Stockley’s Drug Interactions

A source book of interactions, their mechanisms, clinical importance and management

Eighth edition

Edited by
Karen Baxter
BSc, MSc, MRPharmS
Contents

Preface v
Abbreviations vi
Before using this book vii

1. General considerations and an outline survey of some basic interaction mechanisms 1
2. ACE inhibitors and Angiotensin II receptor antagonists 12
3. Alcohol 40
4. Alpha blockers 83
5. Anaesthetics and Neuromuscular blockers 90
6. Analgesics and NSAIDs 133
7. Anorectics and Stimulants 199
8. Anthelmintics, Antifungals and Antiprotozoals 207
9. Antiarrhythmics 243
10. Antibacterials 285
11. Anticholinesterases 352
12. Anticoagulants 358
13. Antidiabetics 468
14. Antiepileptics 517
15. Antihistamines 582
16. Antimigraine drugs 597
17. Antineoplastics 609
18. Antiparkinsonian and related drugs 672
19. Antiplatelet drugs and Thrombolytics 697
20. Antipsychotics, Anxiolytics and Hypnotics 706
21. Antivirals 772
22. Beta blockers 833
23. Calcium-channel blockers 860
24. Cardiovascular drugs, miscellaneous 878
25. Digitalis glycosides 903
26. Diuretics 944
27. Gastrointestinal drugs 960
28. Hormonal contraceptives and Sex hormones 975
29. Immunosuppressants 1009
30. Lipid regulating drugs 1086
31. Lithium 1111
32. MAOIs 1130
33. Respiratory drugs 1158
34. SSRIs, Tricyclics and related antidepressants 1203
35. Miscellaneous drugs 1247

Index 1293
The aim of *Stockley’s Drug Interactions* is to inform busy doctors, pharmacists, surgeons, nurses and other healthcare professionals, of the facts about drug interactions, without their having to do the time-consuming literature searches and full assessment of the papers for themselves. These therefore are the practical questions which this book attempts to answer:

- Are the drugs and substances in question known to interact or is the interaction only theoretical and speculative?
- If they do interact, how serious is it?
- Has it been described many times or only once?
- Are all patients affected or only a few?
- Is it best to avoid these two substances altogether or can the interaction be accommodated in some way?
- And what alternative and safer drugs can be used instead?

To précis the mass of literature into a concise and easy-to-read form, the text has been organised into a series of individual monographs, all with a common format. If you need some insight into the general philosophy underlying the way all this information is handled in this publication, you should have a look at the section, ‘Before using this book . . .’.

There have been several changes for the 8th edition. All of the existing monographs have, as with each edition, been reviewed, revalidated and updated, and many new ones have been added, making a total in excess of 3100 monographs. Many new monographs on herbal interactions have been added, although good quality human studies remain sparse. A new chapter has been added to cover the growing number of interactions about anorectics, and the chapter on sympathomimetics has been removed, with the information redistributed according to the therapeutic use of the drugs in question, to give a better indication of precisely which drugs from this disparate group are likely to interact. We have continued to add information provided by regulatory bodies outside of the UK, which further enhances the international flavour of the publication.

This edition has also seen the growth in our editorial team, with two practising clinical pharmacists recruited to help us ensure we maintain the practical nature of the information given. This has also allowed us to develop our product range, with the publication of the first *Stockley’s Drug Interactions Pocket Companion*, which we have developed for delivery on PDA.

As always, the Editorial team have had assistance from many other people in developing this publication, and the Editor gratefully acknowledges the assistance and guidance that they have provided. The Martindale team continue to be a great source of advice and support, and particular thanks is due to the editor, Sean Sweetman. Thanks are also due to John Wilson and Tamsin Cousins, who handle the various aspects of producing our publications in print. We are also grateful for the support of both Paul Weller and Charles Fry. Ivan Stockley remains an important part of the publication, taking a keen interest in the development of new products, and as ever, we find his advice invaluable.

Stockley’s *Drug Interactions* continues to be available on the Pharmaceutical Press platform, MedicinesComplete, as well as being available on other platforms, both in English and Spanish. With the further development of the integratable Alerts product and the new PDA, we remain indebted to Julie McGlashan, Michael Evans, Elizabeth King, and all those involved in the development of these products, for their advice and support. For more details about these digital products please visit: www.pharmpress.com/Stockley

As ever, we have had feedback from pharmacists and doctors about the content of the publication, which is always valuable, especially in ensuring the publication meets the needs of the users. We are particularly grateful to those who have taken the time to answer our questions about specific aspects of practice. Anyone who wishes to contact the Stockley team can do so at the following address: stockley@rpsgb.org

London, September 2007
Abbreviations

ACE—angiotensin-converting enzyme
ADP—adenosine diphosphate
AIDS—acquired immunodeficiency syndrome
ALL—acute lymphoblastic leukaemia
ALT—alanine aminotransferase
am—ante meridiem (before noon)
AML—acute myeloid leukaemia
aPTT—activated partial thromboplastin time
AST—aspartate aminotransferase
AUC—area under the time–concentration curve
AUC_0–12—area under the time–concentration curve measured over 0 to 12 hours
AV—atrioventricular
BNF—British National Formulary
BP—blood pressure
BP—British Pharmacopoeia
BPC—British Pharmaceutical Codex
BPH—benign prostatic hyperplasia
bpm—beats per minute
BUN—blood urea nitrogen
CAPD—continuous ambulatory peritoneal dialysis
CDC—Centers for Disease Control (USA)
CNS—central nervous system
COPD—chronic obstructive pulmonary disease
CPR—cardiopulmonary resuscitation
CSF—cerebrospinal fluid
CSM—Committee on Safety of Medicines (UK) (now subsumed within the Commission on Human Medicines)
DNA—deoxyribonucleic acid
ECG—electrocardiogram
ECT—electroconvulsive therapy
ED_50—the dose at which 50% of subjects respond
EEG—electroencephalogram
e.g.—exempli gratia (for example)
EMEA—The European Agency for the Evaluation of Medicinal Products
FDA—Food and Drug Administration (USA)
FEF_25–75—maximum expiratory flow over the middle 50% of the vital capacity
FEV_1—forced expiratory volume in one second
FSH—follicle simulating hormone
ft—foot (feet)
FVC—forced vital capacity
GGT—gamma glutamyl transpeptidase
g—gram(s)
h—hour(s)
HAART—highly active antiretroviral therapy
HCV—hepatitis C virus
HIV—human immunodeficiency virus
HRT—hormone replacement therapy
ibid—ibidem, in the same place (journal or book)
i.e.—id est (that is)
INR—international normalised ratio
ITU—intensive therapy unit
IU—International Units
IUD—intrauterine device
kg—kilogram(s)
l—litre
lbs—pound(s) avoirdupois
LDL—low-density lipoprotein
LFT—liver function test
LH—luteinising hormone
LMWH—low-molecular-weight heparin
MAC—minimum alveolar concentration
MAOI—monoamine oxidase inhibitor
MAOI-A—monoamine oxidase inhibitor, type A
MAOI-B—monoamine oxidase inhibitor, type B
MCA—Medicines Control Agency (UK) (now MHRA)
MHRA—Medicines and Healthcare products Regulatory Agency (UK)
MIC—minimum inhibitory concentration
mEq—milliequivalent(s)
mg—milligram(s)
mL—millilitre(s)
mL—millilitre(s) of mercury
mmol—millimole
mol—mole
MRSA—methicillin resistant Staphylococcus aureus
NICE—National Institute for Health and Clinical Excellence (UK)
formerly the National Institute for Clinical Excellence
nM—nanomole
nmol—nanomole
NNRTI—non-nucleoside reverse transcriptase inhibitor
NRTI—nucleoside reverse transcriptase inhibitor
NSAID—non-steroidal anti-inflammatory drug
PABA—para-amino benzoic acid
PCP—pneumocystis pneumonia
pH—the negative logarithm of the hydrogen ion concentration
pm—post meridiem (after noon)
pO_2—plasma partial pressure (concentration) of oxygen
PPI—proton pump inhibitor
ppm—parts per million
PTT—partial thromboplastin time
PUD—peptic ulcer disease
RIMA—reversible inhibitor of monoamine oxidase type A
RNA—ribonucleic acid
sic—written exactly as it appears in the original
SNRI—serotonin and noradrenergic reuptake inhibitor
SSRI—selective serotonin reuptake inhibitor
STD—sexually transmitted disease
SVT—supraventricular tachycardia
TPN—total parenteral nutrition
TSH—thyroid-stimulating hormone
UK—United Kingdom
US and USA—United States of America
USP—The United States Pharmacopeia
UTI—urinary tract infection
Before using this book . . .

. . . you should read this short explanatory section so that you know how the drug interaction data have been set out here, and why – as well as the basic philosophy that has been followed in presenting it.

The monographs

This publication has over 3100 monographs with a common format, which are subdivided into sections like these:

• An abstract or summary for quick reading.
• Clinical evidence, detailing one, two or more illustrative examples of the interaction, followed by most or all of other supportive clinical evidence currently available.
• Mechanism, in brief.
• Importance and management, a short discussion designed to aid rapid clinical decision making. For example:
  – Is the interaction established or not?
  – What is its incidence?
  – How important is it?
  – How can it be managed?
  – And what, if any, are the non-interacting alternatives?
• References, a list of all of the relevant references. The length of the references list gives a very fair indication of the extent of the documentation. A long list indicates a well documented interaction, whereas a short list indicates poor documentation.

Some of the monographs have been compressed into fewer subsections instead of the more usual five, simply where information is limited or where there is little need to be more expansive.

The monographs do not carry the drug interaction Hazard/Severity ratings as used in the electronic Stockley Interactions Alerts because of the difficulties of applying them to monographs that cover multiple pairs of drug–drug interactions, but what is written in each monograph should speak for itself.

Quality of information on interactions

The data on interactions are of widely varying quality and reliability. The best come from clinical studies carried out on large numbers of patients under scrupulously controlled conditions. The worst are anecdotal, uncontrolled, or based solely on animal studies. Sometimes they are no more than speculative and theoretical scaremongering guesswork, hallowed by repeated quotation until they become virtually set in stone.

The aim has been to filter out as much useless noise as possible, so wherever possible ‘secondary’ references are avoided, and ‘primary’ references which are available in good medical and scientific libraries are used instead – although sometimes unpublished, good quality, in-house reports on drug company files have been used where the drug company has kindly allowed access to the information. Product literature (the Summary of Product Characteristics in the UK and the Prescribing Information in the US) rather than the research reports that lie behind them are also cited because they are the only source of published information about new drugs.

The quality of drug company literature is very variable. Some of it is excellent, helpful and very reliable, but regretfully a growing proportion contains a welter of speculative and self-protective statements, probably driven more by the company's medico-legal policy than anything else, and the nervousness of drug regulatory authorities. It is almost unbelievable (but true all the same) that drug companies that are scrupulous in the way they do their research, come out with statements about possible interactions that are little more than guesswork.

When drawing your own conclusions

The human population is a total mixture, unlike selected batches of laboratory animals (same age, weight, sex, and strain etc.). For this reason human beings do not respond uniformly to one or more drugs. Our genetic make up, ethnic background, sex, renal and hepatic functions, diseases and nutritional states, ages and other factors (the route of administration, for example) all contribute towards the heterogeneity of our responses. This means that the outcome of giving one or more drugs to any individual for the first time is never totally predictable because it is a new and unique ‘experiment’. Even so, some idea of the probable outcome of using a drug or a pair of drugs can be based on what has been seen in other patients: the more extensive the data, the firmer the predictions.

The most difficult decisions concern isolated cases of interaction, many of which only achieved prominence because they were serious. Do you ignore them as ‘idiosyncratic’ or do you, from that moment onwards, contraindicate the use of the two drugs totally?

There is no simple ‘yes’ or ‘no’ answer to these questions, but one simple rule-of-thumb is that isolated cases of interaction with old and very well-tried pairs of drugs are unlikely to be of general importance, whereas those with new drugs may possibly be the tip of an emerging iceberg and should therefore initially be taken much more seriously until more is known. The delicate balance between these two has then to be set against the actual severity of the reaction reported and weighed up against how essential it is to use the drug combination in question.

When deciding the possible first-time use of any two drugs in any particular patient, you need to put what is currently known about these drugs against the particular profile of your patient. Read the monograph. Consider the facts and conclusions, and then set the whole against the backdrop of your patient’s unique condition (age, disease, general condition, and so forth) so that what you eventually decide to do is well thought out and soundly based. We do not usually have the luxury of knowing absolutely all the facts, so that an initial conservative approach is often the safest.
General considerations and an outline survey of some basic interaction mechanisms

A. What is a drug interaction?

An interaction is said to occur when the effects of one drug are changed by the presence of another drug, herbal medicine, food, drink or by some environmental chemical agent. Much more colourful and informal definitions by patients are that it is “. . . when medicines fight each other. . .”, or “. . . when medicines fizz together in the stomach . . .”, or “. . . what happens when one medicine falls out with another…”

The outcome can be harmful if the interaction causes an increase in the toxicity of the drug. For example, there is a considerable increase in risk of severe muscle damage if patients on statins start taking azole antifungals (see ‘Statins + Azoles’, p.1093). Patients taking monoamine oxidase inhibitor antidepressants (MAOIs) may experience an acute and potentially life-threatening hypertensive crisis if they eat tyramine-rich foods such as ‘cheese’, (p.1153).

A reduction in efficacy due to an interaction can sometimes be just as harmful as an increase: patients taking warfarin who are given rifampicin need more warfarin to maintain adequate and protective anticoagulation (see ‘Coumarins + Antibacterials; Rifamycins’, p.375), while patients taking ‘tetracyclines’, (p.347) or ‘quinolones’, (p.332) need to avoid antacids (see ‘Coumarins + Antibacterials; Rifamycins’, p.375), while patients taking monoamine oxidase inhibitor antidepressants (MAOIs) may experience an acute and potentially life-threatening hypertensive crisis if they eat tyramine-rich foods such as ‘cheese’, (p.1153).

A reduction in efficacy due to an interaction can sometimes be just as harmful as an increase: patients taking warfarin who are given rifampicin need more warfarin to maintain adequate and protective anticoagulation (see ‘Coumarins + Antibacterials; Rifamycins’, p.375), while patients taking ‘tetracyclines’, (p.347) or ‘quinolones’, (p.332) need to avoid antacids (see ‘Coumarins + Antibacterials; Rifamycins’, p.375), while patients taking monoamine oxidase inhibitor antidepressants (MAOIs) may experience an acute and potentially life-threatening hypertensive crisis if they eat tyramine-rich foods such as ‘cheese’, (p.1153).

Deﬁnitions of a drug interaction are not rigidly adhered to in this publication because the subject inevitably overlaps into other areas of adverse reactions with drugs. So you will ﬁnd in these pages some ‘interactions’ where one drug does not actually affect another at all, but the adverse outcome is the simple additive effects of two drugs with similar effects (for example the combined effects of two or more CNS depressants, or two drugs which affect the QT interval). Sometimes the term ‘drug interaction’ is used for the physico-chemical reactions that occur if drugs are mixed in intravenous fluids, causing precipitation or inactivation. The long-established and less ambiguous term ‘pharmaceutical incompatibilities’ are not covered by this publication.

B. What is the incidence of drug interactions?

The more drugs a patient takes the greater the likelihood that an adverse reaction will occur. One hospital study found that the rate was 7% in those taking 6 to 10 drugs but 40% in those taking 16 to 20 drugs, which represents a disproportionate increase.1 A possible explanation is that the drugs were interacting.

Some of the early studies on the frequency of interactions uncritically compared the drugs that had been prescribed with lists of possible drug interactions, without appreciating that many interactions may be clinically trivial or simply theoretical. As a result, an unrealistically high incidence was suggested. Most of the later studies have avoided this error by looking at only potentially clinically important interactions, and incidences of up to 8.8% have been reported.2,3 Even so, not all of these studies took into account the distinction that must be made between the incidence of potential interactions and the incidence of those where clinical problems actually arise. The simple fact is that some patients experience quite serious reactions while taking interacting drugs, while others appear not to be affected at all.

A screening of 2 422 patients over a total of 25 005 days revealed that 113 (4.7%) were taking combinations of drugs that could interact, but evidence of interactions was observed in only seven patients, representing only 0.3%.2 In another hospital study of 44 patients over a 5-day period taking 10 to 17 drugs, 77 potential drug interactions were identiﬁed, but only one probable and four possible adverse reactions (6.4%) were detected.4 A further study among patients taking anticonvulsant drugs found that 6% of the cases of toxicity were due to drug interactions.5 These ﬁgures are low compared with those of a hospital survey that monitored 927 patients who had received 1004 potentially interacting drug combinations. Changes in drug dosage were made in 44% of these cases.6 A review of these and other studies found that the reported incidence rates ranged from 2.2 to 70.3%, and the percentage of patients actually experiencing problems was less than 11.1%. Another review found a 37% incidence of interactions among 639 elderly patients.7 Yet another review of 236 geriatric patients found an 88% incidence of clinically signiﬁcant interactions, and a 22% incidence of potentially serious and life-threatening interactions.8 A 4.1% incidence of drug interactions on prescriptions presented to community pharmacists in the USA was found in a further study,9 whereas the incidence was only 2.9% in another American study, 10 and just 1.9% in a Swedish study.11 An Australian study found that about 10% of hospital admissions were drug-related, of which 4.4% were due to drug interactions.12 A very high incidence (47 to 50%) of potential drug interactions was found in a study carried out in an Emergency Department in the US.13 One French study found that 16% of the prescriptions for a group of patients taking antihypertensive drugs were contraindicated or unsuitable,14 whereas another study on a group of geriatrics found only a 1% incidence.15 The incidence of problems would be expected to be higher in the elderly because ageing affects the functioning of the kidneys and liver.16,17 These discordant ﬁgures need to be put into the context of the under-reporting of adverse reactions of any kind by medical professionals, for reasons that may include pressure of work or the fear of litigation. Both doctors and patients may not recognise adverse reactions and interactions, and some patients simply stop taking their drugs without saying why. None of these studies give a clear answer to the question of how frequently drug interactions occur, but even if the incidence is as low as some of the studies suggest, it still represents a very considerable number of patients who appear to be at risk when one thinks of the large numbers of drugs prescribed and taken every day.

C. How seriously should interactions be regarded and handled?

It would be very easy to conclude after browsing through this publication that it is extremely risky to treat patients with more than one drug at a time, but this would be an over-reaction. The figures quoted in the previous section illustrate that many drugs known to interact in some patients, simply fail to do so in others. This partially explains why some quite important drug interactions remained virtually unnoticed for many years, a good example of this being the increase in serum digoxin levels seen with quinidine (see ‘Digitalis glycosides + Quinidine’, p.936).

Examples of this kind suggest that patients apparently tolerate adverse interactions remarkably well, and that many experienced physicians accommodate the effects (such as rises or falls in serum drug levels) without consciously recognising that what they are seeing is the result of an interaction.

One of the reasons it is often difficult to detect an interaction is that, as already mentioned, patient variability is considerable. We now know many of the predisposing and protective factors that determine whether or not an interaction occurs but in practice it is still very difficult to predict what will happen when an individual patient is given two potentially interacting drugs. An easy solution to this practical problem is to choose a non-interacting alternative, but if none is available, it is frequently possible to give interacting drugs together if appropriate precautions are taken. If the effects of the interaction are well-monitored they can often be allowed for, though they occur in isolation. For convenience, the mechanisms of interaction that are encountered time and time again. Some of these reactions in a single patient mean that the drugs in question should never be avoided.

The variability in patient response has lead to some extreme responses known to occur in community practice. Med Care (1992) 30, 926–40.

D. Mechanisms of drug interaction

Some drugs interact together in totally unique ways, but as the many examples in this publication amply illustrate, there are certain mechanisms of interaction that are encountered time and time again. Some of these common mechanisms are discussed here in greater detail than space will allow in the individual monographs, so that only the briefest reference need be made there.

Mechanisms that are unusual or peculiar to particular pairs of drugs are often simply by adjusting the dosages. Many interactions are dose-related; so that the dosage of the causative drug is reduced, the effects on the other drug will be reduced accordingly. Thus a non-prescription dosage of cimetidine may fail to inhibit the metabolism of phenytoin, whereas a larger dose may clearly increase phenytoin levels (see ‘Phenytoin + H$_2$-receptor antagonists’, p.559).

The dosages of the affected drug may also be critical. For example, isoniazid causes the levels of phenytoin to rise, particularly in those individuals who are slow acetylators of isoniazid, and levels may become toxic. If the serum phenytoin levels are monitored and its dosage reduced appropriately, the concentrations can be kept within the therapeutic range (see ‘Phenytoin + Antimycobacterials’, p.550). Some interactions can be accommodated by using another member of the same group of drugs. For example, the serum levels of doxycycline can become subtherapeutic if phenytoin, barbiturates or carbamazepine are given, but other ‘tetracyclines’ (p.346) do not seem to be affected. Erythromycin causes serum lovastatin levels to rise because it inhibits its metabolism, but does not affect pravastatin levels because these two statins are metabolised in different ways (see ‘Statins’, (p.1086)). It is therefore clearly important not to uncritically extrapolate the interactions seen with one drug to all members of the same group.

It is interesting to note in this context that a study in two hospitals in Maryland, USA, found that when interacting drugs were given with warfarin (but not theophylline) the length of hospital stay increased by a little over 3 days, with a rise in general costs because of the need to do more tests to get the balance right.1 So it may be easier, quicker and cheaper to use a non-interacting alternative drug (always provided that its price is not markedly greater).

The variability in patient response has lead to some extreme responses among prescribers. Some clinicians have become over-anxious about interactions so that their patients are denied useful drugs that they might reasonably be given if appropriate precautions are taken. This attitude is exacerbated by some of the more alarmist lists and charts of interactions, which fail to make a distinction between interactions that are very well documented and well established, and those that have only been encountered in a single patient, and which in the final analysis are probably totally idiosyncratic. ‘One swallow does not make a summer’, nor does a serious reaction in a single patient mean that the drugs in question should never again be given to anyone else.

At the other extreme, there are some health professionals who, possibly because they have personally encountered few interactions, fail to consider drug interactions, so that some of their patients are potentially put at risk. An example of this is the fact that cisapride continued to be prescribed with known interacting drugs, even after the rare risk of fatal torsade de points arrhythmias, which can cause sudden death, was well established2 (see ‘Cisapride + Miscellaneous’, p.963). The responsible position lies between these two extremes, because a very substantial number of interacting drugs can be given together safely, if the appropriate precautions are taken. There are relatively few pairs of drugs that should always be avoided.

1. Pharmacokinetic interactions

Pharmacokinetic interactions are those that can affect the processes by which drugs are absorbed, distributed, metabolised and excreted (the so-called ADME interactions).

1.1. Drug absorption interactions

Most drugs are given orally for absorption through the mucous membranes of the gastrointestinal tract, and the majority of interactions that go on within the gut result in reduced rather than increased absorption. A clear distinction must be made between those that decrease the rate of absorption and those that alter the total amount absorbed. For drugs that are given long-term, in multiple doses (as the oral anticoagulants) the rate of absorption is usually unimportant, provided the total amount of drug absorbed is not markedly altered. On the other hand for drugs that are given as single doses, intended to be absorbed rapidly (e.g. hypnotics or analgesics), where a rapidly achieved high concentration is needed, a reduction in the rate of absorption may result in failure to achieve an adequate effect. ‘Table 1.1’, (p.2) lists some of the drug interactions that result from changes in absorption.

(a) Effects of changes in gastrointestinal pH

The passage of drugs through mucous membranes by simple passive diffusion depends upon the extent to which they exist in the non-ionised lipid-soluble form. Absorption is therefore governed by the pKa of the drug, its lipid-solubility, the pH of the contents of the gut and various other parameters relating to the pharmaceutical formulation of the drug. Thus the absorption of salicylic acid by the stomach is much greater at low pH than at high. On theoretical grounds it might be expected that alterations in gastric pH caused by drugs such as the H2-receptor antagonists would have a marked effect on absorption, but in practice the outcome is often uncertain because a number of other mechanisms may also come into play, such as chelation, adsorption and changes in gut motility, which can considerably affect what actually happens. However, in some cases the effect can be significant. Rises in pH due to ‘proton pump inhibitors’, (p.218), ‘H2-receptor antagonists’, (p.217) can markedly reduce the absorption of ketoconazole.

(b) Adsorption, chelation and other complexing mechanisms

Activated charcoal is intended to act as an adsorbing agent within the gut for the treatment of drug overdose or to remove other toxic materials, but inevitably it can affect the absorption of drugs given in therapeutic doses. Antacids can also adsorb a large number of drugs, but often other mechanisms of interaction are also involved. For example, the tetracycline antibiotics can chelate with a number of divalent and trivalent metallic ions, such as calcium, aluminium, bismuth and iron, to form complexes that are both poorly absorbed and have reduced antibacterial effects (see ‘Figure 1.1’, (below)).

These metallic ions are found in dairy products and antacids. Separating the dosages by 2 to 3 hours goes some way towards reducing the effects of this type of interaction. The marked reduction in the bioavailability of penicillamine caused by some antacids seems also to be due to chelation, although adsorption may have some part to play. Colestyrarone, an anionic exchange resin intended to bind bile acids and cholesterol metabolites in the gut, binds to a considerable number of drugs (e.g. digoxin, warfarin, levothryroxine), thereby reducing their absorption. ‘Table 1.1’, (p.2) lists some drugs that chelate, complex or adsorb other drugs.

(c) Changes in gastrointestinal motility

Since most drugs are largely absorbed in the upper part of the small intestine, drugs that alter the rate at which the stomach empties can affect absorption. Propantheline, for example, delays gastric emptying and reduces ‘paracetamol (acetaminophen)’ absorption, (p.192), whereas ‘metoclopramide’, (p.191), has the opposite effect. However, the total amount of drug absorbed remains unaltered. Propantheline also increases the absorption of ‘hydrochlorothiazide’, (p.959). Drugs with antimuscarinic effects decrease the motility of the gut, thus the tricyclic antidepressants can increase the absorption of ‘dicoumarol’, (p.457), probably because they increase the time available for dissolution and absorption but in the case of ‘levodopa’, (p.690), they may reduce the absorption, possibly because the exposure time to intestinal mucosal metabolism is increased. The same reduced levodopa absorption has also been seen with ‘homatropine’, (p.682). These examples illustrate that what actually happens is sometimes very unpredictable because the final outcome may be the result of several different mechanisms.

(d) Induction or inhibition of drug transporter proteins

The oral bioavailability of some drugs is limited by the action of drug transporter proteins, which eject drugs that have diffused across the gut lining back into the gut. At present, the most well characterised drug transporter is ‘P-glycoprotein’, (p.8). Digoxin is a substrate of P-glycoprotein, and drugs that induce this protein, such as rifampicin, may reduce the bioavailability of ‘digoxin’, (p.938).

(e) Malabsorption caused by drugs

Neomycin causes a malabsorption syndrome, similar to that seen with non-tropical sprue. The effect is to impair the absorption of a number of drugs including ‘digoxin’, (p.906) and ‘methotrexate’, (p.642).

1.2. Drug distribution interactions

(a) Protein-binding interactions

Following absorption, drugs are rapidly distributed around the body by the circulation. Some drugs are totally dissolved in the plasma water, but many others are transported with some proportion of their molecules in solution and the rest bound to plasma proteins, particularly the albumins. The extent of this binding varies enormously but some drugs are extremely highly bound. For example, dicoumarol has only four out of every 1000 molecules remaining unbound at serum concentrations of 0.5 mg%. Drugs can also become bound to albumin in the interstitial fluid, and some, such as digoxin, can bind to the heart muscle tissue. The binding of drugs to the plasma proteins is reversible, an equilibrium being established between those molecules that are bound and those that are not. Only the unbound molecules remain free and pharmacologically active, while those that are bound form a circulating but pharmacologically inactive reservoir which, in the case of drugs with a low-extraction ratio, is temporarily protected from metabolism and excretion. As the free molecules become metabolised, some of the bound molecules become unbound and pass into solution to exert their normal pharmacological actions, before they, in their turn are metabolised and excreted.

Fig. 1.1 A drug chelation interaction. Tetracycline forms a less-soluble chelate with iron if the two drugs are allowed to mix within the gut. This reduces the absorption and depresses the serum levels and the antibacterial effects (after Neuvonen Pj, BMJ (1970) 4, 532, with permission). The same interaction can occur with other ions such as Al3+, Ca2+, Mg2+, Bi2+ and Zn2+. 
Depending on the concentrations and their relative affinities for the binding sites, one drug may successfully compete with another and displace it from the sites it is already occupying. The displaced (and now active) drug molecules pass into the plasma water where their concentration rises. So for example, a drug that reduces the binding from 99 to 95% would increase the unbound concentration of free and active drug from 1 to 5% (a fivefold increase). This displacement is only likely to raise the number of free and active molecules significantly if the majority of the drug is within the plasma rather than the tissues, so that only drugs with a low apparent volume of distribution (Vd) will be affected. Examples include the sulphonureas, such as tolbutamide (96% bound, Vd 10 litres), oral anticoagulants, such as warfarin (99% bound, Vd 9 litres), and phenytoin (90% bound, Vd 35 litres). However, another important factor is clearance. Clinically important protein-binding interactions are unlikely if only a small proportion of the drug is eliminated during a single-passage through the elimination organ (low-extraction ratio drugs), since any increase in the free fraction will be effectively cleared. Most drugs that are extensively bound to plasma proteins and subject to displacement reactions (e.g. warfarin, sulphonureas, phenytoin, methotrexate, and valproate) have low-extraction ratios, and drug exposure is therefore independent of protein-binding.

An example of displacement of this kind happens when patients stabilised on warfarin are given chloral hydrate because its major metabolite, trichloroacetic acid, is a highly bound compound that successfully displaces warfarin. This effect is only very short-lived because the now free and active warfarin molecules become exposed to metabolism as the blood flows through the liver, and the amount of drug rapidly falls. This transient increase in free warfarin levels is unlikely to change the anticoagulant effect of warfarin because the clotting factor complexes that are produced when warfarin is taken have a very long half-life, and thus take a long time to reach a new steady state. Normally no change in the warfarin dosage is needed (see ‘Coumarins + Cloral and derivatives’, p.396). In vitro many commonly used drugs are capable of being displaced by others but in the body the effects seem almost always to be buffered so effectively that the outcome is not normally clinically important. It would therefore seem that the importance of this interaction mechanism has been grossly over-emphasised. It is difficult to find an example of a clinically important interaction due to this mechanism alone. It has been suggested that this interaction mechanism is likely to be important only for drugs given intravenously that have a high-extraction ratio, a short pharmacokinetic-pharmacodynamic half-life and a narrow therapeutic index. Lidocaine has been given as an example of such a drug fitting these criteria. Some drug interactions that were originally assumed to be due to changes in protein binding have subsequently been shown to have other interaction mechanisms involved. For example, inhibition of metabolism has subsequently been shown to be important in the interactions between ‘warfarin and phenylbutazone’, (p.434), and ‘tolbutamide and sulphonamide’, (p.506).

However, knowledge of altered protein binding is important in therapeutic drug monitoring. Suppose for example a patient taking phenytoin was given a drug that displaced phenytoin from its binding sites. The amount of free phenytoin would rise but this would be quickly eliminated by metabolism and excretion thereby keeping the amount of free active phenytoin the same. However, the total amount of phenytoin would now be reduced. Therefore if phenytoin was monitored using an assay looking at total phenytoin levels it may appear that the phenytoin is subtherapeutic and that the dose may therefore need increasing. However, as the amount of free active phenytoin is unchanged this would not be necessary and may even be dangerous.

Basic drugs as well as acidic drugs can be highly protein bound, but clinically important displacement interactions do not seem to have been described. The reasons seem to be that the binding sites within the plasma are different from those occupied by acidic drugs (alpha-1 acid glycoprotein rather than albumin) and, in addition, basic drugs have a large Vd with only a small proportion of the total amount of drug being within the plasma.

### (b) Induction or inhibition of drug transport proteins

It is increasingly being recognised that distribution of drugs into the brain, and some other organs such as the testes, is limited by the action of drug transport proteins such as P-glycoprotein. These proteins actively transport drugs out of cells when they have passively diffused in. Drugs that are inhibitors of these transporters could therefore increase the uptake of drug substrates into the brain, which could either increase adverse CNS effects, or be beneficial. For more information see ‘Drug transporter proteins’, (p.8).

## 1.3. Drug metabolism (biotransformation) interactions

Although a few drugs are cleared from the body simply by being excreted unchanged in the urine, most are chemically altered within the body to less lipid-soluble compounds, which are more easily excreted by the kidneys. If these were not so, many drugs would persist in the body and continue to exert their effects for a long time. This chemical change is called `metabolism`, `biotransformation`, `biochemical degradation` or sometimes `detoxification`. Some drug metabolism goes on in the serum, the kidneys, the skin and the intestines, but the greatest proportion is carried out by enzymes that are found in the membranes of the endoplasmic reticulum of the liver cells. If liver is homogenised and then centrifuged, the reticulum breaks up into small sacs called microsomes which carry the enzymes, and it is for this reason that the metabolising enzymes of the liver are frequently referred to as the `liver microsomal enzymes`.

We metabolise drugs by two major types of reaction. The first, so-called phase I reactions (involving oxidation, reduction or hydrolysis), turn drugs into more polar compounds, while phase II reactions involve coupling drugs with some other substance (e.g. glucuronic acid, known as glucuronidation) to make usually inactive compounds.

The majority of phase I oxidation reactions are carried out by the haem-containing enzyme cytochrome P450. Cytochrome P450 is not a single entity, but is in fact a very large family of related isoenzymes, about 30 of which have been found in human liver tissue. However, in practice, only a few specific subfamilies seem to be responsible for most (about 90%) of the metabolism of the commonly used drugs. The most important isoenzymes are: CYP3A4, CYP2C9, CYP2C19, CYP2D6, CYP2E1 and CYP3A4. Other enzymes involved in phase I metabolism include monoamine oxidases and epoxide hydrolases.

Less is known about the enzymes responsible for phase II conjugation reactions. However, UDP-glucuronitransferases (UGT), methyltransferases, and N-acetyltransferases (NAT) are examples.

Although metabolism is very important in the body removing drugs, it is increasingly recognised that drugs can be adsorbed, distributed, or eliminated by transporters, the most well understood at present being `P-glycoprotein`, (p.8).
(a) Changes in first-pass metabolism

(i) Changes in blood flow through the liver

After absorption in the intestine, the portal circulation takes drugs directly to the liver before they are distributed by the blood flow around the rest of the body. A number of highly lipid-soluble drugs undergo substantial biotransformation during this first-pass through the gut wall and liver and there is some evidence that some drugs can have a marked effect on the extent of first-pass metabolism by altering the blood flow through the liver. However, there are few clinically relevant examples of this, and many can be explained by other mechanisms, usually altered hepatic metabolism (see (ii) below). One possible example is the increase in rate of absorption of doxetilide with ‘verapamil’, (p.256), which has resulted in an increased incidence of torsade de pointes.

Another is the increase in bioavailability of high-extraction beta blockers with ‘hydralazine’, (p.847), possibly caused by altered hepatic blood flow, or altered metabolism.

(ii) Inhibition or induction of first-pass metabolism

The gut wall contains metabolising enzymes, principally the cytochrome P450 isoenzymes. In addition to the altered metabolism caused by changes in hepatic blood flow (see (i) above) there is evidence that some drugs can have a marked effect on the extent of first-pass metabolism by inhibiting or inducing the cytochrome P450 isoenzymes in the gut wall or in the liver. An example is the effect of grapefruit juice, which seems to inhibit the cytochrome P450 isoenzyme CYP3A4, mainly in the gut, and therefore reduces the metabolism of oral calcium-channel blockers. Although altering the amount of drug ‘absorbed’, these interactions are usually considered drug metabolism interactions. The effect of grapefruit on the metabolism of other drugs is discussed further under ‘Drug-food interactions’, (p.11).

(b) Enzyme induction

When barbiturates were widely used as hypnotics it was found necessary to keep increasing the dosage as time went by to achieve the same hypnotic effect, the reason being that the barbiturates increase the activity of the microsomal enzymes so that extent of metabolism and excretion increases. This phenomenon of enzyme stimulation or ‘induction’ not only accounts for the need for an increased barbiturate dose but if another drug that is metabolised by the same range of enzymes is also present, its enzymatic metabolism is similarly increased and larger doses are needed to maintain the same therapeutic effect. However, note that not all enzyme-inducing drugs induce their own metabolism (a process known as auto-induction). The metabolic pathway that is most commonly induced is phase I oxidation mediated by the cytochrome P450 isoenzymes. The main drugs responsible for induction of the most clinically important cytochrome P450 isoenzymes are listed in ‘Table 1.2’, (p.4), ‘Table 1.3’, (p.6), ‘Table 1.4’, (p.6). ‘Figure 1.2’, (see below) shows the reduction in trough ciclosporin levels when it is given with the enzyme inducer, St John’s wort. ‘St John’s wort’, (p.1037), induces the metabolism of ciclosporin by induction of CYP3A4 and possibly also P-glycoprotein. ‘Figure 1.3’, (see above) shows the effects of another enzyme inducer, rifampicin (rifampin) on the serum levels of ‘ciclosporin’, (p.1022), presumably via its effects on CYP3A4. Phase II glucuronidation can also be induced. An example is when rifampicin induces the glucuronidation of ‘zidovudine’, (p.792).

The extent of the enzyme induction depends on the drug and its dosage, but it may take days or even 2 to 3 weeks to develop fully, and may persist for a similar length of time when the enzyme inducer is stopped. This means that enzyme induction interactions are delayed in onset and slow to resolve. Enzyme induction is a common mechanism of interaction and is not confined to drugs; it is also caused by the chlorinated hydrocarbon insecticides such as dicoflite and lindane, and smoking tobacco.

If one drug reduces the effects of another by enzyme induction, it may be possible to accommodate the interaction simply by raising the dosage of the drug affected, but this requires good monitoring, and there are obvious hazards if the inducing drug is eventually stopped without remembering to reduce the dosage again. The raised drug dosage may be an overdose when the drug metabolism has returned to normal.

(c) Enzyme inhibition

More common than enzyme induction is the inhibition of enzymes. This results in the reduced metabolism of an affected drug, so that it may begin to accumulate within the body, the effect usually being essentially the same as when the dosage is increased. Unlike enzyme induction, which may take several days or even weeks to develop fully, enzyme inhibition can occur within 2 to 3 days, resulting in the rapid development of toxicity. The metabolic pathway that is most commonly inhibited is phase I oxidation by the cytochrome P450 isoenzymes. The main drugs responsible for inhibition of the most clinically important cytochrome P450 isoenzymes are listed in ‘Table 1.2’, (p.4), ‘Table 1.3’, (p.6), ‘Table 1.4’, (p.6). For example a marked increase occurred in the plasma levels of a single dose of sildenafil after ritonavir had also been taken for 7 days, probably because ritonavir inhibits the metabolism of sildenafil by CYP3A4 (see ‘Phosphodiesterase type-5 inhibitors + Protease inhibitors’, p.1273).

An example of inhibition of phase I hydrolytic metabolism, is the inhibition of epoxide hydrolase by valpromide, which increases the levels of ‘ carvedazine’, (p.537). Phase II conjugative metabolism can also be inhibited. Examples are the inhibition of carbamazepine glucuronidation by

sodium valproate’, (p.537), and the inhibition of methyltransferase by aminosalicylates causing raised levels of ‘azathioprine’, (p.665).

The clinical significance of many enzyme inhibition interactions depends on the extent to which the serum levels of the drug rise. If the serum levels remain within the therapeutic range the interaction may not be clinically important.

(d) Genetic factors in drug metabolism

An increased understanding of genetics has shown that some of the cytochrome P450 isoenzymes are subject to ‘genetic polymorphism’, which simply means that some of the population have a variant of the isoenceyme with different (usually poor) activity. The best known example is CYP2D6, for which a small proportion of the population have the variant with low activity and are described as being poor or slow metabolisers (about 5 to 10% of Caucasians, 0 to 2% in Asians and black people). Which group any particular individual falls into is genetically determined. The majority who possess the isoenceyme are called ‘fast or extensive metabolisers’. It is possible to find out which group any particular individual falls into by looking at the way a single dose of a test or ‘probe’ drug is metabolised. This varying ability to metabolise certain drugs may explain why some patients develop toxicity when given an interacting drug while others remain symptom free. CYP2D6, CYP2C9 and CYP2C19 also show polymorphism, whereas CYP3A4 does not, although there is still some broad variation in the population without there being distinct groups. The effects of CYP2C19 polymorphism are discussed in more detail in ‘Gastrointestinal drugs’, (p.960). At present, genotyping of cytochrome P450 isoenzymes is primarily a research tool and is not used clinically. In the future, it may become standard clinical practice and may be used to individualise drug therapy.1

(e) Cytochrome P450 isoenzymes and predicting drug interactions

It is interesting to know which particular isoenceyme is responsible for the metabolism of drugs because by doing in vitro tests with human liver enzymes it is often possible to explain why and how some drugs interact. For example, ciclosporin is metabolised by CYP3A4, and we know that rifampicin (rifampin) is a potent inducer of this isoenceyme, whereas ketoconazole inhibits its activity, so that it comes as no surprise that rifampicin reduces the effects of ciclosporin and ketoconazole increases it. What is very much more important than retrospectively finding out why two drugs interact, is the knowledge such in vitro tests can provide about forecasting which other drugs may possibly also interact. This may reduce the numbers of expensive clinical studies in subjects with the patient and avoids waiting until significant drug interactions are observed in clinical use. A lot of effort is being put into this area of drug development.2-4 However, at present such prediction is, like weather forecasting, still a somewhat hit-and-miss business because we do not know all of the factors that may modify or interfere with metabolism. It is far too simplistic to think that we have all the answers just because we know which liver isoenceymes are concerned with the metabolism of a particular drug, but it is a very good start.

‘Table 1.2’, (p.4), ‘Table 1.3’, (p.6), ‘Table 1.4’, (p.6) are lists of drugs that are inhibitors, inducers, or substrates of the clinically important cytochrome P450 isoenzymes, and each drug has a cross reference to a monograph describing a drug interaction thought to occur via that mechanism. If a new drug is shown to be an inducer, or an inhibitor, and/or a substrate of a given isoenceyme, these tables could be used to predict likely drug interactions. However, what may happen in vitro may not necessarily work in clinical practice because all of the many variables which can come into play are not known (such as how much of the enzyme is available, the concentration of the drug at the site of metabolism, and the affinity of the drug for the enzyme). Remember too that some drugs can be metabolised by more than one cytochrome P450 isoenceyme (meaning that this other isoenceyme may be able to ‘pick up’ more metabolism to compensate for the inhibited pathway); some drugs (and their metabolites) can both induce a particular isoenceyme and be metabolised by it; and some drugs (or their metabolites) can inhibit a particular isoenceyme but not be metabolised by it. With so many factors possibly impinging on the outcome of giving two or more drugs together, it is very easy to lose sight of one of the factors (or not even know about it) so that the sum of 2 plus 2 may not turn out to be the 4 that you have predicted.

For example, ritonavir and other protease inhibitors are well known potent inhibitors of CYP3A4, and in clinical use increase the levels of many drugs that are substrates of this isoenceyme. Methadone is a substrate of CYP3A4, and some in vitro data show that ritonavir (predictably) increased methadone levels. However, unexpectedly, in clinical use the protease inhibitors seem to decrease methadone levels, by a yet unknown mechanism (see, ‘Opioids; Methadone + Protease inhibitors’, (p.182)).

Another factor complicating the understanding of metabolic drug interactions is the finding that there is a large overlap between the inhibitors/inductors and substrates of P-glycoprotein (a ‘drug transporter protein’, (p.8)) and those of CYP3A4. Therefore, both mechanisms may be involved in many of the drug interactions previously thought to be due to effects on CYP3A4.

I.4. Drug excretion interactions

With the exception of the inhalation anaesthetics, most drugs are excreted either in the bile or in the urine. Blood entering the kidneys along the renal arteries is, first of all, delivered to the glomeruli of the tubules where molecules small enough to pass through the pores of the glomerular membrane (e.g. water, salts, some drugs) are filtered through into the lumen of the tubules. Larger molecules, such as plasma proteins, and blood cells are retained within the blood. The blood flow then passes to the remaining parts of the kidney tubules where active energy-using transport systems are able to remove drugs and their metabolites from the blood and secrete them into the tubular filtrate. The renal tubular cells additionally possess active and passive transport systems for the reabsorption of drugs. Interference by drugs with renal tubular fluid pH, with active transport systems and with blood flow to the kidney can alter the excretion of other drugs.

X + H \rightarrow HX

Drug lost in urine

Fig. 1.4 An excretion interaction. If the tubular filtrate is acidified, most of the molecules of weakly acid drugs (HX) exist in an un-ionised lipid-soluble form and are able to return through the lipid membranes of the tubule cells by simple diffusion. Thus they are retained. In alkaline urine most of the drug molecules exist in an ionised non-lipid soluble form (X). In this form the molecules are unable to diffuse freely through these membranes and are therefore lost in the urine.

(a) Changes in urinary pH

As with drug absorption in the gut, passive reabsorption of drugs depends upon the extent to which the drug exists in the non-ionised lipid-soluble form, which in its turn depends on its pKa and the pH of the urine. Only the non-ionised form is lipid-soluble and able to diffuse back through the lipid membranes of the tubule cells. Thus at high pH values (alkaline), weakly acid drugs (pKa 3 to 7.5) largely exist as ionised lipid-insoluble molecules, which are unable to diffuse into the tubule cells and will there-

fore remain in the urine and be removed from the body. The converse will be true for weak bases with pKₐ values of 7.5 to 10.5. Thus pH changes that increase the amount in the ionised form (alkaline urine for acidic drugs, acid urine for basic drugs) increase the loss of the drug, whereas moving the pH in the opposite direction will increase their retention. ‘Figure 1.4’, (p.7) illustrates the situation with a weakly acidic drug. The clinical significance of this interaction mechanism is small, because although a very large number of drugs are either weak acids or bases, almost all are largely metabolised by the liver to inactive compounds and few are excreted in the urine unchanged. In practice therefore only a handful of drugs seem to be affected by changes in urinary pH (possible exceptions include changes in the excretion of ‘quinidine’, (p.277) or ‘analgesic-dose aspirin’, (p.135), due to alterations in urinary pH caused by antacids, and the increase in the clearance of ‘methotrexate’, (p.654), with urinary alkalinisers). In cases of overdose, deliberate manipulation of urinary pH has been used to increase the removal of drugs such as methotrexate and salicylates.

### (b) Changes in active renal tubular excretion

Drugs that use the same active transport systems in the renal tubules can compete with one another for excretion. For example, probenecid reduces the excretion of penicillin and other drugs. With the increasing understanding of drug transporter proteins in the kidneys, it is now known that probenecid inhibits the renal secretion of many other anionic drugs by organic anion transporters (OATs).1 Probenecid possibly also inhibits some of the ABC transporters in the kidneys. The ABC transporter, P-glycoprotein, is also present in the kidneys, and drugs that alter this may alter renal drug elimination. See, ‘Drug transporter proteins’, (p.8), for further discussion. Some examples of drugs that possibly interact by alterations in renal transport are given in ‘Table 1.5’, (see above).

### (c) Changes in renal blood flow

The flow of blood through the kidney is partially controlled by the production of renal vasodilatory prostaglandins. If the synthesis of these prostaglandins is inhibited the renal excretion of some drugs may be reduced. An example of this is the inhibition of renal vasodilatory prostaglandins. If the synthesis of these prostaglandins is inhibited the renal excretion of some drugs may be reduced. An example of this is the inhibition of renal vasodilatory prostaglandins.

### (d) Biliary excretion and the entero-hepatic shunt

#### (i) Enterohepatic recirculation

A number of drugs are excreted in the bile, either unchanged or conjugated (e.g. as the glucuronide) to make them more water soluble. Some of the conjugates are metabolised to the parent compound by the gut flora and are then reabsorbed. This recycling process prolongs the stay of the drug within the body, but if the gut flora are diminished by the presence of an antibacterial, the drug is not recycled and is lost more quickly. This may possibly explain the rare failure of the oral contraceptives that can be brought about by the concurrent use of penicillins or tetracyclines, but see Mechanism in ‘Hormonal contraceptives + Antibacterials; Penicillins’, p.981. Antimicrobial-induced reductions in gut bacteria may reduce the activation of ‘sulfasalazine’, (p.973).

#### (ii) Drug transporters

Increasing research shows that numerous drug transporter proteins (both from the ABC family and SLC family, see ‘Drug transporter proteins’, (see below)) are involved in the hepatic extraction and secretion of drugs into the bile.2 The relevance of many of these to drug interactions is still unclear, but the bile salt export pump (ABC11) is known to be inhibited by a variety of drugs including ciclosporin, glibenclamide, and bosentan. Inhibition of this pump may increase the risk of cholestasis, and the manufacturer of bosentan says that they should be avoided in patients taking bosentan (see ‘glibenclamide’, (p.515) and ‘ciclosporin’, (p.1026)).

### 1.5. Drug transporter proteins

Drugs and endogenous substances are known to cross biological membranes, not just by passive diffusion, but by carrier-mediated processes, often known as transporters. Significant advances in the identification of various transporters have been made, although the contribution of many of these drug interactions in particular, is uncertain.1,2 The most well known is P-glycoprotein, which is a product of the MDR1 gene (ABC1 gene) and a member of the ATP-binding cassette (ABC) family of efflux transporters.1 Its involvement in drug interactions is discussed in (a) below.

Another ABC transporter is sister P-glycoprotein, otherwise called the bile salt export pump (BSEP or ABCB11).1 It has been suggested that inhibition of this pump may increase the risk of cholestasis, see Drug transporters under ‘Drug excretion interactions’, (p.7).

Other transporters that are involved in some drug interactions are the organic anion transporters (OATs), organic anion-transporting polypeptides (OATPs) and organic cation transporters (OCTs), which are members of the solute carrier superfamily (SLC) of transporters.1 The best known example of an OCT inhibitor is probenecid, which affects the renal excretion of a number of drugs, see Changes in active kidney tubule excretion under ‘Drug excretion interactions’, (p.7).

#### (a) P-glycoprotein interactions

More and more evidence is accumulating to show that some drug interactions occur because they interfere with the activity of P-glycoprotein. This is an efflux pump found in the membranes of certain cells, which can push metabolites and drugs out of the cells and have an impact on the extent of drug absorption (via the intestine), distribution (to the brain, testis, or placenta) and elimination (in the urine and bile). So, for example, the P-glycoprotein in the cells of the gut lining can eject some already-absorbed drug molecules back into the intestine resulting in a reduction in the total amount of drug absorbed. In this way P-glycoprotein acts as a barrier to absorption. The activity of P-glycoprotein in the endothelial cells of the blood-brain barrier can also eject certain drugs from the brain, limiting CNS penetration and effects.

The pumping actions of P-glycoprotein can be induced or inhibited by some drugs. So for example, the induction (or stimulation) of the activity of P-glycoprotein by rifampicin (rifampin) within the lining cells of the gut causes digoxin to be ejected into the gut more vigorously. This results in a fall in the plasma levels of digoxin (see ‘Digitalis glycosides + Rifamycins’, p.938). In contrast, verapamil appears to inhibit the activity of P-glycoprotein, and is well known to increase digoxin levels (see ‘Digitalis glycosides + Calcium-channel blockers; Verapamil’, p.916). Ketocana-zole also has P-glycoprotein inhibitory effects, and has been shown to increase CSF levels of ritonavir, possibly by preventing the efflux of ritonavir from the CNS (see ‘Protease inhibitors + Azoles; Ketoconazole’,

### Table 1.6 Some possible inhibitors and inducers of P-glycoprotein shown to alter the levels of P-glycoprotein substrates in clinical studies

Thus the induction or inhibition of P-glycoprotein can have an impact on the pharmacokinetics of some drugs. Note that there is evidence that P-glycoprotein inhibition may have a greater impact on drug distribution (e.g. into the brain) than on drug absorption (e.g. plasma levels).\(^2\)

There is an overlap between CYP3A4 and P-glycoprotein inhibitors, inducers and substrates. Therefore, both mechanisms may be involved in many of the drug interactions traditionally thought to be due to changes in CYP3A4. ‘Table 1.6’, (p.8) lists some possible P-glycoprotein inhibitors and inducers. Many drugs that are substrates for CYP3A4 (see ‘Table 1.4’, (p.6)) are also substrates for P-glycoprotein. Digoxin and talinolol are examples of the few drugs that are substrates for P-glycoprotein but not CYP3A4.

P-glycoprotein is also expressed in some cancer cells (where it was first identified). This has led to the development of specific P-glycoprotein inhibitors, such as valspador, with the aim of improving the penetration of cytotoxic drugs into cancer cells.

### 2. Pharmacodynamic interactions

Pharmacodynamic interactions are those where the effects of one drug are changed by the presence of another drug at its site of action. Sometimes the drugs directly compete for particular receptors (e.g. beta, agonists, such as salbutamol, and beta blockers, such as propranolol) but often the reaction is more indirect and involves interference with physiological mechanisms. These interactions are much less easy to classify neatly than those of a pharmacokinetic type.

#### 2.1. Additive or synergistic interactions

If two drugs that have the same pharmacological effect are given together the effects can be additive. For example, alcohol depresses the CNS and, if taken in moderate amounts with normal therapeutic doses of any of a large number of drugs (e.g. anxioyltics, hypnotics, etc.), may cause excessive drowsiness. Strictly speaking (as pointed out earlier) these are not interactions within the definition given in ‘What is a drug interaction?’ (p.1). Nevertheless, it is convenient to consider them within the broad context of the clinical outcome of giving two drugs together.

Additive effects can occur with both the main effects of the drugs as well as their adverse effects, thus an additive ‘interaction’ can occur with antimuscarinic antiparkinson drugs (main effect) or butyrophenones (adverse effect) that can result in serious antimuscarinic toxicity (see ‘Antipsychotics + Antimuscarinics’, p.708).

Sometimes the additive effects are solely toxic (e.g. additive otoxicity, nephrotoxicity, bone marrow depression, QT interval prolongation). Examples of these reactions are listed in ‘Table 1.7’, (see below). It is common to use the terms ‘additive’, ‘summation’, ‘synergy’ or ‘potentiation’ to describe what happens if two or more drugs behave like this. These words have precise pharmacological definitions but they are often used rather loosely as synonyms because in practice it is often very difficult to know the extent of the increased activity, that is to say whether the effects are greater or smaller than the sum of the individual effects.

### The serotonin syndrome

In the 1950s a serious and life-threatening toxic reaction was reported in patients taking iproniazid (an MAOI) when they were given ‘phetidine (meperidine)’. (p.1140). The reasons were then not understood and even now we do not have the full picture. What happened is thought to have been due to over-stimulation of the 5-HT\(_{1A}\) and 5-HT\(_{1B}\) receptors and possibly other serotonin receptors in the central nervous system (in the brain stem and spinal cord in particular) due to the combined effects of these two drugs. It can occur exceptionally after taking only one drug, which causes over-stimulation of these 5-HT receptors, but much more usually it develops when two or more drugs (so-called serotonergic or serotonin mimetic drugs) act in concert. The characteristic symptoms (now known as the serotonin syndrome) fall into three main areas, namely altered mental status (agitation, confusion, mania), autonomic dysfunction (diaphoresis, diarrhoea, fever, shivering) and neuromuscular abnormalities (hyperreflexia, incoordination, myoclonus, tremor). These are the ‘Sternbach diagnostic criteria’ named after Dr Harvey Sternbach who drew up this list of clinical features and who suggested that at least three of them need to be seen before classifying this toxic reaction as the serotonin syndrome rather than the neuroleptic malignant syndrome.\(^1\)

The syndrome can develop shortly after one serotonergic drug is added to another, or even if one is replaced by another without allowing a long enough washout period in between, and the problem usually resolves within about 24 hours if both drugs are withdrawn and supportive measures are taken. Non-specific serotonin antagonists (cyproheptadine, chlorpromazine, methysergide) have also been used for treatment. Most patients recover uneventfully, but there have been a few fatalities.

</tbody>
</table>

Following the first report of this syndrome, many other cases have been described involving ‘tryptophan and MAOIs’, (p.1151), the ‘tricyclic antidepressants and MAOIs’, (p.1149), and, more recently, the ‘SSRIs’, (p.1142) but other serotonergic drugs have also been involved and the list continues to grow.

It is still not at all clear why many patients can take two, or sometimes several serotonergic drugs together without problems, while a very small number develop this serious toxic reaction, but it certainly suggests that there are as yet other factors involved that have yet to be identified. The full story is likely to be much more complex than just the simple additive effects of two drugs.

### 2.2. Antagonistic or opposing interactions

In contrast to additive interactions, there are some pairs of drugs with activities that are opposed to one another. For example the coumarins can prolong the blood clotting time by competitively inhibiting the effects of dietary vitamin K. If the intake of vitamin K is increased, the effects of the
oral anticoagulant are opposed and the prothrombin time can return to normal, thereby cancelling out the therapeutic benefits of anticoagulant treatment (see ‘Coumarins and related drugs + Vitamin K substances’, p.458). Other examples of this type of interaction are listed in ‘Table 1.8’, (see below).

### 2.3. Drug or neurotransmitter uptake interactions

A number of drugs with actions that occur at adrenergic neurones can be prevented from reaching those sites of action by the presence of other drugs. The tricyclic antidepressants prevent the re-uptake of noradrenaline (norepinephrine) into peripheral adrenergic neurones. Thus patients taking tricyclics and given parenteral noradrenaline have a markedly increased response (hypertension, tachycardia); see ‘Tricyclic antidepressants + Inotropes and Vasopressors’, p.1237. Similarly, the uptake of guanethidine (and related drugs guanoclor, betanidine, debrisoquine, etc.) is blocked by ‘chlorpromazine, haloperidol, tiotixene’, (p.887), a number of ‘amphetamine-like drugs’, (p.886) and the ‘tricyclic antidepressants’, (p.888) so that the antihypertensive effect is prevented. The antihypertensive effects of clonidine are also prevented by the tricyclic antidepressants, one possible reason being that the uptake of clonidine within the CNS is blocked (see ‘Clonidine + Tricyclic and related antidepressants’, p.884). Some of these interactions at adrenergic neurones are illustrated in ‘Figure 1.5’, (see below).

### E. Drug-herb interactions

The market for herbal medicines and supplements in the Western world has markedly increased in recent years, and, not surprisingly, reports of interactions with ‘conventional’ drugs have arisen. The most well known and documented example is the interaction of St John’s wort (Hypericum perforatum) with a variety of drugs, see below. There have also been isolated reports of other herbal drug interactions, attributable to various mechanisms, including additive pharmacological effects.

Based on these reports, there are a growing number of reviews of herbal medicine interactions, which seek to predict likely interactions based on the, often hypothesised, actions of various herbs. Many of these predictions seem tenuous at best. Rather than add to the volume of predicted interactions, at present, Stockley’s Drug Interactions includes only those interactions for which there are published reports.
To aid collection of data in this area, health professionals should routinely ask patients about their use of herbal medicines and supplements, and report any unexpected responses to treatment.

An additional problem in interpreting these interactions, is that the interacting constituent of the herb is usually not known and is therefore not standardised for. It could vary widely between different products, and batches of the same product.

**St John’s wort**

An increasing number of reports have implicated St John’s wort (Hypericum perforatum) in drug interactions. Evidence has shown that the herb can induce the cytochrome P450 isozyme CYP3A4, and can also induce ‘ciclosporin’, (p.1037) and ‘digoxin’, (p.927), respectively. Other less certain evidence suggests that CYP2E1 and CYP1A2 may also be induced. St John’s wort has serotoninergic properties, and this has resulted in a pharmacodynamic interaction with the ‘SSRIs’, (p.1224), namely the development of the serotonin syndrome. St John’s wort contains many possible constituents that could be responsible for its pharmacological effects. The major active constituents are currently considered to be hyperforin (a naphthodianthrone). Hypericin is the major active constituent are currently considered to be hyperforin (a naphthodianthrone). Hypericin is the only constituent that is standardised for, and then only in some St John’s wort preparations.

**General considerations**

**F. Drug-food interactions**

It is well established that food can cause clinically important changes in drug absorption through effects on gastrointestinal motility or by drug binding, see ‘Drug absorption interactions’, (p.3). In addition, it is well known that tyramine (present in some foodstuffs) may reach toxic concentrations in patients taking ‘MAOIs’, (p.1153). With the growth in understanding of drug metabolism mechanisms, it has been increasingly recognised that some foods can alter drug metabolism. Currently, grapefruit juice causes the most clinically relevant of these interactions, see (b) below.

(a) **Cruciferous vegetables and charcoal-broiled meats**

Cruciferous vegetables, such as brussels sprouts, cabbage, and broccoli, contain substances that are inducers of the cytochrome P450 isozyme CYP1A2. Chemicals formed by ‘burning’ meats additionally have these properties. These foods do not appear to cause any clinically important drug interactions in their own right, but their consumption may add another variable to drug interaction studies, so complicating interpretation. In drug interaction studies where alteration of CYP1A2 is a predicted mechanism, it may be better for patients to avoid these foods during the study.

(b) **Grapefruit juice**

By chance, grapefruit juice was chosen to mask the taste of alcohol in a study of the effect of alcohol on felodipine, which led to the discovery that grapefruit juice itself markedly increased felodipine levels, see ‘Calcium-channel blockers + Grapefruit juice’, p.869. In general, grapefruit juice inhibits intestinal CYP3A4, and only slightly affects hepatic CYP3A4. This is demonstrated by the fact that intravenous preparations of drugs that are metabolised by CYP3A4 are not much affected, whereas oral preparations of the same drugs are. These interactions result in increased drug levels.

Some drugs that are not metabolised by CYP3A4 show decreased levels with grapefruit juice, such as ‘fexofenadine’, (p.588). The probable reason for this is that grapefruit juice is an inhibitor of some drug transporters (see ‘Drug transporter proteins’, (p.8)), and possibly affects organic anion-transporting polypeptides (OATPs), although inhibition of P-glycoprotein has also been suggested.

The active constituent of grapefruit juice is uncertain. Grapefruit contains naringin, which degrades during processing to naringenin, a substance known to inhibit CYP3A4. Because of this, it has been assumed that whole grapefruit will not interact, but that processed grapefruit juice will. However, subsequently some reports have implicated the whole fruit. Other possible active constituents in the whole fruit include bergamottin and dihydroxybergamottin.

**General references**

**G. Conclusions**

It is now quite impossible to remember all the known clinically important interactions and how they occur, which is why this reference publication has been produced, but there are some broad general principles that need little memorising:

- Be on the alert with any drugs that have a narrow therapeutic window or where it is necessary to keep serum levels at or above a suitable level (e.g. anticoagulants, anti-diabetic drugs, antiepileptics, antihypertensives, anti-infectives, antinflammatory cytokotyes, digitalis glycosides, immunosuppressants, etc.).
- Remember some of those drugs that are key enzyme inducers (e.g. phenytion, barbiturates, rifampicin, etc) or enzyme inhibitors (e.g. azole antifungal, HIV- protease inhibitors, erythromycin, SSRIs).
- Think about the basic pharmacology of the drugs under consideration so that obvious problems (additive CNS depression for example) are not overlooked, and try to think what might happen if drugs that affect the same receptors are used together. And don’t forget that many drugs affect more than one type of receptor.
- Keep in mind that the elderly are at risk because of reduced liver and renal function on which drug clearance depends.
ACE inhibitors (angiotensin-converting enzyme inhibitors) prevent the production of angiotensin II from angiotensin I. The angiotensin II receptor antagonists are more selective, and target the angiotensin II type I (AT₁) receptor, which is responsible for the pressor actions of angiotensin II.

Angiotensin II is involved in the renin-angiotensin-aldosterone system, which regulates blood pressure, sodium and water homoeostasis by the kidneys, and cardiovascular function. Angiotensin II stimulates the synthesis and secretion of aldosterone and raises blood pressure via a direct vasoconstrictor effect.

Angiotensin converting enzyme (ACE) is identical to bradykinase, so ACE inhibitors may additionally reduce the degradation of bradykinin and affect enzymes involved in the production of prostaglandins.

Many of the interactions of the ACE inhibitors and angiotensin II receptor antagonists involve drugs that affect blood pressure. Consequently in most cases the result is either an increase in the hypotensive effect (e.g. ‘alcohol’, (p.48)) or a decrease in the hypotensive effect (e.g. ‘indometacin’, (p.28)).

In addition, due to their effects on aldosterone, the ACE inhibitors and angiotensin II antagonists may increase potassium concentrations and can therefore have additive hyperkalaemic effects with other drugs that cause elevated potassium levels. Furthermore, drugs that affect renal function may potentiate the adverse effects of ACE inhibitors and angiotensin II antagonists on the kidneys.

Most ACE inhibitor and angiotensin II receptor antagonist interactions are pharmacodynamic, that is, interactions that result in an alteration in drug effects rather than drug disposition, so in most cases interactions of individual drugs will be applicable to the group. In vitro experiments suggest that the role of cytochrome P450 isoenzymes in the metabolism and interactions of the angiotensin II receptor antagonists (candesartan, eprosartan, irbesartan, losartan and valsartan) is small, although losartan, irbesartan, and to a minor extent, candesartan, are metabolised by CYP2C9. Only losartan and irbesartan were considered to have a theoretical potential for pharmacokinetic drug interactions involving the CYP2C9 enzyme.1 See ‘Angiotensin II receptor antagonists + Azoles’, p.35. The ACE inhibitors do not appear to undergo interactions via cytochrome P450 isoenzymes.

‘Table 2.1’, (see below) lists the ACE inhibitors and the angiotensin II receptor antagonists. Although most of the interactions of the ACE inhibitors or angiotensin II receptor antagonists are covered in this section, if the ACE inhibitor or angiotensin II receptor antagonist is the affecting drug, the interaction is dealt with elsewhere.

ACE inhibitors and AT II receptor antagonists

Three cases of Stevens-Johnson syndrome (one fatal) and two cases of hypersensitivity have been attributed to the use of captopril with allopurinol. Anaphylaxis and myocardial infarction occurred in one man taking enalapril when given allopurinol. The combination of ACE inhibitors and allopurinol may increase the risk of leucopenia and serious infection, especially in renal impairment.

Clinical evidence

An elderly man with hypertension, chronic renal failure, congestive heart failure and mild polyarthritis receiving multiple drug treatment, which included captopril 25 mg twice daily and diuretics, developed fatal Stevens-Johnson syndrome about 5 weeks after starting to take allopurinol 100 mg twice daily.1 The authors of the report noted that the manufacturer of captopril was aware of two other patients who developed the syndrome 3 to 5 weeks after allopurinol was started.2 Another report describes fever, arthralgia and myalgia in a diabetic man with chronic renal failure who was also given captopril and allopurinol. He improved when the captopril was withdrawn.2 Exfoliative facial dermatitis occurred in a patient with renal failure who was taking captopril and allopurinol.3 A man taking enalapril had an acute anaphylactic reaction with severe coronary spasm, culminating in myocardial infarction, within 20 minutes of taking allopurinol 100 mg. He recovered and continued to take enalapril without allopurinol.4

The UK manufacturer of captopril also warns that neutropenia and agranulocytosis, resulting in serious infection, have occurred in patients taking captopril and other ACE inhibitors, and that concurrent treatment with allopurinol may be a complicating factor, especially in those with renal impairment.5 However, the US manufacturer notes that, while renal impairment and a relatively high dose of captopril markedly increases the risk of neutropenia, no association between allopurinol and captopril and neutropenia has appeared in US reports.6

No significant pharmacokinetic changes were seen in 12 healthy subjects given allopurinol and captopril alone and in combination.7

Mechanism

Not understood. It is uncertain whether these are interactions because allopurinol alone can cause severe hypersensitivity reactions, particularly in the presence of renal failure and in conjunction with diuretic use. Captopril can also induce a hypersensitivity reaction.

