose-ranging study, quinidine 25 to 30 mg daily produced maximal increases in dextromethorphan levels, with higher doses producing no further increases, and lower doses producing smaller increases.⁵ In one experimental study of citric acid-induced cough, quinidine increased the cough-suppressant effect of dextromethorphan.^{6,7}

Mechanism

Quinidine inhibits the oxidative metabolism of dextromethorphan by the cytochrome P450 isoenzyme CYP2D6 to dextropran, effectively making extensive metabolisers of CYP2D6 into the poor metaboliser phenotype, see ‘Genetic factors in drug metabolism’, (p.4), for further discussion of metaboliser phenotypes.

Importance and management

An established interaction. Extensive metabolisers of CYP2D6 are likely to become more sensitive to dextromethorphan if they are taking quinidine.

Low-dose quinidine has been combined with dextromethorphan to sustain therapeutic levels of dextromethorphan and thereby try and improve its efficacy in various neurological disorders (dextromethorphan is a *N*-methyl-D-aspartate antagonist, which means it can affect pain transmission). A fixed dose combination is being investigated.⁸

Dextromethorphan + Saw palmetto

Saw palmetto does not alter the metabolism of dextromethorphan.

Clinical evidence, mechanism, importance and management

Saw palmetto 320 mg daily, given to 12 subjects for 16 days, did not affect the metabolism of a single 30-mg dose of dextromethorphan given on day 14. No change was seen in the dextromethorphan metabolic ratio.¹ This suggests that saw palmetto is unlikely to alter the pharmacokinetics of drugs that are metabolised by the cytochrome P450 isoenzyme CYP2D6, of which dextromethorphan is a probe substrate.¹ This finding was confirmed by a further study in 12 healthy subjects who were given saw palmetto and debrisoquine, another substrate of CYP2D6.²

For a list of drugs that are substrates of this enzyme, see 'Table 1.3', (p.6).

2. Gurley BJ, Gardner SF, Hubbard MA, Williams DK, Gentry WB, Carrier J, Khan IA, Edwards DJ, Shah A. In vivo assessment of botanical supplementation on human cytochrome P450 phenotypes: *Citrus aurantium*, *Echinacea purpurea*, milk thistle, and saw palmetto. *Clin Pharmacol Ther* (2004) 76, 428–40.

Dextromethorphan + St John's wort (*Hypericum perforatum*)

St John's wort does not affect the pharmacokinetics of dextromethorphan.

Clinical evidence, mechanism, importance and management

St John's wort (*LII160*, Lichtwer Pharma, 0.12 to 0.3% hypericin) 300 mg three times daily was given to 12 healthy subjects for 16 days with a single 30-mg dose of dextromethorphan on day 14. There was no consistent change in the urinary dextromethorphan to dextrorphan metabolic ratio: 6 subjects had an increase in the production of dextrorphan while the other 6 subjects had a reduction in dextrorphan production. This finding was within the normal inter-patient variation in dextromethorphan metabolism,¹ and suggests that St John's wort does not significantly affect the cytochrome P450 isoenzyme CYP2D6. Similar findings were reported in another study in 16 healthy subjects given a single 25-mg dose of dextromethorphan on the last day of a 14-day course of St John's wort (*Jarsin*; 900 micrograms of hypericin) 300 mg three times daily.²

St John's wort would not therefore be expected to alter the pharmacokinetics of other substrates of CYP2D6, for a list see 'Table 1.3', (p.6).

2. Wenk M, Todesco L, Krähenbühl S. Effect of St John's wort on the activities of CYP1A2, CYP3A4, CYP2D6, N-acetyltransferase 2, and xanthine oxidase in healthy males and females. *Br J Clin Pharmacol* (2004) 57, 494–9.

Disulfiram + Cannabis

An isolated case report describes a hypomanic-like reaction when a man taking disulfiram used cannabis.

Clinical evidence, mechanism, importance and management

A man with a 10-year history of drug abuse (alcohol, amfetamines, cocaine, cannabis) taking disulfiram 250 mg daily, experienced a hypomanic-like reaction (euphoria, hyperactivity, insomnia, irritability) on two occasions, associated with the concurrent use of cannabis. The patient said that he felt as though he had been taking amfetamine.¹ The reason for this reaction is not understood. In a randomised study in alcohol dependent subjects who had previously used cannabis, no unusual interaction effects were found in a group of 11 subjects receiving disulfiram and smoking cannabis twice weekly for 4 weeks.² Therefore the interaction described in the case report would not appear to be of general significance.

2. Rosenberg CM, Gerrein JR, Schnell C. Cannabis in the treatment of alcoholism. *J Stud Alcohol* (1978) 39, 1955–8.

Dutasteride + Miscellaneous

Preliminary evidence suggests that diltiazem and verapamil, inhibitors of cytochrome P450 isoenzyme CYP3A4, cause moderate increases in dutasteride levels but this is probably not clinically significant. In the UK, the manufacturer says that dutasteride dosage adjustments may be needed with potent inhibitors of CYP3A4 such as indinavir, itraconazole, ketoconazole, nefazodone and ritonavir. No clinically significant interaction appears to occur between dutasteride and amlodipine, digoxin, or warfarin. There is no interaction when dutasteride is given one hour before colestyramine.

Clinical evidence, mechanism, importance and management

(a) Colestyramine

In a study in 12 healthy subjects the absorption of dutasteride 5 mg was not affected when it was given one hour before a single 12-g dose of colestyramine.^{1,2} No precautions seem necessary if this dosing interval is observed.

(b) CYP3A4 inhibitors and substrates

When dutasteride was given with **amlodipine** (4 subjects), **diltiazem** (5 subjects) or **verapamil** (6 subjects) during dose-ranging studies, **amlodipine** did not significantly affect the clearance of dutasteride but **diltiazem** and **verapamil** were associated with a decrease of 44% and 37%, respectively.² This was thought to be due to the inhibitory effect of **diltiazem** and **verapamil** on P-glycoprotein and the cytochrome P450 isoenzyme CYP3A4. Dutasteride has a wide safety margin, so these changes were not thought to be clinically significant.² However, in the UK, the manufacturers warn that potent CYP3A4 inhibitors (they name **indinavir**, **itraconazole**, **ketoconazole**, **nefazodone** and **ritonavir**) may cause a clinically significant increase in dutasteride levels, and so they suggest reducing the dosing frequency if increased dutasteride adverse effects occur in the presence of these drugs.¹

(c) Digoxin

A placebo-controlled study in 20 healthy subjects taking digoxin found that its pharmacokinetics were unchanged by dutasteride 500 micrograms daily for 3 weeks.² No digoxin dose adjustment would be expected to be necessary on concurrent use.

(d) Warfarin

Dutasteride 500 micrograms daily, given to 23 healthy subjects with warfarin for 35 days had no effect on the pharmacokinetics of *S*- or *R*-warfarin, and the prothrombin time was unaffected by the presence of dutasteride.² No warfarin dose adjustment would be expected to be necessary on concurrent use.

2. Avodart (Dutasteride). GlaxoSmithKline. US Prescribing information, May 2005.

Enteric-coated, delayed-release preparations + Drugs that affect gastric pH

Theoretically, enteric-coated, delayed-release preparations may possibly dissolve prematurely if they are taken at the same time as antacids. This has been seen with some preparations, but not others. Release characteristics are likely to depend on the specific coating, and the manufacturers advice should be followed.

Clinical evidence

(a) Antacid

A placebo-controlled, crossover study in 21 healthy subjects, found that when extended-release **oxybutynin** 10 mg (*Ditropan XL*) was given at the same time as *Maalox* 20 mL (**aluminium/magnesium hydroxide** and **simethicone**) there was no change in the pharmacokinetics of **oxybutynin** or its metabolite.¹

In an identical study in 23 healthy subjects, *Maalox* increased the maximum plasma level of a single 4-mg dose of extended-release **tolterodine** (*Detrol LA*) by 50%, but did not change any other pharmacokinetic parameter (time to maximum level, elimination half-life, AUC).¹

(b) Omeprazole

In a placebo-controlled, crossover study in 39 healthy subjects, pre-treatment with omeprazole 20 mg daily for 4 days did not alter the pharmacokinetics of extended-release oxybutynin 10 mg [*Ditropan XL*]. The metabolites of oxybutynin were similarly unaffected. Pretreatment with omeprazole increased the maximum plasma level a single 4-mg dose of extended release tolterodine [*Detrol LA*] by 38%, but did not change any other pharmacokinetic parameter (time to maximum level, elimination half-life, AUC).²

The bioavailability of enteric-coated preparations of aspirin, diclofenac, and ketoprofen are unaffected by omeprazole, see 'NSAIDs or Aspirin + Proton pump inhibitors', p.155.

Mechanism

A marked rise in pH caused by antacids might cause premature dissolution of the coating of preparations formulated to prevent release of the contents until they reach the more alkaline conditions within the small intestine. Other types of delayed release preparations that have release characteristics independent of pH, such as those based on the osmotic principle, would not be expected to be affected.

Importance and management

Traditionally, it has been considered that drugs formulated with enteric coatings to resist gastric acid, or formulated as delayed release preparations, should not be given with antacids. Accelerated drug release from a delayed release product (dose dumping) might lead to increased adverse effects and lack of efficacy for the duration of the dose interval. The evidence above for extended-release tolterodine suggest that an antacid did cause a faster release of tolterodine from this product, but whether the 50% increase in maximum level is sufficient to cause an increase in adverse effects is not known. Pre-treatment with omeprazole caused a smaller 38% increase in maximum tolterodine levels. The extended-release oxybutynin product was not affected by antacid or omeprazole, which was not unexpected since release from this product is osmotically driven and pH independent.

Release characteristics are likely to depend on the specific coating, and therefore no general advice can be given. The manufacturers advice should be followed.

2. Dmochowski R, Chen A, Sathyan G, MacDiarmid S, Gidwani S, Gupta S. Effect of the proton pump inhibitor omeprazole on the pharmacokinetics of extended-release formulations of oxybutynin and tolterodine. *J Clin Pharmacol* (2005) 45, 961–8.

Ethylene dibromide + Disulfiram

The very high incidence of malignant tumours in rats exposed to both ethylene dibromide and disulfiram is the basis of the recommendation that concurrent exposure to these compounds should be avoided.

Clinical evidence, mechanism, importance and management

Research conducted to establish the occupational safety of exposure to ethylene dibromide found that the incidence of malignant tumours in rats exposed to 20 ppm ethylene dibromide (7 hours daily, 5 days weekly), while receiving a diet containing 0.05% disulfiram by weight, is very high indeed.^{1,2} The reasons are not understood. In addition to the precautions needed to protect workers from the toxic effects of ethylene dibromide, it has been strongly recommended that disulfiram should not be given to those who may be exposed to this compound.² This information is also summarised in another report.³

Evening primrose oil + Phenothiazines

Although seizures have occurred in a few schizophrenics taking phenothiazines and evening primrose oil, no adverse effects were seen in others, and there appears to be no firm evidence that evening primrose oil should be avoided by epileptic patients.

Clinical evidence

Twenty-three patients were enrolled in a placebo-controlled study of evening primrose oil in schizophrenia. During the treatment phase, patients were given 8 capsules of *Efamol* in addition to their normal medication. Seizures developed in 3 patients, one during treatment with placebo. The other two patients were taking evening primrose oil, one was receiving **fluphenazine decanoate** 50 mg once every 2 weeks and the other **fluphenazine decanoate** 25 mg once every 2 weeks with **thioridazine**,

which was later changed to **chlorpromazine**.¹ In another study, 3 long-stay hospitalised schizophrenics were taking evening primrose oil. Their schizophrenia became much worse and all 3 patients showed EEG evidence of temporal lobe epilepsy.²

In contrast, no seizures or epileptiform events were reported in a crossover study of 48 patients (most of them schizophrenics) taking **phenothiazines** when they were given evening primrose oil for 4 months.³ Concurrent use was also apparently uneventful in another study in schizophrenic patients.⁴

Mechanism

Not understood. One suggestion is that evening primrose oil possibly increases the well-recognised epileptogenic effects of the phenothiazines, rather than having an epileptogenic action of its own.¹ Another idea is that it might unmask temporal lobe epilepsy.^{1,2}

Importance and management

The interaction between phenothiazines and evening primrose oil is not well established, nor is its incidence known, but clearly some caution is appropriate during concurrent use, because seizures may develop in a few individuals. There seems to be no way of identifying the patients at particular risk. The extent to which the underlying disease condition might affect what happens is also unclear.

No interaction between anticonvulsants and evening primrose oil has been established and the reports cited above^{1,2} appear to be the sole basis for the suggestion that evening primrose oil should be avoided by epileptics. No seizures appear to have been reported in patients taking evening primrose oil in the absence of phenothiazines. The manufacturers of *Epogam*, an evening primrose oil preparation, claim that it is known to have improved the control of epilepsy in patients previously uncontrolled with conventional antiepileptic drugs, and other patients are said to have had no problems during concurrent treatment.⁵ Even so, until the situation is formally examined it would seem prudent to monitor concurrent use.

Folic acid + Adsorbents

In vitro studies show that folic acid is markedly adsorbed by magnesium trisilicate and edible clay.¹ This would be expected to reduce its absorption from the gut, but the clinical importance of this awaits assessment.

1. Iwuagwu MA, Jideonwo A. Preliminary investigations into the in-vitro interaction of folic acid with magnesium trisilicate and edible clay. *Int J Pharmaceutics* (1990) 65, 63–7.

Folic acid + Sulfasalazine

Sulfasalazine can reduce the absorption of folic acid.

Clinical evidence, mechanism, importance and management

The absorption of folic acid was reduced by about one-third (from 65 to 44.5%) in patients with ulcerative and granulomatous colitis, when compared with healthy subjects, and even further reduced (down to 32%) when sulfasalazine was taken.¹ Another study confirmed that serum folate levels are lower in patients with ulcerative colitis taking sulfasalazine, and that the impairment of the absorption of folates by sulfasalazine was a mechanism in this.² Sulfasalazine is also known to interfere with folate metabolism.

It is well established that sulfasalazine is, rarely, associated with blood dyscrasias due to folate deficiency and also other haematological toxicities, and consequently regular blood counts are recommended to detect

this. The effects of folate deficiency (e.g. macrocytosis, pancytopenia) can be normalised by the administration of folic acid or folinic acid.

Garlic + Cytochrome P450 isoenzyme substrates

Garlic dose not affect the pharmacokinetics of alprazolam or dextromethorphan, and is therefore not expected to interact with drugs metabolised by CYP3A4 or CYP2D6.

Clinical evidence, mechanism, importance and management

A study in 14 healthy subjects found that garlic (*Allium sativum*), 600 mg twice daily for 14 days, did not affect the pharmacokinetics of a single 2-mg dose of **alprazolam** or the metabolism of a single 30-mg dose of **dextromethorphan**. This suggests that garlic is unlikely to affect the metabolism of other drugs that are substrates of the cytochrome P450 isoenzymes CYP3A4 or CYP2D6.¹ For a list of drugs that are substrates of these enzymes, see 'Table 1.3', (p.6), and 'Table 1.4', (p.6).

1. Markowitz JS, DeVane CL, Chavin KD, Taylor RM, Ruan Y, Donovan JL. Effects of garlic (*Allium sativum* L.) supplementation on cytochrome P450 2D6 and 3A4 activity in healthy volunteers. *Clin Pharmacol Ther* (2003) 74, 170–7.

Ginseng + Cytochrome P450 isoenzyme substrates

Ginseng does not appear to affect the metabolism of alprazolam or dextromethorphan.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that Siberian ginseng, 485 mg twice daily for 14 days, did not affect the pharmacokinetics of a single 2-mg dose of **alprazolam** or the metabolism of a single 30-mg dose of **dextromethorphan**. This suggests that Siberian ginseng is unlikely to affect the metabolism of other drugs that are substrates of the cytochrome P450 isoenzymes CYP2D6 or CYP3A4.¹ For a list of drugs that are substrates of these enzymes, see 'Table 1.3', (p.6), and 'Table 1.4', (p.6), respectively.

1. Donovan JL, DeVane CL, Chavin KD, Taylor RM, Markowitz JS. Siberian ginseng (*Eleutherococcus [sic] senticosus*) effects on CYP2D6 and CYP3A4 activity in normal volunteers. *Drug Metab Dispos* (2003) 31, 519–22.

Glucagon + Beta blockers

The blood glucose-elevating effects of glucagon may be reduced by propranolol.

Clinical evidence, mechanism, importance and management

The blood glucose-elevating effects of glucagon was reduced in the presence of **propranolol** in 5 healthy subjects.¹ Blood glucose levels increased by about 45% in the presence of glucagon, but when **propranolol** was also given the increase was only about 15%. The reason is uncertain, but one suggestion is that the **propranolol** inhibits the effects of the catecholamines that are released by glucagon. The clinical importance of this interaction is uncertain.

1. Messerli FH, Kuchel O, Tolis G, Hamet P, Frayasse J, Genest J. Effects of β -adrenergic blockage on plasma cyclic AMP and blood sugar responses to glucagon and isoproterenol in man. *Int J Clin Pharmacol Biopharm* (1976) 14, 189–94.

Goldenseal (*Hydrastis*) + Cytochrome P450 isoenzyme substrates

Goldenseal modestly decreased the metabolism of midazolam and debrisoquine but had no effect on the metabolism of caffeine or chlorzoxazone.

Clinical evidence, mechanism, importance and management

In a study 12 non-smoking healthy subjects were given goldenseal root extract 900 mg three times daily for 28 days before receiving single doses of **caffeine**, **chlorzoxazone**, **debrisoquine** and **midazolam**. No significant changes in the metabolism of **caffeine** or **chlorzoxazone** were noted. Goldenseal (*hydrastis*) appeared to reduce the activity of the cytochrome P450 isoenzymes CYP2D6 and CYP3A4/5 by 40%, measured by the effect on the urinary recovery of **debrisoquine**, and the reduced production of the 1-hydroxy metabolite of **midazolam**.¹

On the basis of this pharmacokinetic probe study it was suggested that goldenseal may have a clinically relevant effect on midazolam (and other substrates of CYP3A4/5, see 'Table 1.4', (p.6)), and debrisoquine (and other substrates of CYP2D6, see 'Table 1.3', (p.6)). Some caution might be required as raised levels of these drugs are possible.

1. Gurley BJ, Gardner SF, Hubbard MA, Williams DK, Gentry WB, Khan IA, Shah A. In vivo effects of goldenseal, kava kava, black cohosh, and valerian on human cytochrome P450 1A2, 2D6, 2E1, and 3A4/5 phenotypes. *Clin Pharmacol Ther* (2005) 77, 415–26.

5-HT₃-receptor antagonists + Aprepitant

Aprepitant had no clinically relevant effect on the pharmacokinetics of dolasetron, granisetron, ondansetron or palonosetron.

Clinical evidence

(a) Dolasetron

In a study in 12 healthy subjects, aprepitant 125 mg on day one, then 80 mg on days 2 and 3 had no effect on the pharmacokinetics of a single 100-mg oral dose of dolasetron given on day one, regardless of CYP2D6 metaboliser type.¹

(b) Granisetron

Aprepitant 125 mg on day one, then 80 mg on days 2 and 3 had no effect on the pharmacokinetics of oral granisetron 2 mg given to healthy subjects on day one.²

(c) Ondansetron

In a study in healthy subjects, aprepitant 375 mg on day one, then 250 mg on days 2 to 5 caused a minor 15% increase in the AUC of intravenous ondansetron 32 mg given on day one.²

(d) Palonosetron

Aprepitant 125 mg on day one, then 80 mg on days 2 and 3 had no effect on the pharmacokinetics of a single 250-microgram intravenous dose of palonosetron given to healthy subjects on day one.³

Mechanism

None.

Importance and management

No important pharmacokinetic interactions occur, therefore no dosage adjustment is required when aprepitant is given with dolasetron, ondansetron, granisetron or palonosetron.

1. Li SX, Pequignot E, Panebianco D, Lupinacci P, Majumdar A, Rosen L, Ahmed T, Royalty JE, Rushmore TH, Murphy MG, Petty KJ. Lack of effect of aprepitant on hydrodolasetron pharmacokinetics in CYP2D6 extensive and poor metabolizers. *J Clin Pharmacol* (2006) 46, 792–801.

- Blum RA, Majumdar A, McCrea J, Busillo J, Orlowski LH, Panebianco D, Hesney M, Petty KJ, Goldberg MR, Murphy MG, Gottesdiener KM, Hustad CM, Lates C, Kraft WK, Van Buren S, Waldman SA, Greenberg HE. - Shah AK, Hunt TL, Gallagher SC, Cullen MT. Pharmacokinetics of palonosetron in combination with aprepitant in healthy volunteers. *Curr Med Res Opin* (2005) 21, 595–601.

5-HT₃-receptor antagonists + Cimetidine

Cimetidine had no important effect on dolasetron or granisetron pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Dolasetron

A study in 18 healthy subjects given dolasetron 200 mg daily found that cimetidine 300 mg four times daily for 7 days increased the AUC and maximum plasma level of the active metabolite of dolasetron, hydrodolasetron, by 24% and 15%, respectively, probably due to the inhibitory effect of cimetidine on the cytochrome P450-mediated metabolism of dolasetron. As 400-mg oral doses of dolasetron have been shown to be well tolerated (the usual oral dose is up to 200 mg) these changes were not considered to be clinically significant.¹ Therefore no special precautions appear necessary if cimetidine and dolasetron are used concurrently.

(b) Granisetron

Pretreatment with cimetidine 200 mg four times daily for 8 days had no effect on the pharmacokinetics of a single 40-microgram/kg intravenous dose of granisetron given on day 8 in a study in 12 healthy subjects.² No granisetron dose adjustments are likely to be necessary if cimetidine is given.

- Dimmitt DC, Cramer MB, Keung A, Arumugham T, Weir SJ. Pharmacokinetics of dolasetron with coadministration of cimetidine or rifampin in healthy subjects. *Cancer Chemother Pharmacol* (1999) 43, 126–32.
- Youlten L. The effect of repeat dosing with cimetidine on the pharmacokinetics of intravenous granisetron in healthy volunteers. *J Pharm Pharmacol* (2004) 56, 169–75.

5-HT₃-receptor antagonists + Drugs that prolong the QT interval

All available 5-HT₃-receptor antagonists (dolasetron, granisetron, ondansetron, palonosetron, tropisetron) have caused small increases (generally not exceeding 15 milliseconds) in the QTc interval. Some consider that these changes are not clinically relevant. Nevertheless, many of the manufacturers give various cautions about using 5-HT₃-receptor antagonists together with other drugs known to prolong the QT interval.

Clinical evidence, mechanism, importance and management

The 5-HT₃-receptor antagonists are now known to cause small increases (generally not exceeding 15 milliseconds) in the QTc interval.¹ It has been concluded that this class effect is too small to be of clinical relevance,^{1,2} and that there is insufficient evidence to differentiate the 5-HT₃-receptor antagonists by this effect.³ Nevertheless, manufacturers issue differing guidance about concurrent use with other QT prolonging drugs as follows:

- Dolasetron:** the UK manufacturer contraindicates⁴ the concurrent use of dolasetron and **class I** or **class III antiarrhythmics**, and recommends caution with other drugs that prolong ECG intervals in patients at risk. The US manufacturer advises caution with all drugs that may prolong the QT interval. They include **diuretics**, with potential for inducing electrolyte abnormalities.⁵
- Granisetron:** Neither the UK nor the UK manufacturers mention QT prolongation.^{6,7}
- Ondansetron:** the UK manufacturer recommends caution in patients treated with **antiarrhythmics** or **beta blockers**,⁸ whereas the US manufacturer does not issue any cautions regarding QT-prolongation.⁹
- Palonosetron:** the UK and US manufacturers recommend caution with other drugs that increase the QT interval.^{10,11} The US manufacturer spe-

cifically mentions **antiarrhythmics** and **diuretics** with potential for inducing electrolyte abnormalities.¹¹

- Tropisetron:** the UK manufacturer recommends care when it is used with other drugs that are likely to prolong the QT interval, and specifically mentions **antiarrhythmics** and **beta blockers**.¹²

For further information about drug interactions involving the QT interval see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

5-HT₃-receptor antagonists + Enzyme inducers

Rifampicin causes a minor reduction in dolasetron levels and a modest reduction in ondansetron levels, and may affect granisetron and tropisetron similarly, but does not appear to alter palonosetron levels. However, with the possible exception of ondansetron, none of the changes are thought to be clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Dolasetron

In a study in 17 healthy subjects given dolasetron 200 mg daily, **rifampicin** (rifampin) 600 mg daily for 7 days decreased the AUC and maximum plasma level of the active metabolite of dolasetron, hydrodolasetron, by 28% and 17%, respectively, probably due to induction of hydrodolasetron metabolism by **rifampicin**.¹ These changes were not considered to be clinically significant and therefore no special precautions appear necessary if **rifampicin** and dolasetron are used concurrently.

(b) Granisetron

The US manufacturer notes that, in a pharmacokinetic study, the enzyme inducer **phenobarbital** increased the clearance of granisetron by 25%. They say that the clinical relevance of this change is unknown,² but such a modest change is not likely to be important.

(c) Ondansetron

Pretreatment with **rifampicin** 600 mg once daily for 5 days markedly decreased the AUC of a single 8-mg dose of oral ondansetron by 65% and intravenous ondansetron by 48% in a study in 10 healthy subjects. This is most likely due to the induction of CYP3A4-mediated metabolism of ondansetron by **rifampicin**. The authors concluded that ondansetron may not be as effective if given to patients taking **rifampicin**.³ Nevertheless, the US manufacturer says that, although the potent inducers CYP3A4, **phenytoin**, **carbamazepine**, and rifampicin increased ondansetron clearance, on the basis of available data, no ondansetron dose adjustment is recommended for patients taking these drugs.⁴

(d) Palonosetron

The UK manufacturer notes that, in a population pharmacokinetic analysis, enzyme inducers (**dexamethasone** and **rifampicin**) had no effect on palonosetron clearance.⁵ No palonosetron dose adjustment is likely to be necessary when given with these drugs.