Importance and management

These interactions are not clearly established, and the reaction appears to be rare and unpredictable. All that can be constructively said is that patients taking both drugs should be very closely monitored for any signs of hypersensitivity (e.g. skin reactions) or low white cell count (sore throat, fever), especially if they have renal impairment. The UK manufacturer of captopril recommends that differential white blood cell counts should be performed before adding allopurinol, then every 2 weeks during the first 3 months of treatment, and periodically thereafter. Similar caution and advice is given by the UK manufacturers of several other ACE inhibitors. For other possible interactions with ACE inhibitors that might result in an increased risk of leucopenia see also ‘ACE inhibitors + Azathioprine’, p.18 and ‘ACE inhibitors + Procaainamide’, p.33.

ACE inhibitors + Angiotensin II receptor antagonists

The combined use of ACE inhibitors and angiotensin II receptor antagonists increases the risk of hypotension, renal impairment and hyperkalaemia in patients with heart failure.

Clinical evidence, mechanism, importance and management

Both ACE inhibitors and angiotensin II receptor antagonists can have adverse renal effects and can cause hyperkalaemia. These effects might be expected to be additive when they are used together. In one randomised clinical study in patients with heart failure taking ACE inhibitors, the addition of candesartan resulted in higher rates of withdrawals than placebo for renal impairment (increase in creatinine 7.8% versus 4.1%) and hyperkalaemia (3.4% versus 0.7%).1 In another double-blind study in patients with heart failure, the combination of valsartan and captopril resulted in a higher incidence of adverse events leading to a dose reduction or a discontinuation of study treatment than either drug alone. For hypotension, treatment was discontinued in 90 (1.9%) of patients in the combined group, 70 (1.4%) of patients in the valsartan group, and 41 (0.8%) of patients in the captopril group. For renal causes the corresponding figures were 61 (1.3%), 53 (1.1%) and 40 (0.8%) of patients, respectively, and for hyperkalaemia the figures were 12 (0.2%), 7 (0.1%) and 4 (0.1%) of patients, respectively.2

Monitor renal function and serum potassium carefully when combination therapy is used.

ACE inhibitors + Antacids

An aluminium/magnesium hydroxide antacid reduced the bioavailability of captopril by 40%, but this did not seem to be clinically important. The bioavailability of fosinopril was reduced by about one-third by Mylanta. An antacid did not affect ramipril pharmacokinetics.

Clinical evidence

In 10 healthy subjects an antacid containing aluminium/magnesium hydroxide and magnesium carbonate reduced the AUC of a single 50-mg dose of captopril by about 40%, when compared with the fasting state. However, this did not alter the extent of the reduction in blood pressure.1 Another study found that Mylanta [aluminium/magnesium hydroxide and simeticon2] reduced the bioavailability of fosinopril 20 mg by about one-third.3

It is briefly noted in a review that antacid use did not affect the pharmacokinetics of ramiprilat, the active metabolite of ramipril.4

Mechanism

The mechanism of this interaction is uncertain, but is unlikely to be due to elevated gastric pH since cimetidine did not have a similar effect.3

Importance and management

Note that greater decreases in captopril bioavailability (caused by ‘food’, (p.26)) were found not to be clinically relevant, therefore, it is unlikely the change seen with antacids will be clinically important.

However, with fosinopril, the manufacturers3 suggest separating administrations of antacids by at least 2 hours.

The UK manufacturers of quinapril and trandolapril also warn that antacids may reduce the bioavailability of ACE inhibitors, quite possibly...
based on the way these named ACE inhibitors interact, but there seems to be no evidence of a clinically significant interaction in practice.

---

**ACE inhibitors + Antipsychotics**

Marked postural hypotension occurred in a patient given chlorpromazine and captopril. The hypotensive adverse effects of antipsychotics such as the phenothiazines may be additive with the effects of ACE inhibitors.

**Clinical evidence, mechanism, importance and management**

A patient fainted and developed marked postural hypotension (standing blood pressure 66/48 mmHg) when given captopril 6.25 mg twice daily and chlorpromazine 200 mg three times daily. He had previously taken chlorpromazine with nadolol, prazosin and hydrochlorothiazide without any problems, although his blood pressure was poorly controlled on these drugs. Since the patient’s blood pressure was quite elevated when taking chlorpromazine or captopril alone, there appeared to be a synergistic hypotensive effect between the two drugs.¹

The manufacturers of several ACE inhibitors warn that ACE inhibitors may enhance the hypotensive effects of certain antipsychotics, and that postural hypotension may occur. Some of these warnings are based, not unreasonably, on the adverse reactions seen with other ACE inhibitors or on direct observations.² If postural hypotension may occur. Some of these warnings are based, not unreasonably, on the adverse reactions seen with other ACE inhibitors or on direct observations.² If postural hypotension occurs warn patients to lay down and elevate their legs if they feel faint or dizzy, and, when recovered, to get up slowly. Dosage adjustments may be necessary to accommodate this interaction.

---

**ACE inhibitors + Aprotinin**

Aprotinin suppressed the hypotensive action of captopril and enalapril in rats.

**Clinical evidence, mechanism, importance and management**

A study in spontaneously hypertensive rats found that aprotinin suppressed the hypotensive responses of captopril and enalapril.¹ Aprotinin is a proteolytic enzyme inhibitor that has many actions including antagonism of the kalikrein-kinin system, which in turn affects bradykinins and renin. It would therefore be expected to have complex interactions with the ACE inhibitors,² which also affect these proteins. However, there does not appear to be any evidence to suggest that this theoretical interaction is of clinical relevance.

---

**ACE inhibitors + Aspirin**

The antihypertensive efficacy of captopril and enalapril may be reduced by high-dose aspirin in about 50% of patients. Low-dose aspirin (less than or equal to 100 mg daily) appears to have little effect. It is unclear whether aspirin attenuates the benefits of ACE inhibitors in heart failure. The likelihood of an interaction may depend on disease state and its severity. Renal failure has been reported in a patient taking captopril and aspirin.

**Clinical evidence**

A. Effects on blood pressure

   (a) Captopril

   Aspirin 600 mg every 6 hours for 5 doses did not significantly alter the blood pressure response to a single 25 to 100-mg dose of captopril in 8 patients with essential hypertension. However, the prostaglandin response to captopril was blocked in 4 of the 8, and in these patients, the blood pressure response to captopril was blunted.¹ In another study, aspirin 75 mg daily did not alter the antihypertensive effects of captopril 25 mg twice daily in 15 patients with hypertension.²

   (b) Enalapril

   Two groups of 26 patients, one with mild to moderate hypertension taking enalapril 20 mg twice daily and the other with severe primary hypertension taking enalapril 20 mg twice daily (with nifedipine 30 mg and atenolol 50 mg daily), were given test doses of aspirin 100 and 300 mg daily for 5 days. The 100-mg dose of aspirin did not alter the efficacy of the antihypertensive drugs, but the 300-mg dose reduced the antihypertensive efficacy in about half the patients in both groups. In these patients, the antihypertensive effects were diminished by 63% in those with mild to moderate hypertension and by 91% in those with severe hypertension.³ In contrast, another study in 7 patients with hypertension taking enalapril (mean daily dose 12.9 mg) found that aspirin 81 mg or 325 mg daily for 2 weeks did not have any significant effect on blood pressure.⁴ A further study in 18 patients also found that aspirin 100 mg daily for 2 weeks did not alter the antihypertensive effect of enalapril 20 or 40 mg daily.⁵

   (c) Unspecified ACE inhibitors

   In a randomised study, the use of low-dose aspirin 100 mg daily for 3 months did not alter blood pressure control in patients taking calcium-channel blockers or ACE inhibitors, when compared with placebo.⁶ Similarly, in a re-analysis of data from the Hypertension Optimal Treatment (HOT) study, long-term low-dose aspirin 75 mg daily did not interfere with the blood pressure-lowering effects of the antihypertensive drugs studied, when compared with placebo. Of 18 790 treated hypertensive patients, about 82% received a calcium-channel blocker, usually felodipine alone or in combination, and 41% received an ACE inhibitor, usually in combination with felodipine.⁷

B. Effects in coronary artery disease and heart failure

Various pharmacological studies have looked at the short-term effects of the combination of ACE inhibitors and aspirin on haemodynamic parameters. In one study in 40 patients with decompensated heart failure, aspirin 300 mg given on the first day and 100 mg daily thereafter antagonised the short-term haemodynamic effects of captopril 50 mg given every 8 hours for 4 days. The captopril-induced increase in cardiac index and the reduction in peripheral vascular resistance and pulmonary wedge pressure were all abolished.⁸ In another study, in 15 patients with chronic heart failure receiving treatment with ACE inhibitors (mainly enalapril 10 mg twice daily), aspirin in doses as low as 75 mg impaired vasodilatation induced by arachidonic acid.⁹ In yet another study, aspirin 325 mg daily worsened pulmonary diffusion capacity and made the ventilatory response to exercise less effective in patients taking enalapril 10 mg twice daily, but did not exert this effect in the absence of ACE inhibitors.¹⁰ However, results from studies are inconsistent. In a review,¹¹ five of 7 studies reported aspirin did not alter the haemodynamic effects of ACE inhibitors whereas the remaining two did. In one of these studies showing an adverse interaction between aspirin and enalapril, ticlopidine did not interact with enalapril.¹²

A number of large clinical studies of ACE inhibitors, mostly post-myocardial infarction, have been re-examined to see if there was a difference in outcome between those receiving aspirin at baseline, and those not. The results are summarised in ‘Table 2.2’, (p.15). However, in addition to the problems of retrospective analysis of non-randomised parameters, the studies vary in the initiation and duration of aspirin and ACE inhibitor treatment and the length of follow-up, the degree of heart failure or ischaemia, the prognosis of the patients, and the final end point (whether compared with placebo or with the benefits of aspirin or ACE inhibitors). The conclusions are therefore conflicting, and, although two meta-analyses of

Continued
these studies found no interaction, an editorial\textsuperscript{13} disputes the findings of one of these analyses.\textsuperscript{14} In addition to these sub-group analyses, there have been a number of retrospective cohort studies. A retrospective study involving 576 patients with heart failure requiring hospitalisation, showed a trend towards an increased incidence of early readmissions (within 30 days after discharge) for heart failure among subjects treated with ACE inhibitors and aspirin, compared with those treated with ACE inhibitors without aspirin (16% versus 10%). In patients with coronary artery disease the increase in readmissions was statistically significant (23% versus 10%).\textsuperscript{15} However, long-term survival in heart failure was not affected by the use of aspirin with ACE inhibitors. Furthermore, among patients with coronary artery disease there was a trend towards improvement in mortality in patients treated with the combination, compared with ACE inhibitor without aspirin (40% versus 56%).\textsuperscript{16} Similarly, a lack of adverse interaction was found in a retrospective study involving 14 129 elderly patients without left ventricular dysfunction, or acute MI.\textsuperscript{17} Similarly, in another cohort of patients discharged after first hospitalisation for heart failure, there was no increase in mortality rates or readmission rates in those taking aspirin and ACE inhibitors.\textsuperscript{18} In another retrospective analysis in patients with stable left ventricular systolic dysfunction, no decrease in survival was seen in patients receiving ACE inhibitors, when comparing those also receiving aspirin (mean dose 183 mg daily, 74% 200 mg or less) and those not.\textsuperscript{19} Conversely, another study found that, compared to patients not taking aspirin, the use of high-dose aspirin (325 mg daily or more) with an ACE inhibitor was associated with a small but statistically significant 3% increase in the risk of death, whereas low-dose aspirin (160 mg daily or less) was not.\textsuperscript{20}

\section*{C. Effects on renal function}

Acute renal failure developed in a woman taking \textit{captopril} when she started to take aspirin for arthritis. Renal function improved when both were stopped.\textsuperscript{21} However, in a re-analysis of data from the Hypertension Optimal Treatment (HOT) study, long-term low-dose aspirin 75 mg daily had no effect on changes in serum creatinine, estimated creatinine clearance or the number of patients developing renal impairment, when compared with placebo. Of 18 790 treated hypertensive patients, 41% received an ACE inhibitor.\textsuperscript{7}

\section*{D. Pharmacokinetic studies}

A single-dose study in 12 healthy subjects found that the pharmacokinetics of \textit{benazepril} 20 mg and aspirin 325 mg were not affected by concurrent use.\textsuperscript{22}

\section*{Mechanism}

Some, but not all the evidence suggests that prostaglandins may be involved in the hypotensive action of ACE inhibitors, and that aspirin, by inhibiting prostaglandin synthesis, may partially antagonise the effect of ACE inhibitors on blood pressure. This effect appears to depend on the
A number of studies have suggested that low-dose aspirin is effective in preventing myocardial infarction and reducing stroke, but the benefits must be weighed against the potential risks. 

**Importance and management**

Low-dose aspirin (less than or equal to 100 mg daily) does not alter the antithrombotic efficacy of captopril and enalapril. No special precautions would therefore be required to start or continue these medications. 

ACE inhibitors + Azathioprine

Anaemia has been seen in patients given azathioprine with enalapril or captopril. Leucopenia occasionally occurs when captopril is given with azathioprine.

Clinical evidence

(a) Anaemia

Nine out of 11 kidney transplant patients taking ACE inhibitors (enalapril or captopril) had a fall in their haemacotrit from 34% to 27%, and a fall in their haemoglobin from 11.6 g/dL to 9.5 g/dL when cilosporin was re-

placed by azathioprine. Two patients were switched back to cilosporin, and had a prompt rise in their haematocrit. Another 10 patients taking both drugs similarly developed a degree of anaemia, when compared with 10 others not taking an ACE inhibitor (haematocrit of 33% compared with 41%, and a haemoglobin of 11.5 g/dL compared with 13.9 g/dL). A later study by the same group of workers (again in patients taking enalapril or captopril) confirmed these findings: however, no pharmacokinetic inter-

action was found between enalapril and azathioprine.

(b) Leucopenia

A patient whose white cell count fell sharply when taking both captopril 50 mg daily and azathioprine 150 mg daily, did not develop leucopenia when each drug was given separately. Another patient who was given captopril (increased to 475 mg daily [sic] then reduced to 100 mg daily) immediately after discontinuing azathioprine, developed leucopenia. She was later successfully treated with captopril 4 to 6 mg daily [sic]. Other patients have similarly shown leucopenia when given both drugs, in one case this did not recur when the patient was rechallenged with captopril alone (at a lower dose).

Mechanism

The anaemia appears to be due to suppression of erythropoietin by the ACE inhibitors, and azathioprine may cause patients to be more suscepti-
ble to this effect. The cause of the leucopenia is unknown. It may just be due to the additive effects of both drugs.

Importance and management

Anaemia caused by captopril and enalapril has been seen in kidney transplant patients and in dialysis patients (see ‘ACE inhibitors and Angi-

otensin II receptor antagonists + Epotoin’, p.25). The evidence that this effect can be potentiated by azathioprine is limited, but it would be prudent to monitor well if these drugs are used together.

The evidence that the concurrent use of ACE inhibitors and azathioprine increases the risk of leucopenia is also limited. However, the UK manu-

facturer of captopril recommends that captopril should be used with ex-
treme caution in patients receiving immunosuppressants, especially if there is renal impairment. They advise that in such patients differential white blood cell counts should be performed before starting captopril, then every 2 weeks in the first 3 months of treatment, and periodically thereaf-

der. The UK manufacturers of a number of other ACE inhibitors also state in their prescribing information that the use of ACE inhibitors with cyto-

static or immunosuppressive drugs may lead to an increased risk of leuco-

penia. For other potential interactions with ACE inhibitors that might lead to an increased risk of leucopenia, see also ‘ACE inhibitors + Allop-

ents caused by concomitant therapy with azathioprine and angiotensin-converting enzyme in-

ACE inhibitors + Beta blockers

The combination of an ACE inhibitor with a beta blocker is in es-

tablished clinical use. Enhanced blood pressure-lowering effects occur, as would be expected. Although not all combinations have been studied, no clinically significant pharmacokinetic interactions appear to occur between the ACE inhibitors and beta block-

ers.

Clinical evidence

(a) Atenolol

In a double-blind, crossover study in hypertensive subjects, the combi-

nation of atenolol 50 mg once daily and enalapril 20 mg once daily increased the hypotensive effect of either drug alone, but the effect was 30 to 50% less than additive.

(b) Bisoprolol

In a single-dose, placebo-controlled, crossover study in 16 healthy men, bisoprolol 5 mg given with imidapril 10 mg did not significantly influ-

ence the pharmacokinetics of its active metabolite imidaprill, and the pharmacodynamic effects, including blood pressure and heart rate reduc-

tions, were mainly additive.

(c) Propranolol

Propranolol 80 mg three times daily did not affect the pharmacokinetics of a single 20-mg dose of quinapril in 10 healthy subjects. The pharma-

cokinetics of ramipril 5 mg daily were unaffected by propranolol 40 mg twice daily. Similarly, the manufacturer of fosinopril reports that the bi-

oavailability of fosinopril, its active metabolite, was not altered by pro-

pranolol. Another study found no significant pharmacokinetic inter-

action between cilazapril 2.5 mg daily and propranolol 120 mg daily in healthy subjects, but the reductions in blood pressure were about dou-

bled and long-lasting in healthy subjects and in patients with hyperten-

sion.

Mechanism, importance and management

Both ACE inhibitors and beta blockers lower blood pressure by different mechanisms, and therefore the enhanced blood pressure-lowering effects of the combination would be expected. No pharmacokinetic interactions have been demonstrated. The combination of an ACE inhibitor and a beta blocker is clinically useful in a number of cardiovascular disorders.

ACE inhibitors + Calcium-channel blockers

The combination of an ACE inhibitor and a dihydropyridine calcium-channel blocker is in established clinical use for hyperten-

sion, and, although only certain combinations have been studied, no clinically significant pharmacokinetic interactions appear to
occur between the dihydropyridine-type calcium-channel blockers and ACE inhibitors.

Clinical evidence

(a) Amlodipine
A study in 12 healthy subjects indicated that there was no pharmacokinetic interaction between single doses of amlodipine 5 mg and benazepril 10 mg.1

(b) Felodipine
No pharmacokinetic interaction occurred between single doses of felodipine 10 mg and ramipril 5 mg in healthy subjects. The blood pressure-lowering effect of the combination was greater, and ramipril attenuated the reflex tachycardia caused by felodipine.2

(c) Manidipine
In a single-dose crossover study in 18 healthy subjects, the concurrent use of manidipine 10 mg and delapril 30 mg did not significantly alter the pharmacokinetics of either drug or their main metabolites.3

(d) Nicardipine
In a study in 12 patients with hypertension taking enalapril 20 mg daily, the addition of nicardipine 30 mg three times daily for 2 weeks did not alter the pharmacokinetics of enalapril.4 The manufacturer of spironal increased spironal plasma levels by about 25% and those of its active metabolite, spironolactone, by about 45%. The bioavailability of nicardipine was reduced by 30%. It was assumed that the interaction took place at the absorption site. However, the changes were not considered clinically relevant.5

(e) Nifedipine
No evidence of either a pharmacokinetic or adverse pharmacodynamic interaction was seen in 12 healthy subjects given single doses of nifedipine retard 20 mg and lisinopril 20 mg; the effects on blood pressure were additive.6 Similarly, there was no pharmacokinetic interaction between single doses of slow-release nifedipine 20 mg and benazepril 10 mg in healthy subjects; the effects on blood pressure were additive and the tachycardic effect of nifedipine was attenuated by benazepril.7 The manufacturer of fosinopril notes that the bioavailability of fosinoprilat, the active metabolite, was not altered by nifedipine.8 Similarly, the manufacturer of moexipril notes that no clinically important pharmacokinetic interaction occurred with nifedipine in healthy subjects.9

(f) Nilvadipine
In a single-dose, placebo-controlled, crossover study in 16 healthy subjects, no pharmacokinetic interaction occurred between nilvadipine 8 mg and imidapril 10 mg, and the pharmacodynamic effects, including the reduction in blood pressure and the decrease in total peripheral resistance, were mostly additive.10

Mechanism
No pharmacokinetic interactions are expected. Enhanced blood pressure-lowering effects occur, as would be expected.

Importance and management
No important pharmacokinetic interactions have been demonstrated. The combination of an ACE inhibitor and a dihydropyridine calcium-channel blocker is clinically useful in the treatment of hypertension. A number of products combining an ACE inhibitor with a calcium-channel blocker are available. It is generally advised that these combination products are only used in patients who have already been stabilised on the individual components in the same proportions.

ACE inhibitors + Capsaicin
An isolated report describes a woman taking an ACE inhibitor who developed a cough each time she used a topical cream containing capsaicin.

Clinical evidence, mechanism, importance and management
A 53-year-old woman who had been taking an unnamed ACE inhibitor for several years, complained of cough each time she applied Axsain, a cream containing capsaicin 0.075%, to her lower extremities. Whether this reaction would have occurred without the ACE inhibitor was not determined,2 but cough is a recognised adverse effect of ACE inhibitors and pre-treatment with an ACE inhibitor has been shown to enhance the cough caused by inhaled capsaicin.3 This potential interaction is probably of little general clinical importance.

Mechanism
No pharmacokinetic interactions are expected. Enhanced blood pressure-lowering effects occur, as would be expected.

Importance and management
No important pharmacokinetic interactions have been demonstrated. The combination of an ACE inhibitor and a dihydropyridine calcium-channel blocker is clinically useful in the treatment of hypertension. A number of products combining an ACE inhibitor with a calcium-channel blocker are available. It is generally advised that these combination products are only used in patients who have already been stabilised on the individual components in the same proportions.

ACE inhibitors + Colloids
Acute hypotension has been seen in a few patients taking enalapril when they were given a rapid infusion of albumin-containing stable plasma protein solution (SPPS). Another case occurred in an infant taking captopril when given albumin 4%. A few other cases have been described with gelatin-type colloids in patients taking ACE inhibitors (cilazapril, enalapril, lisinopril).

Clinical evidence

(a) Albumin
A woman taking enalapril 10 mg in the morning, underwent surgery for groin lymph node resection under spinal and general anaesthesia. When she was given a rapid infusion of 500 mL of the albumin solution, stable plasma protein solution (SPPS, Commonwealth Serum Laboratories, Melbourne, Australia), her pulse rose to 90 to 100 bpm and systolic blood pressure fell from 100 to 60 mmHg and a red flush was noted on all exposed skin. The blood pressure was controlled at 90 to 95 mmHg with metaraminol 4.5 mg, given over 10 minutes. When the SPPS was finished, the blood pressure and pulse rate spontaneously restabilised.1

ACE inhibitors + Clonidine
Potentiation of the antihypertensive effect of clonidine by ACE inhibitors can be clinically useful.2 However, limited evidence suggests that the effects of captopril may be delayed when patients are switched from clonidine.2 Note that sudden withdrawal of clonidine may cause rebound hypertension.

Mechanism
No pharmacokinetic interactions are expected. Enhanced blood pressure-lowering effects occur, as would be expected.

Importance and management
No important pharmacokinetic interactions have been demonstrated. The combination of an ACE inhibitor and a dihydropyridine calcium-channel blocker is clinically useful in the treatment of hypertension. A number of products combining an ACE inhibitor with a calcium-channel blocker are available. It is generally advised that these combination products are only used in patients who have already been stabilised on the individual components in the same proportions.

A 20-month-old infant taking captopril was haemodynamically stable for 35 minutes after induction of anaesthesia while awaiting a donor kidney, but then developed hypotension after a bolus dose of 20 mL of albumin 4% (Albumex) was given. This was reversed with dopamine infusion.  

(b) Gelatin-based colloids

A report describes 3 cases of severe hypotension in patients taking ACE inhibitors (lisinopril, enalapril) while undergoing joint replacement surgery, and after they had been given a gelatin-based plasma expander (Gelofusin), which contains 4% succinylated gelatin in saline. The hypotension was resistant to ephedrine and methoxamine, and responded to adrenaline or dobutamine, which was required for 24 hours and 3 days in two cases. Anaphylactoid reactions were excluded as a cause of the hypotension. In another similar case, a patient taking elazapril developed hypotension refractory to sodium chloride 0.9% after induction of anaesthesia, and this worsened when a gelatin-type colloid (Gelfanudina) was given.  

Mechanism

Not fully established, but it is believed that SPPS contains low levels of pre-kallikrein activator, which stimulates the production of bradykinin, which can cause vasoconstriction and hypotension. Normally the bradykinin is destroyed by kallikrein II (ACE), but this is delayed by the ACE inhibitor so that the hypotensive effects are exaggerated and prolonged. In the case with albumin 4%, a sample of the albumin used was analysed, and it was found to contain less prekallikrein activating factor than maximum permissible levels. It was suggested that the infusion of gelatin-based colloids somehow resulted in raised plasma kinin levels associated with inhibition of ACE.  

Importance and management

The interaction with SPPS would appear to be established and of clinical importance, and would apply to all ACE inhibitors. The author of one report suggested that if rapid expansion of intravascular volume is needed in patients taking ACE inhibitors, an artificial colloid might be a safer choice than SPPS. The manufacturer of SPPS also recommended using an alternative colloid to SPPS in situations where ACE inhibitors are used. It was suggested that the infusion of gelatin-based colloids somehow resulted in raised plasma kinin levels associated with inhibition of ACE.  

ACE inhibitors + Co-trimoxazole or Trimethoprim

Two reports describe serious hyperkalaemia, apparently caused by the use of trimethoprim with enalapril or quinapril in association with renal impairment.

Clinical evidence

A 40-year-old woman with a lung transplant (taking ciclosporin, azathioprine, prednisolone, enalapril, gentamicin inhalation, salbutamol and acetylsalicylate) developed life-threatening hyperkalaemia of 6.8 mmol/L when she was treated with high-dose co-trimoxazole 120 mg/kg daily for suspected Pneumocystis pneumonia. The co-trimoxazole (sulfamethoxazole/trimethoprim) and enalapril were stopped and she was treated with sodium chloride 0.9%, mannitol and furosemide. After 12 hours her serum potassium had decreased to 4.6 mmol/L and she began to recover over a period of a week, but she then developed fatal septic shock with multi-organ failure.  

In another case, an elderly man treated with quinapril 20 mg daily for essential hypertension was found to have hyperkalaemia (serum potassium 7.2–7.4 mmol/L) and azotaemia after 20 days of treatment with co-trimoxazole for mild acute pyelonephritis. Co-trimoxazole and quinapril were stopped, and nifedipine was given to control blood pressure. After treatment with dextrose, insulin, sodium polystyrene sulfonate and calcium gluconate, the azotaemia and hyperkalaemia resolved over 36 hours.  

Mechanism

Hyperkalaemia has been reported in patients receiving co-trimoxazole alone. This is attributed to the trimethoprim component, which can have a potassium-sparing effect on the distal part of the kidney tubules. ACE inhibitors reduce aldosterone synthesis, which results in reduced renal loss of potassium. The interaction is probably due to the additive effects of these two mechanisms, compounded by impaired renal function.  

Importance and management

Clinical examples of this interaction seem to be few, but the possibility of hyperkalaemia with either trimethoprim or ACE inhibitors alone, particularly with other factors such as renal impairment, is well documented. Thus it may be prudent to monitor potassium levels if this combination is used. It has been suggested that trimethoprim should probably be avoided in elderly patients with chronic renal impairment taking ACE inhibitors, and that patients with AIDS taking an ACE inhibitor for associated nephropathy should probably discontinue this treatment during treatment with high-dose co-trimoxazole.  

ACE inhibitors + Dialysis or Transfusion membranes

An anaphylactoid reaction can occur in patients taking ACE inhibitors within a few minutes of starting haemodialysis using high-flux polycrylonitrile membranes (‘AN 69’). Anaphylactoid reactions have also been reported in patients taking ACE inhibitors undergoing low-density lipoprotein apheresis. In addition, hypotensive reactions associated with blood transfusions through leukoreduction filters have occurred in patients taking ACE inhibitors.

Clinical evidence, mechanism, importance and management

(a) High-flux dialysis

In a retrospective study, 9 of 236 haemodialysis patients treated with high-flux polycrylonitrile membranes (‘AN 69’) were found to have had anaphylactoid reactions (severe hypotension, flushing, swelling of face and/or tongue, and dyspnoea) within 5 minutes of starting haemodialysis. Treatment with an ACE inhibitor had been recently started in all 9 patients (7 enalapril, 1 captopril, 1 lisinopril). The anaphylactoid reactions disappeared in all 6 patients who discontinued the ACE inhibitor. Two other patients were given a filter rinsing procedure (the ‘Bioprime’ rinse method) and a new dialysis membrane, and in the final patient further anaphylactoid reactions were prevented by cellulose-tricarboxylate haemofiltration while the ACE inhibitor was continued. Similar reactions have been reported elsewhere and are thought to be bradykinin mediated.  

The CSM in the UK has advised that the combination of ACE inhibitors and such membranes should be avoided, either by substituting an alternative membrane or an alternative antihypertensive drug.  

(b) Lipoprotein apheresis

Anaphylactoid reactions occurred in 2 patients taking ACE inhibitors during removal of low-density lipoproteins (LDL apheresis) with dextran sulfate adsorption.3 Further reactions were reported in 6 patients taking either captopril or enalapril and dextran sulfate apheresis. When the interval between the last dose of the ACE inhibitor and the apheresis was prolonged to 12 to 240 hours, no further adverse reactions occurred.3 However, other workers found lengthening the interval to be ineffective in one patient.2 The manufacturer of enalapril suggests temporarily withholding the ACE inhibitor before each apheresis,3 but other manufacturers of ACE inhibitors recommend using a different class of antihypertensive drug9,10 or changing the method of lipoprotein reduction.9,11

(c) Transfusion reactions

A report describes 8 patients receiving ACE inhibitors and blood transfusions through bedside leucoreduction filters who experienced severe hypotension with the first or second transfusion. The reactions were attributed to bradykinin formation during blood filtration and prevention of bradykinin breakdown due to the ACE inhibitors. Six of the patients tolerated subsequent transfusions, but 3 had discontinued their medication the day before the planned transfusion and one received washed (plasma-depleted) components. One patient experienced a second reaction, but then received washed red cells and had no reaction.12

ACE inhibitors + Diuretics; Loop, Thiazide and related

The combination of captopril or other ACE inhibitors with loop or thiazide diuretics is normally safe and effective, but ‘first dose hypotension’ (dizziness, lightheadedness, fainting) can occur, particularly if the dose of diuretic is high, and often in association with various predisposing conditions. Renal impairment, and even acute renal failure, have been reported. Diuretic-induced hypokalaemia may still occur when ACE inhibitors are used with these potassium-depleting diuretics.

Clinical evidence

(a) First dose hypotensive reaction

The concurrent use of captopril or other ACE inhibitors and loop or thiazide diuretics is normally safe and effective, but some patients experience ‘first dose hypotension’ (i.e. dizziness, lightheadedness, fainting) after taking the first one or two doses of the ACE inhibitor. This appears to be associated with, and exaggerated by certain conditions (such as heart failure, renovascular hypertension, haemodialysis, high levels of renin and angiotensin, low-sodium diet, dehydration, diarrhoea or vomiting) and/or hypovolaemia and sodium depletion caused by diuretics, particularly in high doses. A study describes one woman whose blood pressure of 290/150 mmHg failed to respond to a 10-mg intravenous dose of furosemide. After 30 minutes, she was given captopril 50 mg orally and within 45 minutes her blood pressure fell to 135/60 mmHg, and she required an infusion of saline to maintain her blood pressure.1 In another study, a man developed severe postural hypotension shortly after furosemide was added to captopril treatment.2

Starting with a low dose of the ACE inhibitor reduces the risk of first-dose hypotension. In a study in 8 patients with hypertension, treated with a diuretic (mainly furosemide or hydrochlorothiazide) for at least 4 weeks, captopril was started in small increasing doses from 6.25 mg. Symptomatic postural hypotension was seen in 2 of the 8 patients, but was only mild and transient.3

Hypotension is more common in patients with heart failure who are receiving large doses of diuretics. In a study in 124 patients with severe heart failure, all receiving furosemide (mean dose 170 mg daily; range 80 to 500 mg daily) and 90 also receiving the potassium-sparing diuretic spironolactone, the addition of captopril caused transient symptomatic hypotension in 44% of subjects. The captopril dose had to be reduced, and in 8 patients it was later discontinued. In addition, four patients developed symptomatic hypotension after 1 to 2 months of treatment, and captopril was also discontinued in these patients.

There is some evidence that in patients with heart failure the incidence of marked orthostatic hypotension requiring treatment discontinuation in the first 36 hours was lower with perindopril 2 mg once daily than captopril 6.25 mg three times daily (6 of 357 cases versus 16 of 368 cases, respectively).5

(b) Hypokalaemia

In one study, the reduction in plasma potassium was greater with hydrochlorothiazide 25 mg daily than with hydrochlorothiazide combined with cilazapril 2.5 mg daily, showing that cilazapril reduced the potassium-depleting effect of hydrochlorothiazide.6 In one analysis, 7 of 21 patients taking potassium-depleting diuretics given ACE inhibitors for heart failure developed hypokalaemia. This was corrected by potassium supplementation in 2 cases, an increase in the ACE inhibitor dose in 3 cases, and the use of a potassium-sparing diuretic in the remaining 2 cases.7 In another report, a woman taking furosemide 80 to 120 mg daily remained hypokalaemic despite also taking ramipril 10 mg daily and spironolactone 50 to 200 mg daily.8 However, note that the addition of ‘spironolactone’, (p.23) to ACE inhibitors and loop or thiazide diuretics has generally resulted in an increased incidence of hyperkalaemia.

(c) Hyponatraemia

An isolated report describes a patient who developed severe hyponatraemia 3 days after bendroflumethiazide 10 mg daily was added to treatment with enalapril 20 mg daily and atenolol 100 mg daily. However, on 2 other occasions she only developed mild hyponatraemia when given bendroflumethiazide alone.9 An earlier study reported changes in sodium balance due to captopril in all 6 patients with renovascular hypertension and in 11 of 12 patients with essential hypertension; sodium loss occurred in 12 of the 18 patients.

(d) Impairment of renal function

The risk of ACE inhibitor-induced renal impairment in patients with or without renovascular disease can be potentiated by diuretics.10-13 In an analysis of 74 patients who had been treated with captopril or lisinopril, reversible acute renal failure was more common in those who were also treated with a diuretic (furosemide and/or hydrochlorothiazide) than those who were not (11 of 33 patients compared with 1 of 41 patients).12 Similarly, in a prescription-event monitoring study, enalapril was associated with raised creatinine or urine in 75 patients and it was thought to have contributed to the deterioration in renal function and subsequent deaths in 10 of these patients. However, of 9 of these 10 were also receiving loop or thiazide diuretics, sometimes in high doses.14 Retrospective analysis of a controlled study in patients with hypertensive nephrosclerosis identified 8 of 34 patients who developed reversible renal impairment when treated with enalapril and various other antihypertensives including a diuretic (furosemide or hydrochlorothiazide). In contrast, 23 patients treated with placebo and various other antihypertensives did not develop renal impairment. Subsequently, enalapril was tolerated by 7 of the 8 patients without deterioration in renal function and 6 of these patients later received diuretics.15 One patient was again treated with enalapril with recurrence of renal impairment, but discontinuation of the diuretics (furosemide, hydrochlorothiazide, and triamterene) led to an improvement in renal function despite the continuation of enalapril.16

Renal impairment in patients taking ACE inhibitors and diuretics has also been described in patients with heart failure. A patient with congenital heart failure and pre-existing moderate renal impairment developed
acute non-oliguric renal failure while taking enalapril 20 mg daily and furosemide 60 to 80 mg daily, which resolved when the sodium balance was restored. In a study involving 90 patients with severe congestive heart failure who were receiving furosemide and spironolactone, a decline in renal function occurred in 18 patients during the first month after initiation of captoril treatment; mean serum creatinine levels rose from 220 to 300 micromol/L. All the patients were receiving high daily doses of furosemide and all had renal impairment before receiving the first dose of captoril.

Acute, fatal, renal failure developed in 2 patients with cardiac failure within 4 weeks of being treated with enalapril and furosemide, and in 2 similar patients renal impairment developed over a longer period. Reversible renal failure developed in a patient with congestive heart failure when captoril and metolozone were given.

(e) Pharmacokinetic and diuresis studies

1. Furosemide. A study in healthy subjects given single doses of enalapril and furosemide found no evidence of any pharmacokinetic interaction between these drugs. Another study in hypertensive patients found that captoril did not affect the urinary excretion of furosemide, nor its subsequent diuretic effects. However, a further study in healthy subjects showed that, although captoril did not alter urinary excretion of furosemide, it did reduce diuresis. Yet another study in healthy subjects found that captoril reduced the urinary excretion of furosemide, and reduced the diuretic response during the first 20 minutes to approximately 50%, and the natriuretic response to almost 30%, whereas enalapril and ramipril did not significantly alter the diuretic effects of furosemide. In one single-dose study in healthy subjects the concurrent use of benazepril and furosemide reduced the urinary excretion of furosemide by 10 to 20%, whereas benazepril pharmacokinetics were unaffected. Lisinopril did not alter plasma levels or urinary excretion of furosemide in one study, nor did it alter urinary electrolyte excretion. Similarly, furosemide did not affect the pharmacokinetics of lisinopril either in single-dose or multiple-dose regimens.

2. Hydrochlorothiazide. In a single-dose, randomised, crossover study in 19 elderly patients the pharmacokinetics of enalapril 10 mg were unaffected by hydrochlorothiazide 25 mg. However, there was a significant reduction in renal clearance and a significant increase in the AUC of its metabolite, enalaprillat, resulting in higher serum levels of the active drug. This acute interaction was not thought to be clinically significant for long-term use.

No pharmacokinetic interaction occurred between cilazapril and hydrochlorothiazide in healthy subjects or patients with hypertension. Similarly, no significant pharmacokinetic interaction occurred between imidapril and hydrochlorothiazide in healthy subjects and neither captoril nor ramipril altered the diuresis induced by hydrochlorothiazide. The manufacturer of spirapril briefly noted in a review that there was no clinically relevant pharmacokinetic interaction between spirapril and hydrochlorothiazide. Furthermore no pharmacokinetic interaction was found when spirapril and hydrochlorothiazide were given together as a bi-layer tablet. There was no clinically important pharmacokinetic interaction when moexipril was given with hydrochlorothiazide in a single-dose study in healthy subjects.

Mechanism

The first dose hypotension interaction is not fully understood. One suggestion is that if considerable amounts of salt and water have already been lost as a result of using a diuretic, the resultant depletion in the fluid volume (hypovolaemia) transiently exaggerates the hypotensive effects of the ACE inhibitor.

The cases of hypokalaemia are simply a result of the potassium-depleting effects of the diuretics outweighing the potassium-conserving effects of the ACE inhibitor. The converse can also occur.

Thiazides can cause hypokalaemia, but this enhanced effect may have been due to an alteration in renal haemodynamics caused by the ACE inhibitor, sustained angiotensin-converting enzyme blockade can produce natriuresis.

Marked decreases in blood pressure may affect renal function, and in addition, the renin-angiotensin system plays an important role in the maintenance of the glomerular filtration rate when renal artery pressure is diminished. However, diuretic-induced sodium depletion may also be an important factor in the renal impairment sometimes observed with ACE inhibitors. 

Importance and management

The ‘first dose hypotension’ interaction between ACE inhibitors and diuretics is well established. The BNF in the UK notes that the risk is higher when the dose of diuretic is greater than furosemide 80 mg daily or equivalent, and suggest that, in patients taking these doses of diuretics, consideration should be given to temporarily stopping the diuretic or reducing its dosage a few days before the ACE inhibitor is added. If this is not considered clinically appropriate, the first dose of the ACE inhibitor should be given under close supervision. In all patients taking diuretics, therapy with ACE inhibitors should be started with a very low dose, even in patients at low risk (e.g. those with uncomplicated essential hypertension or low-dose thiazides). To be on the safe side, all patients should be given a simple warning about what can happen and what to do when they first start concurrent use. The immediate problem (dizziness, light-headedness, faintness), if it occurs, can usually be solved by the patient lying down. Taking the first dose of the ACE inhibitor just before bedtime is also preferable. Any marked hypotension is normally transient, but if problems persist it may be necessary temporarily to reduce the diuretic dosage. There is usually no need to avoid the combination just because an initially large hypotensive response has occurred.

A number of products combining an ACE inhibitor with a thiazide diuretic are available for the treatment of hypertension. These products should be used only in those patients who have been stabilised on the individual components in the same proportions.

The use of ACE inhibitors in patients taking potassium-depleting diuretics does not always prevent hypokalaemia developing. Serum potassium should be monitored.

There is only an isolated report of hyponatraemia, but be aware that ACE inhibitors may affect the natriuresis caused by diuretics.

The cases of renal impairment cited emphasise the need to monitor renal function in patients on ACE inhibitors and diuretics. If increases in blood urea and creatinine occur, a dosage reduction and/or discontinuation of the diuretic and/or ACE inhibitor may be required. In a statement, the American Heart Association comments that acute renal failure complicating ACE inhibitor therapy is almost always reversible and repletion of extracellular fluid volume and discontinuation of diuretic therapy is the most effective approach. In addition, withdrawal of interacting drugs, supportive management of fluid and electrolytes, and temporary dialysis, where indicated, are the mainstays of therapy. Combined use of ACE inhibitors and diuretics and NSAIDs may be particularly associated with an increased risk of renal failure, see ‘ACE inhibitors + NSAIDs’, p.28. The possibility of undiagnosed renal artery stenosis should also be considered.

None of the pharmacokinetic changes observed appear to be clinically significant.

References

ACE inhibitors + Diuretics; Potassium-sparing

Combining ACE inhibitors with potassium-sparing diuretics (e.g. amiloride), including the aldosterone antagonists (eprenolone, spironolactone) can result in clinically relevant or severe hyperkalaemia, particularly if other important risk factors are present.

Clinical evidence

(a) Amiloride

The serum potassium levels of two patients taking furosemide and an unnamed combination of spironolactone and potassium supplements rose by 18% and 24%, respectively, when they were given enalapril to 37.5 to 75 mg daily. The rises occurred within one or two days. No clinical signs or symptoms of hyperkalaemia were seen, but one of the patients had an increase in serum potassium to above the upper limits of normal. In a post-marketing survey, 2 patients who had enalapril-associated renal impairment and died were also receiving amiloride and furosemide; one was also taking potassium supplements. Four diabetic patients, with some renal impairment, developed life-threatening hyperkalaemia with severe cardiac arrhythmias and deterioration of renal function, within 8 to 18 days of having an amiloride/hydrochlorothiazide diuretic added to their enalapril treatment. Two suffered cardiac arrest and both died. Potassium levels were between 9.4 and 11 mmol/L. A fifth diabetic patient with normal renal function developed hyperkalaemia soon after receiving amiloride/hydrochlorothiazide and captopril in combination. A further case of hyperkalaemia and cardiac arrest was associated with enalapril and furosemide/amiloride. In a brief report, the manufacturers of enalapril noted that, of 47 serious cases of hyperkalaemia, 25 patients were taking one or more (unnamed) potassium-sparing drugs.

In a brief report, a retrospective case series of 35 patients treated for congestive heart failure found no differences in the serum potassium levels of 16 patients taking furosemide, amiloride and enalapril, when compared with another group of 19 patients taking furosemide and amiloride alone. Patients were excluded from the comparison if they had significant renal impairment or were taking other drugs likely to affect serum potassium.

(b) Eplerenone

In the large Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) the rate of serious hyperkalaemia (defined as serum potassium 6 mmol/L or greater) was 5.5% in patients randomised to eplerenone 25 mg to 50 mg daily (mean 43 mg daily) compared with 3.9% in those receiving placebo: this represented a 1.4-fold increase. More eplerenone recipients required hospitalisation for serious hyperkalaemia than placebo recipients (12 versus 3). The risk of serious hyperkalaemia was increased in those with a baseline creatinine clearance of less than 50 mL/minute (10.1% in the eplerenone group and 5.9% in the placebo group). Eplerenone reduced the risk of serious hyperkalaemia defined as serum potassium 5.5 mmol/L or greater by 1.6-fold (8.4% versus 13.1%). About 86% of patients in this study were also receiving an ACE inhibitor or an angiotensin II receptor antagonist, and about 60% were receiving a loop diuretic. However, the US manufacturer states that the rate of maximum potassium levels greater than 5.5 mmol/L were similar in EPHESUS regardless of the use of ACE inhibitor or angiotensin II receptor antagonist. Nevertheless, they mention another study in diabetics with microalbuminuria, where a higher dose of eplerenone 200 mg combined with enalapril 10 mg increased the frequency of hyperkalaemia (defined as serum potassium greater than 5.5 mmol/L) from 17% with enalapril alone to 38% with this combination. This represented a 2.2-fold increase.

(c) Spironolactone

Twenty-five of 262 patients treated with ACE-inhibitors and spironolactone, and admitted to hospital for medical emergencies, were found to have serious hyperkalaemia (defined as serum potassium levels greater than 6 mmol/L: 11 patients had levels of at least 8 mmol/L). These 25 patients were elderly (mean age 74 years) and were being treated for hypertension, heart failure, diabetic nephropathy, proteinuria, or nephrotic syndrome; 22 had associated renal impairment and 12 had signs of volume depletion. Combined treatment had been started an average of 25 weeks before the admission. The ACE inhibitors involved were enalapril, captopril, lisinopril or perindopril, and the average dose of spironolactone used was 57 mg daily; 10 patients were also receiving a loop or thiazide diuretic. Nineteen patients had ECG changes associated with hyperkalaemia; 2 of them died, another 2 required temporary pacing for third-degree heart block, and 2 others survived after sustained ventricular tachycardia and fibrillation. Of the 19 patients, 17 required at least one haemodialysis session, 12 were admitted for intensive care. Other authors reported a higher 36% incidence of hyperkalaemia (serum potassium levels greater than 5 mmol/L) in 42 patients hospitalised for heart failure and prescribed spironolactone. It was suggested that this may be due to the excessively large doses of spironolactone prescribed, although the specific doses were not mentioned.

Similar risk factors were found in an analysis of 44 patients with congestive heart failure who were taking spironolactone and ACE inhibitors or angiotensin II receptor antagonists, and were admitted for treatment of life-threatening hyperkalaemia. Their mean age was 76 years, the mean dose of spironolactone was 88 mg daily (range 25 to 200 mg daily) and 40 patients also received loop diuretics. In addition, 35 patients had type II diabetes. Haemodialysis was given to 37 patients, but in 6 patients renal function did not recover and 2 patients developed fatal complications. A number of other cases of serious hyperkalaemia have been described in patients taking ACE inhibitors (captopril, enalapril, lisinopril, spironolactone, and loop (furosemide or bumetanide) or thiazide (hydroflumethiazide) diuretics). One diabetic patient with moderate renal impairment was receiving just 25 mg of spironolactone daily.

In one report, the 4 cases had associated enalapril-induced deterioration in renal function and died. Another patient died from complete heart block.

One of the factors that affects the incidence of hyperkalaemia appears to be the dose of spironolactone. In a preliminary investigation for the Randomised Aldactone Evaluation Study (RALES), 214 patients with congestive heart failure taking an ACE inhibitor and a loop diuretic with or without digitalis, were randomised to receive placebo or various doses of spironolactone for 12 weeks. The incidence of hyperkalaemia (defined as serum potassium level of 5.5 mmol/L or greater) was 5% for the placebo group, whereas it was 5%, 13%, 20%, and 24% when spironolactone was...
given in single daily doses of 12.5, 25, 50, or 75 mg, respectively. The main RALES study involving 1663 patients showed a 30% reduction in the risk of mortality in patients with severe heart failure when they were given spironolactone in addition to treatment including an ACE inhibitor, a loop diuretic and in most cases digoxin. During the first year of follow-up, the median creatinine concentration in the spironolactone group increased by about 4 to 9 micromol/L and the median potassium level increased by 0.03 mmol/L, but there was a low incidence of serious hyperkalaemia (2% in the spironolactone group compared with 1% in the placebo group). However, the dose of spironolactone was fairly low (mean dose 26 mg daily; range 25 mg every other day to 50 mg daily depending on serum potassium levels and response). In addition, patients with a serum creatinine of more than 221 micromol/L or a serum potassium of more than 5 mmol/L were excluded.18 In a Canadian population-based time-series analysis, the increase in use of spironolactone for heart failure in patients taking ACE inhibitors after publication of the RALES study was found to be associated with 50 additional hospitalisations for hyperkalaemia for every 1000 additional prescriptions for spironolactone, and there was a 6.7-fold increase in numbers of patients dying from hyperkalaemia. The authors say that spironolactone-related hyperkalaemia is a much greater problem in every day practice than in the setting of a clinical study, and give a number of reasons for this including, less frequent monitoring of potassium levels, presence of conditions predisposing to hyperkalaemia, failure to detect subsequent development of renal impairment, inappropriate high doses of spironolactone, increased in dietary potassium intake, and use of spironolactone in heart failure with causes not included in the RALES study.19 In another study, use of spironolactone with ACE inhibitors in patients with class IV chronic heart failure was associated with a 4.6 odds ratio for developing hyperkalaemia when compared with ACE inhibitors alone. Predictors for hyperkalaemia included increased in creatinine following treatment, and diabetes.20

**(d) Triamterene**

A retrospective analysis found that captopril, given to 6 patients on Dyazide (hydrochlorothiazide/triamterene), had not increased the potassium levels.21

**Mechanism**

ACE inhibitors reduce the levels of aldosterone, which results in the retention of potassium. This would be expected to be additive with the potassium-retaining effects of amiloride and triamterene and aldosterone antagonists such as spironolactone and eplerenone, leading to hyperkalaemia, but usually only if other risk factors are present (see *Importance and management* below).

**Importance and management**

Hyperkalaemia with ACE inhibitors and potassium-sparing diuretics, and particularly the aldosterone antagonist spironolactone, is well documented and well established. If it occurs it can be serious and potentially life threatening. Its incidence depends on the presence of other risk factors, and clinically important hyperkalaemia usually only appears to develop if one or more of these are also present, particularly renal impairment. Other risk factors in patients with heart failure include advanced age and diabetes11,22 (hyperkalaemia has been found to be relatively common in both non-insulin-dependent and insulin-dependent diabetics).23 In addition, doses of spironolactone greater than 25 mg daily increase the risk of hyperkalaemia.

Because ACE inhibitors have potassium-sparing effects, potassium-sparing diuretics such as amiloride and triamterene should normally not be given concurrently. If, however, the use of both drugs is thought to be appropriate the serum potassium levels should be closely monitored so that any problems can be quickly identified. Note that the concurrent use of a potassium-depleting diuretic (a ‘loop or thiazide diuretic’, (p.21)) with the potassium-sparing diuretic may not necessarily prevent the development of hyperkalaemia. The combination of an ACE inhibitor and spironolactone can be beneficial in some types of heart failure, but close monitoring of serum potassium and renal function is needed, especially with any changes in treatment or the patient’s clinical condition. The combination should be avoided in patients with renal impairment with a glomerular filtration rate of less than 30 mL/min.22 In addition, the dose of spironolactone should not exceed 25 mg daily.22 Similarly, the UK manufacturer of eplerenone says that caution is required when it is given with ACE inhibitors, especially in renal impairment, and that potassium levels and renal function should be monitored.23

**ACE inhibitors + Dopamine agonists**

A single report describes severe hypotension when a patient taking lisinopril was given pergolide. Dopamine agonists are well known to be associated with hypotensive reactions during the first few days of treatment.

**Clinical evidence**

A man successfully treated for hypertension with lisinopril 10 mg daily experienced a severe hypotensive reaction within four hours of taking a single 50-microgram dose of pergolide for periodic leg movements during sleep. He needed hospitalisation and treatment with intravenous fluids.1

**Mechanism**

All dopamine agonists can cause hypotensive reactions during the first few days of treatment. It is not clear whether this patient was extremely sensitive to the pergolide or whether what occurred was due to an interaction. However, it is not unreasonable to assume that the hypotensive effects of dopamine agonists and antihypertensives might be additive.

**Importance and management**

Postural hypotension on starting dopamine agonists is a well recognised adverse effect, but this appears to be the only report that this might be of more concern in patients taking antihypertensives. The manufacturers of pergolide recommend caution when it is given with antihypertensives be-
cause of the risk of postural and/or sustained hypotension. The authors of the case report suggest that in patients taking antihypertensives the initial dose of pergolide should be 25 micrograms. It would seem prudent to exercise extra caution with the initial use of pergolide and other dopamine agonists in patients treated with antihypertensives.

**ACE inhibitors and Angiotensin II receptor antagonists + Epoetin**

Epoetin may cause hypertension and thereby reduce the effects of antihypertensive drugs. An additive hyperkalaemic effect is theoretically possible with ACE inhibitors or angiotensin II receptor antagonists and epoetin. It is not entirely clear whether captopril, enalapril, fosinopril or other ACE inhibitors affect the efficacy of epoetin or not, but any interaction may take many months to develop.

**Clinical evidence**

(A) **Antihypertensive effects**

The most frequent adverse effect of epoetin is an increase in blood pressure, so it is important to control any existing hypertension before epoetin is started (the manufacturers contraindicate epoetin in uncontrolled hypertension). Blood pressure should be monitored before and during epoetin treatment, and if necessary antihypertensive drug treatment should be started or increased if the pressure rises.

(B) **Epoetin efficacy**

(a) **Decreased epoetin effects**

In a retrospective analysis of 43 haemodialysis patients given epoetin regularly for about 10 months, the dose of epoetin was not significantly different between patients taking captopril (20 patients) and a control group (23 patients) who did not receive any ACE inhibitors (116.7 versus 98.3 units/kg per week, respectively). However, the haemoglobin and haematocrit values were significantly less at 6.2 mmol/L and 29.3%, respectively, in the captopril group than the values of 7.1 mmol/L and 33.3% in the control group. Another retrospective study of 40 dialysis patients found that the 20 patients taking an ACE inhibitor (captopril 12.5 to 75 mg daily, enalapril 2.5 to 5 mg daily or fosinopril 10 to 20 mg daily) had some evidence of increased epoetin requirements after 1 year, when compared with the control group. However, this was not significant until 15 months when the cumulative epoetin dosage requirements were about doubled (12 092 versus 6 449 units/kg). Similarly, a prospective study with a 12-month follow-up period found that 20 patients receiving enalapril 5 to 20 mg daily required higher doses of epoetin compared with 20 patients receiving nifedipine or 20 patients receiving no antihypertensive therapy. Higher epoetin requirements with ACE inhibitors were also reported in a small study in peritoneal dialysis patients.7

Furthermore, another prospective study found that 15 patients in whom ACE inhibitors (enalapril, captopril, or perindopril) were withdrawn and replaced with amlodipine, felodipine or doxazosin, had an increase in about doubled (12 092 versus 6 449 units/kg). Similarly, a prospective daily had some evidence of increased epoetin requirements after 1 year, particularly for about 10 months, the dose of epoetin was not significantly different from 76 to 121 units/kg per week in the temocapril group, but in the losartan group the epoetin dose was not significantly increased (94 versus 101 units/kg per week).14 Similar results were found in a study with captopril and losartan.15

(b) **No interaction**

A retrospective review of 14 haemodialysis patients receiving epoetin, compared the haematocrit and dosage of epoetin for 16 weeks before, and 16 weeks after, starting ACE inhibitors (8 taking captopril, mean dose 35 mg daily and 6 taking enalapril, mean dose 7.85 mg daily). This study failed to find any evidence of a clinically significant interaction when ACE inhibitors were added.9 Another study investigating 17 chronic haemodialysis patients found that ACE inhibitors (5 taking captopril and 12 taking enalapril) for 3 and 12 months did not increase the epoetin dose requirements or reduce the haematocrits.10 However, given the results of the study reported in (a) above, it is possible that these studies were not continued for long enough to detect an effect. Another study in 14 haemodialysis patients found no difference in epoetin requirements between patients receiving losartan 25 mg daily or placebo,11 but again the losartan was only given for 3 months. A further study (length not specified) in 604 dialysis patients also found that the use of ACE inhibitors or angiotensin II receptor blockers was not associated with epoetin resistance.12

(c) **ACE inhibitors compared with Angiotensin II receptor antagonists**

In one retrospective analysis of dialysis patients, 18 of 24 receiving losartan had decreases in haemoglobin, and 14 of these were using epoetin. A three to fourfold increase in the epoetin dose was required in these patients to restore the haemoglobin levels.13 This study suggests that angiotensin II receptor antagonists can behave similarly to ACE inhibitors. However, in a prospective study in 25 patients who had been undergoing haemodialysis for more than one year, 12 patients were given temocapril 2 mg daily and 13 patients received losartan 25 to 50 mg daily for 12 months. Ten hypertensive significantly decreased haemoglobin levels from 9.8 to 9.1 g/dL at 3 months and reached a minimum of 9 g/dL at 6 months; haemoglobin levels recovered to 9.7 g/dL at the end of the study by increasing the dosage of epoetin. In contrast, no change was found in haemoglobin values in the patients receiving losartan. The dosage of epoetin was gradually increased from 76 to 121 units/kg per week in the temocapril group, but in the losartan group the epoetin dose was not significantly increased (94 versus 101 units/kg per week).14 Similar results were found in a study with captopril and losartan.15

The manufacturers of epoetin comment that increased potassium levels have been reported in a few patients with chronic renal failure receiving epoetin, and that serum potassium levels should be monitored regularly.15 An additive hyperkalaemic effect is therefore theoretically possible with patients also receiving ACE inhibitors or angiotensin II receptor antagonists.

**Mechanism**

(A) Epoetin can cause hypertension, possibly associated with haemodynamic changes produced by the increase in haematocrit.16

(B) It has been argued that ACE inhibitors might possibly reduce the efficacy of epoetin in haemodialysis patients for several reasons. Firstly, because patients with chronic renal failure have a reduction in their haematocrit when given ACE inhibitors but subsequently because ACE inhibitors reduce polycythaemia following renal transplantation, and thirdly because ACE inhibitors reduce the plasma levels of endogenous erythropoietin.4,9,17 Many other factors have also been proposed.18

(C) Drugs that block angiotensin II cause reduced levels of aldosterone, which results in the retention of potassium. This would be expected to be additive with other drugs that cause hyperkalaemia.

**Importance and management**

Blood pressure should be routinely monitored in patients using epoetin, and this monitoring would seem sufficient to detect any interaction that affects the blood pressure-lowering effects of the ACE inhibitors. The dose of ACE inhibitor may need to be increased, but if blood pressure rises cannot be controlled, a transient interruption of epoetin therapy is recommended. Similarly, serum electrolytes, including potassium, should be routinely monitored in patients using epoetin. If potassium levels rise, consider ceasing epoetin until the level is corrected.

The overall picture of the effect of ACE inhibitors on epoetin resistance is unclear, and it would seem that an interaction, if it happens, takes a long time to develop. There is even less evidence regarding any interaction with angiotensin II antagonists. As epoetin dosage is governed by response, no immediate intervention is generally necessary. More long-term study is needed.

Food has little or no effect on the absorption of cilazapril, enalapril, fosinopril, lisinopril, quinapril, ramipril, spirapril, and trandolapril. Although food may reduce the absorption of captopril, this does not appear to be clinically relevant. Food reduced the absorption of imidapril and moexipril, and reduced the conversion of perindopril to perindoprilat, but the clinical relevance of this is uncertain.

Other single-dose studies have shown that food had no statistically significant effect on the pharmacokinetics of lisinopril, or enalaprilat, and its active metabolite, enalapril. Similarly, food had minimal effects on the pharmacokinetics of cilazapril (AUC decreased by only 14%). Food caused small, but statistically significant increases in the time to reach maximum plasma levels of quinapril and its active metabolite. However, as the increase was less than 30 minutes this is not expected to alter the pharmacokinetic profile of quinapril.

Other manufacturers state that food had no effect on the absorption of moexipril.

In one study, food reduced the AUC of the active metabolite of moexipril (moexiprilat) by 40 to 50%. Food did not reduce moexipril-induced ACE-inhibition and therefore the reduced bioavailability was not expected to be clinically relevant. However, the US manufacturers suggest taking moexipril one hour before food.

Although food did not significantly affect the pharmacokinetics of a single 4-mg dose of perindopril, the AUC of its active metabolite perindoprilat was reduced by 44%.

The blood-pressure-lowering effects were not assessed, but it seems possible that they would not be affected (see captopril, above). Nevertheless, the UK manufacturer recommends that perindopril should be taken in the morning before a meal.

The UK manufacturer of imidapril states that a fat-rich meal significantly reduces the absorption of imidapril, and recommends that the drug be taken at the same time each day, about 15 minutes before a meal.

ACE inhibitors + Garlic

In a single report, a patient taking lisinopril developed marked hypotension and became faint after taking garlic capsules.

Clinical evidence, mechanism, importance and management

A man whose blood pressure was 135/90 mmHg while taking lisinopril developed marked hypotension and became faint after taking garlic capsules. In a single report, a patient taking lisinopril developed marked hypotension and became faint after taking garlic capsules.

Peripheral vasodilatation has occurred in some patients receiving gold where ACE inhibitors were given. However, the US manufacturers suggest taking moexipril one hour before food.

Although food did not significantly affect the pharmacokinetics of a single 4-mg dose of perindopril, the AUC of its active metabolite perindoprilat was reduced by 44%.

The blood-pressure-lowering effects were not assessed, but it seems possible that they would not be affected (see captopril, above). Nevertheless, the UK manufacturer recommends that perindopril should be taken in the morning before a meal.

The UK manufacturer of imidapril states that a fat-rich meal significantly reduces the absorption of imidapril, and recommends that the drug be taken at the same time each day, about 15 minutes before a meal.

discontinuing the ACE inhibitor (2), or reducing the dose of sodium aurothiomalate to 25 mg (1). There appear to be few reports of this interaction, possibly because the nitritoid reaction is an established adverse effect of gold. However, a possible interaction should be borne in mind if a patient experiences these reactions and is also taking an ACE inhibitor.

Heparin may increase the risk of hyperkalaemia with ACE inhibitors or angiotensin II receptor antagonists.

Clinical evidence, mechanism, importance and management

Cimetidine did not appear to alter the pharmacokinetics or pharmacological effects of captopril or enalapril, or the pharmacokinetics of fosinopril or quinapril in studies in healthy subjects. The manufacturers of cilazapril say that no clinically significant interaction occurred with H₂-receptor antagonists (not specifically named) and the manufacturers of moexipril, ramipril, and trandolapril say that no important pharmacokinetic interaction occurred with cimetidine. The manufacturers of spirapril briefly note in a review that cimetidine did not alter the plasma concentrations of spirapril or its active metabolite spiraprilat. None of these pairs of drugs appears to interact to a clinically relevant extent, and no special precautions appear to be necessary.

Preliminary findings suggest that cimetidine 400 mg twice daily had no effect on the metabolism of temocapril 20 mg daily in 18 healthy subjects, but the AUC was reduced by 26% on the fifth day of concurrent use. The clinical relevance of this is uncertain, but changes of this magnitude with other ACE inhibitors have often not been clinically relevant.

In general, no clinically significant interactions appear to occur between the H₂-receptor antagonists (including cimetidine) and the ACE inhibitors. However, note that cimetidine modestly reduces the bioavailability of temocapril.

Clinical evidence, mechanism, importance and management

Cimetidine did not appear to alter the pharmacokinetics or pharmacological effects of captopril or enalapril, or the pharmacokinetics of fosinopril or quinapril in studies in healthy subjects. The manufacturers of cilazapril say that no clinically significant interaction occurred with H₂-receptor antagonists (not specifically named) and the manufacturers of moexipril, ramipril, and trandolapril say that no important pharmacokinetic interaction occurred with cimetidine. The manufacturers of spirapril briefly note in a review that cimetidine did not alter the plasma concentrations of spirapril or its active metabolite spiraprilat. None of these pairs of drugs appears to interact to a clinically relevant extent, and no special precautions appear to be necessary.

Preliminary findings suggest that cimetidine 400 mg twice daily had no effect on the metabolism of temocapril 20 mg daily in 18 healthy subjects, but the AUC was reduced by 26% on the fifth day of concurrent use. The clinical relevance of this is uncertain, but changes of this magnitude with other ACE inhibitors have often not been clinically relevant.

Mechanism

ACE inhibitors might potentiate the hypotension associated with anaphylactic reactions by inhibiting the breakdown of bradykinin and decreasing concentrations of the vasconstrictor angiotensin II. It has also been suggested that similar reactions may occur after an insect sting. This is supported by a case report that describes a woman who had generalised angioedema in response to bee stings on at least three occasions while taking captopril and then cilazapril, but experienced only localised swelling before and after treatment with an ACE inhibitor.

Importance and management

On the basis of these few reports, it cannot be said with certainty that an interaction occurs; however, it is possible that ACE inhibitors could exacerbate the response to insect venom immunotherapy. Because of the potential severity of the reaction, extra caution should be taken in patients taking ACE inhibitors and undergoing desensitising treatment with Hymenoptera (bee or wasp) venom. Some authors and manufacturers advise temporarily withholding the ACE inhibitor before each venom injection.

ACE inhibitors + Interleukin-3

Marked hypotension occurred when three patients taking ACE inhibitors were given interleukin-3.

Clinical evidence, mechanism, importance and management

Twenty-six patients with ovarian or small-cell undifferentiated cancers were treated with chemotherapy followed by recombinant human interleukin-3. Three of the 26 were taking ACE inhibitors (not named) and all three developed marked hypotension (WHO toxicity grade 2 or 3) within 1 to 4 hours of the first interleukin-3 injection. Their blood pressures returned to normal while continuing the interleukin-3 when the ACE inhibitors were stopped. When the interleukin-3 was stopped, they once again needed the ACE inhibitors to control their blood pressure. None of the other 23 patients had hypotension, except one who did so during a period of neutropenic fever. The authors of the report suggest (and present some supporting evidence) that the drugs act synergistically to generate large amounts of nitric oxide in the blood vessel walls. This relaxes the smooth muscle in the blood vessel walls causing vasodilatation and consequent hypotension. Information seems to be limited to this single report, but it would be prudent to monitor blood pressure even more closely in patients receiving interleukin-3 while taking ACE inhibitors.

ACE inhibitors + Iron compounds

Serious systemic reactions occurred when three patients taking enalapril were given infusions of ferric sodium gluconate; however, there was no increase in the incidence of such adverse reactions in patients taking ACE inhibitors in a very large clinical study. Oral ferrous sulfate may decrease the absorption of captopril, but this is probably of little clinical importance.

Clinical evidence

(a) Intravenous iron

A man with iron-deficiency anaemia taking furosemide and digoxin was given 125 mg of ferric sodium gluconate (Ferrlecit®) intravenously in 100 mL of saline daily. Four days later, enalapril 5 mg daily was started. After the infusion of only a few drops of his next dose of ferric sodium gluconate, he developed diffuse erythema, abdominal cramps, hypotension, nausea and vomiting. He recovered after being given hydrocortisone 200 mg. Three days later, in the absence of the enalapril, he restarted the iron infusions for a further 10 days without problems, and was later treated uneventfully with the enalapril. Two other patients taking enalapril reacted similarly when given intravenous infusions of ferric sodium gluconate. Neither was given any more intravenous iron and later had no problems while taking enalapril alone. During the same 13-month period in which these three cases occurred, 15 other patients, who were not taking ACE inhibitors, also received intravenous iron therapy with no adverse reactions. In contrast, an interim report of a randomised, crossover study involving 1117 dialysis patients given a placebo or a single intravenous dose of 125 mg of ferric sodium gluconate complex (Ferrlecit) in sucrose, found no evidence of any significant difference in the incidence of immediate allergic reactions or other adverse reactions to the iron in the 308 patients also taking ACE inhibitors. The findings of the full study, which included 707 patients taking ACE inhibitors, were the same. Similarly, the longer-term follow-up of patients from this study who continued to receive intravenous ferric sodium gluconate complex, found that there was no difference in the incidence or severity of adverse events in the 372 patients taking ACE inhibitors, when compared with the 949 patients who were not.

(b) Oral iron

A double-blind study in 7 healthy subjects, given single 300-mg doses of ferrous sulfate or placebo with captopril 25 mg, found that the AUC of unconjugated plasma captopril (the active form) was reduced by 37% although the maximum plasma levels were not substantially changed. The AUC of total plasma captopril was increased by 43%, although this was not statistically significant. There were no significant differences in blood pressure between treatment and placebo groups.