(e) *Tropisetron*

The manufacturer states that drugs known to induce hepatic enzymes might lower tropisetron plasma concentrations. However, they say that such changes are unlikely to be of practical importance with the recommended dosage regimen.⁶

5-HT₃-receptor antagonists; Dolasetron + Miscellaneous

Food does not affect dolasetron absorption. Atenolol modestly reduced the clearance of the active metabolite of dolasetron. One patient taking verapamil and given dolasetron experienced heart block.

Clinical evidence, mechanism, importance and management

(a) *Atenolol*

The US manufacturer¹ notes that atenolol reduced the clearance of the active metabolite of dolasetron, hydrodolasetron, by 27%. This change is not likely to be clinically significant.

(b) *Food*

In a single-dose study, 23 healthy subjects were given 200 mg of dolasetron orally either alone, or following a **high-fat breakfast** (containing fat 55 g, protein 33 g and carbohydrate 58 g). Although there was a slight delay in absorption, dosing with a meal and dosing without a meal were considered to be bioequivalent. Therefore dolasetron may be given without regard to meals.²

(c) *Verapamil*

The US manufacturer notes that, in one case, a 61-year-old woman taking verapamil developed complete heart block following the use of dolasetron,¹ although this was not proven to be as a result of an interaction. In other patients taking verapamil, the clearance of hydrodolasetron (the active metabolite of dolasetron) was unchanged.¹

5-HT₃-receptor antagonists; Ondansetron + Food or Antacids

Food slightly increases the bioavailability of ondansetron, but an antacid was found to have no effect.

Clinical evidence, mechanism, importance and management

When 12 healthy subjects were given an 8 mg ondansetron tablet 5 minutes after a **meal**, its bioavailability was slightly increased (AUC raised by 17%) but the concurrent use of an **aluminium/magnesium hydroxide** antacid (*Maalox*) had no effect on ondansetron.¹

Iron chelators + Ascorbic acid (Vitamin C)

High-dose vitamin C may cause cardiac disorders in some patients treated with desferrioxamine. Doses of up to 200 mg daily appear to be without adverse effect.

Clinical evidence, mechanism, importance and management

Vitamin C is given with iron chelators to patients with iron overload because it mobilises iron stores and thus promotes the excretion of iron. One study in 11 patients with thalassaemia noted that a striking deterioration in left ventricular function occurred when the patients were given 500 mg of vitamin C with intramuscular **desferrioxamine**. In most patients left ventricular function returned to normal when the vitamin C was stopped.¹ For this reason it has been suggested that vitamin C should be used with **desferrioxamine** with caution,² only where there is a demonstrated need,³ and in the lowest possible dose.¹ The manufacturers of **desferrioxamine** recommend that a maximum daily dose of 200 mg of vitamin C should be used in adults, that vitamin C should not be given within the first month of **desferrioxamine** treatment, and that it should not be given to those with cardiac failure.^{4,5}

The manufacturers of the oral iron chelator **deferasirox** note that, although concurrent use with vitamin C has not been formally studied, doses of vitamin C up to 200 mg daily were allowed in clinical studies of **deferasirox** without adverse consequences.^{6,7}

Iron chelators; Deferasirox + Miscellaneous

Deferasirox did not alter the pharmacokinetics of digoxin. Food increases the bioavailability of deferasirox, and it should be taken on an empty stomach. The use of deferasirox with aluminium antacids is not recommended. Rifampicin, phenobarbital and phenytoin are predicted to increase the metabolism of deferasirox, and, until more is known, concurrent use should be monitored. Based on *in vitro* data, deferasirox might inhibit the metabolism of CYP2C8 substrates like paclitaxel and repaglinide. Hydroxycarbamide does not alter deferasirox metabolism.

Clinical evidence, mechanism, importance and management

(a) *Aluminium-containing antacids*

Although concurrent use has not been formally studied, the manufacturer recommends that deferasirox is not taken with aluminium-containing antacids.^{1,2} Deferasirox has a lower affinity for aluminium than for iron, but theoretically aluminium might reduce the efficacy of deferasirox.

(b) *CYP2C8 substrates*

In vitro studies suggested that the only cytochrome P450 isoenzyme that was inhibited by deferasirox at concentrations similar to those that might be achieved clinically was CYP2C8. For this reason, the EMEA have re-

quested that a clinical drug–drug interaction study be conducted to exclude a potential interaction with CYP2C8 substrates.³ Pending the findings of this, the UK manufacturers warn that an interaction between deferasirox and CYP2C8 substrates, such as **paclitaxel** and **repaglinide** cannot be excluded.¹ Therefore, bear the possibility of an interaction in mind. See ‘Table 1.3’, (p.6), for a list of clinically relevant CYP2C8 substrates.

(c) Digoxin

In healthy subjects, deferasirox had no effect on the pharmacokinetics of digoxin.^{1,2} No digoxin dose adjustment would be expected to be necessary on concurrent use.

(d) Food

Food increased the bioavailability of deferasirox to a variable extent, and the manufacturer recommends that it is taken on an empty stomach at least 30 minutes before food.^{1,2} The tablets for oral suspension can be dispersed in water, orange juice, or apple juice.²

(e) Hydroxycarbamide

In vitro, hydroxycarbamide did not inhibit the metabolism of deferasirox.^{2,3} Although an interaction has not been formally studied, the manufacturer considers it unlikely that concurrent use in patients with sickle cell anaemia will result in an interaction.^{2,3}

(f) UGT enzyme inducers

Deferasirox metabolism is predicted to be increased if it is given with UGT enzyme inducers such as **rifampicin (rifampin)**, **phenobarbital** or **phenytoin** because deferasirox is metabolised principally by glucuronidation. Pending the results of a drug–interaction study,³ the UK manufacturer recommends that the efficacy of deferasirox (serum ferritin levels) should be monitored if these drugs are used together with deferasirox, and when they are stopped, and the dose of deferasirox adjusted if necessary.¹

Iron chelators; Desferrioxamine (Deferoxamine) + Prochlorperazine

Prochlorperazine caused unconsciousness in two patients being treated with desferrioxamine.

Clinical evidence, mechanism, importance and management

Administration of prochlorperazine to 2 patients receiving desferrioxamine resulted in unconsciousness for 48 to 72 hours. It was suggested that the drug combination resulted in increased removal of iron from the central nervous system, thereby impairing noradrenergic and serotonergic systems.¹ It has also been suggested that desferrioxamine-induced damage of the retina may be more likely in the presence of phenothiazines.² It would seem wise to avoid the concurrent use of desferrioxamine and prochlorperazine, but there seems to be no direct evidence of adverse interactions with any of the other phenothiazines.

Iron compounds + Antacids

The absorption of iron and the expected haematological response can be reduced by the concurrent use of antacids.

Clinical evidence

A study in healthy subjects who were mildly iron-deficient (due to blood donation or menstruation) found that about 5 mL of **Mylanta II (aluminium/magnesium hydroxide with simeticone)** had little effect on the absorption of 10 or 20 mg of **ferrous sulfate** at 2 hours. However, **sodium**

bicarbonate 1 g almost halved the absorption of **ferrous sulfate**, and **calcium carbonate** 500 mg reduced it by two-thirds. Conversely, iron absorption from a **multivitamin** and **mineral** preparation was little affected by whether or not the tablet contained 200 mg of calcium (as **calcium carbonate**).¹ Another study found that an antacid containing **aluminium/magnesium hydroxides** and **magnesium carbonate** reduced the absorption of **ferrous sulfate** and **ferrous fumarate** (both containing 100 mg of ferrous iron) in healthy iron-replete subjects by 37% and 31%, respectively.² Poor absorption of iron during treatment with **sodium bicarbonate** and **aluminium hydroxide** has been described elsewhere.^{3,4} One study did not find that the absorption of **ferrous sulfate** (iron 10 mg/kg) was affected by doses of **magnesium hydroxide** (5 mg for every 1 mg of iron) when given 30 minutes apart.⁵ However, it has been suggested that iron absorption was not measured for a sufficient period to fully rule out a reduction in absorption.⁶

When oral iron failed to cause an expected rise in haemoglobin levels in patients taking non-absorbable alkalis such as **magnesium trisilicate**, a study was undertaken in 9 patients. Each patient was given 5 mg of isotopically labelled **ferrous sulfate** after a 35-g dose of **magnesium trisilicate**. The **magnesium** reduced the absorption of iron by an average of 70 to 88%, the reduction being small in some patients, but one individual had a fall from 67% to 5%.⁷

Mechanism

Uncertain. One suggestion is that magnesium sulfate changes ferrous sulfate into less easily absorbed salts, or increases its polymerisation.⁷ Carbonates possibly cause the formation of poorly soluble iron complexes.³ Aluminium hydroxide is believed to precipitate iron as the hydroxide and ferric ions can become intercalated into the aluminium hydroxide crystal lattice,⁸ leaving less available for absorption.

Importance and management

Information is limited and difficult to assess because of the many variables (e.g. different dosages ranging from very small to those mimicking overdose, and a mix of subjects and patients). However, a reasonable ‘blanket precaution’ to achieve maximal absorption would be to separate the administration of iron preparations and antacids as much as possible to avoid admixture in the gut. This may not prove to be necessary with some preparations.

Iron compounds or Vitamin B₁₂ + Chloramphenicol

In addition to the serious and potentially fatal bone marrow depression that can occur with chloramphenicol, it may also cause a milder, reversible bone marrow depression, which can oppose the treatment of anaemias with iron or vitamin B₁₂.

Clinical evidence

Ten out of 22 patients receiving **iron dextran** for iron-deficiency anaemia and also given chloramphenicol, failed to show the expected haematological response to the iron.¹ Four patients receiving vitamin B₁₂ for pernicious anaemia were all similarly refractory to treatment until the chloramphenicol was withdrawn.¹

Mechanism

Chloramphenicol can cause two forms of bone marrow depression. One is serious and irreversible, and can result in fatal aplastic anaemia, whereas the other is probably unrelated, milder and reversible, and appears to occur at chloramphenicol serum levels of 25 micrograms/mL or more. This occurs because chloramphenicol can inhibit protein synthesis, the first sign of which is a fall in the reticulocyte count, which reflects inadequate red cell maturation. This response to chloramphenicol has been seen in *animals*,² healthy individuals,³ a series of patients with liver disease,⁴ and in anaemic patients¹ being treated with iron dextran or vitamin B₁₂.

Importance and management

An established interaction of clinical importance. The authors of one study recommend that chloramphenicol dosages of 25 to 30 mg/kg are usually adequate for treating infections without running the risk of elevating serum levels to 25 micrograms/mL or more, which is when this type of marrow depression can occur.⁵ Monitor the effects of using iron or vitamin B₁₂ together with chloramphenicol. A preferable alternative would be to use a different antibacterial. Note that chloramphenicol should not be used in patients with pre-existing bone-marrow depression or blood dyscrasias.

Iron compounds + Coffee or Tea

Coffee may possibly contribute towards the development of iron-deficiency anaemia in pregnant women, and reduce the levels of iron in breast milk. As a result their babies may also be iron deficient. Tea may also possibly be associated with microcytic anaemia in children.

Clinical evidence

(a) Coffee

A controlled study among pregnant women in Costa Rica found that coffee consumption was associated with reductions in the haemoglobin levels and haematocrits of the mothers during pregnancy, and of their babies shortly after birth, despite the fact that the women were taking **ferric sulfate** 200 mg and 500 micrograms of folate daily. The babies also had a slightly lower birth weight (3189 g versus 3310 g). Almost a quarter of the mothers were considered to have iron-deficiency anaemia (haemoglobin levels of less than 11 g/dL), compared with none among the control group of non-coffee drinkers. Levels of iron in breast milk were reduced by about one-third. The coffee drinkers drank more than 450 mL of coffee daily, equivalent to more than 10 g of ground coffee.¹

(b) Tea

A much higher incidence of microcytic anaemia has been described in tea-drinking infants in Israel. The tea-drinkers consumed a median of 250 mL of tea each day, and the incidence of anaemia was 64%, which was about twice that of the non-tea drinking control group (31%).² A case report describes an impaired response to iron, given to correct an iron-deficiency anaemia, in the presence of 2 litres of black tea taken daily. The patient recovered when the black tea was stopped.³ Another report describes no change in the absorption of **iron supplements** in daily doses of 2 to 15.8 mg/kg in 10 iron-deficient tea-drinking children, although note that the children were only given 150 mL of tea.⁴

Mechanism

Tannins are thought to form insoluble complexes with iron and thus reduce its absorption.^{2,4}

Importance and management

The general importance of these findings is uncertain, but be aware that coffee or tea consumption may contribute to iron-deficiency anaemia.

Note that tea and coffee are not generally considered to be suitable drinks for babies and children, because of their effects on iron absorption. More study is needed.

Iron compounds + Colestyramine

Colestyramine binds with ferrous sulfate in the gut and reduces its absorption, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

Studies have shown that colestyramine binds with iron, and in *rats* this was found to halve the absorption of a single 100-microgram dose of **ferrous sulfate**.¹ Nobody seems to have checked on the general clinical importance of this in patients. Until more is known it would seem prudent to separate the dosages of the iron and colestyramine to avoid mixing in the gut, thereby minimising the effects of this possible interaction. The standard recommendation is to avoid other drugs one hour before or 4 to 6 hours after colestyramine.

1. Thomas FB, McCullough F, Greenberger NJ. Inhibition of the intestinal absorption of inorganic and hemoglobin iron by colestyramine. *J Lab Clin Med* (1971) 78, 70–80.

Iron compounds + H₂-receptor antagonists

Apart from a brief and unconfirmed report alleging that cimetidine reduced the response to ferrous sulfate in three patients, there appears to be no other evidence that H₂-receptor antagonists reduce the absorption of iron to a clinically relevant extent. Iron causes only a small and clinically irrelevant reduction in the serum levels of cimetidine and famotidine.

Clinical evidence, mechanism, importance and management

(a) Effect on iron

A brief report describes 3 patients taking **cimetidine** 1 g and **ferrous sulfate** 600 mg daily whose ulcers healed after 2 months, but their anaemia and altered iron metabolism persisted. When the **cimetidine** was reduced to 400 mg daily, but with the same dose of iron, the blood picture resolved satisfactorily within a month.¹ The author of the report attributed this response to the **cimetidine**-induced rise in gastric pH, which reduced the absorption of the iron. However, this suggested mechanism was subsequently disputed, as medicinal iron is already in the most absorbable form, Fe²⁺, and so does not need an acidic environment to aid absorption.² A study in patients with iron deficiency, or iron-deficiency anaemia, found that the concurrent use of **famotidine**, **nizatidine**, or **ranitidine**, did not affect their response to 2.4 g of **iron succinyl-protein complex** (equivalent to 60 mg of iron twice daily).³ No special precautions would seem necessary on concurrent use.

(b) Effect on H₂-receptor antagonists

In a series of 3 studies, healthy subjects were given a 300-mg tablet of **cimetidine** with either a 300-mg tablet of **ferrous sulfate** or 300 mg of **ferrous sulfate** in solution. The reductions in the AUC and the maximum serum levels of the **cimetidine** were small (less than 16%). In the third experiment they were given **famotidine** 40 mg with a 300-mg tablet of **ferrous sulfate**. Again, the AUC and maximum serum level reductions were also very small (10% or less). These small reductions are almost certainly due to the formation of a weak complex between the iron and these H₂-receptor antagonists.⁴ An *in vitro* study with **ranitidine** found that, while it also binds with iron, it forms a very weak complex, and is less likely to bind than **cimetidine** or **famotidine**.⁴ It was concluded that no clinically relevant interaction occurs between **ferrous sulfate** and any of these H₂-receptor antagonists.⁴

Iron compounds + Neomycin

Neomycin may alter the absorption of iron.

Clinical evidence, mechanism, importance and management

A study in 6 patients found that neomycin markedly reduced the absorption of iron (iron⁵⁹ as **ferrous citrate**) in 4 patients, but increased the absorption in the other 2 patients who initially had low serum iron levels. None of the patients were anaemic at any time.¹ The importance of this is uncertain, but consider this possible interaction if the response to iron is poor.

- Jacobson ED, Chodos RB, Faloon WW. An experimental malabsorption syndrome induced by neomycin. *Am J Med* (1960) 28, 524–33.

Iron compounds + Phosphate binders

Calcium carbonate and calcium acetate (in phosphate-binding doses) caused a modest reduction in the absorption of iron from ferrous sulfate, whereas sevelamer had only a minor effect.

Clinical evidence, mechanism, importance and management

In a single-dose study in 23 fasting healthy subjects,¹ the bioavailability of iron from **ferrous sulfate** 200 mg was reduced by 27% by **calcium acetate** 2.7 g, 19% by **calcium carbonate** 3 g, and 10% by **sevelamer** 2.8 g.

It was suggested that calcium may form insoluble complexes with iron, so reducing its absorption.

This study suggests that these calcium phosphate-binders may have a clinically relevant effect on iron absorption, whereas **sevelamer** probably does not. However, the findings need replicating in an appropriate patient group taking the phosphate binders long-term with meals. See also 'antacids', (p.1262) for data suggesting that lower doses of **calcium carbonate** may or may not reduce iron absorption.

- Pruchnicki MC, Coyle JD, Hoshaw-Woodard S, Bay WH. Effect of phosphate binders on supplemental iron absorption in healthy subjects. *J Clin Pharmacol* (2002) 42, 1171–6.

Iron compounds + Vitamin E substances

Vitamin E impaired the response to iron in a group of anaemic children.

Clinical evidence, mechanism, importance and management

A group of 26 anaemic children aged 7 to 40 months were given **iron dextran** 5 mg/kg daily for 3 days. Vitamin E 200 units daily was also given to 9 of the children, starting 24 hours before the **iron dextran** and continued for a total of 4 days. It was noted that after 6 days, those taking vitamin E had a reticulocyte response of only 4.4% compared with 14.4% in the patients not given vitamin E. The vitamin E group also had reduced haemoglobin levels and a lower haematocrit. The reasons are not understood. Check for any evidence of a reduced haematological response in anaemic patients given iron and vitamin E. The authors of the report point out that this dosage of vitamin E was well above the recommended daily dietary intake.¹

- Melhorn DK, Gross S. Relationships between iron-dextran and vitamin E in iron deficiency anemia in children. *J Lab Clin Med* (1969) 74, 789–802.

Kava + Cytochrome P450 isoenzyme substrates

Kava does not appear to affect the metabolism of debrisoquine and mephenytoin. Kava may inhibit the metabolism of chlorzoxazone but not all studies have found this effect.

Clinical evidence, mechanism, importance and management

In a study in 6 subjects (3 of whom smoked tobacco), who usually took 7 to 27 g of kavalactones weekly as an aqueous kava extract, the metabolism of **chlorzoxazone**, **debrisoquine**, and **mephenytoin** (which are substrates of CYP2E1, CYP2D6, and CYP2C19, respectively), was not affected when the subjects stopped taking kava for 30 days.¹ Similar results were found in a study in 12 healthy subjects given kava kava root extract 1 g twice daily for 28 days before receiving a single dose of **debrisoquine**, but when the interaction between kava kava root extract and **chlorzoxazone** was also studied in these subjects a 40% inhibitory effect of kava on CYP2E1 was seen, which is in contrast to the previous study.² For a list of drugs which are substrates of CYP2E1, CYP2D6, and CYP2C19, see 'Table 1.3', (p.6).

Consider also 'midazolam', (p.730), 'caffeine', (p.1165), which are substrates for CYP3A4 and CYP1A2, respectively.

Melatonin + Caffeine

Caffeine increases the levels of both endogenous and orally administered melatonin.

Clinical evidence

A crossover study in 12 healthy subjects found that a single 200-mg dose of caffeine (equivalent to one large or two small cups of coffee), taken 1 hour before and 1 and 3 hours after a single 6-mg oral dose of melatonin, increased the average AUC and maximum levels of melatonin by 120% and 137%, respectively, although the half-life of melatonin was not significantly affected. The interaction was less pronounced in smokers (6 subjects) than in non-smokers (6 subjects).¹

Another crossover study in 12 healthy subjects (by the same authors) found that a single 200-mg dose of caffeine, taken 12 or 24 hours before a single 6-mg dose of melatonin, did not affect the melatonin levels, although 2 subjects had raised melatonin levels when caffeine was taken 12 hours, but not 24 hours, before melatonin.²

In 12 healthy subjects given a single 200-mg dose of caffeine, taken in the evening, endogenous, nocturnal melatonin levels were found to be increased, and the AUC of melatonin was increased by 32%.³

Mechanism

Caffeine is thought to reduce the metabolism of melatonin by competing for metabolism by the cytochrome P450 isoenzyme CYP1A2.^{1–3}

Importance and management

Melatonin is produced by the pineal gland in the body and is also available as a supplement in some parts of the world. However, the effects of long-term use of this supplement are unknown. From the above studies, it appears that caffeine significantly increases the levels of single doses of supplementary melatonin, however the long-term effects of caffeine and concurrent multiple dosing of melatonin do not appear to have been studied. Melatonin can cause drowsiness when taken on its own, so patients who take melatonin should be advised that this effect may be increased if they also take caffeine. This increased drowsiness may oppose the stimulating effect of caffeine.

- Härter S, Nordmark A, Rose D-M, Bertilsson L, Tybring G, Laine K. Effects of caffeine intake on the pharmacokinetics of melatonin, a probe drug for CYP1A2 activity. *Br J Clin Pharmacol* (2003) 56, 679–682.

Methoxsalen + Phenytoin

The serum levels of methoxsalen can be markedly reduced by the concurrent use of phenytoin. This resulted in failure of treatment for psoriasis in one patient.

Clinical evidence, mechanism, importance and management

A patient with epilepsy failed to respond to treatment for psoriasis with PUVA (12 treatments of methoxsalen 30 mg given orally and ultraviolet A irradiation) while taking phenytoin 250 mg daily. Methoxsalen serum levels were normal in the absence of phenytoin, but abnormally low while taking phenytoin,¹ due, it is suggested, to the enzyme inducing effects of the phenytoin. This interaction could lead to serious erythema and blistering if the phenytoin dose is reduced during therapy, as methoxsalen levels rise and therefore photosensitivity caused by the methoxsalen may be increased. Concurrent use should be avoided or very closely monitored.

- Staberg B, Hueg B. Interaction between 8-methoxypsoralen and phenytoin. Consequence for PUVA therapy. *Acta Derm Venereol* (1985) 65, 553–5.

Metyrapone + Miscellaneous

The results of the metyrapone test for Cushing's syndrome are unreliable in patients taking cyproheptadine or phenytoin. The manufacturer also states that barbiturates, antidepressants, some hormones, and antipsychotics may influence the results of the test.

Clinical evidence

(a) Cyproheptadine

Pretreatment with cyproheptadine 4 mg every 6 hours, 2 days before and throughout a standard metyrapone test (750 mg every 4 hours for 6 doses), reduced the metyrapone-induced urinary 17-hydroxycorticosteroid response in 9 healthy subjects by 32%, and also reduced the serum 11-deoxycortisol response.¹

(b) Phenytoin

A study in 5 healthy subjects and 3 patients taking phenytoin 300 mg showed that their serum metyrapone levels 4 hours after taking a regular 750-mg dose were very low, when compared with a control group (6.5 versus 48.2 micrograms/100 mL). The response to metyrapone (i.e. the fall in circulating glucocorticoids) is related to serum levels and was therefore proportionately lower.² Other reports confirm that the urinary steroid response to metyrapone is subnormal in patients taking phenytoin.^{3,4}

Doubling the dose of metyrapone from 750 mg every 4 hours to every 2 hours has been shown to give results similar to those in subjects not taking phenytoin.²

Mechanism

Phenytoin is a potent liver enzyme inducer that increases the metabolism of metyrapone, thereby reducing its effects.^{2,5}

Importance and management

The results of metyrapone tests for Cushing's syndrome will be unreliable in patients taking cyproheptadine and phenytoin, and therefore these should be withdrawn prior to the test. The manufacturer also states that **barbiturates**, antidepressants (they name **amitriptyline**) and antipsychotics (they name **chlorpromazine**), hormones that affect the hypothalamo-pituitary axis, and **antithyroid drugs** may influence the results of the test. They recommend that, if any of these drugs cannot be withdrawn prior to the test, the necessity of carrying out the metyrapone test should be reviewed.⁶

Mifepristone + Aspirin or NSAIDs

The manufacturers of mifepristone say that the antiprostaglandin effects of NSAIDs including aspirin could theoretically decrease the efficacy of mifepristone. They recommend using non-NSAID analgesics.¹

- Mifegyne (Mifepristone). Exelgyn Laboratories. UK Summary of product characteristics, February 2006.

Milk thistle + Cytochrome P450 isoenzyme substrates

Milk thistle does not alter the metabolism of caffeine, chlorzoxazone, or debrisoquine.

Clinical evidence, mechanism, importance and management

Milk thistle 175 mg, standardised to 80% silymarins, was given to 12 healthy subjects twice daily for 28 days. Subjects also received single doses of **caffeine** 100 mg, **chlorzoxazone** 250 mg, and **debrisoquine** 5 mg, before and at the end of the treatment with milk thistle. The metabolism of these drugs was not affected by the concurrent use of milk thistle, which suggests that milk thistle is unlikely to affect the metabolism of drugs that are substrates of the cytochrome P450 isoenzymes *CYP1A2*, *CYP2E1*, or *CYP2D6*.¹ For a list of drugs that are substrates of these isoenzymes, see 'Table 1.2', (p.4), and 'Table 1.3', (p.6).

For the lack of effect of milk thistle on *CYP3A4*, see 'Benzodiazepines + Milk thistle', p.732.

Moxisylyte + Miscellaneous

There is a theoretical possibility of increased blood pressure lowering effects if moxisylyte is used with antihypertensives or tricyclic antidepressants.

Clinical evidence, mechanism, importance and management

Moxisylyte is an alpha-1, and to a lesser extent, an alpha-2 blocker, which may be used orally as a peripheral vasodilator in Raynaud's syndrome. The manufacturers suggest that if moxisylyte is used by patients taking antihypertensives, it may theoretically potentiate the antihypertensive effect, although at the recommended doses this has not been reported.¹

They also say that tricyclic antidepressants might increase any hypotensive effect of moxisylyte.¹

- Opilon (Moxisylyte hydrochloride). Concord Pharmaceuticals Ltd. UK Summary of product characteristics, April 2004.

Nicotine + Vasopressin

A case report described marked hypotension and bradycardia in a young woman during surgery, attributed to the combined effects of vasopressin and nicotine from a transdermal patch.

Clinical evidence

A 22-year-old woman in good health was anaesthetised for surgery with nitrous oxide/oxygen and isoflurane. Twenty minutes after induction she was given an injection of 0.2 units of vasopressin into the cervix. Within seconds she developed severe hypotension and bradycardia, and over the next 30 minutes blood pressures as low as 70/35 mmHg and heart rates as low as 38 bpm were recorded. She was treated with atropine and adrenaline (epinephrine), and eventually made a full recovery. This patient was wearing a transdermal nicotine patch.¹

Mechanism

The circulatory collapse was attributed by the authors to the combined effects of the injected vasopressin and the nicotine from the transdermal patch. Both of these drugs can increase afterload and cause coronary artery vasoconstriction, which the authors suggest may have decreased the blood supply to the heart and resulted in cardiac depression.¹

Importance and management

This is an isolated report and any interaction is therefore not well established. Nevertheless the recommendation of the authors seems sensible, namely that nicotine patches should be removed the night before or 24 hours before surgery, and that patients should be asked to avoid smoking before surgery to make sure that nicotine levels are minimal. More study is needed.

1. Groudine SB, Morley JN. Recent problems with paracervical vasopressin: a possible synergistic reaction with nicotine. *Med Hypotheses* (1996) 47, 19–21.

Oxiracetam + Antiepileptics

The half-life of oxiracetam was shorter in patients taking carbamazepine and valproate or clobazam, but oxiracetam did not affect the serum levels of sodium valproate, carbamazepine or clobazam.

Clinical evidence, mechanism, importance and management

Oxiracetam 800 mg twice daily for 14 days did not affect the serum levels of **sodium valproate, carbamazepine, or clobazam** and their metabolites in 3 epileptics taking **carbamazepine** and **valproate** and one taking **carbamazepine** and **clobazam**.¹ However, it was noted that the oxiracetam half-life was 2.8 to 7.56 hours,¹ which tended to be shorter than that seen in a previous study in healthy subjects who had been given oxiracetam 2 g (half-life 5.6 to 11.7 hours).² The clinical relevance of this is uncertain, but the authors suggest that it may be necessary to raise the oxiracetam dosage or give it more frequently in the presence of these drugs.¹

1. van Wieringen A, Meijer JWA, van Emde Boas W, Vermeij TAC. Pilot study to determine the interaction of oxiracetam with antiepileptic drugs. *Clin Pharmacokinetics* (1990) 18, 332–8.

Oxygen; hyperbaric + Miscellaneous

It has been suggested, but not confirmed, that because increased levels of carbon dioxide in the tissues can increase the ‘sensitivity’ to oxygen-induced convulsions, carbonic anhydrase inhibitors, such as acetazolamide, are contraindicated in those given hyperbaric oxygen, because they cause carbon dioxide to persist in the tissues. Nor should hyperbaric oxygen be given during opioid or barbiturate withdrawal because the convulsive threshold of such patients is already low.¹

1. Gunby P. HBO can interact with preexisting patient conditions. *JAMA* (1981) 246, 1177–8.

Papaverine + Diazepam

Two men given normal test doses of papaverine for the investigation of impotence had prolonged erections attributed to the concurrent use of diazepam.

Clinical evidence, mechanism, importance and management

Undesirably prolonged erections (duration of 5 and 6 hours) occurred in 2 patients who had been given 5 or 10 mg of diazepam intravenously for anxiety before a 60-mg intracavernosal injection of papaverine.¹ Papaverine acts by relaxing the arterioles that supply the corpora so that the pressure rises. The increased pressure in the corpora compresses the trabecular venules so that the pressure continues to maintain the erection. Diazepam also relaxes smooth muscle and it would seem that this can be additive with the effects of papaverine. The authors of the report say that caution should be exercised in the choice of papaverine dosage in patients taking anxiolytics (i.e. use less) although these two cases involving diazepam seem to be the only ones recorded.¹

1. Vale JA, Kirby RS, Lees W. Papaverine, benzodiazepines, and prolonged erections. *Lancet* (1991) 337, 1552.

Penicillamine + Antacids

The absorption of penicillamine from the gut can be reduced by 30 to 40% if antacids containing aluminium/magnesium hydroxide are taken.

Clinical evidence

Maalox-plus (aluminium/magnesium hydroxide, simeticone) 30 mL reduced the absorption of a single 500-mg dose of penicillamine in 6 healthy subjects by one-third.¹ Another study found that 30 mL of **Aludrox (aluminium/magnesium hydroxide)** reduced the absorption of penicillamine by about 40%.²

Mechanism

The most likely explanation is that the penicillamine forms less soluble chelates with magnesium and aluminium ions in the gut, which reduces its absorption.² Another idea is that the penicillamine is possibly less stable at the higher pH values caused by the antacid.¹

Importance and management

An established interaction of clinical importance. If maximal absorption is needed the administration of the two drugs should be separated to avoid mixing in the gut. Two hours or so has been found enough for most other drugs which interact similarly. There seems to be nothing documented about other antacids.

2. Ifan A, Welling PG. Pharmacokinetics of oral 500-mg penicillamine: effect of antacids on absorption. *Biopharm Drug Dispos* (1986) 7, 401–5.

Penicillamine + Food

Food can reduce the absorption of penicillamine by as much as a half.

Clinical evidence

The presence of food reduced the plasma levels of penicillamine 500 mg by about 50% in healthy subjects. The total amount absorbed was similarly reduced.^{1,2} These figures are in good agreement with previous findings.³

Mechanism

Uncertain. One suggestion is that food delays gastric emptying so that the penicillamine is exposed to more prolonged degradation in the stomach.² Another idea is that the protein in food reduces penicillamine absorption.

Importance and management

An established interaction. If maximal effects are required the penicillamine should be taken at least 30 minutes before food.

Penicillamine + Iron compounds

The absorption of penicillamine can be reduced as much as two-thirds by oral iron compounds.

Clinical evidence

Ferrous iron 90 mg (as *Fersamal*) reduced the absorption of penicillamine 250 mg in 5 healthy subjects by about two-thirds (using the cupruric effects of penicillamine as a measure).¹

A two-thirds reduction in absorption has been described in 6 other subjects given penicillamine 500 mg and **ferrous sulfate** 300 mg.² Other studies confirm this interaction.^{3,4} There is also evidence that the withdrawal of iron from patients stabilised on penicillamine can lead to the development of toxicity (nephropathy) unless the penicillamine dosage is reduced.⁵

Mechanism

It is believed that the iron and penicillamine form a chemical complex or chelate within the gut, which is less easily absorbed.

Importance and management

An established and clinically important interaction. For maximal absorption give the iron at least 2 hours after the penicillamine. This should reduce their admixture in the gut.¹ Do not withdraw iron suddenly from patients stabilised on penicillamine because the marked increase in absorption that follows may precipitate penicillamine toxicity. The toxic effects of penicillamine seem to be dependent on the size of the dose and possibly also related to the rate at which the dosage is increased.⁵ Only ferrous sulfate and fumarate have been studied but other iron compounds would be expected to interact similarly.

Penicillamine + Miscellaneous

Penicillamine plasma levels are increased by chloroquine and an increase in penicillamine toxicity is possible. Penicillamine should not be used with gold. Indometacin slightly increases penicillamine levels, and its use with any NSAID might increase the risk of renal damage. An isolated report describes penicillamine-induced breast enlargement in a woman taking a combined oral contraceptive.

Clinical evidence, mechanism, importance and management

(a) Disease-modifying antirheumatic drugs

Studies in which **chloroquine** was given to patients taking penicillamine found that it was more effective, less effective, or indistinguishable from penicillamine alone. However in some instances penicillamine toxicity was reported to be increased.¹ A pharmacokinetic study in patients with rheumatoid arthritis taking penicillamine 250 mg daily found that a single 250-mg dose of **chloroquine phosphate** increased the AUC by 34%, and raised the peak plasma levels by about 55%.¹ It therefore seems possible that any increased toxicity is simply a reflection of increased plasma pen-

icillamine levels. Be alert for evidence of toxicity if both drugs are used. Note that the US manufacturer states that penicillamine should not be used in patients who are receiving antimalarials (which would include **chloroquine** and **hydroxychloroquine**) because these drugs are also associated with serious haematological effects.²

There is some evidence that using **gold** with penicillamine may increase the risk of adverse effects, and the manufacturer says that they should not be used together.^{2,3} In addition, patients who have had an adverse reaction to **gold** may be at a greater risk of serious adverse reactions to penicillamine,^{2,3} and caution is recommended.³

(b) NSAIDs

Indometacin has been found to increase the AUC of penicillamine by 26% and the peak plasma levels by about 22%.¹ The UK manufacturer notes that use of NSAIDs may increase the risk of renal damage with penicillamine.³ The US manufacturer specifically recommends avoiding **oxyphenbutazone** or **phenylbutazone** because these drugs are also associated with serious haematological and renal effects.² Urinalysis for detection of haematuria or proteinuria should be regularly carried out in patients taking penicillamine.^{2,3} Be alert for evidence of toxicity if NSAIDs and penicillamine are used together.

(c) Oral contraceptives

A woman with Wilson's disease began to develop dark facial hair about 10 months after starting to take penicillamine 1.25 to 1.5 g daily. After 20 months her testosterone levels were found to be slightly raised, and so she was given a combined oral contraceptive, but within a month her breasts began to enlarge and become more tender. After a further 6 months the penicillamine was replaced by trientine hydrochloride.⁴ The reasons are not understood, but the authors of the report suggest that the penicillamine was the prime cause of the macromastia, but it possibly needed the presence of a 'second trigger' (i.e. the oral contraceptive) to set things in motion.⁴

There are 12 other cases of macromastia and gynaecomastia on record associated with the use of penicillamine, in some of which the second trigger may possibly have been a **corticosteroid** or **cimetidine**.⁴ Macromastia appears to be an unusual adverse effect of penicillamine and there would seem to be no general reason for patients taking penicillamine to avoid oral contraceptives.

Phenylpropranolamine + Indinavir

A report describes a hypertensive crisis when a patient taking indinavir was also given phenylpropranolamine.

Clinical evidence, mechanism, importance and management

A 28-year-old woman was prescribed HIV-prophylaxis following a needle stick injury. She was initially given zidovudine, indinavir and lamivudine, but after one week stavudine was substituted for zidovudine as she was experiencing nausea and vomiting. Six hours after taking *Tavist-D* (clemastine with phenylpropranolamine) for a sinus complaint she had a feeling of chest tightness associated with difficulty in breathing, and shortly afterwards she experienced left-sided upper extremity weakness, followed by a severe right-sided temporal headache. Her blood pressure was 220/120 mmHg, but returned to normal within 4 hours, and the neurological deficit resolved over the next 8 hours. However, 12 hours later, the same neurological deficit recurred, although no increase in blood pressure was noted. The neurological deficit was thought to be due to reversible cerebral vasoconstriction, secondary to phenylpropranolamine toxicity. She was treated with nimodipine 60 mg every 4 hours and aspirin 325 mg daily, and her symptoms did not recur.¹

The patient had been taking phenylpropranolamine intermittently for several years without any adverse reaction and it was thought that the recent addition of the anti-HIV regimen potentiated the effect of the phenylpropranolamine.¹ It seems likely that the indinavir was responsible for the interaction as it is a potent enzyme inhibitor. This is an isolated report and

its general significance is not known, but it would be prudent to be alert for this interaction in patients given both drugs.

Phenylpropanolamine + Indometacin

An isolated report describes a patient taking phenylpropanolamine who developed serious hypertension after taking a single dose of indometacin, but a controlled study in other subjects failed to find any evidence of an adverse interaction.

Clinical evidence

A woman who had been taking phenylpropanolamine 85 mg daily for several months as an appetite suppressant, developed a severe bifrontal headache within 15 minutes of taking indometacin 25 mg. Thirty minutes later her systolic blood pressure was 210 mmHg and her diastolic blood pressure was unrecordable. A later study in this patient confirmed that neither drug on its own caused this response, but when they were taken together the blood pressure rose to a maximum of 200/150 mmHg within about 30 minutes of taking the indometacin, and was associated with bradycardia. The blood pressure was rapidly reduced by phentolamine.¹

In contrast, a controlled study in 14 healthy young women found no evidence that sustained-release indometacin 75 mg twice daily given with sustained-release phenylpropanolamine 75 mg daily caused a rise in blood pressure.²

Mechanism

Not understood.

Importance and management

Direct information seems to be limited to these reports. They suggest that an adverse hypertensive response is unlikely in most individuals given these drugs. However, note that phenylpropanolamine alone has been associated with severe hypertension and has been implicated in causing stroke.³ It is therefore no longer available in the US and UK and its use has been restricted in many other countries.

Phosphodiesterase type-5 inhibitors + Alpha blockers

Postural hypotension may occur with higher doses of sildenafil, tadalafil or vardenafil given at the same time as doxazosin or terazosin. The effect may be less marked with tamsulosin.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

Retrospective analysis of pooled data from various clinical studies including patients taking non-nitrate antihypertensives such as the alpha blockers suggests that the adverse effect profile, blood pressure, or heart rate were not significantly different when they also took sildenafil or placebo.¹ However, the manufacturer notes that when sildenafil 100 mg was given simultaneously with **doxazosin** 4 mg after at least 14 consecutive daily doses of **doxazosin**, severe postural hypotension occurred in one of 4 subjects with benign prostatic hypertrophy, and 2 others had mild dizziness. Two of the subjects had a standing systolic BP of less than 85 mmHg. This did not occur in a further 17 subjects who, as a result of these effects, were given a lower dose of sildenafil 25 mg. In two other studies, 2 of 19 and 3 of 20 patients had a standing systolic BP of less than 85 mmHg after receiving 14 days of **doxazosin** then a single simultaneous dose of sildenafil

50 mg or 100 mg with **doxazosin**.²

The manufacturers recommend that patients should be stable on an alpha blocker before sildenafil is started and that consideration should be given to starting sildenafil at the lowest dose (25 mg).^{2,3} The UK manufacturer notes that a hypotensive effect is most likely within 4 hours of taking an alpha blocker. When starting an alpha blocker in a patient taking sildenafil, the US manufacturer states that the alpha blocker should be started at the lowest dose.²

(b) Tadalafil

A placebo-controlled, randomised, two-period, crossover study in 18 healthy subjects found that a single 20-mg dose of tadalafil increased the blood pressure-reducing effects of **doxazosin** following 7 days of treatment with **doxazosin** 8 mg daily. The mean maximum systolic falls for the combination were 3.6 mmHg when lying and 9.8 mmHg when standing. Some of the subjects felt dizzy, but none of them fainted.⁴ Conversely, a small and clinically irrelevant effect was seen when tadalafil 10 or 20 mg was given with **tamsulosin**.^{4,5} A further study in which a single 20-mg oral dose of tadalafil or placebo was given to 17 healthy subjects on the seventh day of taking extended-release **alfuzosin** 10 mg daily found that none of the subjects had a decrease in standing systolic BP of more than 30 mmHg. No syncope or severe adverse events were reported. However, note that the doses were separated by 4 hours.⁴

The UK manufacturer of tadalafil says that the concurrent use of alpha blockers and tadalafil is not recommended as it may lead to symptomatic hypotension in some patients.⁵ Conversely, the US manufacturer recommends that patients should be stable on their alpha blocker before tadalafil is used, and that tadalafil should be initiated at the lowest recommended dose. When starting an alpha blocker in a patient taking the optimum dose of tadalafil, the alpha blocker should be initiated at the lowest possible dose.⁴

(c) Vardenafil

The manufacturers of vardenafil have conducted several placebo-controlled, randomised, crossover studies, in patients with BPH and in healthy subjects taking alpha blockers, to assess the effects of concurrent vardenafil on blood pressure.

Vardenafil 5 mg was given to 21 patients taking **terazosin** 5 or 10 mg daily. Vardenafil given simultaneously caused significant hypotension in one patient (BP 80/60 mmHg) and 5 patients experienced postural hypotension of greater than 30 mmHg (compared with only 2 patients in the placebo group). When vardenafil was given 6 hours after the alpha blocker no adverse effects were reported.⁶ Vardenafil 10 or 20 mg was also given to healthy subjects taking **terazosin** 10 mg daily. Due to significant hypotension in a large number of the subjects the study was halted.⁶

Vardenafil 5 mg was given to 21 patients taking **tamsulosin** 400 micrograms daily. Vardenafil given simultaneously caused significant hypotension in 2 patients (systolic BP less than 85 mmHg) and 2 patients experienced postural hypotension of greater than 30 mmHg (compared with only one patient in the placebo group). When vardenafil was given 6 hours after the alpha blocker significant hypotension still occurred in 2 patients and one experienced postural hypotension of greater than 30 mmHg.⁶ Larger doses of vardenafil (10 or 20 mg) given to 23 patients taking **tamsulosin** 400 or 800 micrograms resulted in postural hypotension of greater than 30 mmHg in one patient, and 3 patients became dizzy. When vardenafil was given to 20 healthy subjects with **tamsulosin** 400 micrograms daily 7 subjects became dizzy.⁶

The manufacturer recommends that patients should be stable on their alpha blocker before using vardenafil, and that vardenafil should be initiated at a dose of 5 mg^{6,7} (or less in the presence of potent inhibitors of CYP3A4 such as the 'azoles', (p.1270) or the 'protease inhibitors', (p.1273)).⁶ The UK manufacturer also says that the doses should be separated if vardenafil is to be given with an alpha blocker (with the exception of **tamsulosin**, where they consider this precaution unnecessary).⁷ From the data above, 6 hours would seem adequate. When starting an alpha blocker in a patient taking vardenafil, the US manufacturer states that the alpha blocker should be started at the lowest dose.⁶

Phosphodiesterase type-5 inhibitors + Antacids

No clinically significant interaction appears to occur between sildenafil, tadalafil or vardenafil and aluminium/magnesium hydroxide antacids.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

In a single dose study in 12 healthy subjects the bioavailability of sildenafil was not affected by single 30-mL doses of an **aluminium/magnesium hydroxide** antacid.¹

(b) Tadalafil

An open-label, randomised, crossover study in 12 healthy subjects found that 20 mL of *Maalox* (**aluminium/magnesium hydroxide**) reduced the mean maximum serum level of a single 10-mg dose of tadalafil by 30%. Although peak tadalafil levels were delayed by 2.5 hours, the total amount of tadalafil absorbed was unchanged. None of the changes caused were considered to be clinically relevant, and there would appear to be no reason for avoiding concurrent use.²

(c) Vardenafil

In a two-way crossover study a single 20-mg dose of vardenafil was given to 12 healthy subjects with 10 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox 70*). The bioavailability of vardenafil was not significantly altered by the antacid, therefore no additional precautions are needed if these drugs are used together.³

Phosphodiesterase type-5 inhibitors + Antihypertensives

No clinically relevant interactions appear to occur between sildenafil, tadalafil or vardenafil and most antihypertensive drugs. The exceptions may be diltiazem and verapamil. The potentially serious interactions of sildenafil, tadalafil and vardenafil with the alpha blockers and nitrates are discussed elsewhere. See ‘Phosphodiesterase type-5 inhibitors + Alpha blockers’, p.1268 and ‘Phosphodiesterase type-5 inhibitors + Nitrates’, p.1272.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

In a study in 8 hypertensive men taking one to five antihypertensives (**amlodipine** (5 patients), a **diuretic** (4), an **ACE inhibitor** (3), an **angiotensin II receptor antagonist** (2), **diltiazem** (1)), a single 50-mg dose of sildenafil reduced the systolic BP by a mean maximum of 24 mmHg, compared with only 6 mmHg for placebo. One patient had a blood pressure fall of 48/23 mmHg, but none complained of hypotensive symptoms.¹ Two retrospective analyses of pooled data from various clinical trials suggests that patients on non-nitrate antihypertensives (**ACE inhibitors**, **alpha blockers**, **beta blockers**, **calcium-channel blockers**, **diuretics**) and sildenafil showed no significant difference blood pressure, or heart rate compared with those taking antihypertensives and placebo,² and that the incidence of dizziness did not differ between sildenafil recipients on antihypertensives and those not.^{2,3} In a placebo-controlled study in patients with hypertension receiving stable therapy with 2 or more antihypertensives (including **diuretics**, **calcium-channel blockers**, **ACE inhibitors**, **beta blockers**, **alpha blockers**, **angiotensin II receptor antagonists**), the occurrence of adverse events potentially related to hypotensive effects (dizziness, hypotension, labile BP, vertigo) was less than 4% in sildenafil recipients.⁴ Note that combined use with alpha blockers may be especially likely to induce

hypotensive events, see ‘Phosphodiesterase type-5 inhibitors + Alpha blockers’, p.1268.

The manufacturers report that in population pharmacokinetic analysis, there was no effect on sildenafil pharmacokinetics in those taking **ACE inhibitors**, **calcium-channel blockers** and **thiazide and related diuretics**^{5,6} whereas the AUC of the less potent active metabolite of sildenafil is increased by 62% by **loop** and **potassium-sparing diuretics** and by 102% by **non-selective beta blockers**, although these changes were not considered clinically relevant.⁶

When sildenafil 100 mg was given to hypertensive patients taking **amlodipine** the mean additional fall in blood pressure (8/7 mmHg) was of the same magnitude as that seen when sildenafil was given alone to healthy subjects.^{5,6}

It should be noted that some calcium-channel blockers (e.g. **diltiazem**, **verapamil**) are known to inhibit the cytochrome P450 isoenzyme CYP3A4, by which sildenafil is metabolised, and so these calcium-channel blockers have the potential to raise sildenafil levels. Although the manufacturers do not specifically mention these drugs, they do recommend a lower starting dose of sildenafil in patients taking potent inhibitors of CYP3A4,^{5,6} and this would seem a sensible precaution in patients taking **diltiazem** or **verapamil** (usually considered to be moderate CYP3A4 inhibitors). There is a case of a patient taking **diltiazem** 30 mg three times daily who underwent coronary angiography 48 hours after taking sildenafil 50 mg, and who developed profound and persistent hypotension (BP 90/60 mmHg) after receiving sublingual nitrate for pain related to angina during the procedure.⁷ It was suggested that **diltiazem** may have inhibited the metabolism of sildenafil so that it interacted with the nitrate,^{7,8} although the time scale for this interaction has been disputed.⁹

The manufacturer notes that in population pharmacokinetic analysis of patients with pulmonary hypertension, there appeared to be an increase in sildenafil exposure when it was taken with beta blockers (none named) in combination with CYP3A4 substrates (none named).^{10,11} The clinical relevance of this is uncertain, and further study is needed.

(b) Tadalafil

Placebo-controlled studies in patients taking **enalapril**, **metoprolol** or **bendroflumethiazide**, found that a 10-mg dose of tadalafil did not affect blood pressure or heart rate.¹² Similar results were seen in a study in patients taking **amlodipine** and given tadalafil 20 mg.¹² In another study in patients taking unnamed **angiotensin II receptor antagonists** (alone or in combination with thiazides, **calcium-channel blockers** or **beta blockers**¹³), tadalafil 20 mg lowered the mean BP by 8/4 mmHg more than placebo, and about twice as many patients had a potentially clinically relevant decrease in blood pressure, although no potential hypotensive symptoms (e.g. dizziness) occurred.¹² In phase III studies, there was no difference in blood pressure changes in patients taking antihypertensives (**ACE inhibitors**, **calcium-channel blockers**, **thiazide diuretics**, **beta blockers**, **angiotensin II receptor antagonists**, **alpha blockers** and **loop diuretics**) between those given tadalafil and those given placebo, and there was no difference in the number of patients with a potentially clinically relevant reduction in systolic BP (greater than 30 mmHg). Similarly, in patients taking tadalafil, there was a similar incidence of dizziness between those taking antihypertensives and those not.¹² The manufacturers say that tadalafil 20 mg may induce a small fall in blood pressure in patients taking antihypertensives, but this is unlikely to be clinically relevant, with the exception of ‘alpha blockers’, (p.1268). Nevertheless, they still advise caution on concurrent use as some patients with underlying cardiovascular disease may possibly be affected.^{13,14}

There would therefore appear to be no reason for avoiding the concurrent use of any of these drugs nor (the implication is) with other drugs that fall into these drug classes. However, it should be noted that some **calcium-channel blockers** (e.g. **diltiazem**, **verapamil**) are known to have a moderate inhibitory effect on the cytochrome P450 isoenzyme CYP3A4, an enzyme involved in the metabolism of tadalafil, and so may have the potential to raise tadalafil levels.¹³ Although the manufacturers do not specifically mention these **calcium-channel blockers**, they do recommend caution¹³ or a lower dose of tadalafil¹⁴ in patients taking *potent* inhibitors of CYP3A4. Some caution is therefore appropriate.

(c) Vardenafil

In a randomised, double-blind, crossover study, 22 patients with hypertension, stabilised on slow-release **nifedipine** 30 or 60 mg daily were given a single 20-mg dose of vardenafil, or placebo. Vardenafil slightly decreased the maximum plasma levels and relative bioavailability of **nifedipine**, as well as causing a further decrease in supine blood pressure

of about 6/5 mmHg. Heart rate was increased by 4 bpm.¹⁵ **Nifedipine** did not alter vardenafil levels.¹⁶

Vardenafil alone may decrease blood pressure, and the US manufacturer cautions that vardenafil may add to the blood pressure lowering effects of antihypertensive drugs.¹⁶

The UK manufacturers say that, although not specifically studied, population pharmacokinetic analysis has suggested that **ACE inhibitors, beta blockers, and diuretics** have no effect on vardenafil pharmacokinetics.¹⁷

Phosphodiesterase type-5 inhibitors + Aspirin

Sildenafil, tadalafil and vardenafil do not potentiate the increased bleeding time seen with aspirin.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

In a pharmacological study, sildenafil 50 mg did not potentiate the increase in bleeding time seen with aspirin 150 mg.¹ No additional precautions therefore seem necessary on concurrent use.

(b) Tadalafil

A randomised, double-blind, parallel-group study in a total of 28 subjects found that a single 10-mg dose of tadalafil did not increase the bleeding time after aspirin 300 mg daily was taken for 5 days.² There would seem to be no reason for taking special precautions if both drugs are used.