Mechanism

(a) Uncertain. Intravenous iron may cause a variety of systemic reactions including fever, myalgia, arthralgia, hypotension, and nausea and vomiting, which are believed to be due to the release of various inflammatory mediators such as bradykinin, caused by iron-catalysed toxic free radicals. The authors of the report suggest that ACE inhibitors like enalapril decrease the breakdown of kinins so that the toxic effects of the iron become exaggerated.

(b) Reduced levels of unconjugated captopril in the plasma are probably due to reduced absorption resulting from a chemical interaction between ferric ions and captopril in the gastrointestinal tract.

Importance and management

(a) The interaction with intravenous iron is not firmly established because up to 25% of all patients given iron by this route develop a variety of systemic reactions, ranging from mild to serious anaphylactoid reactions. In addition, information from the large clinical study indicates that there is no increased risk in patients taking ACE inhibitors. This suggests that no extra precautions are required if intravenous iron is given to patients taking any ACE inhibitor.

(b) There is limited evidence that oral iron may reduce the absorption of captopril. The clinical relevance of this is unknown, but probably small. Information about the effect of oral iron on other ACE inhibitors is lacking.

ACEMorphine causes some moderate alterations in the pharmacokinetics of free captopril, but these are unlikely to be clinically important.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 19 healthy subjects were given morphine 250 mg or captopril 50 mg, both every 8 hours, either alone or together, for 22 doses. When taken together the pharmacokinetics of the morphine and total captopril remained unchanged, but the maximum blood levels of the free captopril and its AUC decreased by 32% and 14%, respectively. The half-life of the free captopril was reduced by 44%. These modest changes are unlikely to be clinically relevant.

ACE inhibitors + Moracizine

ACE inhibitors + NSAIDs

There is evidence that most NSAIDs can increase blood pressure in patients taking antihypertensives, including ACE inhibitors, although some studies have not found the increase to be clinically relevant. Some variation between drugs possibly occurs, with in-
dometacin appearing to have the most significant effect. The combination of an NSAID and an ACE inhibitor can increase the risk of renal impairment and hyperkalaemia.

Clinical evidence

(A) Effects on blood pressure

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAI7s on blood pressure in patients taking antihypertensives, and the findings of these are summarised in ‘Table 23.2’, (p.862). In these studies, NSAI7s were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both coxibs and non-selective NSAI7s. In two meta-analyses,1,2 the effects were evaluated by NSAID. The findings of individual studies that have studied the effects of specific NSAI7s on ACE inhibitors are outlined in the subsections below.

(a) Celecoxib

In a double-blind study in hypertensive patients taking lisinopril 10 to 40 mg daily, celecoxib did not have a clinically or statistically significant effect on blood pressure. The 24-hour blood pressure increased by 2.6/1.5 mmHg in 91 patients taking celecoxib 200 mg twice daily for 4 weeks compared with 1.0/3 mmHg in 87 patients taking placebo.3 In another large study in 810 elderly patients with osteoarthritis and controlled hypertension given either celecoxib 200 mg or rofecoxib 25 mg daily for 6 weeks, approximately 40% of the patients randomised to the celecoxib group were receiving ACE inhibitors. Systolic blood pressure increased by a clinically significant amount (greater than 20 mmHg) in 11% of patients receiving celecoxib,4 while in another study, only 4 of 87 (4.6%) of hypertensive patients taking ACE inhibitors had clinically significant increases in blood pressure after taking celecoxib 200 mg twice daily for 4 weeks.5 A further study in 25 hypertensive patients with osteoarthritis taking trandolapril (with or without hydrochlorothiazide) found that the 24-hour blood pressure was not significantly increased by celecoxib 200 mg daily, but, at its peak activity, celecoxib increased blood pressure by about 5/4 mmHg.6 In another randomised study, 16% of 138 patients given celecoxib 200 mg daily developed hypertension within 6 weeks (defined as a 24-hour systolic blood pressure greater than 135 mmHg). These patients had well-controlled hypertension at baseline; 83% were receiving an ACE inhibitor and 64% an additional antihypertensive.7 The proportion of patients who developed hypertension was similar to that with naproxen (19%) and less than that with rofecoxib (30%).

(b) Ibuprofen

In 90 patients taking ACE inhibitors, giving ibuprofen for 4 weeks resulted in clinically significant increases in blood pressure in 1.5 of the patients. For the group as a whole, diastolic blood pressure was increased by 3.5 mmHg.8 In one single-dose study, ibuprofen 800 mg or indometacin 50 mg abolished the hypotensive effect of captopril 50 mg in 8 healthy subjects when they took a high sodium diet, but not when they took a low sodium diet.8 A case report describes attenuation of the antihypertensive effects of captopril by ibuprofen in an elderly woman.9 However, two studies in African women found that ibuprofen 800 mg three times daily for one month did not alter the antihypertensive effect of either fosinopril 10 to 40 mg daily or lisinopril 10 to 40 mg daily (given with hydrochlorothiazide 25 mg daily).10 It was thought that the diuretics might have enhanced salt depletion and renin stimulation making the antihypertensive action of the combination less prostaglandin dependent.10

(c) Indometacin

1. Captopril. In a randomised, double-blind study, 105 patients with hypertension were given captopril 25 to 50 mg twice daily for 6 weeks, which reduced their blood pressure by a mean of 8.6/5.6 mmHg. Indometacin 75 mg once daily was then added for one week, which caused a rise in blood pressure in the group as a whole of 4.6/2.7 mmHg (an attenuation of the effect of captopril of about 50%). Clear attenuation was seen in 67% of the patients, and occurred regardless of baseline blood pressure.12 This same interaction has been described in numerous earlier studies, in both patients with hypertension and healthy subjects, given indometacin 8.13-20

A man whose blood pressure was well controlled with captopril 75 mg daily had a rise in his blood pressure from 145/80 to 220/120 mmHg when he started using indometacin suppositories 200 mg daily.21 In contrast, a randomised, placebo-controlled, crossover study in 11 patients found that indometacin 50 mg twice daily did not alter the antihypertensive efficacy of captopril 50 mg twice daily.22

2. Enalapril. In 9 patients with hypertension indometacin 50 mg twice daily for 1 week significantly reduced the antihypertensive effect of enalapril 20 to 40 mg once daily by about 18 to 22%.23 In another study in 18 patients, indometacin 25 mg three times daily attenuated the antihypertensive effect of enalapril 20 to 40 mg daily. The reduction in hypotensive effect was about 42% when taking indometacin 25 to 40 mg daily blood-pressure monitoring (9.4/4.1 mmHg increase in blood pressure with indometacin), and 12 to 23% when assessed by clinic blood pressure monitoring.24 Similar results were found in other studies.25-28 A further study in 10 normotensive subjects receiving a fixed sodium intake and enalapril 20 mg daily, with or without indometacin 50 mg twice daily for one week, found that indometacin reduced the natriuretic response to the ACE inhibitor.29 A single case report describes a patient taking enalapril 10 mg daily whose hypertension was not controlled when indometacin 100 mg daily in divided doses was added.30 However, other studies found indometacin did not significantly alter the blood pressure response to enalapril.19,22,31

3. Lisinopril. In a placebo-controlled, crossover study, indometacin 50 mg twice daily for 2 weeks produced mean blood pressure increases of 5.5/3.2 mmHg in 56 patients 20 to 40 mg daily.32 Similarly, results of an earlier study suggested that indometacin increased the blood pressure of 9 patients taking lisinopril.26 In contrast in a placebo-controlled study in 16 patients, indometacin 50 mg twice daily for 4 weeks was found to have little effect on the antihypertensive efficacy of lisinopril 40 mg daily.33

4. Other ACE inhibitors. A placebo-controlled, randomised, crossover study in 16 hypertensive patients found that indometacin 50 mg twice daily reduced the blood pressure-lowering effects of cilazapril 2.5 mg daily. The reduction was greater when cilazapril was added to indometacin than when indometacin was added to cilazapril (approximately 60% versus 30% reduction in hypotensive effect measured 3 hours after the morning dose).33 The antihypertensive effects of perindopril 4 to 8 mg daily were also found to be reduced by about 50% by indometacin 50 mg twice daily in 10 hypertensive patients.35 A brief mention is made in a review that the pharmacodynamics of ramipril were unaffected by indometacin (dosage not stated) given to healthy subjects for 3 days.36 Indometacin 25 mg three times daily did not alter the hypotensive effects of trandolapril 2 mg daily in 17 hypertensive patients.37

(d) Naproxen

In a randomised study, 19% of 130 patients given naproxen 500 mg twice daily developed hypertension within 6 weeks (defined as a 24-hour systolic blood pressure greater than 135 mmHg). These patients had well-controlled hypertension at baseline; 83% were receiving an ACE inhibitor and 66% an additional antihypertensive.3 The proportion of patients who developed hypertension was similar to that with celecoxib (16%) and less than that with rofecoxib (30%).

(e) Rofecoxib

The manufacturer of rofecoxib noted that in patients with mild-to-moderate hypertension, rofecoxib 25 mg daily, taken with benazepril 10 to 40 mg daily, for four weeks, was associated with a small attenuation of the antihypertensive effect (average increase in mean arterial pressure of 2.8 mmHg).38 Similarly, a case report describes a patient taking lisinopril 10 mg daily whose blood pressure rose from 127/78 to 143/89 mmHg when he was given rofecoxib 25 mg daily. His blood pressure was controlled by increasing the dose of lisinopril to 20 mg daily.39 In another study in 810 elderly patients with osteoarthritis and controlled hypertension given either celecoxib 200 mg or rofecoxib 25 mg daily for

ACE inhibitors and AT II receptor antagonists 29
6 weeks, approximately 29% of the patients randomised to the rofecoxib group were receiving ACE inhibitors. Systolic blood pressure increased by a clinically significant amount (greater than 20 mmHg) in 17% of the patients receiving rofecoxib. In another similar randomised study, 30% of 138 patients given rofecoxib 25 mg daily developed hypertension within 6 weeks (defined as a 24-hour systolic blood pressure greater than 135 mmHg). These patients had well-controlled hypertension at baseline; 84% were receiving an ACE inhibitor and 62% an additional antihypertensive. The proportion of patients who developed hypertension was greater than with celecoxib (16%) or naproxen (19%).

(f) Sulindac

In one study, sulindac 200 mg twice daily given to patients taking captopril 100 to 200 mg twice daily caused only a small rise in blood pressure (from 132/92 to 137/95 mmHg) after 2 hours.25 In 29 patients with hypertension oxaprozin 1.2 g daily for 3 weeks did not affect the pharmacodynamics of enalapril 10 to 40 mg daily.29 Twenty-five hypertensive patients with osteoarthritis taking trandolapril 2 to 4 mg daily (with or without hydrochlorothiazide) had an increase in blood pressure of about 3/4 mmHg when they were given diclofenac 75 mg twice daily.25 However, diclofenac 75 mg twice daily for one month did not alter the antihypertensive effect of lisinopril 10 to 40 mg daily when given with hydrochlorothiazide.11 A study found that only 5 of 91 (5.5%) hypertensive patients stabilised on ACE inhibitors had clinically significant increases in blood pressure when they were given nabumetone 1 g twice daily for 4 weeks.3 A study in 17 black women found that nabumetone 1 g twice daily for one month did not alter the antihypertensive effect of fosinopril 10 to 40 mg daily or lisinopril 10 to 40 mg daily (given with hydrochlorothiazide 25 mg daily).10

(B) Effects on renal function

In a retrospective analysis, 3 of 162 patients who had been taking ACE inhibitors and NSAIDs developed reversible renal failure, compared with none of 166 patients taking ACE inhibitors alone and none of 2116 patients taking NSAIDs alone. One patient was taking naproxen or salicylate and had a progressive decline in renal function over 19 months after captopril was started. Another man taking unnamed NSAIDs developed reversible renal failure 4 days after starting to take captopril.41 In another similar analysis, in patients aged over 75 years, 2 out of 12 patients given an ACE inhibitor and an NSAID developed acute renal failure (1 died) and a further 4 showed deterioration in renal function. All of these 6 patients were also taking ‘diuretics’, (p.21), but of the 6 with unaffected renal function, only two were taking diuretics.42 A randomised, crossover study in 17 black patients receiving fosinopril with hydrochlorothiazide and NSAIDs for a month, found that acute renal failure (a decrease in glomerular filtration rate of greater than or equal to 25%) occurred in 4 of the 17 patients when receiving ibuprofen, 1 of 17 receiving sulindac and 0 of 17 receiving nabumetone.40 In a multivariate analysis, significant renal impairment was associated with use of two or more of ACE inhibitors or angiotensin II receptor antagonists with NSAIDs or diuretics.41 In a case-control study, recently starting an NSAID was associated with a 2.2-fold increased risk of hospitalisation for renal impairment in patients taking ACE inhibitors.44 In 2002, 28 of 129 reports to the Australian Adverse Drug Reactions Advisory Committee of acute renal failure were associated with the combined use of ACE inhibitors (or angiotensin II receptor antagonists), diuretics, and NSAIDs (including coxibs), and these cases had a fatality rate of 10%. In patients taking this triple combination, renal failure appeared to be precipitated by mild stress such as diarrhoea or dehydration. In other patients, the addition of a third drug (usually an NSAID) to a stable combination of the other two, resulted in acute renal failure.45

In contrast, another retrospective analysis found no evidence that the adverse effects of ACE inhibitors on renal function were greater in those taking NSAIDs.46 A further study in 17 hypertensive patients with normal baseline renal function, found that indometacin 25 mg three times daily did not adversely affect renal function when it was given with trandolapril 2 mg daily for 3 weeks.47

(C) Hyperkalaemia

Hyperkalaemia, resulting in marked bradycardia, was attributed to the use of ibuprofen in an elderly woman taking imidapril.48 A 77-year-old woman with mild hypertension and normal renal function taking enalapril 2.5 mg daily arrested and died 5 days after starting treatment with rofecoxib for leg pain. Her potassium was found to be 8.8 mmol/L. Infec-

tion and dehydration could have contributed to the hyperkalaemia in this patient.49

(D) Pharmacokinetic studies

The manufacturer of spirapril briefly noted in a review that there was no relevant pharmacokinetic interaction between spirapril and diclofenac.50

Oxaprozin 1.2 g daily for 3 weeks did not affect the pharmacokinetics of enalapril 10 to 40 mg daily in 29 patients with hypertension.51 A brief mention is made in a review that, in healthy subjects, the pharmacokinetics of ramipril were unaffected by indometacin [dosage not stated] given for 3 days.36

Mechanism

Some, but not all the evidence suggests that prostaglandins may be involved in the hypotensive action of ACE inhibitors, and that NSAIDs, by inhibiting prostaglandin synthesis, may partially antagonise the effect of ACE inhibitors. Another suggestion is that NSAIDs promote sodium retention and so blunt the blood pressure lowering effects of several classes of antihypertensive drugs, including ACE inhibitors. This interaction may be dependent on sodium status and on plasma renin, and so drugs that affect sodium status e.g. diuretics may possibly influence the effect. Therefore, the interaction does not occur in all patients. It may also depend on the NSAID, with indometacin being frequently implicated, and sulindac less so, as well as on the dosing frequency.52

Both NSAIDs and ACE inhibitors alone can cause renal impairment. In patients whose kidneys are underperfused, they may cause further deterioration in renal function when used together.53 Impaired renal function is a risk factor for hyperkalaemia with ACE inhibitors.

Importance and management

The interaction between indometacin and ACE inhibitors is well established, with several studies showing that indometacin can reduce the blood pressure-lowering effect of a number of ACE inhibitors. The interaction may not occur in all patients. If indometacin is required in a patient taking any ACE inhibitor, it would be prudent to monitor blood pressure. In a few small comparative studies, indometacin has been shown to have less effect on the calcium-channel blockers amlodipine, felodipine, and nifedipine, than on enalapril.24,27,28 See also, ‘Calcium-channel blockers + Aspirin or NSAIDs’, p.861. Therefore, a calcium-channel blocker may sometimes be an alternative to an ACE inhibitor in a patient requiring indometacin.

Limited information suggests that sulindac has little or no effect on ACE inhibitors, and may therefore be less likely to cause a problem, but further study is needed. The coxibs appear to have similar (celecoxib) or greater (rofecoxib) effects on ACE inhibitors than conventional NSAIDs (naproxen).

Although information about other NSAIDs is limited, the mechanism suggests that all of them are likely to interact similarly. Until more is known, it may be prudent to increase blood pressure monitoring when any NSAID is added or discontinued in a patient taking any ACE inhibitor, and intermittent use of NSAIDs should be considered as a possible cause of erratic control of blood pressure. In addition, sodium status and therefore diuretic use may affect any interaction. However, some consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.52 While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inadequate control of blood pressure, other reasons may be more likely than any effect of concurrent NSAIDs.52 Further study is needed. For the effects of NSAIDs on other antihypertensive drug classes see ‘beta blockers’, (p.835), ‘calcium-channel blockers’, (p.861) and ‘thiazide diuretics’, (p.956). There is an increased risk of deterioration in renal function or acute re-
nal failure with the combination of NSAIDs and ACE inhibitors, especially if poor renal perfusion is present. Renal function should be monitored periodically in patients taking ACE inhibitors with NSAIDs, particularly in volume depleted patients. In a statement, the American Heart Association comments that acute renal failure complicating ACE inhibitor therapy is almost always reversible and repletion of extracellular fluid volume and discontinuation of diuretics and ACE inhibitor therapy should be approached, with withdrawal of interacting drugs, supportive management of fluid and electrolyte, and temporary dialysis, where indicated, are the mainstays of therapy. The Australian Adverse Drug Reactions Advisory Committee consider that the triple combination of ACE inhibitors, ‘diuretics’, and NSAIDs (including coxibs) should be avoided if possible, and that great care should be taken when giving ACE inhibitors and NSAIDs to patients with renal impairment. Deterioration in renal function increases the risk of hyperkalaemia.

The Uppsala Adverse Drug Reaction database has two reports of aggravated hypertension in women taking antihypertensives and orlistat.1 Hypertension has also been reported in previously normotensive individuals taking orlistat, which, in one case, responded to stopping orlistat.2,3

However, the manufacturer has found no evidence of an association between orlistat and hypertension. In clinical studies, orlistat use was associated with a small reduction in blood pressure compared with placebo, which was as a result of weight reduction. Moreover, the incidence of hypertension of new onset and hypertensive crisis did not differ between orlistat and placebo (1.2% versus 1.3%, and 0% versus 0.1%, respectively).4

In studies in healthy subjects, orlistat had no effect on steady-state losartan pharmacokinetics, and no clinically significant effect on the pharmacokinetics of single-dose captopril, atenolol, furosemide or nifedipine.5

**Mechanism**

Not understood. Suggestions include a decrease in the absorption of the drugs due to accelerated gastrointestinal transit, increased defaecation, diarrhoea, or an increase in the amount of fat in the chyme.1 An explanation for the difference between the clinical cases and pharmacokinetic studies may be that the latter tended to be single-dose studies and in healthy subjects only. Alternatively, these cases could just be idiosyncratic and not related to orlistat treatment.

**Importance and management**

The interactions between the antihypertensives and orlistat seem to be confined to the reports cited here, and their general significance is unclear. Given that the manufacturers report that specific drug interaction studies have not found any evidence of an interaction, the incidence seems likely to be small.

**ACE inhibitors + Potassium compounds**

ACE inhibitors maintain serum potassium levels. Hyperkalaemia is therefore a possibility if potassium supplements or potassium-containing salt substitutes are given, particularly in those patients where other risk factors are present, such as decreased renal function.

**Clinical evidence**

(a) Potassium levels increased by concurrent use

1. Potassium supplements. The serum potassium levels of a patient taking a potassium supplement rose by 66% when captopril was added, with signs of a deterioration in renal function. Four others taking potassium supplements and furosemide (2 also taking unnamed potassium-sparing diuretics) had rises in their potassium levels of only 8 to 24% when given captopril. The rises occurred within 1 or 2 days. No clinical signs or symptoms of hyperkalaemia were seen, but 3 of the 5 patients had rises to above the upper limits of normal.1 A post-marketing survey identified 10 patients in whom enalapril appeared to have been associated with renal impairment and death. Eight of them were also taking potassium supplements and/or potassium-sparing diuretics, and hyperkalaemia appeared to have been the immediate cause of death in two of them.1 In a review of 47 patients treated with enalapril for heart failure, and who experienced serious hyperkalaemia, 8 had also received potassium supplements.2

In another survey of 53 patients taking ACE inhibitors who had hyperkalaemia in the absence of significant renal impairment, less than 5% were taking a potassium supplement, but 30% were using a potassium-containing salt substitute (see 2. below).4

2. Dietary potassium. Two patients with renal impairment, one taking lisinopril and the other enalapril, developed marked hyperkalaemia shortly after starting to take ‘Lo salt’ (a salt substitute containing 34.6 g potassium in every 100 g). One developed a life-threatening arrhythmia.5 A similar report describes a man taking captopril who developed hyperkalaemia and collapsed 2 weeks after starting to use a salt substitute containing potassium.6 In a further report, severe hyperkalaemia occurred in a patient on a very-low-calorie diet with a protein supplement who was taking lisinopril 10 mg daily. The protein supplement contained 48 mmol of potassium and salad topped with lemon juice and potassium chloride salt added at least another 72 mmol daily.7 In 53 patients taking ACE inhibitors who had hyperkalaemia in the absence of significant renal impairment, 30% were using a salt substitute, and 72% were eating a moderate-to-high potassium diet, consisting of 2 or more servings of a potassium-rich food daily.8 Hyperkalaemia and acute renal failure has also been reported in a diabetic patient taking lisinopril 20 mg twice daily following the use of a potassium-based water softener.9

(b) Potassium levels unaltered by concurrent use

A retrospective analysis of 14 patients without renal impairment taking potassium supplements and either furosemide or hydrochlorothiazide, found that the levels of serum potassium, during a 4-year period, had not significantly increased after the addition of captopril.10 Another study in 6 healthy subjects found that intravenous potassium chloride caused virtually the same rise in serum potassium levels in those given enalapril as in those given a placebo.10

**Mechanism**

The potassium-retaining effects of ACE inhibitors (due to reduced aldosterone levels) are additive with an increased intake of potassium, particularly when there are other contributory factors such as poor renal function or diabetes.

**Importance and management**

The documentation of this interaction appears to be limited, but it is well established. In practice, a clinically relevant rise in potassium levels usually occurs only if other factors are also present, the most important of which is impaired renal function. In general, because ACE inhibitors have potassium-sparing effects, potassium supplements should not routinely be given concurrently. If a supplement is needed, serum potassium should be closely monitored. This is especially important where other possible contributory risk factors are known to be present.

Other sources of dietary potassium should also be borne in mind. Patients with heart disease and hypertension are often told to reduce their salt (sodium) intake. One way of doing this is to use potassium-containing salt substitutes. However, it appears that there is some risk associated with excess use of these substitutes, especially in patients taking ACE inhibitors.

ACE inhibitors + Probencide

Probencide decreases the renal clearance of captopril, but this is probably not clinically important. Probencide decreases the renal clearance of enalapril, and raises its serum levels.
Clinical evidence, mechanism, importance and management

Steady-state levels of unchanged and total captopril, given by intravenous infusion, were slightly increased (14% and 36%, respectively) by the use of probenecid in 4 healthy subjects. Renal clearance of unchanged captopril decreased by 44%, but total clearance was reduced by only 19%.1 These moderate changes are unlikely to be clinically important.

In 12 healthy subjects probenecid 1 g twice daily for 5 days increased the AUC of a single 20-mg oral dose of enalapril and its active metabolite, enalaprilat by about 50%. The renal clearance of enalapril decreased by 73%.2 A moderate increase in the hypotensive effects might be expected, but there do not appear to be any reports of adverse effects.

ACE inhibitors + Procainamide

The combination of captopril or other ACE inhibitors and procainamide possibly increases the risk of leucopenia. No pharmacokinetic interaction occurs between captopril and procainamide.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects the concurrent use of captopril 50 mg twice daily and probenecid 250 mg every 3 hours did not affect the pharmacokinetics of either drug.1 The US manufacturer of captopril notes that in patients with heart failure who developed neutropenia, about 50% had a serum creatinine of 1.6 mg/dL or greater, and more than 75% were also receiving procainamide.2 Similarly, the UK manufacturer of captopril notes that neutropenia or agranulocytosis and serious infection have occurred in patients taking captopril, and that concurrent treatment with procainamide may be a complicating factor. They recommend that the combination should be used with caution, especially in patients with impaired renal function. They suggest that differential white blood cell counts should be performed before concurrent use, then every 2 weeks in the first 3 months of treatment and periodically thereafter.3 The UK manufacturers of a number of other ACE inhibitors suggest that concurrent use of ACE inhibitors and procainamide may lead to an increased risk of leucopenia. For reports of other possible interactions with ACE inhibitors that might result in an increased risk of leucopenia see also ‘ACE inhibitors + Allopurinol’, p.13 and ‘ACE inhibitors + Azathioprine’, p.18.

ACE inhibitors + Sevelamer

Sevelamer did not alter the pharmacokinetics of enalapril.

Clinical evidence, mechanism, importance and management

The concurrent use of a single 2.418-g dose of sevelamer hydrochloride (equivalent to 6 capsules) and did not alter the AUC of a single 20-mg dose of enalapril or its active metabolite, enalaprilat, in 28 healthy subjects.1 Thus it appears that sevelamer does not bind to enalapril within the gut to reduce its absorption.

ACE inhibitors + Sibutramine

Sibutramine had only a minimal effect on blood pressure control with ACE inhibitors.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind study over 52 weeks in 220 obese, hypertensive patients, whose hypertension was well controlled with an ACE inhibitor (benazepril, enalapril or lisinopril) with or without a thiazide diuretic, two-thirds of the patients were also given sibutramine and one-third were given placebo. Sibutramine 20 mg daily caused small increases in mean blood pressure compared with placebo (133.1/85.5 mmHg compared with 130.4/82.8 mmHg, at 52 weeks, respectively), but overall, hyperten-\nsion remained well controlled.1

Angiotensin II receptor antagonists + Antacids

Antacids slightly reduce irbesartan and olmesartan absorption, but this is not clinically relevant.
Clinical evidence, mechanism, importance and management

In a single-dose, crossover study in 18 healthy subjects, 10 mL of an antacid containing aluminium/magnesium hydroxides (Unimalelax) given with, or 2 hours before, a single 300-mg dose of irbesartan had little effect on irbesartan pharmacodynamics. The only difference was that the AUC was reduced by 10% when the antacid was given 2 hours before irbesartan, when compared with irbesartan alone. However, this change is not considered to be clinically relevant.1

The steady-state AUC of olmesartan 20 mg daily was 12% lower when it was given 15 minutes after a daily dose of an aluminium/magnesium hydroxide antacid, when compared with olmesartan alone, but this was not considered to be clinically significant.2

Indometacin may attenuate the antihypertensive effect of losartan, valsartan, or other angiotensin II receptor antagonists. However, low-dose aspirin does not appear to alter the antihypertensive effect of losartan. No clinically relevant pharmacokinetic interactions occur between telmisartan and ibuprofen or paracetamol (acetaminophen), or between valsartan and indometacin. The combination of an NSAID and angiotensin II receptor antagonist can increase the risk of renal impairment and hyperkalaemia.

Clinical evidence

(A) Effects on blood pressure

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with antihypertensives, and the findings of these are summarised in Table 23.2, (p.862). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg.

(a) Aspirin

A double-blind, placebo-controlled study in 10 patients with hypertension taking losartan (mean daily dose 47.5 mg) found that neither aspirin 81 mg nor 325 mg daily for 2 weeks had any significant effect on blood pressure.3

(b) Indometacin

In a study in 111 patients with hypertension, losartan 50 mg once daily for 6 weeks reduced their blood pressure by a mean of 7.9/5.3 mmHg. Indometacin 75 mg once daily was then added for one week and this caused a rise in blood pressure in the group as a whole of 3.8/2.2 mmHg (reduction of about 45% in the effect of losartan). A rise in ambulatory diastolic blood pressure was seen in 69% of the losartan-treated patients during indometacin use.4 In contrast, a much smaller study in 10 patients with essential hypertension taking losartan found that indometacin 50 mg twice daily for one week caused sodium and fluid retention, but did not significantly attenuate the antihypertensive effects of losartan.5

In a placebo-controlled, crossover study in 56 hypertensive patients whose blood pressure was adequately controlled by valsartan 80 mg to 160 mg daily, the addition of indometacin 50 mg twice daily for 2 weeks produced an increase in mean blood pressure of 2.1/1.9 mmHg.6 A study in normotensive subjects given a fixed sodium intake and valsartan 80 mg daily, with or without indometacin 50 mg twice daily for one week, demonstrated that indometacin reduced the natriuretic response to the angiotensin receptor blockade.5

(B) Effects on renal function

In 2002, 28 of 129 reports to the Australian Adverse Drug Reactions Advisory Committee of acute renal failure were associated with the combined use of ACE inhibitors or angiotensin II receptor antagonists, diuretics, and NSAIDs (including coxibs), and these cases had a fatality rate of 10%. In patients taking this triple combination, renal failure appeared to be precipitated by mild stress such as diarrhoea or dehydration. In other patients, the addition of a third drug (usually an NSAID) to a stable combination of the other two, resulted in acute renal failure.6 In a multivariate analysis, significant renal impairment was associated with the use of two or more of an ACE inhibitor or angiotensin II receptor antagonist, and NSAIDs or diuretics.7

(C) Pharmacokinetic studies

(a) Ibuprofen

In a crossover study in 12 healthy subjects, telmisartan 120 mg daily had no effect on the pharmacokinetics of ibuprofen 400 mg three times a day for 7 days. Similarly, the pharmacokinetics of telmisartan were unaffected by the concurrent use of ibuprofen, when compared with previous studies of telmisartan alone.8

(b) Indometacin

In 12 healthy subjects the pharmacokinetics of single oral doses of valsartan 160 mg or indometacin 100 mg were not significantly changed when the drugs were given together, although the pharmacokinetics of valsartan showed wide variations between subjects.9

(c) Paracetamol (Acetaminophen)

Telmisartan 120 mg had no effect on the pharmacokinetics of paracetamol 1 g in a single-dose study in 12 healthy subjects. The pharmacokinetics of telmisartan were also unaffected by paracetamol, when compared with previous studies of telmisartan alone.5

Mechanism

Some evidence suggests that prostaglandins may be partially involved in the hypotensive action of angiotensin II receptor antagonists, and that NSAIDs, by inhibiting prostaglandin synthesis, may antagonise their effects. However, a non-specific mechanism such as sodium retention may also be involved, as indometacin has been shown to reduce the hypotensive effect of other classes of antihypertensive drugs.5,6 Both NSAIDs and angiotensin II receptor antagonists alone can cause renal impairment. In patients whose kidneys are underperfused, they may cause further deterioration in renal function when used together. Renal impairment increases the risk of hyperkalaemia.

Importance and management

As with other antihypertensives, the antihypertensive effect of angiotensin II receptor antagonists may be attenuated by NSAIDs such as indometacin. Patients taking losartan or valsartan or other angiotensin II receptor antagonists, who require indometacin and probably other NSAIDs, should be monitored for alterations in blood pressure control. See also ‘ACE inhibitors + NSAIDs’, p.28. Low-dose aspirin is unlikely to alter the blood pressure-lowering effect of angiotensin II receptor antagonists. However, for a discussion of the controversy as to whether low-dose aspirin might attenuate the benefits of ACE inhibitors in patients with heart failure, see ‘ACE inhibitors + Aspirin’, p.14.

Poor renal perfusion may increase the risk of renal failure if angiotensin II receptor antagonists are given with NSAIDs and so regular hydration of the patient and monitoring of renal function is recommended.10 The Australian Adverse Drug Reactions Advisory Committee consider that the triple combination of angiotensin II receptor antagonists or ACE inhibitors with diuretics and NSAIDs (including coxibs) should be avoided if possible.11 See also ‘ACE inhibitors + NSAIDs’, p.28.

---

Angiotensin II receptor antagonists + Azoles

**Fluconazole reduces the conversion of losartan to its active metabolite and decreases the metabolism of irbesartan, but the clinical relevance of these changes is uncertain. Fluconazole does not appear to influence the pharmacokinetics of eprosartan; candesartan and valsartan. Itraconazole does not significantly affect the pharmacokinetics or antihypertensive effects of losartan, and ketoconazole does not affect the pharmacokinetics of eprosartan or losartan.**

**Clinical evidence, mechanism, importance and management**

(a) **Fluconazole**

In a study of 32 healthy subjects, half were given losartan 100 mg daily and half were given eprosartan 300 mg twice daily for 20 days. Fluconazole increased the AUC and maximum plasma levels of losartan by 69% and 31%, respectively, and reduced those of E-3174, the active metabolite of losartan, by 41% and 54%, respectively. However, fluconazole had no significant effect on the pharmacokinetics of eprosartan. In a randomised, crossover study, 11 healthy subjects were given a single 50-mg dose of losartan after 4 days of fluconazole (400 mg on day 1 and 200 mg daily on days 2 to 4). The AUC of losartan was increased by 27% while its maximum plasma level was reduced by 23%. The AUC and the maximum plasma levels of E-3174 were reduced by 47% and 77%, respectively. However, no significant changes in the hypotensive effect of losartan were noted. It is thought that fluconazole inhibits the conversion of losartan to its active metabolite mainly by inhibiting the cytochrome P450 isoenzymes CYP2C9 and CYP3A4, although other isoenzymes may play a minor role. The lack of pharmacodynamic changes suggests that this pharmacokinetic interaction may not be clinically important, but the possibility of a decreased therapeutic effect should be kept in mind.2 A study in 15 healthy subjects given irbesartan 150 mg daily for 20 days found that the steady-state AUC and maximum blood levels were increased by about 55% and 18%, respectively, by fluconazole 200 mg daily on days 11 to 20. Irbesartan is primarily metabolised by CYP2C9, and these increased levels probably occur as a result of CYP2C9 inhibition by fluconazole. These modest increases were considered unlikely to be clinically relevant and a dosage reduction would not generally be required. Other angiotensin II receptor antagonists would not be expected to interact, see the ‘introduction’, (p.12), to this section.

(b) **Itraconazole**

In 11 healthy subjects the pharmacokinetics and hypotensive effects of a single 50-mg dose of losartan and its active metabolite, E-3174, were not significantly affected by itraconazole 200 mg daily for 4 days. Inhibition of the cytochrome P450 isoenzymes CYP3A4 alone (caused by itraconazole) does not appear to prevent the conversion of losartan to E-3174. No special precautions would appear to be needed if these drugs are used concurrently.

(c) **Ketoconazole**

A placebo-controlled, crossover study in 11 healthy subjects given a single 30-mg intravenous dose of losartan, found that ketoconazole 400 mg daily for 4 days did not affect the conversion of losartan to its active metabolite, E-3174, or the plasma clearance of losartan. Inhibition of the cytochrome P450 iso enzyme CYP3A4 alone (caused by ketoconazole) does not appear to prevent the conversion of losartan to E-3174. The plasma clearance of a 20-mg intravenous dose of E-3174 was also unaffected by pretreatment with ketoconazole. Similar results were found in a study involving 27 healthy subjects. Ketoconazole 200 mg daily for 5 days was found to have no effect on the pharmacokinetics of eprosartan or losartan and its active metabolite.6 No special precautions would appear to be needed if these drugs are used concurrently.

---

Angiotensin II receptor antagonists + Beta blockers

**There appears to be no clinically significant pharmacokinetic interaction between atenolol and valsartan, and concurrent use enhances the hypotensive effects. The combination of angiotensin II receptor antagonists and beta blockers is in established clinical use.**

**Clinical evidence, mechanism, importance and management**

In a single-dose, crossover study in 12 healthy subjects, the pharmacokinetics of valsartan 160 mg and atenolol 100 mg were not significantly altered by concurrent use. The combination had some additive effects on resting blood pressure. Although pharmacokinetic information is apparently limited to this drug pair, no significant adverse interaction would be expected between angiotensin II receptor antagonists and beta blockers, and the combination is clinically useful in a number of cardiovascular disorders.

---

Angiotensin II receptor antagonists + Calcium-channel blockers

**No significant pharmacokinetic interactions occur between nifedipine and candesartan or irbesartan, or between amlo dine and telmisartan or valsartan. Calcium-channel blockers have been given safely with eprosartan or irbesartan.**

**Clinical evidence, mechanism, importance and management**

(a) **Amlodipine**

In a study in 12 healthy subjects, telmisartan 120 mg daily had no clinically relevant effect on the pharmacokinetics of amlodipine 10 mg daily for 9 days, and there was no evidence of any marked effect of amlo dipine on the pharmacokinetics of telmisartan. Although there were no serious adverse effects, mild to moderate adverse events (most commonly headache) occurred slightly more frequently with the combination, compared with amlodipine alone (19 events versus 12 events).1

In 12 healthy subjects the pharmacokinetics of single oral doses of valsartan 160 mg and amlodipine 5 mg were not significantly altered on concurrent use, although the pharmacokinetics of valsartan showed wide variations between subjects. No special precautions would therefore appear to be necessary if any of these drugs are used together, although be aware that an increase in adverse effects may occur.
In 12 healthy subjects nifedipine 30 mg daily did not significantly affect the pharmacokinetics of candesartan 16 mg daily.¹

In vitro studies indicated that nifedipine inhibited the oxidation of irbesartan, which was mediated by the cytochrome P450 isoenzyme CYP2C9.² However, a randomised, crossover study in 11 healthy subjects given irbesartan 300 mg daily alone or with nifedipine 30 mg daily for 4 days, found that nifedipine did not alter the pharmacokinetics of irbesartan.³ The manufacturer says that irbesartan has been safely given with antihypertensives such as long-acting calcium-channel blockers.⁴ Similarly the manufacturer of eprosartan notes that it has been safely given with calcium-channel blockers (such as sustained-release nifedipine).⁵

Angiotensin II receptor antagonists + Diuretics; Loop, Thiazide and related

Symptomatic hypotension may occur when an angiotensin II receptor antagonist is started in patients taking high-dose diuretics. Potassium levels may be either increased, decreased or not affected. No clinically relevant pharmacokinetic interactions appear to occur between candesartan, eprosartan, irbesartan, losartan, telmisartan or valsartan and hydrochlorothiazide, although the bioavailability of hydrochlorothiazide may be modestly reduced. Similarly, there is no clinically significant pharmacokinetic interaction between valsartan and furosemide.

Clinical evidence, mechanism, importance and management

(a) Hypotension

Angiotensin II receptor antagonists and thiazide or related diuretics have useful additive effects in the control of hypertension and are generally well tolerated. For example, in one double-blind, placebo-controlled study in 604 patients with hypertension, losartan 50 mg given with hydrochlorothiazide 12.5 mg once daily produced an additive reduction in trough sitting systolic and diastolic blood pressure, and the incidence of dizziness and headache was not significantly different from placebo.¹ However, symptomatic hypotension, especially after the first dose, may occur when angiotensin II receptor antagonists are started in patients with heart failure or those with hypertension who also have sodium and/or volume depletion, such as those taking high-dose diuretics. It is recommended that any volume and/or sodium depletion should be corrected before the angiotensin II receptor antagonist is given. In some situations it may be appropriate to reduce the dose of the diuretic and/or use a lower starting dose of the angiotensin II receptor antagonist.

A similar problem occurs with the ACE inhibitors, see ‘ACE inhibitors + Diuretics; Loop, Thiazide and related’, p.21.

(b) Pharmacokinetic studies

The changes in furosemide and hydrochlorothiazide pharmacokinetics appear to be of no practical importance, and the combination with an angiotensin II receptor antagonist can produce a significant and useful additional reduction in blood pressure. Details of these studies are given below.

1. Furosemide. In 12 healthy subjects the relative bioavailability of furosemide 40 mg was reduced by about 26% when it was given with valsartan 160 mg. However, this pharmacokinetic interaction had no influence on the diuretic effect of furosemide. Simultaneous use of valsartan and furosemide did not modify the pharmacokinetics of valsartan.²
2. Hydrochlorothiazide. In 18 healthy subjects the concurrent use of hydrochlorothiazide 25 mg daily and candesartan 12 mg daily for 7 days increased the AUC and maximum serum levels of candesartan by 18% and 23%, respectively, and reduced the AUC of hydrochlorothiazide by 14%, but those changes were not considered to be clinically relevant.³ Eprosartan 800 mg also decreased the AUC of hydrochlorothiazide 25 mg by about 20% in 18 healthy subjects, but again this was not considered to be clinically important. In addition, hydrochlorothiazide had no effect on eprosartan pharmacokinetics.⁴ Similarly, in a study of 12 patients with mild or moderate hypertension given losartan 50 mg alone or with hydrochlorothiazide 12.5 mg daily for 7 days, the AUC of hydrochlorothiazide was decreased by 17% during concurrent use (not clinically significant) while the pharmacokinetics of losartan were unchanged.⁵ A single-dose study in 12 healthy subjects found that valsartan 160 mg reduced the systemic availability of hydrochlorothiazide 25 mg (AUC decreased by 31%), but the mean amount of hydrochlorothiazide excreted in the urine did not seem to change significantly. The pharmacokinetics of valsartan were not significantly affected by hydrochlorothiazide.⁶

In a randomised, crossover study in 13 healthy subjects, telmisartan 160 mg daily was given with hydrochlorothiazide 25 mg daily for 7 days. There was no difference in AUC and maximum plasma concentrations of either drug compared with when they were given alone.⁷ Similarly, no pharmacokinetic interactions were found between irbesartan and hydrochlorothiazide.⁸

(c) Serum potassium levels

Angiotensin receptor II antagonists are potassium sparing, whereas loop and thiazide diuretics are potassium depleting. Giving an angiotensin receptor II antagonist with a diuretic could result in an increase, a decrease, or no change to the potassium levels, although logically adding an angiotensin II receptor antagonist to established treatment with a diuretic would seem more likely to raise potassium, and vice versa. Serum potassium should be routinely monitored when angiotensin II antagonists are used in patients with heart failure, renal impairment, or in the elderly.

Angiotensin II receptor antagonists + Diuretics; Potassium-sparing

There is an increased risk of hyperkalaemia if angiotensin II receptor antagonists are given with potassium-sparing diuretics (such as amiloride and the aldosterone antagonists, eplerenone and spironolactone), particularly if other risk factors are also present.

Clinical evidence

Life-threatening hyperkalaemia occurred in 6 patients with congestive heart failure who were taking spironolactone and an angiotensin II receptor antagonist (candesartan, losartan or telmisartan). Analysis of these patients, together with another 38 similar patients who had received ACE...
Angiotensin II receptor antagonists + Food

**Mechanism**

Angiotensin II receptor antagonists reduce the levels of aldosterone, which results in the retention of potassium. This would be expected to be additive with the potassium-retaining effects of amiloride, triamterene, spironolactone and eplerenone, leading to hyperkalaemia, but usually only if other risk factors are present.

**Importance and management**

Concurrent use of potassium-sparing diuretics (namely amiloride, triamterene and the aldosterone antagonists eplerenone and spironolactone) may increase serum potassium. There is a greater risk of hyperkalaemia if renal impairment and/or heart failure or diabetes are present. Because angiotensin II receptor antagonists have potassium-sparing effects, amiloride and triamterene should not normally be given concurrently. Aldosterone antagonists such as spironolactone may be useful in heart failure, but the combined use of angiotensin II receptor antagonists requires increased monitoring of serum potassium. Note that the combination should be avoided in patients with a glomerular filtration rate of less than 30 mL/minute. In addition, the dose of spironolactone should not exceed 25 mg daily. Similarly, the UK manufacturer of eplerenone says that caution is required when it is combined with angiotensin II receptor antagonists, especially in renal impairment, and that potassium levels and food should be monitored.

Consider also ‘ACE inhibitors + Diuretics; Potassium-sparing’, p.23.

Angiotensin II receptor antagonists + Food

Food slightly increases the AUC of eprosartan and losartan, slightly reduces the AUC of telmisartan, and modestly reduces the AUC of valsartan. However, none of these changes is likely to be clinically important. Food has no effect on the AUC of candesartan, irbesartan or olmesartan.

**Clinical evidence, mechanism, importance and management**

(a) Candesartan

Food does not affect the bioavailability of candesartan, and the manufacturer states that it may be given with or without food.

(b) Eprosartan

Food delays eprosartan absorption, and slightly increases its AUC and maximum serum concentrations by up to 25%. The UK manufacturer recommends that eprosartan is given with food, but the US manufacturer suggests that the change in absorption is not clinically significant, and that eprosartan may be taken with or without food.

(c) Irbesartan

In a study in 16 healthy men, a high-fat breakfast had no clinically relevant effects on the bioavailability of a single 300-mg dose of irbesartan, therefore it may be taken with or without food.

(d) Losartan

In a crossover study in healthy subjects, the AUC and maximum levels of a single 100-mg dose of losartan, given 30 minutes before a high-fat breakfast was increased by 17% and 35%, respectively, when compared to the fasted state. Food caused a less than 10% decrease in AUC and maximum level of the losartan metabolite, E-3174. These minor changes are unlikely to be clinically significant, and the manufacturer says that losartan may be given with or without food.

(e) Olmesartan

Food does not affect the bioavailability of olmesartan, and the manufacturer states that it may be given with or without food.

(f) Telmisartan

Food slightly reduces the AUC of telmisartan by about 6 to 20% depending on dose, but this would not be expected to cause a reduction in therapeutic efficacy, and telmisartan may be taken with or without food.

(g) Valsartan

Food modestly decreases the AUC of valsartan by 40%, but the manufacturer states that it may be taken with or without food.

Cimetidine may cause a small rise in plasma concentrations of valsartan, but this is unlikely to be clinically significant. Cimetidine did not significantly affect the pharmacokinetics and blood pressure-lowering effect of losartan, and ranitidine did not significantly alter the pharmacokinetics of eprosartan.

**Clinical evidence, mechanism, importance and management**

(a) Cimetidine

1. Losartan. In a randomised, crossover study in 8 healthy subjects when losartan 100 mg was given after cimetidine 400 mg four times daily for 6 days, the pharmacokinetics and pharmacodynamics of losartan and its active metabolite, E-3174, were not changed to a clinically relevant extent, although there was a minor increase of 18% in the AUC of losartan. No special precautions are needed if these drugs are used concurrently.

2. Valsartan. In a single-dose, crossover study, cimetidine 800 mg, given one hour before valsartan 160 mg, increased the initial rate of absorption of valsartan (attributed to a raised gastric pH) resulting in a roughly 50% increase in its maximum plasma concentration. However, the AUC was only slightly increased and there were large inter-subject variations in the pharmacokinetics of valsartan. The changes in valsartan pharmacokinetics seen with cimetidine are unlikely to be clinically relevant.

(b) Ranitidine

A single 400-mg dose of eprosartan was given to 17 healthy subjects, both alone and after ranitidine 150 mg twice daily for 3 days. The ranitidine caused some slight, but statistically insignificant, changes in the pharmacokinetics of the eprosartan (maximum plasma concentration and AUC reduced by about 7% and 11%, respectively).
Clinical evidence, mechanism, importance and management

Ten healthy subjects were given losartan 50 mg daily for a week and then, after a 6-day washout period, losartan 50 mg daily with rifampicin 300 mg twice daily for a week. It was found that rifampicin reduced the AUC of losartan by 36%, reduced its half-life from 2 to 0.9 hours, and increased its clearance by 60%. The AUC of the active metabolite, E3174, was reduced by 41% and its half-life was reduced from 5.1 to 2.5 hours. Diastolic blood pressure was significantly reduced by losartan alone, but not by the combination.\(^1\) The presumed reason for this interaction is that rifampicin (a recognised enzyme inducer) increases the metabolism of losartan to its active metabolite by the cytochrome P450 isoenzyme CYP2C9.

The clinical importance of this interaction still awaits assessment, but it would seem likely that the antihypertensive effects of losartan would be reduced by rifampicin. If both drugs are used, be alert for the need to no significant effect on the pharmacokinetics of losartan, but note that irbesartan, and to a limited extent candesartan, are also metabolised by CYP2C9 (see the ‘introduction’, (p.12)).

---

**Angiotensin II receptor antagonists + Mannitol**

A report describes mannitol-induced acute renal failure in a diabetic patient taking losartan.

Clinical evidence, mechanism, importance and management

A man with diabetic nephropathy taking losartan 25 mg twice daily for hypertension developed acute renal failure after being given a total of 420 g of intravenous mannitol over 4 days for haemorrhagic glaucoma. The patient recovered after the mannitol and losartan were discontinued, and after receiving haemodialysis.\(^2\) It is not fully understood why this combination caused acute renal failure, but it may result in a marked decrease in glomerular filtration rate. Caution is recommended.\(^3\) For comment on the potentiation of ACE inhibitor-induced renal damage by diuretics, see ‘ACE inhibitors + Diuretics; Loop, Thiazide and related’, p.21.

---

**Angiotensin II receptor antagonists + Potassium compounds**

There may be a risk of hyperkalaemia if angiotensin II receptor antagonists are given with potassium supplements or potassium-containing salt substitutes, particularly in those patients where other risk factors are present, such as decreased renal function, heart failure, or diabetes.

Clinical evidence, mechanism, importance and management

Angiotensin II receptor antagonists are potassium-sparing, via their effects on aldosterone, and their potential to cause clinically important hyperkalaemia is well established. The incidence of hyperkalaemia varies depending on the clinical indication and other disease conditions, being lowest in essential hypertension, and highest in heart failure, diabetes, and renal impairment. For example, the incidence of hyperkalaemia in clinical studies in patients with hypertension was 0.9% with eprosartan\(^1,2\) and 1.5% with losartan;\(^3\) in type II diabetic patients with nephropathy, the incidence was 9.9% with losartan\(^4\) and 18.6% with irbesartan;\(^4\) and in those with heart failure the incidence was 6.3% with candesartan.\(^5\)

The concurrent use of potassium-containing supplements or salt substitutes and angiotensin II receptor antagonists is likely to further increase serum potassium. Therefore potassium supplements are generally unlikely to be needed in patients taking angiotensin II receptor antagonists, particularly if they have other risk factors for hyperkalaemia, and it may be prudent for such patients to be told to avoid using potassium-containing salt substitutes. If concurrent use is considered necessary, potassium levels should be closely monitored. For reports of hyperkalaemia associated with ACE inhibitors and dietary potassium, see ‘ACE inhibitors + Potassium compounds’, p.32.

---

**Angiotensin II receptor antagonists + Rifampicin (Rifampin)**

Rifampicin increases the metabolism of losartan and its active metabolite, E-3174, which may result in reduced antihypertensive effects.

Clinical evidence, mechanism, importance and management

When 10 healthy subjects were given losartan 50 mg daily for a week and then, after a 6-day washout period, losartan 50 mg daily with erythromycin 300 mg four times daily for a week, it was found that erythromycin had no significant effect on the pharmacokinetics of losartan or its active metabolite, E-3174. In addition, erythromycin did not alter the blood pressure-lowering effect of losartan.\(^1\) Inhibition of the cytochrome P450

---

**Angiotensin II receptor antagonists; Losartan + AST-120**

AST-120 does not appear to have an important effect on the pharmacokinetics of losartan.

Clinical evidence, mechanism, importance and management

When a single 100-mg dose of losartan was given 30 minutes before a high-fat breakfast, with AST-120 3 g three times daily for 48 hours started 30 minutes after the breakfast, the AUC of losartan was not significantly altered, although there was a minor 12.3% decrease in the maximum losartan level. Similarly, various other schedules (losartan with breakfast, then AST-120 started 30 minutes later, or AST-120 started 30 minutes after breakfast, then losartan given 30 minutes after that), did not significantly alter the AUC of losartan, when compared with losartan given 30 minutes before breakfast. However, there were minor to modest increases in the AUC of losartan (of up to 37%) when these schedules were compared with losartan given in the fasting state, which was attributed to the effect of food.\(^1\)

AST-120 is a predominantly carbon-based oral absorbent, and might therefore interfere with absorption of other drugs.

Data from this pharmacokinetic study indicate that AST-120 has minimal effects on the pharmacokinetics of losartan. The authors suggest that giving AST-120 one hour after losartan may be preferred.\(^1\)

---

**Angiotensin II receptor antagonists; Losartan + Erythromycin**

The pharmacokinetics and blood pressure-lowering effect of losartan do not seem to be affected by erythromycin.

Clinical evidence, mechanism, importance and management

When 10 healthy subjects were given losartan 50 mg daily for a week and then, after a 6-day washout period, losartan 50 mg daily with erythromycin 300 mg four times daily for a week, it was found that erythromycin had no significant effect on the pharmacokinetics of losartan or its active metabolite, E-3174. In addition, erythromycin did not alter the blood pressure-lowering effect of losartan.\(^1\) Inhibition of the cytochrome P450
ACE inhibitors and AT II receptor antagonists

Isoenzyme CYP3A4 alone does not appear to prevent the conversion of losartan to E-3174. There would therefore appear to be no reason to take any special precautions if both drugs are used concurrently.

Grapefruit juice has a minor effect on the pharmacokinetics of losartan and its active metabolite, E-3174, which is unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management
In a study in 9 healthy subjects, grapefruit juice approximately doubled the time for a single 50-mg dose of losartan to be detected in the serum (from 0.6 to 1.3 hours) and reduced the AUC of its active metabolite, E-3174, by 21%. Losartan is partly metabolised by the cytochrome P450 isoenzyme CYP3A4 and transported by P-glycoprotein, both of which can be affected by grapefruit juice. This may explain the minor changes seen. However, this interaction is unlikely to be clinically relevant.

Phenobarbital minimally alters the levels of losartan and its active metabolite.

Clinical evidence, mechanism, importance and management
In a placebo-controlled study 15 healthy subjects were given phenobarbital 100 mg daily for 16 days with a single 100-mg dose of losartan. Phenobarbital slightly reduced the AUC of losartan and its active metabolite, E-3174, by about 20%, but this was not considered to be clinically significant.

Phenytoin inhibited the metabolism of losartan to its active metabolite, E-3174, but the clinical relevance of the changes seen are unknown.

Clinical evidence, mechanism, importance and management
The concurrent use of phenytoin and losartan for 10 days reduced the AUC of the active metabolite of losartan, E-3174, by 63%, but did not significantly alter the AUC of losartan. The pharmacokinetics of phenytoin were not affected by losartan. In this crossover study in 16 healthy subjects, phenytoin was given at a dose of 4 mg/kg rounded to the nearest 100 mg, not to exceed 400 mg daily, and the dose was adjusted on the fourth day, if necessary, based on serum phenytoin levels. The losartan dose was 50 mg daily. Phenytoin did not alter the effect of losartan on blood pressure. The effect of phenytoin appeared to be CYP2C9 genotype-specific, with increases in losartan AUC seen in the 14 subjects who were extensive metabolisers of CYP2C9, and decreases in the 2 subjects who were poor metabolisers.

Both phenytoin and losartan are substrates for the cytochrome P450 isoenzyme CYP2C9. It appears that phenytoin had an inhibitory effect on losartan metabolism. The conversion of losartan to E3174 represents about 5 to 15% of the clearance of an oral losartan dose, but E3174 is much more active than losartan.

The clinical importance of this interaction still awaits assessment. Until more is known, if phenytoin is added to established losartan therapy, it may be prudent to initially monitor blood pressure more closely. More study is needed.

For social and historical reasons alcohol is usually bought from a store or in a bar or restaurant, rather than from a pharmacy, because it is considered to be a drink and not a drug. However, pharmacologically it has much in common with medicinal drugs that depress the central nervous system. Objective tests show that as blood-alcohol levels rise, the ability to perform a number of skills gradually deteriorates as the brain becomes progressively disorganised. The myth that alcohol is a stimulant has arisen because at parties and social occasions it helps people to lose some of their inhibitions and it allows them to relax and unwind. Professor JH Gaddum put it amusingly and succinctly when, describing the early effects of moderate amounts of alcohol, he wrote that “logical thought is difficult but after dinner speeches easy.” The expansiveness and loquaciousness that are socially acceptable can lead on, with increasing amounts of alcohol, to unrestrained behaviour in normally well-controlled individuals, through to drunkenness, unconsciousness, and finally death from respiratory failure. These effects are all a reflection of the progressive and deepening depression of the CNS.

‘Table 3.1’, (p.41) gives an indication in very broad terms of the reactions of men and women to different amounts and concentrations of alcohol.

On the whole women have a higher proportion of fat in which alcohol is not very soluble, their body fluids represent a smaller proportion of their total body mass, and their first-pass metabolism of alcohol is less than men because they have less alcohol dehydrogenase in their stomach walls. Consequently if a man and woman of the same weight matched each other, drink for drink, the woman would finish up with a blood alcohol level about 50% higher than the man. The values shown assume that the drinkers regularly drink, have had a meal and weigh between 9 and 11 stones (55 to 70 kg). Higher blood-alcohol levels would occur if alcohol was drunk on an empty stomach and lower values in much heavier individuals. The liver metabolises about one unit per hour so the values will fall with time.

Since alcohol impairs the skills needed to drive safely, almost all national and state authorities have imposed maximum legal blood alcohol limits (see ‘Table 3.2’, (p.41)). In a number of countries this has been set at 80 mg/100 mL (35 micrograms per 100 mL in the breath) but impairment is clearly detectable at lower concentrations, for which reason some countries have imposed much lower legal limits.

Alcohol can interact with many drugs both by pharmacokinetic and/or pharmacodynamic mechanisms. The quantity and frequency of alcohol consumption can affect the bioavailability of alcohol and other drugs. Several hepatic enzymes are important in the metabolism of alcohol; primarily alcohol dehydrogenases convert alcohol into acetaldehyde, but other enzymes, in particular the cytochrome P450 isoenzyme CYP2E1, are also involved, especially in moderate to heavy alcohol consumption. Enzyme induction of CYP2E1 (and possibly other isoenzymes) occurs after prolonged heavy alcohol intake, and this can result in an increased metabolic rate and lower blood levels of drugs metabolised via this system. Conversely, short term binge drinking is likely to cause inhibition of this enzyme group by direct competition for binding sites and therefore decrease the metabolism of other drugs.

Probably the most common drug interaction of all occurs if alcohol is drunk by those taking other drugs that have CNS depressant activity, the result being even further CNS depression. Blood-alcohol levels well within the legal driving limit may, in the presence of other CNS depressants, be equivalent to blood-alcohol levels at or above the legal limit in terms of worsened driving and other skills. This can occur with some antihistamines, antidepressants, anxiolytics, hypnotics, opioid analgesics, and others. This section contains a number of monographs that describe the results of formal studies of alcohol combined with a number of recognised CNS depressants, but there are still many other drugs that await study of this kind, and which undoubtedly represent a real hazard.

A less common interaction that can occur between alcohol and some drugs, chemical agents, and fungi, is the flushing (Antabuse) reaction. This is exploited in the case of disulfiram (Antabuse) as a drink deterrent (see ‘Alcohol + Disulfiram’, p.61), but it can occur unexpectedly with some other drugs, such as some antifungals and cephalosporins, chlorpropamide and metronidazole, and can be both unpleasant and possibly frightening, but it is not usually dangerous.
### Table 3.1 Reactions to different concentrations of alcohol in the blood

<table>
<thead>
<tr>
<th>Amounts of alcohol drunk</th>

</table>

Note: For easy comparison the legally allowable blood alcohol limits have all been expressed as mg%. Thus: blood alcohol levels of 80 mg% = 80 mg of alcohol in 100 mL blood = 0.8 g/L.

Variations occur within these countries e.g. in Australia no alcohol is allowed for drivers of heavy, dangerous goods, public transport vehicles; learners and drivers under 25 years of age for first three years of driving.

Alcohol + Alpha blockers

The plasma levels of both indoramin and alcohol may be raised by concurrent use. The combination of alcohol and indoramin has been reported to increase drowsiness, which may possibly increase the risks when driving or using machinery. Prazosin appears to enhance the hypotensive effects of alcohol.

Clinical evidence

(a) Indoramin

When 10 healthy subjects were given a single 50-mg oral dose of indoramin together with alcohol 0.5 g/kg in 600 mL of alcohol-free lager, the AUC of indoramin was increased by 25% and the peak plasma levels were raised by 58%.1, 2 When the subjects were given a single 175-microgram/kg intravenous dose of indoramin together with the same oral dose of alcohol, a 26% rise in blood-alcohol levels occurred during the first 1.25 hours after dosing, but no change in indoramin pharmacokinetics were seen. The combination of alcohol and indoramin caused more sedation than either drug alone.2

(b) Prazosin

A study in 10 Japanese hypertensive patients found that alcohol 1 mL/kg decreased blood pressure for several hours. Treatment with prazosin 1 mg three times daily caused a significant reduction in blood pressure and enhanced alcohol-induced hypotension.3 These effects may be restricted to Oriental/Asian patients because the alcohol flush syndrome, caused by accumulation of vasodilative acetaldehyde due to a genetic alteration in alcohol dehydrogenase, is rare in whites and blacks.3 The clinical significance is uncertain as the dose of prazosin in the study was relatively small and the dose of alcohol was relatively large, therefore these findings may not apply to more moderate drinking or higher doses of prazosin.

Mechanism

Uncertain. Increased absorption of indoramin from the gut or reduced liver metabolism may be responsible for the raised indoramin serum levels. The increase in sedation would appear to be due to the additive sedative effects of the two drugs.

Importance and management

Information is limited but the interaction between indoramin and alcohol appears to be established. The clinical importance of the raised levels of both drugs is uncertain. However since indoramin sometimes causes drowsiness when it is first given, there is the possibility that alertness will be reduced, which could increase the risks of driving or handling machinery. Patients should be warned. Prazosin appears to enhance the hypotensive effect of alcohol, see also, ‘Alcohol + Antihypertensives’, p. 48.

Alcohol + Aminosalicylic acid

Alcohol can abolish the lipid-lowering effects of aminosalicylic acid.

Clinical evidence, mechanism, importance and management

The effectiveness of PAS-C (purified aminosalicylic acid recrystallised in vitamin C) and on the treatment of hyperlipidaemia types IIa and IIb was studied in a group of 63 subjects. It was noted that when 3 of the subjects drank unstated amounts of alcohol (beer or cocktails), the effects of the PAS-C on lowering serum cholesterol, triglyceride and LDL-cholesterol levels were completely abolished.5 The reasons are not understood. There seems to be no evidence that alcohol affects the treatment of tuberculosis with aminosalicylic acid.

Alcohol + Aminosulphate

No pharmacokinetic interaction appears to occur between amisulpride and alcohol.

Clinical evidence, mechanism, importance and management

No significant pharmacokinetic interactions were seen in 18 healthy subjects given single 50- and 200-mg doses of amisulpride with alcohol 0.8 g/kg, nor were the detrimental effects of alcohol on performance...
increased by amisulpride. Nevertheless, the manufacturer advises that the central effects of alcohol may be enhanced by amisulpride, and so they do not recommend the combination.1

Alcohol + Antibacterials; Cephalosporins

Disulfiram-like reactions can occur in those who take cefamandole, cefmenoxime, cefoperazone, cefotetan, latamoxef (moxalactam) and possibly cefonicid, and drink alcohol. This is not a general reaction of the cephalosporins, but is confined to those with particular chemical structures.

Clinical evidence
A young man with cystic fibrosis was given latamoxef 2 g intravenously every 8 hours for pneumonia. After 3 days of treatment he drank, as was his custom, a can of beer with lunch. He rapidly became flushed with a florid macular eruption over his face and chest. This faded over the next 30 minutes but he complained of severe nausea and headache. Similarly, a patient taking latamoxef became flushed, diaphoretic and nauseated after drinking a cocktail of vodka and tomato juice. This reaction has also been described in 2 subjects who drank alcohol while receiving latamoxef,2 two of 10 subjects given latamoxef and alcohol,3 and a patient taking latamoxef given theophylline elixir containing alcohol 20%.2 It has also been seen in a patient taking latamoxef following the injection of alcohol into the para-aortic space for coeliac plexus block.2 The symptoms experienced by these patients have included flushing of the face, arms and neck, shortness of breath, headache, tachycardia, dizziness, hyper- and hypotension, and nausea and vomiting.

Similar reactions have been described in patients or subjects receiving cefamandole,5-7 cefoperazone,8-15 cefmenoxime,16 cefonicid17 and cefotetan,18 after drinking wine, beer, or other alcoholic drinks, or after the ingestion of an 8.5% alcoholic elixir.16

This disulfiram-like reaction is not a general reaction of all the cephalosporins. One study found no interaction in those taking cefpirome and alcohol,19 and in another cepfizoxime was reported not to interact with alcohol.20 No interaction was seen with cefonicid and alcohol in one placebo-controlled study,21 however a case report describes a disulfiram-like reaction in one patient taking the combination.17

Mechanism
These reactions appear to have the same pharmacological basis as the disulfiram/alcohol reaction (see ‘Alcohol + Disulfiram’, p 61). Three of these cephalosporins (latamoxef, cefamandole and cefoperazone) can raise blood acetaldehyde levels in rats when alcohol is given, but to a lesser extent than disulfiram.2,21,22 It appears that any reaction normally only occurs with cephalosporins that possess a methyltetrazoloethiol group in the 3-position on the cephalosporin molecule,11,22 but it has also been seen with cefonicid, which possesses a methyl sulphhonltetrazoloic group in stead.17 Some amine-containing cephalosporins (cefalexin, cefadroxil and cefradine) have also been reported to interact with acetaldehyde in vitro, but the clinical significance of this is unknown.2,23

Importance and management
Established but unpredictable interactions of varying incidence. In studies, two out of 10 subjects given latamoxef and alcohol reacted,3 five out of 8 taking cefotetan reacted,18 and 8 out of 9 receiving cefoperazone reacted.14,15 The reaction appears normally to be more embarrassing or unpleasant and frightening than serious, with the symptoms subsiding spontaneously after a few hours. There is evidence that the severity varies; in one study cefoperazone was said to be worse than latamoxef, which in turn was said to be worse than cefmetazole.22 Treatment is not usually needed but there are two reports4,6 of two elderly patients who needed treatment for hypotension, which was life-threatening in one case; plasma expanders and dopamine have been used as treatment.4,6

Because the reaction is unpredictable, warn all patients taking these potentially interacting cephalosporins that it can occur during and up to 3 days after the course of treatment is over. Advise them to avoid alcohol. Those with renal or hepatic impairment in whom the drug clearance is prolonged should wait a week. It should not be forgotten that some foods and pharmaceuticals contain substantial amounts of alcohol, and a reaction with some topicaly applied products cannot be excluded (see ‘Alcohol + Disulfiram’, p 61).

A number of other cephalosporins are possible candidates for this reaction because they possess the methyltetrazoloethiol group in the 3-position. These include, ceforanide, cefotiam, and cefpiramide,12,23 but there do not appear to be any reports of an interaction between alcohol and these drugs.

Alcohol + Antibacterials; Ciprofloxacin

Ciprofloxacin does not significantly affect the pharmacokinetics of alcohol or the psychomotor performance observed with alcohol alone. There is an isolated report of a cutaneous reaction to ciprofloxacin, which may have been precipitated by alcohol ingestion.

Clinical evidence, mechanism, importance and management
A 3-day course of ciprofloxacin 500 mg twice daily had no significant effect on the pharmacokinetics of a single 30-g oral dose of alcohol (75 mL of vodka) in 12 healthy subjects, nor was the performance of a number of psychomotor tests affected.1

There is an isolated report of red blotches developing on the face and body of a tetraplegic patient receiving ciprofloxacin 250 mg twice daily, which developed within 10 minutes of drinking 2 cans of beer containing alcohol 4.7%. He did not feel unwell or drowsy and the blottes faded over a period of 30 minutes. Previous courses of ciprofloxacin had not produced any adverse effects and the same brand of alcohol caused no...
problems in the absence of ciprofloxacin. The general clinical importance of this report is unknown, but it seems likely to be small.

Alcohol + Antibacterials; Co-trimoxazole

A disulfiram-like reaction has been reported when two patients taking co-trimoxazole drank beer.

Clinical evidence, mechanism, importance and management

A 31-year-old man who had been taking prophylactic double-strength co-trimoxazole twice daily for 3 days experienced flushing, palpitations, dyspnoea, headache and nausea 10 to 20 minutes after drinking two 12-oz beers (about 340 mL each). Symptoms resolved gradually over 2 to 3 hours, but occurred again the next day when he drank 6 oz of beer. A similar experience occurred in another man taking double-strength co-trimoxazole after drinking three 12-oz beers. However, on the previous day, he had ingested 4 to 5 beers without a problem, even though he had taken co-trimoxazole. The clinical and practical significance of these case reports is unknown as there do not appear to be any other reports of this interaction.

Alcohol + Antibacterials; Erythromycin

Alcohol can cause a moderate reduction in the absorption of erythromycin ethylsuccinate. There is some evidence that intravenous erythromycin can raise blood-alcohol levels but the extent and the practical importance of this is unknown.

Clinical evidence, mechanism, importance and management

(a) Effects on alcohol

A study in 10 healthy subjects found that erythromycin base 500 mg three times daily did not alter the pharmacokinetics of oral alcohol 0.8 g/kg, and the subjects’ perception of intoxication was unaltered. In contrast, another study in 8 healthy subjects, primarily investigating the effects of intravenous erythromycin lactobionate 3 mg/kg on gastric emptying, found that when they were given a liquid meal of orange juice, alcohol 0.5 g/kg and lactulose 10 g immediately after a solid meal, the mean peak blood-alcohol levels were raised by about 40% and the AUC over the first hour was increased by 33%. After that the curve was virtually the same as that seen with a saline placebo. The authors suggest that the increased blood-alcohol levels are a result of erythromycin causing more rapid gastric emptying, so that the alcohol is exposed to metabolism by the gastric mucosa for a shorter time.

What this means in terms of an increase in the effects of alcohol (e.g. on driving) is not known.

(b) Effects on erythromycin

When a single 500-mg dose of erythromycin ethylsuccinate was taken by 9 healthy subjects with two 150-mL alcoholic drinks (one immediately and the other 2.5 hours later) the erythromycin AUC was decreased by about 27% and its absorption was delayed. One subject had a 185% increase in absorption. The alcoholic drink was picco sour, which contains lemon juice, sugar and picco (a brandy-like liqueur). Blood alcohol levels achieved were about 50 mg%. The reason for the reduced absorption of erythromycin is not understood but it is suggested that the slight delay occurs because alcohol delays gastric emptying, so erythromycin reaches its absorption site in the duodenum a little later. The extent to which this reduced absorption might affect the control of an infection is uncertain but it seems likely to be small.

Alcohol + Antibacterials; Metronidazole

A disulfiram-like reaction has occurred when some patients taking oral metronidazole have drunk alcohol. There is one report of its occurrence when metronidazole was applied as a vaginal insert, and another when metronidazole was given intravenously. Some clinical studies have not confirmed the interaction, and its existence is disputed in some reports. The interaction is alleged to occur with all other 5-nitromidazoles (e.g. tinidazole).

Clinical evidence

A man who had been in a drunken stupor for 3 days was given two metronidazole tablets (a total of 500 mg) one hour apart by his wife in the belief that they might sober him up. Twenty minutes after the first tablet he was awake and complaining that he had been given disulfiram (which he had taken some months before). Immediately after the second tablet, he took another drink and developed a classic disulfiram-like reaction with flushing of the face and neck, nausea and epigastric discomfort. Other individual cases have been reported, including a reaction with a metronidazole vaginal insert.

In a test of the value of metronidazole 250 mg twice daily as a possible drink-deterrant, all 10 alcoholic patients studied experienced some disulfiram-like reactions of varying intensity (facial flushing, headaches, sensation of heat, fall in blood pressure, vomiting) when given alcohol. In another study in 60 alcoholic patients, given metronidazole 250 to 750 mg daily, most developed mild to moderate disulfiram-like reactions during an alcohol tolerance test. A lower incidence of this reaction, between 2 and 24%, has been reported. Pharmaceutical preparations containing alcohol have also been implicated. A 2-year-old child became flushed and dyspnoeic when metronidazole was given with both *Stopayne* syrup and a phenobarbital syrup, both of which contained alcohol. Another reaction has been seen in a patient receiving intravenous metronidazole and a trimethoprim-sulfamethoxazole (co-trimoxazole) preparation containing alcohol 10%. A further patient who had just finished a 7-day course of metronidazole developed severe, prolonged nausea and vomiting postpartum: she had received a single 800-mg dose of prophylactic clindamycin intravenously before the birth and it was thought that the benzyl alcohol present in the clindamycin preparation could have caused the reaction. However, other factors such as intrathecal anaesthesia may have also contributed to the adverse effects. For mention of other preparations containing alcohol, see ‘Alcohol + Disulfiram’, p. 61.

An interaction has also been reported in association with metabolic acidosis in an intoxicated man 4 hours after he was given intravenous metronidazole as prophylaxis following injury. A fatality occurred in a frail 31-year-old woman, which was attributed to cardiac arrhythmia caused by acetaldehyde toxicity resulting from the alcohol/metronidazole interaction, linked to autonomic distress caused by a physical assault. Alcohol is also said to taste unpleasant or to be less pleasurable while taking metronidazole. Some drug abusers apparently exploit the reaction for ‘kicks’. In contrast, a study in 207 patients with inflammatory bowel disease assessed (using a phone survey) the presence of adverse reactions to alcohol in patients taking chronic metronidazole and/or mercaptopurine or neither drug; all of the patients consumed less than 4 alcoholic beverages per day. There was a trend towards more adverse effects in both the metronidazole and mercaptopurine study groups, but no statistically significant interaction between alcohol and metronidazole was found. There are other reports, including two well-controlled studies, showing that metronidazole has no disulfiram-like effects.

Mechanism

Not understood. In the disulfiram reaction, the accumulation of acetaldehyde appears to be responsible for most of the symptoms (see ‘Alcohol + Disulfiram’, p. 61). Some workers have reported an increase in acetaldehyde levels due to the metronidazole/alcohol interaction, but others have
Importance and management

A reasonably well studied interaction, but it remains a controversial issue. The incidence is variously reported as between 0 and 100%, with more recent reports disputing its existence. Nevertheless because of the uncertainty, all patients given metronidazole should be warned about what may happen if they drink alcohol. The manufacturer recommends avoidance of alcohol when metronidazole is taken, and for at least 48 hours after it has been stopped. However, the authors of one report suggest a cautious trial of alcohol in patients that are starting and will be taking metronidazole on a chronic basis.

The reaction, when it occurs, normally seems to be more unpleasant and possibly frightening than serious, and usually requires no treatment, although one report describes a serious reaction when intravenous metronidazole was given to an intoxicated man, and one possible fatality has been reported. The risk of a reaction with metronidazole used intravenously seems to be small because the absorption is low (about 20% compared with about 100% orally), but evidently it can happen, even if only rarely.

15. Ginzburg L, Present DH. Alcohol is well tolerated in IBD patients taking either metronidazole or oral tetracyclines. Am J Gastroenterol (2000) 95, 999–1000.
rise in the AUC of tetracycline. The clinical relevance of this rise is unknown.

Another study in healthy subjects found that cheap red wine, but not whisky (both 1 g/kg) delayed the absorption of doxycycline, probably because of the presence of acetic acid, which slows gastric emptying. However, the total absorption was not affected. The authors concluded that acute intake of alcoholic beverages has no clinically relevant effects on the pharmacokinetics of doxycycline.

Mechanism

Heavy drinkers can metabolise some drugs much more quickly than non-drinkers due to the enzyme-inducing effects of alcohol. The interaction with doxycycline would seem to be due to this effect, possibly allied with some reduction in absorption from the gut.

Importance and management

Information is limited, but the interaction between doxycycline and alcohol appears to be established and of clinical significance in alcoholics but not in non-alcoholic individuals. One possible solution to the problem of enzyme induction is to give alcoholic subjects double the dose of doxycycline. Alternatively tetracycline may be a suitable non-interacting alternative. There is nothing to suggest that moderate or even occasional heavy drinking has a clinically relevant effect on any of the tetracyclines in non-alcoholic subjects.

Alcohol + Antiepileptics: Carbamazepine

Moderate social drinking does not appear to affect the serum levels of carbamazepine, ethosuximide or phenytoin. Some small changes are seen in the serum levels of phenobarbital and sodium valproate, but no changes in the control of epilepsy seem to occur. No pharmacokinetic interaction was detected between tiagabine and alcohol, and tiagabine did not alter the cognitive effect of alcohol. The adverse effects of both alcohol and antiepileptics, such as enhanced sedation, may be additive.

Clinical evidence, mechanism, importance and management

A study in 29 non-drinking epileptics found that when they drank 1 to 3 glasses of an alcoholic beverage (1 to 3 units) over a 2-hour period, twice a week for 16 weeks the serum levels of carbamazepine, ethosuximide and phenytoin were unchanged, when compared with those from a control group of 23 epileptics given drinks without alcohol. There was a marginal change in phenobarbital levels, and some increase in serum valproate levels. However, this effect is hard to interpret as valproate levels are known to fluctuate and are hard to reproduce. Other antiepileptics used were clonazepam, primidone and sulfate, but too few patients used these for a valid statistical analysis to be carried out. Maximum blood-alcohol levels ranged from 5 to 33 mg%. More important than any changes that occurred in serum antiepileptic levels, was the finding that this social drinking had no effect on the frequency of tonic-clonic convulsions, partial complex seizures, or on the epileptic activity as measured by EEGs.

Another study in healthy subjects excluded any pharmacodynamic or pharmacokinetic interaction between tiagabine and alcohol. In this study, tiagabine 4 mg three times daily did not alter the effect of a single dose of alcohol as assessed in a range of cognitive tests.

For the effect of chronic heavy drinking on the pharmacokinetics of carbamazepine or phenytoin, see ‘carbamazepine’, (p.46) and ‘phenytoin’, (p.47).

There are very few studies, but there seem to be no reasons for epileptics to avoid alcohol in moderate social amounts (1 or 2 drinks per occasion; no more than 3 to 6 drinks per week). However, patients who drink moderate to heavy amounts of alcohol (3 to 4 drinks or more) should be warned that they are at increased risk of seizures, with the greatest risk occurring 7 to 48 hours after the last drink.

The British Epilepsy Association comments that most people with epilepsy find they can have one or two units of alcohol, perhaps more, without increasing the chances of having a seizure, whereas other people find that even a small amount of alcohol triggers their seizures. Patients who drink heavily may also get alcohol withdrawal seizures and binge drinking has been associated with seizures even in non-epileptic people. They also say that anyone taking antiepileptics is likely to be more sensitive to the effects of alcohol and can exaggerate the adverse effects of the antiepileptics.

Some antiepileptics such as carbamazepine, clonazepam, ‘phenobarbital’, (p.52), primidone, and topiramate have sedative effects, which may be additive with those of alcohol.

Individuals need to decide what level of alcohol intake is appropriate for them, and be aware that a change in medication, or an increase in dose of antiepileptics may reduce their ability to perform certain skilled tasks, such as driving.

Alcohol + Antiepileptics

Moderate social drinking does not affect the serum levels of carbamazepine. Heavy drinking may possibly increase the metabolism of carbamazepine, and this may be further increased in alcoholic who abstain from drinking alcohol.

Clinical evidence, mechanism, importance and management

(a) Heavy drinking and alcohol withdrawal

A study in 7 alcoholics who consumed a mean dose of 750 mL of spirits (240 g of alcohol) daily found that the early (0 to 4 hours) bioavailability of a single 400-mg dose of carbamazepine was not affected by 9 days of controlled alcohol withdrawal. However, over the 4 to 12-hour period, carbamazepine levels were higher and those of its epoxy metabolite lower in alcoholics following alcohol exposure, when compared with abstinence. This effect was thought to be due to the acute inhibition of carbamazepine metabolism by alcohol and/or accelerated carbamazepine metabolism in the abstinence phase. The absorption rate of carbamazepine in alcoholics appeared to be slower compared with 8 healthy subjects, probably due to alcoholism-induced chronic gastrointestinal changes although this did not significantly affect the maximum serum levels of alcohol. However, adverse effects occurred in all of the healthy subjects but in none of the alcoholics, possibly indicating that long-term alcohol exposure may make the patient less sensitive to acute carbamazepine exposure.

The long-term use of alcohol can cause induction of hepatic enzyme systems possibly resulting in increased metabolism and reduced plasma levels of carbamazepine. The risk of seizures may also increase on tapering or stopping alcohol because of an increase in metabolism and elimination caused by the relative lack of a competing substrate.

(b) Moderate social drinking

Alcohol 25 g did not affect the bioavailability of carbamazepine in 8 healthy subjects. A study in non-drinking epileptics (21 in the experimental alcohol group, 18 in the control group) found that the serum levels of carbamazepine were unchanged by moderate drinking (1 to 3 glasses of an alcoholic beverage, containing 9.85 g of alcohol, twice weekly), and there was no influence on tonic-clonic convulsions or partial complex seizures.

For comment on moderate social drinking in epileptics and also the possible increased sedative effect of carbamazepine with alcohol, see ‘Alcohol + Antiepileptics’, above.

Acute alcohol intake may possibly increase serum phenytoin levels, but moderate social drinking appears to have little clinical effect. However, chronic heavy drinking reduces serum phenytoin levels so that above-average doses of phenytoin may be needed to maintain adequate levels.

Clinical evidence

(a) Acute alcohol ingestion

In a study designed to test the effects of acute alcohol intoxication in epileptics, 25 patients were given a 12 oz (about 340 mL) drink of alcohol 25%. Blood-alcohol levels ranged from 39 to 284 mg%. All patients had signs of alcohol intoxication without any effect on seizure frequency.3 The metabolism of a single dose of phenytoin was not affected in one study in healthy subjects by the acute ingestion of alcohol.2 However, the manufacturers say that acute alcoholic intake may increase phenytoin serum levels.8

(b) Moderate social drinking

A study in non-drinking epileptics (17 in the experimental group, 14 in the control group) found that the serum levels of phenytoin were unchanged by moderate drinking, and there was no influence on tonic-clonic convulsions or partial complex seizures. The experimental group drank 1 to 3 glasses of an alcoholic beverage (equivalent to a glass of beer containing 9.85 g of ethanol) over a 2-hour period, twice a week, for 16 weeks, and their maximum blood alcohol levels ranged from 5 to 33 mg%.9

Mechanism

Supported by animal data,10 the evidence suggests that repeated exposure to large amounts of alcohol induces liver microsomal enzymes so that the rate of metabolism and clearance of phenytoin is increased. Conversely, acute alcohol intake may decrease hepatic metabolism.11

Importance and management

An established and clinically important interaction, although the documentation is limited. Heavy drinkers may need above-average doses of phenytoin to maintain adequate serum levels. However, be aware that patients with liver impairment usually need lower doses of phenytoin, so the picture may be more complicated. Moderate drinking appears to be safe in those taking phenytoin.9 Consider also ‘Alcohol + Antiepileptics’, p.46.

Alcohol + Antihistamines

Some antihistamines cause drowsiness, which can be increased by alcohol. The detrimental effects of alcohol on driving skills are considerably increased by the use of the older more sedative antihistamines and appear to be minimal or absent with the newer non-sedating antihistamines.

Clinical evidence

(a) Non-sedating antihistamines

A double-blind study found that terfenadine 60 to 240 mg alone did not affect psychomotor skills, nor did it affect the adverse effects of alcohol.12 Another study had similar findings.2 However, a later study found that terfenadine 240 mg slowed brake reaction times in the laboratory when given either alone or with alcohol.3 Acrivastine 4 and 8 mg, given with and without alcohol, was found in a study to behave like terfenadine (which interacts minimally or not at all). Other studies have shown that astemizole 10 to 30 mg daily,5,11 desloratadine,6 ebastine 20 mg,6 fexofenadine 120 to 240 mg,10,11 levocabastine 2 nasal puffs of 0.5 mg/mL,11 loratadine 10 to 20 mg,12 and mizolastine 10 mg did not interact with alcohol.7 Cetirizine 10 mg did not appear to interact with alcohol in two studies13,14 but some slight additive effects were detected in other studies.13,16 Similarly, a single oral dose of rupatadine 10 mg did not interact with alcohol, but a 20-mg dose given with alcohol produced more cognitive and psychomotor impairment than alcohol alone.16

(b) Sedating antihistamines

The effects of alcohol (blood levels about 50 mg%) and antihistamines, alone or together, on the performance of tests designed to assess mental and motor performance were examined in 16 subjects. Clemizole 40 mg or triprolidine 50 mg alone did not significantly affect the performance under the stress of delayed auditory feedback, neither did they potentiate the effect of alcohol.17 Clemastine in 3-mg doses had some additive detrimental effects with alcohol on co-ordination, whereas clemastine 1.5 mg and 1 mg did not.18,19 A study in 5 subjects showed that the detrimental effects of 100 mL of whiskey on the performance of driving tests on a racing car simulator (blood alcohol estimated as less than 80 mg%) were not increased by cyclizine 50 mg.20 However 3 of the subjects experienced drowsiness after cyclizine, and other studies have shown that cyclizine alone causes drowsiness in the majority of subjects.21 Significant impairment of psychomotor performance was seen in healthy subjects given chlorpheniramine 12 mg with alcohol 0.5 g/kg.5 A further study similarly found significant impairment in driving skills when chlorpheniramine was given with alcohol, see (c) below. In 13 healthy subjects alcohol 0.75 g/kg given with dexchlorpheniramine 4 mg/70 kg significantly impaired the performance of a number of tests (standing steadiness, reaction time, manual dexterity, perception, etc.).22 A study in 17 subjects found that mebhydrolin 0.71 mg/kg enhanced the alcohol-induced deficits in the performance of a number of tests on perceptual, cognitive and motor functions.23 No interaction was detected in one study of the combined effects of pheniramine aminosaliclyate 50 mg or cyproheptadine hydrochloride 4 mg and alcohol 0.95 mL/kg.24 Triprolidine 10 mg alone can significantly affect driving performance,2 and marked deterioration in driving skills has been demonstrated with 10 mL of Actifed Syrup (triprolidine with pseudoephedrine) alone and with a double whiskey.25

(c) Significantly-sedating antihistamines

Diphenhydramine in doses of 25 or 50 mg was shown to increase the detrimental effects of alcohol on the performance of choice reaction and coordination tests in subjects who had taken 0.5 g/kg of alcohol.18 The interaction between diphenhydramine in doses of 50, 75 or 100 mg and alcohol in doses of 0.5 to 0.75 g/kg has been confirmed in other reports.17,26–28 Emesedine in oral doses of 2 or 4 mg twice daily was found to be sedating and impair driving ability in 19 healthy subjects. The addition of alcohol increased this impairment.29 A marked interaction can also occur with hydroxyzine or promethazine.30 A very marked deterioration in driving skills was clearly demonstrated in a test of car drivers given 20 mL of Beechams Night Nurse (promethazine with dextrometh-
Mechanism

When an interaction occurs it appears to be due to the combined or additive central nervous depressant effects of both the alcohol and the antihistamine. The ‘non-sedating antihistamines’ are highly lipophilic and readily cross the blood-brain barrier; consequently they have considerable sedative effects that may persist into the next day. The ‘sedating antihistamines’ do not cross the blood-brain barrier so readily, and are therefore less sedating. Most of the non-sedating antihistamines, such as fexofenadine, do not appear to cross the blood-brain barrier. The authors of one study found that the sedating effects of cetirizine and emedastine were more marked in women than in men, and they noted that they had also previously seen this with acrivastine, clemastine and mizolastine. The reason for this is not established although it has been suggested that a smaller volume of distribution in women may result in higher plasma antihistamine levels.

Importance and management

An adverse interaction between alcohol and the highly-sedating antihistamines (see ‘Table 15.1’, (p.582)) is well established and clinically important. Marked drowsiness can occur with these antihistamines taken alone, which makes driving or handling other potentially dangerous machinery much more hazardous. This can be further worsened by alcohol. Patients should be strongly warned. Remember that some of these antihistamines are present in non-prescription products licensed as antihistemics and sedatives, and as components of cough, cold and influenza remedies (e.g. some preparations of Benylin, Lemsip or Night Nurse). Emedastine may also cause marked sedation when used orally, but it is usually given as eye drops.

The situation with some of the ‘sedating antihistamines’ is less clear cut, and tests with some of them failed to detect an interaction with normal doses and moderate amounts of alcohol; however, it has been clearly seen with Actifed Syrup (containing tripolidrine). It would therefore be prudent to exercise cautionary warnings, particularly if the patient is likely to drive.

The non-sedating antihistamines seem to cause little or no drowsiness in most patients and the risks if taken alone or with alcohol appear to be minimal or absent. However, the incidence of sedation varies with the dose and individual (e.g. women may be more affected than men). Therefore, patients should be advised to be alert to the possibility of drowsiness if they have not taken the drug before. Any drowsiness would be apparent after the first few doses. The patient information leaflets for acrivastine and cetirizine suggest avoidance of alcohol or excessive amounts of alcohol, and caution is advised with levocetirizine. The possible interactions of alcohol with other antihistamines not cited here do not seem to have been formally studied, but increased drowsiness and increased driving risks would be expected with any that cause some sedation. Patients should be warned about drinking alcohol when taking sedative antihistamines. The risks with antihistamines given as eye drops or nasal spray (e.g. azelastine, epinastine) are probably minimal, but this needs confirmation.

Alcohol + Antihypertensives

Chronic moderate to heavy drinking raises the blood pressure and reduces, to some extent, the effectiveness of antihypertensive drugs. A few patients may experience postural hypotension, dizziness, and fainting shortly after having drunk alcohol. Alpha blockers may enhance the hypertensive effect of alcohol in subjects susceptible to the alcohol flush syndrome.

Clinical evidence, mechanism, importance and management

(a) Hypertensive reaction

A study in 40 men with essential hypertension involving beta blockers, captopril, diuretics, methyldopa, prazosin or verapamil who were moderate to heavy drinkers, found that when they reduced their drinking over a 6-week period from an average of 450 mL of alcohol weekly (about 6 drinks daily) to 64 mL of alcohol weekly, their average blood pressure fell by 5/3 mmHg. The reasons for this effect are uncertain.

The Atherosclerosis Risk in Communities (ARIC) study involving 8334 subjects who were free from hypertension at baseline and were assessed after 6 years, found that higher levels of consumption of alcoholic beverages (210 g or more of alcohol per week; approximately 3 drinks or more per day) were associated with a higher risk of hypertension. Low to moderate consumption of alcohol (up to 3 drinks/day) was associated with an increase in blood pressure in black, but not in white men. A study in Japanese men found that the effect of alcohol intake on the risk of developing hypertension was dose-dependent, starting at low-to-moderate levels of alcohol (less than 23 g/day).
These findings are consistent with those of other studies in hypertensive and normotensive subjects. It seems likely that this effect will occur with any antihypertensive. Patients with hypertension who are moderate to heavy drinkers should be encouraged to reduce their intake of alcohol. It may then become possible to reduce the dosage of the antihypertensive. It should be noted that epidemiological studies show that regular light to moderate alcohol consumption is associated with a lower risk of cardiovascular disease.

(b) Hypotensive reaction

A few patients taking some antihypertensives feel dizzy or begin to ‘black out’ or faint if they stand up quickly or after exercise. This orthostatic and exertional hypotension may be exaggerated in some patients shortly after drinking alcohol, possibly because it lowers the cardiac output (noted in patients with various types of heart disease). For other reports of postural hypotension with alcohol, see ‘alpha blockers’, (p.42), and ‘calcium channel blockers’, (p.57). Some manufacturers of antihypertensives e.g. ACE inhibitors and thiazide diuretics warn that acute alcohol intake may enhance the hypotensive effects, particularly at the start of treatment, and this could apply to any antihypertensive. Patients just beginning antihypertensive treatment should be warned.

(c) CNS and other effects

For mention of the possibility of increased sedation with alcohol and clonidine or indoramin, see ‘Clonidine and related drugs + CNS depressants’, (p.49), and ‘Calcium channel blockers’, (p.57). Some manufacturers of antihypertensives e.g. ACE inhibitors and thiazide diuretics warn that acute alcohol intake may enhance the hypotensive effects, particularly at the start of treatment, and this could apply to any antihypertensive. Patients just beginning antihypertensive treatment should be warned.

(d) Isoniazid

(e) Propantheline

Propantheline appears not to affect blood-alcohol levels, whereas atropine may cause a modest reduction. Marked impairment of attention can occur if alcohol is taken in the presence of atropine or glycopyrrolate, probably making driving more hazardous. No adverse interaction usually appears to occur with transdermal hyoscine and alcohol.

Clinical evidence, mechanism, importance and management

Oral propantheline (15 mg four times daily or 30 mg three times daily for 5 days, and 30 mg or 60 mg 2 hours before alcohol) did not affect blood-alcohol levels in 3 subjects. Another 3 mg oral dose of atropine 2 hours before alcohol reduced the AUC of alcohol by a modest 20% in 3 subjects. Another study in healthy subjects found that oral atropine 500 micrograms or glycopyrrolate 1 mg given with alcohol 0.5 g/kg either did not affect or improved reaction times and co-ordination, there was a marked impairment of attention, which was large enough to make driving more hazardous. Patients should be warned.

A double-blind crossover study in 12 healthy subjects found that a transdermal hyoscine preparation (Scopoderm-TTS) did not alter the effects of alcohol on the performance of several psychometric tests (Critical Flicker Fusion Frequency, Choice Reaction Tasks), nor was the clearance of alcohol or hyoscine changed. Blood-alcohol levels of up to 80 mg%, and 130 mg%, were studied. Nevertheless, the manufacturer suggests caution in patients receiving drugs that act on the CNS, and advises that patients should not drink alcohol while using Scopoderm-TTS. This is presumably because drowsiness and other CNS adverse effects have occasionally been reported with the transdermal preparation. The manufacturers of travel tablets and injections containing hyoscine butylbromide or hyoscine methobromide recommend avoidance of alcohol. However, unlike hyoscine and hyoscine hydrobromide, the quaternary derivatives such as hyoscine butylbromide or hyoscine methobromide do not readily pass the blood-brain barrier, and would be expected to be less likely to cause additive adverse effects with alcohol.

Alcohol + Antimycobacterials

The hepatotoxicity of some antimycobacterials may possibly be increased by high alcohol consumption. Alcohol may increase the risk of epileptic episodes in patients taking cycloserine. A psychotomotic reaction in a patient taking ethionamide was attributed to concurrent heavy alcohol consumption. Isoniazid slightly increases the hazards of driving after drinking alcohol. Isoniazid-induced hepatitis may also possibly be increased by alcohol, and the effects of isoniazid are possibly reduced in some heavy drinkers. Acute alcohol intake does not appear to affect the pharmacokinetics of a single-dose of isoniazid.

Clinical evidence, mechanism, importance and management

(a) Combined antitubercular regimens

Hepatotoxicity can occur with several antitubercular drugs including ethionamide, isoniazid, pyrazinamide and rifampicin and high alcohol consumption/chronic alcoholism has been reported to increase the risk. However, one study in patients with active tuberculosis taking rifampicin and pyrazinamide, found that of the 14 patients who developed hepatotoxicity, only 5 of these reported alcohol use (not quantified), and alcohol was not found to be associated with an increased risk of hepatotoxicity. Similarly, another study found that alcohol consumption was not a risk factor for antimycobacterial-induced hepatotoxicity.

(b) Cycloserine

A brief report describes an enhancement of the effects of alcohol in 2 patients taking cycloserine. The clinical significance of this case report is unclear. However, the manufacturers of cycloserine state that it is ‘incompatible’ with alcohol because of an increased risk of epileptic episodes, and contraindicate its use in alcohol abuse.

(c) Ethionamide

A psychotomotic reaction seen in a patient taking ethionamide was attributed to the concurrent heavy consumption of alcohol. It is unclear whether this represents a clinically meaningful interaction but it appears to be the only case on record. However, the manufacturers advise avoidance of excessive alcohol ingestion.

(d) Isoniazid

The effects of isoniazid 750 mg with alcohol 0.5 g/kg were examined in 100 subjects given various psychomotor tests, and in a further 50 drivers using a driving simulator. No major interaction was seen in the psychomotor tests, but the number of drivers who drove off the road on the simulator was increased. There would therefore appear to be some extra risks for patients taking isoniazid who drink and drive, but the effect does not appear to be large. Patients should nevertheless be warned.

The incidence of severe progressive liver damage due to isoniazid is said to be higher in those who drink alcohol regularly. The clinical effects...
of isoniazid are also said to be reduced by heavy drinking in some patients; however, acute alcohol intake in 16 healthy subjects did not have any effect on the pharmacokinetics of a single 200-mg dose of isoniazid. Alcoholic metabolism is reversibly inhibited and the acetaldehyde-modified drug formed could mediate some adverse effects. The manufacturer advises care in giving isoniazid to patients with chronic alcoholism.

11. Linnolla M, Mattila MJ. Interaction of alcohol and drugs on psychomotor skills as demonstrated by a driving simulation. Br J Pharmacol (1973) 47, 671P–672P.

Alcohol + Antipsychotics

The detrimental effects of alcohol on the skills related to driving are made worse by chlorpromazine, and, to a lesser extent, by flupenthixol, sulpiride and thioridazine. Small or single-dose studies with haloperidol or tiapride suggest that any interaction would seem to be mild; nevertheless, all antipsychotic drugs which cause drowsiness have the potential to enhance the effects of alcohol. There is evidence that drinking can precipitate the emergence of extrapyramidal adverse effects in patients taking antipsychotics.

Clinical evidence

(a) Effect on driving and other skills

Twenty-one subjects showed a marked deterioration in the performance of a number of skills related to driving when given chlorpromazine 200 mg daily and alcohol (blood levels 42 mg%). Many complained of feeling sleepy, lethargic, dull, groggy, and poorly coordinated; and most considered themselves more unsafe to drive than with alcohol alone. A later study confirmed these findings with chlorpromazine 1 mg/kg and blood-alcohol levels of 80 mg%. Increased sedation was clearly seen in another study with alcohol and chlorpromazine, and clear impairment of psychomotor skills related to driving have also been found.

Single 500-microgram doses of haloperidol or flupenthixol strongly impaired attention, but did not significantly interact with alcohol in one study. However, a double-blind study in subjects given flupenthixol 500 micrograms three times a day for 2 weeks found that, when combined with alcohol 0.5 g/kg, their performance of a number of tests (choice reaction, coordination, attention) was impaired to such an extent that driving or handling other potentially dangerous machinery could be hazardous.

Sulpiride 50 mg three times daily for 2 weeks caused a mild decrease in psychomotor skills with alcohol in healthy subjects, but not as much as that seen with chlorpromazine and alcohol. Thioridazine 25 mg caused some additive effects with alcohol, with a moderately deleterious effect on attention. Another study found that thioridazine and alcohol affected skills related to driving, but not as much as the effects seen with chlorpromazine. A further study found no difference between the effects of thioridazine and a placebo with alcohol. A study in 9 alcoholics given tiapride 400 to 600 mg daily showed that wakefulness was not impaired when alcohol 0.5 g/kg was given, and in fact appeared to be improved, but the effect on driving skills was not studied.

(b) Precipitation of extrapyramidal adverse effects

A report describes 7 patients who developed acute extrapyramidal adverse effects (akathisia, dystonia) while taking trifluoperazine, fluphenazine, perphenazine, or chlorpromazine and drinking alcohol. The authors stated that these were examples of numerous such alcohol-induced toxicity reactions observed by him over an 18-year period involving phenothiazines and butyrophenones. Elsewhere he describes the emergence of drug-induced parkinsonism in a woman taking perphenazine and amitriptyline when she began to drink alcohol. Eighteen cases of haloperidol-induced extrapyramidal reactions among young drug abusers, in most instances associated with the ingestion of alcohol, have also been described. Similarly, a study involving 41 patients with schizophrenia found that those with a substance use disorder (alcohol or cannabis ± cocaine) displayed more extrapyramidal symptoms compared with non-abusing patients.

(c) Toxicity

A study involving 332 fatal poisonings in Finland found that alcohol was present in 65% of cases involving promazine, and when alcohol was present, relatively small overdoses of promazine could result in fatal poisoning. It appears that promazine and possibly levomepromazine may be more toxic when combined with alcohol.

(d) Pharmacokinetic studies

A study in 12 patients receiving chlorpromazine 600 mg to 1.2 g daily long-term, found that chlorpromazine had no apparent effect on alcohol metabolism. However, about half of the patients had a statistically significant decrease (up to 33%) in urinary excretion of chlorpromazine and its metabolites during the 24-hour period following the consumption of 50 to 75 mL of alcohol. A study in 7 schizophrenics found that when they were given 40 g of alcohol to drink at about the same time as their regular injection of fluphenazine decanoate (25 to 125 mg every 2 weeks), their serum fluphenazine levels were reduced by 30% at 2 hours and by 16% at 12 hours.

Mechanism

Uncertain. Additive CNS depressant effects are one explanation of this interaction. One suggestion to account for the emergence of the drug adverse effects is that alcohol lowers the threshold of resistance to the neurotoxicity of these drugs. Also alcohol may possibly impair the activity of tyrosine hydroxylase so that the dopamine/acytelycholine balance within the corpus striatum is upset. In addition, chlorpromazine has been found to inhibit alcohol dehydrogenase, which may facilitate the formation of biogenic amines that have been implicated in extrapyramidal adverse effects.

Pharmacokinetic interactions between acute and chronic alcohol ingestion, and single or multiple doses of antipsychotic drug are complex; acute alcohol intake can decrease metabolic clearance, whereas chronic intake can increase clearance. Alcohol may also affect the peripheral circulation and membrane permeability, which might affect absorption from an injection site.

Importance and management

The documentation is limited. The manufacturers of flupenthixol and haloperidol warn that, in common with other antipsychotic drugs, the effects of alcohol may be enhanced. Warn patients that if they drink alcohol while taking chlorpromazine, and to a lesser extent flupenthixol, sulpiride or thioridazine (probably other related drugs as well), they may become very drowsy, and should not drive or handle other potentially dangerous machinery. Some risk is possible with any antipsychotic that causes drowsiness, including those used as antiemetics, such as prochlorperazine.

The authors of the reports describing the emergence of serious adverse effects to antipsychotics in those who drink alcohol, consider that patients should routinely be advised to abstain from alcohol during antipsychotic treatment.
Heavy alcohol intake may affect the virological response to HAART. Theoretically, alcohol consumption may induce liver enzymes, which interfere with the metabolism of some antivirals such as the protease inhibitors. Alcohol reduces the metabolism of abacavir but this does not appear to be clinically significant.

Clinical evidence, mechanism, importance and management

(a) Alcohol and HAART regimens

A study of 94 HIV-positive patients receiving HAART, which included 2 ‘nucleoside analogues’ plus either indinavir, ritonavir, saquinavir, nelfinavir, or ritonavir/saquinavir, found that the amount of alcohol consumed did not affect the antiviral response. However, the proportion of those who consumed 21 or more drinks a week there was a large association between bleeding and the ingestion of aspirin alone, and the combination with alcohol produced a significant synergistic effect. A large case-controlled study found similar results: the overall relative risk of bleeding with regular use of aspirin at doses greater than 325 mg was 7 among drinkers and 5.1 among people who never drink alcohol. For those who drank less than 1 to 20 drinks a week, there was no evidence of a trend of increasing or decreasing relative risk as levels of alcohol consumption increased, but among those who consumed 21 or more drinks a week, there was a large association with upper gastrointestinal bleeding (crude estimated risk 27). For regular aspirin use at doses of 325 mg or less, the overall relative risk among all current drinkers was 2.8 and among people who never drank alcohol was 2.2. Endoscopic examination revealed that aspirin and alcohol have additive damaging effects on the gastric mucosa (not on the duodenum), but the extent is small. However, a further case-control study found that large amounts of red wine (roughly over 500 mL of wine daily) increased the risk of upper gastrointestinal bleeding associated with low-dose aspirin, and small amounts of red wine (roughly less than 200 mL of wine daily) reduced this risk. Another study using gastric mucosal potential difference as a measure of mucosal damage found that aspirin with alcohol caused additive damage to the mucosa. In a review of the evidence, it was considered that while more study was needed, data available are highly suggestive that the gastrointestinal toxicity of alcohol and aspirin are combined.

Clinical evidence

(b) Effect of alcohol on abacavir

A study in 24 HIV-positive patients found that alcohol 0.7 g/kg increased the AUC of a single 600-mg dose of abacavir by 41%. The half-life of abacavir was increased by 26%, from 1.42 to 1.79 hours. The pharmacokinetics of abacavir were not affected by alcohol. Alcohol may inhibit the formation of abacavir carboxylate resulting in a trend towards increased abacavir glucuronide formation and reduced abacavir metabolism. The increase in exposure to abacavir was not considered to be clinically significant, since it is within levels seen in other studies using higher doses, which demonstrated no additional safety concerns at doses of up to three times the recommended daily dose of abacavir. No special precautions therefore appear to be necessary.

Alcohol + Aspirin

A small increase in the gastrointestinal blood loss caused by aspirin occurs in patients if they drink alcohol, but any increased damage to the lining of the stomach is small and appears usually to be of minimal importance in most healthy individuals. However, heavy drinkers who regularly take aspirin should be warned of the increased risk of gastric bleeding. Some limited evidence suggests that aspirin can raise or lower blood alcohol levels.

Clinical evidence

(a) Effect on blood loss

The mean daily blood loss from the gut of 13 healthy men was 0.4 mL while taking no medication, 3.2 mL while taking 2.1 g of soluble unbuffed aspirin (Disprin) and 5.3 mL while taking aspirin with 180 mL of Australian whiskey (alcohol 31.8%). In this study, alcohol alone did not cause gastrointestinal bleeding. Similar results were reported in another study in healthy subjects. An epidemiological study of patients admitted to hospital with gastrointestinal haemorrhage showed a statistical association between bleeding and the ingestion of aspirin alone, and the combination with alcohol produced a significant synergistic effect. A large case-controlled study found similar results: the overall relative risk of bleeding with regular use of aspirin at doses greater than 325 mg was 7 among drinkers and 5.1 among people who never drink alcohol. For those who drank less than 1 to 20 drinks a week, there was no evidence of a trend of increasing or decreasing relative risk as levels of alcohol consumption increased, but among those who consumed 21 or more drinks a week, there was a large association with upper gastrointestinal bleeding (crude estimated risk 27). For regular aspirin use at doses of 325 mg or less, the overall relative risk among all current drinkers was 2.8 and among people who never drank alcohol was 2.2. Endoscopic examination revealed that aspirin and alcohol have additive damaging effects on the gastric mucosa (not on the duodenum), but the extent is small. However, a further case-control study found that large amounts of red wine (roughly over 500 mL of wine daily) increased the risk of upper gastrointestinal bleeding associated with low-dose aspirin, and small amounts of red wine (roughly less than 200 mL of wine daily) reduced this risk. Another study using gastric mucosal potential difference as a measure of mucosal damage found that aspirin with alcohol caused additive damage to the mucosa. In a review of the evidence, it was considered that while more study was needed, data available are highly suggestive that the gastrointestinal toxicity of alcohol and aspirin are combined.
bined in individuals who are heavy daily drinkers and heavy aspirin users. Consider also ‘Alcohol + NSAIDs’, p. 71.

No increased gastrointestinal bleeding occurred in 22 healthy subjects given three double gums or whiskies (equivalent to 142 mL of alcohol 40%) and 728 mg of buffered sodium acetylsalicylate (Alka-Seltzer).9

Importance and management

The combined effect of aspirin and alcohol on the stomach wall is established. Aspirin 3 g daily for a period of 3 to 5 days induces an average blood loss of about 5 mL or so. Some increased loss undoubtedly occurs with alcohol, but it seems to be quite small and unlikely to be of much importance in most healthy individuals using moderate doses. In one study it was found that alcohol was a mild damaging agent or a mild potentiating agent for other damaging drugs.3 On the other hand it should be remembered that chronic and/or gross overuse of salicylates and alcohol may result in increased blood loss.4

Mechanism

(a) Effect on blood loss

Aspirin and alcohol can damage the mucosal lining of the stomach, one measure of the injury being a fall in the gastric potential difference. Once the protective mucosal barrier is breached, desquamation of the cells occurs and damage to the capillaries follows. Aspirin causes a marked prolongation in bleeding times, and this can be increased by alcohol.14 The total picture is complex.

(b) Effect on blood alcohol levels

The increased blood alcohol levels in the presence of food and aspirin may possibly occur because the aspirin reduces the enzymatic oxidation of the alcohol by alcohol dehydrogenase in the gastric mucosa, so that more remains available for absorption.10 Any decreases with low-dose aspirin may possibly be due to delayed gastric emptying.13

Importance and management

The combined effect of aspirin and alcohol on the stomach wall is established. Aspirin 3 g daily for a period of 3 to 5 days induces an average blood loss of about 5 mL or so. Some increased loss undoubtedly occurs with alcohol, but it seems to be quite small and unlikely to be of much importance in most healthy individuals using moderate doses. In one study it was found that alcohol was a mild damaging agent or a mild potentiating agent for other damaging drugs.3 On the other hand it should be remembered that chronic and/or gross overuse of salicylates and alcohol may result in gastric ulceration. People who consume at least 3 or more alcoholic drinks daily and who regularly take more than 325 mg of aspirin have been shown to have a high risk of bleeding.13 The FDA in the US has ruled that non-prescription pain relievers and fever reducers, containing aspirin or salicylates, must carry a warning label advising people who consume 3 or more alcoholic drinks every day to consult their doctor before using these drugs, and that stomach bleeding may occur with these drugs.16 However, the Australian Medicines Evaluation Committee has decided against such action as, for most people with mild to moderate alcohol intake, there is little risk especially if the aspirin is taken only as needed.15

Information about the increase in blood alcohol levels caused by aspirin after food is very limited and contradictory, and of uncertain practical importance. However, no practically relevant interaction has been seen with other drugs (such as the ‘H2-receptor antagonists’, (p.64)), which have been extensively studied, and which appear to interact by the same mechanism. The pattern for these drugs is that the increases in blood alcohol levels are appreciable with small doses of alcohol, but usually they become proportionately too small to matter with larger doses of alcohol (i.e. those that give blood and breath levels at or around the legal driving limit in the UK).

Alcohol + Barbiturates

Alcohol and the barbiturates are CNS depressants, which together can have additive and possibly even synergistic effects. Activities requiring alertness and good co-ordination, such as driving a car or handling other potentially dangerous machinery, can be made more difficult and more hazardous. Alcohol may also continue to interact the next day if the barbiturate has hangover effects.

Clinical evidence

A study in healthy subjects of the effects of a single 0.5-g/kg dose of alcohol, taken in the morning after a dose of amobarbital 100 mg every night for 2 weeks, found that the performance of co-ordination skills was much more impaired than with either drug alone.3 This increased CNS depression due to the combined use of alcohol and barbiturates has been described in other clinical studies with phenobarbital.2,3 However, a study in healthy subjects found that although phenobarbital 45 mg daily for one week and alcohol (35 to 45 mg%) affected some perceptual-motor tests when given separately, these effects were not always found when they were given together.4 Nevertheless, high doses of phenobarbital can affect driving skills7 and increased CNS depression has featured very many times in coroners’ reports of fatal accidents and suicides involving barbiturates and alcohol.8 A study of the fatalities due to this interaction indicated that with some barbiturates the CNS depressant effects are more than additive.9 There is also some evidence that blood-alcohol levels may be reduced in the presence of a barbiturate,8,9 for the interaction between thiopental and alcohol, see ‘Anaesthetics, general + Alcohol’, p.92.

Mechanism

Both alcohol and the barbiturates are CNS depressants, and simple additive CNS depression provides part of the explanation. Acute alcohol ingestion may inhibit the liver enzymes concerned with the metabolism of barbiturates such as phenobarbital and pentobarbital, but chronic exposure to alcohol increases hepatic microsomal enzyme activity and may reduce sedation from barbiturates in patients without liver impairment.10 Similarly, chronic exposure to a barbiturate such as phenobarbital may increase alcohol metabolism due to enzyme induction and consequently reduce blood-alcohol levels.
Importance and management

Few formal studies in normal clinical situations have been made of the interactions between alcohol and the barbiturates, and most of these studies are old and involved barbiturates used as hypnotics. However, the effects (particularly those that result in fatalities) are very well established, serious, and of clinical importance. The most obvious hazards are increased drowsiness, lack of alertness and impaired co-ordination, which make the handling of potentially dangerous machinery (e.g. car driving), and even the performance of everyday tasks (e.g. walking downstairs) more difficult and dangerous. Only amobarbital and phenobarbital appear to have been specifically studied, but this interaction would be expected with all of the barbiturates. Some barbiturate hangover effects may be present the next morning and may therefore continue to interact significantly with alcohol. Patients should be warned.

For comments on the use of alcohol in epileptic patients taking antiepileptics including phenobarbital, see ‘Alcohol + Antiepileptics’, p. 46.

Alcohol + Benzodiazepines and related drugs

Benzodiazepine and related hypno-sedatives increase the CNS depressant effects of alcohol to some extent. The risks of car driving and handling other potentially dangerous machinery are increased. The risk is heightened because the patient may be unaware of being affected. Some benzodiazepines used at night for sedation are still present in appreciable amounts the next day and therefore may continue to interact. Alcohol may also increase the plasma levels of brotizolam, clobazam, diazepam, and possibly triazolam, whereas alprazolam may increase blood-alcohol levels. Alcohol has been reported to increase aggression or amnesia and/or reduce the anxiolytic effects of some benzodiazepines.

Clinical evidence

(a) Additive CNS depressant effects

It is very difficult to assess and compare the results of the very many studies of this interaction because of the differences between the tests, their duration, the dosages of the benzodiazepines and alcohol, whether given chronically or acutely, and a number of other variables. However, the overall picture seems to be that benzodiazepines and related drugs including diazepam, alprazolam, bromazepam, brotizolam, chlordiazepoxide, clorazepate, flunitrazepam, flurazepam, lorazepam, medazepam, midazolam, nitrazepam, oxazepam, temazepam, triazolam, zopidem enhance the effects of alcohol i.e. cause increased drowsiness, impaired performance and driving skills.

Patients taking benzodiazepines including lorazepam or triazolam may be unaware of the extent of the impairment that occurs. Furthermore, changes in CNS functioning may possibly occur in heavy social drinkers; a placebo-controlled study in 20-year-olds suggested that lorazepam 2 mg had more impairment on delayed auditory verbal memory performance in those who were heavy social drinkers (more than 20 drinks; 200 g of alcohol per week) than light social drinkers (20 g or less of alcohol per week).47

Some of the benzodiazepines and related drugs that are used primarily to aid sleep, such as flunitrazepam, flurazepam, lorazepam, nitrazepam, and temazepam, and zopiclone have been reported not to do so. The sedative effects of midazolam alone, and midazolam with fentanyl have been shown to have dissipated within 4 hours, and to not be affected by alcohol after this time.51,52 However, some patients may metabolise midazolam more slowly and so an interaction could still be possible, especially in older patients or those receiving additional drugs.53

Some contrasting effects have also been reported. One study suggested that alcohol might mitigate the effects of lorazepam on psychological performance.32 Similarly, some antagonism has been reported between clordiazepoxide and alcohol, but this is unlikely to be of practical importance.18,19 The development of tolerance between benzodiazepines and alcohol with chronic use has also been suggested.55,56

(b) Increased aggression, anxiety, or amnesia

The anxiolytic effects of lorazepam and possibly clordiazepoxide may be opposed by alcohol. Alprazolam and alcohol together may possibly increase behavioural aggression and may cause violent behaviour, impulsive decision-making and anterograde amnesia: a report looking at violent crimes committed by abusers of flunitrazepam found that alcohol was almost always also present.58 Alcoholic drinks also enhance the effects of flunitrazepam when it is used as a ‘date rape’ drug.59

(c) Pharmacokinetic effects

Several studies have reported that alcohol increases plasma levels of diazepam and that alcohol accelerates the absorption of diazepam, but others have suggested that alcohol has no significant effect on diazepam pharmacokinetics.9,11,61 Plasma levels of brotizolam and clobazam may be increased by alcohol. One study reported that the plasma levels of triazolam were increased by alcohol,44 but other studies have found only a minimal pharmacokinetic interaction.45,46 However, an in vitro study demonstrated that alcohol inhibited the metabolism of triazolam by the cytochrome P450 isoenzyme CYP3A.62 Another in vitro study reported that the formation of flunitrazepam metabolites was weakly inhibited by alcohol,53 but a pharmacokinetic study suggested that there was no interaction.63 Alcohol appears to have minimal effects on the pharmacokinetics of alprazolam and zopiclone.

The pharmacokinetics of alcohol do not appear to be affected to a clinically significant extent by diazepam,11 flunitrazepam,26 zopiclone,50 or zopiclone but alprazolam may increase blood-alcohol levels.

Mechanism

The CNS depressant actions of the benzodiazepines and alcohol are mainly additive and it appears that different aspects of CNS processing may be involved.41,65

A pharmacokinetic interaction can sometimes occur, but the mechanisms seem to be quite complex. Acute alcohol intake increases the absorption and raises the serum levels of some benzodiazepines and there may be direct competitive inhibition of metabolism.66 It has been suggested that clearance of benzodiazepines via phase I metabolism, by N-demethylation and/or hydroxylation, tends to be more affected by alcohol intake than that of drugs such as lorazepam, oxazepam or temazepam that only undergo phase II conjugation. In addition, phase I metabolism is inhibited or decreases with increasing age and liver disease.66 However, phase I metabolism is increased by chronic administration of substances that induce the cytochrome P450 isoenzyme system, such as alcohol,66 and moderate alcohol consumption may cause intestinal CYP3A induction resulting in reduced bioavailability of some benzodiazepines, such as midazolam.65
Extensively studied, well established and clinically important interactions. The overall picture is that these drugs worsen the detrimental effects of alcohol. Up to a 20% to 30% increase in the impairment of psychomotor function has been suggested. The deterioration in skills will depend on the particular drug in question, its dosage and the amounts of alcohol taken. With modest amounts of alcohol the effects may be quite small in most patients (although a few may be more markedly affected), but anyone taking any of these drugs should be warned that their usual response to alcohol may be greater than expected, and their ability to drive a car, or carry out any other task requiring alertness, may be impaired. They may be quite unaware of the deterioration or that the effects may still be present the following day. Benzodiazepines and alcohol are frequently found in the blood of car drivers involved in traffic accidents, which suggests that the effects are real. Furthermore, alcohol may contribute to fatal poisons and other deaths involving benzodiazepines, particularly diazepam and temazepam. Alcohol may contribute to drug-related accidents and deaths due to a disregard for safety, and there is also an association between alcohol and benzodiazepines and violence-related accidents.

The haemodynamic and pharmacokinetic effects of atenolol and metoprolol in healthy subjects do not appear to be changed by alcohol. There is some evidence that alcohol modestly reduces the haemodynamic effects of propranolol, and some of the effects of sotalol may also be changed by alcohol. Some evidence suggests that the effects of alcohol and atenolol/chlortalidone or propranolol are additive on the performance of some psychomotor tests, but the importance of this is uncertain.

Clinical evidence, mechanism, importance and management

(a) CNS effects

In 12 healthy subjects the performance of a number of psychomotor tests was found to be impaired by alcohol 0.6 g/kg and by one tablet of Tenoretic (atenolol 100 mg with chlortalidone 25 mg). When alcohol and Tenoretic were taken together there was some evidence of additive effects but the practical importance of this is not clear.1

In 12 healthy subjects propranolol 40 mg every 6 hours had no effect on the alcohol-induced impairment of performance on a number of psychomotor tests given 50 mL/70 kg of alcohol, except that propranolol antagonised the effect of alcohol in one test (pursuit meter).2 However, in another study, propranolol enhanced the effects of alcohol on some tests (inebriation and divided attention).3

The manufacturer of propranolol warns that the effects of alcohol and beta blockers on the CNS have been observed to be additive and it is possible that symptoms such as dizziness may be exaggerated if they are taken together.4

(b) Haemodynamic and pharmacokinetic effects

In 8 healthy subjects the pharmacokinetics of single 100-mg doses of atenolol or metoprolol were unaffected 6 hours after they had drunk the equivalent of 200 mL of absolute alcohol. No clinically significant changes in blood pressure or pulse rate were seen.5 A study in 6 healthy subjects found that alcohol (sufficient to maintain blood-alcohol levels of 80 mg%) raised the mean AUC of a single 80-mg oral dose of propranolol by 17.4% in 5 subjects and decreased it by 37% in the other subject, but this was considered unlikely to be clinically important. No changes in heart rate or blood pressure were seen.6 In contrast, a double-blind study in 14 healthy subjects found that alcohol (equivalent to 200 mL of absolute alcohol) increased the clearance of a single 80-mg dose of propranolol and diminished its ability to lower blood pressure. Propranolol was not able to abolish the alcohol-induced rise in heart rate.7 Similarly, another study found that alcohol decreased the rate of absorption and increased the rate of elimination of propranolol, but the clinical significance of this small alteration was not assessed.8

A further study in 6 healthy subjects found that although the blood pressure lowering effects of sotalol 160 mg were increased by alcohol, sotalol did not cancel out the alcohol-induced rise in heart rate.9

It would seem prudent to be alert for changes in response to beta blockers that may be due to alcohol. See also, 'Alcohol + Antihypertensives', p.48.

reduce alcohol tolerance and there is an increased risk of seizures if alco-
hol is withdrawn abruptly, see ‘Bupropion + Miscellaneous’, p.1206.

### Alcohol + Buspirone

Buspirone with alcohol may cause drowsiness and weakness, al-
though it does not appear to impair the performance of a number of
psychomotor tests.

**Clinical evidence, mechanism, importance and management**

A study in 12 healthy subjects showed that, in contrast to lorazepam, bus-
pirone 10 or 20 mg did not appear to interact with alcohol (i.e. worsen the
performance of certain psychomotor tests), but it did make the subjects
feel drowsy and weak.1,2 Similarly, another study in 13 healthy subjects
found that combining buspirone (15 and 30 mg/70 kg) and alcohol caused sedation, but very little impairment of performance. In this study, the sed-
ative effects were broadly similar to those seen with alprazolam plus alco-
hol, but alprazolam plus alcohol clearly impaired performance.3 Similar
findings were reported in another earlier comparison with diazepam.4 A
further study reported that single 5 to 15-mg doses of buspirone had a min-
imal effect on performance in both light and moderate female social drink-
ers.5 The UK manufacturer notes that there is no information on higher ther-
apeutic doses of buspirone combined with alcohol, and they suggest that
it would be prudent to avoid alcohol while taking buspirone.6 They also
caution patients of the potential hazards of driving or handling other po-
tentially dangerous machinery until they are certain that buspirone does
not adversely affect them.6

### Alcohol + Butyraldoxime

A disulfiram-like reaction can occur in those exposed to N-bu-
yraldoxime if they drink alcohol.

**Clinical evidence, mechanism, importance and management**

Workers in a printing company complained of flushing of the face, neck
and upper trunk, shortness of breath, tachycardia and drowsiness very
shortly after drinking alcohol (1.5 oz about 45 mL) of whiskey), and were
found to have increased levels of acetaldehyde in their blood. The reason
appeared to be that the printing ink they were using contained
butyraldoxime, an antioxidant which, like disulfiram, can inhibit the metabolism
of alcohol causing acetaldehyde to accumulate (see ‘Alcohol + Dis-
sulfiram’, p.61).1 It is possible that it is a metabolite of N-butyraldoxime
that causes this effect, rather than N-butyraldoxime itself.2 This reaction
would seem to be more unpleasant and socially disagreeable than serious.
No treatment normally seems necessary.

### Alcohol + Caffeine

Objective tests show that caffeine may counteract some of the ef-
facts of alcohol. However, it does not completely sober up those
who have drunk too much, and may even make them more acci-
cident-prone.

**Clinical evidence**

A study in a large number of healthy subjects given a cup of coffee con-
taining caffeine 300 mg/70 kg, either alone or immediately after drinking
alcohol 0.75 g/kg, found that caffeine did not antagonise the deleterious
effect of alcohol on the performance of psychomotor skill tests. Only re-
action times were reversed.1 Two other studies also found that caffeine did
not antagonise the effects of alcohol in a variety of tests.2,3 A further study
in 8 subjects found that, contrary to expectations, caffeine increased the
frequency of errors in the performance of a serial reaction time task,4 and
similarly, caffeine has been reported to increase the detrimental effects of
alcohol5

In contrast, more recent studies usually using caffeine in capsule form,
have found that some of the performance-imparing effects of alcohol such
as increased simple reaction time,6,7 increased errors with four choice re-
action time,8 sedation,9 and slowing of psychomotor speed10 can be antag-
onised by caffeine given with the alcohol. However, caffeine does not
appear to restore most subjective effects e.g. feeling of drunkenness.6,9,10
One study found that the alcohol-caffeine combination typically altered the
effects of caffeine alone rather than altering the effects of alcohol
alone. For example the addition of alcohol reduced the jiteriness and
alertness produced by caffeine, and although caffeine modestly antago-
ised alcohol impairment of driving, there was still a 9% increase in brake-
response time, when compared with placebo.10

In a double-blind, placebo-controlled, crossover study in 8 healthy sub-
jects, the AUC of a 400-mg caffeine capsule was 30% greater when it was
taken with alcohol 0.8 g/kg than when taken alone. Blood-alcohol levels
were not affected by caffeine use.11 Similarly, other studies reported that
alcohol increases serum-caffeine levels2 and that blood-alcohol levels
were not modified by caffeine.1,2

**Mechanism**

Not fully understood. Caffeine is a CNS stimulant, which seems to oppose
some of the CNS depressant effects of alcohol. It appears that only those
objective tests able to detect an enhancement due to a CNS stimulant show
the clearest antagonistic effects.6

Alcohol appears to inhibit the hepatic metabolism of caffeine.2

**Importance and management**

It is not known why some studies report that caffeine antagonises some of
the detrimental effects of alcohol and others report no interaction. Howev-
er, the type of psychomotor test, the amount of alcohol and caffeine con-
sumed, and the timing and administration of the caffeine may affect the
results.

Caffeine does appear to improve some of the detrimental effects of alco-
hol in some psychomotor tests, which is probably why there is a long-
standing and time-hallowed belief in the value of strong black coffee to so-
ber up those who have drunk too much. In addition, it is just possible that
the time taken to drink the coffee gives the liver just a little more time to
metabolise some of the alcohol. However, it seems that it is not effective
in all aspects of alcohol impairment, particularly subjective effects. In ad-
dition, caffeine does not reduce blood-alcohol levels. Coffee and other
sources of caffeine do not make it safe to drive or handle dangerous ma-
chinery, and it may even make drivers more accident-prone.

Alcohol + Calcium carbimide

Alcohol causes a disulfiram-like reaction in patients taking calcium carbimide. Calcium carbimide has been used as an alcohol deterrent.

Clinical evidence, mechanism, importance and management
 Calcium carbimide interacts with alcohol in a similar way to disulfiram and by a similar mechanism (see ‘Alcohol + Disulfiram’, p. 61). Both of these drugs bind to aldehyde dehydrogenase, but calcium carbimide is said to have fewer adverse effects because it does not bind to dopamine beta hydroxylase. However, marked cardiovascular effects and fatalities have occurred in those who drank alcohol while taking calcium carbimide. Like disulfiram it is used to deter alcoholics from continuing to drink. 1, 2

Importance and management
 Information seems to be limited to these reports and they need confirmation. An alcohol concentration rise of around 17% as caused by verapamil is quite small, but it could be enough to raise legal blood levels to illegal levels if driving. Moreover the intoxicant effects of alcohol may persist for a much longer period of time (five times longer in this instance). The bioavailability of felodipine and nifedipine appear to be increased by alcohol. The manufacturers of some calcium-channel blockers warn that inter-individual variations in the response to these drugs can occur and some patients ability to drive or operate machinery may be impaired, particularly at the start of treatment and in conjunction with alcohol. 8, 9

Mechanism
 Not understood. It seems possible that verapamil inhibits the metabolism of alcohol by the liver, thereby reducing its loss from the body. Alcohol also appears to inhibit the metabolism of nifedipine, and to increase the bioavailability of felodipine. Red wine may have caused “dose dumping” of felodipine from the extended-release preparation which altered its pharmacokinetic profile, but the reason why the felodipine levels remained low until after a meal is unclear. 4 An in vitro study demonstrated that alcohol inhibited the oxidative metabolism of nifedipine by the cytochrome P450 isozyme CYP3A. 3

Alcohol + Calcium-channel blockers

Blood-alcohol levels can be raised and may remain elevated for a much longer period of time in patients taking verapamil. Alcohol may also increase the bioavailability of felodipine and nifedipine, but amlodipine appears not to interact. An increased incidence of postural hypotension has been reported in patients who took felodipine with alcohol

Clinical evidence

(a) Amlodipine

A study in 30 healthy subjects found that single and multiple doses of amlodipine 10 mg for 15 days (with or without lisinopril and simvastatin) had no effect on the pharmacokinetics of alcohol 0.8 g/kg nor on subjective psychological performance. Alcohol did not alter the pharmacokinetics of amlodipine. 1

(b) Felodipine

A study in 8 healthy subjects given enough alcohol to maintain their blood levels at 80 to 120 mg% found that their felodipine levels (following a single 10-mg oral dose) were approximately doubled (AUC increased by 77%, maximum blood levels increased by 98%). Diuresis was approximately doubled and heart rates were increased. 2

A double-blind, crossover study in 10 patients found that alcohol 0.75 g/kg in grapefruit juice enhanced the haemodynamic effects of a single 5-mg dose of felodipine. Four hours after dosing, felodipine with alcohol in grapefruit juice produced lower total peripheral resistance and diastolic blood pressure, and a higher heart rate, compared with felodipine with grapefruit juice alone. Furthermore, the greater blood pressure reduction caused symptoms in 50% of the patients; postural lightheadedness occurred in 5 patients given alcohol and felodipine, compared with 1 patient given felodipine without alcohol. However, felodipine plasma levels were higher than expected, although this may have largely been due to the ‘grapefruit juice’, (p. 869), and the incidence of adverse effects for both groups was also higher. 3

In a study, 8 non-smoking, healthy subjects were given a single 10-mg dose of an extended-release preparation of felodipine with 250 mL red wine on an empty stomach and 4 hours before a meal. Plasma felodipine levels were lower for the first 4 hours of the study than when taken with 250 mL water, but rose rapidly at 5 hours after dosing, resulting in a peak level that was higher than when taken with water. 4

Alcohol + Cannabis

The detrimental effects of drinking alcohol and smoking cannabis may be additive on some aspects of driving performance. However, there is some evidence that regular cannabis use per se does not potentiate the effects of alcohol. Smoking cannabis may alter the bioavailability of alcohol.
Clinical evidence and mechanism

Simultaneous use of alcohol and oral Δ9-tetrahydrocannabinol (THC, the major active ingredient of cannabis) reduced the performance of psychomotor tests, suggesting that those who use both drugs together should expect the deleterious effects to be additive.1 In a further placebo-controlled study, subjects smoked cannabis containing 100 or 200 micrograms/kg of Δ9-tetrahydrocannabinol and drank alcohol (to achieve an initial blood level of 70 mg%, with further drinks taken to maintain levels at 40 mg% 30 minutes before driving. They found that cannabis, even in low to moderate doses, negatively affected driving performance in real traffic situations. Further, the effect of combining moderate doses of both alcohol and cannabis resulted in dramatic performance impairment as great as that observed with blood-alcohol levels of 140 mg% alone.2,3

Opposing or no additive CNS effects

One study in 14 regular cannabis users (long-term daily use) and 14 infrequent cannabis users found that regular use reduced the disruptive effects of alcohol on some psychomotor skills relevant to driving, whereas infrequent use did not have this effect. This study, neither group had smoked any cannabis in the 12 hours before the alcohol test. Another study found that moderate doses of alcohol and cannabis, consumed either alone or in combination, did not produce significant behavioural or subjective impairment the following day.5

A study in 12 healthy subjects who regularly used both cannabis and alcohol found that alcohol 0.5 g/kg significantly increased break latency without affecting body sway, whereas cannabis given as a cigarette containing Δ9-tetrahydrocannabinol 3.33%, increased body sway but did not affect brake latency. There were no significant additive effects on brake latency, body sway, or mood when the two drugs were used together.6 A population-based study of 2,777 drivers involved in fatal road crashes, who drank alcohol and/or used cannabis, found that although both cannabis and alcohol increased the risk of being responsible for a fatal crash, no statistically significant interaction was observed between the two drugs.7

Pharmacokinetic studies

Fifteen healthy subjects given alcohol 0.7 g/kg developed peak plasma alcohol levels of 78.25 mg% at 50 minutes, but if they smoked a cannabis cigarette 30 minutes after the drink, their peak plasma alcohol levels were only 54.8 mg% and they occurred 55 minutes later. In addition, their subjective experience of the drugs decreased when used together.5 However, another study found that smoking cannabis 10 minutes before alcohol consumption did not affect alcohol levels.8 A further study found that blood-alcohol levels were not affected by Δ9-tetrahydrocannabinol given orally one hour before alcohol.1

Importance and management

Several studies have found that cannabis and alcohol produce additive detrimental effects on driving performance, but other studies have failed to show any potentiation. This is probably due to the variety of simulated driving tests used and possibly the time lag between the administration of alcohol and cannabis, behavioural impairment after cannabis has been reported to peak within 30 minutes of smoking.5 Nevertheless, both drugs have been shown to affect some aspects of driving performance and increase the risk of fatal car accidents. Concurrent use of cannabis and alcohol before driving should therefore be avoided.9

Alcohol + Carmofur

A disulfiram-like reaction occurred in a patient taking carmofur when he was given a coeliac plexus blockade with alcohol.

Clinical evidence, mechanism, importance and management

A man with pancreatic carcinoma taking carmofur 500 mg daily for 25 days experienced a disulfiram-like reaction (facial flushing, diaphoresis, hypotension with BP 60/30 mmHg, and tachycardia of 128 bpm) within 30 minutes of being given a coeliac plexus alcohol blockade for pain relief. Blood acetaldehyde levels were found to have risen sharply, supporting the belief that the underlying mechanism is similar to the disulfiram-alcohol interaction (see ‘Alcohol + Disulfiram’, p.61). It is suggested that alcohol blockade should be avoided for 7 days after treatment with carmofur.1

Alcohol + Clomethiazole

Clomethiazole has been successfully used to treat alcohol withdrawal, but the long-term use of alcohol with clomethiazole can cause serious, even potentially fatal CNS depression, due to additive CNS depressant effects; fatal respiratory depression can occur even with short-term use in alcoholics with cirrhosis. The concurrent use of clomethiazole and alcohol may also affect driving skills. Clomethiazole bioavailability may be increased by alcohol.

Clinical evidence, mechanism, importance and management

The following is taken from an editorial in the British Medical Journal, which was entitled ‘Chlormethiazole and alcohol: a lethal cocktail’.1

Clomethiazole is commonly used to treat withdrawal from alcohol because of its hypnotic, anxiolytic and anticonvulsant effects. It is very effective if a rapidly reducing dosage regimen is followed over six days, but if it is used long-term and drinking continues it carries serious risks. Alcoholics readily transfer dependency to clomethiazole and may visit several practitioners and hospitals to get their supplies. Tolerance develops so that very large amounts may be needed to be taken (up to 25 g daily). Often alcohol abuse continues and the combination of large amounts of alcohol and clomethiazole can result in coma and even fatal respiratory depression, due mainly to simple additive CNS depression.1

Other factors are that alcohol increases the bioavailability of clomethiazole (probably by impairing first pass metabolism),2 and in the case of those with alcoholic cirrhosis, the systemic bioavailability may be increased tenfold because of venous shunting.3 However, one study in 6 healthy subjects reported that intravenous alcohol 0.8 mL/kg given acutely had no effect on the disposition or elimination of clomethiazole. It was proposed that alcohol given orally might affect the absorption or rate of uptake of clomethiazole.4

Clomethiazole should not be given long-term for alcohol withdrawal states1 or to those who continue to drink alcohol.5 Use for more than 9 days is not recommended.5,6 It has been said that if prescribers choose to manage detoxification at home, it should be done under very close supervision, issuing prescriptions for only one day’s supply to ensure daily contact and to minimise the risk of abuse. And if the patient shows evidence of tolerance or clomethiazole dependency or of continuing to drink alcohol, the only safe policy is rapid admission for inpatient care.1 The manufacturer warns that alcohol combined with clomethiazole particularly in alcoholics with cirrhosis can lead to fatal respiratory depression even with short-term use.5

(b) Effects on driving and related skills

There do not appear to be any studies on the combined effects of clomethiazole and alcohol on driving and related skills, but concurrent use would be expected to increase the risks. There is a report of a man who had a blood-alcohol level of 23 mg% who was driving dangerously and caused a traffic accident. The clinical signs

References

2. National Highway Traffic Safety Administration. Marijuana and alcohol combined severely increase the risk of fatal car accidents. Concurrent use of cannabis and alcohol before driving should therefore be avoided.