(c) Vardenafil

The manufacturers say that population pharmacokinetic analysis suggests that aspirin had no effect on vardenafil pharmacokinetics.³ In addition, vardenafil 10 mg and 20 mg did not potentiate the bleeding time caused by aspirin 162 mg.^{3,4} No additional precautions therefore seem necessary on concurrent use.

Phosphodiesterase type-5 inhibitors + Azoles

Ketoconazole and itraconazole markedly raise the levels of sildenafil, tadalafil and vardenafil.

Clinical evidence

(a) Sildenafil

'Erythromycin', (p.1272), increases sildenafil levels threefold. The manufacturers therefore predict that other more potent CYP3A4 inhibitors such as **itraconazole** and **ketoconazole** will have even greater effects.^{1,2} They say that population data from clinical studies suggests that CYP3A4 inhibitors such as **ketoconazole** reduced sildenafil clearance without increasing the incidence of adverse effects.^{1,2} In a study in *dogs*, the concurrent use of **itraconazole** enhanced and prolonged the adverse effects of sildenafil.³ However, a case report describes the apparently uneventful concurrent use of sildenafil 100 mg with **itraconazole** 400 mg daily for 7 days each month in a 56-year-old man.⁴

(b) Tadalafil

In an open label, randomised study in 12 healthy subjects, **ketoconazole** 200 mg daily increased the AUC of a single 10-mg dose of tadalafil by twofold,^{5,6} and **ketoconazole** 400 mg daily increased the AUC fourfold.^{5,6} The manufacturers predict that **itraconazole** will interact similarly.^{5,6} This prediction has been borne out by a case report of a 56-year-old man who was taking **itraconazole** 400 mg daily for 7 days each month. Within a few hours of his first 10-mg dose of tadalafil he developed priapism, which lasted for more than 4 hours. The same reaction occurred when he took tadalafil during the following month. He had seemingly previously taken sildenafil with **itraconazole** without adverse effect.⁴

(c) Vardenafil

Ketoconazole 200 mg daily increased the AUC of a 5-mg dose of vardenafil tenfold, and increased the maximum plasma levels fourfold. Although not specifically studied, **itraconazole** is expected to cause similar rises in vardenafil levels.^{7,8}

Mechanism

Sildenafil, tadalafil and vardenafil are all metabolised by the cytochrome P450 isoenzyme CYP3A4. Ketoconazole and itraconazole are potent inhibitors of CYP3A4, and therefore inhibit sildenafil, tadalafil and vardenafil metabolism, which leads to an increase in their levels.

Importance and management

Information about the interaction between phosphodiesterase type-5 inhibitors and azoles is sparse, but what is known is in line with the predicted effects.

For **sildenafil**, when used for erectile dysfunction, the manufacturers recommend that a low starting dose of sildenafil (25 mg) should be considered if ketoconazole or itraconazole are used concurrently.^{1,2} When used for pulmonary hypertension, the manufacturers say that concurrent use of sildenafil with ketoconazole and itraconazole is contraindicated in the UK,⁹ or not recommended in the US.¹⁰

For **tadalafil**, the UK manufacturer advises caution⁵ and the US manufacturer advises that the dose of tadalafil should not exceed 10 mg in a 72-hour period for patients taking potent CYP3A4 inhibitors such as ketoconazole.⁶ However, note that this dose has caused priapism in one patient taking itraconazole.

Vardenafil levels are greatly increased by ketoconazole and probably itraconazole so the UK manufacturer advises avoiding concurrent use in all patients. The use of ketoconazole or itraconazole in patients over 75 years is specifically contraindicated with vardenafil.⁷ In contrast, the US prescribing information recommends that the dose of vardenafil should not exceed 5 mg in 24 hours when used with ketoconazole or itraconazole 200 mg daily, or 2.5-mg in 24 hours with ketoconazole or itraconazole 400 mg daily.⁸

Phosphodiesterase type-5 inhibitors + CYP3A4 inducers

Rifampicin markedly reduced tadalafil levels, and is predicted to interact similarly with sildenafil and vardenafil. Other CYP3A4 inducers are likely to have the same effect with these phosphodiesterase type-5 inhibitors.

Clinical evidence

(a) Sildenafil

On the basis of the 63% reduction in AUC seen with the moderate CYP3A4 inducer 'bosentan', (p.1274), the US manufacturer of sildenafil says that concurrent use with potent inducers of CYP3A4 such as **rifampicin** is predicted to cause a greater reduction in sildenafil levels.^{1,2}

(b) Tadalafil

A study^{3,4} in 12 healthy subjects found that **rifampicin** 600 mg daily given for 13 days decreased the AUC of a single 10-mg dose of tadalafil by 88%.

Mechanism

Rifampicin induces the activity of the cytochrome P450 isoenzyme CYP3A4, the principal enzyme concerned with the metabolism of sildenafil, tadalafil and vardenafil.

Importance and management

The pharmacokinetic interaction between rifampicin and tadalafil is established, and will almost certainly occur with sildenafil. It is unlikely that standard doses of these phosphodiesterase type-5 inhibitors would be as effective as usual in patients taking rifampicin. Other CYP3A4 inducers such as **barbiturates**,² **carbamazepine**,^{2,5} **efavirenz**,² **nevirapine**,² **phenobarbital**,³⁻⁵ **phenytoin**,²⁻⁵ **rifabutin**,² and **St John's wort**⁵ are predicted by the manufacturers to do the same (for a list of CYP3A4 inducers see 'Table 1.4', (p.6)). Despite the marked interaction, the US manufacturer of tadalafil states that no dosage adjustment is warranted.⁴ Conversely, the manufacturers of sildenafil state that efficacy should be closely monitored in patients taking CYP3A4 inducers,⁵ or that dose adjustment may be necessary.² If these phosphodiesterase type-5 inhibitors are not effective in a patient taking a CYP3A4 inducer, it would seem sensible to try a higher dose with close monitoring.

Although the manufacturer of **vardeafil** does not mention CYP3A4 inducers,^{6,7} like tadalafil and sildenafil, vardenafil is principally metabolised by CYP3A4, and its levels are markedly raised by CYP3A4 inhibitors such as 'ketoconazole', (p.1270). It is therefore very likely that vardenafil levels will be reduced by rifampicin and similar drugs, and concurrent use should be monitored.

Phosphodiesterase type-5 inhibitors + Grapefruit juice

Grapefruit juice modestly increases the absorption of sildenafil. Tadalafil and vardenafil are predicted to interact similarly.

Clinical evidence, mechanism, importance and management

Grapefruit juice 250 mL was given to 24 healthy subjects both one hour before and with a 50-mg dose of **sildenafil**. The AUC of **sildenafil** was

increased by 23% by grapefruit juice, but the maximum plasma level was not significantly changed. Inter-individual variation in **sildenafil** pharmacokinetics was also increased by grapefruit juice. The authors suggest that although the slight rise in AUC is unlikely to be clinically significant, the combination is best avoided due to the increased variability in **sildenafil** pharmacokinetics.¹ However, this seems overcautious, since the manufacturer permits reduced doses of **sildenafil** with much more potent inhibitors of CYP3A4, such as 'itraconazole', (p.1270).

The manufacturers of **tadalafil** predict that grapefruit juice will increase its levels^{2,3} and the UK manufacturer advises caution with concurrent use.²

The manufacturers of **vardeafil** also predict that grapefruit juice will increase its levels^{4,5} and recommend avoiding this combination.⁴

Phosphodiesterase type-5 inhibitors + H₂-receptor antagonists

Sildenafil levels are modestly raised by cimetidine. No interaction appears to occur when nizatidine is given with tadalafil and when cimetidine or ranitidine is given with vardenafil.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

In a study in 10 healthy subjects, **cimetidine** 800 mg daily for 4 days increased the AUC of a single 50-mg dose of sildenafil given on day 3 by 56%, when compared with 10 healthy subjects given sildenafil and placebo.¹ It has been suggested that these changes occur because **cimetidine** is a non-specific cytochrome P450 inhibitor.² The manufacturers say that population pharmacokinetic analysis revealed a reduced clearance of sildenafil in patients taking CYP3A4 inhibitors, such as ketoconazole, erythromycin and **cimetidine**.^{2,3} The UK manufacturers say that, although no increase in adverse effects was seen, a starting dose of 25 mg of sildenafil should be considered.³ For **cimetidine**, studies suggest the increase is modest, compared to 'erythromycin', (p.1272), and this therefore seems overcautious. Furthermore, no recommendation is made about the sildenafil dose with **cimetidine** by the US manufacturer.²

(b) Tadalafil

An open-label, randomised, three-period, crossover study in 12 healthy subjects found that **nizatidine** 300 mg reduced the mean maximum serum levels of tadalafil by 14% following a single 10-mg dose, but other pharmacokinetic parameters, including the extent of absorption, were largely unchanged. None of the changes caused were considered to be clinically relevant and there would appear to be no reason for avoiding concurrent use.⁴

Any alterations in the absorption of tadalafil are therefore unlikely to be caused by changes in gastric pH.⁴

(c) Vardenafil

In a three-way crossover study, a single 20-mg dose of vardenafil was given to 10 healthy subjects following a 3-day course of **cimetidine** 400 mg twice daily, **ranitidine** 150 mg twice daily or with no pre-treatment. **Cimetidine** slightly increased the relative bioavailability of vardenafil (by about 12%, not considered clinically relevant), while **ranitidine** had no effect. It was concluded that any alterations in the absorption of vardenafil are not caused by changes in gastric pH.⁵ No special precautions appear to be necessary during concurrent use.

Phosphodiesterase type-5 inhibitors + Macrolides

Erythromycin raises sildenafil levels almost threefold and raises vardenafil levels fourfold. Clarithromycin raises sildenafil levels about twofold. Erythromycin is predicted to similarly raise tadalafil levels. Azithromycin does not interact with sildenafil.

Clinical evidence

(a) Sildenafil

In a study in 24 healthy subjects, **erythromycin** 500 mg twice daily for 5 days was found to increase the AUC of single 100-mg doses of sildenafil almost threefold.¹ In the same study, **azithromycin** 500 mg once daily for 3 days had no effect on the pharmacokinetics of sildenafil.¹ In another study, in 12 healthy subjects, **clarithromycin** 500 mg increased the AUC of sildenafil 50 mg 2.3-fold, and the maximum level 2.4-fold.²

(b) Tadalafil

'Ketoconazole', (p.1270), doubles tadalafil levels. The manufacturers therefore predict that other CYP3A4 inhibitors such as **erythromycin**^{3,4} will interact similarly.

(c) Vardenafil

Erythromycin 500 mg three times daily increased the AUC of a 5-mg dose of vardenafil fourfold, and increased the maximum plasma levels threefold in healthy subjects.^{5,6}

Mechanism

Sildenafil, tadalafil and vardenafil are all metabolised by the cytochrome P450 isoenzyme CYP3A4. Many macrolides are moderate inhibitors of this isoenzyme and therefore inhibit sildenafil, tadalafil and vardenafil metabolism, which leads to increased levels of the phosphodiesterase inhibitors. Azithromycin does not usually act as a CYP3A4 inhibitor and therefore does not interact.

Importance and management

The interaction of the macrolides with the phosphodiesterase type-5 inhibitors is established, although most of the studies concern the use of erythromycin. These interactions are expected to result in both increased efficacy and increased incidence of adverse effects.

For **sildenafil**, the manufacturers recommend that a low starting dose of sildenafil 25 mg should be considered in patients with erectile dysfunction taking inhibitors of CYP3A4 such as erythromycin.^{7,8} For pulmonary hypertension, the UK manufacturer says that a downward reduction of the sildenafil dose to 20 mg twice daily should be considered with erythromycin, and 20 mg once daily with clarithromycin or **telithromycin**,⁹ (however, note that erythromycin had a greater effect than clarithromycin in the studies above) whereas the US manufacturer says that no dose adjustment is needed with erythromycin.¹⁰

For **tadalafil**, caution is advised by the UK manufacturers as adverse effects may be increased in some patients. They specifically mention erythromycin and clarithromycin.³

For **vardenafil**, the UK manufacturer says that dosage adjustment might be necessary in patients taking erythromycin, and recommend that the dose of vardenafil should not exceed 5 mg.⁵ The US prescribing information similarly recommends that the dose of vardenafil should not exceed 5 mg in 24 hours for erythromycin, but further restricts the dose in the presence of clarithromycin to 2.5 mg in 24 hours.⁶

Dosing guidance is not given for the other macrolides, but it would seem prudent to follow the advice given for erythromycin in patients taking any macrolide known to inhibit CYP3A4 (e.g. clarithromycin, **telithromycin**). Azithromycin seems unlikely to interact.

Phosphodiesterase type-5 inhibitors + Nitrates

The phosphodiesterase type-5 inhibitors potentiate the hypotensive effects of nitrates in a proportion of patients, which might result in potentially serious hypotension or even precipitate myocardial infarction. Therefore, the concurrent use of sildenafil, tadalafil or vardenafil with organic nitrates (glyceryl trinitrate (nitroglycerin), isosorbide dinitrate, isosorbide mononitrate, etc.) is contraindicated. The concurrent use of nicorandil and all phosphodiesterase type-5 inhibitors is also contraindicated.

Clinical evidence

(a) Sildenafil

1. *Erectile dysfunction*. Two double-blind, placebo-controlled studies in groups of 15 or 16 men with angina found that the fall in blood pressure seen when taking nitrates and a single 50-mg dose of sildenafil was about doubled. Those given sildenafil and **isosorbide dinitrate** 20 mg twice daily had a mean blood pressure fall of 44/26 mmHg compared with 22/13 mmHg with placebo. Those who used 500 micrograms of sublingual **glyceryl trinitrate** one hour before the sildenafil had a mean blood pressure fall of 36/21 mmHg compared with 26/11 mmHg with **glyceryl trinitrate** and placebo. Individual blood pressure falls as great as 84/52 mmHg were seen.¹

A postmarketing report from the FDA in the US for the period late March to July 1998 briefly lists 69 fatalities after taking sildenafil. These were mostly in middle-aged and elderly men (average age 64), 12 of whom had also taken **glyceryl trinitrate (nitroglycerin)** or a nitrate medication, but it is not clear what part (if any) the nitrates played in the deaths.²

In a limited and preliminary study it was reported that no blood pressure alteration was seen when a small dose of **glyceryl trinitrate** (amount not specified) was given as a dermal patch while subjects were taking 50 mg of sildenafil. In addition, the beneficial effects of the **glyceryl trinitrate** on the radial artery pressure waveform were approximately doubled, and persisted for up to 8 hours.³

2. *Pulmonary hypertension*. In a study of the combined use of intravenous sildenafil and **inhaled nitric oxide** in the management of pulmonary hypertension in 15 infants, significant hypotension occurred, which, along with a decrease in oxygenation, was considered sufficiently detrimental for the study to be stopped early.⁴ Conversely, beneficial combined use has been described in one adult patient with severe hypoxemia caused by pulmonary hypotension.⁵ Note that **nitric oxide** is not to be confused with the anaesthetic **nitrous oxide**, which is not a nitric oxide donor and therefore poses no risk,⁶ see Mechanism below.

(b) Tadalafil

In a double-blind, randomised, placebo-controlled study, 51 patients with chronic stable angina were given tadalafil 5 mg, 10 mg or a placebo, followed 2 hours later by a single 400-microgram dose of sublingual **glyceryl trinitrate**. Although tadalafil caused little additional decrease in blood pressure to that seen with **glyceryl trinitrate**, a potentially clinically significant blood pressure reduction (standing systolic BP less than 85 mmHg) was seen in 13 and 11 of the patients when given tadalafil 5 and 10 mg, respectively, compared with one patient in the placebo group.^{7,8} In a similar study in 45 patients taking long-term oral **isosorbide mononitrate**, tadalafil 5 or 10 mg had minimal effects on the decrease in blood pressure caused by this nitrate, but again, more patients had a standing systolic BP of less than 85 mmHg when receiving tadalafil 10 mg than placebo (6 versus 0).^{7,8} Another similar study in 48 healthy subjects compared the effects of tadalafil 10 mg, sildenafil 50 mg, and placebo, in combination with sublingual **glyceryl trinitrate** 400 micrograms. Again, it was found that the presence of the tadalafil had minimal effects on the mean maximum decreases in blood pressure, but it was noted that 23 pa-

tients given tadalafil and 23 given sildenafil had a standing systolic blood pressure of 85 mmHg or less following the use of the nitrate, compared with 12 in the placebo group.^{8,9} In a further study, a haemodynamic interaction between tadalafil 20 mg and sublingual **glyceryl trinitrate** was seen when the **glyceryl trinitrate** was given 4, 8 and 24 hours after the tadalafil, and was not seen at 48 hours and beyond. Note that no time points between 24 and 48 hours were examined.¹⁰

An analysis of the rates of serious cardiovascular adverse events (mortality, myocardial infarction, thrombotic strokes) in clinical studies involving tadalafil indicated that adverse events were no more frequent than in the general population of men with erectile dysfunction.⁸

(c) Vardenafil

A single 400-microgram dose of sublingual **glyceryl trinitrate** (nitroglycerin) given to 18 healthy subjects 1 to 24 hours after a single 10-mg dose of vardenafil was found to be no different to placebo in causing changes in seated heart rate and blood pressure.^{11,12} However, a single 20-mg dose of vardenafil did potentiate the blood pressure-lowering effects and increases in heart rate (about an 8 mmHg additional drop in systolic BP compared with placebo) seen with **sublingual nitrates** (400 micrograms) taken 1 and 4 hours after the vardenafil. These effects were not seen when the nitrate was taken 24 hours after the vardenafil dose.^{11,13}

Mechanism

Sexual stimulation causes the endothelium of the penis to release nitric oxide (NO), which in turn activates guanylate cyclase to increase the production of cyclic guanosine monophosphate (cGMP). This relaxes the blood vessel musculature of the corpus cavernosum thus allowing it to fill with blood and cause an erection. The erection ends when the guanosine monophosphate is removed by an enzyme (type 5 cGMP phosphodiesterase, or PDE5). Sildenafil, tadalafil and vardenafil inhibit this enzyme thereby increasing and prolonging the effects of the guanosine monophosphate. Because this vasodilation is usually fairly localised (these drugs are highly selective for PDE5) it normally only causes mild to moderate falls in blood pressure (on average about 10 mmHg) with mild headache or flushing. However, if other nitrates (e.g. glyceryl trinitrate) are taken concurrently, high levels of nitric oxide enter the circulation, and this markedly increases systemic vasodilation and hence the hypotensive effect.

Importance and management

The interaction between phosphodiesterase type-5 inhibitors and nitrates is established, clinically important, potentially serious and even possibly fatal. Sildenafil and organic nitrates of any form are contraindicated both for erectile dysfunction^{14,15} (within 24 hours of each other⁶) and for pulmonary hypertension^{16,17} because of the risk of precipitating serious hypotension, or even myocardial infarction.¹⁸ The ACC/AHA Expert consensus document provides a useful list of many of the organic nitrates available, which include glyceryl trinitrate (nitroglycerin), isosorbide mononitrate, **isosorbide dinitrate** and illicit substances such as **amyl nitrite**.⁶

Similarly, the manufacturers of vardenafil^{11,13} and tadalafil^{19,20} say that their combination with nitrates (taken either regularly and/or intermittently) is contraindicated. Nitrates should not be given for at least 48 hours after the last dose of tadalafil.^{19,20}

It is not yet known whether **nicorandil** interacts with the phosphodiesterase inhibitors to a clinically relevant extent or not,²¹ but because part of its vasodilatory actions are mediated by the release of nitric oxide (like conventional nitrates), the manufacturers of **nicorandil** contraindicate its use with all phosphodiesterase inhibitors.²²

Phosphodiesterase type-5 inhibitors + Protease inhibitors

Indinavir, saquinavir and ritonavir can cause marked rises in serum sildenafil levels. A fatal heart attack occurred in a man taking ritonavir and saquinavir when he also took sildenafil. Similar marked interactions occur between vardenafil and indinavir or ritonavir, and are predicted to occur between vardenafil and the other protease inhibitors. Ritonavir caused less marked increases in tadalafil levels.

Clinical evidence

A. Sildenafil

(a) Indinavir

A study in 6 HIV-positive patients found that sildenafil 25 mg did not significantly alter the plasma levels of indinavir. However, the sildenafil AUC was about 4.4-fold higher than the AUC in historical control patients taking sildenafil (data normalised to a 25 mg dose) without indinavir.¹ A study in 2 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of indinavir.²

(b) Nelfinavir

A study in 5 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of nelfinavir.²

(c) Ritonavir

In a randomised, placebo-controlled, double-blind, crossover study, 28 healthy subjects were given sildenafil 100 mg before and after taking ritonavir for 7 days (300, 400 and 500 mg twice daily on days 1, 2 and 3 to 7, respectively). It was found that the sildenafil AUC was increased 11-fold and the maximum serum levels 3.9-fold by ritonavir, but the incidence and severity of the sildenafil adverse effects and the steady-state levels of ritonavir remained unchanged.³ However, the clinical significance of this interaction is highlighted by a case report of a 47-year-old man, with no cardiovascular risk factors apart from smoking, who had a fatal heart attack when he took sildenafil 25 mg while he was also taking ritonavir and **saquinavir**. One hour after the ninth dose, he had an onset of severe chest pain, and died soon after.⁴

A study in 2 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of ritonavir (given with **saquinavir**).²

(d) Saquinavir

In a randomised, placebo-controlled, double-blind crossover study, 28 healthy subjects were given sildenafil 100 mg before and after taking saquinavir 1.2 g three times daily for 7 days. It was found that the sildenafil AUC was increased 3.1-fold and the maximum serum levels 2.4-fold, but the incidence and severity of the sildenafil adverse effects and the steady-state levels of saquinavir remained unchanged.³ Also see (c) above for a case report of a fatal interaction involving sildenafil, **ritonavir** and saquinavir.

A study in 2 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of **ritonavir**-boosted saquinavir.²

B. Tadalafil

Ritonavir 200 mg twice daily increased the AUC of a single 20-mg dose of tadalafil twofold (124%), without affecting the maximum serum levels.^{5,6}

C. Vardenafil

When a single 10-mg dose of vardenafil was given with **indinavir** 800 mg three times daily, the AUC of vardenafil was increased 16-fold, and the maximum plasma level was increased sevenfold.^{7,8} Moreover, **ritonavir** 600 mg twice daily produced a 49-fold increase in the AUC of vardenafil, and prolonged the half-life to 26 hours.⁸

Mechanism

Protease inhibitors inhibit the activity of the cytochrome P450 isoenzyme CYP3A4, the enzyme that metabolises sildenafil, tadalafil and vardenafil. This results in an increase in their serum levels. Ritonavir is the most potent CYP3A4 inhibitor, followed by indinavir, nelfinavir, amprenavir, and then saquinavir, see 'Antivirals', (p.772).

Importance and management

Information about interactions between phosphodiesterase type-5 inhibitors and protease inhibitors appears to be limited to the studies and case cited, but the interactions would seem to be established and of clinical importance.

For **sildenafil**, because of the very marked rises in levels, concurrent use of ritonavir and sildenafil for pulmonary hypertension is not advised,⁹ or in the UK, contraindicated.¹⁰ When single doses of sildenafil are used for erectile dysfunction, the UK manufacturer also says concurrent use with ritonavir is not advised.¹¹ In this situation, if the decision is taken to use sildenafil in a patient taking ritonavir, the dose of sildenafil should not exceed a single 25-mg dose in a 48-hour period,^{3,11,12} but note that the fatality described above⁴ occurred despite the use of this dose. For other CYP3A4 inhibitors such as saquinavir, the recommendation for erectile dysfunction is that a low starting dose (25 mg) should be considered.^{3,11,12} For pulmonary hypertension, the UK manufacturer says that a downward reduction of the sildenafil dose to 20 mg twice daily should be considered with saquinavir,¹⁰ whereas the US manufacturer says that no dose adjustment is needed with saquinavir.⁹ The authors of the indinavir study suggest that a starting dose of 12.5 mg may be more appropriate for erectile dysfunction in those taking indinavir, and that the maximum dosage frequency should be reduced to once or twice weekly.¹ Direct evidence for other protease inhibitors is lacking but they would be expected to interact similarly (see Mechanism above) and it would seem consistent to follow the broad principle of starting with a low sildenafil dosage.

For **tadalafil**, the US manufacturer advises that the dose should not exceed 10 mg every 72 hours in patients taking ritonavir,⁵ whereas the UK manufacturer advises caution on concurrent use.⁶ It is probably prudent to apply this advice to patients taking any protease inhibitor.

For **vardenafil**, due to the very large rises in levels, the UK manufacturer contraindicates its use with protease inhibitors that are potent CYP3A4 inhibitors (they name ritonavir and indinavir).⁷ In contrast, the US prescribing information recommends dose restrictions as follows: the dose of vardenafil should not exceed 2.5 mg in 24 hours when used with atazanavir, indinavir, or saquinavir, and should not exceed 2.5 mg in 72 hours when used with ritonavir.⁸

Phosphodiesterase type-5 inhibitors; Sildenafil + Antidepressants

Retrospective analysis of clinical study data suggested that SSRIs and tricyclic antidepressants did not alter sildenafil pharmacokinetics. However, in one study fluvoxamine was found to modestly increase the levels and vascular effects of sildenafil.

Clinical evidence

The manufacturer notes that population pharmacokinetic analysis of clinical study data indicate that inhibitors of cytochrome P450 isoenzyme CYP2D6 such as **SSRIs** and **tricyclic antidepressants** do not have any effect on the pharmacokinetics of sildenafil.^{1,2} However, in a double-blind, placebo-controlled study in healthy subjects, pre-treatment with **fluvoxamine** 50 mg daily for 3 days then 100 mg daily for 6 days increased the AUC of sildenafil 50 mg by 40%. This resulted in an increase in the vascular effects of sildenafil.³

Mechanism

Sildenafil is principally metabolised by cytochrome P450 isoenzyme CYP3A4, and to a lesser extent by CYP2C9. Fluvoxamine probably raises sildenafil by inhibition of both of these isoenzymes. Grouping all SSRIs and tricyclics together in a retrospective analysis would not be a sensitive enough technique to have picked up this modest effect of fluvoxamine.