4. Laumon B, Gadeqbeku B, Martin J-L, Biecheler M-B; the SAM Group. Cannabis intoxication and drank alcohol (to achieve an initial blood level of 70 mg%, with further drinks taken to maintain levels at 40 mg% 30 minutes before driving. They found that cannabis, even in low to moderate doses, negatively affected driving performance in real traffic situations. Further, the effect of combining moderate doses of both alcohol and cannabis resulted in dramatic performance impairment as great as that observed with blood-alcohol levels of 140 mg% alone.2,3

of impairment were far greater than expected and further analysis of the blood sample identified a high level of clomethiazole (5 mg/L). In 13 other impaired driving cases where clomethiazole was detected in blood samples, the concentrations ranged from 0.3 to 3.3 mg/L. The manufacturer warns that clomethiazole may potentiate or be potentiated by CNS depressants, including alcohol.5

Alcohol + CNS depressants

The concurrent use of small or moderate amounts of alcohol and therapeutic doses of drugs that are CNS depressants can increase drowsiness and reduce alertness. These drugs include antidepressants, antiemetics, antiepileptics, antihistamines, antipsychotics, anxiolytics, barbiturates, hypnotics, opioid analgesics, skeletal muscle relaxants, and others. This increases the risk of accident when driving or handling other potentially dangerous machinery, and may make the performance of everyday tasks more difficult and hazardous.

Alcohol + CNS depressants

Both alcohol and cloral hydrate are CNS depressants, and their effects may be at least additive, or possibly even synergistic. Some patients may experience a disulfiram-like flushing reaction if they drink alcohol after taking cloral hydrate for several days.

Clinical evidence

Studies in 5 healthy subjects given cloral hydrate 15 mg/kg and alcohol 0.5 g/kg found that both drugs given alone impaired their ability to carry out complex motor tasks. When taken together, the effects were additive, and possibly even more than additive. After taking cloral hydrate for 7 days, one of the subjects experienced a disulfiram-like reaction (bright red-purple flushing of the face, tachycardia, hypotension, anxiety and persistent headache) after drinking alcohol.1,2 The disulfiram-like reaction has been described in other reports.3 Note that the earliest report was published more than a century ago in 1872 and described two patients taking cloral hydrate who experienced this reaction after drinking half a bottle of beer.2

Mechanism

Alcohol, cloral and trichloroethanol (to which cloral hydrate is metabolised) are all CNS depressants. During concurrent use, the metabolic pathways used for their elimination are mutually inhibited: blood-alcohol levels rise because the trichloroethanol competitively depresses the oxidation of alcohol to acetaldehyde, while trichloroethanol levels also rise because the trichloroethanol competitively depresses the oxidation of alcohol to acetaldehyde during the use of cloral hydrate with alcohol.4 Another similar metabolite produced by the interaction of the two drugs is cocaethylene, an active and potentially toxic metabolite.1

Importance and management

A well-documented and established interaction, which has been comprehensively reviewed.1,2 Only a few references are given here. Patients given cloral hydrate should be warned about the extensive CNS depression that can occur if they drink, and of the disulfiram-like reaction that may occur after taking cloral hydrate for a period of time. Its incidence is uncertain. The legendary Mickey Finn, which is concocted of cloral hydrate and alcohol, is reputed to be so potent that deep sleep can be induced in an unsuspecting victim within minutes of ingestion, but the evidence seems to be largely anecdotal. Very large doses of both drugs would be likely to cause serious and potentially life-threatening CNS depression.

It seems likely that cloral betaine, triclofos and other compounds closely related to cloral hydrate will interact with alcohol in a similar manner, but this requires confirmation.5

Alcohol + Cocaine

Alcohol increases cocaine levels and the active metabolite cocaethylene. Subjective effects such as euphoria are enhanced and some of the CNS-depressant effects of alcohol, such as sedation, are potentiated by cocaine. The combination may be potentially more toxic, with increased cardiovascular effects particularly heart rate. The use of alcohol with cocaine may increase violent behaviour.

Clinical evidence

A study in 8 cocaine users found that intranasal cocaine 100 mg and alcohol 0.8 g/kg produced a greater euphoria and feeling of well-being than cocaine alone, and reduced alcohol sedation without altering the feeling of drunkenness. Compared with placebo, the peak heart-rate was increased by 17, 23, and 41 bpm, with alcohol, cocaine, or the combination, respectively. In addition, the combination resulted in higher plasma levels of cocaine and the appearance of cocaethylene, an active and potentially toxic metabolite produced by the interaction of the two drugs.1 Another similar study with intranasal cocaine 1 mg/kg every 30 minutes for 4 doses and oral alcohol 1 g/kg reported very similar findings.2 A further study found that intranasal cocaine 96 mg/70 kg improved behavioural performance, measured by the digit symbol substitution test (DSST), whereas alcohol 1 g/kg decreased DSST performance. The combination of alcohol 1 g/kg with intranasal cocaine 48 or 96 mg/70 kg reduced the DSST below that found with cocaine alone. The combination also additively increased heart rate and diastolic blood pressure. The blood-alcohol levels were not significantly affected by the concurrent use of intranasal cocaine.3

Mechanism

In the presence of alcohol, cocaine is metabolised in the liver to cocaethylenes, which appears to have the same stimulant effects as cocaine, but a longer half-life (2 hours compared with about 38 minutes for cocaine). Animal studies suggest that this metabolite is more toxic than cocaine.8

addition, chronic alcohol exposure may facilitate the metabolism of cocaine, promoting the formation of intermediate metabolites that may cause liver damage, potentiating the hepatotoxic properties of alcohol.\(^5\)

**Importance and management**

It has been suggested that the enhanced psychological effects associated with alcohol and cocaine may lead to the use of larger amounts of the combination with an increased risk for toxic effects,\(^2\) such as cardiotoxicity.\(^1\) It has been reported that users of alcohol and cocaine who also have coronary artery disease have 21.5 times the risk for sudden death than users of cocaine alone.\(^1\) The longer half-life of the metabolite cocaethylene explains why many people who experience cocaine-related heart attacks and strokes do so when the cocaine levels in their blood are low, as cocaethylene can remain active in the body for 7 hours after cocaine has disappeared.\(^4\) Patients with coronary artery disease or alcoholics may be particularly vulnerable to the combined toxic effects of alcohol and cocaine.

**Alcohol + Codergocrine mesilate (Ergoloid mesylates)**

Codergocrine mesilate causes a very small reduction in blood-alcohol levels.

**Clinical evidence, mechanism, importance and management**

Thirteen subjects were given 0.5 g/kg of alcohol 25% in orange juice after breakfast, before and after taking 4.5 mg of codergocrine mesilate (ergoloid mesylates, *Hydergine*) every 8 hours for nine doses. The codergocrine caused a small reduction in blood-alcohol levels (maximum serum levels reduced from 59 mg% to 55.7 mg%), and the clearance was reduced by a modest 11%.\(^1\) The reason is not understood. This interaction is almost certainly not of clinical importance.

**Alcohol + Cyproterone acetate**

Excessive alcohol consumption may reduce the antiandrogenic effect of cyproterone acetate in the treatment of hypersexuality, but the relevance of this in prostatic carcinoma is not known; there seems to be no evidence that normal social amounts of alcohol interact.

**Clinical evidence, mechanism, importance and management**

The UK manufacturer of cyproterone acetate says that alcohol appears to reduce its effects, and so it is of no value in chronic alcoholics.\(^1\) This appears to be based solely on a simple and unelaborated statement in an abstract of studies\(^2\) in 84 men whose hyper- or abnormal sexuality was not of clinical importance.\(^2\) It would seem prudent to limit alcohol intake in patients taking cyproterone.

**Alcohol + Disopyramide**

In healthy subjects, the renal clearance of disopyramide may be slightly increased by alcohol-induced diuresis.

**Clinical evidence, mechanism, importance and management**

A crossover study in 6 healthy subjects found that the half-life and total body clearance of disopyramide were not affected by alcohol, but the amount of the metabolite mono-N-dealkylated disopyramide excreted in
the urine was reduced. Alcohol increased diuresis in 5 of the 6 subjects, and the renal clearance of disopyramide was increased by 19% in these subjects.1 The overall clinical effect is likely to be minimal.

### Alcohol + Disulfiram

The ingestion of alcohol while taking disulfiram will result in flushing and fullness of the face and neck, tachycardia, breathlessness, giddiness, hypotension, and nausea and vomiting. This is called the disulfiram or Antabuse reaction. It is used to deter alcoholic patients from drinking. A mild flushing reaction of the skin may possibly occur in particularly sensitive individuals if alcohol is applied to the skin or if the vapour is inhaled.

### Clinical evidence

(a) Alcoholic drinks

One of the earliest descriptions of this toxic interaction was made in 1937 by Dr EE Williams1 who noted it amongst workers in the rubber industry who were handling tetramethylthiuram disulphide:

“Even beer will cause a flushing of the face and hands, with rapid pulse, and some of the men describe palpitations and a terrible fullness of the face, eyes and head. After a glass of beer the blood pressure falls about 10 points, the pulse is slightly accelerated and the skin becomes flushed in the face and wrists. In 15 minutes the blood pressure falls another 10 points, the heart is more rapid, and the patient complains of fullness in the head.”

The later observation2 by Hald and his colleagues of the same reaction with the ethyl congener of tetramethylthiuram disulphide, disulfiram, led to its introduction as an alcoholic drink deterrent. Patients experience throbbing in head and neck, giddiness, sweating, nausea, vomiting, thirst, chest pain, difficulty in breathing, and headache. The severity of the reaction can depend upon the amount of alcohol ingested, but some individuals are extremely sensitive. Respiratory depression, cardiovascular collapse, cardiac arrhythmias, unconsciousness, and convulsions may occur. There have been fatalities.

An unusual and isolated report describes painful, intermittent and transient myoclonic jerking of the arms and legs as the predominant manifestation of the disulfiram reaction in one patient.3 Another unusual case has been reported in which a woman with a history of bipolar disorder and alcoholism, who was taking disulfiram, was admitted to hospital with a 3- to 4-day history of changes in her mental state, including difficulties with orientation, concentration and visual hallucinations. The confusional state was attributed to alcohol consumption while taking disulfiram, and the probability of this was supported by an earlier similar, though less intense episode experienced by the patient.5 Some alcoholics find that disulfiram potentiates the euphoric effects of low doses of alcohol, which alone would be relatively ineffective.

(b) Products containing alcohol

A mild disulfiram reaction is said to occur in some patients who apply alcohol to the skin, but it is probably largely due to inhalation of the vapour.7 It has been reported after using after-shave lotion (50% alcohol),8 tar gel (33% alcohol)9 and a beer-containing shampoo (3% alcohol).10 A contact lens wetting solution (containing polyvinyl alcohol) used to irrigate the eye has also been implicated in a reaction,10,11 although the probability of an interaction with this secondary alcohol has been disputed.12 It has also been described in a patient who inhaled vapour from paint in a poorly ventilated area and from the inhalation of ‘mineral spirits’.13 Furthermore, an unusual case describes a woman taking disulfiram who reported vaginal stinging and soreness during sexual intercourse, and similar discomfort to her husband’s penis, which seemed to be related to the disulfiram dosage and how intoxicated her husband was.14

The UK manufacturer of the oral solution of ritonavir (Norvir) says that since it contains alcohol 43% v/v (which they say is about equivalent to 27 mL of wine per dose) the preparation should not be taken with disulfiram or other drugs such as metronidazole because a disulfiram-like reaction is possible.15 However, in practice the risk is probably fairly small because the recommended dose of ritonavir in this form is only 7.5 mL. Ritonavir (Norvir) soft capsules also contain alcohol 12% w/w.16 The oral concentrate of sertraline (Zoloft oral concentrate) is contraindicated with disulfiram due to the alcohol content (12%).17

### Mechanism

Partially understood. Alcohol is normally rapidly metabolised within the liver, firstly by alcohol dehydrogenase to acetaldehyde, then by acetaldehyde dehydrogenase, and then by a series of biochemical steps to water and carbon dioxide. Disulfiram inhibits the enzyme acetaldehyde dehydrogenase so that the acetaldehyde accumulates.5 The symptoms of the disulfiram-alcohol reaction are due partly to the high levels of acetaldehyde. However, not all of the symptoms can be reproduced by injecting acetaldehyde, so that some other biochemical mechanism(s) must also be involved. The conversion of dopamine to noradrenaline is also inhibited and the depletion of noradrenaline in the heart and blood vessels allows acetaldehyde to act directly on these tissues to cause flushing, tachycardia and hypotension.18 Prostaglandin release may also be involved.19 It has been suggested that the mild skin flush that can occur if alcohol is applied to the skin is not a true disulfiram reaction.20

However, some individuals appear to be more sensitive than others, which might be partially due to liver function and variations in the metabolism of disulfiram to its active metabolite by the cytochrome P450 isoenzymes.21,22 Disulfiram is eliminated slowly from the body and ingestion of alcohol may produce unpleasant symptoms up to 14 days after taking the last dose of disulfiram.23

### Importance and management

An extremely well-documented and important interaction exploited therapeutically to deter alcoholics from drinking alcohol. Initial treatment should be closely supervised because an extremely intense and potentially serious reaction occurs in a few individuals, even with quite small doses of alcohol. Apart from the usual warnings about drinking alcohol, patients should also be warned about the unwitting ingestion of alcohol in some pharmaceutical preparations.24 The risk of a reaction is real. It has been seen following a single-dose of an alcohol-containing cough mixture,25 whereas the ingestion of small amounts of communion wine and the absorption of alcohol from a bronchial nebuliser spray or ear drops did not result in any reaction in 3 individuals.26 The severity of the reaction is reported to be proportional to the dosage of both disulfiram and alcohol.23 Patients should also be warned about the exposure to alcohol from some foods, cosmetics, solvents etc. The manufacturers advise that certain foods (sauces and vinegars), liquid medicines, remedies (cough mixtures, tonics, back rubs), and toiletries (aftershave, perfumes and aerosol sprays) may contain sufficient alcohol to elicit a reaction.18,23 Caution should also be exercised with low-alcohol and “non-alcohol” or “alcohol-free” beers and wines, which may provoke a reaction when consumed in sufficient quantities.18

### Treatment

The disulfiram reaction can be treated, if necessary, with ascorbic acid. A dose of 1 g given orally is reported to be effective in mild cases (heart rate less than 100 bpm and general condition good). It works within 30 to 45 minutes. Moderately severe cases (heart rate 100 to 150 bpm, blood pressure 150/100 mmHg) can be treated with 1 g of intravenous ascorbic acid.45 minutes. Moderately severe cases (heart rate 100 to 150 bpm, blood pressure 150/100 mmHg) can be treated with 1 g of intravenous ascorbic acid.4

7. Mercuro F. Antabuse®-alcohol reaction following the use of after-shave lotion. JAMA (1952) 149, 82.

Alcohol + Ecstasy

Ecstasy may reduce subjective sedation associated with alcohol, without reversing the effects of alcohol on impulsivity or psychomotor skills. Alcohol may enhance the transient immune dysfunction associated with ecstasy. Alcohol may slightly increase the plasma levels of ecstasy, while alcohol levels may be slightly reduced by ecstasy.

Clinical evidence, mechanism, importance and management

Note that the chemical name of ecstasy is methylenedioxymethamphetamine (MDMA).

(a) Effect on behaviour or psychomotor skills

A study in 9 healthy subjects found that the combination of alcohol 0.8 g/kg and ecstasy 100 mg induced a longer lasting euphoria and sense of well-being than either ecstasy or alcohol alone. Ecstasy reversed the subjective feelings of sedation associated with alcohol, but did not reverse feelings of drunkenness, or the effects of alcohol on psychomotor performance.1 Similarly, in a double-blind, placebo-controlled, crossover study in 18 recreational users of ecstasy, alcohol-induced impairment in response inhibition tasks was not affected by single 75- or 100-mg doses of ecstasy. This indicated that the CNS-stimulating effects of ecstasy do not overcome alcohol-induced impairment of impulse-control or risk-taking behaviour.2 This may have implications for road safety, as subjects may consider they are driving better when actual performance is impaired by alcohol.3 More study is needed. Consider also ‘Alcohol + Amphetamines’, p.42.

(b) Effect on immune system

A study in 6 healthy subjects found that a single dose of ecstasy produced a time-dependent immune dysfunction. Ecstasy impaired CD4 T-cell function, which is responsible for cellular immunity. Alcohol alone may produce a decrease in T-helper cells and in B lymphocytes, which are responsible for humoral immunity. Concurrent ecstasy and alcohol increased the suppressive effect of ecstasy on CD4 T-cells and increased natural killer cells. It was suggested that the transient defect in immunological homeostasis could have clinical consequences such as increased susceptibility to infectious diseases.4 More study is needed.

(c) Pharmacokinetic studies

A study in 9 healthy subjects found that alcohol 0.8 g/kg increased the maximum plasma levels of a single 100-mg dose of ecstasy by 13%, with no change in AUC. The AUC and maximum plasma levels of alcohol were reduced by 9% and 15%, respectively, after ecstasy use.5 Another single-dose study in 18 recreational users of ecstasy found a similar decrease in mean blood-alcohol levels and a small increase in ecstasy levels when the two drugs were given together, but the results were not statistically significant.6

Alcohol + Edible fungi

A disulfiram-like reaction can occur if alcohol is taken after eating the smooth ink(y) cap fungus (Coprinus atramentarius) or certain other edible fungi.

Clinical evidence

A man who drank 3 pints of beer 2 hours after eating a meal of freshly picked and fried ink(y) caps (Coprinus atramentarius) developed facial flushing and a blotchy red rash over the upper half of his body. His face and hands swelled and he became breathless, sweat profusely, and vomited during the 3 hours when the reaction was most severe. On admission to hospital he was tachycardic and 12 hours later he was in atrial fibrillation, which lasted for 60 hours. The man’s wife, who ate the same meal but without an alcoholic drink, did not show the reaction.7

This reaction has been described on many occasions in medical and pharmacological reports8,9 and in books devoted to descriptions of edible and poisonous fungi. Only a few are listed here. Mild hypotension and ‘... alarming orthostatic features. ...’ are said to be common symptoms but the arrhythmia seen in the case cited here10 appears to be rare. Recovery is usually spontaneous and uncomplicated. A similar reaction has been described after eating Boletus luridus,12 and other fungi including Coprinus micaceus, Clitocybe claviceps and certain morels.13

An African relative of Coprinus atramentarius, Coprinus africanus, which also causes this reaction, is called the Ajeimutin fungus by the Nigerian Yoruba people. The literal translation of this name is ‘eat-without-drinking-alcohol’ mushroom.14

Mechanism

An early and attractive idea was that the reaction with Coprinus atramentarius was due to the presence of disulfiram (one group of workers actually claimed to have isolated it from the fungus15), but this was not confirmed by later work,16,17 and it now appears that the active ingredient is coprine (N-5-(1-hydroxycyclopropyl)-glutamine).16,18 This is metabolised in the body to l-aminoacrylopropanol, which appears, like disulfiram, to inhibit aldehyde dehydrogenase (see ‘Alcohol + Disulfiram’, p.61). The active ingredients in the other fungi are unknown.

Importance and management

An established and well-documented interaction. It is said to occur up to 24 hours after eating the fungus. The intensity depends upon the quantity of fungus and alcohol consumed, and the time interval between them.14,17 Despite the widespread consumption of edible fungi and alcohol, reports of this reaction in the medical literature are few and far between, suggesting that even though it can be very unpleasant and frightening, the outcome is usually uncomplicated. Treatment appears normally not to be necessary.

The related fungus Coprinus comatus (the ‘shaggy ink cap’ or ‘Lawyers wig’) is said not to interact with alcohol,18,19 nor is there anything to suggest that it ever occurs with the common field mushroom (Agaricus campestris) or the cultivated variety (Agaricus bistorps).18

Alcohol + Fluvastatin

Alcohol does not significantly interact with fluvastatin.

Clinical evidence, mechanism, importance and management

Ten healthy subjects took a single 40-mg dose of fluvastatin and 70 g of alcohol diluted in lemonade. This acute ingestion of alcohol had no effect on the peak serum levels of fluvastatin or its AUC, but the half-life was reduced by about one-third.1 In a second related study, 20 patients with hypercholesterolaemia were given 40 mg of fluvastatin and 20 g of alcohol daily for 6 weeks. The AUC of fluvastatin was slightly increased and the half-life was increased by almost one-third, but the lipid profile with fluvastatin plus alcohol was little different from fluvastatin alone.1,2 The conclusion was reached that although long-term moderate drinking has some small effect on the pharmacokinetics of fluvastatin, its safety and efficacy are unaltered. There would seem to be no reason for patients taking fluvastatin to avoid alcohol.

Alcohol + Food

Food and milk decrease the absorption of alcohol and meals increase the metabolism of alcohol. Foods rich in serotonin (e.g. bananas) taken with alcohol may produce adverse effects such as diarrhea and headache. Previous alcohol consumption and the glycemic load of a meal appear to interact to influence both mood and memory.

Clinical evidence, mechanism, importance and management

(a) Alcohol absorption and metabolism

In one study 10 subjects were given 25 mL of alcohol (equivalent to a double whiskey) after drinking a pint and a half of water or milk during the previous 90 minutes. Blood-alcohol levels at 90 minutes were reduced by about 40%, and at 120 minutes by about 25% by the presence of the milk. The intoxicating effects of the alcohol were also clearly reduced.1 In a randomized, crossover study, 24 healthy subjects were given alcohol 0.3 g/kg about 40%, and at 120 minutes by about 25% by the presence of the milk. The intoxicating effects of the alcohol were also clearly reduced.1 In a randomized, crossover study, 24 healthy subjects were given alcohol 0.3 g/kg

(b) Dietary serotonin

Serotonin (5-hydroxytryptamine, 5-HT) is excreted in the urine as 5-hydroxyindole-3-acetic acid (5-HIAA) and 5-hydroxytryptophol (5-HTOL) and the ratio of 5-HTOL to 5-HIAA is normally very low (less than 0.01). A study in 10 healthy subjects found that 4 hours after the ingestion of alcohol 0.5 g/kg the ratio was increased by about 70-fold. When the same amount of alcohol was given with 3 bananas, a food rich in 5-HT, the ratio was increased about 100-fold at 4 hours and was still significantly raised at 24 hours. Within 4 hours, 7 of the 10 subjects experienced adverse effects including diarrhoea, headache and fatigue. The symptoms were attributed to high levels of 5-HTOL, which is usually a minor metabolite of serotonin. Other foods rich in serotonin such as pineapple, kiwi fruit or walnuts may produce similar effects if taken with even moderate amounts of alcohol.

Alcohol + Furazolidone

A disulfiram-like reaction may occur in patients taking furazolidone if they drink alcohol.

Clinical evidence

A patient taking furazolidone 200 mg four times daily complained of facial flushing, lachrymation, conjunctivitis, weakness, and light-headedness within 10 minutes of drinking beer. It occurred on several occasions and lasted 30 to 45 minutes.1 A man prescribed furazolidone 100 mg four times daily and who had taken only three doses, developed intense facial flushing, wheezing and dyspnoea (lasting one hour), within one hour of drinking 2 oz (about 60 mL) of brandy. The same thing happened again the next day after drinking a Martini cocktail. No treatment was given.2 A report originating from the manufacturers of furazolidone stated that by 1976, 43 cases of a disulfiram-like reaction had been reported, of which 14 were produced experimentally using above-normal doses of furazolidone.3 A later study in 1986 described 9 out of 47 patients (19%) who complained of a disulfiram-like reaction after drinking alcohol while taking furazolidone 100 mg four times daily for 5 days.4

Mechanism

Uncertain. It seems possible that furazolidone acts like disulfiram by inhibiting the activity of acetaldehyde dehydrogenase (see ‘Alcohol + Disulfiram’, p.61).

Importance and management

An established and clinically important interaction of uncertain incidence. One report suggests that possibly about 1 in 5 may be affected. Reactions of this kind appear to be more unpleasant and possibly frightening than serious, and normally need no treatment, however patients should be warned about what may happen if they drink alcohol.

Alcohol + Glutethimide

The combination of glutethimide and alcohol results in greater impairment in some psychomotor tests, but improvement in others. Alcohol does not interact with glutethimide taken the previous night.

Clinical evidence, mechanism, importance and management

In a series of studies, blood-alcohol levels were raised a mean of 11% by glutethimide, while plasma and urinary glutethimide levels were reduced. Neither glutethimide nor alcohol alone significantly impaired reaction times, but the combination did. However, in two other tests (tracking efficacy and finger tapping) impairment was greatest after glutethimide alone and reduced by the presence of alcohol. In contrast, a later study found that glutethimide did not subjectively or objectively impair the performance of a number of psychomotor skill tests related to driving, and did not interact with alcohol given the morning after the glutethimide dose. Both drugs are CNS depressants and their effects would be expected to be additive.

The information is limited and somewhat contradictory, nevertheless patients should be warned about the probable results of taking glutethimide and alcohol together. Driving, handling dangerous machinery, or undertaking any task needing alertness and full coordination, is likely to be made more difficult and hazardous. There is no evidence of a hangover effect, which could result in an interaction with alcohol the next day.2

Clinical evidence

A study in 6 healthy subjects also found that an interaction between alcohol and promethazine was observed.3

Importance and management

The documentation is extremely sparse, which would seem to suggest that adverse interactions between alcohol and griseofulvin are uncommon. Concurrent use need not be avoided but it may be prudent to warn patients about the possible effects. The disulfiram-like reaction described was unusually severe. The manufacturer cautions that the effects of alcohol may be potentiated by griseofulvin, producing such adverse effects as tachycardia and flush.5

Mechanism

Not understood. The reaction described above might possibly have the same pharmacological basis as the disulfiram/alcohol reaction (see ‘Alcohol + Disulfiram’, p.61).

Alcohol + Glyceryl trinitrate (Nitroglycerin)

Patients who take glyceryl trinitrate while drinking may feel faint and dizzy.

Clinical evidence, mechanism, importance and management

The results of studies1,2 on the combined haemodynamic effects of alcohol and glyceryl trinitrate give support to earlier claims that concurrent use increases the risk of exaggerated hypotension and fainting.3 Their vasodilatory effects4 would appear to be additive. The greatest effect was seen when the glyceryl trinitrate was taken one hour or more after starting to drink alcohol.1 It is suggested that this increased susceptibility to postural hypotension should not be allowed to stop patients from using glyceryl trinitrate if they want to drink alcohol, but they should be warned about the possible effects and told what to do if they feel faint and dizzy (i.e. sit or lie down).1

Clinical evidence

A man took griseofulvin 500 mg daily for about 2 weeks without problems. Subsequently he drank a can of beer, took his usual dose of griseofulvin about one hour later, and within 30 to 60 minutes developed a severe disulfiram-like reaction (flushing, severe nausea, vomiting, diarrhoea, hypotension and paraesthesias of all extremities). He was successfully treated with intravenous sodium chloride 0.9%, potassium, dopamine, and intramuscular promethazine.1

Another isolated case of flushing and tachycardia attributed to the concurrent use of alcohol and griseofulvin has also been described; rechallenge produced the same effects.2

It has been suggested that griseofulvin can increase the effects of alcohol, but the descriptions of this response are very brief. One of them describes a man who had a decreased tolerance to alcohol and emotional instability manifested by crying and nervousness, which was said to be so severe that the drug was stopped. Another4 states that this effect has been noted in a very small number of patients, but gives no further information.

Mechanism

Not understood. The reaction described above might possibly have the same pharmacological basis as the disulfiram/alcohol reaction (see ‘Alcohol + Disulfiram’, p.61).

Alcohol + H2-receptor antagonists

Although some studies have found that blood-alcohol levels can be raised to some extent in those taking some H2-receptor antagonists and possibly remain elevated for longer than usual, others report that no significant interaction occurs. Drinking may worsen the gastrointestinal disease for which these H2-receptor antagonists are being given. Hypoglycaemia associated with alcohol may be enhanced by H2-receptor antagonists.

Clinical evidence

(a) Evidence of an interaction

A double-blind study in 6 healthy subjects found that cimetidine 300 mg four times daily for 7 days, increased the peak plasma levels of alcohol 0.8 g/kg by about 12% (from 146 to 163 mg%) and increased the AUC by about 7%. The subjects assessed themselves as being more intoxicated while taking cimetidine and alcohol than with alcohol alone.1

An essentially similar study2,3 found that the blood-alcohol levels were raised by 17% (from 73 to 86 mg%) by cimetidine but not by ranitidine. However, another study found that cimetidine almost doubled peak blood-alcohol levels, whereas ranitidine raised the levels by about 50%.4 A study in 6 healthy subjects also found that cimetidine 400 mg twice daily for one week approximately doubled the AUC following a single 0.15-g/kg oral dose of alcohol and raised peak alcohol levels by about 33%. No changes were seen when the alcohol was given intravenously.5

A further study in healthy subjects given cimetidine or ranitidine for only 2 days found that peak plasma alcohol levels were raised by 17% and 28%, respectively, and the time that blood levels remained above the 80 mg% mark (the legal driving limit in some countries) was prolonged by about one-third.6
A number of studies have been published which show that cimetidine may increase blood alcohol levels. However, these studies have been criticized for methodological flaws, and the issue remains controversial. Some studies have found that cimetidine increases blood alcohol levels, while others have not. The mechanism by which cimetidine increases blood alcohol levels is not fully understood, but it may involve changes in liver metabolism or gastric emptying. Further research is needed to clarify the role of cimetidine in the absorption of alcohol.
Clinical evidence, mechanism, importance and management

Fourteen healthy subjects, each acting as their own control, were given alcohol (72 g/65 kg as a 25% solution) with and without a ginseng extract (3 g/65 kg) mixed in with it. They drank the alcohol or the alcohol/ginseng mixture over a 45-minute period in 7 portions, the first four at 3-minute intervals and the next three at 10-minute intervals. Measurements taken 40 minutes later showed that the presence of the ginseng lowered blood-alcohol levels by an average of 38.9%. The alcohol levels of 10 subjects were lowered by 32 to 51% by the ginseng, 3 showed reductions of 14 to 18% and one showed no changes at all.3

The reasons for this interaction are uncertain, but it is suggested that ginseng possibly increases the activity of the enzymes (alcohol and aldehyde dehydrogenase)2 that are concerned with the metabolism of the alcohol. There are reports of idiosyncratic hepatotoxicity.3 It was found that kava alone had no effect on the tests, but when given with alcohol it potentiated both the perceived and measured impairment that occurred with alcohol alone.1 However, another study found that a kava extract (WS 1490) did not enhance the negative effects of alcohol on performance tests.2

No very strong conclusions can be drawn from the results of the studies, but it is possible that car driving and handling other machinery may be more hazardous if kava and alcohol are taken together. However, note that the use of kava-kava to treat alcoholic patients and those with acute alcohol intoxication,1 Panax ginseng has been shown to reduce voluntary alcohol intake in animals.3

Alcohol + Herbal medicines; Kava

There is some evidence that kava may worsen the CNS depressant effects of alcohol.

Clinical evidence, mechanism, importance and management

Forty healthy subjects underwent a number of cognitive tests and visuo-motor tests after taking alcohol alone, kava (Kava-Kava; the pepper plant Piper methysticum) alone, or both together. The subjects took 0.75 g/kg of alcohol (enough to give blood alcohol levels above 50 mg%) and the kava dose was 1 g/kg. The kava drink was made by mixing middle grade Fijian kava with water and straining it to produce about 350 mL of kava liquid. It was found that kava alone had no effect on the tests, but when given with alcohol it potentiated both the perceived and measured impairment that occurred with alcohol alone.1 However, another study found that a kava extract (WS 1490) did not enhance the negative effects of alcohol on performance tests.2

No very strong conclusions can be drawn from the results of the studies, but it is possible that car driving and handling other machinery may be more hazardous if kava and alcohol are taken together. However, note that the use of kava-kava is restricted in the UK because of reports of idiosyncratic hepatotoxicity.3

Alcohol + Herbal medicines; Liv.52

Liv.52, an Ayurvedic herbal remedy, appears to reduce the hangover symptoms after drinking, reducing both urine and blood-alcohol and acetaldehyde levels at 12 hours. However it also raises the blood alcohol levels of moderate drinkers for the first few hours after drinking.

Clinical evidence

Nine healthy subjects who normally drank socially (alcohol 40 to 100 g weekly) took six tablets of Liv.52 two hours before drinking alcohol (four 60 mL doses of whiskey, equivalent to 90 g of alcohol). Their blood-alcohol levels at one hour were increased by 15% (from 75 to 86.2 mg%). After taking three tablets of Liv.52 daily for two weeks, their 1-hour blood-alcohol levels were raised by 27% (from 75 to 95.3 mg%).1 Acetaldehyde levels in the blood and urine were markedly lowered at 12 hours, and hangover symptoms seemed to be reduced.1 In a similar study, the blood-alcohol levels of 9 moderate drinkers were raised over the first 2 hours by about 28 to 44% after taking three tablets of Liv.52 twice daily for two weeks, and by 17 to 19% over the following 2 hours.2 Only a minor increase in the blood-alcohol levels of 8 occasional drinkers occurred.2

Mechanism

Not understood. Liv.52 contains the active principles from Capparis spinosa, Cichorium intybus, Solanum nigrum, Cassia occidentalis, Terminalia arjuna, Achillea millefolium, Tamarix gallica and Phyllanthus amarus.1 These appear to increase the absorption of alcohol, or reduce its metabolism by the liver, thereby raising the blood-alcohol levels. It is suggested that the reduced hangover effects may possibly occur because it prevents the binding of acetaldehyde to cell proteins allowing a more rapid elimination.1

Importance and management

Direct pharmacokinetic evidence seems to be limited to these two studies.1,2 Liv.52 appears to reduce the hangover effects after drinking, but at the same time it can significantly increase the blood alcohol levels of moderate drinkers, for the first few hours after drinking. Increases of up to 30% may be enough to raise the blood alcohol from legal to illegal levels when driving. Moderate drinkers should be warned. Occasional drinkers appear to develop higher blood-alcohol levels than moderate drinkers but Liv.52 does not seem to increase them significantly.2

Alcohol + Hormonal contraceptives

The detrimental effects of alcohol may be reduced to some extent in women taking oral contraceptives, but alcohol clearance may also possibly be reduced. Alcohol does not affect the pharmacokinetics of ethinylestradiol.

Clinical evidence, mechanism, importance and management

(a) Effect of oral contraceptives on alcohol

A controlled study in 54 women found that those taking a combined oral contraceptive (30, 35, or 50 micrograms of oestrogen) unexpectedly tolerated the effects of alcohol better than those not taking oral contraceptives (as measured by a reaction-time test and a bead-threading test), but their blood-alcohol levels and its rate of alcohol clearance were unchanged.1 For mention of a trend towards improved cognitive performance with small amounts of alcohol and oestrogen replacement therapy, see “Alcohol + HRT”, p.67.

The authors say that they do not recommend women taking oral contraceptives should attempt to drink more than usual, since even if alcohol is tolerated better, blood-alcohol levels are not reduced.1 However, two other studies suggest that peak blood-alcohol levels may be reduced in those taking oral contraceptives, but alcohol clearance is also reduced and so alcohol may be present longer in women who are taking oral contraceptives.2,3

(b) Effect of alcohol on oral contraceptives

Alcohol ingestion did not have any significant effect on ethinylestradiol pharmacokinetics in 9 healthy women taking a combined oral contraceptive (ethinylestradiol/gestodene 30/75 micrograms). In this study, alcohol was given as a single dose of 0.4 g/kg (2 to 3 standard drinks) on day 14 then 0.4 g/kg twice daily for 7 days. The findings of this study contrast

with those of the effect of alcohol on estradiol in postmenopausal women (see ‘Alcohol + HRT’, below). This may be because the ethinylestradiol confers protection from the effects of alcohol.4

Alcohol + HRT

Acute ingestion of alcohol markedly increases the levels of circulating estradiol in women using oral HRT; a smaller increase is seen with transdermal HRT. In addition, alcohol intake appears to increase the risk of breast cancer in women receiving HRT. Small amounts of alcohol may possibly improve some aspects of cognitive function in patients using HRT. Estradiol does not affect blood-alcohol levels.

Clinical evidence, mechanism, importance and management

(a) Hormone and blood-alcohol levels

Twelve healthy postmenopausal women receiving HRT (estradiol 1 mg daily and medroxyprogesterone acetate 10 mg daily for 10 out of each 25 days) were given an alcoholic drink (0.7 g/kg, a dose shown to achieve mean peak alcohol serum levels of about 97 mg% after about 1 hour) during the oestrogen-only phase of the HRT cycle. It was found that their peak estradiol levels rose threefold and were significantly above the baseline.1 A similar, small 1.2-fold increase in peak ethinylestradiol levels was seen in another study when women using transdermal estradiol were given alcohol.2

The reasons for these changes are not understood. Alcohol can increase endogenous estradiol levels in postmenopausal women, although the findings are variable. Another possible explanation is altered clearance of estradiol in women who drink alcohol.3 Note that alcohol does not affect ethinylestradiol levels, see ‘Alcohol + Hormonal contraceptives’, p.66.

(b) Risk of breast cancer

Since both alcohol and HRT are linked with a small increase in breast cancer risk, it has been postulated that the combination of HRT and alcohol could be additive.4 A prospective study of 51,847 postmenopausal women confirmed an association with alcohol intake and breast cancer risk (for oestrogen receptor-positive (ER+) tumours, but not ER– tumours). Furthermore, among women who consumed alcohol, postmenopausal hormone use was associated with an increased risk for the development of ER+ tumours. For women with the highest alcohol intake (10 g (approximately 1 drink) or more daily) the relative risk of developing oestrogen receptor-positive/progesterone receptor-positive (ER+PR+) breast cancer was 1.2 and 1.8 for non-users and users of HRT, respectively, compared with non-drinkers who had never used postmenopausal hormones; the relative risk of developing ER–PR– tumours was even greater, being approximately 2.5 and 3.5, respectively.5 Another study also reported a similar increased risk of developing ER+PR+ tumours with alcohol and oestrogen replacement therapy, but only a slight risk for ER+PR– tumours; the risk for ER–PR– breast cancer was, however, greatest.6

Regular consumption of alcohol as low as 1 to 2 drinks per day may possibly contribute to a modest increased risk, and it has been suggested that women taking HRT should limit their alcohol intake;4 about one drink or less per day has been proposed.3 More study is needed to confirm the amount and frequency of alcohol consumption needed to have a deleterious effect in both women who use HRT and in non-users.

(c) Visuospatial performance

A study of 214 postmenopausal women suggested that small amounts of alcohol may enhance visuospatial processes (improved cognitive function measured by block design performance). HRT also appeared to be linked with better visuospatial performance, but only when the task was difficult. There was a trend (not statistically significant) towards improved performance with alcohol consumption (up to approximately half a standard drink per day) and oestrogen replacement therapy.7 For mention of improved tolerance to alcohol in premenopausal women taking oestrogen, see ‘Alcohol + Hormonal contraceptives’, p.66.

Alcohol + Interferons

A study found a reduced response to interferon in patients who drank alcohol.

Clinical evidence, mechanism, importance and management

In a study involving 245 patients, alcohol intake, and its effect on treatment were retrospectively evaluated between 1 and 3 years after diagnosis of hepatitis C virus-related chronic liver disease. Less than 50% of the patients who drank alcohol stopped after being diagnosed with liver disease, despite being advised to abstain from alcohol. Alcohol intake affected fibrosis, especially in women, and response to interferon therapy. Seventeen out of 65 patients (26.1%) who were treated with interferon alfa had a sustained response to therapy. However, the number of responders decreased as alcohol intake increased; there were more drinkers (63.1%) than abstainers (10.7%) among the 73.8% of patients who did not respond.6 One manufacturer notes that hepatotoxicity has been reported with interferon beta-1a and the potential additive toxicity with hepatotoxic drugs such as alcohol has not been determined, and caution is warranted.5

There appears to be insufficient information to suggest that patients receiving interferons should avoid alcohol completely, however, alcohol intake, particularly heavy drinking, may increase the risk of hepatotoxicity with interferon.

Alcohol + Ivermectin

Alcohol may increase the bioavailability of ivermectin.

Clinical evidence, mechanism, importance and management

Anecdotal reports from Nigeria suggest that ivermectin is more potent when taken with palm wine, a local alcoholic drink, and a few cases of ataxia and postural hypotension occurring with ivermectin were considered to be due to an interaction with alcohol.4 Ivermectin formulated as an alcoholic solution has been found to have about twice the systemic availability of tablets and capsules.5 In another study, 20 healthy subjects were given ivermectin 150 micrograms/kg with either 750 mL of beer (alcohol 4.5%) or 750 mL of water. Plasma levels of ivermectin at 1 to 4 hours were increased by about 51% to 66%, respectively, when it was given with beer, when compared with water. No adverse effects were reported in either group.5 The evidence suggest that concurrent use may be of benefit.
A few cases of disulfiram-like reactions have been reported in patients who drank alcohol while taking ketoconazole.

Clinical evidence, mechanism, importance and management

One patient (an alcoholic), out of group of 12 patients with Candida infections taking ketoconazole 200 mg daily, experienced a disulfiram-like reaction (nausea, vomiting, facial flushing) after drinking alcohol. No further details are given, and the report does not say whether any of the others drank alcohol. A woman taking ketoconazole 200 mg daily developed a disulfiram-like reaction when she drank alcohol. Another report describes a transient ‘sunburn-like’ rash or flush on the face, upper chest and back of a patient taking ketoconazole 200 mg daily when she drank modest quantities of wine or beer. The reasons for the reactions are not known but it seems possible that ketoconazole may act like disulfiram and inhibit the activity of acetaldehyde dehydrogenase (see ‘Alcohol + Disulfiram’, p.61). The incidence of this reaction appears to be very low (these appear to be the only reports) and its importance is probably small. Reactions of this kind are usually more unpleasant than serious, with symptoms resolving within a few hours. Nevertheless, the manufacturer advises avoidance of alcohol while taking ketoconazole.

Alcohol + Meprobamate

Clinical evidence, mechanism, importance and management

A study in 22 subjects, given meprobamate 400 mg four times daily for one week, showed that with blood-alcohol levels of 50 mg% their performance of a number of coordination and judgement tests was much more impaired than with either drug alone. Four of the subjects were quite obviously drunk while taking both meprobamate and alcohol showed marked incoordination and social disinhibition. Two could not walk without assistance. The authors say this effect was much greater than anything seen with alcohol alone.

Alcohol + Mefloquine

Mefloquine does not normally appear to interact with alcohol, although excessive alcohol may possibly contribute to its adverse effects on the liver. An isolated report describes two incidents of severe psychosis and depression in a man taking mefloquine who drank large quantities of alcohol.

Clinical evidence, mechanism, importance and management

Mefloquine 250 mg or placebo was given to two groups of 20 healthy subjects on three occasions, each time the day before they took enough alcohol to achieve blood levels of about 35 mg%. Mefloquine did not affect blood-alcohol levels, nor did it increase the effects of alcohol on two real-highway driving tests or on psychomotor tests done in the laboratory. In fact, the mefloquine group actually drove better than the placebo group.

The broad picture is that mefloquine appears not to worsen the psychomotor effects of moderate amounts of alcohol. Just why an unusual toxic reaction developed in one individual is not known, although mefloquine alone can increase the risk of psychiatric events. It has been postulated that many of the adverse effects of mefloquine are associated with liver damage, and concurrent insults to the liver, such as from alcohol and dehydration, may be related to the development of severe or prolonged adverse reactions to mefloquine. In a review of 516 published case reports of mefloquine adverse effects, 11 cited alcohol as a possible contributing factor. It was suggested that travellers taking mefloquine should avoid alcohol particularly within 24 hours of their weekly mefloquine dose. However, the manufacturers have not issued such a warning.

Alcohol + Nizoral Tablets (Ketoconazole)

A patient taking ketoconazole 200 mg daily when she drank large quantities of alcohol.

Clinical evidence, mechanism, importance and management

Summary of product characteristics, and back of a patient taking ketoconazole 200 mg daily when she drank large quantities of alcohol.

Some limited evidence suggests that lithium carbonate combined with alcohol may make driving more hazardous.

Clinical evidence, mechanism, importance and management

In 9 out of 10 healthy subjects alcohol 0.5 g/kg raised the serum levels of a single 600-mg dose of lithium carbonate by 16%. Four subjects had at least a 25% increase in lithium levels. However these rises were not considered to be clinically important. In contrast a study in 20 healthy subjects given lithium carbonate (to achieve lithium serum levels of 0.75 mmol/L) and alcohol 0.5 g/kg, and who were subjected to various psychomotor tests (choice reaction, coordination, attention) to assess any impairment of skills related to driving, indicated that lithium carbonate both alone and with alcohol may increase the risk of an accident. In this study, lithium did not affect blood-alcohol levels. Information is very limited, but patients should be warned about the possible increased risk of driving or other potentially hazardous activities when taking both drugs.

Importance and management

A well-documented and potentially serious interaction. Normal daily dosages of meprobamate in association with relatively moderate blood-alcohol levels, well within the UK legal limit for driving, can result in obviously hazardous intoxication. Patients should be warned; the patient information leaflet for meprobamate says that alcohol should be avoided.9

Mechanism

Alcohol, methaqualone and ‘diphenhydramine’, (p.47), are all CNS depressants, the effects of which are additive. A hangover can occur because the elimination half-life of methaqualone is long (10 to 40 hours).

Importance and management

An established interaction of importance. Those taking either methaqualone or methaqualone with diphenhydramine should be warned that handling machinery, driving a car, or any other task requiring alertness and full coordination, will be made more difficult and hazardous if they drink alcohol. Levels of alcohol below the legal driving limit with normal amounts of methaqualone may cause considerable sedation. Patients should also be told that a significant interaction may possibly occur the following day, because it has a long half-life.

Note that methaqualone has been withdrawn from the market in many countries because of problems of abuse.

Alcohol 69

Alcohol has been tolerated in patients receiving mercaptopurine.

Clinical evidence, mechanism, importance and management

A study in 207 patients with inflammatory bowel disease assessed (using a phone survey) the presence of adverse reactions to alcohol in patients taking chronic mercaptopurine and/or methotrexate or neither drug. All of the patients consumed less than 4 alcoholic beverages per day. The proportion of patients experiencing any clinically significant adverse effects was: mercaptopurine group 16.3%, methotrexate group 14.5%, control group (not taking either drug) 8.97%. Although there was a trend towards more adverse effects in the drug study groups, this was not statistically significant. The authors suggest a cautious trial of alcohol is advisable in patients that are starting and will be taking either of the medications on a chronic basis.1

1. Ginzburg L, Present DH. Alcohol is well tolerated in IBD patients taking either metronidazole or 6-mercaptopurine. Am J Gastroenterol (2003) 98 (Suppl), S241.

Alcohol + Methotrexate

There is some inconclusive evidence that the consumption of alcohol may increase the risk of methotrexate-induced hepatic cirrhosis and fibrosis.

Clinical evidence, mechanism, importance and management

It has been claimed that alcohol can increase the hepatotoxic effects of methotrexate.1 Two reports of patients treated for psoriasis indicate that this may be so; in one, 3 out of 5 patients with methotrexate-induced cirrhosis were reported to have taken alcohol concurrently (2 patients greater than 85 g, one patient 25 to 85 g of alcohol per week),2 and in the other, the subject was known to drink excessively.3 The evidence is by no means conclusive and no direct causal relationship has been established. However, the manufacturers of methotrexate advise the avoidance of drugs, including alcohol, which have hepatotoxic potential,4 and contraindicate its use in patients with alcoholism or alcoholic liver disease.5

tobolite, efelphenidinate, which has CNS activity. However, a more recent study found that the efelphenidinate formed is predominantly of the inactive enantiomer, so is unlikely to contribute to the additive CNS effects of alcohol and efelphenidinate.

The manufacturer of efelphenidinate advises that alcohol may exacerbate the CNS effects of efelphenidinate and therefore recommends that alcohol should be avoided during treatment. In addition, efelphenidinate should be given cautiously to patients with a history of drug dependence or alcoholism because of its potential for abuse.

Alcohol + Metoclopramide

There is some evidence that metoclopramide can increase the rate of absorption of alcohol, raise maximum blood-alcohol levels, and possibly increase alcohol-related sedation.

Clinical evidence, mechanism, importance and management

A study in 7 subjects found that 20 mg of intravenous metoclopramide increased the rate of alcohol absorption, and the peak blood levels were raised from 55 to 86 mg%. Similar results were seen in 2 healthy subjects given metoclopramide orally. Another study in 7 healthy subjects found that 10 mg of intravenous metoclopramide accelerated the rate of absorption of alcohol 70 mg/kg given orally, and increased its peak levels, but not to a statistically significant extent. Blood alcohol levels remained below 12 mg%. More importantly the sedative effects of the alcohol were increased. The reasons for this effect are not fully understood, but it appears to be related to an increase in gastric emptying. These two studies were done to find out more about intestinal absorption mechanisms rather than to identify daily practicalities, so the importance of the findings is uncertain. However, it seems possible that the effects of alcohol will be increased. Metoclopramide alone can sometimes cause drowsiness, and if affected, patients should not drive or operate machinery.

Alcohol + Mirtazapine

The sedative effects of mirtazapine may be increased by alcohol.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects alcohol (equivalent to 60 g) had a minimal effect on plasma levels of mirtazapine 15 mg. However the sedation and CNS impairment seen with mirtazapine is additive with that produced by alcohol, and the manufacturers recommend avoiding concurrent use. Mirtazapine does not affect the absorption of alcohol.

Clinical evidence, mechanism, importance and management

(a) Baclofen

The manufacturer of baclofen warns that baclofen may enhance the sedative effect of alcohol. However, tolerance to baclofen’s sedative effect has been reported in alcohol-addicted patients after a period of abstinence, as well as after a relapse.

(b) Dantrileone

The manufacturer of dantrileone advises caution if it is given with alcohol and the patient information leaflet suggests that alcohol should be avoided because it may increase drowsiness.

(c) Methocarbamol

Fatal cerebral anoxia produced by CNS respiratory depression occurred in a 31-year-old man after ingestion of significant amounts of methocarbamol and alcohol. Two other lethal overdoses have been reported with these 2 drugs. In all 3 cases the methocarbamol doses exceeded the recommended daily dosages, but were estimated to be less than the reported maximum tolerated single dose of 12 g. Acute alcohol intoxication combined with methocarbamol usage can lead to combined CNS depression, which may be sufficient to cause death. The manufacturers of methocarbamol warn that it may potentiate the effects of alcohol and the patient information leaflet suggests that patients taking methocarbamol should avoid alcohol.

(d) Other muscle relaxants

For enhanced CNS effects with alcohol with other muscle relaxants, see ‘benzodiazepines’, (p.53), ‘meprobamate’, (p.68), and ‘tizanidine’, (p.1287).

Alcohol + Nefazodone

In one study nefazodone 400 mg was found not to increase the sedative-hypnotic effects of alcohol.

Alcohol + Niclosamide

Alcohol may possibly increase the adverse effects of niclosamide.

Clinical evidence, mechanism, importance and management

The manufacturer of niclosamide advises avoiding alcohol while taking niclosamide. The reasoning behind this is that while niclosamide is virtually insoluble in water, it is slightly soluble in alcohol, which might possibly increase its absorption by the gut, resulting in an increase in its adverse effects. There are no formal reports of this but the manufacturer says that they have some anecdotal information that is consistent with this suggestion.

Alcohol + Nicotine

Nicotine (as a patch) may possibly enhance the effect of alcohol on heart rate and reduce the time to peak alcohol levels. The concur-
rent use of alcohol and a nicotine nasal spray did not affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 12 otherwise healthy tobacco smokers found that alcohol-induced increases in heart rate were enhanced by pretreatment with a 21-mg nicotine transdermal patch. The time to peak alcohol levels with a 0.4 g/kg dose of ethanol was faster with nicotine pretreatment (43 minutes compared with 52 minutes, respectively); however, this effect was not seen with a 0.7 g/kg dose of ethanol. Another study in 12 otherwise healthy tobacco smokers found that although alcohol 0.4 or 0.8 g/kg (equivalent to approximately 2 or 4 drinks, respectively) influenced selected subjective responses and heart rate, pre-treatment with alcohol did not affect the subjects responses to low-dose nicotine 3 to 20 micrograms/kg given as a nasal spray (20 micrograms/kg dose is equivalent to about one-half of a cigarette). Neither nicotine or alcohol influenced the blood levels of the other.

Clinical evidence, mechanism, importance and management

An isolated report describes delirium and metabolic acidosis when a patient taking nicotinic acid for hypercholesterolaemia drank about one litre of wine. The manufacturers warn that the concurrent use of nicotinic acid and alcohol may result in an increase in adverse effects such as flushing and pruritus, and possibly liver toxicity.

Clinical evidence, mechanism, importance and management

An isolated report describes delirium and metabolic acidosis when a patient taking nicotinic acid for hypercholesterolaemia drank about one litre of wine. Delirium had occurred on a previous similar occasion after he drank a large quantity of beer while taking nicotinic acid. It is suggested that the nicotinic acid may have caused liver impairment, which was exacerbated by the large amount of alcohol. The patient did have some elevations in liver enzymes. Acidosis has been associated with alcohol intoxication and there has been a report of lactic acidosis associated with high-dose (3 g daily) nicotinic acid treatment, and therefore a combined effect would seem possible. However, no general conclusions can be drawn from this single case.

Hepatic toxicity can occur with nicotinic acid and the manufacturers advise caution in patients who consume substantial quantities of alcohol. They also suggest the avoidance of alcohol around the same time as ingestion of nicotinic acid as the adverse effects of flushing and pruritus may be increased.

Clinical evidence, mechanism, importance and management

In a double-blind study in 11 healthy subjects there were several instances when alcohol 0.25 to 5 g/kg (equivalent to 1 to 3 drinks) enhanced the effects of nitrous oxide 30% in oxygen, inhaled for 35 minutes. Some effects were seen with the drug combination, which were not seen with either drug alone; these included subjective effects and delayed free recall. For mention of the effect of alcohol following anaesthesia, see ‘Anaesthetics, general + Alcohol’, p.92.

Alcohol + Nicotinic acid (Niacin)

An isolated report describes delirium and metabolic acidosis when a patient taking nicotinic acid for hypercholesterolaemia drank about one litre of wine. The manufacturers warn that the concurrent use of nicotinic acid and alcohol may result in an increase in adverse effects such as flushing and pruritus, and possibly liver toxicity.

Clinical evidence, mechanism, importance and management

Alcohol + NSAIDs

Alcohol may increase the risk of gastrointestinal haemorrhage associated with NSAIDs. The skills related to driving are impaired by indometacin and phenylbutazone and this is made worse if patients drink alcohol while taking phenylbutazone, but this does not appear to occur with indometacin. A few isolated reports attribute acute renal failure to the concurrent use of NSAIDs and acute excessive alcohol consumption.

Clinical evidence, mechanism, importance and management

(a) Gastrointestinal complications

In healthy subjects the concurrent use of alcohol with ibuprofen 2.4 g over 24 hours increased the damaging effect of ibuprofen on the stomach wall, although this did not reach statistical significance. A case-control study involving 1224 patients admitted to hospital with upper gastrointestinal bleeding and 2945 controls found that alcohol consumption was associated with a threefold increase in the incidence of acute upper gastrointestinal haemorrhage from light drinking (less than one alcoholic drink per week) to heavy drinking (21 alcoholic drinks or more per week). There was some evidence to suggest that the risk of upper gastrointestinal bleeding was increased by the concurrent use of ibuprofen.

Another case-control study found that the use of prescription NSAIDs or non-prescription naproxen or ibuprofen in those with a history of alcohol abuse produced a ratio of adverse gastrointestinal effects that was greater than the expected additive risk. Both NSAID use and excessive alcohol consumption carry the risk of gastrointestinal adverse effects. This information suggests that NSAIDs should be used with caution in heavy drinkers. The FDA in the US has ruled that non-prescription pain relievers and fever reducers containing ibuprofen, ketoprofen, or naproxen must carry a warning label advising people who consume 3 or more alcoholic drinks every day to consult their doctor before using these drugs, and that stomach bleeding may occur with these drugs.

Consider also ‘Alcohol + Aspirin’, p.51.

(b) Psychomotor skills and alcohol levels

A study in a large number of healthy subjects showed that the performance of various psychomotor skills related to driving (choice reaction, coordination, divided attention tests) were impaired by single doses of indometacin 50 mg or phenylbutazone 200 mg. Alcohol 0.5 g/kg made things worse in those taking phenylbutazone, but the performance of those taking indometacin was improved to some extent. The reasons are not understood. The study showed that the subjects were subjectively unaware of the adverse effects of phenylbutazone. Information is very limited, but patients should be warned if they intend to drive. In two studies, ibuprofen 800 mg had no significant effect on blood-alcohol levels of healthy subjects.

The pharmacokinetics of alcohol 1 g/kg and the results of performance tests were found to be similar in subjects given dipyrone 1 g or a placebo.

No special precautions seem to be necessary.

(c) Renal complications

After taking ibuprofen 400 mg the evening before, 400 mg the following morning, and then 375 mL of rum later in the day, followed by two further 400-mg tablets of ibuprofen, a normal healthy young woman with no history of renal disease developed acute renal failure. Another similar case was reported in a 22-year-old woman who had taken ibuprofen 1.2 g the morning after binge drinking. Both recovered.

A further case describes renal impairment in a young woman, which was associated with the use of ketoprofen 600 mg and binge drinking. It is suggested that volume depletion caused by the alcohol (and compounded by vomiting) predisposed these patients to NSAID-induced renal toxicity. The general importance of these isolated cases remains to be determined.

Alcohol + Nitrous oxide

In a double-blind study in 11 healthy subjects there were several instances when alcohol 0.25 to 5 g/kg (equivalent to 1 to 3 drinks) enhanced the effects of nitrous oxide 30% in oxygen, inhaled for 35 minutes. Some effects were seen with the drug combination, which were not seen with either drug alone; these included subjective effects and delayed free recall. For mention of the effect of alcohol following anaesthesia, see ‘Anaesthetics, general + Alcohol’, p.92.

Alcohol + Olanzapine

Postural hypotension and possibly drowsiness may be increased when alcohol is given with olanzapine.

Clinical evidence, mechanism, importance and management

The manufacturer says that patients taking olanzapine have shown an increased heart rate and accentuated postural hypotension when given a single-dose of alcohol. In a study, 9 of 11 subjects experienced orthostatic hypotension when they drank alcohol one hour after taking olanzapine 10 mg. No pharmacokinetic interaction has been seen. Practical terms this means that patients should be warned of the risk of faintness and dizziness if they stand up quickly. The manufacturers also say that drowsiness is a common adverse effect of olanzapine, and they warn about taking other products that can cause CNS depression, including alcohol. The US manufacturer says that patients should not drink alcohol with olanzapine because of the potential drowsiness that would result.

Alcohol + Opioids

In general the opioid analgesics can enhance the CNS depressant effects of alcohol, which has been fatal in some cases: this appears to be a particular problem with dextropropoxyphene. Alcohol has been associated with rapid release of hydromorphone and morphine from extended-release preparations, which could result in potentially fatal doses. Acute administration of alcohol and methadone appears to increase the blood levels of methadone. The bioavailability of dextropropoxyphene is increased by alcohol, but the bioavailability of the dextropropoxyphene has been reported to be raised by 25 to 31% by alcohol. A retrospective study involving 332 fatal poisonings in Finland found that alcohol was present in 73% of cases involving dextropropoxyphene and, when alcohol was present, relatively small overdoses of dextropropoxyphene could result in fatal poisoning. Further reports describe alcohol reducing the lethal dose of dextropropoxyphene.

(a) Buprenorphine

See under methadone, below.

(b) Codeine

Double-blind studies in a large number of professional army drivers found that 50 mg of codeine and alcohol 0.5 g/kg, both alone and together, impaired their ability to drive safely on a static driving simulator. The number of ‘collisions’, neglected instructions and the times they ‘drove off the road’ were increased. Alcohol does not appear to affect the pharmacokinetics of codeine. See also, controlled-release opioids, below.

(c) Dextropropoxyphene

In a study in 8 healthy subjects, alcohol alone (blood levels of 50 mg%) impaired the performance of various psychomotor tests (motor co-ordination, mental performance and stability of stance) more than dextropropoxyphene 65 mg alone. When given together there was some evidence that the effects were greater than with either drug alone, but in some instances the impairment was no greater than with just alcohol. The effect of alcohol clearly predominated. In contrast, other studies have found that dextropropoxyphene does not enhance the psychomotor impairment seen with alcohol. but the bioavailability of the dextropropoxyphene has been reported to be raised by 25 to 31% by alcohol. A retrospective study involving 332 fatal poisonings in Finland found that alcohol was present in 73% of cases involving dextropropoxyphene and, when alcohol was present, relatively small overdoses of dextropropoxyphene could result in fatal poisoning. Further reports describe alcohol reducing the lethal dose of dextropropoxyphene.

(d) Hydromorphone

A young man died from the combined cardiovascular and respiratory depressant effects of hydromorphone and alcohol. He fell asleep, the serious nature of which was not recognised by those around him. Post-mortem analysis revealed alcohol and hydromorphone concentrations of 90 mg% and 100 nanograms/mL, respectively, neither of which is particularly excessive. A study in 9 healthy subjects found that pre-treatment with hydromorphone 1 or 2 mg did not significantly affect the subject-rated effects of alcohol 0.5 or 1 g/kg. However, hydromorphone enhanced the sedative scores of alcohol on the adjective rating scale. See also, controlled-release opioids, below.

(e) Methadone

A study in 21 opioid-dependent subjects who had been receiving maintenance methadone or buprenorphine for 3 months, and 21 matched non-drug-using controls, found that although alcohol (target blood-alcohol level around 50 mg%) resulted in decreased driving performance, there appeared to be no difference in simulated driving tests in the opioid-treated patients, when compared with controls. It was suggested that restrictions on opioids and driving are not necessary in stabilised patients receiving maintenance buprenorphine or methadone treatment, but little is known about the effects in the initial treatment period. This study also found that blood-alcohol levels were lower in the opioid-treated patients when compared with the controls despite receiving the same amount of alcohol. However, clinical anecdotal reports have indicated that co-ingestion of alcohol and methadone produces an additive and/or synergistic response, which may result in serious respiratory depression and hypotension.

(f) Controlled-release opioids

Pharmacokinetic data in healthy subjects has shown that consuming alcohol with a particular 24-hour extended-release formulation of hydromorphone (Palladone XL Capsules; Purdue Pharma, USA) could lead to rapid release (dose dumping) and absorption of a potentially fatal dose of hydromorphone. Although no reports of serious problems had been received, the FDA in the US asked for the product to be withdrawn from the market. Health Canada warned that this interaction might occur with other slow-release opioid painkillers. However, the Canadian distributor of hydromorphone has commented that the controlled-release technology employed in Palladone XL is not the same as that of many other controlled-release opioid formulations. Dose-dumping with alcohol is said not to occur with:

- morphine sustained-release tablets: MS Contin, MST continua sus-sension tablets, MXL capsules,
- codeine controlled-release tablets: Codeine Contin,
- dihydromorphone controlled-release tablets: DHC Contin tablets,
- hydromorphone controlled-release capsules: Hydromorphp Contin,
- oxycodone controlled-release tablets: OxyContin,
- or tramadol (once daily and twice daily formulations).

In contrast, in laboratory studies, an extended-release capsule preparation of morphine (Avinza; Ligand Pharmaceuticals, USA) was found to release morphine earlier than expected when exposed to alcohol, and this effect increased dramatically with increasing alcohol concentration. The product literature for Avinza now carries a warning to avoid alcohol, including medications containing alcohol, while taking this preparation. Although most opioid preparations do not appear to interact with alcohol in this way, co-ingestion of alcohol and opioid analgesics is never advisable because of the potential for an interaction between CNS depressant drugs, see above.

Mechanism

Both opioids and alcohol are CNS depressants, and there may be enhanced suppression of the medullary respiratory control centre. Acute administration of alcohol appears to increase methadone effects due to inhibition
of hepatic microsomal enzymes, but chronic alcoholism reduces the AUC and half-life of methadone because of induction of cytochrome P450 isoenzymes.\textsuperscript{15}

**Importance and management**

The fatality and increased sedation emphasise the importance of warning patients about the potentially hazardous consequences of drinking while taking potent CNS depressants like the opioids. This seems to be a particular risk with dextropropoxyphene overdose, and it has been suggested that a less dangerous alternative could be chosen when indications of alcohol abuse or suicide risk are present.\textsuperscript{25} The US manufacturers recommend caution when prescribing dextropropoxyphene in patients who use alcohol in excess.\textsuperscript{20} There is less information about therapeutic doses of dextropropoxyphene with moderate social drinking. In general it is suggested that alcohol intake should be avoided where possible, or limited in those taking opioids, but some manufacturers actually recommend adequate alcohol. The objective evidence is that the interaction with moderate doses of alcohol and opioids is quite small (with the exception of the dose dumping effect). It would seem prudent to warn patients that opioids can cause drowsiness and this may be exaggerated to some extent by alcohol. They should be warned that driving or handling potentially hazardous machinery may be more risky, but total abstinence from alcohol does not seem to be necessary. Smaller doses, such as those available without a prescription, would be expected to have a smaller effect, but this does not appear to have been studied.

2. Linnoila M, Mattila MJ. Interaction of alcohol and drugs on psychomotor skills as demonstrated by a driving simulator. *Br J Pharmacol* (1973) 47, 671P–672P.
mediated after stopping alcohol use (the assumed time of greatest susceptibility, see Mechanism, Below). A systematic review by the same research group concluded that the use of therapeutic doses of paracetamol in alcoholic patients is not associated with hepatic injury.

(c) Effect on alcholar levels

Paracetamol 1 g was found to have no effect on the single-dose pharmacokinetics of alcohol in 12 healthy subjects. Another study found that blood-alcohol levels were raised by 1 g of paracetamol but this was not statistically significant. Mechanism

Uncertain. The paracetamol-alcohol interaction is complex, because acute and chronic alcohol consumption can have opposite effects. Paracetamol is usually predominantly metabolised by the liver to non-toxic sulfate and glucuronide conjugates. Persistent heavy drinking appears to stimulate a normally minor biochemical pathway involving the cytochrome P450 isoenzyme CYP2E1, and possibly CYP3A, which allows the production of unusually large amounts of highly hepatotoxic metabolites via oxidation. Unless sufficient glutathione is present to detoxify these metabolites (alcoholics often have an inadequate intake of protein), they become covalently bound to liver macromolecules and damage results. Fasting may also make things worse by reducing the availability of glucose, and thus shifting paracetamol metabolism from glucuronidation towards microsomal oxidation. However, most studies have failed to demonstrate an increase in hepatotoxic metabolites in alcoholics. In fact alcoholics may possibly be most susceptible to toxicity during alcohol withdrawal because, while drinking, alcohol may possibly compete with the paracetamol for metabolism, and even inhibit it. Acute ingestion of alcohol does not influence alcohols possibly protect them against damage because the damaging biochemical pathway is inhibited rather than stimulated. The relative timing of alcohol and paracetamol intake is therefore critical.

Importance and management

The incidence of unexpected paracetamol toxicity in chronic alcoholics is uncertain, but possibly fairly small, bearing in mind the very wide-spread use of paracetamol and alcohol. Note that most of the evidence for an interaction comes from anecdotal case reports and case series, albeit in large numbers. However, the damage, when it occurs, can be serious and therefore some have advised that alcoholics and those who persistently drink heavily should avoid paracetamol or limit their intake considerably. The normal daily recommended ‘safe’ maximum of 4 g is said to be too high in some alcoholics. Because of this, the FDA in the US have required that all paracetamol-containing non-prescription products bear the warning that those consuming 3 or more alcohol drinks every day should ask their doctor whether they should take paracetamol. Others consider that the evidence does not prove that there is an increase in paracetamol hepatotoxicity in alcoholics, and is insufficient to support any change in paracetamol use or dose in alcoholics. They note that the alternatives, aspirin and NSAIDs, are associated with a greater risk of gastrointestinal adverse effects in alcoholics, see ‘Alcohol + Aspirin’, p. 51 and ‘Alcohol + NSAIDs’, p. 71. Further study is needed. The risk for non-alcoholics, moderate drinkers and those who very occasionally drink a lot appears to be low, although some chronic moderate social drinkers may be at risk, especially if they take other agents such as antacids. It is still prudent to consider patients who are alcoholics as being at high risk of hepatotoxicity after a paracetamol overdose, and to treat them with acetylcysteine. Some workers have questioned the use of a lower plasma-paracetamol concentration threshold for the treatment of paracetamol poisoning in alcoholics, but most advocate treatment at the lower threshold. Possible malnutrition and fasting in these patients would further support the need for such treatment.

Alcohol + Paraldehyde

Both alcohol and paraldehyde have CNS depressant effects, which can be additive. The use of paraldehyde in the treatment of acute alcohol intoxication has caused fatalities.

Clinical evidence, mechanism, importance and management

A report describes 9 patients who died suddenly and unexpectedly after treatment for acute alcohol intoxication with 30 to 90 mL of paraldehyde (the authors quote a normal dose range of 8 to 30 mL; fatal dose 120 mL or more, usually preceded by coma). None of the patients had hepatic injury, although one did have some fatty changes. Both drugs are CNS depressants and may therefore be expected to have additive effects at any dosage, although an animal study suggested that it might be less than additive, and cross-tolerance may occur as paraldehyde is pharmacologically similar to alcohol.

Alcohol + Phosphodiesterase type-5 inhibitors

Sildenafil, tadalafl and vardenafil do not usually alter the effects of alcohol on blood pressure, although postural hypotension has been seen in some subjects given tadalafl and alcohol, and headache and flushing has been reported in one patient taking sildenafil.
Alcohol does not affect the pharmacokinetics of tadalafil or vardenafil.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

Sildenafil 50 mg did not potentiate the hypotensive effect of alcohol (mean maximum blood-alcohol levels of 80 mg%) in healthy subjects.1,2 A study in 8 healthy subjects also found that sildenafil 100 mg did not affect the haemodynamic effects of red wine (e.g. heart rate, mean arterial pressure).3 However, a case report describes potentiation of the adverse effects of sildenafil when alcohol was consumed within one hour of taking the drug. A 36-year-old hypertensive patient receiving regular treatment with a calcium-channel blocker (amlodipine) was additionally prescribed sildenafil 25 mg, which he used 3 times a week without any adverse effects. However, after having 2 drinks of whiskey (55.2 g of alcohol) he experienced severe headache and flushing about 15 minutes after taking sildenafil. The next day he took sildenafil 25 mg without any alcohol and no symptoms developed, but one week later, a challenge dose of sildenafil was given after a single 30-mL drink of whiskey and similar symptoms of severe headache and flushing occurred.4 The UK patient information leaflet says that drinking alcohol can temporarily impair the ability to get an erection and advises patients not to drink large amounts of alcohol before taking sildenafil.5

(b) Tadalafil

Studies in subjects given alcohol 0.6 or 0.7 g/kg found that the effect of alcohol on blood pressure was unchanged by tadalafil 20 mg, although some subjects experienced dizziness and postural hypotension. In addition, the effects of alcohol on cognitive function were unchanged by tadalafil 10 mg.6 The pharmacokinetics of tadalafil 10 or 20 mg and alcohol were also unaffected by concurrent use.6,7 However, the manufacturers say that because both alcohol and tadalafil can cause peripheral vasodilation, additive blood pressure lowering effects are possible,7,8 especially with substantial amounts of alcohol (5 units) and the US manufacturer states that this may result in postural hypotension, increased heart rate, dizziness and headache.7 Alcohol may also affect the ability to have an erection.8

(c) Vardenafil

Alcohol (mean blood level of 73 mg%) did not affect the pharmacokinetics of vardenafil 20 mg.9 The effects of alcohol on heart rate and blood pressure were also not affected by vardenafil.9,10 There would therefore seem to be no need to avoid the combination. However, alcoholic drink can worsen erection difficulties,11 this was due to increased acetylation of procainamide to its active metabolite N-acetylprocainamide.1 The clinical relevance of these modest changes is probably small.

Alcohol + Procarbazine

A flushing reaction has been seen in patients taking procarbazine who drank alcohol.

Clinical evidence

One report describes 5 patients taking procarbazine whose faces became very red and hot for a short time after drinking wine.1 Another says that flushing occurred in 3 patients taking procarbazine after they drank beer.2 Two out of 40 patients taking procarbazine in a third study complained of facial flushing after taking a small alcoholic drink, and one patient thought that the effects of alcohol were markedly increased.3 Yet another study describes a ‘flush syndrome’ in 3 out of 50 patients who drank alcohol while taking procarbazine.4

Mechanism

Unknown, but it seems possible that in man, as in rats,5 the procarbazine inhibits acetaldehyde dehydrogenase in the liver causing a disulfiram-like reaction (see ‘Alcohol + Disulfiram’, p.61).

Importance and management

An established interaction but of uncertain incidence. It seems to be more embarrassing, possibly frightening, than serious and if it occurs it is unlikely to require treatment, however patients should be warned. The manufacturers say it is best to avoid alcohol.6 Procarbazine is also a weak MAOI and therefore interactions with certain foodstuffs, including alcoholic drinks, especially heavy red wines, although very rare, must be borne in mind (see ‘Procarbazine + Sympathomimetics’, p.657).

Alcohol + Proton pump inhibitors

Lansoprazole, omeprazole and pantoprazole do not interact with alcohol: other proton pump inhibitors therefore seem unlikely to interact.

Clinical evidence

(a) Lansoprazole

A study in 30 healthy subjects given 0.6 g/kg of alcohol before and after taking lansoprazole 30 mg daily for 3 days found that the pharmacokinetics of alcohol were not significantly changed, and blood-alcohol levels were not raised, by lansoprazole.1

(b) Omeprazole

A number of studies have shown that omeprazole does not affect blood alcohol levels.2,6

(c) Pantoprazole

Pantoprazole 40 mg daily or placebo were given to 16 healthy subjects for 7 days. On day 7 they were also given alcohol 0.5 g/kg in 200 mL of or-
Mechanism
The proton pump inhibitors do not affect alcohol dehydrogenase activity\(^3\)\(^,\)\(^4\) (compare with the ‘H\(_2\)-receptor antagonists’, (p.64)), and would not be expected to alter the first-pass metabolism of alcohol.

Importance and management
The proton pump inhibitors do not appear to interact with alcohol, and no special precautions are necessary with concurrent use. But note that some of the conditions for which these drugs are used may be made worse by alcohol, so restriction of drinking of alcohol may be prudent.

Alcohol + Quetiapine

Postural hypotension and possibly drowsiness may be increased when alcohol is given with quetiapine. Quetiapine does not appear to affect the pharmacokinetics of alcohol.

Clinical evidence, mechanism, importance and management
A randomised, crossover study in 8 men with psychotic disorders found that quetiapine 250 mg three times daily did not affect the mean breath alcohol concentration after they took 0.8 g/kg of alcohol in orange juice. Some statistically significant changes in the performance of psychomotor tests were seen, but these were considered to have little clinical relevance. However, the US manufacturers of quetiapine say that, in clinical studies, the motor and cognitive effects of alcohol were potentiated by quetiapine. Therefore the US manufacturers of quetiapine advise avoiding alcohol, and the UK manufacturers advise caution with the concurrent use of alcohol.\(^3\)\(^,\)\(^4\) Note that drowsiness is the most common adverse effect of quetiapine, occurring in over 10% of patients.\(^1\)\(^,\)\(^2\) Quetiapine may occasionally induce postural hypotension,\(^1\)\(^,\)\(^2\) which could be exacerbated by alcohol administration.

Alcohol + Salbutamol (Albuterol)

A patient with high blood-alcohol levels developed lactic acidosis after being exposed to smoke and receiving salbutamol.

Clinical evidence, mechanism, importance and management
An isolated report describes a 49-year-old male alcoholic who developed severe lactic acidosis after exposure to fire smoke and treatment of bronchospasm with salbutamol. The correction of lactic acidosis followed salbutamol withdrawal and a transitory increase in lactate after salbutamol re-introduction suggested hypersensitivity to salbutamol. However, the patient also had a very high plasma-alcohol level (240 mg%), and the metabolism of the alcohol was thought to have competed with the conversion of lactate to pyruvate resulting in reduced lactate clearance, thus potentiating the acidosis caused by the salbutamol.\(^1\) The clinical significance of this report is unclear as beta agonist-induced exacerbation of lactic acidosis has been reported in asthmatics, both adults and children. The authors of the above report suggest close monitoring of lactate levels in alcoholic patients receiving beta-agonists.\(^1\)

Alcohol + Sibutramine

There does not seem to be a clinically relevant interaction between sibutramine and alcohol.

Clinical evidence, mechanism, importance and management
In a randomised study, 20 healthy subjects were given sibutramine 20 mg with 0.5 g/kg of alcohol diluted in ginger beer, or placebo. Sibutramine did not potentiate the cognitive or psychomotor effects of alcohol, and in one test, sibutramine slightly reduced the impairment caused by alcohol.\(^1\)

Alcohol + Reboxetine

A study in 10 healthy subjects found that reboxetine does not affect cognitive or psychomotor function, and there is no interaction with alcohol.\(^1\)

Alcohol + Retinoids

There is evidence that the consumption of alcohol may increase the serum levels of etretinate in patients taking acitretin. A single case report describes a marked reduction in the effects of isotretinoin following the acute intake of alcohol.

Clinical evidence, mechanism, importance and management
(a) Acitretin
A study in 10 patients with psoriasis taking acitretin found that the concurrent use of alcohol seemed to be associated with an increase in the formation of its metabolite etretinate, which has a much longer half-life than acitretin. The implications of this study are not known, but it is suggested that it may have some bearing on the length of the period after acitretin therapy during which women are advised not to conceive.\(^1\)

(b) Isotretinoin
A former alcoholic, who no longer drank alcohol, was treated for acne conglobata, with some success, with isotretinoin 60 mg daily for 3 months. When for 2 weeks he briefly started to drink alcohol again as part of his job (he was a sherry taster) his skin lesions reappeared and the isotretinoin adverse effects (mucocutaneous dryness) vanished. When he stopped drinking alcohol his skin lesions became controlled again and the drug adverse effects re-emerged. The following year, while receiving another course of isotretinoin, the same thing happened when he started and stopped drinking alcohol. The reasons are not known, but one suggestion is that the alcohol briefly induced the liver microsomal enzymes responsible for the metabolism of isotretinoin, thereby reducing both its therapeutic and adverse effects.\(^2\) The general importance of this apparent interaction is not known.

However, the manufacturer notes that the consumption of alcohol is generally not compatible with recommended adjuvant dietary modification.1

Alcohol + SNRIs

No important psychomotor interaction normally appears to occur between duloxetine or venlafaxine and alcohol. However, the manufacturer warns that use of duloxetine with heavy alcohol intake may be associated with severe liver injury.

Clinical evidence, mechanism, importance and management

(a) Duloxetine

In a single-dose study in healthy subjects, duloxetine 60 mg, and alcohol given in a dose sufficient to produce blood levels of about 100 mg%, did not worsen the psychomotor impairment observed with alcohol alone.1 Nevertheless, the UK manufacturer advises caution,2 and the US manufacturer warns that duloxetine should ordinarily not be prescribed for patients with substantial alcohol use as severe liver injury may result.3

(b) Venlafaxine

Venlafaxine 50 mg every 8 hours was found to have some effect on psychomotor tests (digit symbol substitution, divided attention reaction times, profile of mood scales) in 15 healthy subjects, but these changes were small and not considered to be clinically significant. No pharmacodynamic or pharmacokinetic interactions occurred when alcohol 0.5 g/kg was also given.4 In therapeutic doses venlafaxine does not appear to interact significantly with alcohol, however, the manufacturers state that, as with all centrally-active drugs, patients should be advised to avoid alcohol whilst taking venlafaxine.5,6 This is presumably because both drugs act on the CNS and also because alcohol is more likely to be abused by depressed patients.7

Alcohol + Sodium cromoglicate (Cromolyn sodium)

No adverse interaction occurs between sodium cromoglicate and alcohol.

Clinical evidence, mechanism, importance and management

A double-blind, crossover study in 17 healthy subjects found that the inhalation of 40 mg of sodium cromoglicate had little or no effect on the performance of a number of tests on human perceptual, cognitive, and motor skills, whether taken alone or with alcohol 0.75 g/kg. Nor did it affect blood-alcohol levels.1 This is in line with the common experience of patients, and no special precautions seem to be necessary.

Alcohol + SSRIs

Citalopram, escitalopram, fluoxetine, paroxetine and sertraline have no significant pharmacokinetic interaction with alcohol, but some modest increase in sedation may possibly occur with fluvoxamine and paroxetine.

Clinical evidence and mechanism

(a) Citalopram

The manufacturers of citalopram say that no pharmacodynamic interactions have been noted in clinical studies in which citalopram was given with alcohol.1,2

(b) Escitalopram

The manufacturers of escitalopram say that no pharmacokinetic or pharmacodynamic interactions are expected to occur with concurrent use of alcohol and escitalopram.3

(c) Fluoxetine

The concurrent use of fluoxetine 30 to 60 mg and alcohol (4 oz of whiskey) did not affect the pharmacokinetics of either drugs in healthy subjects, and fluoxetine did not alter the effect of alcohol on psychomotor activity (stability of stance, motor performance, manual co-ordination).4 Similarly, blood-alcohol levels of 80 mg% impaired the performance of a number of psychomotor tests in 12 healthy subjects, but the addition of fluoxetine 40 mg daily taken for 6 days before the alcohol had little further effect.5 Another study also found no change in the performance of a number of psychophysiological tests when fluoxetine was combined with alcohol.6 No problems were found in a study of 20 alcohol-dependent patients taking fluoxetine 60 mg daily when they drank alcohol, or in approximately 31 patients taking fluoxetine 20 mg daily who drank unspecified small quantities of alcohol.7

(d) Fluvoxamine

One study found that fluvoxamine 150 mg daily with alcohol impaired alertness and attention more than alcohol alone,8 whereas another study in subjects given 40 g of alcohol (blood-alcohol levels up to 70 mg%) found no evidence to suggest that the addition of fluvoxamine 50 mg twice daily worsened the performance of the psychomotor tests, and it even appeared to reverse some of the effects.9 The pharmacokinetics of alcohol were hardly affected by fluvoxamine, but the steady state maximum plasma levels of the fluvoxamine were increased by 20%, although the fluvoxamine AUC was unchanged.10 It was suggested that administration of alcohol may have promoted dissolution of fluvoxamine and increased the absorption rate without affecting bioavailability.11 Another study also found that fluvoxamine does not appear to enhance the detrimental effects of alcohol on the performance of psychomotor tests.12

(e) Paroxetine

Studies have found that paroxetine alone caused little impairment of a series of psychomotor tests related to car driving, and with alcohol the effects were unchanged, except for a significant decrease in attentiveness and an increase in reaction time.13,14 Another study suggested that the alcohol-induced sedation was antagonised by paroxetine.15

(f) Sertraline

Sertraline (in doses of up to 200 mg for 9 days) was found not to impair cognitive or psychomotor performance, and it also appeared not to increase the effects of alcohol.16

Importance and management

The results of the few studies reported above suggest that no pharmacokinetic or pharmacodynamic interactions occur with most SSRIs and alcohol, although modest effects were seen with fluvoxamine and possibly paroxetine. However, most manufacturers of SSRIs suggest that concurrent use with alcohol is not advisable. This is presumably because both drugs act on the CNS and also because of the risk of alcohol abuse in depressed patients.17

Disulfiram-like reactions have been seen in at least three patients who drank alcohol after using a solution of sulfiram for the treatment of scabies.

**Clinical evidence**

A man who used undiluted Tetmosol (a solution of sulfiram) for 3 days on the skin all over his body developed a disulfiram-like reaction (flushing, sweating, skin swelling, severe tachycardia and nausea) on the third day, after drinking 3 double whiskies. The same thing happened on two subsequent evenings again after drinking 3 double whiskies. Similar reactions have been described in 2 other patients who drank alcohol while using Tetmosol or Ascabiol (also containing sulfiram).

**Mechanism**

Sulfiram (tetraethylthiuram monosulfide) is closely related to disulfiram (tetraethylthiuram disulfide) and can apparently undergo photochemical conversion to disulfiram when exposed to light. The longer it is stored, the higher the concentration. The reaction with alcohol appears therefore to be largely due to the presence of disulfiram, see ‘Alcohol + Disulfiram’, p.61.

**Importance and management**

An established interaction. The manufacturers of sulfiram preparations and others advise abstention from alcohol before, and for at least 48 hours after application, but this may not always be necessary. The writer of a letter, commenting on one of the cases cited, wrote that he had never encountered this reaction when using a diluted solution of Tetmosol on patients at the Dreadnought Seaman’s Hospital in London who he described as “not necessarily asthmatic”. This would suggest that the reaction is normally uncommon and unlikely to occur if the solution is correctly diluted (usually with 2 to 3 parts of water), thereby reducing the amount absorbed through the skin. However, one unusually sensitive patient is said to have had a reaction (flushing, sweating, tachycardia) after using diluted Tetmosol, but without drinking alcohol. It was suggested that she reacted to the alcohol base of the formulation passing through her skin.

**Alcohol + Sumatriptan**

Alcohol does not alter the pharmacokinetics of sumatriptan.

**Clinical evidence, mechanism, importance and management**

A single 0.8-g/kg dose of alcohol was given to 16 healthy subjects, followed 30 minutes later by 200 mg of sumatriptan. No statistically significant changes were seen in the pharmacokinetics of sumatriptan. There is nothing to suggest that alcohol should be avoided while taking sumatriptan.

**Alcohol + Tacrolimus or Pimecrolimus**

Alcohol may cause facial flushing or skin erythema in patients being treated with tacrolimus ointment; this reaction appears to be fairly common. Alcohol intolerance has been reported rarely with pimecrolimus cream.

**Clinical evidence**

Six patients reported facial flushing with small quantities of beer or wine during facial treatment with tacrolimus ointment. Re-exposure to tacrolimus 0.1% ointment, applied to the face twice daily for 4 days, followed by 100 mL of white wine on the fifth day, resulted in a facial flush reaction in all the patients, which occurred within 5 to 15 minutes of alcohol ingestion. The intensity of the erythema varied among the patients and was not confined to the treated areas, but started to fade after 30 minutes; a slight headache occurred in one patient. Forearm skin was also exposed to an epicutaneous patch containing 70 mg of tacrolimus 0.1% ointment, but these sites remained unchanged following alcohol exposure. After a tacrolimus washout period of at least 4 weeks, controlled exposure to alcohol in 2 patients was tolerated normally. Another report describes one patient using tacrolimus ointment for mild eyelid eczema who experienced eyelid erythema, limited to the area the tacrolimus ointment was applied, after wine ingestion. Two other patients experienced an erythematous rash after alcohol when using topical tacrolimus; areas affected included the elbows, ears, eyes and face. The response to alcohol disappeared within 2 weeks of discontinuing tacrolimus ointment.

Three patients experienced application site erythema following the consumption of alcohol after using topical tacrolimus or pimecrolimus for the treatment of facial dermatoses. Two of the patients then participated in a double-blind, controlled evaluation of the reaction. Both patients consumed alcohol (240 mL of red or white wine) without experiencing flushing, but following tacrolimus or pimecrolimus application, they experienced moderate or severe facial flushing (limited to the area of application) 5 to 10 minutes after alcohol consumption. The intensity of the erythema was sharply reduced after taking aspirin 325 mg twice daily for 3 days before alcohol consumption, but cetirizine 10 mg daily with cimetidine 400 mg twice daily for 3 days appeared to have little effect.

There are other reports of this interaction between tacrolimus and alcohol. The reaction is usually confined to the face and the intensity may be related to the amount of alcohol ingested. In an open study of 316 patients, alcohol intolerance (facial flushing) was observed in 19% of the patients using tacrolimus 0.1% ointment and in a controlled study, 6.9% of patients experienced the reaction with tacrolimus 0.1% ointment, and 3.4% of patients experienced the reaction with tacrolimus 0.03% ointment.

**Mechanism**

The mechanism of this interaction is not understood. It has been proposed that tacrolimus may act on the same biochemical pathway as alcohol potentiating a capsaicin-mediated release of neuropeptides, which increase vasodilatory effects. Alternatively, cutaneous aldehyde dehydrogenase inhibition in areas where tacrolimus has been applied may increase cutaneous aldehyde levels that, through prostaglandins as mediators, could lead to vasodilation following alcohol consumption.
Alcohol + Tianeptine

Alcohol reduced the absorption of tianeptine and lowered plasma levels by about 30%.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects the absorption and peak plasma levels of a single 12.5-mg dose of tianeptine were reduced by about 30% by alcohol. The subjects were given vodka diluted in orange juice to give blood alcohol levels between 64 and 77 mg%. The plasma levels of the major metabolite of tianeptine were unchanged. No behavioural studies were done so that the clinical significance of these studies is as yet uncertain.

Alcohol + Tolazoline

A disulfiram-like reaction may occur in patients taking tolazoline if they drink alcohol.

Clinical evidence, mechanism, importance and management

Seven healthy subjects were given tolazoline 25 mg daily for 4 days. Within 15 to 90 minutes of drinking 90 mL of port wine (alcohol 18.2%), 2 hours after the last dose of tolazoline, 6 experienced tingling over the head, and 4 developed warmth and fullness of the head. The reasons are not understood, but this reaction is not unlike a mild disulfiram reaction, and may possibly have a similar mechanism (see ‘Alcohol + Disulfiram’, p.61). Patients given tolazoline should be warned about this reaction if they drink alcohol, and advised to limit their consumption. Reactions of this kind with drugs other than disulfiram are usually more unpleasant or frightening than serious, and treatment is rarely needed. In infants given tolazoline, it would seem sensible to avoid preparations containing alcohol, where possible.

Alcohol + Trazodone

Trazodone can make driving or handling other dangerous machinery more hazardous, particularly during the first few days of treatment, and further impairment may occur with alcohol.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects comparing the effects of single-doses of amitriptyline 50 mg and trazodone 100 mg found that both drugs impaired the performance of a number of psychomotor tests, causing drowsiness and reducing ‘clearheadedness’ to approximately the same extent. Only manual dexterity was further impaired when the subjects taking trazodone were given sufficient alcohol to give blood levels of about 40 mg%. Another study similarly found that the impairment of psychomotor performance by trazodone was increased by alcohol. This appears to be due to a simple additive depression of the CNS. This is an established interaction, and of practical importance. Patients should be warned that their ability to drive, handle dangerous machinery or to do other tasks needing...
complex psychomotor skills might be impaired by trazodone, and further worsened by alcohol.

Alcohol + Trichloroethylene

A flushing skin reaction similar to a mild disulfiram reaction can occur in those who drink alcohol following exposure to trichloroethylene. Alcohol may also increase the risk of liver toxicity due to solvent exposure.

Clinical evidence

An engineer from a factory where trichloroethylene was being used as a degreasing agent, developed facial flushing, a sensation of increased pressure in the head, lachrymation, tachypnoea and blurred vision within 12 minutes of drinking 85 mL of bourbon whiskey. The reaction did not develop when he was no longer exposed to the trichloroethylene. Other workers in the same plant reported the same experience.1 Vivid red blotches in a symmetrical pattern on the face, neck, shoulders and back were seen in other workers when they drank about 2 pints of beer2 after having been exposed for a few hours each day for 3 weeks to increasing concentrations of trichloroethylene vapour (up to 200 ppm). Note that this was twice the maximum permissible level for trichloroethylene in air at that time.3 This reaction has been described as the “degreasers’ flush”.2

A later study involving 188 workers occupationally exposed to trichloroethylene found a statistically significant synergistic toxic interaction between trichloroethylene and alcohol. There were 30 cases (15.9%) of degreasers’ flush and 10 cases (5.3%) of clinical liver impairment.4 There is also some evidence that short-term exposure to the combination may possibly reduce mental capacity, although in this study the concentration of trichloroethylene was quite high (200 ppm).5

Another study investigated the metabolism of trichloroethylene in 5 healthy subjects who inhaled trichloroethylene 50 ppm for 6 hours per day for 5 days and then again 2 weeks later in the presence of alcohol. Inhalation of trichloroethylene with blood-alcohol concentrations of 0.6% resulted in increased blood and expired air concentrations of trichloroethylene 2 to 3 times greater than without alcohol.6 A simulation study suggested that ingestion of moderate amounts of alcohol (0.23 to 0.92 g/kg) before the start of work or at lunchtime, but not at the end of work, could cause pronounced increases in blood-trichloroethylene concentrations and decreases in the urinary excretion rates of trichloroethylene metabolites. However, the effect of enzyme induction on trichloroethylene metabolism by consumption of alcohol the previous evening was negligible when exposure to trichloroethylene was below 100 ppm.7

Mechanism

Uncertain. One suggested mechanism is a disulfiram-like inhibition of acetaldehyde metabolism by trichloroethylene (see ‘Alcohol + Disulfiram’, p.61). Another suggested mechanism is inhibition of trichloroethylene metabolism in the presence of alcohol, resulting in increased plasma levels and possibly an accumulation of trichloroethylene in the CNS.9

Importance and management

The flushing reaction is an established interaction that has been reported to occur in about 16% of workers exposed to trichloroethylene when they drink alcohol. It would seem to be more unpleasant and socially disagreeable than serious, and normally requires no treatment. However, the hepatoxicity of trichloroethylene and other organic solvents may be increased by alcohol. Several factors have been shown to affect the handling of solvents by the liver and the final toxicity. Increased body fat has been reported to increase the risk of solvent toxicity and heavy alcohol consumption may further increase the risk of liver toxicity.8

Alcohol + Tricyclic antidepressants

The ability to drive, to handle dangerous machinery or to do other tasks requiring complex psychomotor skills may be impaired by amitriptyline, and to a lesser extent by doxepin or imipramine, particularly during the first few days of treatment. This impairment can be increased by alcohol. Amoxapine, clomipramine, desipramine, and nortriptyline appear to interact with alcohol only minimally. Information about other tricyclics appears to be lacking, although most manufacturers of tricyclics warn that the effects of alcohol may be enhanced. There is also evidence that alcohol (without liver disease) may need larger doses of desipramine and imipramine to control depression. However, the toxicity of some tricyclics may be increased by alcohol, and in alcoholics with liver disease.

Clinical evidence

(a) Amitriptyline

A single-dose, crossover study in 5 healthy subjects found that the plasma levels of amitriptyline 25 mg over an 8-hour period were markedly increased by alcohol (blood-alcohol concentration maintained at approximately 80 mg%). Compared with amitriptyline alone, the AUC0-8 increased by a mean of 44% following alcohol consumption, and was associated with decreased standing steadiness, recent memory and alertness.1 Amitriptyline 800 micrograms/kg impaired the performance of three motor skills tests related to driving in 21 healthy subjects. When alcohol to produce blood levels of about 80 mg% was also given the performance was even further impaired.2 Similar results have been very clearly demonstrated in considerable numbers of subjects using a variety of psychomotor skill tests.1,3,4 The interaction being most marked during the first few days of treatment, but tending to wane as treatment continues.5 Unexplained blackouts lasting a few hours have been described in 3 women after they drank only modest amounts of alcohol;7 they had been taking amitriptyline or imipramine for a month. There is some limited evidence from animal studies that amitriptyline may possibly enhance the fatty changes induced in the liver by alcohol,8 but this still needs confirmation from human studies.

A study involving 332 fatal poisonings in Finland found that alcohol was present in 67% of cases involving amitriptyline, and when alcohol was present, relatively small overdoses of amitriptyline could result in fatal poisoning.9 It appears that amitriptyline may be more toxic when given with alcohol and it has been suggested that a less dangerous alternative could be chosen when indications of alcohol abuse or suicide risk are present.10

(b) Amoxapine

The interaction between amoxapine and alcohol is said to be slight,11 but two patients have been described who experienced reversible extrapyramidal symptoms (parkinsonism, akathisia) while taking amoxapine, apparently caused by drinking alcohol.12

(c) Clomipramine

Studies in subjects with blood-alcohol levels of 40 to 60 mg% found that clomipramine had only slight or no effects on various choice reaction, coordination, memory and learning tests.4,11,12 A case describes a fatal poisoning in a chronic alcoholic patient taking clomipramine for depression. The ultimate toxic effect was thought to be due to alcohol-induced decreased biotransformation of clomipramine, as post-mortem examination revealed toxic liver damage, and low levels of the metabolite were found in blood and hair samples.13
Plasma desipramine levels were transiently, but non-significantly increased after healthy subjects drank alcohol, and breath-alcohol concentrations were not affected by the antidepressant. Further, skilled performance tests in subjects given desipramine 100 mg indicated that no significant interaction occurred with alcohol. The half-life of oral desipramine was about 30% lower in recently detoxified alcoholics (without liver disease), when compared with healthy subjects, and the intrinsic clearance was 60% greater.

A double-blind, crossover study in 20 healthy subjects given various combinations of alcohol and either desipramine or a placebo found that with blood-alcohol levels of 40 to 50 mg% their choice reaction test times were prolonged and the number of mistakes increased. Coordination was obviously impaired after 7 days of treatment with desipramin, but not after 14 days. In an earlier study doxepin appeared to cancel out the deleterious effects of alcohol on the performance of a simulated driving test. It appears that doxepin may be more toxic when given with alcohol and it has been suggested that a less dangerous alternative could be chosen when indications of alcohol abuse or suicide risk are present.

Imipramine 150 mg daily has also been reported to enhance some of the hypo-sedative effects of alcohol, and unexplained blackouts lasting a few hours have been described in women after they drank only modest amounts of alcohol; they had been taking amitriptyline or imipramine for only a month. The half-life of oral imipramine was about 45% lower in recently detoxified alcoholics (without liver disease) compared with healthy subjects, and the intrinsic clearance was 200% greater.

Studies in subjects with blood-alcohol levels of 40 to 60 mg% found that nortriptyline had only slight or no effects on various choice reaction, coordination, memory and learning tests, although the acute use of alcohol with nortriptyline impaired learning in one study.

Mechanism

Part of the explanation for the increased CNS depression is that both alcohol and some of the tricyclics, particularly amitriptyline, cause drowsiness and other CNS depressant effects, which can be additive with the effects of alcohol. The sedative effects have been reported to be greatest with amitriptyline, then doxepin and imipramine, followed by nortriptyline, and least with amoxapine, clomipramine, desipramine, and protriptyline. In addition, acute alcohol intake causes marked increases (100 to 200%) in the plasma levels of amitriptyline, probably by inhibiting its first pass metabolism. Alcohol-induced liver damage could also result in impaired amitriptyline metabolism. The lower serum levels of imipramine and desipramine seen in abstinent alcoholics are attributable to induction of the cytochrome P450 isoenzymes by alcohol.

Importance and management

The increased CNS depression resulting from the interaction among amitriptyline and alcohol is well documented and clinically important. The interaction between alcohol and doxepin or imipramine is less well documented and the information is conflicting. Amoxapine, clomipramine, desipramine, and nortriptyline appear to interact only minimally with alcohol. Direct information about other tricyclics seems to be lacking, but there appear to be no particular reasons for avoiding concurrent use, although tricyclics with greater sedation such as trimipramine are more likely to interact. During the first 1 to 2 weeks of treatment many tricyclics (without alcohol) may temporarily impair the skills related to driving. Therefore it would seem prudent to warn any patient given a tricyclic that whilst taking tricyclic antidepressants.

Also be aware that alcoholic patients (without liver disease) may need higher doses of imipramine (possibly doubled) and desipramine to control depression, and if long-term abstinence is achieved the dosages may then eventually need to be reduced.

Men exposed to trinitrotoluene (TNT) in a munitions factory were found to have a greater risk of TNT-induced liver damage if they had a long history of heavy alcohol drinking than if they were non-drinkers.

Heavy consumption of alcohol may also increase betacarotene levels and affect vitamin A metabolism; there have been reports of possible increased toxicity.

Clinical evidence, mechanism, importance and management

A study involving 30 abstinent male alcoholics found that 5 of 15 given high-dose vitamin A (10 000 units daily by mouth) for 4 months developed...
Some individuals exposed to xylene vapour, who subsequently drink alcohol, may experience dizziness and nausea. A flushing skin reaction has also been seen.

### Clinical evidence, mechanism, importance and management

Studies in subjects exposed to m-xylene vapour at concentrations of approximately 145 or 280 ppm for 4 hours who were then given 0.4 or 0.8 g/kg of alcohol found that about 10 to 20% experienced dizziness and nausea. One subject exposed to 300 ppm of m-xylene vapour developed a conspicuous dermal flush on his face, neck, chest and back. He also showed some erythema with alcohol alone. A study using a population-based pharmacokinetic and pharmacodynamic model predicted that the probability of experiencing CNS effects following exposure to xylene at the current UK occupational exposure standard (100 ppm time-weighted average over 8 hours) increased markedly and non-linearly with alcohol dose.

The reasons for these reactions are not fully understood, but it is possible that xylene plasma levels are increased because alcohol impairs its metabolic clearance by the cytochrome P450 isoenzyme CYP2E1. After alcohol intake, blood xylene levels have been reported to rise about 1.5- to 2-fold; acetaldehyde levels may also be transiently increased.

Alcoholic beverages are quite often consumed during lunchtime or after work, and since the excretion of xylene is delayed by its high solubility and storage in lipid-rich tissues, the simultaneous presence of xylene and alcohol in the body is probably not uncommon and could result in enhancement of the toxicity of xylene.

The selective and non-selective alpha blockers are categorised and listed in ‘Table 4.1’, (see below). The principal interactions of the alpha blockers are those relating to enhanced hypotensive effects. Early after the introduction of the selective alpha blockers it was discovered that, in some individuals, they can cause a rapid reduction in blood pressure on starting treatment (also called the ‘first-dose effect’ or ‘first-dose hypotension’). The risk of this may be higher in patients already taking other antihypertensive drugs. The first-dose effect has been minimised by starting with a very low dose of the alpha blocker, and then escalating the dose slowly over a couple of weeks. A similar hypotensive effect can occur when the dose of the alpha blocker is increased, or if treatment is interrupted for a few days and then re-introduced. Some manufacturers recommend giving the first dose on retiring to bed, or if not, avoiding tasks that are potentially hazardous if syncope occurs (such as driving) for the first 12 hours. If symptoms such as dizziness, fatigue or sweating develop, patients should be warned to lie down, and to remain lying flat until they abate completely.

It is unclear whether there are any real differences between the alpha blockers in their propensity to cause this first-dose effect. With the exception of indoramin, postural hypotension, syncope, and dizziness are listed as adverse effects of the alpha blockers available in the UK and for most it is recommended that they should be started with a low dose and titrated as required. Tamsulosin is reported to have some selectivity for the alpha receptor 1A subtype, which are found mostly in the prostate, and therefore have less effect on blood pressure: an initial titration of the dose is therefore not considered to be necessary. Nevertheless, it would be prudent to exercise caution with all the drugs in this class.

Alpha blockers are also used to increase urinary flow-rate and improve obstructive symptoms in benign prostatic hyperplasia. In this setting, their effects on blood pressure are more of an adverse effect, and their additive hypotensive effect with other antihypertensives may not be beneficial.

**Alpha blockers + ACE inhibitors**

Severe first-dose hypotension, and synergistic hypotensive effects that occurred when a patient taking enalapril was given bunazosin or tamsulosin have been replicated in healthy subjects. The first-dose effect seen with other alpha blockers (particularly alfuzosin, prazosin and terazosin) is also likely to be potentiated by ACE inhibitors. In one small study tamsulosin did not have any clinically relevant effects on blood pressure that was already well controlled by enalapril.

**Clinical evidence**

After a patient taking enalapril developed severe first-dose hypotension after being given bunazosin, this interaction was further studied in 6 healthy subjects. When given enalapril 10 mg or bunazosin 2 mg, their mean blood pressure over 6 hours was reduced by 9.5/6.7 mmHg. When bunazosin was given one hour after enalapril the blood pressure fell by 27/28 mmHg, and still fell by 19/22 mmHg, even when the dose of enalapril was reduced to 2.5 mg.

The manufacturers of alfuzosin and prazosin warn that patients receiving antihypertensive drugs (the manufacturers of prazosin specifically name the ACE inhibitors) are at particular risk of developing postural hypotension after the first dose of alpha blocker.

Retrospective analysis of a large multinational study in patients given terazosin 5 or 10 mg daily found that terazosin only affected the blood pressure of patients taking ACE inhibitors (enalapril, lisinopril or perindopril) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by ACE inhibitors). The most common adverse effect in the 10-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than those not (21 to 25%).

However, the manufacturer of terazosin notes that the incidence of dizziness in patients with BPH taking terazosin was higher when they were also receiving an ACE inhibitor.

In a placebo-controlled study in 6 hypertensive men with blood pressure well controlled by enalapril, the addition of tamsulosin 400 micrograms daily for 7 days then 800 micrograms daily for a further 7 days had no clinically relevant effects on blood pressure (assessed after 6 and 14 days of tamsulosin). In addition, no first-dose hypotensive effect was seen on the day tamsulosin was started, or on the day the tamsulosin dose was increased.

**Mechanism**

The first-dose effect of alpha blockers (see ‘Alpha blockers’, (p.83)) may be potentiated by ACE inhibitors. Tamsulosin possibly has less effect on blood pressure since it has some selectivity for alpha receptors in the prostate.

**Importance and management**

Direct information is limited. Acute hypotension (dizziness, fainting) sometimes occurs unpredictably with the first dose of some alpha blockers (particularly, alfuzosin, prazosin and terazosin; but see ‘Alpha blockers’, (p.83)), and this can be exaggerated if the patient takes or is already taking a beta blocker or a calcium-channel blocker (see ‘Alpha blockers + Beta blockers’, below, and ‘Alpha blockers + Calcium-channel blockers’, (p.85)). It would therefore seem prudent to apply the same precautions to ACE inhibitors, namely reducing the dose of the ACE inhibitor to a maintenance level if possible, then starting the alpha blocker at the lowest dose, with the first dose given at bedtime. Note that the acute hypotensive reaction appears to be short-lived. There is limited evidence that terazosin and tamsulosin may not cause an additional hypotensive effect in the longer term in patients with BPH who have hypertension already well-controlled with ACE inhibitors. Nevertheless, caution should be exercised in this situation, and a dose reduction of the ACE inhibitor may be required.

---

**Alpha blockers + Beta blockers**

The risk of first-dose hypotension with prazosin is higher if the patient is already taking a beta blocker. This is also likely to be true of other alpha blockers, particularly alfuzosin, bunazosin and terazosin. In a small study tamsulosin did not have any clinically relevant effects on blood pressure that was already well controlled by atenolol. Alpha blockers and beta blockers may be combined for additional lowering of blood pressure in patients with hypertension.

**Clinical evidence**

(a) Alfuzosin

No pharmacokinetic interaction occurred between alfuzosin 2.5 mg and atenolol 100 mg in a single-dose study in 8 healthy subjects. The manufacturer notes that postural hypotension may occur in patients receiving antihypertensives when they start alfuzosin, although they do note that the most common adverse reactions associated with doxazosin are of a postural hypertension type. They specifically note that doxazosin has been given with atenolol and propranolol without evidence of an adverse interaction.

(b) Doxazosin

The manufacturer of doxazosin states that no adverse drug interaction has been observed between doxazosin and beta blockers, although they do note that the most common adverse reactions associated with doxazosin are of a postural hypertension type.

(c) Indoramin

The manufacturer of indoramin states that concurrent use with beta blockers may enhance their hypotensive action, and that titration of the dose of the beta blocker may be needed when initiating therapy.

(d) Prazosin

A marked hypotensive reaction (dizziness, pallor, sweating) occurred in 3 out of 6 hypertensive patients taking alprenolol 400 mg twice daily when they were given the first 500-microgram dose of prazosin. All 6 patients had a greater reduction in blood pressure after the first prazosin dose than after 2 weeks of treatment with prazosin 500 microgram three times daily with no beta blocker (mean reduction 22/11 mmHg compared with 4/4 mmHg). A further 3 patients already taking prazosin 500 microgram three times daily had no unusual fall in blood pressure when they were given the first dose of alprenolol 200 mg. Two studies have shown that the pharmacokinetics of prazosin are not affected by either alprenolol or propranolol.

The severity and the duration of the first-dose effect of prazosin was also found to be increased in healthy subjects given a single dose of propranolol.

(e) Tamsulosin

In a placebo-controlled study in 8 hypertensive men with blood pressure well controlled by atenolol, the addition of tamsulosin 400 micrograms daily for 7 days, then 800 micrograms daily for a further 7 days, had no clinically relevant effect on blood pressure (assessed after 6 and 14 days of tamsulosin). No hypotension was seen with the first dose of tamsulosin or when the dose of tamsulosin was increased.

(f) Terazosin

Retrospective analysis of a large multinational study in patients given terazosin 5 or 10 mg daily found that terazosin only affected the blood pressure of patients taking beta blockers (atenolol, labetalol, metoprolol, sotalol, and timolol) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by beta blockers). The most common adverse effect in the 10-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than those not (21 to 25%).

---

In addition to these drugs the manufacturers of terazosin note that it has been taken by at least 50 patients with propranolol without evidence of an adverse interaction.12

Mechanism
The normal cardiovascular response (a compensatory increased heart output and rate) that should follow the first-dose hypotensive reaction to alpha blockers is apparently compromised by the presence of a beta blocker. The problem is usually only short-lasting because some physiological compensation occurs within hours or days, and this allows the blood pressure to be lowered without falling precipitously. Tamsulosin possibly has less effect on blood pressure since it has some selectivity for alpha receptors in the prostate (see ‘Alpha blockers’, (p.83)).

Importance and management
An established interaction. Some patients experience acute postural hypotension, tachycardia and palpitations when they begin to take prazosin or other alpha blockers (particularly alfuzosin, bunazosin and terazosin; but see also ‘Alpha blockers’, (p.83)). A few patients even collapse in a sudden faint within 30 to 90 minutes, and this can be exacerbated if they are already taking a beta blocker. It is recommended that those already taking a beta blocker should have their dose of beta blocker reduced to a maintenance dose and begin with a low-dose of these alpha blockers, with the first dose taken just before going to bed. They should also be warned about the possibility of postural hypotension and how to manage it (i.e. lay down, raise the legs and get up slowly). Similarly, when adding a beta blocker to an alpha blocker, it may be prudent to decrease the dose of the alpha blocker and re-titrate as necessary. There is limited evidence that terazosin and tamsulosin may not cause an additional hypotensive effect in the longer term in patients with BPH who have hypotension already well-controlled with beta blockers. Nevertheless, caution should be exercised in this situation, and a dose reduction of the beta blocker may be required.

Alpha blockers + Calcium-channel blockers

Blood pressure may fall sharply when calcium-channel blockers are first given to patients already taking alpha blockers (particularly prazosin and terazosin), and vice versa. In a small study, tamsulosin did not have any clinically relevant effects on blood pressure well controlled by nifedipine. Verapamil may increase the AUC of prazosin and terazosin. Alpha blockers and calcium-channel blockers may be combined for additional blood pressure lowering in patients with hypertension.

Clinical evidence
(a) Dihydropyridine calcium-channel blockers
1. Doxazosin. Although there was a tendency for first-dose hypotension no serious adverse events or postural symptoms were seen in 6 normotensive subjects given nifedipine 20 mg twice daily for 20 days, with doxazosin 2 mg once daily for the last 10 days. The same results were noted in 6 other normotensive subjects given the drugs in the opposite order. No pharmacokinetic interactions were found.13 However, the US manufacturers note a study in which slight (less than 20%) alterations were found in the pharmacokinetics of nifedipine and doxazosin when they were given concurrently. As would be expected, blood pressures were lower when both drugs were given.14
2. Prazosin. In a placebo-controlled, crossover study 12 hypertensive subjects were given nifedipine 20 mg and prazosin 2 mg, separated by one hour. Concurrent use reduced blood pressure more than either drug alone, but when prazosin was given after nifedipine its effects were delayed.15 Two patients with severe hypertension given prazosin 4 or 5 mg experienced a sharp fall in blood pressure shortly after being given nifedipine sublingually. One of them complained of dizziness and had a reduction in standing blood pressure from 232/124 to 88/48 mmHg about 20 minutes after taking nifedipine 10 mg. However, in a further 5 patients with hypertension taking prazosin, the reduction in blood pressure 20 minutes after the addition of sublingual nifedipine was smaller (mean reduction of 25/12 mmHg when lying and 24/17 mmHg when standing).16 It is not clear what contribution prazosin had to the effect seen with sublingual nifedipine, since the experiment was not repeated using a prazosin placebo, but blood pressure in these patients had earlier remained unchanged 1 hour after taking prazosin alone. Note that sublingual nifedipine alone may cause a dangerous drop in blood pressure.
3. Tamsulosin. In a placebo-controlled study in 8 hypertensive men with blood pressure well controlled by nifedipine, the addition of tamsulosin 400 micrograms daily for 7 days then 800 micrograms daily for a further 7 days had no clinically relevant effect on blood pressure (assessed after 6 and 14 days of tamsulosin). In addition, no first-dose hypotension was seen on the first day of tamsulosin, or when the tamsulosin dose was increased.17
4. Terazosin. Retrospective analysis of a large multinational study in patients given terazosin 5 or 10 mg daily found that terazosin only affected the blood pressure of patients taking calcium-channel blockers (amiodipine, felodipine, flunarizine, isradipine and nifedipine) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by calcium-channel blockers). The most common adverse effect in the 1-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than those not taking antihypertensives (21 to 25%).
5. Diltiazem
The US manufacturers note that when diltiazem 240 mg daily was given with alfuzosin 2.5 mg three times daily the maximum serum levels and AUC of alfuzosin were raised by 50% and 30%, respectively, and the maximum serum levels and AUC of diltiazem were raised by 40%. However, no changes in blood pressure were seen.18
(c) Verapamil
1. Prazosin. A study in 8 normotensive subjects given a single 1-mg dose of prazosin found that the peak serum prazosin levels were raised by 85% (from 5.2 to 9.6 nanograms/mL) and the prazosin AUC was increased by 25%. In contrast, in another study in hypertensive volunteers no change in blood pressure was noted in 6 hypertensive patients if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by calcium-channel blockers). The most common adverse effect in the 1-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than those not taking antihypertensives (21 to 25%).
2. Tamsulosin. A study into the safety of tamsulosin, with particular regard to the use of other medications, found that the concurrent use of verapamil increased the risk of adverse events related to tamsulosin treatment by threefold. The use of other calcium-channel blockers (not specified) did not appear to increase adverse effects, although there was a trend towards an increase.19
(1 mg increased to 5 mg daily) had no effect on verapamil pharmacokinetics. Both groups of patients had significant falls in standing blood pressure when they first started taking both drugs. Symptomatic orthostatic hypotension (which lessened within about 3 weeks) occurred in 4 patients when terazosin was first added to terazosin, and in 2 patients when terazosin was first added to verapamil.11

Mechanism
Not fully understood. It would seem that the vasodilatory effects of the alpha blockers and the calcium-channel blockers can be additive or synergistic, particularly after the first dose.12 The fall in blood pressure seen with prazosin and verapamil may, in part, result from a pharmacokinetic interaction. The interaction between alfuzosin and diltiazem. Tamsulosin possibly has less effect on blood pressure since it has some selectivity for alpha receptors in the prostate (see ‘Alpha blockers’, (p.83)).

Importance and management
The interaction between calcium-channel blockers and alpha blockers would appear to be established and of clinical importance, although the documentation is limited. Marked additive hypotensive effects can occur when concurrent use is first started, particularly with alfuzosin, bunazosin, prazosin and terazosin; but see also ‘Alpha blockers’, (p.83). It is recommended that patients already taking calcium-channel blockers should have their dose of calcium-channel blocker reduced and begin with a low-dose of alpha blocker, with the first dose taken just before going to bed. Caution should also be exercised when calcium-channel blockers are added to established treatment with an alpha blocker. Patients should be warned about the possibilities of exaggerated hypotension, and told what to do if they feel faint and dizzy. There is limited evidence that terazosin and tamsulosin may not cause an additional hypotensive effect in the longer term in patients with BPH who have hypertension already well-controlled with calcium-channel blockers. Nevertheless, caution should be exercised in this situation, and a dose reduction of the calcium-channel blocker may be required. It seems likely that any pharmacokinetic interaction will be accounted for by this dose titration.

Alpha blockers + Cimetidine

No important interaction occurs between cimetidine and either alfuzosin or doxazosin. Tamsulosin does not appear to have a clinically significant interaction with cimetidine, but caution is recommended with high tamsulosin doses.

Clinical evidence, mechanism, importance and management
In 10 healthy subjects cimetidine 1 g daily in divided doses for 20 days was found to have minimal effects on the pharmacokinetics of a single 5-mg dose of alfuzosin. The maximum serum levels and AUC of alfuzosin were increased by up to 24%, (not statistically significant) and the half-life was shortened by 14%. Cimetidine did not appear to increase the incidence of postural hypotension seen with alfuzosin.1 These changes are not clinically relevant, and there would seem to be no reason for avoiding concurrent use.

The manufacturer of doxazosin note that in a placebo-controlled study in healthy subjects cimetidine 400 mg twice daily increased the AUC of a single 1-mg dose of doxazosin given on day 4 by 10%.2,3 This seems unlikely to be of clinical significance, especially as this is within the expected intersubject variation of the doxazosin AUC.4

A study in 10 healthy subjects found that giving cimetidine 400 mg four times daily with a single 400-microgram dose of tamsulosin resulted in a 44% increase in the AUC of tamsulosin and a 26% reduction in tamsulosin clearance. Adverse events were not increased by concurrent use.4 The UK manufacturer of tamsulosin considers that no dosage adjustment is necessary.5 However, the US manufacturers advise caution, particularly with doses greater than 400 micrograms.6 In practice this probably means being aware that any increase in the adverse effects of tamsulosin occurs as a result of this interaction. If adverse effects do occur, consider changing to a non-interacting, alternative alpha blocker, such as alfuzosin. Other H1-receptor antagonists would not be expected to interact, but there does not seem to be any evidence to support this suggestion.

Alpha blockers + CYP3A4 inhibitors

Potent CYP3A4 inhibitors may increase the levels of alfuzosin.

Clinical evidence, mechanism, importance and management
The US manufacturers of alfuzosin XL briefly cite a study in which ketoconazole 400 mg increased the AUC and maximum levels of a 10-mg dose of alfuzosin by 3.2-fold and 2.3-fold, respectively. They therefore contraindicate the concurrent use of potent CYP3A4 inhibitors (they name itraconazole, ketoconazole and ritonavir).

Based on the information available the contraindication with alfuzosin seems somewhat cautious, although the protease inhibitors may be expected to have a greater effect than ketoconazole. If any of the potent CYP3A4 inhibitors named is given with alfuzosin it would seem prudent to use the minimum dose of the alpha blocker and titrate the dose as necessary, monitoring for adverse effects, particularly first-dose hypotension when the dose is increased. Be aware that risks are likely to be greater in patients also taking other antihypertensives. There is no evidence to suggest that other alpha blockers interact similarly, and they may therefore be suitable alternatives in some patients.

Alpha blockers + Diuretics

As would be expected, the use of an alpha blocker with a diuretic may result in an additive hypotensive effect, but aside from first-dose hypotension, this usually seems to be a beneficial interaction in patients with hypertension. The effects in patients with congestive heart failure may be more severe.

Clinical evidence, mechanism, importance and management
(a) Alfuzosin
No pharmacokinetic interaction occurred between alfuzosin 5 mg and hydrochlorothiazide 25 mg in a single-dose study in 8 healthy subjects.1 The manufacturer notes that postural hypotension may occur in patients receiving antihypertensives when they start alfuzosin.2
(b) Doxazosin

The manufacturer of doxazosin notes that no adverse drug interaction has been seen between doxazosin and thiazides or furosemide. However, they point out that doxazosin doses of greater than 4 mg daily increase the likelihood of adverse effects such as postural hypotension and syncope.

(c) Indoramin

The manufacturer of indoramin states that concurrent use with diuretics may enhance their hypotensive action, and that titration of the dose of the diuretic may be needed.

(d) Prazosin

The acute first-dose hypotension that can occur with alpha blockers such as prazosin can be exacerbated by ‘beta blockers’, and ‘calcium-channel blockers’, but there seems to be no direct evidence that diuretics normally do the same. However, the manufacturer of prazosin suggests that it is particularly important that patients with congestive heart failure who have undergone vigorous diuretic treatment should be given the initial dose of prazosin at bedtime and started on the lowest dose (500 micrograms two to four times daily). The reason is that left ventricular filling pressure may decrease in these patients with a resultant fall in cardiac output and systemic blood pressure. There seems to be no reason for avoiding concurrent use if these precautions are taken.

(e) Tamsulosin

The US manufacturer of tamsulosin notes that when 10 healthy subjects taking tamsulosin 800 micrograms daily were given a single 20-mg intravenous dose of furosemide the AUC of tamsulosin was reduced by 12%. Both the UK and US manufacturers note that as levels remained within the normal range no change in dosage is necessary.

(f) Terazosin

Retrospective analysis of a large multinational study in patients given terazosin 5 or 10 mg daily found that terazosin only affected the blood pressure of patients taking diuretics (amiloride, bendroflumethiazide, chlortalidone, hydrochlorothiazide and spironolactone) if the blood pressure was uncontrolled. No change in blood pressure was seen in those with normal blood pressure (i.e. those without hypertension and those with hypertension controlled by diuretics). The most common adverse effect in the 10-week terazosin phase was dizziness, and the incidence of this appeared to be lower in those taking antihypertensives (13 to 16%) than those not taking antihypertensives (21 to 25%). However, the UK manufacturer of terazosin notes that the incidence of dizziness in patients with BPH taking terazosin was higher when they were also taking a diuretic. Similarly, in clinical studies in patients with hypertension, a higher proportion experienced dizziness when they took terazosin with a diuretic, than when they took a placebo with a diuretic (20% versus 13%). The manufacturer states that when terazosin is added to a diuretic, dose reduction and re-titration may be necessary.

Alpha blockers + Dutasteride or Finasteride

No clinically important interaction has been found to occur between finasteride and doxazosin. In one study terazosin did not interact with finasteride, but in another there was a suggestion of modestly increased finasteride levels. No clinically significant interaction appears to occur between tamsulosin and terazosin.

Clinical evidence, mechanism, importance and management

(a) Dutasteride

A study in 24 subjects given dutasteride 500 micrograms daily for 14 days found that when tamsulosin 400 micrograms or terazosin (titrated to 10 mg) were also given once daily for 14 days, the pharmacokinetics of the alpha blockers remained unchanged. Furthermore, a clinical study in 327 men demonstrated that the combination of tamsulosin and dutasteride was well-tolerated over a period of 6 months.

(b) Finasteride

In a parallel study, 48 healthy subjects were divided into three groups. One group took terazosin 10 mg daily for 18 days, another took finasteride 5 mg daily for 18 days, and the third group took both drugs. The pharmacokinetics and pharmacodynamics of both drugs remained unchanged, and the serum levels of testosterone and dihydrotestosterone were also unaltered by concurrent use. However, another study, comparing groups of healthy subjects taking finasteride and alpha blockers found that after 5 days of combined use the group taking finasteride and doxazosin had an 18% lower maximum plasma level of finasteride and a 12% higher AUC, compared with the group taking terazosin alone (both differences were not statistically significant). Conversely, after 10 days of combined use, the maximum finasteride level was 16% higher and the AUC 31% higher, which was statistically significant. The levels of the group taking finasteride and doxazosin were not significantly different. The clinical significance of the possible modest increased finasteride levels with terazosin is not clear, but is likely to be small.

Alpha blockers + Miscellaneous

The manufacturers of several of the alpha blockers provide lists of drugs that are not expected to interact. These are shown in Table 4.2, (p.88). In some cases these predictions are based on in vitro studies or from observation of clinical usage. Although this type of data can provide a guide, remember that it gives only the broadest indication of whether or not a drug interacts.

Alpha blockers + NSAIDs

Indomethacin reduces the blood pressure-lowering effects of prazosin in some individuals. Other alpha blockers do not appear to interact with NSAIDs.

Clinical evidence

A study in 9 healthy subjects found that indomethacin 50 mg twice daily for 3 days had no statistically significant effect on the hypotensive effect of a single 5-mg dose of prazosin. However, in 4 of the subjects it was noted that the maximum fall in the mean standing blood pressure due to the prazosin was 20 mmHg less when they were taking indomethacin. Three of these 4 felt faint when given prazosin alone, but not while taking the indomethacin as well.

Mechanism

Not established. It seems probable that indometacin inhibits the production of hypotensive prostaglandins by the kidney.

Importance and management

Direct information seems to be limited to this study but what occurred is consistent with the way indometacin reduces the effects of many other different antihypertensives (e.g. see ‘ACE inhibitors + NSAIDs’, p.28, and ‘Beta blockers + Aspirin or NSAIDs’, p.835). It apparently does not affect every patient. If indometacin is added to established treatment with prazosin, be alert for a reduced antihypertensive response. It is not known exactly what happens in patients taking both drugs long-term, but note that with other interactions between antihypertensives and NSAIDs the effects seem to be modest. The manufacturers say that prazosin has been given with indometacin (and also aspirin and phenylbutazone) without any adverse interaction in clinical experience to date. Other manufacturers also note that no adverse interaction has been seen between doxazosin and NSAIDs, or terazosin and aspirin, ibuprofen, or indometacin.\(^1,4\)

Bunazosin + Rifampicin (Rifampin)

Rifampicin markedly reduces bunazosin serum levels.

Clinical evidence, mechanism, importance and management

In 15 healthy subjects a 7-day course of rifampicin 600 mg daily reduced the mean maximum serum levels of bunazosin 6 mg daily by 82% (from 11.6 to 2.1 nanograms/mL). The bunazosin AUC was reduced by more
than sevenfold. The duration of the blood pressure-lowering effect of bunazosin was shortened, the heart rate increase was less pronounced, and some adverse effects of bunazosin treatment (fatigue, headache) disappeared.\textsuperscript{1,2} The probable reason is that the rifampicin (a recognised, potent enzyme inducer) increases the metabolism of bunazosin by the liver so that its levels are reduced, and its effects therefore diminished.

The evidence seems to be limited to this study, but anticipate the need to raise the bunazosin dosage if rifampicin is added. Information about other alpha blockers does not seem to be available.

| Indoramin + MAOIs |

Based on early theoretical considerations, the manufacturers of indoramin contraindicate its use with MAOIs.

\textsuperscript{1} Doralese Tiltab (Indoramin hydrochloride). GlaxoSmithKline UK. UK Summary of product characteristics, June 2007.

\textsuperscript{2} GlaxoSmithKline. Personal communication, August 2003.

**Clinical evidence, mechanism, importance and management**

The concurrent use of MAOIs is contraindicated by the manufacturers of indoramin.\textsuperscript{1} This was included in the datasheet at the time indoramin was first licensed, and was based on a theoretical suggestion that the effects of noradrenaline (norepinephrine) may be potentiated by indoramin,\textsuperscript{2} leading to vasoconstriction with a possible increase in blood pressure. However, the pharmacology of these drugs suggests just the opposite, namely that hypotension is the more likely outcome. (Note that the hypertensive effects of noradrenaline (norepinephrine) may be treated with a non-selective alpha blocker such as phentolamine.) The manufacturers are not aware of any reported interactions between indoramin and MAOIs.\textsuperscript{2} Note that the MAOIs are not contraindicated with any of the other alpha blockers.
This section is concerned with the interactions where the effects of anaesthetics (both general and local) and neuromuscular blocking drugs are affected by the presence of other drugs. Where the anaesthetics or neuromuscular blocking drugs are responsible for an interaction they are dealt with under the heading of the drug affected.

Many patients undergoing anaesthesia may be taking long-term medication, which may affect their haemodynamic status during anaesthesia. This section is limited to drug interactions and therefore does not cover the many precautions relating to patients taking long-term medication and undergoing anaesthesia in general (for example, drugs affecting coagulation).

(a) General anaesthetics and neuromuscular blockers

In general anaesthesia a balanced approach is often used to meet the main goals of the anaesthetic procedure. These goals are unconsciousness/amnesia, analgesia, muscle relaxation, and maintenance of homeostasis. Therefore general anaesthesia often involves the use of several drugs, including benzodiazepines, opioids, and anticholinesterases, as well as general anaesthetics (sometimes more than one) and neuromuscular blockers. The use of several different types of drugs in anaesthesia means that there is considerable potential for drug interactions to occur in the peri-operative period, but this section is limited to the effects of drugs on general anaesthetics and neuromuscular blockers. The interactions of drugs affecting these other drugs used in anaesthesia are covered in other sections ('anticholinesterases', (p.352), 'benzodiazepines', (p.706), and 'opioids', (p.133)).

There may be difficulty in establishing which of the drugs being used in a complex regimen are involved in a suspected interaction. It should also be borne in mind that disease processes and the procedure for which anaesthesia is used may also be factors to be taken into account when evaluating a possible interaction.

Some established interactions are advantageous and are employed clinically. For example, the hypnotic and anaesthetic effects of ‘propofol and midazolam’, (p.96), are found to be greater than the expected additive effects and this synergy allows for lower dosage regimens in practice. Similarly nitrous oxide reduces the required dose of inhalational general anaesthetics (see ‘Anaesthetics, general + Anaesthetics, general’, p.92). Anticholinesterases oppose the actions of competitive neuromuscular blockers, and are used to restore muscular activity after surgery (see ‘Neuromuscular blockers + Anticholinesterases’, p.114).

The general anaesthetics mentioned in this section are listed in ‘Table 5.1’, (p.91). Barbiturates used as anaesthetics (e.g. thiopental) are largely covered here, whereas those used predominantly for their antiepileptic or sedative properties (e.g. phenobarbital or secobarbital) are dealt with in the appropriate sections.

The competitive (non-depolarising) neuromuscular blockers and depolarising neuromuscular blockers mentioned in this section are listed in ‘Table 5.2’, (p.91). The modes of action of the two types of neuromuscular blocker are discussed in the monograph ‘Neuromuscular blockers + Neuromuscular blockers’, p.128. It should be noted that mivacurium (a competitive blocker) and suxamethonium (a depolarising blocker) are hydrolysed by cholinesterase, so share some interactions in common that are not relevant to other competitive neuromuscular blockers.

(b) Local anaesthetics

The local anaesthetics mentioned in this section are listed in ‘Table 5.1’, (p.91). The interactions discussed in this section mainly involve the interaction of drugs with local anaesthetics used for epidural or spinal anaesthesia. The interactions of lidocaine used as an antiarrhythmic is dealt with in ‘Antiarrhythmics’, (p.243).

Anaesthetics, general + Alcohol

Those who regularly drink alcohol may need more thiopental or propofol than those who do not. In theory, alcohol may increase the risk of renal damage with sevoflurane. It is also probably unsafe to drink for several hours following anaesthesia because of the combined central nervous depressant effects.

Clinical evidence, mechanism, importance and management

A study in 532 healthy patients, aged from 20 to over 80 years, found that those who normally drank alcohol (more than 40 g weekly, roughly 400 mL of wine) needed more thiopental to achieve anaesthesia than non-drinkers. After adjusting for differences in age and weight distribution, men and women who were heavy drinkers (more than 40 g alcohol daily) needed 33% and 44% more thiopental, respectively, for induction than non-drinkers. Chronic alcohol intake is known to increase barbiturate metabolism by cytochrome P450 enzymes.2

Another study found that 26 chronic alcoholics (drinkers of about 40 g of alcohol daily, with no evidence of liver impairment) needed about one-third more propofol to induce anaesthesia than another 20 patients who only drank socially. However, there was great interindividual variation in the alcoholic group.3

When 12 healthy subjects were given 0.7 g/kg of alcohol 4 hours after receiving 5 mg/kg of thiopental 2.5%, body sway and lightheadedness were accentuated.4 This suggests that an interaction may occur if an ambulatory patient drinks alcohol within 4 hours of receiving an induction dose of thiopental. Patients should be cautioned not to drink alcohol following anaesthesia and surgery.

The manufacturer of sevoflurane notes that its metabolism is increased by known inducers of the cytochrome P450 isoenzyme CYP2E1 including alcohol.5,6 This may increase the risk of kidney damage because of an increase in plasma fluoride, although no cases appear to have been reported.

In a study in 20 healthy patients the concurrent use of either halothane or isoflurane increased the serum concentrations of propofol by about 20% during the maintenance of general anaesthesia.1 The US manufacturer of propofol notes that inhalational anaesthetics (such as halothane or isoflurane) would be expected to increase the effects of propofol. The manufacturer also states that the dosage of propofol required may be reduced if it is given with supplemental nitrous oxide.2

Synergy has been reported between propofol and etomidate – patients given induction doses of either etomidate or propofol alone required about a 15% higher dose than those given half etomidate and half propofol in sequence.3

For reports of enhanced sedation when propofol is given with midazolam, thiopental or other anaesthetics, see ‘Anaesthetics, general + Benzodiazepines’, p.96.

In a study of the induction of anaesthesia in patients undergoing ECT, subjects were given one of three treatments: propofol 1.5 mg/kg intravenously, sevoflurane 5% in oxygen, or propofol followed by sevoflurane in oxygen. Sevoflurane alone was associated with greater increases in heart rate and blood pressure than the other regimens and seizure duration was greatest in patients receiving propofol alone. Recovery time was longest with the propofol/sevoflurane combination, possibly because the combination produced deeper anaesthesia than the individual drugs alone.4 The manufacturer of sevoflurane notes that lower concentrations may be required following the use of an intraindiverse anaesthetic such as propofol.5 Note that the UK manufacturers of propofol do not recommend its use in ECT.6

(b) Miscellaneous anaesthetics

Nitrous oxide usually reduces the MAC of inhalational anaesthetics in a simple additive manner; an increased concentration of 60 to 70% nitrous oxide is commonly used with volatile anaesthetics.7 Similarly, the concurrent use of nitrous oxide reduces the dose of intravenous barbiturate anaesthetics and sevoflurane required for anaesthesia.

The manufacturers of ketamine note that barbiturates may prolong the effects of ketamine and delay recovery.10,11 Myoclonic activity occurred in a healthy 23-year-old man after anaesthesia was induced with 2.5 mL of Alfathesin (alfaxalone/alfadalone) given intravenously over 2 minutes, and then maintained with 2% enfurane in oxygen. The myoclonic activity subsided after stopping the enfurane, and anaesthesia was maintained with nitrous oxide/oxygen. The myoclonus recurred when the enfurane was replaced with halothane.12 Since both Alfathesin and enfurane can cause CNS excitation, it seems possible that these effects might have been additive, and it was suggested that concurrent use should be avoided, particularly in patients with known convulsive disorders.13 However, note that Alfathesin has been withdrawn from general use.

Anaesthetics, general + Anaesthetics, general

In general, the effects of the combined use of general anaesthetics are at least additive. The required dose of propofol will be lower if it is given with nitrous oxide, halothane or isoflurane. The anaesthetic effects of propofol and sevoflurane appear to be additive in ECT, and synergy has been reported between propofol and etomidate.