Importance and management

The increases in sildenafil levels with fluvoxamine are modest, and the authors concluded that they do not suggest a large clinically relevant interaction. Nevertheless, they suggest it may be prudent to consider a 25-mg starting dose of sildenafil in patients taking fluvoxamine.³ This may be sensible. Although retrospective analyses of clinical study data are useful to identify potentially important drug interactions, they are not sensitive enough to rule out interactions, and should not replace prospective pharmacokinetic studies.

Phosphodiesterase type-5 inhibitors; Sildenafil + Bosentan

Bosentan markedly reduces sildenafil levels.

Clinical evidence

In 10 patients with pulmonary hypertension, bosentan 62.5 mg twice daily for one month decreased the AUC of a single 100-mg dose of sildenafil by 53% and increased its clearance 2.3-fold. After a second month of bosentan at an increased dose of 125 mg twice daily, the AUC of a single 100-mg dose of sildenafil was reduced by 69%, and the clearance increased 3.4-fold. The AUC of the primary metabolite, desmethyl-sildenafil, was also decreased in a dose-dependent manner by bosentan.¹ In a further study in healthy subjects, the concurrent use of bosentan 125 mg twice daily and sildenafil 80 mg three times daily for 6 days decreased the AUC of sildenafil by 63%.²

Mechanism

Bosentan induces the cytochrome P450 isoenzyme CYP3A4 and CYP2C9, by which sildenafil is metabolised.

Importance and management

This pharmacokinetic interaction is established and potentially clinically important. The efficacy of sildenafil is likely to be reduced in patients taking bosentan, and should be closely monitored.

Phosphodiesterase type-5 inhibitors; Sildenafil + Dihydrocodeine

Two men using sildenafil had prolonged erections following orgasm while also taking dihydrocodeine.

Clinical evidence, mechanism, importance and management

Two men, successfully treated with 100-mg doses of sildenafil for erectile dysfunction, experienced prolonged erections after orgasm while also taking dihydrocodeine 30 to 60 mg every 6 hours for soft tissue injuries. One of them had two erections lasting 4 and 5 hours, and this did not occur on subsequent occasions when the dihydrocodeine was stopped. The other had 2 to 3 hour erections on three occasions during the first week of dihydrocodeine use, but no problems over the next 2 weeks while continuing to take the dihydrocodeine.¹ The reasons are not understood.

According to the manufacturers of sildenafil, priapism (painful prolonged abnormal erection) associated with its use is rare, and there appear to be no other reports about an interaction between sildenafil and dihydrocodeine. Excessively prolonged erections can have serious consequences and may need urgent treatment. Therefore, the authors suggest it would now be prudent to warn patients about this possible (though remote) problem if opioids are being used, and advise them to contact the prescriber if priapism occurs.¹

1. Goldmeier D, Lamba H. Prolonged erections produced by dihydrocodeine and sildenafil. *BMJ* (2002) 324, 1555.

Phosphodiesterase type-5 inhibitors; Sildenafil + Ecstasy

The abuse of sildenafil and ecstasy (MDMA, methylenedioxyamfetamine) has been reported to result in serious headache and priapism requiring emergency treatment.

Clinical evidence, mechanism, importance and management

A journalist's account, based purely on anecdotal reports, claims that the illicit use of sildenafil with ecstasy (MDMA, methylenedioxyamfetamine) causes "hammerheading" because of the pounding headache and the prolonged and painful penile erections that require emergency medical treatment.¹ The report does not say how much of each of these drugs is taken to produce these adverse effects. The outcome can clearly be unpleasant, painful and, the priapism, potentially serious.

1. Breslau K, Peraino K, Fantz A. The 'sextasy' craze. *Newsweek*, June 3, 2002, 30.

Phosphodiesterase type-5 inhibitors; Sildenafil + Miscellaneous

No pharmacokinetic interaction appears to occur between sildenafil and a combined oral contraceptive or tolbutamide.

Clinical evidence, mechanism, importance and management

(a) Oral contraceptives

The pharmacokinetics of sildenafil were not altered by concurrent use of a combined oral contraceptive (**ethinylestradiol/levonorgestrel**), and the plasma levels of these contraceptive steroids were not altered by sildenafil.^{1,2}

(b) Tolbutamide

Sildenafil 50 mg did not alter the pharmacokinetics of tolbutamide 250 mg,^{3,4} probably because sildenafil is only a weak inhibitor of the cytochrome P450 isoenzyme CYP2C9 (consider also 'warfarin', (p.441)).

2. Revatio (Sildenafil citrate). Pfizer Inc. US Prescribing information, July 2006.
3. Viagra (Sildenafil citrate). Pfizer Ltd. UK Summary of product characteristics, June 2006.
4. Viagra (Sildenafil citrate). Pfizer Inc. US Prescribing information, October 2006.

Phosphodiesterase type-5 inhibitors; Vardenafil + Miscellaneous

The manufacturers of vardenafil suggest the avoidance of class Ia and III antiarrhythmics because of fears of possible QT interval prolongation. No clinically significant interaction has been seen between vardenafil and food, glibenclamide (glyburide), metformin or sulphonylureas.

Clinical evidence, mechanism, importance and management

(a) Antiarrhythmics (class Ia and III)

Vardenafil 10 mg and 80 mg caused very small (8 and 10 millisecond) increases in the corrected QT interval in healthy subjects.^{1,2} This increase was similar to that seen with a single 400-mg dose of moxifloxacin,² a drug known to cause moderate QT-prolongation. Because of this, the manufacturers recommend that vardenafil is not used in those taking class Ia antiarrhythmics (e.g. **quinidine**, **procainamide**) or class III antiarrhythmics (e.g. **amiodarone**, **sotalol**), which are also known to prolong the QT interval.^{1,2} Note that prolongation of the QT interval is associated with an increased risk of the potentially fatal torsade de pointes arrhythmia (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257).

(b) Antidiabetics

The manufacturers say that the pharmacokinetics of **glibenclamide (glyburide)** were not affected by a single 20-mg dose of vardenafil,¹ and that vardenafil had no effect on **glibenclamide** pharmacodynamics (glucose and insulin levels).² Also, although no specific pharmacokinetic study has been conducted, the manufacturers say that population pharmacokinetic analysis suggests that **sulphonylureas** (not named) and **metformin** have no effect on vardenafil pharmacokinetics. No additional precautions therefore seem necessary on concurrent use.¹

(c) Food

In a single-dose study, healthy subjects were given a single 20-mg dose of vardenafil on four occasions; after an overnight fast, on an empty stomach, following a **high-fat breakfast** (fat 58 g), or following a **moderate-fat evening meal** (fat 23 g). No pharmacokinetic changes were noted in the fasting or moderate-fat periods. Although the **high-fat breakfast** caused a slight decrease and a slight delay in the absorption of vardenafil this was not considered to be sufficient to warrant changing the dosing time or making dosage adjustments. Therefore vardenafil may be given without regard to meals.³

3. Rajagopalan P, Mazzu A, Xia C, Dawkins R, Sundaresan P. Effect of high-fat breakfast and moderate-fat evening meal on the pharmacokinetics of vardenafil, an oral phosphodiesterase-5 inhibitor for the treatment of erectile dysfunction. *J Clin Pharmacol* (2003) 43, 1–8.

Pseudoephedrine + Antacids or Antidiarrhoeals

Kaolin does not appear to interact significantly with pseudoephedrine, but aluminium hydroxide may possibly cause a more rapid onset of action.

Clinical evidence

In a single-dose crossover study in 6 healthy subjects, 30 mL of **aluminium hydroxide gel** did not affect the total amount of pseudoephedrine absorbed from a single 60-mg dose over 24 hours, but the rate of absorption was significantly increased during the first 3 hours.¹ Conversely, 30 mL of a 30% suspension of **kaolin** reduced the amount of pseudoephedrine absorbed from a single 60-mg dose by just 10%. The rate of absorption was also decreased.¹

Mechanism

The increased rate of absorption of pseudoephedrine seen with aluminium hydroxide is probably also due to pH rises, which favour the formation of the lipid-soluble absorbable form of pseudoephedrine. The reduced absorption with kaolin is probably due to adsorption of the pseudoephedrine onto the surface of the kaolin.

Importance and management

Aluminium hydroxide may possibly cause a more rapid onset of pseudoephedrine activity (but this needs confirmation). Any interaction seems unlikely to be clinically significant. Similarly, the effects of kaolin on absorption are small and unlikely to be clinically important. For the effect of sodium bicarbonate on pseudoephedrine and ephedrine, see 'urinary alkalinisers', (p.1277).

1. Lucarotti RL, Colaizzi JL, Barry H, Poust RI. Enhanced pseudoephedrine absorption by concurrent administration of aluminium hydroxide gel in humans. *J Pharm Sci* (1972) 61, 903–5.

Pseudoephedrine and related drugs + Caffeine

Phenylpropanolamine can raise blood pressure and in some cases this may be further increased by caffeine. Combined use has resulted in hypertensive crises in a few individuals. Ephedrine may interact similarly. Phenylpropanolamine can markedly raise plasma caffeine levels, and isolated reports describe the development of acute psychosis when caffeine was given with phenylpropanolamine or ephedrine.

Clinical evidence

(a) Ephedrine

In a single-dose, randomised study, 15 healthy subjects were given ephedrine 25 mg, caffeine 200 mg, both drugs together, or placebo. An assessment of systolic blood pressure found that ephedrine had no significant effect, caffeine caused a 9.1 mmHg increase, and the use of both drugs resulted in an 11.7 mmHg increase. Caffeine alone did not increase heart rate, but both ephedrine and ephedrine plus caffeine caused increases of roughly 11%. Subjective tests suggested that there was no significant difference in feelings of headache, chest pain, heart pounding or shortness of breath between the treatments. There was no significant pharmacokinetic interaction between the drugs.¹ In another randomised study, investigating the combination of ephedrine 20 mg and caffeine 200 mg, both three times daily, for weight loss, did not find any significant hypertensive effects with the combination, although the authors suggested that this may have been due to the favourable effects of weight loss on blood pressure. However, one patient was withdrawn due to a rise in blood pressure, to 185/125 mmHg.²

A review of reports from the FDA in the US revealed that several patients have experienced severe adverse effects (subarachnoid haemorrhage, cardiac arrest, hypertension, tachycardia and neurosis) after taking dietary supplements containing ephedrine or **ephedra** alkaloids with caffeine.³ However, it is not possible to definitively say that these effects were the result of an interaction because none of the patients took either drug separately. Similarly, a meta-analysis assessing the safety of ephedra or ephedrine and caffeine found a two- to threefold increase in the risk of adverse events (including psychiatric symptoms and palpitations) with ephedra or ephedrine, but concluded that it was not possible to assess the contribution of caffeine to these events.⁴

Two episodes of acute psychosis occurred in a 32-year-old man after he took *vigueur fit* tablets (containing **ephedra** alkaloids and caffeine), *Red Bull* (containing caffeine) and alcohol. He had no previous record of aberrant behaviour despite regularly taking 6 to 9 tablets of *vigueur fit* daily (about twice the recommended dose). However, on this occasion, over a 10-hour period, he consumed 3 or 4 bottles of *Red Bull* (containing about 95 mg of caffeine per 250-mg bottle) and enough alcohol to reach a blood-alcohol level of about 335 mg%. No more episodes occurred after he stopped taking the *vigueur fit* tablets. **Ephedra** alkaloids (ephedrine and **pseudoephedrine**) may cause psychosis and it appears that their effects may be exaggerated by an interaction with caffeine and alcohol.⁵

(b) Phenylpropanolamine

In a placebo-controlled study, the mean blood pressure of 16 healthy subjects rose by 11/12 mmHg after they took caffeine 400 mg, by 12/13 mmHg after they took phenylpropanolamine 75 mg, and by 12/11 mmHg when both drugs were taken. Phenylpropanolamine 150 mg caused a greater rise of 36/18 mmHg. One of the subjects had a hypertensive crisis after taking phenylpropanolamine 150 mg and again 2 hours after taking caffeine 400 mg. This needed antihypertensive treatment.⁶ The same group of workers describe a similar study in which the AUC of caffeine 400 mg increased by more than threefold, and the mean peak caffeine concentration increased almost fourfold (from 2.1 to 8 micrograms/mL) after phenylpropanolamine 75 mg was given.⁷ Additive increases in blood pressure are described in another report.⁸

Mania with psychotic delusions occurred in a healthy woman (who normally drank 7 to 8 cups of **coffee** daily) within 3 days of her starting to take a phenylpropanolamine-containing decongestant. She recovered within a week of stopping both the **coffee** and the phenylpropanolamine.⁹

Mechanism

Uncertain. Simple additive hypertensive effects would seem to be part of the explanation. The effects of caffeine may compound the effects of these sympathomimetic drugs on the cardiovascular and central nervous systems by blocking adenosine receptors (causing vasoconstriction) and also augmenting the release of catecholamines.^{3,5}

Importance and management

Fairly well established interactions. These studies illustrate the potential hazards of these drugs, even in normal healthy individuals. However, it has to be said that there seem to be no other reports of adverse interactions, which is perhaps surprising bearing in mind that coffee/caffeine is very widely used and ephedrine and phenylpropanolamine have also been widely available over the counter. One possible explanation for this could be that these interactions may go unrecognised or be attributed to one drug only e.g. phenylpropanolamine, whereas caffeine has also been taken either as part of the preparation^{3,10} or in beverages (often not reported). Nevertheless, serious adverse events have been reported with caffeine and phenylpropanolamine or dietary supplements containing ephedra alkaloids (sometimes called *ma huang*) and therefore these preparations may pose a serious health risk to some users.³ The risk may be affected by individual susceptibility, the additive stimulant effects of caffeine, the variability in the contents of alkaloids in non-prescription dietary supplements, or pre-existing medical conditions.³ One study in healthy subjects that found no adverse clinical response to the enhanced cardiac effects of the combination concluded that the cardiac effects could be clinically significant in patients with compromised cardiac function.¹ The authors of one report⁶ advised that likely users of phenylpropanolamine (those with allergies or the overweight) and those particularly vulnerable (elderly or hypertensive patients) should be warned about taking more than the recommended dose of phenylpropanolamine, and also about taking caffeine at the same time, because of the possible risk of intracranial haemorrhage.

Note that, phenylpropanolamine is no longer available in the US and UK and its use has been restricted in many other countries. In addition, because of the associated health risks, the FDA bans combinations of caffeine with ephedrine or pseudoephedrine, and also bans herbal products containing ephedra.

Pseudoephedrine and related drugs + Urinary acidifiers or alkalinisers

Alkalinisation of the urine (e.g. by sodium bicarbonate) causes retention of ephedrine and pseudoephedrine by the kidneys, leading to the possible development of toxicity (tremors, anxiety, insomnia, tachycardia). Acidification of the urine (e.g. with ammonium chloride) has the opposite effect.

Clinical evidence

(a) Ephedrine

When the urine was made acidic (pH of about 5) with **ammonium chloride**, the excretion of ephedrine in the urine of three healthy subjects was two to fourfold higher than when the urine was made alkaline (pH of about 8) with **sodium bicarbonate**.¹

(b) Pseudoephedrine

A patient with renal tubular acidosis and persistently alkaline urine developed unexpected toxicity (cachexia and personality changes) when given therapeutic doses (not stated) of pseudoephedrine for 2.5 months. She was found to have a very prolonged pseudoephedrine half-life of 50 hours (10 times normal). Therefore 8 subjects (adults and children) were studied, to establish the possible effects of changing the urinary pH on pseudoephedrine elimination. When the urinary pH was adjusted using **ammonium chloride** or **sodium bicarbonate**, within the approximate range of 5.7 to 7.8, the half-life of a single dose of pseudoephedrine (about 5 mg/kg) was found to increase from 1.9 hours at the lowest pH to 21 hours at the highest pH.²

This confirms an earlier study, in which it was found that at a urinary pH of 8, the half-life of pseudoephedrine was 16, 9.2, and 15 hours in 3 subjects, respectively. At a urinary pH of about 5, the half-life was 4.8, 3, and 6.4 hours, respectively.³ **Sodium bicarbonate** was given to raise urinary pH and **ammonium chloride** to lower urinary pH.

Another study in 6 healthy subjects found that **sodium bicarbonate** 5 g initially increased the excretion rate of a single 60-mg dose of pseudoephedrine, but as the urinary pH increased the excretion of pseudoephedrine was reduced.⁴

Mechanism

Ephedrine and pseudoephedrine are basic drugs, which are mainly excreted unchanged in the urine. In acidic urine, most of the drug is ionised in the tubular filtrate and unable to diffuse passively back into the circulation, and is therefore lost in the urine. In alkaline urine, these drugs mostly exist in the lipid-soluble form, which are reabsorbed.

The increased rate of absorption of pseudoephedrine seen with sodium bicarbonate is probably also due to pH rises, which favour the formation of the lipid-soluble absorbable form of pseudoephedrine.

Importance and management

The interaction between ephedrine or pseudoephedrine and urinary alkalinisers are established but reports of adverse reactions in patients appear to be rare. Be aware that any increase in the adverse effects of these drugs (tremor, anxiety, insomnia, tachycardia, etc.) could be due to drug retention brought about by this interaction. **Acetazolamide** makes the urine alkaline and would be expected to interact with ephedrine and pseudoephedrine in the same way as sodium bicarbonate.

Acidification of the urine with ammonium chloride increases the loss of ephedrine and pseudoephedrine in the urine and could be exploited in cases of drug overdose.

PUVA therapy + Herbal medicines or Foods

Two case reports describe photosensitivity, one in a patient taking rue (*Ruta graveolens*) and another in a patient who ate large amounts of celery soup.

Clinical evidence, mechanism, importance and management

A 35-year-old woman taking methoxsalen and undergoing PUVA for psoriasis unexpectedly developed increased photosensitivity. Over the previous weekend and on the morning of therapy she had been drinking a concoction of **rue (*Ruta graveolens*)**.¹ This plant naturally contains 5-methoxypsoralen so it would appear that a pharmacodynamic interaction occurred, which resulted in the photosensitivity.

The authors note that other herbal products contain photosensitising substances (e.g. those containing members of the **Umbelliferae** family; such as **celery**, or ***Chlorella*** species), and so suggest that patients undergoing PUVA should be warned about the potential interactions.¹ This warning appears justified by the case of a woman taking methoxsalen and undergoing PUVA, who developed photosensitivity after eating a large quantity of soup containing **celery**, parsnip and parsley.²

Raloxifene + Miscellaneous

The absorption of raloxifene is reduced by colestyramine, and their concurrent use is not recommended. No clinically relevant changes in raloxifene pharmacokinetics occur with aluminium/magnesium hydroxide, amoxicillin, ampicillin or calcium carbonate. Raloxifene does not alter digoxin or methylprednisolone levels. Oral antibacterials, antihistamines, aspirin, benzodiazepines, H₂-receptor antagonists, ibuprofen or paracetamol (acetaminophen) were used in clinical studies without any obvious effect on raloxifene levels. Smoking does not appear to alter the efficacy of raloxifene.

Clinical evidence, mechanism, importance and management

(a) Ampicillin and Amoxicillin

Ampicillin is reported to reduce the maximum serum levels of raloxifene by 28% and the extent of the absorption by 14% without affecting the elimination rate.¹ This is thought to be because ampicillin reduces the number of enteric bacteria and so reduces enterohepatic recycling of raloxifene. These small changes are unlikely to be clinically relevant. In another clinical efficacy study, there was no discernible difference in plasma raloxifene levels when taken with amoxicillin.¹

(b) Antacids

The manufacturers of raloxifene report that in studies, an antacid containing **aluminium/magnesium hydroxide** given 1 hour before and 2 hours after raloxifene had no effect on its absorption. Also, no interaction was seen with **calcium carbonate**.² There would therefore appear to be no reason for avoiding concurrent use.

(c) Colestyramine

The manufacturers report that colestyramine reduced the absorption of raloxifene by about 60% due to an interruption in enterohepatic cycling.¹ It is recommended that these two drugs should not be used concurrently.^{1,3}

(d) Digoxin

Raloxifene is reported not to affect the steady-state AUC of digoxin, while the maximum serum levels of digoxin were increased by less than 5%.³

(e) *Methylprednisolone*

Steady state raloxifene had no effect on the pharmacokinetics of a single oral dose of methylprednisolone.^{1,3}

(f) *Tobacco*

Retrospective analysis of data from a placebo-controlled study of raloxifene found that raloxifene was equally effective in current tobacco smokers as non-smokers, although smokers had a lower baseline bone mineral density.⁴

(g) *Miscellaneous*

Data from clinical efficacy studies revealed no clinically relevant differences in the plasma levels of raloxifene when stratified according to concurrent drug use. These drugs included **oral antibacterials** (not named), **antihistamines** (not named), **aspirin**, **benzodiazepines** (not named), **H₂-receptor antagonists** (not named), NSAIDs (**ibuprofen**, **naproxen**), and **paracetamol (acetaminophen)**.³ There would therefore appear to be no reason for avoiding the concurrent use of any of these drugs with raloxifene.

Retinoids + Food

Fatty foods increase the absorption of acitretin, etretinate and isotretinoin.

Clinical evidence

(a) *Acitretin*

The absorption of acitretin was increased by 90% and the peak plasma concentrations were increased by 70% when acitretin 50 mg was taken by 18 healthy subjects with a **standard breakfast**. The **breakfast** consisted of two poached eggs, two slices of toast, two pats of margarine and 8 oz (about 240 mL) of skimmed milk.¹

(b) *Etretinate*

Studies have found that **high-fat meals** and **milk** cause about a two to fivefold increase in the absorption of **etretinate**, when compared with **high-carbohydrate meals** or when fasting.^{2,3}

(c) *Isotretinoin*

In a study in 20 healthy subjects the AUC of a single 80-mg dose of isotretinoin was increased 1.4-fold, 1.7-fold, and 1.9-fold when taken one hour before a **standard breakfast**, during **breakfast**, and one hour after **breakfast**, respectively, when compared with the same dose of isotretinoin taken 4 hours before breakfast.⁴

Mechanism

It is thought that because these retinoids are lipid soluble they become absorbed into the lymphatic system by becoming incorporated into the bile-acid micelles of the fats in the food. In this way losses due to first-pass liver metabolism and gut wall metabolism are minimised, and bioavailability increased.

Importance and management

Established interactions of clinical importance. The manufacturers of acitretin recommend taking it with meals^{5,6} or with milk,⁵ and the manufacturers of isotretinoin recommend taking it with food.^{7,8} Similar recommendations were made with etretinate.⁹

Retinoids + Tetracyclines

The development of ‘pseudotumour cerebri’ (benign intracranial hypertension) has been associated with the concurrent use of acitretin or isotretinoin and tetracyclines.

Clinical evidence, mechanism, importance and management

The concurrent use of **isotretinoin** and a tetracycline has resulted in the development of ‘pseudotumour cerebri’ (i.e. a clinical picture of cranial hypertension with headache, dizziness and visual disturbances). By 1983, the FDA in the US had received reports of 10 patients with ‘pseudotumour cerebri’ and/or papilloedema associated with the use of **isotretinoin**. Four had retinal haemorrhages, and 5 of the 10 were also taking a tetracycline.¹ The manufacturers also have similar reports on file of 3 patients given **isotretinoin** and either **minocycline** or **tetracycline**.² The same reaction has been seen in a patient given **etretinate** with **minocycline**.³ It seems that the tetracyclines and retinoids have an additive effect in increasing intracranial pressure. The manufacturers of **acitretin**^{4,5} and **isotretinoin**^{6,7} contraindicate their use with tetracyclines.

7. Accutane (Isotretinoin). Roche Laboratories Inc. US Prescribing information, August 2005.

Retinoids + Vitamin A (Retinol)

A condition similar to vitamin A (retinol) overdose may occur if acitretin or isotretinoin are given with vitamin A.

Clinical evidence, mechanism, importance and management

Combined treatment with **isotretinoin** and vitamin A may result in a condition similar to overdose with vitamin A. Concurrent use should therefore be avoided or very closely monitored because changes in bone structure can occur, including premature fusion of the epiphyseal discs in children.¹

The manufacturers of **acitretin**² say that the concurrent use of vitamin A should be avoided. In the UK² they advise no more than 4000 to 5000 units daily, which is the recommended daily allowance, and in the US³ they advise doses of no more than the minimum recommended daily allowance. Similarly, the manufacturers of **isotretinoin** say that vitamin A should be avoided.^{4,5}

Ritodrine + Miscellaneous

Supraventricular tachycardia developed in a woman given ritodrine when she was also given glycopyrronium (glycopyrrolate). Tachycardia has also been reported in two patients when atropine was used with ritodrine. Hypertension has been reported when cyclopropane was given to patients who had recently received ritodrine. The abuse of cocaine does not appear to increase the incidence of adverse effects in patients given ritodrine.

Clinical evidence, mechanism, importance and management

(a) Anaesthetics

In an analysis of 43 women who had a caesarean section under **cyclopropane** anaesthesia, all of the 6 who had previously been given ritodrine developed unacceptably high blood pressure (185/103 mmHg) after **cyclopropane** was started. Arrhythmias were reported in 2 of these patients.¹

(b) Antimuscarinics

Premature labour in a 39-year-old woman who was 28 weeks pregnant was arrested with an intravenous infusion of ritodrine hydrochloride. Two weeks later, while she was on the maximum dose of ritodrine (300 micrograms/minute), her uterine contractions began again and she was scheduled for emergency caesarean section. The ritodrine was discontinued 40 minutes before the operation. It was noted in the operating room that she had copious oral secretions so she was given 100% oxygen by mask and 200 micrograms of intravenous **glycopyrronium (glycopyrrolate)**. Shortly afterwards she developed a supraventricular tachycardia (a rise in heart rate from 80 up to 180 bpm), which was converted to sinus tachycardia of 130 bpm when she was given intravenous propranolol 500 micrograms, in divided doses over several minutes.²

The reason for this reaction is not understood. Ritodrine alone has been responsible for tachyarrhythmias and one possible explanation for this interaction is that the effects of these two drugs were additive. Two other patients given intravenous ritodrine 6 mg over 3 minutes developed tachyarrhythmias when they were premedicated with **atropine**.³ Information is very limited and the interaction is not well established but some caution is clearly appropriate if both drugs are used. The authors of the first report advise avoidance.