The dose requirement of inhalational anaesthetics and barbiturate anaesthetics is reduced by nitrous oxide, and the effect of ketamine may be prolonged by barbiturate anaesthetics.

An isolated report described myoclonic seizures in a man anaesthetised with Alfathesin (alfaxalone/alfadalone) when he was also given enfurane.

Clinical evidence, mechanism, importance and management

In general, the effects of the combined use of general anaesthetics are at least additive.

(a) Propofol

In a study in 20 healthy patients the concurrent use of either halothane or isoflurane increased the serum concentrations of propofol by about 20% during the maintenance of general anaesthesia.1 The US manufacturer of propofol notes that inhalational anaesthetics (such as halothane or isoflurane) would be expected to increase the effects of propofol. The manufacturer also states that the dosage of propofol required may be reduced if it is given with supplemental nitrous oxide.2

Synergy has been reported between propofol and etomidate – patients given induction doses of either etomidate or propofol alone required about a 15% higher dose than those given half etomidate and half propofol in sequence.3

For reports of enhanced sedation when propofol is given with midazolam, thiopental or other anaesthetics, see ‘Anaesthetics, general + Benzodiazepines’, p.96.

In a study of the induction of anaesthesia in patients undergoing ECT, subjects were given one of three treatments: propofol 1.5 mg/kg intravenously, sevoflurane 5% in oxygen, or propofol followed by sevoflurane in oxygen. Sevoflurane alone was associated with greater increases in heart rate and blood pressure than the other regimens and seizure duration was greatest in patients receiving propofol alone. Recovery time was longest with the propofol/sevoflurane combination, possibly because the combination produced deeper anaesthesia than the individual drugs alone.4 The manufacturer of sevoflurane notes that lower concentrations may be required following the use of an intraindiverse anaesthetic such as propofol.5 Note that the UK manufacturers of propofol do not recommend its use in ECT.6

(b) Miscellaneous anaesthetics

Nitrous oxide usually reduces the MAC of inhalational anaesthetics in a simple additive manner; an increased concentration of 60 to 70% nitrous oxide is commonly used with volatile anaesthetics.7 Similarly, the concurrent use of nitrous oxide reduces the dose of intravenous barbiturate anaesthetics and sevoflurane required for anaesthesia.

The manufacturers of ketamine note that barbiturates may prolong the effects of ketamine and delay recovery.10,11 Myoclonic activity occurred in a healthy 23-year-old man after anaesthesia was induced with 2.5 mL of Alfathesin (alfaxalone/alfadalone) given intravenously over 2 minutes, and then maintained with 2% enfurane in oxygen. The myoclonic activity subsided after stopping the enfurane, and anaesthesia was maintained with nitrous oxide/oxygen. The myoclonus recurred when the enfurane was replaced with halothane.12 Since both Alfathesin and enfurane can cause CNS excitation, it seems possible that these effects might have been additive, and it was suggested that concurrent use should be avoided, particularly in patients with known convulsive disorders.13 However, note that Alfathesin has been withdrawn from general use.

Anaesthetics, general + Anaesthetics, local

An isolated report describes convulsions associated with the use of propofol with topical cocaine. Cocaine abuse may increase the risk of cardiovascular complications during inhalational anaesthesia. Abstinence from cocaine or the avoidance of anaesthetics with sympathomimetic properties has been suggested.

The dosage of propofol may need to be reduced after the use of bupivacaine or lidocaine (e.g. during regional anaesthetic techniques). Similarly, epidural lidocaine reduces sevoflurane requirements, and is likely to have the same effect on other inhalational anaesthetics.
Clinical evidence, mechanism, importance and management

(a) Cocaine

A patient with no history of epilepsy, undergoing septorhinoplasty for cosmetic reasons, was premedicated with pапaveretum and hyoscine, and intubated after propofol and suxamethonium (succinylcholine) were given. Anaesthesia was maintained with nitrous oxide/oxygen and 2% isoflurane. During anaesthesia a paste containing 10% cocaine was applied to the nasal mucosa. During recovery the patient experienced a dystonic reaction, which developed into a generalised convulsion. The authors of the report suggest that a possible interaction between the propofol and cocaine might have been responsible, although they also suggest that the convulsions may have been an adverse effect of the propofol.1

Reviews of the anaesthetic implications of illicit drug use have stated that anaesthetists should be aware of the medical complications of cocaine abuse, such as myocardial ischaemia, hypertension and tachycardia due to sympathetic nervous system stimulation.2,3 It was suggested that the concurrent use of cocaine and inhalational anaesthetics, such as halothane, that are known to significantly sensitise the myocardium to circulating catecholamines, should be avoided, and that other halogenated anaesthetics should be used with caution.2,3 Theoretically, isoflurane would be a better choice of inhalational anaesthetic since it has less cardiovascular effects.2 Ketamine should also be avoided because of its sympathomimetic effects. Nitrous oxide, thiopental and fentanyl were considered to be useful for general anaesthesia in patients who regularly abuse cocaine.2,3 Although it has been suggested that anaesthesia is safe for patients with chronic cocaine abuse after abstinence for 24 hours, the occurrence of ventricular fibrillation in one such patient during anaesthesia with thiopental and isoflurane, led the authors of the case report to conclude that there should be a cocaine-free interval of at least one week before elective surgical procedures. They also suggest that if an emergency operation is required during acute cocaine intoxication, all sympathomimetic anaesthetic drugs should be avoided.4

(b) Lidocaine or Bupivacaine

A double-blind, randomised study of 17 patients requiring ventilatory support demonstrated that hourly laryngotracheal intubation of 5 mL of 1% lidocaine significantly reduced the dose of propofol required to maintain adequate sedation (overall reduction of 50%) when compared with pre-study values.5 In a placebo-controlled, double-blind study of 90 patients undergoing minor gynaecological surgery, intramuscular administration of 4% lidocaine (1 to 3 mg/kg) 10 minutes before induction of anaesthesia or 0.5% bupivacaine (500 to 1000 micrograms/kg) 30 minutes before induction of anaesthesia, significantly enhanced the hypnotic effect of intravenous propofol in a dose-dependent manner. Only the lowest doses of lidocaine and bupivacaine tested (500 and 250 micrograms/kg, respectively) lacked a significant effect on the hypnotic dose of propofol. The highest doses of lidocaine and bupivacaine (3 and 1 mg/kg, respectively) reduced the hypnotic requirements for propofol by about 34% and 40%, respectively. The dose of propofol should therefore be modified after the intramuscular use of lidocaine or bupivacaine.6 The UK manufacturer of propofol also notes that required doses may be lower when general anaesthesia is used in association with regional anaesthetic techniques.7 An in vitro study using liver microsomes found that propofol inhibited the metabolism of lidocaine by cytochrome P450 isoenzymes.8 However, a further study by the same authors in 31 patients undergoing anaesthesia with either propofol or sevoflurane, and receiving epidural lidocaine, found that, compared with sevoflurane (which does not inhibit lidocaine metabolism), propofol similarly did not affect the metabolism of epidural lidocaine. The lack of interaction in the latter study could be due to the lower doses of propofol involved and because other isoenzymes or extrahepatic metabolism of lidocaine might possibly be involved.9

A randomised, double-blind, placebo-controlled study involving 44 patients found that lidocaine epidural anaesthesia (15 mL of 2% plain lidocaine) reduced the MAC of sevoflurane required for general anaesthesia by approximately 50% (from 1.18 to 0.52%). This implies that a lower dose of inhalational anaesthetic provides adequate anaesthesia during combined epidural-general anaesthesia than for general anaesthesia alone.10

(c) Adrenaline in local anaesthetics

Note that drugs such as adrenaline (epinephrine), which are used with local anaesthetics, may interact with inhalational anaesthetics such as halothane to increase the risk of arrhythmias, see ‘Anaesthetics, general + Inotropes and Vasopressors’, p.99.

Anaesthetics, general + Anthracyclines

Pretreatment with anthracyclines may result in prolongation of the QT interval during isoflurane anaesthesia.

Clinical evidence, mechanism, importance and management

A study in women with breast cancer found that the QTc interval was prolonged (to more than 440 milliseconds) during anaesthesia with isoflurane (end-tidal concentration 0.5 vol%) in more than 50% of the 20 patients who had received treatment (about 1 month before surgery) with fluorouracil and cyclophosphamide and either doxorubicin or epirubicin, compared with only 1 of 20 patients who had not previously received chemotherapy. However, QTc intervals of 600 milliseconds and above, which may be associated with serious arrhythmias, were not observed. Anthracyclines (such as doxorubicin and epirubicin) and isoflurane can prolong the QT interval. The patients had also received midazolam, which is reported to reduce QTc prolongation induced by other anaesthetics. It was noted that the use of higher isoflurane concentrations in patients given anthracyclines could result in greater QTc interval prolongation.1 In patients treated with anthracyclines or other drugs that prolong the QT interval, it should also be borne in mind that several drugs used in anaesthesia may affect the QT interval. For example thiopental and sufentanil are also reported to prolong the QT interval, while propofol and halothane are said to shorten it.1

three drugs: sevoflurane or isoflurane (adjusted to 1.5 MAC), or intravenous propofol 6 to 12 mg/kg per hour. Neuromuscular block was induced with rocuronium and monitored using train-of-four stimulation (TOF) of the ulnar nerve. Neostigmine was given when the first response in TOF had recovered to 20 to 25%. At this point isoflurane or sevoflurane was stopped, or the propofol dose reduced, in half of the patients in each of the three groups. The times to recovery of the TOF ratio to 0.8 were 12 and 6.8 minutes in the sevoflurane continued and stopped groups respectively, and 9 and 5.5 minutes in the isoflurane continued and stopped groups respectively, and 5.2 and 4.7 minutes in the propofol continued and reduced groups respectively. Only 9/20 and 15/20 patients in the

Note that inhalation anaesthetics potentiate neuromuscular blockers, see ‘Anaesthetics, general + Neuromuscular blockers’ p.101.

A study of 40 patients found that physostigmine pre-treatment (2 mg intravenously 5 minutes before induction) increased propofol requirements by 20%. Propofol does not appear to delay the reversal of rocuronium block by neostigmine. See (a) above.

**Anaesthetics, general + Antiemetics**

Metoclopramide pre-treatment reduces the dosage requirements of propofol and thiopental. Droperidol, but not ondansetron, reduces the dose requirements of thiopental.

**Clinical evidence**

(a) Metoclopramide or Droperidol

In a randomised, placebo-controlled, double-blind study of 60 surgical patients, half of whom were given metoclopramide 150 micrograms/kg 5 minutes before induction, it was found that the induction dose of propofol was reduced by 24% in the group given metoclopramide. Similar results were seen in another study of 21 patients, in which metoclopramide 10 or 15 mg reduced the dose requirements of propofol by 24.5% and 41.2%, respectively. In a randomised, double-blind, placebo-controlled study in 96 women patients, both metoclopramide and droperidol reduced the amount of thiopental needed to induce anaesthesia by about 45%.

(b) Ondansetron

In a double-blind, placebo-controlled, randomised study of 168 female patients ondansetron 100 or 200 micrograms/kg given intravenously 5 minutes before thiopental induction did not influence the hypnotic requirements of the thiopental.

**Mechanism**

The exact mechanism by which metoclopramide reduces propofol or thiopental dose requirements is unclear, but it appears to involve the blockade of dopamine (D2) receptors.

**Importance and management**

Although the evidence is limited these interactions between metoclopramide and thiopental or propofol, and between droperidol and thiopental would appear to be established. Droperidol has not been studied with propofol, but, on the basis of other interactions it would be expected to behave like metoclopramide. When patients are pretreated with either metoclopramide or droperidol, be alert for the need to use less propofol and thiopental to induce anaesthesia. Ondansetron appears not to interact.

**Anaesthetics, general + Antihypertensives**

The concurrent use of general anaesthetics and antihypertensives generally need not be avoided but it should be recognised that the normal homeostatic responses of the cardiovascular system will be impaired. For example, marked hypotension has been seen in patients taking ACE inhibitors or angiotensin-II receptor antagonists during anaesthetic induction. Profound hypotension may occur in patients taking alfaxosin during general anaesthesia.

**Clinical evidence, mechanism, importance and management**

The antihypertensive drugs differ in the way they act, but they all interfere with the normal homeostatic mechanisms that control blood pressure and, as a result, the reaction of the cardiovascular system during anaesthesia to fluid and blood losses, body positioning, etc. is impaired to some extent. For example, enhanced hypotension was seen in a study of the calcium-channel blocker nimodipine during general anaesthesia (see ‘Anaesthetics, general + Calcium-channel blockers’, p.98), and marked hypotension has also been seen with ACE inhibitors in this setting (see below). This instability of the cardiovascular system needs to be recognised and allowed for, but it is widely accepted that antihypertensive treatment should normally be continued. In some cases there is a real risk in stopping, for example a hypertensive rebound can occur if clonidine or the beta blockers are suddenly withdrawn. See also ‘Anaesthetics, general + Beta blockers’, p.97.

(a) ACE inhibitors

Marked hypotension (systolic BP 75 mmHg), which did not respond to surgical stimulation, occurred in a 42-year-old man taking enalapril when he was anaesthetised with propofol. He responded slowly to the infusion of one litre of Hartmann’s solution. Severe and unexpected hypotension has been seen during anaesthetic induction in patients taking captopril. In a randomised clinical study, the incidence of hypotension during anaesthetic induction was higher in patients who had taken captopril or enalapril on the day of surgery than in those who had stopped these drugs 12 or 24 hours prior to surgery. In 18 patients induction of anaesthesia for coronary artery bypass surgery resulted in a significant reduction in blood pressure and heart rate, irrespective of whether or not they were taking ACE inhibitors. The patients taking ACE inhibitors showed a marked decrease in cardiac index but no changes in systemic vascular resistance compared with the patients not taking ACE inhibitors. In another study in patients undergoing coronary artery bypass surgery, short-lasting hypotensive episodes (less than 60 seconds) occurred in 9 of 16 patients receiving captopril, enalapril, perindopril or lisinopril, compared with 2 of 16 who were not taking ACE inhibitors. In patients undergoing coronary artery bypass surgery, short-lasting hypotensive episodes (less than 60 seconds) occurred in 9 of 16 patients receiving captopril, enalapril, perindopril or lisinopril, compared with 2 of 16 who were not taking ACE inhibitors. The patients experiencing hypotension required additional intravenous fluids and vasoconstrictors to maintain haemodynamic stability. Similar findings are reported in another study which included patients taking captopril, enalapril, ramipril, or lisinopril. Another experimental study found that a single dose of captopril at induction of anaesthesia caused a small reduction in cerebral blood flow, when compared with control patients or patients given metoprolol.

Particular care would seem to be needed with patients taking ACE inhibitors, but there is insufficient evidence to generally recommend discontinuing ACE inhibitors before surgery. It is noted that whether ACE inhibitors are discontinued or continued, haemodynamic instability may occur after induction of anaesthesia. One report in patients undergoing cardiac surgery found that intravenous enalaprilat effectively reduced blood pressure and also exerted a beneficial effect on the endocrine regulators of macro- and microcirculation by blunting the increase in vasoconstrictors.

One recommendation is that intravenous fluids should be given to all patients taking ACE inhibitors who are anaesthetised. If hypotension occurs, blood pressure can be restored in most patients by giving sympathomimetics such as phenylephrine. However, sympathomimetics may not be fully effective in treating hypotension due to ACE inhibitors.
and anaesthesia because ACE inhibitor administration may result in a decrease in the adrenergic vasoconstrictive response. Terlipressin (a vasopressin analogue that has some effects as a vasopressin agonist) is reported to be an effective treatment for refractory hypotension during anaesthesia in patients taking ACE inhibitors. One study found that severe hypotension during anaesthetic induction in patients chronically taking ACE inhibitors could be controlled with an intravenous injection of angiotensin II (Hypertensine). Terlipressin has been found to be effective in patients with refractory hypotension taking angiotensin II receptor antagonists.

(c) Angiotensin II receptor antagonists

A study in 12 hypertensive patients taking angiotensin-II receptor antagonists found that hypotension occurred in all patients after induction of anaesthesia. This was more frequent than that found in matched groups of hypertensive patients receiving either beta blockers and/or calcium-channel blockers (27 out of 45) or ACE inhibitors (18 of 27). The magnitude of hypotension was also significantly greater in those treated with angiotensin II receptor antagonists and it was less responsive to ephedrine and phenylephrine.

Terlipressin has been found to be effective in patients with refractory hypotension taking angiotensin II receptor antagonists.

The anaesthetic dosage of thiopental is reduced, and its effects prolonged by pretreatment with aspirin or probenecid.

Clinical evidence

A study in patients about to undergo surgery found that pretreatment with aspirin 1 g (given as intravenous lysine acetylsalicylate) one minute before induction reduced the dosage of thiopental by 34%, from 5.3 to 3.5 mg/kg. Initially thiopental 2 mg/kg was given followed by increments of 25 mg until the eyelash reflex was abolished. The same study also found that oral probenecid 1 g given one hour before anaesthesia reduced the required thiopental dosage by 23%, from 5.3 to 4.1 mg/kg.

A further double-blind study in 86 women found that probenecid given 3 hours before surgery prolonged the duration of anaesthesia with thiopental:

- In patients pretreated with atropine 7.5 micrograms/kg, pethidine (meperidine) 1 mg/kg, and 500 mg of probenecid, the duration of anaesthesia with thiopental 7 mg/kg was prolonged by 65%.
- In patients pretreated with atropine 7.5 micrograms/kg, pethidine 1 mg/kg, and 1 g of probenecid, the duration of anaesthesia with thiopental 7 mg/kg was prolonged by 46%.
- In patients pretreated with atropine 7.5 micrograms/kg (no pethidine) and 500 mg of probenecid, the duration of anaesthesia with thiopental 7 mg/kg was prolonged by 26%.
- In patients pretreated with atropine 7.5 micrograms/kg (no pethidine) and 500 mg of probenecid, and no surgical stimulus the duration of anaesthesia with thiopental 4 mg/kg was prolonged by 109%.

Mechanism

Not understood. It has been suggested that aspirin and probenecid increase the amount of free and active thiopental in the plasma since they compete for the binding sites on the plasma albumins.

Importance and management

Information is limited but what is known shows that the effects of thiopental are increased by aspirin and probenecid. Be alert for the need to reduce the dosage. However, note also that regular aspirin use may increase the risk of bleeding during surgery, and it is often recommended that aspirin should not be taken in the week before surgery.

An isolated report describes a grand mal seizure in a man taking chlorpromazine and flupentixol when he was anaesthetised with enflurane. The sedative properties of antipsychotics may be enhanced by thiopental. Lower etomidate doses are recommended in patients taking antipsychotics.

An isolated report describes an unexpected grand mal seizure in a schizophrenic patient without a history of epilepsy when he was given enflurane anaesthesia. He was taking chlorpromazine 50 mg three times daily (irregularly) and flupentixol 40 mg intramuscularly every 2 weeks. The suggested reason is that the enflurane had a synergistic effect with the two antipsychotics, all of which are known to lower the seizure threshold. The general importance of this interaction is not known.

The manufacturer of thiopental notes that, as would be expected, the sedative properties of antipsychotics may be potentiated by thiopental.

The manufacturer of etomidate recommends that the dose of etomidate should be reduced in patients taking antipsychotics.

Drorperidol reduces the dose requirements of thiopental, see ‘Anaesthetics, general + Antimetabolites’, p.94.

Midazolam markedly potentiated the anaesthetic action of halothane. Similarly, the effects of propofol or thiopental are greater than would be expected by simple addition when midazolam is given concurrently, although the extent varies between the end-points measured (analgesic, motor, hypnotic). Quazepam reduces induction time for propofol anaesthesia and premedication with diazepam reduces the dose of ketamine required.

Clinical evidence

(a) Halothane

In a study in 50 women undergoing surgery midazolam markedly potentiated the anaesthetic action of halothane: a mean midazolam dose of 278 micrograms/kg reduced the halothane MAC by 51.3%.1

(b) Ketamine

A study in patients undergoing major abdominal surgery found that in 10 patients premedicated with rectal diazepam one hour before induction, the haemodynamic effects of ketamine (increases in heart rate and blood pressure) were significantly reduced, when compared with 31 controls. Also, a lower rate of ketamine infusion was required during the initial 30 minutes of anaesthesia, the half-life of ketamine was significantly increased and the plasma levels of the hydroxylated metabolites were reduced. These findings suggest that both pharmacodynamic and pharmacokinetic interactions exist between diazepam and ketamine. In the same study, 3 patients were given 20 mg of intravenous clorazepate about one hour before induction of anaesthesia, but this did not affect either the dose of ketamine required or its pharmacokinetics.2

(c) Propofol

Two studies found that if propofol and midazolam were given together, the hypnotic and anaesthetic effects were greater than would be expected by the simple additive effects of both drugs.3,4 In one of these studies, the ED₅₀ (the dose required for 50% of the patients to respond) for hypnosis was 44% less than that expected of the individual drugs and the addition of midazolam 130 micrograms/kg caused a 52% reduction in the ED₅₀ of propofol required for anaesthesia.5 A pharmacokinetic study found a very modest 20% increase in the levels of free midazolam in the plasma when it was given with propofol, but this was considered too small to explain the considerable synergism.5 In a further double-blind, placebo-controlled study in 24 patients, premedication with intravenous midazolam, 50 micrograms/kg given 20 minutes before induction of anaesthesia, reduced the propofol dose requirements for multiple anaesthetic end-points, including hypnotic, motor, EEG and analgesia. However, the potentiation effect and the mechanism of the interaction appeared to vary with the anaesthetic end-point and the dose of propofol. Notably, the interaction was most marked for analgesia.6 Another double-blind, placebo-controlled study in 60 children aged 1 to 3 years found that oral midazolam 500 micrograms/kg approximately 30 minutes before the induction of anaesthesia delayed early recovery from anaesthesia, which was induced with propofol and maintained with sevoflurane and nitrous oxide/oxygen. However, the time to hospital discharge was not prolonged.7 A further double-blind, placebo-controlled study in 24 patients found that propofol decreased the clearance of midazolam by 37% and increased its elimination half-life by 61%.8 A study in 33 patients found that quazepam 15 or 30 mg given the night before induction of anaesthesia with propofol and fentanyl reduced the induction time when compared with a third group of patients not given a hypnotic. Quazepam did not affect blood pressure or heart rate, but the 30 mg dose of quazepam did increase anterograde amnesia.9

(d) Thiopental

Thiopental has been shown to act synergistically with midazolam at induction of anaesthesia in two studies.10,11 In one of these studies, midazolam reduced the dose of thiopental required to produce anaesthesia by 50%.11 In a further double-blind, placebo-controlled study in 23 patients, premedication with intravenous midazolam 50 micrograms/kg, given 20 minutes before the induction of anaesthesia, reduced the thiopental dose requirements for multiple anaesthetic end-points, including hypnotic, motor, EEG and analgesia. Potentiation was greatest for the motor end-point (about 40%) and smallest for analgesia (18%).12

Mechanism

Propofol, barbiturates and halothane appear to interact with benzodiazepines through their effects on the gamma-aminobutyric acid (GABA) receptor.

Diazepam appears to undergo similar oxidative processes as ketamine and therefore competitively inhibits ketamine metabolism.2 Clorazepate is only slowly decarboxylated and is therefore not affected.2 An in vitro study suggests that propofol may reduce the clearance of midazolam by inhibition of the cytochrome P450 isoenzyme CYP3A4.8

Importance and management

The interactions between propofol or thiopental and midazolam are well established. This synergy has been utilised for the induction of anaesthesia.13 Midazolam also reduces the dose requirements of halothane. Other benzodiazepines may also potentiate the effects of general anaesthetics.

Clinical evidence, mechanism, importance and management

Two patients developed ventricular arrhythmias while anaesthetised with halothane and nitrous oxide/oxygen when given terbutaline 250 to 350 micrograms subcutaneously for wheezing. Both developed unifocal premature ventricular contractions followed by bigeminy, which responded to lidocaine.1 Halothane was replaced by enflurane in one case, which allowed the surgery to be completed without further incident.1

Halothane is known to cause arrhythmias and it has been suggested that it may increase susceptibility to the adverse cardiac effect of beta-agonist bronchodilators,2 which can cause arrhythmias. Note that beta agonists such as terbutaline are sympathomimetics (see ‘Table 24.1’, (p.879)), like adrenaline (epinephrine), which has also been shown to cause arrhythmias in the presence of halothane (see ‘Anaesthetics, general + Inotropes and Vasopressors’, p.99).

Anaesthetics, general + Beta blockers

Anaesthesia in the presence of beta blockers normally appears to be safer than withdrawal of the beta blocker before anaesthesia, provided certain inhalational anaesthetics are avoided (methoxyflu- rane, cyclopropane, ether, trichloroethylene) and atropine is used to prevent bradycardia. Bradycardia and marked hypoten-
sion occurred in a man using timolol eye drops when he was anaesthetised.

Acute peri-operative administration of beta blockers may reduce the dose of anaesthetic required for induction and may result in deeper anaesthesia.

Clinical evidence and mechanism

A. Cardiac depressant effects

It used to be thought that beta blockers should be withdrawn from patients before surgery because of the risk that their cardiac depressant effects would be additive with those of inhalational anaesthetics, resulting in a re-
duction in cardiac output and blood pressure, but it seems that any effect depends on the anaesthetic used.1 It has been suggested that the ranking order of compatibility (from the least to the most compatible with beta blockers) is as follows: methoxyflurane, ether, cyclopropane, trichlo-roethylene, enflurane, halothane, isoflurane.4

(a) Cyclopropane, Ether, Methoxyflurane, and Trichloroethylene

A risk of cardiac depression certainly seems to exist with cyclopropane and ether because their depressant effects on the heart are normally counteracted by the release of catecholamines, which would be blocked by the presence of a beta blocker. There is also some evidence (clinical and/or animal) that unacceptable cardiac depression may occur with methoxyflu-
rane and trichloroethylene when a beta blocker is present. This has been the subject of two reviews.2,3 For these four inhalational anaesthetics it has been stated that an absolute indication for their use should exist before giving them in combination with a beta blocker.1

(b) Enflurane, Halothane, and Isoflurane

Although a marked reduction in cardiac performance has been described in a study in dogs given propranolol and enflurane (discussed in two reviews4,5) these drugs have been widely used without apparent difficulties.3 Normally beta blockers and halothane or isoflurane appear to be safe. On the positive side there appear to be considerable benefits to be gained from the continued use of beta blockers during anaesthesia. Their sudden withdrawal from patients treated for angina or hypertension can re-
sult in the development of acute and life-threatening cardiovascular com-
plications whether the patient is undergoing surgery or not. In the peri-operative period patients benefit from beta blockade because it can minimise the effects of sympathetic overactivity of the cardiovascular system during anaesthesia and surgery (for example during endotra-
cheal intubation, laryngoscopy, bronchoscopy and various surgical manoeuvres), which can cause cardiac arrhythmias and hypertension.

(c) Unnamed general anaesthetic

A 75-year-old man being treated with timolol eye drops for glaucoma de-
veloped bradycardia and severe hypotension when anaesthetised [drug not
named], and responded poorly to intravenous atropine, dextrose-saline inf-
fusion and elevation of his feet.4 It would seem that there was sufficient systemic absorption of the timolol for its effects to be additive with the ana-
esthetic and cause marked cardiovascular depression.

B. Reduction of anaesthetic requirements

Intra-operative intravenous atenolol given in 5-mg stepwise doses (medi-
an dose 20 mg; range 10 to 80 mg) was found to reduce the isoflurane re-
quirement by about 40% without affecting the bispectral index (BIS; a predictor of the depth of anaesthesia). Patients also received on average 21% less fentanyl compared with control patients who were not given atenolol.5

Several studies have similarly found that the use of esmolol reduced the required dose of isoflurane or propofol, or resulted in a deeper anaesthe-
sia (as measured by BIS), but only in the presence of an opioid.6–10 As there appears to be no pharmacokinetic interaction between esmolol and propofol6,8 it has been suggested that esmolol could be interacting with the opioid 6,10.

However, in one study 60 patients were given one of three treatments be-
fore induction of anaesthesia with propofol: esmolol 1 mg/kg followed by an infusion of 250 micrograms/kg per minute; midazolam; or placebo (so-
dium chloride 0.9%). No opioids were given. Esmolol and midazolam re-
duced the required induction doses of propofol by 25% and 45%, respectively. Esmolol reduced the mean heart rate by 7.6 bpm compared with placebo in the pre-induction period, and the only adverse effect noted was a transient episode of bradycardia (44 bpm) in one patient receiving esmolol. Esmolol reduces cardiac output by reduction of heart rate and stroke volume and this possibly reduces the required induction dose of propofol by changing its distribution.11

Another study found that a single 80-mg dose of esmolol after induction of anaesthesia with propofol and either fentanyl or placebo did not affect the depth of anaesthesia (measured by BIS) in either group of patients, even though cardiovascular effects were seen (reduction in systolic arteri-
al pressure and heart rate).12

Importance and management

A. The consensus of opinion is that beta blockers should not be withdrawn before anaesthesia and surgery11,14 because of the advantages of maintain-
ing beta-blockade, and because the risks accompanying withdrawal are considerable. But, if inhalational anaesthetics are used, it is important to select the safest anaesthetics (isoflurane, halothane), and avoid those that appear to be most risky (methoxyflurane, ether, cyclopropane, trichlo-roethylene: most of which are no longer regularly used), as well as ensur-
ing that the patient is protected against bradycardia by atropine.

The authors of the report4 concerning topically applied beta blockers suggest that if such patients are to be anaesthetised, low concentrations of timolol should be used (possibly withhold the drops pre-operatively), and that “induction agents should be used judiciously and beta-blocking antag-
onists kept readily available.” It is easy to overlook the fact that systemic absorption from eye drops can be high enough to cause adverse interac-
tions.

B. Several studies suggest that beta blockers, such as atenolol and esmolol, given before induction reduce the anaesthetic dose requirement and may potentiate hypnotic. However, there are concerns that reducing the dose of anaesthetic may increase the risk of intra-operative awareness and it has been suggested that the use of BIS to predict the depth of anaesthesia in the presence of beta blockers may not be valid.15 There is a possibility that acute as well as chronic administration of beta blockers may prevent peri-
operative cardiac complications,12,13 but more study is needed on this.13,14

Impaired myocardial conduction has been seen in two patients taking diltiazem after they were anaesthetised with enflurane, and prolonged anaesthesia has been seen with verapamil and etomidate, but it has been suggested that chronic administration of oral calcium-channel blockers up to the day of surgery is usually beneficial. Intravenous dihydropyridines have been used to control peri-operative hypertension, but the use of intravenous verapamil is not recommended in patients anaesthetised with either halothane or enflurane.

Clinical evidence, mechanism, importance and management

(a) Dihydropyridines

Enhanced hypotension was seen in a study in which patients were given intravenous nimodipine during general anaesthesia, which included either halothane or isoflurane.\(^1\) The presence of low concentrations of isoflurane (0.6%) or sevoflurane (0.9%) are reported not to have a marked effect on the pharmacological action of nicardipine.\(^2\) In one study intravenous nicardipine 17 micrograms/kg was given to 30 neurological patients anaesthetised with either enflurane, isoflurane or sevoflurane. Peak reductions in blood pressure occurred 3 minutes after nicardipine was given and were greatest in the group receiving sevoflurane. However, peak reductions in blood pressure persisted for longer (30 minutes), as did increases in heart rate, with isoflurane. However, clearance of nicardipine was most rapid in patients given isoflurane anaesthesia.\(^3\)

Some caution is clearly appropriate, especially with intravenous calcium-channel blockers given during surgery, but general experience suggests that long-term treatment with oral dihydropyridine calcium-channel blockers need not be avoided in most patients undergoing anaesthesia, and may be continued until the day of surgery. Further, intravenous dihydropyridines have been reported to be safe and effective for the control of peri-operative hypertension.\(^4\)

(b) Diltiazem or Verapamil

The author of a review about calcium-channel blockers and anaesthetics concludes that their concurrent use in patients with reasonable ventricular function is normally beneficial, except where there are other complicating factors. Thus he warns about possible decreases in ventricular function in patients undergoing open chest surgery given intravenous verapamil or diltiazem.\(^5\) A report describes a patient taking diltiazem and atenolol who had impaired AV and sinus node function before anaesthesia, which worsened following the use of enflurane.\(^6\) Another patient also taking diltiazem (and atenolol) had to be paced due to bradycardia of 35 bpm at induction, but despite this he developed severe sinus bradycardia, which progressed to asystole when enflurane was given.\(^6\) The authors of this latter report suggest that enflurane and diltiazem can have additive depressive effects on myocardial conduction. Two cases of prolonged anaesthesia and Cheyne-Stokes respiration have been reported in patients who were undergoing cardiovascular. Both received verapamil and were induced with etomidate.\(^7\) The presence of low concentrations of isoflurane (0.6%) or sevoflurane (0.9%) are reported not to have a marked effect on the pharmacological action of diltiazem.\(^2\)

The authors of a review concluded that intravenous verapamil or diltiazem are not recommended in patients anaesthetised with either halothane or enflurane, especially if the patients have cardiac failure or conduction disturbances.\(^8\)
prior to surgery, and so the blood loss was attributed to an interaction between the herbal medicine and the sevoflurane, which was used to maintain anaesthesia.

Sevoflurane can inhibit platelet aggregation by inhibiting thromboxone A2, and aloe vera affects prostaglandin synthesis, which may also impair platelet aggregation. However, it should be noted that the patient’s aPTT and INR were not assessed pre-operatively and the authors do state that the vasality and size of the haemangioma were the most important factors in the blood loss, so an interaction is by no means proven.

(b) Kava kava

There is one case report of kava kava potentiating the effect of benzodiazepines (see ‘Benzodiazepines + Kava’, p.730), and it has been suggested that it could potentiate other CNS depressants including barbiturates\(^1^,\(^2^,\(^3^\)) (e.g. thiopental), and may prolong or potentiate the effects of anaesthetics.\(^4^,\(^5^\) Kava may act via GABA receptors, and kavalactones (one group of active constituents) also have skeletal muscle relaxant and local anaesthetic properties.\(^2^,\(^3^\) Toxic doses can produce muscle weakness and paralysis.\(^2^,\(^3^\)

(c) St John’s wort (Hypericum perforatum)

It has been suggested that St John’s wort (Hypericum perforatum) may prolong anaesthesia,\(^4^,\(^7\) but there are no reports of this. This appears to have been based on the possibility that St John’s wort acts as an MAOI,\(^5^,\(^7\) although this has been disputed\(^8^\) and the limited evidence that MAOIs may cause hepatic enzyme inhibition and potentiate the effects of barbiturates (see ‘MAOIs + Barbiturates’, p.1132). However, there is now increasing evidence that St John’s wort induces hepatic enzymes, and might therefore increase the metabolism of barbiturates (see ‘Antiepileptics + St John’s wort (Hypericum perforatum)’, p.523), which suggests that it could increase requirements for thiopental anaesthesia. The possible MAOI activity of St John’s wort has led to the recommendation that the same considerations apply as for other MAOIs and general anaesthetics,\(^5^,\(^7^\) see ‘Anaesthetics, general + MAOIs’, p.100. A case report describes a healthy 23-year-old woman who had been taking St John’s wort on a daily basis for 6 months, who developed severe hypotension (BP 60/20 mmHg) during general anaesthesia, which responded poorly to ephedrine and phenylephrine (BP increased to 70/40 mmHg). It was suggested that the St John’s wort might have caused adrenergic desensitisation with decreased responsiveness to the vasopressors.\(^9^\)

(d) Valerian

An ethanol extract of valerian (Valeriana officinalis) was shown to modestly prolong thiopental anaesthesia in mice, possibly via its effects on the GABA-benzodiazepine receptor.\(^11^\)

Importance and management

Not established. The evidence presented suggests that caution may be warranted in patients using valerian, kava kava, or St John’s wort if the same considerations apply as for other MAOIs and general anaesthetics, which may also impair platelet aggregation. However, it should be noted that the patient’s aPTT and INR were not assessed pre-operatively and the authors do state that the vasality and size of the haemangioma were the most important factors in the blood loss, so an interaction is by no means proven.

Anaesthetics, general + Inotropes and Vaspressors

Patients anaesthetised with inhalational anaesthetics (particularly cyclopropane and halothane, and to a lesser extent desflurane, enflurane, ether, isoflurane, methoxyflurane, and sevoflurane) can develop cardiac arrhythmias if they are given adrenaline (epinephrine) or noradrenaline (norepinephrine), unless the dosages are very low. Children appear to be less susceptible to this interaction. The addition of adrenaline to intrathecal tetracaine enhances the sedative effects of propofol.

Clinical evidence, mechanism, importance and management

As early as 1895, it was noted that an adrenal extract could cause ventricular fibrillation in a dog anaesthetised with chloroform,\(^1^\) and it is now very well recognised that similar cardiac arrhythmias can be caused by adrenaline and noradrenaline in humans anaesthetised with inhalational anaesthetics. The mechanism appears to be a sensitisation of the myocardium to β-adrenergic stimulation, caused by the inhalational anaesthetic. The likelihood of arrhythmias is increased by hypoxia and marked hypercapnia. It has been reported that the highest incidence of complications has been in patients anaesthetised with cyclopropane, but that the incidence is also high with trichloethylen and halothane.\(^2^\) A suggested listing of inhalational anaesthetics in order of decreasing sensitising effect on the myocardium is as follows:\(^3^\) cyclopropane, halothane, enflurane/methoxyflurane, isoflurane, ether. Sevoflurane\(^4^\) and desflurane\(^5^\) appear to behave like isoflurane.

It has been recommended that if adrenaline is used to reduce surgical bleeding in patients anaesthetised with halothane/nitrous oxide/oxygen the dosage should not exceed 10 mL of 1:100 000 in any given 10 minute period, nor 30 mL per hour (i.e. about a 100 microgram bolus or 1.5 micrograms/kg per 10 minutes for a 70 kg person), and adequate alveolar ventilation must be assured.\(^6^\) This dosage guide should also be safe for use with other inhalational anaesthetics since halothane is more arrhythmogenic than the others,\(^7^\) with the exception of cyclopropane, which is no longer widely used. However, some have suggested that concurrent halothane and adrenaline may have been a contributing factor in 3 deaths in patients undergoing tooth implant surgery.\(^7^\) Others consider that if adrenaline is used for haemostasis during surgery, isoflurane or sevoflurane carry less risk of cardiac arrhythmias than halothane.\(^8^\) Solutions containing 0.5% lidocaine with adrenaline 1:200 000 also appear to be safe because lidocaine may help to control the potential dystrophic effects. For example, a study in 19 adult patients anaesthetised with halothane found that the dose of adrenaline needed to cause three premature ventricular contractions in half the group was 2.11 micrograms/kg when it was given in saline, but 3.69 micrograms/kg when it was given in 0.5% lidocaine. Note that both these values were less than that in 16 patients anaesthetised with isoflurane (6.72 micrograms/kg), demonstrating that isoflurane was still safer.\(^9^\) It should be borne in mind that the arrhythmogenic effects of adrenaline are increased if sympathetic activity is increased, and in hyperthyroidism and hypercapnia.\(^9^\)

Children appear to be much less susceptible to these effects than adults. A retrospective study of 28 children found no evidence of arrhythmia during halothane anaesthesia with adrenaline doses of up to 8.8 micrograms/kg, and a subsequent study in 83 children (aged 3 months to 17 years) found that 10 micrograms/kg doses of adrenaline were safe.\(^10^\)

A study in 20 patients undergoing spinal anaesthesia with tetracaine found that propofol sedation (as measured by bispectral index monitoring (BIS)) was enhanced when adrenaline was added to the intrathecal tetra- caine.\(^11^\) A study in sheep found that adrenaline, noradrenaline and dopamine decreased propofol concentrations during a continuous propofol infusion, with the result that propofol anaesthesia was reversed. This was thought to be due to increased first pass clearance of propofol secondary to increased cardiac output. It was concluded that this could be of clinical importance if propofol is used in hyperdynamic circulatory conditions induced by either catecholamine infusions or disease states such as sepsis.\(^12^\)

Isoniazid may increase the metabolism of enflurane, isoflurane or sevoflurane and thereby increase plasma-fluoride concentrations. However, this does not seem to have resulted in clinically important renal impairment.

Clinical evidence, mechanism, importance and management

A 46-year-old woman underwent anaesthesia for renal transplantation 6 days after starting isoniazid 300 mg daily. Anaesthesia was induced with intravenous thiopental and maintained for 4 hours with 60% nitrous oxide, fentanyl and isoflurane. Serum fluoride ions increased from 4.3 micromol preoperatively to approximately 30 micromol between 2 and 8 hours after starting isoflurane. However, no impairment of renal function occurred. A second patient who was given 5 times the first patient’s exposure to isoniazid and who had received isoniazid for 13 years showed no increase in serum fluoride concentrations over preoperative values, but did show an increase in trifluoroacetic acid levels.

When enflurane was given to 20 patients who had been taking isoniazid 300 mg daily for between one week and one year, 9 had an increase in peak fluoride ion levels. These 9 patients had a fourfold higher fluoride level than 36 control subjects not taking isoniazid and the 11 other subjects taking isoniazid. By 48 hours after anaesthesia, there was no difference in fluoride levels. Despite the increase in fluoride levels, there was no change in renal function.

Isoniazed may increase the metabolism of enflurane, isoflurane or sevoflurane in some patients (probably related to isoniazid acetylator phenotype) and so increase the release of fluoride ions that may cause nephrotoxicity. However, there do not appear to be any reports of a significant clinical effect on renal function.

The BNF states that ‘in view of their hazardous interactions MAOIs should normally be stopped 2 weeks before surgery.’ It has also been suggested that a longer period of time (more than 20 days) between discontinuing MAOIs and surgery may be required, so much to recover MAO enzyme activity but to recover depressed adrenergic receptor function. These warnings are probably more to avoid interactions with the anesthetic adjuncts mentioned above, rather than the MAOIs themselves. Therefore in an emergency situation it would seem possible to anaesthetise a patient, but it must be remembered that the choice of anaesthetic adjuncts is likely to be restricted.

### Anaesthetics, general + Methylphenidate

A single report described difficulty in sedating a child taking methylphenidate, and a possible delayed interaction between ketamine and methylphenidate, which resulted in nausea, vomiting, and dehydration. The use of methylphenidate after ketamine anaesthesia increased the incidence of vomiting, excessive talking, and limb movements in one study. Methylphenidate should probably be withheld before surgery using inhalational anaesthetics, because of the potential risk of hypertension and/or arrhythmias.

#### Clinical evidence, mechanism, importance and management

A 6-year-old boy weighing 22 kg, who was taking methylphenidate 5 mg twice daily for attention deficit disorder, was found to be difficult to sedate for an echocardiogram. Sedation was attempted with oral chloral hydrate 75 mg/kg without success. One week later he received midazolam 20 mg orally, but was only mildly sedated 20 minutes later and would not lie still. Despite an additional oral dose of midazolam 10 mg mixed with oral ketamine 60 mg the child was still alert and uncooperative 20 minutes later. He was finally given intravenous glycopyronium (glycopyrrolate) 100 micrograms followed by intravenous midazolam 5 mg given over 5 minutes and was successfully sedated. He recovered from sedation uneventfully, but developed nausea, vomiting and lethargy after discharge from hospital, which responded to rehydration treatment. In a double-blind study, methylphenidate was given as a single 20-mg intravenous dose to try to speed recovery at the end of ketamine anaesthesia for short urological procedures. However, methylphenidate did not improve recovery, and increased the incidence of vomiting, excessive talking, and limb movements.

In the first case, the stimulant effect of the methylphenidate was thought to have antagonised the sedative effect of the midazolam and ketamine. The methylphenidate may also have delayed the absorption of the oral drugs. In addition, methylphenidate may inhibit liver microsomal enzymes and could therefore possibly delay elimination of both ketamine and midazolam so that hazardous plasma concentrations could develop.

However, the study did not find evidence of these effects.

These appear to be the only reports, so any effect is not established. Be aware that methylphenidate may possibly antagonise the effect of sedative

### Anaesthetics, general + Neuromuscular blockers

The inhalational anaesthetics increase the effects of the neuromuscular blockers to differing extents, but nitrous oxide appears not to interact significantly. Ketamine has been reported to potentiate the effects of the neuromuscular blockers. Propofol does not appear to interact with mivacurium or vecuronium. Xenon is reported not to interact with mivacurium or rocuronium, and has less effect than sevoflurane on vecuronium neuromuscular blockade. Bradycardia has been seen in patients given vecuronium with etomidate, but not with thiopental. Propofol can cause serious bradycardia if it is given with suxamethonium (succinylcholine) without adequate antimuscarinic premedication, and asystole has been seen when fentanyl, propofol and suxamethonium were given sequentially.

#### Clinical evidence, mechanism, importance and management

The effects of neuromuscular blockers are increased by inhalational anaesthetics, the greater the dosage of the anaesthetic the greater the increase in blockade. In broad terms desflurane, ether, enflurane, isoflurane, methoxyflurane and sevoflurane have a greater effect than halothane, which is more potent than cyclopropane, whereas nitrous oxide appears not to interact significantly with competitive blockers.

The mechanism is not fully understood but seems to be multifactorial. It has been suggested that the anaesthetic may:

- have an effect via the CNS (including depression of spinal motor neurones);
- have an effect on the neuromuscular junction (including a decrease in the release of acetylcholine and in the sensitivity of the motor end-plate to acetylcholine);
- affect the muscle tissue itself.

It has also been suggested that for mivacurium, higher plasma levels, especially of the potent trans-trans isomer, occur in the presence of isoflurane, and these could contribute to the enhanced neuromuscular blockade observed.

One study in children found that the potentiation of vecuronium was greater with isoflurane than with enflurane, and halothane had a lesser effect.

The dosage of the neuromuscular blocker may need to be adjusted according to the anaesthetic in use. For example, the dosage of atracurium can be reduced by 25 to 30% if, instead of balanced anaesthesia (with thiopental, fentanyl and nitrous oxide/oxygen), enflurane is used, and by up to 50% if isoflurane or desflurane are used. Another study recommended reduced doses of neuromuscular blockers such as atracurium and tubocurarine in children undergoing anaesthesia with enflurane or isoflurane. In one study, enflurane and isoflurane reduced the vecuronium infusion rate requirements by as much as 70%, when compared with fentanyl anaesthesia. Another study demonstrated that although halothane and isoflurane could both increase the neuromuscular potency of vecuronium, only isoflurane prolonged the recovery from neuromuscular blockade.
The respiratory depressant effects of ketamine and morphine may be additive. The dose requirements of desflurane, etomidate, propofol and thiopental may be lower after opioid use. Opioid- or grand mal seizures have rarely been associated with the use of propofol with alfentanil and/or fentanyl. The effects of inhalational anaesthetics may be enhanced by opioid analgesics.

Clinical evidence, mechanism, importance and management

(a) Inhalational anaesthetics

Opioid analgesics have been reported to reduce the MAC values of inhalational anaesthetics. For example, fentanyl has been shown to lower the MAC value of desflurane, probably in a dose-dependent manner, and this has been the subject of a review. The manufacturer notes that lower doses of desflurane are required in patients receiving opioids. Remifentanil at a target-controlled plasma level of 1 nanogram/mL was found to decrease the MAC of sevoflurane with nitrous oxide by 60%, and remifentanil 3 nanograms/mL produced a further 30% decrease in the MAC of sevoflurane. Another study found that remifentanil (dose-dependently) decreased the level of sevoflurane required to maintain anaesthesia. However, 100 microgram/kg doses of morphine given during anaesthesia did not alter the awakening concentration of sevoflurane.

(b) Etomidate

The manufacturer of etomidate recommends that the dose of etomidate should be reduced in patients who have already received opioids.

(c) Ketamine

Ketamine is a respiratory depressant like morphine, but less potent, and its effects can be additive with morphine. A study in 11 healthy subjects found that the combination of ketamine and morphine almost abolished windup-like pain (progressive increase in pain intensity on repeated stimulation) in a skin burn injury. This effect was not found with either drug alone. Further, ketamine alone, but not morphine reduced the area of secondary hyperalgesia of the local burn and increased the pain threshold, but the combination did not appear to enhance this effect. The reduction of wind-up pain may be due to ketamine-induced prevention of acute tolerance to morphine.

Another study in healthy subjects using various experimental pain models found that ketamine antagonised the respiratory depressive effect of remifentanil. Remifentanil alone produced analgesic effects with all pain tests, but ketamine only enhanced the effect of remifentanil on intra- muscular electrical stimulation. Acute remifentanil-induced hyperalgesia and tolerance were detected only by the pressure pain test and were not suppressed by ketamine. The combined effects of remifentanil and ketamine probably depend on the type of pain.

(d) Propofol

A 71-year-old man undergoing a minor orthopaedic operation was given a 500-microgram intravenous injection of alfentanil followed by a slow injection of propofol 2.5 mg/kg. Approximately 15 seconds after the propofol, the patient developed strong bilateral fits and grimaces, which lasted for 10 seconds. Anaesthesia was maintained with nitrous oxide/oxygen and halothane and there were no other intra- or postoperative complications. The patient had no history of convulsions. Propofol has also been associated with opisthotonos (a spasm where the head and heels bend backwards and the body arches forwards) in two patients given fentanyl with or without alfentanil. There is a further report of opisthotonos during recovery from anaesthesia with alfentanil, propofol and nitrous oxide. Seizures have been reported in patients with and without epilepsy receiving propofol. They mainly occur during induction and emergence or are delayed after anaesthesia, suggesting that they may be caused by changes in cerebral levels of propofol, and postanaesthetic opisthotonos may be due to a propofol-induced tolerance to inhibitory transmitters (glycine and gamma-aminobutyric acid). Any association with the opioid remains unknown, although it has been suggested that opioids may aggravate propofol-induced opisthotonos by antagonising the actions of glycine.

Alfentanil has been found to reduce the amount of propofol needed for loss of eyelash reflex and loss of consciousness, as well as increasing the blood pressure fall produced by propofol. Propofol inhibits both alfentanil and sufentanil metabolism causing an increase in plasma concentrations of these opioids, while alfentanil also increases propofol concentrations (reviewed by Vuyk and also described in more recent reports). Pretreatment with fentanyl may also decrease the propofol requirements for induction of anaesthesia, and increase blood concentrations of propofol. However, another study was unable to confirm an effect on blood propofol concentrations. Remifentanil has been reported to reduce the dose of propofol needed for anaesthesia and also to reduce the recovery time. Further, propofol and remifentanil caused dose-dependent respiratory-depression, which, during combined use, was synergistic.

Two reviews have discussed the use of opioids and propofol in anaesthesia, their pharmacokinetic and pharmacodynamic interactions, and administration and monitoring techniques.
Phenylephrine eye drops given to patients undergoing general anaesthesia caused marked cyanosis and bradycardia in a baby, and hypertension in a woman.

Clinical evidence, mechanism, importance and management
A 3-week-old baby anaesthetised with halothane and nitrous oxide/oxygen became cyanosed shortly after 2 drops of 10% phenylephrine solution were put into one eye. The heart rate decreased from 160 to 60 bpm, S-T segment and T wave changes were seen, and blood pressure measurements were unobtainable. The baby recovered uneventfully when anaesthesia was stopped and oxygen given. It was suggested that the phenylephrine caused severe peripheral vasoconstriction, cardiac failure and reflex bradycardia. A 54-year-old woman anaesthetised with isoflurane developed hypertension (a rise from 125/70 to 200/90 mmHg) shortly after having two drops of 10% phenylephrine put into one eye. The hypertension responded to nasal glyceryl trinitrate (nitroglycerin) and increasing concentrations of isoflurane. The authors of this report consider that general anaesthesia may have contributed to the systemic absorption of the phenylephrine. They suggest that phenylephrine should be given 30 to 60 minutes prior to anaesthesia, and not during anaesthesia. However, if it is necessary, use the lowest concentrations of phenylephrine (2.5%). They also point out that the following are effective mydriatics: single drop combinations of 0.5% cyclopentolate and 2.5% phenylephrine or 0.5% tropicamide and 2.5% phenylephrine.

Phenylephrine is a sympathetic stimulant, and as such may carry some risk of potentiating arrhythmias if it is used with inhalational anaesthetics such as halothane –see ‘Anaesthetics, general + Inotropes and Vasopressors’, p.99. However, it is considered that it is much less likely than adrenaline (epinephrine) to have this effect, since it has primarily alpha-agonist activity.1

Anaesthetics, general + Phenylephrine, topical

Phenylephrine toxicity occurred in a child following halothane anaesthesia. A near fatal hepatic reaction occurred in a woman given rifampicin (rifampin) after halothane anaesthesia, and hepatitis occurred in a patient taking phenobarbital who was given halothane anaesthesia. See also ‘Anaesthetics, general + Isoniazid’, p.100 and ‘Anaesthetics, general; Methoxyflurane + Antibacterials or Barbiturates’, p.107.

Clinical evidence
A 10-year-old girl receiving long-term treatment with phenytoin 300 mg daily was found to have phenytoin plasma levels of 25 micrograms/mL before surgery. Three days after anaesthesia with halothane her plasma phenytoin levels had risen to 41 micrograms/mL and she had marked signs of phenytoin toxicity. A woman taking promethazine and phenobarbital 60 mg three times daily died from halothane associated hepatitis within 6 days of being given halothane for the first time. A nearly fatal shock-producing hepatic reaction occurred in a woman 4 days after having halothane anaesthesia immediately followed by a course of rifampicin 600 mg daily and isoniazid 300 mg daily.

Anaesthetics, general + Phenytoin, Phenobarbital or Rifampicin (Rifampin)

Limited evidence suggests phenobarbital does not affect the pharmacokinetics or clinical effects of propofol. Phenobarbital does not appear to interact with nitrous oxide and isoflurane.

Clinical evidence, mechanism, importance and management
A randomised, placebo-controlled, double-blind, crossover study in 12 healthy subjects found that pretreatment with 40 mg of intravenous phenobarbital given one hour before a 2 mg/kg intravenous bolus of propofol did not significantly affect the pharmacokinetics of the propofol. Moreover, phenobarbital did not alter the clinical effects of propofol (e.g. the time to loss of consciousness or the speed of awakening). These limited data suggest that no special precautions should be required during concomitant use.

The UK manufacturer of phenobarbital says that no formal interaction studies have been done with inhalational anaesthetics, but in surgical studies, where phenobarbital was given preoperatively, there was no evidence of pharmacodynamic interactions in patients who had been given nitrous oxide and isoflurane.2

Mechanism

It seems possible that the general adverse hepatotoxic effects of halothane can slow the normal rate of phenytoin metabolism. One suggested explanation for the increased adverse effects on the liver is that, just as in animals, pre-treatment with phenobarbital and phenytoin increases the rate of drug metabolism and therefore the hepatotoxicity of halogenated hydrocarbons, including carbon tetrachloride and halothane. As well as increased metabolism, the halothane-rifampicin interaction might also involve additive hepatotoxicity.

Importance and management

No firm conclusions can be drawn from these isolated cases, but they serve to emphasise the potential hepatotoxicity when halogenated anaesthetics are given to patients taking these drugs. It has been suggested that patients taking enzyme-inducing drugs such as phenobarbital and phenytoin may constitute a high-risk group for liver damage after halogenated anaesthetics. Consider also ‘Anaesthetics, general + Isoniazid’, p. 100 and ‘Anaesthetics, general; Methoxyflurane + Antibacterials or Barbiturates’, p. 107.

Anaesthetics, general + Sparteine sulfate

Patients given thiamyllal sodium had a marked increase in cardiac arrhythmias when they were given intravenous sparteine sulfate, but those given thiopental or etomidate did not.

Clinical evidence, mechanism, importance and management

A group of 109 women undergoing dilatation and curettage were premedicated with atropine and fentanyl, and given either 2% thiamyllal sodium (5 mg/kg), 0.2% etomidate (0.3 mg/kg) or 2.5% thiopental (4 mg/kg) to induce anesthesia, which was maintained with nitrous oxide/oxygen. During the surgical procedure they were given a slow intravenous injection of sparteine sulfate 100 mg. Fourteen out of 45 patients given thiamyllal sodium developed cardiac arrhythmias; 10 had bigeminy and 4 had frequent ventricular premature contractions. Only two patients given etomidate or thiopental developed any cardiac arrhythmias. It is not understood why sparteine should interact with thiamyllal sodium in this way. Although the arrhythmias were effectively treated with lidocaine, the authors of this report suggest that the concurrent use of sparteine and thiamyllal sodium should be avoided.

Anaesthetics, general + SSRIs

One patient had a seizure when she was given methohexital while taking paroxetine. Spontaneous movements have been seen in two patients taking fluoxetine when they were anaesthetised with propofol.

Clinical evidence, mechanism, importance and management

(a) Methohexital

A generalised tonic-clonic seizure occurred in a 42-year-old woman immediately after she was anaesthetised with 120 mg of intravenous methohexital for the last in a series of six electroconvulsive therapies. She had been receiving paroxetine 40 mg daily throughout the series. The authors suggest that paroxetine should be given with caution to patients receiving ECT or methohexital anaesthesia. Note that this appears to be an isolated report.

(b) Propofol

Two women in their mid-twenties, who had been taking fluoxetine 20 mg daily for 4 to 6 months, had pronounced involuntary upper limb movements lasting 20 to 30 seconds immediately after anaesthetic induction with 180 mg of propofol (2 to 2.5 mg/kg). The movements ceased spontaneously and the rest of the anaesthesia and surgery were uneventful. Neither had any history of epilepsy or movement disorders. It is not clear whether this was an interaction between propofol and fluoxetine or just a rare (but previously reported) reaction to propofol.

Anaesthetics, general + Sulfonamides

The anaesthetic effects of thiopental are increased but shortened by sulfafurazole. Phenobarbital appears not to affect the pharmacokinetics of sulfafurazole or sulfisomidine.

Clinical evidence

A study in 48 patients found that intravenous sulfafurazole 40 mg/kg reduced the required anaesthetic dosage of thiopental by 36%, but the duration of action was shortened. This interaction has also been observed in animal experiments. A study in children showed that phenobarbital did not affect the pharmacokinetics of sulfafurazole or sulfisomidine.

Mechanism

It has been suggested that sulfafurazole successfully competes with thiopental for plasma protein binding sites, the result being that more free and active barbiturate molecules remain in circulation to exert their anaesthetic effects and therefore smaller doses are required.

Importance and management

The evidence for an interaction between sulfafurazole and thiopental is limited, but it appears to be strong. Less thiopental than usual may be required to achieve adequate anaesthesia, but since the awakening time is shortened repeated doses may be needed. Phenobarbital does not appear to affect the pharmacokinetics of the sulfonamides.

Anaesthetics, general and/or Neuromuscular blockers + Theophylline

Cardiac arrhythmias can develop during the concurrent use of halothane and aminophylline but this seems less likely with isoflurane. One report attributes seizures to an interaction between ketamine and aminophylline. Supraventricular tachycardia occurred in a patient taking aminophylline when pancuronium was given. Isolated cases suggest that the effects of pancuronium, but not vecuronium, can be opposed by aminophylline.

Clinical evidence, mechanism, importance and management

(a) Development of arrhythmias

A number of reports describe arrhythmias apparently due to an interaction between halothane and theophylline or aminophylline. One describes intraoperative arrhythmias in three out of 45 adult asthmatics who had received preoperative theophylline or aminophylline then halothane
anaesthesia.1 Nine other patients developed heart rates exceeding 140 bpm when given aminophylline and halothane, whereas tachycardia did not occur in 22 other patients given only halothane.1 There are other reports of individual adult and child patients who developed ventricular tachycardias attributed to this interaction.2–5 One child had a cardiac arrest.3 The same interaction has been reported in animals.6 One suggested reason for the interaction with halothane is that theophylline causes the release of endogenous catecholamines (adenine, epinephrine, noradrenaline (norepinephrine)), which are known to sensitise the myocardium (see also ‘Anaesthetics, general + Inotropes and Vasopressors’, p.99). Another report describes supraventricular tachycardia in a patient taking aminophylline who was anaesthetised with thiopental and fentanyl, and then given pancuronium. Three minutes later his heart rate rose to 180 bpm and an ECG revealed supraventricular tachycardia.7 The authors of this report attributed this reaction to an interaction between the pancuronium and the aminophylline, because previous surgery with these drugs in the absence of aminophylline had been without incident.8

The authors of one of the reports advise the avoidance of concurrent use i.e. to wait approximately 13 hours after the last dose of aminophylline before using halothane but another9 says that: "...my own experience with the liberal use of these drugs has convinced me of the efficacy and wide margin of safety associated with their use in combination." A possibly safer anaesthetic may be isoflurane, which in studies with dogs has been shown not to cause cardiac arrhythmias in the presence of aminophylline,10 and is considered to be less arrhythmogenic than halothane.

(b) Development of seizures

Over a period of 9 years, tachycardia and extensor-type seizures were observed in 4 patients taking theophylline or aminophylline, who were initially anaesthetised with ketamine, and later with halothane or enflurane.11 Based on subsequent study in mice, the authors attributed the seizures to an interaction between ketamine and theophylline or aminophylline, and they suggest that the combination should perhaps be avoided in some, or antiseizure medication be given to patients at risk. However, these cases come from one isolated report. Note that, in mice, ketamine had no effect on aminophylline-induced seizures.12

(c) Altered neuromuscular blockade

Marked resistance to the effects of pancuronium (but not vecuronium) was seen in one patient receiving an aminophylline infusion.13 Two other patients are reported to have shown a similar resistance but they had also been given hydrocortisone, which could have had a similar effect14,15 (see also ‘Neuromuscular blockers + Corticosteroids’, p.121). These appear to be the only reports of such an interaction.

A study in rabbits showed that, at therapeutic concentrations of theophylline, the effects of tubocurarine were increased,16 but there do not appear to have been any studies done in humans.

Anaesthetics, general + Topiramate

A placebo-controlled study in healthy subjects found that pre-treatment with topiramate 50 mg did not affect the reaction time after sub-anaesthetic doses of ketamine (slow intravenous injection of 120 micrograms/kg followed by 500 micrograms/kg over one hour).1

Anaesthetics, general + Trichloroethane

Two patients with chronic cardiac toxicity after repeated exposure to trichloroethane had a deterioration in cardiac function following halothane anaesthesia.

Clinical evidence, mechanism, importance and management

Two patients who had been repeatedly exposed to trichloroethane (one during solvent abuse including Tipp-Ex typewriter correcting fluid thinner and the other due to industrial exposure including Genkline for degreasing steel) showed evidence of chronic cardiac toxicity. In both cases there was circumstantial evidence of cardiac deterioration after routine anaesthesia with halothane. Some solvents have a close chemical similarity to inhalational anaesthetic drugs, particularly the halogenated hydrocarbons, and these related compounds might have a toxic interaction.1

Anaesthetics, general and/or Neuromuscular blockers + Tricyclic and related antidepressants

Tricyclic antidepressants may increase the risk of arrhythmias and hypotension during anaesthesia. Tachyarrhythmias have been seen in patients taking imipramine who were given halothane and pancuronium. Some very limited evidence suggests that amitriptyline may increase the likelihood of enflurane-induced seizure activity. A man taking maprotiline and lithium developed a tonic-clonic seizure when given propofol. Tricyclics may cause an increase in the duration of barbiturate anaesthesia and lower doses of barbiturates may be required.

Clinical evidence, mechanism, importance and management

(a) Development of arrhythmias

Two patients who were taking nortriptyline (one also taking fluphenazine) developed prolonged cardiac arrhythmias during general anaesthesia with halothane.1 Two further patients taking imipramine developed marked tachyarrhythmias when anaesthetised with halothane and given pancuronium.2 This adverse interaction was subsequently clearly demonstrated in dogs.2 The authors concluded on the basis of their studies that:

• pancuronium should be given with caution to patients taking any tricyclic antidepressant if halothane is used;
• gallamine probably should be avoided but tubocurarine may be an acceptable alternative to pancuronium;
• pancuronium is probably safe in the presence of a tricyclic if enflurane is used.

However, this last conclusion does not agree with that reached by the authors of another report3, who found that this combination increased the risk of seizures.

Some manufacturers4 have recommended stopping tricyclics several days before elective surgery where possible. However, the BNF advises that tricyclic antidepressants need not be stopped, but there may be an increased risk of arrhythmias and hypotension (and dangerous interaction with va-
The duration of barbiturate anaesthetics such as thiopental and halothane. The movements stopped when the enfurane was replaced by halothane. A possible reason is that amitriptyline can lower the seizure threshold at which enfurane-induced seizure activity occurs. It is suggested that it may be advisable to avoid enfurane in patients needing tricyclic antidepressants, particularly in those who have a history of seizures, or when hyperventilation or high concentrations of enfurane are likely to be used.

2. Propofol + Maprotiline. A man with a bipolar disorder taking maprotiline 200 mg four times daily and lithium carbonate 300 mg daily, underwent anaesthesia during which he received fentanyl, tubocurarine and propofol 200 mg. Shortly after the injection of the propofol the patient complained of a burning sensation in his face. He then became rigid, his back and neck extended and his eyes turned upwards. After 15 seconds, rhythmic twitching developed in his eyes, arms and hands. This apparent seizure lasted about 1 minute until suxamethonium (suxcinylcholine) was given. The patient regained consciousness after several minutes and the surgery was cancelled. It is not known whether the reaction was due to an interaction between propofol and the antidepressants, or due to just one of the drugs, because both propofol and maprotiline have been associated with seizures. However, the authors of this report suggest that it would now be prudent to avoid using propofol in patients taking drugs that significantly lower the convulsive threshold. More study of this possible interaction is needed.

(c) Increased duration of anaesthesia

A study in dogs found that imipramine caused about a 50% increase in the duration of thiopeal-induced sleep. In an early review of electroconvulsive therapy and anaesthetic considerations, it was noted that tricyclics interact with barbiturates resulting in an increased sleep time and duration of anaesthesia, and therefore it was suggested that lower doses of barbiturate anaesthetics such as thiopental should be employed during concurrent use. However, in a later review, it was noted that no complications have been attributed to the use of ECT (which is often undertaken using methohexitol or possibly propofol) in patients taking tricyclic antidepressants. Apart from the study in animals, there seems little published information to suggest that tricyclics interact significantly with barbiturate anaesthetics, but even if there is an interaction, as the dose of barbiturate should be carefully adjusted according to the patient’s response any interaction will probably be accounted for by standard anaesthetic procedures. See also ‘Tricyclic antidepressants + Barbiturates’, p.1231.

Anaesthetics, general; Methoxyflurane + Antibacterials or Barbiturates

The nephrotoxic effects of methoxyflurane appear to be increased by the use of tetracyclines, and possibly some aminoglycoside antibiotics and barbiturates.

Clinical evidence, mechanism, importance and management

Methoxyflurane has been withdrawn in many countries because it is nephrotoxic. This damage can be exacerbated by the concurrent use of other nephrotoxic drugs or possibly by the chronic use of hepatic enzyme-inducing drugs. Five out of 7 patients anaesthetised with methoxyflurane who had been given tetracycline before or after surgery showed rises in blood urea nitrogen, and three died. Post-mortem examination showed pathological changes (oxalosis) in the kidneys. Another study identified renal tubular necrosis associated with calcium oxalate crystals in 6 patients who had been anaesthetised with methoxyflurane and given tetracycline (4 patients) and penicillin with streptomycin (2 patients). Other reports support the finding of increased nephrotoxicity with tetracycline and methoxyflurane. Another study suggested that penicillin, streptomycin and chloromphenicol appear not to increase the renal toxicity of methoxyflurane, but gentamicin and kanamycin possibly do so. There is also some evidence that barbiturates can exacerbate the renal toxicity because they enhance the metabolism of the methoxyflurane and increase the production of nephrotoxic metabolites.

The risk of nephrotoxicity with methoxyflurane would therefore appear to be increased by some of these drugs and the concurrent use of tetracycline or other nephrotoxic antibiotics should be avoided. Similarly, methoxyflurane should only be used with great care, if at all, following the chronic use of hepatic enzyme-inducing drugs.