Other sympathomimetics have also been seen to interact with antimuscarinics, see 'Inotropes and Vasopressors + Antimuscarinics', p.889.

(c) Cocaine

A study in 51 pregnant patients given ritodrine for premature labour found no evidence of an increase in adverse effects in 17 of the patients who had been abusing cocaine.⁴

4. Darby MJ, Mazdisnian F. Does recent cocaine use increase the risk of side effects with β -adrenergic tocolysis? *Am J Obstet Gynecol* (1991) 164, 377.

Sodium oxybate + Miscellaneous

Patients taking sodium oxybate should not drink alcoholic beverages with sodium oxybate. Additive CNS depressant effects are predicted with other CNS depressant drugs, and concurrent use of sedative hypnotics should be avoided. No pharmacokinetic interaction occurs with omeprazole, protriptyline, zolpidem or modafinil, but a pharmacodynamic interaction cannot be ruled out. Food markedly delays and modestly reduces the absorption of sodium oxybate.

Clinical evidence, mechanism, importance and management

(a) Alcohol and other CNS depressants

Sodium oxybate is the sodium salt of **gamma hydroxybutyrate (GHB)** a CNS depressant substance with well known abuse potential. When used clinically it is predicted to have additive effects with alcohol and other CNS depressants and the manufacturers specifically say it should not be used with these.^{1,2} Patients should be warned not to drink alcoholic beverages while taking sodium oxybate.^{1,2}

1. Antidepressants. The manufacturer notes that there was no pharmacokinetic interaction between sodium oxybate and **protriptyline**, but that the possibility of a pharmacodynamic interaction was not assessed.^{1,2} The UK manufacturer states that the rate of adverse effects was increased when sodium oxybate was given with **tricyclic antidepressants**.¹

2. Barbiturates. The UK manufacturer specifically contraindicates the use of sodium oxybate in patients taking barbiturates.¹

3. Benzodiazepines and related hypnotics. The manufacturer states that sodium oxybate should not be given in combination with sedative hypnotics,^{1,2} and the UK manufacturer specifically cautions against the concurrent use of benzodiazepines because of the possibility of increased risk of respiratory depression.¹

The manufacturer notes that there was no pharmacokinetic interaction between sodium oxybate and **zolpidem**, but that the possibility of a pharmacodynamic interaction was not assessed,¹ and cannot be ruled out.²

4. Opioids. The UK manufacturer specifically contraindicates the use of sodium oxybate in patients taking opioids.¹

(b) Food

In a study in 34 healthy subjects 4.5 g of sodium oxybate solution was given after a high-fat meal. It was found that food delayed the time to maximum level from 0.75 to 2 hours, reduced the maximum level by 58% and reduced the AUC by 35%, when compared with the fasted state.³ The first dose of sodium oxybate should be taken at least 2 to 3 hours after the evening meal, and patients should always try to keep the same timing of dosing in relation to meals.^{1,2}

(c) Modafinil and other CNS stimulants

The manufacturer notes that there was no pharmacokinetic interaction between sodium oxybate and **modafinil**, but that the possibility of a pharmacodynamic interaction was not assessed.^{1,2} About 80% of patients in clinical studies were also taking CNS stimulants.¹

(d) Proton pump inhibitors

In a crossover study in 44 healthy subjects pretreatment with **omeprazole** 40 mg daily for 5 days did not alter the pharmacokinetics of a single 3-g dose of sodium oxybate. There was no difference in the frequency and severity of adverse events.⁴ No sodium oxybate dose adjustment is therefore expected to be needed in patients taking proton pump inhibitors.¹

Sodium polystyrene sulfonate + Antacids

The concurrent use of antacids with sodium polystyrene sulfonate can result in metabolic alkalosis. Use with aluminium hydroxide has resulted in intestinal obstruction.

Clinical evidence, mechanism, importance and management

A man with hyperkalaemia developed metabolic alkalosis when given 30 g of sodium polystyrene sulfonate with 30 mL of **magnesium hydroxide** mixture three times daily.¹ Alkalosis has also been described in a study in a number of patients given this cation exchange resin with **Maalox (magnesium/aluminium hydroxide)** and **calcium carbonate**.² The suggested reason is that the breakdown of the **magnesium hydroxide** usually requires equal amounts of bicarbonate and hydrogen ions, and so does not cause any acid-base disturbance. However, when sodium polystyrene sulfonate is given, it binds the **magnesium**, while the hydroxide is neutralised by the hydrogen ions. This results in a relative excess of bicarbonate ions, which are absorbed, leading to metabolic alkalosis. This interaction appears to be established. Concurrent use should be undertaken with caution and serum electrolytes should be closely monitored. Administration of the resin rectally as an enema can avoid the problem.

In addition to alkalosis, the manufacturer also notes that concurrent use of **aluminium hydroxide** and the resin has resulted in intestinal obstruction due to 'concretions' of **aluminium hydroxide**.³ Caution is advised.

- Resonium A (Sodium polystyrene sulfonate). Sanofi-Aventis. UK Summary of product characteristics, February 2005.

Sodium polystyrene sulfonate + Sorbitol

Potentially fatal colonic necrosis may occur if sodium polystyrene sulfonate is given as an enema with sorbitol.

Clinical evidence

Five patients with uraemia developed severe colonic necrosis after being given enemas containing sodium polystyrene sulfonate and sorbitol for the treatment of hyperkalaemia. Four of the 5 died as a result. Associated studies in uraemic rats found that all of them died over a 2-day period after being given enemas of sodium polystyrene sulfonate with sorbitol. Extensive haemorrhage and transmural necrosis developed. No deaths occurred when enemas without sorbitol were given.¹

Mechanism

Not understood.

Importance and management

Information is very limited and the interaction is not firmly established, nevertheless its seriousness indicates that sodium polystyrene sulfonate should not be given as an enema in aqueous vehicles containing sorbitol. More study is needed. Note that the manufacturer advises against the concurrent use of both *oral* and rectal sorbitol with sodium polystyrene sulfonate, because of the risk of colonic necrosis.²

St John's wort (*Hypericum perforatum*) + Cimetidine

Cimetidine does not significantly alter the metabolism of the constituents of St John's wort, hypericin and pseudohypericin.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in healthy subjects taking St John's wort (*L1160*, Lichtwer Pharma) 300 mg three times daily found that, apart from a modest 25% increase in the AUC of pseudohypericin, cimetidine 1 g daily (in divided doses) did not significantly affect the pharmacokinetics of either the hypericin or pseudohypericin constituents of St John's wort. The available evidence therefore suggests that cimetidine is unlikely to affect the dose requirements of St John's wort.¹

Strontium ranelate + Miscellaneous

Food, dairy products and calcium compounds markedly reduce the absorption of strontium ranelate, and administration should be separated by at least 2 hours. Aluminium and magnesium antacids only slightly reduce strontium ranelate absorption. Strontium ranelate is predicted to reduce the absorption of the quinolones and the tetracyclines, and strontium should be stopped during courses of these antibacterials. Vitamin D does not affect strontium ranelate bioavailability.

Clinical evidence, mechanism, importance and management

(a) Antacids

The manufacturer notes that **aluminium/magnesium hydroxide** slightly reduced the absorption of strontium ranelate (AUC decreased by 20 to 25%) when given either at the same time or 2 hours before the strontium. However, when the antacid was given 2 hours *after* strontium, absorption was barely affected.¹ Therefore, the manufacturers recommend that antacids should be taken 2 hours after strontium ranelate. However, because it is also recommended that strontium ranelate is taken at bedtime, they say that, if this is impractical, concurrent intake is acceptable.¹ Note that **calcium**-containing antacids would have a greater effect, see (b) below, and concurrent intake would not be recommended.

(b) Food, Dairy products, and Calcium compounds

The manufacturers note that food, milk, dairy products, and calcium supplements reduce the bioavailability of strontium ranelate by about 60 to 70%, when compared with administration 3 hours after a meal.¹ This is because divalent cations such as calcium form complexes with strontium ranelate so preventing its absorption. Therefore, strontium ranelate should not be taken within 2 hours of eating, or presumably within 2 hours of any calcium compound. The manufacturer recommends that strontium ranelate should be taken at bedtime, at least 2 hours after eating.¹

(c) Quinolones and Tetracyclines

The manufacturer predicts that strontium will complex with quinolones and tetracyclines, so preventing their absorption. Because of this, they recommend that when treatment with quinolones or tetracyclines is required, strontium ranelate therapy should be temporarily suspended.¹

(d) Vitamin D

The manufacturer notes that vitamin D supplements had no effect on strontium ranelate bioavailability.¹

Sulfinpyrazone + NSAIDs

The uricosuric effects of sulfinpyrazone are not opposed by the concurrent use of flufenamic acid, meclofenamic acid or mefenamic acid.^{1,2} Consider also 'Aspirin or other Salicylates + Sulfinpyrazone', p.138).

- Robinson RG, Radcliff FJ. The effect of meclofenamic acid on plasma uric acid levels. *Med J Aust* (1972) 1, 1079–80.

Sulfinpyrazone + Probenecid

Probenecid reduces the urinary excretion of sulfinpyrazone, but the overall uric acid clearance remains unaltered.

Clinical evidence, mechanism, importance and management

A study in 8 patients with gout showed that while probenecid was able to inhibit the renal tubular excretion of sulfinpyrazone, reducing it by about 75%, the maximal uric acid clearance was about the same as when either drug was given alone.¹ There would therefore seem to be no advantage in using these drugs together. The possibility of an increase in the adverse effects of sulfinpyrazone does not seem to have been studied.

- Pere J, Dayton PG, Snell MM, Yu TF, Gutman AB. Studies of interactions among drugs in man at the renal level: probenecid and sulphinpyrazone. *Clin Pharmacol Ther* (1969) 10, 834–40.

Thyroid hormones + Antacids

A few reports describe reduced levothyroxine effects in patients given aluminium or magnesium-containing antacids.

Clinical evidence, mechanism, importance and management

A man with hypothyroidism corrected with **levothyroxine** 150 micrograms daily developed high serum TSH levels (a rise from 1.1 up to 36 mU/L) while taking an **aluminium/magnesium hydroxide** antacid (*Silain-Gel*), and on two subsequent occasions when rechallenged. The reasons are not understood. Although he remained asymptomatic throughout,¹ the rise in the levels of TSH indicated that the dosage of the **levothyroxine** had become insufficient in the presence of the antacid. Two similar cases have also been reported, where the presence of an **aluminium/magnesium** antacid or **magnesium oxide** reduced the response to **levothyroxine**. One patient required four times her normal dose of **levothyroxine**.²

The general importance of this interaction is not known, but be alert for the need to increase the **levothyroxine** dosage in any patient given antacids. More study is needed. See also 'calcium carbonate', (below), which can reduce levothyroxine effects.

Thyroid hormones + Antiepileptics

An isolated report describes a patient, previously stable taking **levothyroxine**, who developed clinical hypothyroidism when **phenytoin** was given. Both **carbamazepine** and **phenytoin** can reduce endogenous serum thyroid hormone levels, but clinical hypothyroidism caused by an interaction seems to be rare.

Clinical evidence

A patient with hypothyroidism had been successfully managed with 150 micrograms of **levothyroxine** daily for 4 years, developed hypothyroidism when given 300 mg of **phenytoin** daily. Doubling the **levothyroxine** dosage proved to be effective. Later this interaction was confirmed when stopping and restarting the **phenytoin** produced the same effect.¹

A number of other reports describe very significant reductions in endogenous markers of thyroid function in subjects and patients taking **phenytoin**^{2–5} or **carbamazepine**,^{4–6} but not **sodium valproate**.⁵ However, there seems to be only two cases in which reversible hypothyroidism was seen, one with **carbamazepine** and **phenytoin**, and the other with **carbamazepine** alone.⁷ There is also a report of an arrhythmia in a patient with hypothyroidism and rheumatic heart disease given **phenytoin**; this was attributed to the displacement of protein bound **levothyroxine** by **phenytoin** leading to an increase in free **levothyroxine** in the plasma.⁸ This report was later criticised by others, who suggested that the arrhythmia, if indeed there was one, was caused directly by the cardiac actions of **phenytoin**.^{9,10}

Mechanism

Both **phenytoin** and **carbamazepine** can increase the metabolism of endogenous thyroid hormones, thereby reducing their plasma levels. **Phenytoin** can also displace levothyroxine and triiodothyronine from thyroxine binding globulin.¹¹

Importance and management

Despite very clear evidence that both **carbamazepine** and **phenytoin** can cause a marked reduction in endogenous serum thyroid hormone levels, the development of clinical hypothyroidism seems to be very rare, and there seems to be only one case on record of an interaction between levothyroxine and **phenytoin**. There seems to be little reason for avoiding concurrent use, but the outcome should be monitored. Increase the levothyroxine dosage if necessary. Thyroid hormones + Barbiturates

An isolated report describes a reduction in the response to **levothyroxine** when a woman also took a barbiturate. See also 'Thyroid hormones + Antiepileptics', p.1281.

Clinical evidence, mechanism, importance and management

An elderly woman taking 300 micrograms of **levothyroxine** daily for hypothyroidism complained of severe breathlessness within a week of reducing her nightly dose of **Tuinal** (**secobarbital** 100 mg with **amobarbital** 100 mg) from two capsules to one capsule. She was subsequently found to be thyrotoxic. She became symptom-free again when the dosage of the **levothyroxine** was halved.¹ The reason for this effect is not known, but **phenobarbital** has been shown to reduce the serum levels of endogenous thyroid hormones in some studies,² and it seems possible that in this case these other two barbiturates acted in the same way, probably by enzyme induction. The general importance of this interaction is almost certainly small, but be alert for any evidence of changes in thyroid status if barbiturates are added or withdrawn from patients taking **levothyroxine**. Consider also 'Thyroid hormones + Antiepileptics', above.

Thyroid hormones + Calcium carbonate

The efficacy of **levothyroxine** can be reduced by calcium carbonate.

Clinical evidence

Twenty patients with hypothyroidism were given **levothyroxine**, to which calcium carbonate 1.2 g daily was then added for 3 months. While taking the calcium carbonate their mean free thyroxine levels fell from 16.7 to 15.4 picomol/L and rose again to 18 picomol/L when it was stopped. The mean total thyroxine levels over the same period were about 118, 111 and 120 nanomol/L, respectively, and the mean TSH levels were 1.6, 2.7 and 1.4 mU/L, respectively.¹

A woman with thyroid cancer taking **levothyroxine** 125 micrograms daily to suppress serum TSH levels had a reduced response (fatigue, weight gain) when she took **Tums** containing calcium carbonate, for the prevention of osteoporosis. She often took the two together. Over a 5-month period her serum TSH levels rose from 0.08 mU/L to 13.3 mU/L. Within 3 weeks of stopping the calcium carbonate, her serum TSH levels had fallen to 0.68 mU/L.² Other reports have described 4 patients who had elevations in their TSH levels while taking calcium carbonate concurrently with **levothyroxine**. All levels returned to normal when administration was separated by about 4 hours.^{2–4}

Mechanism

In vitro studies indicate that levothyroxine is adsorbed onto calcium carbonate when the pH is low (as in the stomach), which would reduce the amount available for absorption.¹

Importance and management

An established interaction, which seems to be of limited clinical significance. The study cited¹ shows that the mean reduction in the absorption of levothyroxine is quite small, but the case reports^{2,3} show that some individuals can experience a reduction in the absorption that is clinically im-

portant. Since it is impossible to predict which patients are likely to be affected significantly, the cautious approach would be to advise all patients to separate the dosages of the two preparations by at least 4 hours to avoid admixture in the gut. This interaction would be expected to occur with calcium carbonate in any form but it is not known whether other thyroid hormone preparations interact in the same way as levothyroxine.

Thyroid hormones + Ciprofloxacin

There is a report of unexplained hypothyroidism in two patients taking levothyroxine who had also been taking oral ciprofloxacin for 3 to 4 weeks.

Clinical evidence, mechanism, importance and management

An 80-year-old patient with advanced thyroid cancer taking **levothyroxine** 125 micrograms daily required treatment with oral ciprofloxacin 750 mg twice daily and intravenous dicloxacillin for osteomyelitis complicating a fracture. After 4 weeks of treatment she complained of increasing tiredness, and was found to have a markedly raised TSH level (10 times of the upper limit of normal). Increasing the **levothyroxine** dose to 200 micrograms daily did not have any effect on TSH, so the dose was returned to 125 micrograms. The ciprofloxacin was then stopped, and the thyroid function tests rapidly normalised.¹

Another woman stable taking **levothyroxine** 150 micrograms daily had a more than 10-fold increase in TSH levels after taking ciprofloxacin 500 mg twice daily for 3 weeks.¹ When administration of **levothyroxine** and ciprofloxacin was separated by 6 hours, thyroid function tests normalised, which suggests that concurrent administration somehow reduces the absorption of **levothyroxine**.

This interaction is not established, but the two cases suggest that long-term ciprofloxacin should be considered as a possible cause of hypothyroidism in patients taking **levothyroxine**. Further study is needed.

1. Cooper JG, Harboe K, Frost SK, Skadberg Ø. Ciprofloxacin interacts with thyroid replacement therapy. *BMJ* (2005) 330, 1002.

Thyroid hormones + Colestyramine

The absorption of thyroid extract, levothyroxine, and tri-iodothyronine from the gut is reduced by the concurrent use of colestyramine.

Clinical evidence

A patient with hypothyroidism, taking **levothyroxine**, had a fall in his basal metabolic rate when given colestyramine: this prompted a further study in two similar patients taking **thyroid extract** 60 mg daily or **levothyroxine sodium** 100 micrograms daily, and 5 healthy subjects. Colestyramine 4 g four times daily reduced their absorption of **levothyroxine**¹³¹, the amount recovered in the faeces being roughly doubled. One of the patients had a worsening of her hypothyroidism. Giving the **levothyroxine** 4 to 5 hours after the colestyramine reduced but did not completely prevent the interaction.¹

Another report describes a patient taking **levothyroxine** whose TSH levels rose when colestyramine was taken, and fell again when it was stopped, indicating an impairment of **levothyroxine** absorption.²

Mechanism

Colestyramine binds to levothyroxine in the gut, thereby reducing its absorption. Since levothyroxine probably also undergoes enterohepatic recirculation, continued contact with the colestyramine is possible and separating administration may not entirely eliminate the interaction.

Importance and management

An established interaction (although the documentation is very limited) and of clinical importance. *In vitro* tests show that **liothyronine** interacts similarly.¹ The interaction can be minimised by separating the dosages by 4 to 6 hours (but see 'Mechanism'). Even so, the outcome should be monitored so that any necessary thyroid hormone dosage adjustments can be made.

2. Harmon SM, Seifert CF. Levothyroxine-colestyramine interaction reemphasized. *Ann Intern Med* (1991) 115, 658–9.

Thyroid hormones + Grapefruit juice

In a pharmacokinetic study, grapefruit juice had little effect on the absorption of levothyroxine, suggesting a clinically relevant interaction is unlikely. However, there is one case of unexplained hypothyroidism in a patient taking levothyroxine, which resolved when grapefruit juice consumption was reduced.

Clinical evidence, mechanism, importance and management

A 36-year-old woman previously stable taking **levothyroxine** 100 micrograms daily and with a marked consumption of grapefruit juice (specific volumes not stated) had a very high TSH level even after an increase in her **levothyroxine** dose to 150 micrograms daily. When she was advised to drink less grapefruit juice, her TSH fell to within the normal range.¹

This case prompted a crossover study in 10 healthy subjects; however, grapefruit juice caused only a slight 11% reduction in the maximal increase in thyroxine after a single 600-microgram dose of **levothyroxine**. In this study, normal-strength grapefruit juice 200 mL was taken 3 times a day for 2 days, then on the third day, grapefruit juice 200 mL was taken one hour before, simultaneously with, and one hour after, **levothyroxine**.¹

The pharmacokinetic study established that grapefruit juice appears to have only small effects on **levothyroxine** levels, which suggests that a clinically relevant interaction is unlikely. However, consider this case in the event of an unexpected decreased response to **levothyroxine**.

1. Lilja JJ, Laitinen K, Neuvonen PJ. Effects of grapefruit juice on the absorption of levothyroxine. *Br J Clin Pharmacol* (2005) 60, 337–41.

Thyroid hormones + H₂-receptor antagonists

Cimetidine, but not ranitidine, causes a small reduction in the absorption of levothyroxine.

Clinical evidence, mechanism, importance and management

When 10 women with simple goitre were given 400 mg of **cimetidine** 90 minutes before a single capsule of **levothyroxine**, the absorption of **levothyroxine** was reduced over the first 4 hours by about 21%. The reasons are not understood. A single 300-mg dose of **ranitidine** was found not to affect the **levothyroxine** absorption in a matched group of 10 women.¹

The clinical importance of this interaction with **cimetidine** awaits assessment, but it seems unlikely to be generally significant.

1. Jonderko G, Jonderko K, Marcisz CZ, Kotulska A. Effect of cimetidine and ranitidine on absorption of [¹²⁵I] levothyroxine administered orally. *Acta Pharmacol Sin* (1992) 13, 391–4.

Thyroid hormones + HRT

HRT appears to increase the requirement for levothyroxine in some patients.

Clinical evidence

In 25 postmenopausal women taking stable doses of **levothyroxine** (for hypothyroidism or TSH suppression), the addition of hormone replacement therapy (**conjugated estrogens** 0.625 mg daily with or without **medroxyprogesterone acetate** 5 mg daily for 12 days each month)

decreased serum free thyroxine levels and increased TSH levels. The changes in TSH were clinically important in 10 of the 25 women, requiring increased doses of **levothyroxine**, although only one woman had symptoms of hypothyroidism.¹

Mechanism

Estrogens increase thyroxine binding-globulin. In women with normal thyroid function this does not alter free thyroxine levels or TSH levels,¹ as the thyroxine secretion can increase to accommodate the changes. However, in women with hypothyroidism who cannot compensate for the increased thyroxine binding, decreased free thyroxine and therefore increased TSH can result.

Importance and management

Although this study appears to be the only evidence of an interaction, it would now be prudent to monitor thyroid function several months after starting or stopping HRT to check levothyroxine requirements.

1. Arafah BM. Increased need for thyroxine in women with hypothyroidism during estrogen therapy. *N Engl J Med* (2001) 344, 1743–9.

Thyroid hormones + Imatinib

Imatinib appears to cause hypothyroidism in thyroidectomy patients taking levothyroxine.

Clinical evidence, mechanism, importance and management

Retrospective analysis of 11 patients taking **levothyroxine** and with thyroid cancer found that 8 patients who had previously undergone a total thyroidectomy developed markedly elevated TSH levels and were clinically hypothyroid after receiving treatment with imatinib. Despite a mean increase in the dose of **levothyroxine** of about 200%, hypothyroidism was reversed in only 3 patients. Thyroid function tests normalised on discontinuing imatinib. Conversely, no effect on thyroid status was seen in the 3 patients who had not had their thyroid gland removed.¹

The authors postulated that imatinib might increase the clearance of the thyroid hormones thyroxine and tri-iodothyronine by induction of glucuronosyltransferases (UGTs).¹ Patients who have undergone a thyroidectomy cannot respond to these changes and therefore become hypothyroid.

The findings from this study appear to be established. TSH levels should be closely monitored in thyroidectomy patients taking **levothyroxine** if they are given imatinib, anticipate the need to increase the **levothyroxine** dose. The authors suggest that in thyroidectomy patients the dose of **levothyroxine** should be doubled before starting imatinib.¹

1. de Groot JWB, Zonnenberg BA, Plukker JTM, van Der Graaf WTA, Links TP. Imatinib induces hypothyroidism in patients receiving levothyroxine. *Clin Pharmacol Ther* (2005) 78, 433–8.

Thyroid hormones + Iron compounds

Ferrous sulfate causes a reduction in the effects of levothyroxine in patients with hypothyroidism.

Clinical evidence

Fourteen patients with primary hypothyroidism had an increase in TSH levels from 1.6 to 5.4 mU/L when given **ferrous sulfate** 300 mg daily for 12 weeks along with their usual **levothyroxine** dose. The symptoms of hypothyroidism in 9 patients worsened.¹ In another report a woman with hypothyroidism, taking **levothyroxine**, had a very marked rise in TSH levels when she took **ferrous sulfate**. Her **levothyroxine** dosage needed to be raised from 175 to 200 micrograms daily.²

Mechanism

The addition of iron to levothyroxine *in vitro* was found to produce a poorly soluble purple iron-levothyroxine complex suggesting that this might also occur in the gut.¹

Importance and management

Information is limited to these reports but it appears to be a clinically important interaction. Monitor the effects of concurrent use and separate the doses of ferrous sulfate and levothyroxine by 2 hours or more on the assumption that reduced absorption accounts for this interaction. Monitor well. The same precautions would seem appropriate with any other iron compound.

2. Schlienger JL. Accroissement des besoins en thyroxine par le sulfate de fer. *Presse Med* (1994) 23, 492.

Thyroid hormones + Protease inhibitors

A man needed to have his levothyroxine dosage doubled when he took ritonavir/saquinavir, and another woman possibly had a similar reaction when given indinavir then nelfinavir. Conversely, another woman needed a markedly reduced dose of levothyroxine when given indinavir.

Clinical evidence, mechanism, importance and management

An HIV-positive man, taking **levothyroxine** for autoimmune thyroiditis, developed an enlarged thyroid gland and marked lethargy about a month after his HIV treatment was changed to include stavudine, lamivudine, **saquinavir** and **ritonavir**. It became necessary to double his maintenance dose of levothyroxine to re-stabilise him. When the **ritonavir** and **saquinavir** were withdrawn and replaced by **indinavir**, the patient was able to go back to the original dose of **levothyroxine**. It is thought that this interaction occurred because **ritonavir** increases the activity of the glucuronosyl transferases, which are concerned with the metabolism (conjugation) of **levothyroxine**.¹

Although this case suggested that **indinavir** did not interact with **levothyroxine**, a further case suggests the opposite. A 36-year-old HIV-positive woman taking **levothyroxine** 750 micrograms daily (following partial thyroid gland destruction for Grave's disease) was started on stavudine, lamivudine and **indinavir**. After about 7 weeks she presented with symptoms of hyperthyroidism (including nervousness, palpitations and weight loss). Her serum TSH was low and thyroxine was high. After stepped dose decreases she was finally restabilised on **levothyroxine** 120 micrograms daily, with normal thyroid indices. The authors postulated that **indinavir** reduces the activity of glucuronosyl transferases (in contrast to **ritonavir**).²

Conversely, in another woman a 4-week course of antiretroviral prophylaxis, including 2 weeks of **indinavir** then 2 weeks of **nelfinavir**, tended to reduce the efficacy of **levothyroxine** 125 micrograms daily. She was fatigued and had elevated TSH and hypercholesterolaemia, which resolved after the antiretroviral therapy was stopped.³

Direct information of the interactions of protease inhibitors and thyroid hormones seems limited. Whether or not an interaction occurs seems to depend on the individual protease inhibitor, how it affects glucuronidation, and how much remaining thyroid function a patient has.³ Until more is known about this interaction it would seem prudent to monitor thyroid function more closely if a protease inhibitor is given to a patient with pre-existing hypothyroidism.

3. Nerad JL, Kessler HA. Hypercholesterolemia in a health care worker receiving thyroxine after postexposure prophylaxis for human immunodeficiency virus infection. *Clin Infect Dis* (2001) 32, 1635–6.

Thyroid hormones + Proton pump inhibitors

In one study, patients who had been taking levothyroxine and omeprazole for a least 6 months required a modest 37% increase in the median levothyroxine dose required to suppress TSH levels to those seen before starting omeprazole. Conversely, in a pharmacokinetic study, pantoprazole did not alter the absorption of a single dose of levothyroxine.

Clinical evidence

In a randomised, crossover study in 20 healthy subjects, pre-treatment with **pantoprazole** 40 mg daily for one week had no effect on the AUCs of TSH or thyroxine after a single 4-micrograms/kg dose of **levothyroxine**.¹

In contrast, in a non-randomised study in 10 women with multinodular goitre and gastroesophageal reflux disease taking a stable dose of **levothyroxine** to suppress thyroid growth, the use of **omeprazole** 40 mg daily for at least 6 months caused a variable increase in TSH levels (median 1.7 mU/L versus 0.1 mU/L before treatment). At that time, the dose of **levothyroxine** was increased to suppress TSH levels: this required a median dose of **levothyroxine** of 2.16 micrograms/kg compared with 1.58 micrograms/kg before starting **omeprazole** (a 37% increase).²

Mechanism

A decrease in gastric acidity might decrease levothyroxine absorption. Supporting this is the finding that in patients with impaired gastric acid secretion the required dose of levothyroxine was 22 to 34% higher than in patients free of gastric disease.² However, this effect could be due to the disease rather than gastric acid *per se*.³

Importance and management

An interaction between levothyroxine and proton pump inhibitors is not established. The pharmacokinetic study with pantoprazole did not reveal a change in levothyroxine absorption, whereas the study in patients who had been taking omeprazole for 6 months suggested that patients may need a modest increase in levothyroxine dose. Bear in mind the possibility of an interaction if a patient starting a proton pump inhibitor shows signs of reduced levothyroxine efficacy. Any interaction may take several months to develop. Further study is needed.

Thyroid hormones + Raloxifene

There are two reports of patients who developed increased levothyroxine requirements after taking raloxifene for a number of months.

Clinical evidence

A 79-year-old woman taking **levothyroxine** 150 micrograms daily developed elevated TSH levels and symptoms of hypothyroidism within 2 to 3 months of starting to take raloxifene 60 mg daily. Over the next 6 months the **levothyroxine** dose was progressively increased to 300 micrograms daily without normalising TSH levels. This patient took the raloxifene early in the morning at the same time as the **levothyroxine**. Subsequently, separating the dose of raloxifene and **levothyroxine** by 12 hours led to a drop in TSH levels. In a single-dose study in this patient, serum thyroxine levels were reduced when **levothyroxine** 1 mg was given with raloxifene 60 mg, and separating the doses of raloxifene and **levothyroxine** by 12 hours was found to reduce TSH levels.¹ Another very similar case has been reported in a 47-year-old woman, which also, resolved on separating administration by 12 hours.²

Mechanism

Raloxifene is known to increase levels of thyroxine binding globulin, which results in increased levels of total thyroxine, without altering free thyroxine.³ However, this is not likely to be the mechanism in the cases described, since separating the doses would not reduce any effect by this mechanism. It appears that raloxifene reduced the absorption of levothyroxine, but the mechanism for this is not known.

Importance and management

The interaction is not established, but the similar outcomes in both case reports suggest that an interaction may occur. Further study is needed, but

until then it would be prudent to monitor TSH levels in patients taking levothyroxine and starting raloxifene, especially if they complain of tiredness. If TSH levels are raised, try separating administration by 12 hours before increasing the levothyroxine dose.

Thyroid hormones + Rifampicin (Rifampin)

Two case reports suggest that rifampicin might possibly reduce the effects of thyroid hormones.

Clinical evidence, mechanism, importance and management

A woman with Turner's syndrome, who had undergone a total thyroidectomy and who was being treated with **levothyroxine** 100 micrograms daily, had a marked fall in serum **levothyroxine** levels and free **levothyroxine** index with a dramatic rise in TSH levels when given rifampicin. However, no symptoms of clinical hypothyroidism developed, and the drop in serum **levothyroxine** occurred prior to starting rifampicin, which may reflect the clinical picture of an acute infection.¹ Another case describes a *fall* in TSH levels when rifampicin was discontinued.²

A possible reason for the changes is that rifampicin, a potent enzyme inducer, can markedly increase the metabolism of many drugs and thereby reduce their effects. Rifampicin has been found to reduce endogenous serum thyroxine levels in healthy subjects³ and possibly in patients.²

There seem to be no reports of adverse effects in other patients given both drugs and the evidence for this interaction is by no means conclusive. Although rifampicin can affect thyroid hormones, it appears that healthy individuals can compensate for this. Since hypothyroid patients may not be able to compensate in the same way, bear this interaction in mind if rifampicin is given to a patient taking **levothyroxine**.

Thyroid hormones + Sertraline

Limited evidence suggests that the effects of levothyroxine can be opposed in some patients by sertraline.

Clinical evidence, mechanism, importance and management

Nine patients with hypothyroidism were noted to have elevated TSH levels (indicating a decrease in the efficacy of their treatment with **levothyroxine**, when they also received sertraline. Two other patients with thyroid cancer, whose TSH levels had been deliberately depressed, developed TSH levels in the normal range while taking sertraline. None of the patients showed any signs of hypothyroidism at the time, and all of them had been taking the same dose of **levothyroxine** for at least 6 months. TSH levels of up to almost 17 mU/L (normal range 0.3 to 5 mU/L) were seen in some patients. The **levothyroxine** dosages were increased by 11 to 50%, until the TSH levels were back to normal. The authors of this report say that they know of 3 patients whose TSH levels were unaltered by sertraline.¹

The manufacturers of sertraline say that their early-alert safety database to the end of July 1997 had identified 14 cases of hypothyroidism where a possible relation to sertraline could not be excluded. Seven of the patients were taking **levothyroxine**.²

The mechanism of this interaction (if such it is) is not known, but these cases draw attention to the need to monitor the effects of adding sertraline

in patients taking **levothyroxine**, the dosage of which may need to be increased. More study is needed.

Thyroid hormones + Sodium polystyrene sulfonate

A woman with hypothyroidism taking levothyroxine relapsed when she took sodium polystyrene sulfonate.

Clinical evidence

A woman taking **levothyroxine** 150 micrograms daily for hypothyroidism, following total thyroidectomy, later developed renal impairment and required dialysis. She was also taking digoxin, clofibrate, calcium carbonate, ferrous sulfate, nicotinic acid, folic acid, and magnesium sulfate. Because of persistent hyperkalaemia she started taking sodium polystyrene sulfonate 15 g daily. After 6 months, she developed lethargy, a hoarse voice, facial fullness and weight gain (all symptoms of hypothyroidism). These symptoms resolved within 6 weeks of raising the **levothyroxine** dosage to 200 micrograms daily and separating its administration from the sodium polystyrene sulfonate by 10 hours (previously taken at the same time as the **levothyroxine**).¹

Mechanism

Sodium polystyrene sulfonate is a cation-exchange resin that is used to bind potassium ions in exchange for sodium. An *in vitro* study found that when levothyroxine 200 micrograms was dispersed in 100 mL water with 15 g sodium polystyrene sulfonate, the concentration of the levothyroxine at pH 2 fell by 93% and at pH 7 by 98%.¹ This drop in concentration would almost certainly occur in the gut as well, thereby markedly reducing the amount of levothyroxine available for absorption.

Importance and management

Information seems to be limited to this study, but the interaction would appear to be of general importance. Separate the dosages of levothyroxine and sodium polystyrene sulfonate as much as possible (10 hours seems to be effective) and monitor the thyroid function to confirm that this is effective.

Thyroid hormones + Statins

An isolated report describes raised serum thyroid hormone levels and evidence of thyrotoxicosis in a man taking levothyroxine with lovastatin. In contrast another isolated case report describes hypothyroidism in a woman taking levothyroxine with lovastatin. Another report describes reduced efficacy of levothyroxine in two patients taking simvastatin, one of whom was successfully treated with pravastatin.

Clinical evidence, mechanism, importance and management

(a) Lovastatin

A 54-year-old diabetic man taking 150 micrograms of **levothyroxine** daily for Hashimoto's thyroiditis, and a number of other drugs (gemfibrozil, clofibrate, propranolol, diltiazem, quinidine, aspirin, dipyridamole, insulin) started taking lovastatin 20 mg daily. Weakness and muscle aches (with a normal creatinine phosphokinase) developed within 2 to 3 days and over a 27-day period he lost 10% of his body weight. His serum **levothyroxine** levels rose from 11.3 to 27.2 micrograms/dL. The author of

the report postulated that the lovastatin may have displaced the thyroid hormones from their binding sites, thereby increasing their effects and causing this acute thyrotoxic state. It was suggested that the patient did not have any cardiac symptoms because of his pre-existing drug regimen.¹

In contrast, a woman with goitrous hypothyroidism due to Hashimoto's thyroiditis, which was being treated with 125 micrograms of **levothyroxine sodium** daily, developed evidence of hypothyroidism (elevated TSH) on two occasions while taking lovastatin 20 or 60 mg daily. No clinical signs of hypothyroidism developed, apart from some increased fatigue, and possibly an increased sensitivity to insulin. The author suggested that lovastatin may have influenced the absorption or clearance of **levothyroxine**.²

When the second report was published, the manufacturers of lovastatin reported that at that time (August 1989) more than 1 million patients had taken lovastatin, and hypothyroidism had only been reported in 3 patients.³ It seems that any interaction is a very rare event and consequently unlikely to happen in most patients. No special precautions would therefore seem to be necessary.

(b) Simvastatin

A 75-year-old woman who had been stable taking **levothyroxine** 800 micrograms weekly for many years had a gradual increase in TSH levels and increasing tiredness after starting to take simvastatin 10 mg daily. After 4 months the **levothyroxine** dose was increased to 900 micrograms daily, but the patient's symptoms had not improved in 2 weeks and the simvastatin was stopped. The patient's symptoms gradually resolved, and the dose of levothyroxine was reduced back to the previous level.⁴

Another patient, who had recently started taking **levothyroxine** 50 micrograms daily, because of rising TSH levels, was also given simvastatin 10 mg daily. TSH levels continued to increase, so the simvastatin was stopped, and the TSH levels decreased to the normal range within 4 weeks without the need for an alteration in the **levothyroxine** dose. This patient was subsequently treated with **pravastatin** without a change in thyroid status.⁴

The authors conclude that any interaction must be extremely rare given the frequent use of simvastatin and **levothyroxine**.⁴ No special precautions would appear to be required on concurrent use, but bear the possibility of this interaction in mind in the event of an unexpected response to treatment.

Thyroid hormones + Sucralfate

An isolated report describes a marked reduction in the effects of levothyroxine in a patient taking sucralfate, whereas a subsequent study in patients did not find any interaction.

Clinical evidence, mechanism, importance and management

A woman with hypothyroidism did not respond to **levothyroxine** despite taking 4.8 micrograms/kg daily while taking sucralfate (dose not stated). Her response remained inadequate (TSH levels high, thyroxine levels low) even when the **levothyroxine** was taken 2.5 hours after the sucralfate, but when **levothyroxine** was taken 4.5 hours before the sucralfate, the thyroxine and TSH levels gradually became normal. A later *in vitro* study demonstrated that sucralfate binds strongly to **levothyroxine**, and it is presumed that this can also occur in the gut, thereby reducing its absorption.¹ However, sucralfate 1 g daily taken with **levothyroxine** in the morning for 6 weeks did not alter levels of thyroxine or TSH in 10 patients with hypothyroidism taking stable doses of levothyroxine.²

This seems to be the first and only report of this interaction, and its findings were not backed up by the subsequent study. Nevertheless, it might

be prudent not to take sucralfate until a few hours after the **levothyroxine**. Patients should be advised accordingly and the response well monitored.

Tizanidine + Antihypertensives

Tizanidine may increase the effects of antihypertensive drugs. There are two case reports of severe hypotension with lisinopril. The manufacturer of tizanidine contraindicates the concurrent use of α_2 -adrenergic agonists (e.g. clonidine).

Clinical evidence

A 10-year-old child taking **lisinopril** developed severe hypotension within a week of starting to take tizanidine.¹ Similarly, a 48-year-old stroke patient taking **amlodipine**, **nimodipine**, **lisinopril**, and **labetalol**, which had been added sequentially to control hypertension, had a dramatic reduction in blood pressure (from 130/85 to 66/42 mmHg) within 2 hours of her first dose of tizanidine 2 mg. She was given dopamine to maintain her blood pressure, and tizanidine and all the antihypertensives were withdrawn. Later **labetalol**, **amlodipine**, **nimodipine** and tizanidine were successfully resumed without producing similar problems.²

Mechanism

Tizanidine is a centrally acting α_2 -adrenergic agonist structurally related to clonidine and can cause dose related hypotension (66% of patients given a single 8-mg dose of tizanidine had a 20% reduction in blood pressure). This can result in bradycardia, dizziness or light-headedness, and rarely syncope. The antihypertensive effects of tizanidine are said to be less than one-tenth of those of clonidine.³ These effects are expected to be additive with other antihypertensive drugs. However, in the cases with lisinopril, it was suggested that ACE inhibition, combined with the alpha-agonist effects of tizanidine prevented the usual sympathetic response to hypotension (that is, it was not thought to be due to simple additive hypotensive effects).^{1,2}

Importance and management

Tizanidine alone can cause hypotension, an effect which is usually minimised by titration of the dose. Patients should be warned about this effect. Because of this, the manufacturers caution that tizanidine might increase the effects of antihypertensive drugs, including **diuretics**, and recommend caution on concurrent use. This is a prudent precaution. The US manufacturer specifically states that tizanidine (an α_2 -adrenergic agonist that is structurally related to clonidine) should not be used with other α_2 -adrenergic agonists [e.g. **clonidine**, **methyl dopa**].³

The UK manufacturers also say that the concurrent use of **beta blockers** may potentiate bradycardia and hypotension.⁴

Tizanidine + CYP1A2 inhibitors

Fluvoxamine causes a very marked 33-fold increase in tizanidine levels with a consequent increase in hypotensive and sedative effects. The combination is potentially hazardous and should be avoided. Ciprofloxacin markedly increases tizanidine levels and adverse effects, and particular caution is required if this combination is considered essential. Combined oral contraceptives increase tizanidine levels fourfold and might increase adverse effects. Other inhibitors of CYP1A2 are predicted to interact similarly.

Clinical evidence

(a) Ciprofloxacin

In a placebo-controlled, crossover study in 10 healthy subjects ciprofloxacin 500 mg twice daily for 3 days markedly increased the AUC of a single 4-mg dose of tizanidine by tenfold and the maximum level by sevenfold, without significantly affecting the half-life. The hypotensive and sedative effects of tizanidine were also markedly increased by ciprofloxacin.¹

A 45-year-old Japanese woman with multiple sclerosis taking tizanidine 3 mg daily had a reduction in blood pressure (from 124/88 to 102/74 mmHg) and heart rate (from 86 to 58 bpm) shortly after starting to take ciprofloxacin 400 mg daily. After 2 days she complained of drowsiness and her blood pressure was 92/54 mmHg.² Retrospective analysis revealed 8 patients who had received tizanidine and ciprofloxacin concurrently. In these patients, the mean reduction in blood pressure on starting ciprofloxacin was 21.3/15.4 mmHg, and the heart rate reduction was 14.9 bpm. Adverse effects attributable to tizanidine occurred in three of the patients.²

(b) Fluvoxamine

In a placebo-controlled, crossover study in 10 healthy subjects fluvoxamine 100 mg once daily for 4 days very markedly increased the AUC of a single 4-mg dose of tizanidine by 33-fold and the maximum level by 12-fold. The elimination half-life was prolonged from 1.5 to 4.3 hours. The hypotensive and sedative effects of tizanidine were also markedly increased by fluvoxamine, with all of the 10 subjects somnolent and dizzy for 3 to 6 hours.³

A 70-year-old Japanese woman started taking tizanidine 3 mg daily 15 days after starting fluvoxamine 100 mg increased to 150 mg daily. Her heart rate dropped from about 85 bpm to a range of 56 to 60 bpm. After tizanidine was stopped, the symptoms improved immediately.⁴ Retrospective analysis revealed 23 patients who had received tizanidine with fluvoxamine. Of these patients, 6 had adverse effects including low heart rate, dizziness, drowsiness and hypotension. The patients with adverse effects were, on average, taking higher doses of fluvoxamine and tizanidine than those without adverse effects.⁴

(c) Oral contraceptives

In a study in 15 healthy women taking a combined oral contraceptive (**ethinylestradiol/gestodene**), the AUC of a single 4-mg dose of tizanidine was 3.9-fold higher than in 15 healthy women not taking an oral contraceptive, without any difference in the elimination half-life. In addition, the blood pressure-lowering effect of tizanidine was increased by 12/8 mmHg in the oral contraceptive users.⁵ The manufacturer also notes that retrospective analysis of population pharmacokinetic data showed that the clearance of tizanidine is about 50% lower in women taking oral contraceptives.^{6,7}

(d) Rofecoxib

In a placebo-controlled, crossover study in 9 healthy subjects rofecoxib 25 mg daily for 4 days markedly increased the AUC of a single 4-mg dose of tizanidine by 13.6-fold and the maximum level by 6.1-fold. The hypotensive and sedative effects of tizanidine were also markedly increased by rofecoxib. There was no evidence of QT prolongation in this study.⁸

An otherwise healthy 59-year-old woman developed extreme sinus bradycardia (30 bpm) with chest pain and acute right heart failure while taking tizanidine, diclofenac and rofecoxib. This resolved promptly after stopping the medication.⁹ Note that rofecoxib was generally withdrawn worldwide in 2004 because of its cardiovascular adverse effects, but these data are included here for completeness.

Mechanism

Tizanidine is a substrate of the cytochrome P450 isoenzyme CYP1A2, which undergoes substantial presystemic metabolism by this isoenzyme. Ciprofloxacin appears to inhibit mainly the presystemic metabolism leading to increased absorption, as reflected by the increase in maximum level without a change in elimination half-life. Rofecoxib and fluvoxamine inhibited both presystemic metabolism and the elimination phase. Fluvoxamine, which is a known potent inhibitor of CYP1A2, had the most marked effect. The contraceptive steroids were modest inhibitors of CYP1A2 by comparison.

Importance and management

These pharmacokinetic interactions are well established, and clinically important. The common adverse effects of tizanidine, such as hypotension and sedation, are dose related, and consequently the manufacturers recommend starting with a low dose of tizanidine (2 or 4 mg) and carefully titrating to the usual maximum of 24 mg daily, and not exceeding 36 mg daily.^{6,7} This represents a maximum 18-fold variation in dosage. **Fluvoxamine** increases the exposure to tizanidine by a mean of 33-fold, which, broadly speaking, changes a 2 mg dose into a 66 mg dose, which is far higher than the maximum recommended dose. For this reason, the authors of one of the studies conclude that the combination is potentially hazardous and should be avoided.³ The US manufacturer also contraindicates the combination.⁷ Given the available data this is sensible advice. Note that other **SSRIs** are generally not considered to inhibit CYP1A2, see 'Theophylline + SSRIs', p.1197, and may therefore be suitable alternatives to fluvoxamine.

For **ciprofloxacin**, there is a marked tenfold increase in exposure to tizanidine, with a consequent increase in adverse effects. Some authors recommend that this combination be avoided,² whereas others recommend caution.¹ The US manufacturer contraindicates the combination,⁷ whereas the UK manufacturers do not mention this potential interaction.⁶ If ciprofloxacin is considered the most appropriate antibacterial to use in a patient already taking tizanidine, anticipate the need to reduce the tizanidine dose before starting the ciprofloxacin, and closely monitor adverse effects: starting ciprofloxacin may cause marked hypotension, bradycardia, and sedation. Other quinolones also inhibit CYP1A2, but to varying degrees, see 'Table 33.4', (p.1193).

For **combined oral contraceptives**, the increase in exposure to tizanidine is a more moderate fourfold. The manufacturer states that clinical response or adverse effects might occur at lower doses of tizanidine in patients taking oral contraceptives,⁶ and that during dose titration, individual doses should be reduced.⁷ Care is needed.⁷

In addition, the US manufacturer also recommends caution if tizanidine is given with other inhibitors of CYP1A2, of which they mention **amiodarone**, **mexiletine**, **propafenone**, **cimetidine** and **ticlopidine**.⁷ For a list of clinically important CYP1A2 inhibitors, see 'Table 1.2', (p.4).

Tizanidine + Miscellaneous

The sedative effects of tizanidine and other sedative drugs and alcohol are additive. Increased bradycardia might occur with digoxin. It is unclear whether tizanidine prolongs the QT interval in humans. No interaction occurs with paracetamol (acetaminophen).

Clinical evidence, mechanism, importance and management

(a) CNS depressants

One of the most common adverse effects of tizanidine is somnolence or drowsiness (occurring in up to 50% of patients¹) for which reason the manufacturers warn about the possibility of increased sedation with other **sedative drugs**, and **alcohol**.^{2,3} In addition to additive sedative effects, **alcohol** increased the AUC of tizanidine by about 20% and its maximum level by 15%, which was associated with an increase in adverse effects of tizanidine.³ Patients should be warned.

(b) Digoxin

Tizanidine alone can cause bradycardia.^{2,3} The UK manufacturers say that the concurrent use of digoxin may potentiate bradycardia.²

(c) Drugs that prolong the QT interval

The US manufacturer information states that prolongation of the QT interval and bradycardia were noted in chronic toxicity studies in *dogs* at doses equal to the maximum dose.³ The UK information states that caution should be exercised when tizanidine is prescribed with drugs known to increase the QT interval.² In one pharmacological interaction study in healthy subjects, there was no evidence of QT prolongation either with tizanidine 4 mg, or almost 14-fold increased tizanidine levels caused by 'rofecoxib', (p.1286), despite increased bradycardia and hypotension.⁴ This suggests that a clinically significant interaction resulting in QT-prolongation is unlikely.

(d) Paracetamol

In 20 healthy subjects, no clinically significant interaction occurred between 325 mg of paracetamol (acetaminophen) and 4 mg of tizanidine.¹

4. Backman JT, Karjalainen MJ, Neuvonen M, Laitila J, Neuvonen PJ. Rofecoxib is a potent inhibitor of cytochrome P450 1A2: studies with tizanidine and caffeine in healthy subjects. *Br J Clin Pharmacol* (2006) 62, 345–57.

Tizanidine + Rifampicin

Rifampicin moderately decreases the plasma concentrations of tizanidine.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study in 10 healthy subjects, pre-treatment with rifampicin 600 mg daily for 5 days moderately reduced the AUC and peak level of a single 4-mg dose of tizanidine given on day 6 by about 50%, without altering the half-life.¹

Rifampicin appears to be only a weak inducer of the cytochrome P450 isoenzyme CYP1A2, by which tizanidine is metabolised.¹

Rifampicin moderately reduces the levels and effects of tizanidine. Because tizanidine dose is titrated to effect, this is probably not that clinically important. A small increase in dose might be required.

1. Backman JT, Granfors MT, Neuvonen PJ. Rifampicin is only a weak inducer of CYP1A2-mediated presystemic and systemic metabolism: studies with tizanidine and caffeine. *Eur J Clin Pharmacol* (2006) 62, 451–61.

Trientine + Miscellaneous

Trientine can possibly chelate with iron thereby reducing its absorption. On theoretical grounds a similar chelation interaction may occur with calcium and magnesium antacids and mineral supplements.

Clinical evidence, mechanism, importance and management

(a) Iron compounds

Trientine is a copper chelating agent used for Wilson's disease. One of the adverse effects of trientine is that it can cause iron deficiency, probably because it chelates with iron in the gut and thereby reduces its absorption. It is usual to make good this iron deficiency where necessary by giving an iron supplement. The manufacturers suggest that the iron supplement should be given at a different time of the day from trientine to minimise their admixture in the gut.^{1,2} A separation of at least 2 hours is recommended.²

(b) Other mineral supplements and antacids

Trientine may be inactivated by metal binding in the gastrointestinal tract. The UK manufacturers say that there is no evidence that **calcium** or **magnesium antacids** alter the efficacy of trientine, but it is good practice to separate their administration.¹ The US manufacturers say that, in general, mineral supplements should not be given with trientine. They say that it is

important that trientine is taken at least one hour apart from any other drug or **milk**.²

Tyramine + Cimetidine

A woman taking cimetidine experienced a severe headache and hypertension when she drank Bovril and ate some cheese.

Clinical evidence, mechanism, importance and management

A 77-year-old woman with hiatus hernia, who had been taking cimetidine 400 mg four times daily for 3 years, experienced a severe frontal headache and hypertension, which appeared to be related to the ingestion of a cup of **Bovril** and some **English cheddar cheese**, both of which can contain substantial amounts of tyramine.¹ Although the authors point out the similarity between this reaction and that seen in patients on MAOIs who eat tyramine-rich foods (see 'MAOIs or RIMAs + Tyramine-rich foods', p.1153), there is no satisfactory explanation for what occurred. They note that she was also taking salbutamol (another sympathomimetic) but rule out any contribution from this drug.

This is an isolated report and there is no reason why in general patients taking cimetidine should avoid tyramine-rich foods.

1. Griffin MJ, Morris JS. MAOI-like reaction associated with cimetidine. *Drug Intell Clin Pharm* (1987) 21, 219.

Urinary antimuscarinics; Darifenacin + CYP3A4 inhibitors

Ketoconazole markedly increases darifenacin levels, whereas erythromycin and fluconazole have only a modest effect on darifenacin levels.

Clinical evidence

(a) Azoles

The manufacturers note that, in a study in 16 healthy subjects, **ketoconazole** 400 mg daily for 6 days markedly increased the steady-state AUC of darifenacin 30 mg once daily by about tenfold.^{1,2} The UK manufacturers also note that **ketoconazole** 400 mg caused a fivefold increase in the AUC of a 7.5-mg dose of darifenacin.³

Fluconazole 200 mg then 100 mg daily had much less effect, causing an 84% increase in the steady-state AUC of darifenacin 30 mg once daily.^{1,2}

(b) Erythromycin

The manufacturers note that erythromycin 500 mg daily increased the steady-state AUC of darifenacin 30 mg once daily by 95% in a study in healthy subjects.^{1,2}

Mechanism

Darifenacin is principally metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a potent inhibitor, and erythromycin and fluconazole are moderate inhibitors.

Importance and management

Although the clinical relevance of these pharmacokinetic interactions have not been assessed, the manufacturers recommend that the daily dose of darifenacin is limited to 7.5 mg if it is given with ketoconazole or other potent inhibitors of CYP3A4.¹ They specifically name **clarithromycin**, **itraconazole**, (**miconazole**)², **nefazodone**, **nelfinavir** and **ritonavir**.¹ They say that dose adjustments are not required for moderate CYP3A4 inhibitors of which they list **erythromycin**, **fluconazole**, **diltiazem** and **verapamil**.¹ The UK manufacturers of darifenacin say that the concurrent use of potent CYP3A4 inhibitors is contraindicated. They specifically name **ritonavir**, **ketoconazole** and **itraconazole**. They then recommend a 7.5 mg dose of darifenacin in those taking moderate CYP3A4 inhibitors (they specifically name **grapefruit juice**, **clarithromycin**, **erythromy-**

cin, **telithromycin** and **fluconazole**). For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

2. Skerjanec A. The clinical pharmacokinetics of darifenacin. *Clin Pharmacokinet* (2006) 45, 325–50.
3. Emslex (Darifenacin hydrobromide). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, March 2007.

Urinary antimuscarinics; Darifenacin + Miscellaneous

Paroxetine and cimetidine cause small, clinically irrelevant, increases in darifenacin levels. Darifenacin increases imipramine levels, and caution is required with this and other tricyclics. Darifenacin does not significantly affect the pharmacokinetics of midazolam or combined oral contraceptives.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

The manufacturers note that, in a study in healthy subjects, cimetidine 800 mg twice daily increased the steady-state AUC of darifenacin 30 mg once daily by 34%.^{1,2} This change is unlikely to be clinically relevant. However, the UK manufacturers recommend that the dose of darifenacin should be started at 7.5 mg daily and, if well tolerated, titrated to 15 mg daily in the presence of cimetidine.³ This seems a cautious approach.

(b) CYP2D6 inhibitors

The manufacturers note that, in a study in healthy subjects, **paroxetine** 20 mg daily increased the steady-state AUC of darifenacin 30 mg once daily by 33%.^{1,2} This change is unlikely to be clinically relevant, and no dosage adjustments are recommended by the US manufacturers in the presence of CYP2D6 inhibitors.¹ However, the UK manufacturers recommend that the dose of darifenacin should be started at 7.5 mg daily and, if well tolerated, titrated to 15 mg daily in the presence of CYP2D6 inhibitors (they name **paroxetine**, **terbinafine** and **quinidine**).³ This seems a cautious approach. For a list of CYP2D6 inhibitors, see 'Table 1.3', (p.6).

(c) CYP2D6 substrates

The manufacturers note that steady-state darifenacin 30 mg once daily increased the AUC of **imipramine** by 70% and increased the AUC of its active metabolite, desipramine, 2.6-fold in a study in healthy subjects.² Because of these changes, the manufacturer recommends caution with tricyclic antidepressants and other CYP2D6 substrates that have a narrow therapeutic window.^{1,3} They name **flecainide** and **thioridazine** (see 'Table 1.3', (p.6), for a list).

(d) Midazolam

The manufacturers note that darifenacin 30 mg daily increased the AUC of a single 7.5-mg dose of midazolam by just 17% in a study in healthy subjects.^{1–3} This change is not clinically important.³

(e) Oral contraceptives

The manufacturers note that steady-state darifenacin 10 mg three times daily had no effect on the pharmacokinetics of a combined oral contraceptive (**ethinylestradiol/levonorgestrel**) in a study in 22 healthy women.^{1,2}

1. Enblex (Darifenacin hydrobromide). Novartis. US Prescribing information, February 2007.
2. Skerjanec A. The clinical pharmacokinetics of darifenacin. *Clin Pharmacokinet* (2006) 45, 325–50.
3. Emslex (Darifenacin hydrobromide). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, March 2007.

Urinary antimuscarinics; Oxybutynin + CYP3A4 inhibitors

Itraconazole and ketoconazole double the serum levels of oxybutynin. The clinical relevance of this is uncertain.

Clinical evidence

A single 5-mg dose of oxybutynin was given to 10 healthy subjects after they had taken **itraconazole** 200 mg daily or placebo for 4 days. The peak serum levels and the AUC of the oxybutynin were approximately doubled, while the pharmacokinetics of the active metabolite of oxybutynin were

unchanged. The sum of the oxybutynin and its metabolite concentrations were on average about 13% higher than with the placebo. No increase in adverse effects was seen. Similarly, some manufacturers note that **ketoconazole** increases oxybutynin levels about twofold.^{1,2}

Mechanism

This interaction is almost certainly due to itraconazole and ketoconazole inhibiting the metabolism of oxybutynin by the cytochrome P450 isoenzyme CYP3A4, in the intestinal wall and liver.

Importance and management

The authors of this report consider that this interaction is only of minor importance, but note that this was only a single-dose study and may not necessarily reflect the full picture in practice. Nevertheless, because itraconazole is a known and potent enzyme inhibitor, they predict that other CYP3A4 inhibitors that are less potent (they name **erythromycin**, **diltiazem**, and **verapamil**) are unlikely to interact with oxybutynin significantly.³ Nevertheless, some manufacturers recommend caution with concurrent use,^{1,2} and until more is known this seems prudent. Bear in mind the possibility of an interaction if antimuscarinic effects (dry mouth, constipation, drowsiness) are increased.

2. Lyrinel XL (Oxybutynin hydrochloride). Janssen-Cilag Ltd. UK Summary of product characteristics, June 2006.
3. Lukkari E, Juhakoski A, Aranko K, Neuvonen PJ. Itraconazole moderately increases serum concentrations of oxybutynin but does not affect those of the active metabolite. *Eur J Clin Pharmacol* (1997) 52, 403–6.

Urinary antimuscarinics; Solifenacin + CYP3A4 inhibitors

Ketoconazole markedly increases solifenacin levels, and the solifenacin dose should be limited if ketoconazole or other potent inhibitors of CYP3A4 are used.

Clinical evidence

In a crossover study in healthy subjects, **ketoconazole** 200 mg daily for 20 days increased the AUC of a single 10-mg dose of solifenacin given on day 7 twofold.¹ Moreover, the manufacturer notes that a higher dose of **ketoconazole** 400 mg daily increased the AUC threefold.^{2,3}

Mechanism

Solifenacin is principally metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a known, potent inhibitor.

Importance and management

Although the clinical relevance of this interaction has not been assessed, the manufacturers recommend that the daily dose of solifenacin succinate is limited to 5 mg if it is given with ketoconazole or other potent inhibitors of CYP3A4.^{2,3} The UK manufacturer specifically names **itraconazole**, **nelfinavir** and **ritonavir**.² In addition, in patients with severe renal impairment or moderate hepatic impairment, the combined use of solifenacin and potent CYP3A4 inhibitors is contraindicated.² For a list of clinically significant CYP3A4 inhibitors, see 'Table 1.4', (p.6).

1. Swart PJ, Krauwinkel WJJ, Smulders RA, Smith NN. Pharmacokinetic effect of ketoconazole on solifenacin in healthy volunteers. *Basic Clin Pharmacol Toxicol* (2006) 99, 33–6.
2. Vesicare (Solifenacin succinate). Astellas Pharma Ltd. UK Summary of product characteristics, September 2005.
3. Vesicare (Solifenacin succinate). GlaxoSmithKline. US Prescribing information, November 2004.

Urinary antimuscarinics; Solifenacin + Miscellaneous

The manufacturer notes that solifenacin had no significant effect on the pharmacokinetics of an oral contraceptive containing ethinylestradiol and levonorgestrel.^{1,2} They predict that inducers of the cytochrome P450 isoenzyme CYP3A4 such as carbamazepine,

phenytoin, and rifampicin will interact with solifenacin;¹ reduced efficacy is possible. Note that, as significant interactions have occurred with potent CYP3A4 inhibitors (such as 'ketoconazole', (p.1289), this prediction seems reasonable. Food did not affect solifenacin pharmacokinetics.³

Urinary antimuscarinics; Tolterodine + CYP3A4 inhibitors

Ketoconazole can increase tolterodine levels in those who are deficient in the cytochrome P450 isoenzyme CYP2D6 (poor metabolisers). The manufacturers of tolterodine currently say that potent CYP3A4 inhibitors such as clarithromycin, erythromycin, itraconazole and ketoconazole, and protease inhibitors should be used with caution or avoided because of a risk of increased tolterodine effects.

Clinical evidence

A study¹ in 8 healthy subjects who were deficient in the cytochrome P450 isoenzyme CYP2D6 (poor metabolisers) found that after taking **ketoconazole** 200 mg daily for 4 days the clearance of a single 2-mg dose of tolterodine was reduced by 61% and its AUC was increased 2.5-fold. A subsequent multiple-dose study in 6 of the original subjects given tolterodine 1 mg twice daily (half the usual dose) found similar increased levels: **ketoconazole** 200 mg once daily caused a 2.1-fold increase in tolterodine AUC, and a 2.2-fold increase in the AUC of the active moiety (unbound tolterodine plus metabolite).¹

Mechanism

Although tolterodine is normally metabolised to its active metabolite by CYP2D6, in those with low levels of this isoenzyme (about 5 to 10% of the population), metabolism by CYP3A4, becomes more important. It should be noted that tolterodine levels are already higher in poor CYP2D6 metabolisers than extensive metabolisers² but are likely to rise even further when a potent CYP3A4 inhibitor such as ketoconazole blocks this other route of metabolism.

Importance and management

The UK manufacturers³ consider that this increase in levels represents a risk of overdose in poor CYP2D6 metabolisers. Consequently, they do not recommend the use of potent CYP3A4 inhibitors (they name **clarithromycin**, **erythromycin**, **ketoconazole**, and **itraconazole**, and **protease inhibitors**) with tolterodine in any patient (note that metaboliser status is rarely known). However, the US manufacturers² recommend only that the dose of tolterodine be reduced to 1 mg twice daily in patients currently taking drugs that are potent inhibitors of CYP3A4, and this seems the more sensible advice. It may be prudent to assess experience of adverse effects in these patients, and to reduce the dose further or withdraw the drug if it is not tolerated.

2. Detrol (Tolterodine tartrate). Pharmacia & Upjohn Company. US prescribing information, December 2006.
3. Detrusitol (Tolterodine tartrate). Pharmacia Ltd. UK Summary of product characteristics, May 2007.

Urinary antimuscarinics; Tolterodine + Duloxetine

Duloxetine increased the maximum levels of tolterodine by 64%, but this was not considered to be clinically significant.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study, 14 healthy subjects received duloxetine 40 mg twice daily and tolterodine 2 mg twice daily for 5 days. Duloxetine increased the steady-state AUC of tolterodine by 71% and its maximum level by 64%. However, duloxetine had no effect on the pharmacokinetics of 5-hydroxymethyl-tolterodine the active metabolite of tolterodine.¹

Duloxetine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, by which tolterodine is metabolised.

The increases in tolterodine levels were not considered to be clinically relevant, and no routine dosage adjustment of tolterodine dosage was considered necessary when given with duloxetine.¹ Consider also 'Urinary antimuscarinics; Tolterodine + Fluoxetine', p.1290.

- Hua TC, Pan A, Chan C, Poo YK, Skinner MH, Knadler MP, Gonzales CR, Wise SD. Effect of duloxetine on tolterodine pharmacokinetics in healthy volunteers. *Br J Clin Pharmacol* (2004) 57, 652–6.

Urinary antimuscarinics; Tolterodine + Fluoxetine

Although fluoxetine can markedly inhibit the metabolism of tolterodine in some patients this is unlikely to cause a clinically important increase in the effects of tolterodine.

Clinical evidence, mechanism, importance and management

Thirteen psychiatric patients with symptoms of urinary incontinence were given tolterodine 2 mg twice daily for 5 doses, followed by fluoxetine 20 mg daily for 3 weeks, and then both drugs for a further 3 days. Nine of the 13 completed the study, the other 4 withdrew because of fluoxetine-related adverse effects. Fluoxetine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, the main enzyme involved in the metabolism of tolterodine. However, levels of this enzyme can vary between individuals and in the 7 patients with high CYP2D6 levels (extensive metabolisers) there was a 4.8-fold increase in the AUC of tolterodine and a minor reduction in its active and equipotent metabolite. In contrast the AUC of tolterodine increased by about 25% in 2 patients with low levels of CYP2D6 (poor metabolisers). These changes in AUC represent an increase of about 25% in active moiety (unbound tolterodine plus metabolite) for both poor and extensive metabolisers, a figure within normal variation.¹

In practical terms this means that the antimuscarinic (anticholinergic) effects of the tolterodine are only moderately increased, and it seems unlikely that any tolterodine dosage changes are likely to be needed. Consider also 'Antimuscarinics + Antimuscarinics', p.674.

- Bryne N, Svanström C, Åberg-Wistedt A, Hallén B, Bertilsson L. Fluoxetine inhibits the metabolism of tolterodine—pharmacokinetic implications and proposed clinical relevance. *Br J Clin Pharmacol* (1999) 48, 553–63.

Ursodeoxycholic acid (Ursodiol) + Bile-acid binding resins

The absorption of ursodeoxycholic acid can be more than halved by colestilan or colestyramine given simultaneously, and efficacy might be reduced.

Clinical evidence*(a) Colestilan*

Following a test meal with an overnight fast, 5 healthy subjects were given 200 mg of ursodeoxycholic acid alone or with 1.5 g of colestilan granules. It was found that the ursodeoxycholic acid serum levels at 30 minutes were reduced by the colestilan by more than 50% in 4 out of the 5 subjects, and the mean level was decreased from 9.2 to 3.4 micromol/L.¹

(b) Colestyramine

Simultaneous administration of colestyramine 4 g daily with ursodeoxycholic acid reduced the fasting serum levels of ursodeoxycholic acid by about 60% in a study in 5 healthy subjects. Separation of administration

by 5 hours tended to diminish the reduction (serum levels reduced by less than 40%).²

Mechanism

The mechanism of this interaction would appear to be that the bile-acid binding resins bind with ursodeoxycholic acid (a bile acid) in the intestine and thereby reduce its absorption.

Importance and management

These interactions would appear to be established, and are probably clinically important. One UK manufacturer actually advises that **colestipol** and colestyramine should be avoided when ursodeoxycholic acid is given, as they may limit the effectiveness of therapy.³ The authors of the reports recommend that in order to reduce the effects of this interaction, these two drugs should be separated,^{1,2} by at least 2 hours.¹

Valerian + Cytochrome P450 isoenzyme substrates

Valerian root extract does not affect the metabolism of caffeine, chlorzoxazone, debrisoquine and metabolism.

Clinical evidence, mechanism, importance and management

In a study 12 non-smoking healthy subjects were given valerian root extract 125 mg three daily for 28 days before receiving single doses of caffeine, chlorzoxazone, debrisoquine and midazolam. Valerian root extract caused no significant changes in the metabolism of these drugs, and it is therefore unlikely that other drugs metabolised by the cytochrome P450 isoenzymes CYP1A2, CYP2E1, CYP2D6 or CYP3A4 will be affected by the use of valerian.¹ See tables 'Table 1.2', (p.4), 'Table 1.3', (p.6), and 'Table 1.4', (p.6), for a list of substrates for these isoenzymes.

- Gurley BJ, Gardner SF, Hubbard MA, Williams DK, Gentry WB, Khan IA, Shah A. In vivo effects of goldenseal, kava kava, black cohosh, and valerian on human cytochrome P450 1A2, 2D6, 2E1, and 3A4/5 phenotypes. *Clin Pharmacol Ther* (2005) 77, 415–26.

Vinpocetine + Antacids

Aluminium/magnesium hydroxide gel (1 sachet four times daily) had no significant effects on the serum levels of vinpocetine (20 mg three times daily) in 18 healthy subjects.¹ No special precautions seem necessary if they are taken together.

- Lohmann A, Grobara P, Dingler E. Investigation of the possible influence of the absorption of vinpocetine with concomitant application of magnesium-aluminium-hydroxide gel. *Arzneimittelforschung* (1991) 41, 1164–7.

Vitamin A (Retinol) + Neomycin

Neomycin can markedly reduce the absorption of vitamin A (retinol) from the gut.

Clinical evidence, mechanism, importance and management

Neomycin 2 g markedly reduced the absorption of a test dose of vitamin A in 5 healthy subjects. It is suggested that this was due to a direct chemical interference between the neomycin and bile in the gut, which disrupted the absorption of fats and fat-soluble vitamins.¹ The extent to which

long-term treatment with neomycin (or other aminoglycosides) would impair the treatment of vitamin A deficiency has not been determined.

1. Barrowman JA, D'Mello A, Herxheimer A. A single dose of neomycin impairs absorption of vitamin A (Retinol) in man. *Eur J Clin Pharmacol* (1973) 5, 199–201.

Vitamin B₁₂ + Miscellaneous

Neomycin, aminosallyclic acid and the H₂-receptor antagonists can reduce the absorption of vitamin B₁₂ from the gut, but no interaction is likely when B₁₂ is given by injection.

Clinical evidence, mechanism, importance and management

Neomycin causes a generalised malabsorption syndrome, which has been shown¹ to reduce the absorption of vitamin B₁₂. **Colchicine** has also been shown to decrease B₁₂ absorption.¹ **Aminosallyclic acid** reduces vitamin B₁₂ absorption for reasons that are not understood, but which are possibly related to a mild generalised malabsorption syndrome.² Review of the literature³ suggests that H₂-receptor antagonists (such as **cimetidine** and **ranitidine**) can also reduce vitamin B₁₂ absorption, primarily because they reduce gastric acid production. The acid is needed to aid the release of B₁₂ from dietary protein sources. There is therefore a possibility that on long-term use patients could become vitamin B₁₂ deficient.

Within the context of adverse drug interactions, none of these drugs is normally likely to be clinically important, because for anaemia, vitamin B₁₂ should be given parenterally for convenience and to avoid well-established problems with absorption.

3. Force RW, Nahata MC. Effect of histamine H₂-receptor antagonists on vitamin B₁₂ absorption. *Ann Pharmacother* (1992) 26, 1283–6.

Vitamin D substances; Alfacalcidol + Danazol

An isolated report describes hypercalcaemia when a woman taking alfacalcidol also took danazol.

Clinical evidence, mechanism, importance and management

A woman with idiopathic hypoparathyroidism, treated with alfacalcidol, developed hypercalcaemia when she was given danazol 400 mg daily for endometriosis. She needed a reduction in the dosage of alfacalcidol from 4 to 0.75 micrograms daily. When the danazol was stopped 6 months later, the alfacalcidol dosage was raised to 4 micrograms daily and she remained normocalcaemic.¹ The reasons for this interaction are not understood and the general importance is limited as this appears to be an isolated case.

1. Hepburn NC, Abdul-Aziz LAS, Whiteoak R. Danazol-induced hypercalcaemia in alfacalcidol-treated hypoparathyroidism. *Postgrad Med J* (1989) 65, 849–50.

Vitamin D substances + Phenytoin and Barbiturates

The long-term use of phenytoin, phenobarbital, or primidone can disturb vitamin D and calcium metabolism and may result in osteomalacia. There are a few reports of patients taking vitamin D supplements who responded poorly to vitamin replacement while taking phenytoin or barbiturates. Serum phenytoin levels are not altered by vitamin D.

Clinical evidence

(a) *Effect on vitamin D*

A 16-year-old with grand mal epilepsy and idiopathic hypoparathyroidism did not adequately respond to daily doses of **alfacalcidol** 10 micrograms and 6 to 12 g of calcium, apparently because phenytoin 200 mg and **primidone** 500 mg daily were also being taken. However, when **dihydrodrotachysterol** 0.6 to 2.4 mg daily was given normal calcium levels were achieved.¹

Other reports describe patients whose response to usual doses of vitamin D was poor, because of concurrent anticonvulsant treatment with phenytoin and **phenobarbital** or **primidone**.^{2–4} Other reports clearly show low serum calcium levels,^{5,6} low serum vitamin D levels,⁷ osteomalacia,⁶ and bone structure alterations^{5,7} in the presence of phenytoin.

(b) *Effect on phenytoin*

A controlled study in 151 epileptic patients taking phenytoin and calcium showed that the addition of 2000 units of vitamin D₂ daily over a 3-month period had no significant effect on serum phenytoin levels.⁸

Mechanism

The enzyme-inducing effects of phenytoin and other anticonvulsants increase the metabolism of the vitamin D, thereby reducing its effects and disturbing calcium metabolism.³ In addition, phenytoin may possibly reduce the absorption of calcium from the gut.¹

Importance and management

The disturbance of calcium metabolism by phenytoin and other anticonvulsants is very well established, but there are only a few reports describing a poor response to vitamin D. The effects of concurrent treatment should be well monitored. Those who need vitamin D supplements may possibly need greater than usual doses.

Vitamin K substances + Antibacterials

Seven patients in intensive care did not respond to intravenous vitamin K for hypoprothrombinaemia while receiving gentamicin and clindamycin.

Clinical evidence, mechanism, importance and management

Some patients, particularly those in intensive care who are not eating, can quite rapidly develop acute vitamin K deficiency, which leads to prolonged prothrombin times and possibly bleeding.^{1,2} This can normally be controlled by giving vitamin K parenterally. However, one report describes 7 such patients, all with normal liver function, who unexpectedly did not respond to intravenous **phytomenadione**. Examination of their records showed that all were receiving **gentamicin** and **clindamycin**.² Just why, or if, these two antibacterials might have opposed the effects of intravenous vitamin K is not understood. More study is needed.

2. Rodriguez-Erdmann F, Hoff JV, Carmody G. Interaction of antibiotics with vitamin K. *JAMA* (1981) 246, 937.

Vitamins + Orlistat

Orlistat decreases the absorption of supplemental beta-carotene and vitamin E. There is some evidence to suggest that some patients may have low vitamin D levels while taking orlistat, even if they are also taking multivitamins.

Clinical evidence

Studies in healthy subjects have found that about two-thirds of a supplemental dose of **beta-carotene**¹ and roughly half the dose of **vitamin E** (**α -tocopherol**)² was absorbed in the presence of orlistat, while the absorp-

tion of **vitamin A** was not affected.² In the first study, beta-carotene was given within about 30 minutes of the orlistat,¹ whereas in the second, the vitamin supplement was given at the same time as orlistat.² In another study, 17 obese adolescents were given orlistat 120 mg three times daily with meals and a daily multivitamin (containing **vitamins A, D, E, and K**) to be taken at night. Levels of **vitamins A, E and K** were not significantly altered over 6 months of orlistat use, but **vitamin D** concentrations dropped after the first month, but had returned to baseline by 3 months. Three subjects (all African-Americans) required additional **vitamin D** supplementation, but all had a low dietary intake of **vitamin D**.^{3,4}

Mechanism

Orlistat reduces dietary fat absorption by inhibiting gastrointestinal lipase. Consequently, it reduces the absorption of fat soluble vitamins.

Importance and management

To maximise vitamin absorption, the manufacturers recommend that any multivitamin preparations should be taken at least 2 hours before or after orlistat, such as at bedtime.^{5,6} The US manufacturers suggest that patients taking orlistat should be advised to take multivitamins, because of the possibility of reduced vitamin levels.⁶ Note that the authors of the study in adolescents suggest that monitoring of vitamin D may be required, even if multivitamins are given.³

Zinc sulphate + Calcium compounds

Calcium compounds reduce the absorption of zinc.

Clinical evidence, mechanism, importance and management

Elemental calcium in doses of 600 mg (either as **calcium carbonate** or **calcium citrate**) was given to 9 healthy women with a single 20-mg oral dose of zinc sulphate.¹ The AUC of zinc was reduced by 72% by **calcium carbonate** and by 80% by **calcium citrate**. The reason for this interaction is not understood, nor is the clinical importance of this interaction known, but it would seem prudent to separate the administration of zinc from the administration of any calcium compound. Two to three hours separation is often sufficient to achieve maximal absorption with interactions like this. More study of this interaction is needed to confirm the extent and to determine if separation of the doses is an adequate precaution.

1. Argiratos V, Samman S. The effect of calcium carbonate and calcium citrate on the absorption of zinc in healthy female subjects. *Eur J Clin Nutr* (1994) 48, 198–204.

Index

All of the pairs of drugs included in this book, whether interacting or not, are listed in this index. They may also be listed under the group names if the interaction is thought to apply to the group as a whole, or if several members of the group have been shown to interact. Note that in some circumstances, broad terms (e.g. analgesics) have been used, where the information is insufficient to allow more specific indexing. It is therefore advisable to look up both the

individual drug and its group to ensure all the relevant information is obtained. It may also be advisable to look up both drugs of interest if you don't initially find what you are looking for as drug name synonyms are also included as lead-ins. You can possibly get a lead on the way unlisted drugs behave if you look up those which are related, but bear in mind that none of them are identical and any conclusions reached should only be tentative.