Anaesthetics, local + Acetazolamide

The mean procaine half-life in 6 healthy subjects was increased by 66% (from 1.46 to 2.43 minutes) 2 hours after they were given acetazolamide 250 mg orally. This appears to be because the hydrolysis of the procaine is inhibited by the acetazolamide. As the evidence of this interaction is limited to one report, its general significance is unclear.

Anaesthetics, local + Alcohol and/or Antirheumatics

Limited evidence suggests that the failure rate of spinal anaesthesia with bupivacaine may be markedly increased in patients who are receiving antirheumatic drugs and/or who drink alcohol.

Clinical evidence, mechanism, importance and management

The observation that regional anaesthetic failures seemed to be particular high among patients undergoing orthopaedic surgery who were suffering from rheumatic joint diseases, prompted further study of a possible interaction. It was found that the failure rate of low-dose spinal anaesthesia with 0.5% bupivacaine (average volume of 2 mL) increased from 5% in the control group (no alcohol or long-term treatment) to 32% to 42% in those who had been taking antirheumatic drugs (indometacin or unspecified) for at least 6 months or who drank at least 80 g of ethanol daily, or both. The percentage of those patients who had a reduced response (i.e. an
extended latency period and/or a reduced duration of action) also increased from 3% up to 39 to 42%. The reasons are not understood. This appears to be the only report of such an effect.

**Anaesthetics, local + Anaesthetics, local**

Mixtures of local anaesthetics are sometimes used to exploit the most useful characteristics of each drug. This normally seems to be safe although it is sometimes claimed that it increases the risk of toxicity. There is a case report of a man who developed toxicity when bupivacaine and mepivacaine were mixed together. Spinal bupivacaine followed by epidural ropivacaine may also interact to produce profound motor blockade. However, the effectiveness of bupivacaine in epidural anaesthesia may be reduced if it is preceded by chloroprocaine.

**Clinical evidence and mechanism**

(a) Evidence of no interaction

A study designed to assess the possibility of adverse interactions retrospectively studied the records of 10 538 patients over the period 1952 to 1970 who had been given tetracaine combined with chloroprocaine, lidocaine, mepivacaine, prilocaine or propoxycaine for caudal, epidural, or peripheral nerve block. The incidence of systemic toxic reactions was found to be no greater than when used singly and the conclusion was that these interactions are not significant.

(b) Evidence of reduced analgesia

A study set up to examine the clinical impression that bupivacaine given epidurally did not relieve labour pain effectively if preceded by chloroprocaine confirmed that this was so. Using an initial 10-mL dose of 2% chloroprocaine followed by an 8-mL dose of 0.5% bupivacaine, given when pain recurred, the pain relief was less and the block took longer to occur, had a shorter duration of action and had to be augmented more frequently than if only bupivacaine was used. This interaction could not be corrected by adjusting the pH of the local anaesthetics.

(c) Evidence of enhanced effect/toxic interaction

There is a single case report of a patient given 0.75% bupivacaine and 2% mepivacaine who demonstrated lethargy, dysarhgia and mild muscle tremor, which the authors of the report correlated with a marked increase in the percentage of unbound (active) mepivacaine. They attributed this to its displacement by the bupivacaine from protein binding sites. Bupivacaine has also been shown in vitro to displace lidocaine from \( \alpha_1 \)-acid glycoprotein. Two cases of prolonged, profound motor blockade, with patient-controlled epidural analgesia using 0.1% ropivacaine following spinal bupivacaine for caesarean section, have been reported. Including these two patients, a total of 11 out of 23 patients given regional anaesthesia with bupivacaine had clinical evidence of motor weakness 8 hours after starting ropivacaine.

**Importance and management**

Well studied interactions. The overall picture is that combined use does not normally result in increased toxicity, although there may be some exceptions. For example, until more is known, caution should be exercised when giving epidural ropivacaine postoperatively to patients who have had bupivacaine spinal anaesthesia, as unexpected motor block may occur. Reduced effectiveness might be seen if bupivacaine is preceded by chloroprocaine.

5. Hodgkinson R, Husain FJ, Bluhm C. Reduced effectiveness of bupivacaine 0.5% to relieve labor pain after prior injection of chloroprocaine 2%. Anaesthesiology (1982) 57, A201.

**Anaesthetics, local + Antihypertensives**

Severe hypotension and bradycardia have been seen in patients taking captopril or verapamil when they were given epidural anaesthesia with bupivacaine. Acute hypotension also occurred in a man taking prazosin when he was given epidural anaesthesia with bupivacaine. Clonidine may increase the duration of caudal block with bupivacaine, although there are reports of reduced plasma levels of lidocaine with concurrent clonidine. Verapamil does not appear to interact with epidural lidocaine.

(a) ACE inhibitors

An 86-year-old man who had been receiving captopril 25 mg twice daily and bendroflumethiazide 25 mg daily [sic] for hypertension, underwent a transurethral resection of his prostate under spinal anaesthesia using 3 to 3.5 mL of ‘heavy’ bupivacaine 0.5%. At the end of surgery, he was returned to the supine position and suddenly developed a severe sinus bradycardia (35 bpm), his arterial blood pressure fell to 65/35 mmHg and he became unresponsive. Treatment with head-down tilt, oxygen and 1.2 mg of atropine produced rapid improvement in cardiovascular and cerebral function. A further hypotensive episode (without bradycardia) occurred approximately one hour later, which responded rapidly to 4 mg of methoxamine.

(b) Alpha blockers

A man taking prazosin (5 mg three times daily for hypertension) developed marked hypotension (BP 60/40 mmHg) within 3 to 5 minutes of receiving 100 mg of bupivacaine through an L3–4 lumbar epidural catheter. He was unresponsive to intravenous phylephrine (five 100-microgram boluses) but his blood pressure rose within 3 to 5 minutes of starting an infusion of adrenaline (epinephrine) 0.05 micrograms/kg per minute.

(c) Beta blockers

See ‘Anaesthetics, local + Beta blockers’, p.110.

(d) Calcium-channel blockers

Four patients taking long-term verapamil developed severe hypotension (systolic pressure as low as 60 mmHg) and bradycardia (48 bpm) 30 to 60 minutes after an epidural block with bupivacaine 0.5% and adrenaline (epinephrine). This was totally resistant to atropine and ephedrine, and responded only to calcium gluconate or chloride. No such interaction was seen in a similar group of patients when epidural lidocaine was used.

Animal experiments have shown that the presence of verapamil increases the toxicity of lidocaine, and greatly increases the toxicity of bupivacaine, and that pretreatment with calcium chloride blocked this effect. Another animal study found that bupivacaine had a more marked cardio-depressant effect than lidocaine when given with either verapamil or diltiazem. The animal study found that bupivacaine accentuates the cardiovascular depressant effects of verapamil. Other studies in animals have found that diltiazem, felodipine, nifedipine, nitren...
dipine,16 and verapamil17,18 increase the toxicity of bupivacaine. However, another animal study indicated that pretreatment with nimodipine or verapamil reduced bupivacaine cardiotoxicity.12

(e) Clonidine
A study in 35 children undergoing ureteroneocystostomy found that the addition of clonidine 1 microgram/kg increased the duration of caudal block with bupivacaine 0.125% (with adrenaline (epinephrine) 1:400 000) and reduced the postoperative morphine requirements.13 A study in animals found that clonidine increased the levels of bupivacaine and decreased its clearance.14 However, another study in children found that oral clonidine premedication reduced the plasma levels of lidocaine by 25 to 50%.15 Similar findings are reported in another study in which clonidine was given with epidural lidocaine.16

Mechanism
Spinal anaesthesia can produce bradycardia and a fall in cardiac output resulting in arterial hypotension, which may be magnified by the action of the antihypertensive drug, and by hypovolaemia. Other factors probably contributed to the development of this interaction in these particular patients.

The reported differences in effects of clonidine on levels of local anaesthetics are not fully understood. An in vitro study using liver microsomes found that clonidine at clinical levels is unlikely to affect the metabolism of lidocaine.17 However, the haemodynamic effects of clonidine may lead to decreased hepatic blood flow and reduced metabolism.17

Importance and management
Direct information seems to be limited to the reports cited. Their general relevance is uncertain, but they serve to emphasise the importance of recognising that all antihypertensive drugs interfere in some way with the normal homeostatic mechanisms that control blood pressure, so that the normal physiological response to hypotension during epidural anaesthesia may be impaired. In this context lidocaine would appear to be preferable to bupivacaine. Intravenous calcium effectively controls the hypotension produced by verapamil and other calcium-channel blocking effects.3,18

Accidental intravenous administration of local anaesthetics during spinal anaesthesia may cause cardiovascular collapse and, on theoretical grounds, the serious cardiac depressant effects could be enhanced in patients taking antihypertensives, especially elderly patients with impaired cardiovascular function.11 Particular care would seem to be important with any patient given epidural anaesthesia while taking antihypertensives.

Itraconazole may reduce the clearance of bupivacaine, and itraconazole, ketoconazole or clarithromycin may slightly decrease ropivacaine clearance, but the clinical importance of these interactions appears to be limited.

Clinical evidence, mechanism, importance and management
(a) Bupivacaine
In a double-blind, placebo-controlled, crossover study in 7 healthy subjects pretreatment with itraconazole 200 mg once daily for 4 days reduced the clearance of bupivacaine (0.3 mg/kg given intravenously over 60 minutes) by 20 to 25%. The increase in plasma concentrations of bupivacaine may be taken into account when itraconazole is used concurrently, although the interaction is probably of limited clinical significance.1

(b) Ropivacaine
Pretreatment with itraconazole 200 mg daily or clarithromycin 250 mg twice daily for 4 days did not significantly affect the pharmacokinetics of ropivacaine 600 microgram/kg given intravenously to 8 healthy subjects. However, there was considerable interindividual variation. A small but insignificant 20% increase in the AUC of ropivacaine occurred, and the peak plasma concentrations of the metabolite 2’-6'-piperoxalidide were significantly decreased by clarithromycin and itraconazole, by 44% and 74%, respectively. Both itraconazole and clarithromycin inhibit the formation of this metabolite by the cytochrome P450 isoenzyme CYP3A4.2 Similar results were found with ketoconazole and ropivacaine.2 Potent inhibitors of CYP3A4 appear to cause only a minor decrease in clearance of ropivacaine and thus are unlikely to be of clinical relevance.1 For a report of erthyromycin, an inhibitor of CYP3A4 enhancing the effect of fluvoxamine, an inhibitor of CYP1A2, on the clearance of ropivacaine, see ‘Anaesthetics, local + Fluvoxamine’, p.110.

Anaesthetics, local + Benzodiazepines
Diazepam may increase the maximum plasma concentrations of bupivacaine, but its rate of elimination may also be increased. Midazolam has been reported to cause a modest decrease in lidocaine but not mepivacaine levels. Spinal anaesthesia with bupivacaine, lidocaine, or tetracaine may increase the sedative effects of midazolam. A case of possible lidocaine toxicity has been described when a woman taking sertraline was given flurazepam before intraperative lidocaine.

Clinical evidence, mechanism, importance and management
(a) Effect of benzodiazepines on local anaesthetics
Twenty-one children aged 2 to 10 years were given single 1-mL/kg caudal injections of a mixture of 0.5% lidocaine and 0.125% bupivacaine for regional anaesthesia. Pretreatment with diazepam 10 mg rectally half-an-hour before the surgery had no significant effect on the plasma levels of lidocaine, but the AUC and maximum plasma bupivacaine levels were increased by 70 to 75%.1 In another study, prior use of intravenous diazepam in adult patients slightly, but not significantly, increased the mean maximum plasma levels of epidural bupivacaine or etidocaine. However, the elimination half-lives of both anaesthetics were significantly decreased by about a half.2

A study in 20 children aged 2 to 7 years receiving caudal block with 1 mL/kg of a solution containing 0.5% lidocaine and 0.125% bupi-
vaccine, found that midazolam 400 micrograms/kg given rectally half-
hour before surgery caused a slight but not significant reduction in the
AUC and serum levels of bupivacaine, whereas the AUC of lidocaine
was reduced by 24%. In contrast, midazolam 400 micrograms/kg given
rectally as a premedication was found to have no significant effect on plas-
ma mepivacaine levels.

There has been a single report of possible lidocaine toxicity following
tumescent liposuction in a patient given perioperative sedation with flu-
razepam 30 mg orally. Ten hours after the completion of the procedure,
in which a total of 58 mg/kg of lidocaine was used, the patient had nausea
and vomiting, unsteady gate, mild confusion, and speech impairment. Her
lidocaine level was 6.3 mg/L (levels greater than 6 mg/L were considered
to be associated with an increased risk of toxicity). The patient was also
on long-term treatment with sertraline. The authors suggested that sertra-
line and flurazepam may have had an additive effect on reducing the rate
of lidocaine metabolism via inhibition of cytochrome P450 isoenzyme
CYP3A4. The clinical importance of these interactions is uncertain, but anesthetic-
ists should be aware that increased bupivacaine plasma levels have been
seen with diazepam, and reduced lidocaine levels have been seen with
midazolam. More study is needed.

(b) Effect of local anaesthetics on benzodiazepines

Twenty patients undergoing surgery were given repeated 1-mg intrave-
nous doses of midazolam as induction anaesthesia every 30 seconds until
they failed to respond to three repeated commands to squeeze the anaes-
thetist’s hand. This was considered as the induction end-point ‘titrated’
dose. It was found that the 10 who had been given prior spinal anaesthesia
with tetracaine 12 mg needed only half the dose of midazolam (7.6 mg)
than the 10 other patients who had not received tetracaine (14.7 mg). The
reasons are not known. The authors of this report simply advise care in this
situation. In another study in which patients were given intravenous
midazolam following an intramuscular injection of either bupivacaine
lidocaine or saline, it was found that both anaesthetics enhanced the effect
of midazolam. This effect was dose-dependent and it was concluded that
the use of lidocaine or bupivacaine for regional blocks or local infiltra-
tion could alter the effect of midazolam from sedative to hypnotic.

(c) Local anaesthetics with vasoconstrictors

In a double-blind, randomised, placebo-controlled, crossover study in 10
healthy subjects, the upper lateral incisor teeth were anaesthetised using
lidocaine with or without adrenaline (epinephrine). The mean duration of
anaesthesia using 1 mL of 2% lidocaine containing 1:100 000 adrenaline
was increased by 58% (17 minutes) for pulpal anaesthesia and 19%
(16.5 minutes) for soft-tissue anaesthesia in subjects pretreated with
nadolol 80 mg orally. Pretreatment with the beta blocker did not affect the
duration of anaesthesia when lidocaine without adrenaline was used. It is
likely that the combined effects of adrenaline and nadolol caused
increased local vasoconstriction, which resulted in the lidocaine persisting
for longer. Therefore when a small amount of local anaesthetic with adren-
acline is injected for dental procedures an increased duration of analgesia
may result. Also note that a case report describes a transient hypertensive
reaction in a patient taking propranolol when injections of 2% mepi-
vacaine with 1:20 000 corbadrine were given for dental anaesthesia.
Larger doses of adrenaline have resulted in serious hypertension and
bradycardia because of the interaction between non-selective beta block-
ers and adrenaline (see ‘Beta blockers + Inotropes and Vasopressors’, p.848). It has been suggested that, for dental procedures, the minimum
amount of local anaesthetic containing the lowest concentration of adren-
aline should be used. Alternatively, if excessive bleeding is unlikely, a
local anaesthetic without adrenaline is preferred. Propranolol and some other beta blockers are known to reduce the me-
tabolism of lidocaine—see ‘Lidocaine + Beta blockers’, p.263.

Anaesthetics, local + Beta blockers

Propranolol reduces the clearance of bupivacaine and so theoretically
the toxicity of bupivacaine may be increased. There has been a single report of enhanced bupivacaine cardiotoxicity in a patient also receiv-
ing metoprolol and digoxin. The coronary vasoconstriction caused by cocaine is increased by propranolol. Beta blockers may interact with adrenaline (epinephrine)-containing
local anaesthetics.

Clinical evidence, mechanism, importance and management

(a) Bupivacaine

1. Metoprolol. There is a case report of possible enhanced bupivacaine car-
diotoxicity in a patient who was taking enalapril 5 mg daily, metoprolol
25 mg twice daily and digoxin 250 micrograms four times a day (serum
digoxin level 1.1 nanograms/mL). Cardiac arrest occurred 15 minutes af-
after the injection of 0.5% bupivacaine with adrenaline (epinephrine) for
intercostal nerve block (total dose 100 mg). The cardiodepressant effects of
metoprolol, digoxin and bupivacaine may have combined to produce tox-
icity at a dose of bupivacaine not usually considered toxic. The authors
caution that patients taking digoxin with a calcium channel blocker and/or
beta blocker should be considered at higher risk for bupivacaine cardio-
toxicity.

2. Propranolol. The clearance of bupivacaine was reduced by about 35% in
6 healthy subjects given bupivacaine 30 to 50 mg intravenously over 10 to
15 minutes after taking propranolol 40 mg every 6 hours for a day. The
reason is thought to be that the propranolol inhibits the activity of the liver
microsomal enzymes, thereby reducing the metabolism of the bupi-
vacaine. Changes in blood flow to the liver are unlikely to affect bupi-
vacaine metabolism substantially because it is relatively poorly extracted
from the blood. The clinical importance of this interaction is uncertain, but
it is suggested that an increase in local anaesthetic toxicity might occur
and caution should be exercised if multiple doses of bupivacaine are giv-
en.

(b) Cocaine

A study in 30 patients being evaluated for chest pain found that 2 mg/kg
of a 10% intranasal solution of cocaine reduced coronary sinus flow by
about 14% and coronary artery diameter by 6 to 9%. The coronary vascu-
lar resistance increased by 22%. The addition of propranolol 400 micrograms/minute by intracoronary infusion, (to a total of 2 mg) re-
duced coronary sinus flow by a further 15% and increased the coronary
vascular resistance by 17%. The probable reason is that the cocaine stimu-
lates the alpha-receptors of the coronary blood vessels causing vasocon-
striction. When the beta-receptors are blocked by propranolol, the
resultant unopposed alpha-adrenergic stimulation may lead to enhanced
coronary vasoconstriction (see also ‘Beta blockers + Inotropes and Vasopres-
sors’, p.848). The clinical importance of these findings is uncertain but
the authors of the report suggest that beta blockers should be avoided
in patients with myocardial ischaemia or infarction associated with the use
of cocaine.

(c) Local anaesthetics with vasoconstrictors

Fluvoxamine inhibits the clearance of ropivacaine; therefore,
prolonged administration of ropivacaine should be avoided in pa-

Anaesthetics, local + Fluvoxamine

Fluvoxamine inhibits the clearance of ropivacaine; therefore,
prolonged administration of ropivacaine should be avoided in pa-

tients taking fluvoxamine.
Clinical evidence, mechanism, importance and management

Fluvoxamine decreased the mean total plasma clearance of ropivacaine by 68% from 354 to 112 mL/minute, and almost doubled the half-life of ropivacaine in a randomised, crossover study in 12 healthy subjects. Fluvoxamine was given at a dose of 25 mg twice daily for 2 days, and a single 40 mg intravenous dose of ropivacaine was given over 20 minutes one hour after the morning dose of fluvoxamine on the second day.1

Fluvoxamine is a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2 and so reduces the metabolism of ropivacaine to its major metabolite 3-hydroxyropivacaine. In one study in healthy subjects the combination of fluvoxamine with erythromycin, an inhibitor of CYP3A4, which on its own has little effect on the pharmacokinetics of ropivacaine, was found to decrease the clearance of ropivacaine more than fluvoxamine alone.2

The UK manufacturer recommends that prolonged administration of ropivacaine should be avoided in patients concurrently treated with potent CYP1A2 inhibitors such as fluvoxamine.3 Be aware that CYP3A4 inhibitors such as erythromycin in combination with CYP1A2 inhibitors may further reduce ropivacaine clearance.2

Anaesthetics, local + H₂-receptor antagonists

Some studies suggest that both cimetidine and ranitidine can raise plasma bupivacaine levels, whereas other evidence suggests that no significant interaction occurs. Ranitidine does not appear to significantly affect lidocaine. Some studies found that cimetidine does not affect lidocaine when used as an anaesthetic. Other studies found that cimetidine increased plasma lidocaine levels and that famotidine had less effect. See also ‘Lidocaine + H₂-receptor antagonists’, p.264 for interactions of lidocaine used as an antiarrhythmic.

Clinical evidence

(a) Cimetidine + Bupivacaine

Pretreatment with cimetidine 300 mg intramuscularly 1 to 4 hours before epidural anaesthesia with 0.5% bupivacaine (for caesarean section) had no effect on the pharmacokinetics of bupivacaine in 16 women or their foetuses when compared with 20 control women, although the maternal unbound bupivacaine plasma levels rose by 22%.1 These findings were confirmed in two similar studies2,3 in which women were pretreated with cimetidine before caesarean section, and a further study4 in 7 healthy subjects (6 women and one man) given two oral doses of cimetidine 400 mg before intramuscular bupivacaine. However, the AUC of bupivacaine in 4 healthy male subjects was increased by 40% (when compared to placebo) by cimetidine 400 mg at 10 pm the previous evening and 8 am on the study day, followed by a 50-mg infusion of bupivacaine at 11 am.5

(b) Cimetidine + Lidocaine

In 5 women given epidural anaesthesia for caesarean section, the pharmacokinetics of 400 mg of lidocaine 2% (administered with adrenaline (epinephrine) 1:200 000) were unchanged by a single 400-mg oral dose of cimetidine given about 2 hours preoperatively.6 Another very similar study in 9 women found no statistically significant rises in whole blood lidocaine levels (although they tended to be higher), in the presence of cimetidine 300 mg given intramuscularly, at least an hour preoperatively.6 However, in patients pretreated with cimetidine (200 mg orally on the night before surgery and 400 mg one hour before induction) peak plasma levels of epidural lidocaine 2% (with adrenaline 1:200 000) were 3.2 micrograms/mL. Lidocaine levels in patients who did not receive pre-treatment with H₂-receptor antagonists were 2.3 micrograms/mL.8

(c) Famotidine + Lidocaine

In patients pretreated with famotidine (20 mg orally on the night before surgery plus 20 mg intramuscularly one hour before induction) peak plasma levels of epidural lidocaine 2% (with adrenaline 1:200 000) were 2.4 micrograms/mL. Lidocaine levels in patients who did not receive pre-treatment with H₂-receptor antagonists were 2.3 micrograms/mL.8 In another study the effects of famotidine on lidocaine were found to be less than those of cimetidine but greater than in patients not given an H₂-receptor antagonist.9

Mechanism

Not understood. It has been suggested that cimetidine reduces the hepatic metabolism of bupivacaine. Protein binding displacement has also been suggested.

Importance and management

A confusing situation. No clinically important interaction has been established, but be alert for any evidence of increased bupivacaine toxicity resulting from raised total plasma levels and rises in unbound bupivacaine levels during the concurrent use of cimetidine and possibly ranitidine. Cimetidine (but not ranitidine) has been shown to raise plasma lidocaine levels when lidocaine is used as an antiarrhythmic (see ‘Lidocaine + H₂-receptor antagonists’, p.264), but some of the studies cited above found cimetidine did not affect lidocaine levels when lidocaine is used as an anaesthetic. However, in the studies comparing the effects of cimetidine and famotidine, cimetidine was found to increase lidocaine levels and it was suggested that famotidine may be preferable to cimetidine as pretreatment before epidural lidocaine.8,9

Anaesthetics, local + Ondansetron

In a placebo-controlled study oral ondansetron 4 mg was given to patients the evening before surgery, followed by intravenous ondansetron 4 mg given over 15 minutes before subarachnoid anaesthesia with lidocaine 5% in dextrose 8%. Ondansetron
Rifampicin increases the metabolism of ropivacaine, but this probably has little clinical relevance to its use as a local anaesthetic. Smoking appears to have only a minor effect on ropivacaine pharmacokinetics. Tobacco smoking may enhance cocaine-associated myocardial ischaemia.

Clinical evidence, mechanism, importance and management

(a) Cocaine

In a study involving 42 smokers (36 with proven coronary artery disease) the mean product of the heart rate and systolic arterial pressure increased by 11% after intranasal cocaine 2 mg/kg, by 12% after one cigarette and by 45% after both cocaine use and one cigarette. Compared with baseline measurements, the diameters of non-diseased coronary arterial segments decreased on average by 7% after cocaine use, 7% after smoking and 6% after cocaine and smoking. However, the diameters of diseased segments decreased by 9%, 5% and 19%, respectively.1 Cigarette smoking increases myocardial oxygen demand and induces coronary-artery vasoconstriction through an alpha-adrenergic mechanism similar to cocaine and therefore tobacco smoking may enhance cocaine-associated myocardial ischaemia.1,2

(b) Ropivacaine

A study in 10 healthy non-smokers and 8 healthy smokers given ropivacaine 600 micrograms/kg by intravenous infusion over 30 minutes found that smoking increased the urinary excretion of the metabolite 3-hydroxyropivacaine and decreased the urinary excretion of 2,6'-piperocollidide by 62%, but did not significantly affect the ropivacaine AUC. However, pretreatment with rifampicin 600 mg daily for 5 days increased the clearance (by 93% and 46%) and decreased the AUC by 52% and 38% and half-life of ropivacaine in both non-smokers and smokers, respectively.3 Ropivacaine undergoes oxidative hepatic metabolism mainly by the cytochrome P450 isoform CYP1A2 and CYP3A4. Cigarette smoking may increase CYP1A2-mediated metabolism of ropivacaine, and the elimination of ropivacaine may be considerably accelerated by rifampicin, which is a potent cytochrome P450 enzyme inducer. However, in clinical use the local anaesthetic is given near the nerves to be desensitised and in-duction of isoenzymes is not likely to affect the local anaesthetic before it enters the systemic blood circulation.4 This interaction is therefore of little clinical relevance.

Rifampicin may also increase the metabolism of lidocaine to a minor extent, see ‘Lidocaine + Rifampicin (Rifampin)’, p.267, and smoking may reduce the oral bioavailability of ‘lidocaine’, (p.267).

clinically, botulinum A toxin is injected for local effect in specific muscles, and is not used systematically; and so the situation is not analogous to that described in the case of the child with systemic botulism.

Up until 2002, the UK manufacturers of botulinum A toxin stated in their prescribing information that the aminoglycosides and spectinomycin were contraindicated. They also advised caution with polymyxins, tetacyclines and lincomycin, and a reduced starting dose with muscle relaxants with a long-lasting effect, or the use of an intermediate action drug such as neomycin or atracurium. Later prescribing information notes that these interactions are theoretical. Similarly the UK manufacturer of botulinum B cautions use with aminoglycosides or other drugs that affect neuromuscular transmission.

Neuromuscular blockers + Aminoglycosides

The aminoglycoside antibacterials possess neuromuscular blocking activity. Appropriate measures should be taken to accommodate the increased neuromuscular blockade and the prolonged and potentially fatal respiratory depression that can occur if these antibacterials are used with conventional neuromuscular blocking drugs.

Clinical evidence

Two examples from many:

A 38-year-old patient anaesthetised with cyclopropane experienced severe respiratory depression after being given intraperitoneal neomycin 500 mg. She had also received suxamethonium (succinylcholine) and tubocurarine. This antibacterial-induced neuromuscular blockade was resistant to treatment with edrophonium.

A 71-year-old woman received a standard bowel preparation consisting of oral erythromycin and neomycin (a total of 3 g). Surgery was postponed for one day and she received a second similar bowel preparation and maintained with isoflurane and sufentanil.

Surgery was postponed for one day and she received a second similar bowel preparation and maintained with isoflurane and sufentanil.

A 38-year-old patient anaesthetised with cyclopropane experienced severe respiratory depression after being given intraperitoneal neomycin 500 mg. She had also received suxamethonium (succinylcholine) and tubocurarine. This antibacterial-induced neuromuscular blockade was resistant to treatment with edrophonium.

The routes of antibacterial administration were oral, intraperitoneal, oesophageal, intraluminal, retroperitoneal, intramuscular, intraperitoneal, cystic, beneath skin flaps, extraluminal and intravenous. Later reports involve:

- tubocurarine with neomycin or streptomycin,
- gallamine with neomycin, kanamycin or streptomycin,
- suxamethonium with neomycin, kanamycin or streptomycin.

The routes of antibacterial administration were oral, intraperitoneal, oesophageal, intraluminal, retroperitoneal, intramuscular, intraperitoneal, cystic, beneath skin flaps, extraluminal and intravenous. Later reports involve:

- pancuronium with amikacin, gentamicin, neomycin or streptomycin,
- piperacillin with netilmicin,
- suxamethonium with dibekacin.

- tubocurarine with amikacin, dibekacin, framycetin (eye irrigation), ribostamycin, tobramycin,
- suxamethonium with amikacin, gentamicin, tobramycin.
- gentamicin, tobramycin.
- ribostamycin with suxamethonium.

Aminoglycosides and neuromuscular blockers that have been reported not to interact are:

- tobramycin with alcuronium, atracurium or suxamethonium,
- gentamicin with atracurium,
- ribostamycin with suxamethonium.

Mechanism

The aminoglycosides appear to reduce or prevent the release of acetylcholine at neuromuscular junctions (related to an impairment of calcium influx) and they may also lower the sensitivity of the post-synaptic membrane, thereby reducing transmission. These effects would be additive with those of conventional neuromuscular blockers, which act at the post-synaptic membrane.

Importance and management

Extremely well documented, very long established, clinically important and potentially serious interactions. Ten out of the 111 cases in one review were fatal, related directly or indirectly to aminoglycoside-induced respiratory depression. Concurrent use need not be avoided, but be alert for increased and prolonged neuromuscular blockade with every aminoglycoside and neuromuscular blocker although the potencies of the aminoglycosides differ to some extent. In animal studies at concentrations representing the maximum therapeutic levels, the neuromuscular blocking potency of various aminoglycosides was rated (from highest to lowest) neomycin, streptomycin, gentamicin, kanamycin. The postoperative recovery period should also be closely monitored because of the risk of recurarisation if the aminoglycoside is given during surgery. High-risk patients appear to be those with renal disease and hypocalcaemia, who may have elevated serum antibacterial levels, and those with pre-existing muscular weakness. Treatment of the increased blockade with anticholinesterases and calcium has met with variable success because the response seems to be inconsistent.

The neuromuscular blockade due to suxamethonium (succinylcholine) can be increased and prolonged by lidocaine, procaine and possibly procainamide. These local anaesthetics all have some neuromuscular blocking activity and may theoretically also enhance the block produced by competitive neuromuscular blockers. Increased toxicity occurred when mivacurium and prilocaine were given together for regional anaesthesia.

Clinical evidence

A patient anaesthetised with flurxone and nitrous oxide demonstrated 100% blockade with suxamethonium (succinylcholine) and tubocurarine. About 50 minutes later when twitch height had fully returned and tidal volume was 400 mL, she was given lidocaine 50 mg intravenously for premature ventricular contractions. She immediately stopped breathing and the twitch disappeared. About 45 minutes later the tidal volume was 450 mL. Later it was found that the patient had a dibucaine number (a measure of cholinesterase activity) of 23%.

A study in 10 patients has confirmed that lidocaine and procaine prolong the apnoea following the use of suxamethonium 700 micrograms/kg. A dose-relationship was established. The duration of apnoea was approximately doubled by 5 mg/kg of lidocaine or 2.2 mg/kg of procaine intravenously, and tripled by 16.6 mg/kg and 11.2 mg/kg, respectively, although the effects of procaine at higher doses were more marked.

Procainamide has been reported to increase the effects of suxamethonium in animals, increase muscle weakness in a myasthenic patient, and reduce plasma cholinesterase activity in healthy subjects. An animal study demonstrated potentiation of the neuromuscular blocking effect of tubocurarine by lidocaine alone and combined with antibiotics having neuromuscular blocking activity (neomycin or polymyxin B).

In a study of 10 healthy subjects, prolonged muscle weakness and symptoms of local anaesthetic toxicity were experienced after deflation of the tourniquet when 40 mL of lidocaine 5% and procaine 0.5% and mivacurium 800 micrograms were used together for intravenous regional anaesthesia.

Mechanism

Uncertain. Some local anaesthetics (ester-type) such as procaine appear to inhibit plasma cholinesterase, which might prolong the activity of suxamethonium. There may additionally be competition between suxamethonium and procaine for hydrolysis by plasma cholinesterase, which metabolises them both. These effects are particularly important in patients with abnormal plasma cholinesterase.

Therapeutic procainamide plasma concentrations of 5 to 10 micrograms/mL have been found to inhibit cholinesterase activity by 19 to 32%.

All local anaesthetics have some neuromuscular blocking activity and may enhance the block produced by competitive neuromuscular blockers if given in sufficient doses. Procainamide also has acetylcholine receptor channel blocking activity.

Importance and management

Information is limited but the interactions of suxamethonium with lidocaine, and suxamethonium with procaine appear to be established and of clinical importance. Be alert for signs of increased blockade and/or neuromuscular blockade associated with apnoea during the recovery period from suxamethonium.

Despite the potential for an interaction between suxamethonium and procainamide, no marked interaction has yet been reported. Nevertheless be aware that some increase in the neuromuscular blocking effects is possible.

Lidocaine, procaine and procainamide all have some neuromuscular blocking activity and may also enhance the block produced by competitive neuromuscular blockers if given in sufficient doses. However, again, there seems to be an absence of reports of this, probably because the amount of local anaesthetic absorbed into the circulation following a local block is usually modest.

Animal studies indicate that low and otherwise safe doses of lidocaine given with other drugs having neuromuscular blocking activity (e.g., polymyxin B, aminoglycosides) may possibly be additive with conventional neuromuscular blockers and so some caution may be warranted.

Anticholinesterases

Anticholinesterases oppose the actions of competitive neuromuscular blockers (e.g., tubocurarine) and can therefore be used as an antidote to restore muscle function following their use. Conversely, anticholinesterases increase and prolong the actions of the depolarising neuromuscular blockers (e.g., suxamethonium (succinylcholine)). Anticholinesterases used to treat Alzheimer’s disease may also interact with neuromuscular blockers.

Clinical evidence, mechanism, importance and management

There are two main types of neuromuscular blockers: competitive (non-depolarising) and depolarising, see ‘Table 5.2’, (p.91).

(a) Competitive (non-depolarising) neuromuscular blockers

Competitive (non-depolarising) neuromuscular blockers (e.g., tubocurarine) compete with acetylcholine for receptors on the motor endplate. Anticholinesterases (e.g., ambenonium, edrophonium, neostigmine, physostigmine, pyridostigmine, etc.) can be used as an antidote to this kind of neuromuscular blockade, because they inhibit the enzymes that destroy acetylcholine so that the concentration of acetylcholine at the neuromuscular junction builds up. In this way the competition between the neuromuscular blocker and acetylcholine for occupancy of the receptors swings in favour of the acetylcholine so that transmission is restored.

These drugs are used routinely following surgery to reactivate paralysed muscles. However, note that the aminoglycosides can act as neuromuscular blockers (see ‘Neuromuscular blockers + Aminoglycosides’, p.113) and therefore their use may unintentionally antagonise the effects of the anticholinesterases.

Some inhalational anaesthetics can impair the effect of anticholinesterases on neuromuscular blockers (see ‘Anaesthetics, general + Anticholinesterases’, p.93).

(b) Depolarising neuromuscular blockers

The depolarising blockers (such as suxamethonium (succinylcholine)) act like acetylcholine to depolarise the motor endplate, but unlike acetylcholine, they are not immediately removed by cholinesterase. The anticholinesterase drugs increase the concentration of acetylcholine at the neuromuscular junction, which enhances and prolongs this type of blockade, and therefore anticholinesterases cannot be used as an antidote for this kind of block. Care should be taken if an anticholinesterase has been given to antagonise a competitive neuromuscular block prior to the use of suxamethonium, as the duration of the suxamethonium block may be prolonged.

(c) Tacrine and other centrally-acting anticholinesterases

Tacrine, like other anticholinesterases, has been used intravenously in an anaesthetic practice to reverse the effects of competitive (non-depolarising) blockers such as tubocurarine and to prolong the effects of depolarising...
blocks such as suxamethonium. For example, one study found that only one-third of the normal dosage of suxamethonium was needed in the presence of 15 mg of intravenous tacrine. However, tacrine is now more commonly used orally for its central effects in the treatment of Alzheimer’s disease. Therefore be alert for changes in the effects of both types of neuromuscular blocking drugs in patients taking tacrine, or other cholinesterase inhibitors (including galantamine, rivastigmine and possibly donepezil) and tauconine will behave like tacrine. There is a report of such an interaction in a 72-year-old woman taking donepezil who had prolonged paralysis after induction of anaesthesia with propofol and suxamethonium. It is possible that levels of donepezil in this patient were high due to concurrent omeprazole and fluoxetine and surgery was on average 65% shorter in those taking carbamazepine. Patients undergoing craniotomy for tumours, seizure foci or cerebrovascular with propofol and suxamethonium and pancuronium to reverse the effects of pancuronium (she had also received suxamethonium). This patient probably had atypical pseudocholinesterase activity, and the authors suggest the interaction may not be clinically relevant in patients with normal enzyme activity.

(d) Organophosphorus compounds
Organophosphorus compounds are potent anticholinesterases, see ‘Neuromuscular blocks + Organophosphorus compounds’, p.130.

Neuromuscular blocks + Antiepileptics
The effects of many competitive neuromuscular blockers are reduced and shortened if carbamazepine or phenytoin are given for longer than one week, but they appear to be increased if phenytoin, and possibly carbamazepine, are given acutely (e.g. during surgery). Carbamazepine and phenytoin appear not to interact with mivacurium.

Clinical evidence
(a) Carbamazepine given long term: neuromuscular blocking effects reduced
The recovery from neuromuscular blockade with pancuronium in 18 patients undergoing cranioectomy for tumours, seziure focci or cerebrovascular surgery was on average 65% shorter in those taking carbamazepine. Another 9 patients taking carbamazepine for at least 1 week and undergoing surgery were given doxacurium took 66 minutes to reach 50% recovery compared with 161 minutes in the control group.2 Similar findings were obtained in another study. Further studies found that carbamazepine significantly shortened the recovery time from vecuronium blockade in adults4 and in children. Several reports and studies have demonstrated a shorter duration of action of rocuronium following long-term carbamazepine use,9,9 although preliminary investigations found no ef- fect.10 A reduced duration of action has been reported with rapacuronium in a patient taking carbamazepine.12 The effects of piper- curonium are also reduced by carbamazepine.13,14 In one study it was found that the onset time for pipercuronium blockade was lengthened (although this was not statistically significant) in patients with therapeutic plasma concentrations of phenytoin or carbamazepine, but not in those with subtherapeutic levels. However, a shorter duration of action occurred regardless of the anticonvulsant level.14 A reduced recovery time from atracurium-induced neuromuscular blockade was found in one study in patients taking long-term antiepileptics including phenytoin but other studies have reported a minimal ef- fect, see (e) below. For a report of reduced recovery time, increased clearance of cisatracurium and increased resistance to its actions in the presence of phenytoin, see (a) above.

(b) Carbamazepine given short term: neuromuscular blocking effects increased
An in vitro study found that the acute neuromuscular effects of car- bamazepine reduced the concentrations required for 50% paralysis with both a depolarising neuromuscular blocker (suxamethonium (succinyl- choline)) and a competitive neuromuscular blocker (atracurium) by about 30.15

(c) Phenyltoin given long term: neuromuscular blocking effects reduced
In the preliminary report of a study, the reduction in the time to recover from 25 to 75% of the response to ulnar nerve stimulation, in patients who had received phenytoin for longer than one week was: metocurine 58%, pancuronium 40%, tubocurarine 24%, atracurium 8% (the last two were not statistically significant).18 The metocurine results are published in full elsewhere. In another study about 80% more pancuronium was needed by 9 patients taking long-term phenytoin (58 micrograms/kg per hour) than in 18 others not receiving phenytoin (32 micrograms/kg per hour).20 Resistance to pancuronium and a shortening of the recovery period due to long-term phenytoin21 or unspecified antiepileptics22 has also been described in other reports. The recovery period from doxacurium,23 pipercuronium,13,14 rapacuronium (case report),12 rocuronium23,24 and vecuronium25,26 is also reduced by phenytoin. In one study it was found that the onset time for pipercuronium blockade was lengthened (although this was not statistically significant) for patients with therapeutic plasma concentrations of phenytoin or carbamazepine, but not in those with subtherapeutic levels. How- ever, a shorter duration of action occurred regardless of the anticonvulsant level.14 A reduced recovery time from atracurium-induced neuromuscular blockade was found in one study in patients taking long-term antiepileptics including phenytoin but other studies have reported a minimal ef- fect, see (e) below. For a report of reduced recovery time, increased clearance of cisatracurium and increased resistance to its actions in the presence of phenytoin, see (a) above.

(d) Phenyltoin given short term: neuromuscular blocking effects increased
A retrospective review of 8 patients taking long-term phenytoin (greater than 2 weeks) and 3 others given phenytoin within 8 hours of surgery found that the average doses of vecuronium used from induction to extubation was 155 micrograms/kg per hour (long term) and 61.5 micrograms/kg per hour (acute).29 Others have reported similar results.30 Short-term phenytoin use may have been a contributing factor in the prolonged clearance of vecuronium in another patient.30 Another study found that the sensitivity of patients to vecuronium was increased by phenytoin given intravenously during surgery,31 and this has also been seen in animal studies using tubocurarine and phenytoin.32 Similarly, a study of 20 patients undergoing cranioectomy found that phenytoin (10 mg/kg over about 30 minutes) given during the operation augmented the neuromuscular block produced by rocuronium.34

(e) Antiepileptics given long term: neuromuscular blocking effects not significantly affected
Long-term (greater than 4 weeks) carbamazepine appears not to affect mivacurium-induced neuromuscular blockade.33 Similarly, a study in 32 patients who had been taking carbamazepine alone or with phenytoin or valproic acid for greater than 2 weeks found no resistance to mivacurium,36 although an earlier preliminary study by the same research group found a trend towards a shorter recovery from mivacurium in 13 patients taking unspecified antiepileptics (not statistically significant). Carbamazepine has also been reported to have no effect on atracurium38 and two studies suggest that atracurium is normally minimally affected by phenytoin.39,40 However, one study15 found that the recovery time from atracurium blockade was significantly reduced in patients on long-term anticonvulsant therapy, see (a) and (c) above.

Eight patients who had been taking phenytoin and/or carbamazepine for at least one month took longer to recover from suxamethonium (succinylcholine) blockade compared with 9 control patients; the time for re-
turn to baseline twitch height was 14.3 and 10 minutes, respectively. The slight prolongation of *suxamethonium* action was considered to have few clinical implications.\(^\text{20}\)

**Mechanism**

Not fully understood, but it appears to be multifactorial. Acute administration of phenytoin or carbamazepine may result in neuromuscular block and potentiation of the action of competitive (non-depolarising) blockers.\(^\text{17}\)

Long-term therapy with antiepileptics may produce subclinical neuromuscular block thought to be due to modest blockage of acetylcholine receptors and a decrease in acetylcholine release; this antagonism may induce changes at the neuromuscular junction including increased number of acetylcholine receptors on the muscle membrane (up-regulation), with decreased sensitivity. Other suggestions to account for the reduced response with chronic antiepileptics include: induction of liver enzyme activity (phenytoin and carbamazepine are both potent inducers of cytochrome P450 isoenzymes), which would increase the metabolism and clearance of the neuromuscular blocker; and changes in plasma protein binding.\(^\text{20,40}\)

It has been shown that carbamazepine doubles the clearance of vecuronium,\(^\text{42}\) and phenytoin possibly increases the plasma clearance of pancuronium\(^\text{21}\) and rocuronium.\(^\text{23}\)

**Importance and management**

Established and clinically important interactions. More is known about phenytoin and carbamazepine than other antiepileptics.

Anticipate the need to use more (possibly up to twice as much) doxacurium, metocurine, pancuronium, pipercuronium, rocuronium and vecuronium in patients who have taken these antiepileptics for more than a week,\(^\text{26}\) and expect an accelerated recovery. The effects on tubocurarine and atracurium appear only to be small or moderate, whereas mivacurium appears not to interact.

Anticipate the need to use a smaller neuromuscular blocker dosage, or prepare for a longer recovery time if phenytoin and possibly carbamazepine are given acutely.

15. Kim CS, Arnold FJ, Iannone MS, Martyn JAJ. Decreased sensitivity to muscle during long-term phenytoin therapy may be attributable to protein binding and acetylcholine receptor changes. *Anesthesiology* (1992) 77, 500–6.

**Neuromuscular blockers + Antineoplastics**

The effects of *suxamethonium* (succinylcholine) can be increased and prolonged in patients receiving cyclophosphamide because their plasma cholinesterase levels are depressed. Respiratory insufficiency and prolonged apnoea have been reported. Irinotecan may prolong the neuromuscular blocking effects of *suxamethonium* and antagonise that of non-depolarising drugs. Animal data suggests that thiotepa may also enhance the effects of *suxamethonium*. An isolated report describes a marked increase in the neuromuscular blocking effects of pancuronium in a myasthenic patient who was given thiotepa, but normally it appears not to interact with competitive neuromuscular blockers.

**Clinical evidence**

**(a) Cyclophosphamide**

**Respiratory insufficiency and prolonged apnoea** occurred in a patient on two occasions while receiving cyclophosphamide and undergoing anaesthesia during which *suxamethonium* (succinylcholine) and tubocurarine were used. Plasma cholinesterase levels were found to be low. Anaesthesia without the *suxamethonium* was uneventful. Seven out of 8 patients subsequently examined also showed depressed plasma cholinesterase levels while taking cyclophosphamide.

**Respiratory depression** and low plasma cholinesterase levels have been described in other reports in patients receiving cyclophosphamide.\(^\text{2-4}\) Similarly, in the discussion of an *in vitro* study, the authors report preliminary studies.
results from a study in patients, showing a 35 to 70% reduction in cholinesterase activity for several days after cyclophosphamide use. See also (d) below.

(b) Irinotecan

The manufacturer warns that irinotecan could possibly prolong the neuromuscular blocking effects of suxamethonium (succinylcholine) and antagonise the neuromuscular blockade of competitive (non-depolarising) drugs. This is based on the fact that irinotecan has anticholinesterase activity (see also ‘Neuromuscular blockers + Anticholinesterases’, p.114, for an explanation of this mechanism).

(c) Thiopenta

A myasthenic patient developed very prolonged respiratory depression very shortly after being given thiopenta intraperitoneally, following the use of pancuronium. Thiopenta has also been shown to increase the duration of suxamethonium (succinylcholine) neuromuscular blockade in dogs. However, an in vitro study showed that thiopenta was a poor inhibitor of plasma cholinesterase. See also (d) below.

(d) Other antineoplastics

A patient with myasthenia gravis and thymoma experienced severe respiratory depression during the second cycle of treatment. It was suggested that at least one of the antineoplastics had a direct inhibitory effect on neuromuscular transmission leading to exacerbation of pre-existing myasthenia gravis.

An in vitro study found that human motor endplate or red blood cell acetylcholineesterase was inhibited by alkylating antineoplastics, with chloramthinet exerting the greatest effect, followed by dacarbazine, nimustine, cyclophosphamide and ifosfamide. Chlormethine and cyclophosphamide inhibited plasma pseudocholinesterase most strongly, followed by thiotepa, nimustine, dacarbazine, ifosfamide, and carmustine.

Mechanism

Cyclophosphamide inhibits the activity of plasma cholinesterase, and as a result the metabolism of the suxamethonium is reduced and its actions are enhanced and prolonged. Other alkylating agents are also reported to reduce plasma cholinesterase activity.

Importance and management

The interaction between suxamethonium and cyclophosphamide is well documented and established. It is of clinical importance, but whether all patients are affected to the same extent is uncertain. The depression of the plasma cholinesterase levels may last several days, possibly weeks, so that ideally plasma cholinesterase levels should be checked before using suxamethonium. In patients taking antineoplastics, it should certainly be used with caution, and the dosage should be reduced. Some have suggested that concurrent use should be avoided.

Irinotecan may possibly enhance the effects of suxamethonium and antagonise the effects of non-depolarising drugs. Animal data suggest thiopenta may enhance the effects of suxamethonium and in vitro data suggest some other antineoplastics may also have an effect. The general silence in the literature would seem to indicate that no special precautions are normally necessary. However, patients with malignant tumours often have a reduced plasma cholinesterase activity, so care is warranted in these patients.

Neuromuscular blockers + Antipsychotics

An isolated report describes prolonged apnoea in a patient given promazine while recovering from neuromuscular blockade with suxamethonium (succinylcholine). Recovery from the neuromuscular blocking effects of suxamethonium is prolonged by fentanyl/droperidol.

Clinical evidence

(a) Suxamethonium (succinylcholine) + Fentanyl/droperidol

The observation that patients who had received Innovar (fentanyl/droperidol) before anaesthesia appeared to have prolonged suxamethonium effects, seen as apnoea, prompted further study of this possible interaction. An average delay in recovery from neuromuscular blockade of 36% to 80% was seen in two studies. Another study showed that the droperidol component of Innovar was probably responsible for this interaction.

(b) Suxamethonium (succinylcholine) + Promazine

A woman recovering from surgery during which she had received suxamethonium, was given promazine 25 mg intravenously for sedation. Within 3 minutes she had become cyanotic and apnoeic, and required assisted respiration for 4 hours.

Mechanism

Not understood. It has been suggested that promazine and droperidol depress plasma cholinesterase levels, which would reduce the metabolism of the suxamethonium and thereby prolong recovery. It has also been suggested that droperidol might act as a membrane stabiliser at neuromuscular junctions.

Importance and management

Some caution would seem appropriate if promazine is given to any patient who has been given suxamethonium. There seems to be no information about other phenothiazines and other neuromuscular blockers.

Delayed recovery should be anticipated in patients given suxamethonium if droperidol is used. This is an established interaction.

Neuromuscular blockers + Aprotinin

Apnoea developed in a number of patients after they were given aprotinin while recovering from neuromuscular blockade with suxamethonium (succinylcholine) alone or with tubocurarine.

Clinical evidence

Three patients undergoing surgery who had received suxamethonium (succinylcholine), alone or with tubocurarine, were given aprotinin intravenously in doses of 2500 to 12 000 KIU (kallikrein inactivator units) at the end of, or shortly after the operation, when spontaneous breathing had resumed. In each case respiration rapidly became inadequate and apnoea lasting periods of 7, 30 and 90 minutes occurred. Seven other cases have been reported elsewhere.

Mechanism

Not fully understood. Aprotinin is only a very weak inhibitor of serum cholinesterase and so is unlikely to significantly affect the metabolism of suxamethonium. However, it might tip the balance in those whose cholinesterase was already very depressed.
Neuromuscular blockers + Benzodiazepines

A few studies report that diazepam and other benzodiazepines increase the effects of neuromuscular blockers, but many others have not found an interaction. If an interaction does occur, the response is likely to be little different from the individual variations in response of patients to neuromuscular blockers.

Clinical evidence

(a) Increased blockade

A comparative study of 10 patients given gallamine and 4 others given gallamine with intravenous diazepam 150 to 200 micrograms/kg found that the diazepam prolonged the duration of activity of the blocker by a factor of three, and doubled the depression of the twitch response. Persistent muscle weakness and respiratory depression was seen in 2 other patients given tubocurarine after premedication with diazepam. A small reduction (approximately 10%) in neuromuscular blocker requirement has been described with diazepam and tubocurarine or succinylcholine, but see also (b) below.

Another study found that recovery to 25% and 75% of the twitch height after vecuronium was prolonged by about 25% by 15 mg of intravenous midazolam, when compared with control patients. The same study found that midazolam prolonged the recovery from the effects of atracurium by about 20%. However, the increased recovery time due to midazolam was not statistically significant when compared with control patients, but was significantly longer when compared with patients receiving 20 mg of intravenous diazepam. See also (b) below.

(b) Reduced blockade or no effect

The duration of paralysis due to suxamethonium was reduced in one study by 20% when diazepam (150 micrograms/kg) was also given and the recovery time was shortened. Diazepam also slightly reduced the time to 25% and 75% recovery of twitch height in patients given vecuronium by about 15% (not statistically significant). In animals, diazepam increased the mean dose of rocuronium required by 13%, but this was not statistically significant.

In other studies diazepam was found to have no significant effect on the neuromuscular blockade due to alcuronium, atracurium, gallamine, pancuronium, succinylcholine, tubocurarine, lorazepam and lormetazepam have been reported to have little or no effects on atracurium or vecuronium, and midazolam has been reported to have no effect on succinylcholine or pancuronium.

Mechanism

Not understood. One suggestion is that some alteration in response is seen it may be a reflection of a central depressant action rather than a direct effect on the myoneural junction. Another study instead suggests that a direct action on the muscle may be responsible.

Importance and management

There is no obvious explanation for these discordant observations. What is known shows that the benzodiazepines may sometimes unpredictably alter the depth and prolong the recovery period from neuromuscular blockade, but the extent may not be very great and may possibly be little different from the individual variations in the response of patients to neuromuscular blockers.

Given that benzodiazepines are commonly given as pre-medication it seems likely that any significant interaction would have come to light by now.

**Neuromuscular blockers + Benzodiazepines**

**Clinical evidence**

(a) Increased blockade

A comparative study of 10 patients given gallamine and 4 others given gallamine with intravenous diazepam 150 to 200 micrograms/kg found that the diazepam prolonged the duration of activity of the blocker by a factor of three, and doubled the depression of the twitch response. Persistent muscle weakness and respiratory depression was seen in 2 other patients given tubocurarine after premedication with diazepam. A small reduction (approximately 10%) in neuromuscular blocker requirement has been described with diazepam and tubocurarine or succinylcholine, but see also (b) below.

Another study found that recovery to 25% and 75% of the twitch height after vecuronium was prolonged by about 25% by 15 mg of intravenous midazolam, when compared with control patients. The same study found that midazolam prolonged the recovery from the effects of atracurium by about 20%. However, the increased recovery time due to midazolam was not statistically significant when compared with control patients, but was significantly longer when compared with patients receiving 20 mg of intravenous diazepam. See also (b) below.

(b) Reduced blockade or no effect

The duration of paralysis due to suxamethonium was reduced in one study by 20% when diazepam (150 micrograms/kg) was also given and the recovery time was shortened. Diazepam also slightly reduced the time to 25% and 75% recovery of twitch height in patients given vecuronium by about 15% (not statistically significant). In animals, diazepam increased the mean dose of rocuronium required by 13%, but this was not statistically significant.

In other studies diazepam was found to have no significant effect on the neuromuscular blockade due to alcuronium, atracurium, gallamine, pancuronium, succinylcholine, tubocurarine, lorazepam and lormetazepam have been reported to have little or no effects on atracurium or vecuronium, and midazolam has been reported to have no effect on succinylcholine or pancuronium.

Mechanism

Not understood. One suggestion is that some alteration in response is seen it may be a reflection of a central depressant action rather than a direct effect on the myoneural junction. Another study instead suggests that a direct action on the muscle may be responsible.

**Neuromuscular blockers + Beta-agonist bronchodilators**

Bambuterol can prolong the recovery time from neuromuscular blockade with suxamethonium (succinylcholine) or mivacurium. A case report describes modestly enhanced neuromuscular blockade when pancuronium or vecuronium were given after intravenous salbutamol.

**Clinical evidence**

(a) Bambuterol

A double-blind study in 25 patients found that the recovery time from neuromuscular blockade with suxamethonium (succinylcholine) was prolonged by about 30% in those who had received 10 mg of bambuterol 10 to 16 hours before surgery, and by about 50% in those who had received 20 mg of bambuterol.

This confirms two previous studies, one of which found that 30 mg of bambuterol given about 10 hours before surgery approximately doubled the duration of suxamethonium blockade. Furthermore, in 7 patients who were heterozygous for abnormal plasma cholinesterase, 20 mg of bambuterol taken 2 hours before surgery prolonged suxamethonium blockade two- to threefold, and in 4 patients a phase II block occurred.

A case report describes a 28-year-old man undergoing elective surgery who was given intravenous doses of salbutamol 125 micrograms over 3.5 hours for treatment and prophylaxis of bronchospasm. Muscle relaxation was maintained with pancuronium and then vecuronium. The neuromuscular blockade (measured by the force of contraction of the aductor pollicis in response to ulnar nerve stimulation) increased following salbutamol injection, from 45 to 66% during pancuronium blockade and from 66 to 86% following vecuronium. In addition, recovery of neuromuscular function with neostigmine appeared to be slower than expected.

**Mechanism**

Bambuterol is an inactive prodrug which is slowly converted enzymatically in the body to its active form, terbutaline. The carbamate groups that are split off can selectively inhibit the plasma cholinesterase that is necessary for the metabolism of suxamethonium and mivacurium. As a result, the metabolism of these neuromuscular blockers is reduced and their effects are thereby prolonged. The effect appears to be related to the dose of the...
bambuterol and the time lag after administration; maximal depression of plasma cholinesterase activity appears to occur about 2 to 6 hours following oral administration, but is still markedly depressed after 10 hours. The effect of intravenous salbutamol was probably a direct effect at the neuromuscular junction.6

Importance and management
The interaction with bambuterol is an established interaction, which anaesthetists should be aware of. It may be more important where other factors reduce plasma cholinesterase activity or affect the extent of blockade in other ways (e.g. subjects heterozygous for abnormal plasma cholinesterase). This interaction only applies to beta agonists that are metabolised to carboxamide (bambuterol appears to be the only one available).

The interaction between intravenous salbutamol and pancuronium or vecuronium appeared to be limited to this single report and is probably of only minor clinical importance.

Neuromuscular blockers + Beta blockers

Increases or decreases (often only modest) in the extent of neuromuscular blockade have been seen in patients taking beta blockers. The bradycardia and hypotension sometimes caused by anaesthetics and beta blockers is not counteracted by atracurium.

Clinical evidence

(a) Reduced neuromuscular blockade

The effects of suxamethonium (succinylcholine) were slightly, but not significantly, reduced in 8 patients given a dose of propranolol of 1 mg/15 kg body weight intravenously 15 minutes pre-operatively. In another 8 patients, propranolol, given intravenously 20 to 40 minutes after the onset of action of tubocurarine, was also observed to shorten the recovery from tubocurarine.1 Another study described a shortened recovery period from tubocurarine due to oxprenolol or propranolol, but pindolol only slightly affected a few subjects.2

(b) Increased neuromuscular blockade

Two patients with thyrotoxicosis showed prolonged neuromuscular blockade with tubocurarine after they had received propranolol 120 mg daily for 14 days prior to surgery.3 In 8 patients, intravenous esmolol 300 to 500 micrograms/kg per minute reduced the increase in heart rate during intubation, and slightly but significantly prolonged the recovery from blockade with suxamethonium by approximately 3 minutes when compared with 8 patients given placebo.4 See also (d) below.

(c) Bradycardia and hypotension

Eight out of 42 patients taking unnamed beta blockers given atracurium developed bradycardia (less than 50 bpm) and hypotension (systolic pressure less than 80 mmHg). Most of them had been premedicated with diazepam, induced with methohexitol, and maintained with droperidol, fentanyl and nitrous oxide/oxygen. A further 24 showed bradycardia, associated with hypotension on 9 occasions. All responded promptly to 300 to 600 micrograms of intravenous atropine.5

Another patient using timolol 0.5% eye drops for glaucoma similarly developed bradycardia and hypotension when atracurium was given.6 Bradycardia and hypotension have been seen in 2 other patients, one given alcuronium while using timolol eye drops for glaucoma, and the other given atracurium while taking atenolol for hypertension.7

For reports of bradycardia associated with vecuronium and opioids in patients also receiving beta blockers, see ‘Neuromuscular blockers + Opioids’, p.130.

(d) No interaction

A study of 16 patients who had been taking various beta blockers (propranolol 5, atenolol 5, metoprolol 2, bisoprolol 2, oxprenolol 1, celiprolol 1) for longer than one month found no difference in the onset and duration of action of rocuronium, when compared with a control group.8 Similarly, intra-operative esmolol did not affect the onset and recovery time from suxamethonium (succinylcholine) blockade in patients with normal plasma cholinesterase (pseudocholinesterase) activity,9 but see also (b) above.

Mechanism

The changes in the degree of blockade are not understood but the interaction appears to occur at the neuromuscular junction. It has been seen in animal studies.10,11 The bradycardia and hypotension (c) were probably due to the combined depressant effects on the heart of the anaesthetics and the beta blocker not being offset by atracurium, which has little or no effect on the vagus nerve at doses within the recommended range. Note that neuromuscular blockers with vagolytic activity can cause tachycardia and hypotension.

Importance and management

Information is fairly sparse, but these interactions appear normally to be of relatively minor importance. Be aware that changes in neuromuscular blockade (increases or decreases) can occur if beta blockers are used, but they seem to be unpredictable, and then often only modest in extent. The possible combined cardiac depressant effects of beta blockade and anaesthesia are well known (see ‘Anaesthetics, general + Beta blockers’, p.97). These effects may not be prevented when a neuromuscular blocker is used that has little or no effect on the vagus (such as atracurium or vecuronium).

Neuromuscular blockers + Bretylium

In theory there is the possibility of increased and prolonged neuromuscular blockade if bretylium is given with neuromuscular blockers.

Clinical evidence, mechanism, importance and management

Although case reports seem to be lacking, there is some evidence from animal studies that the effects of tubocurarine can be increased and prolonged by bretylium.1 There is a theoretical possibility that if the bretylium were to be given during surgery to control arrhythmias, its effects (which are delayed) might be additive with the residual effects of the neuromuscular blocker during the recovery period, resulting in apnoea.

Neuromuscular blockers + Calcium-channel blockers

Limited evidence indicates that intra-operative intravenous diltiazem, nicardipine, nifedipine and verapamil can increase the neuromuscular blocking effects of vecuronium and other competitive neuromuscular blockers. Intraoperative nimodipine did not alter vecuronium effects in one study.

An isolated case report describes potentiation of tubocurarine and pancuronium by oral verapamil. However, long-term oral nifedipine did not alter vecuronium or atracurium effects, and long-term therapy with various calcium-channel blockers did not interact with rocuronium. Calcium-channel blockers do not increase the plasma potassium rise due to suxamethonium (succinyllcholine).

Clinical evidence

(a) Competitive (non-depolarising) neuromuscular blockers + Intra venous calcium-channel blockers

A study in 24 surgical patients anaesthetised with nitrous oxide and isoflurane found that diltiazem 5 or 10 microgram/kg per minute decreased the vecuronium requirements by up to 50%. Another study in 24 surgical patients found that diltiazem (5 mg bolus followed by a 4-microgram/kg per minute infusion) decreased vecuronium requirements by 45% when compared with a control group (no diltiazem), or those receiving diltiazem at half the infusion dose. Reductions in the requirements for vecuronium were also noted in other surgical patients receiving intravenous diltiazem or nicardipine. A study in patients given vecuronium 100 micrograms/kg for tracheal intubation found that nicardipine 10 micrograms/kg shortened the onset of blockade, making it the same as in other patients given a higher dose of vecuronium 150 micrograms/kg alone. Recovery times were unaffected by the nicardipine. Yet another study showed that nicardipine reduced the requirements for vecuronium in a dose-dependent manner: nicardipine 1, 2 and 3 micrograms/kg per minute reduced the vecuronium dose requirement to 79%, 60% and 53% of control, respectively. A study involving 44 patients anaesthetised with isoflurane in nitrous oxide/oxygen found that 1 mg of intravenous nifedipine prolonged the neuromuscular blockade due to atracurium from 29 to 40 minutes, and increased the neuromuscular blockade of atracurium or vecuronium from 75 to 90%. In contrast, a study involving 20 patients found that an intravenous infusion of nimodipine had no significant effect on the time course of action of vecuronium.

A 66-year-old woman with renal impairment, receiving 5 mg of intravenous verapamil three times a day for supraventricular tachycardia, underwent abdominal surgery during which she was initially anaesthetised with verapamil alone. Recovery times were unaffected by the vecuronium. However, the authors of this report say that many patients taking long-term verapamil do not show a clinically significant increase in sensitivity to muscle relaxants. This case also contrasts with another study in which 30 predominantly elderly patients taking chronic nifedipine (mean daily dose 33 mg) showed no changes in the time of onset to maximum block nor the duration of clinical relaxation in response to atracurium or vecuronium, when compared with 30 control patients. Similarly, a study of 17 patients taking calcium-channel blockers (nifedipine 12, diltiazem 2, nicardipine 2 and amlodipine 1) found no changes in the neuromuscular blocking effects of rocuronium.

Mechanism

Not fully understood. Although one suggested explanation has been given: nerve impulses arriving at nerve endings release calcium ions, which in turn cause the release of acetylcholine. Calcium-channel blockers can reduce the concentration of calcium ions within the nerve so that less acetylcholine is released. This would be additive with the effects of a neuromuscular blocker.

Importance and management

Direct information so far seems to be limited. Be alert for increased neuromuscular blockade in any patient given an intravenous calcium-channel blocker during surgery. However, this may not apply to nimodipine. From the limited evidence available it appears that increased blockade is not likely in patients taking long-term oral calcium-channel blockers, although one case has been reported for nimodipine.

It would seem from the study quoted above that patients taking chronic calcium-channel blocker treatment are at no greater risk of hyperkalaemia with suxamethonium than other patients.

(c) Suxamethonium + Oral calcium-channel blockers

A comparative study in 21 patients taking calcium-channel blockers long term (diltiazem, nifedipine, verapamil) and 15 other patients not taking calcium-channel blockers found that, although suxamethonium (succinylcholine) caused a modest average peak rise of 0.5 mmol/L in plasma potassium levels, there were no differences between the two groups. See also (a) above.

Neuromuscular blockers + Chloroquine or Quinine

A report describes respiratory insufficiency during the recovery period following surgery, which was attributed to the use of chloroquine diorotate. An isolated report describes recurarisation and dyspnoea in a patient given intravenous quinine after recovering from neuromuscular blockade with suxamethonium (succinylcholine) and pancuronium.

Clinical evidence, mechanism, importance and management

(a) Chloroquine

Studies were carried out on the possible neuromuscular blocking actions of chloroquine diorotate in animals, because it was noticed that when it was used in the peritoneal cavity to prevent adhesions following abdominal surgery in man, it caused respiratory insufficiency during the recovery period. These studies found that it had a non-depolarising blocking action at the neuromuscular junction, which was opposed by neostigmine. It
would seem therefore that during the recovery period the effects of the chloroquine can be additive with the residual effects of the conventional neuromuscular blocker used during the surgery.

Although this appears to be the only report of this interaction, it is consistent with the way chloroquine can unmask or aggravate myasthenia gravis, or oppose the effects of drugs used in its treatment. Be alert for this reaction if chloroquine is used.

(b) Quinine

A 47-year-old man with acute pancreatitis, taking quinine 600 mg three times daily, was given penicillin and gentamicin intravenously before undergoing surgery, during which suxamethonium and pancuronium (succinylcholine) were used uneventfully. After surgery the neuromuscular blockade was reversed with neostigmine and atropine, and the patient awoke and was breathing well. A 6-hour intravenous infusion of quinine 500 mg was started 90 minutes postoperatively. Within 10 minutes (after receiving about 15 mg of quinine) he became dyspnoeic, his breathing became totally ineffective and he needed reintubation. Muscle flaccidity increased by about 50% (10 mg of quinine) and he became dyspnoeic, his breathing became totally ineffective and he needed re-intubation. Muscle flaccidity persisted for 3 hours. The reason for this reaction is not fully understood. A possible explanation is that it may have been the additive neuromuscular blocking effects of the gentamicin (well recognised as having neuromuscular blocking activity; see ‘Neuromuscular blockers + Aminoglycosides’, p.113) and the quinine (an optical isomer of quinidine; see ‘Neuromuscular blockers + Quinidine’, p.131) and the residual effects of the pancuronium and suxamethonium.

There seem to be no other reports of problems in patients receiving neuromuscular blockers with quinine, but this isolated case serves to emphasise the importance of being alert for any signs of recurrarisation in patients concurrently treated with one or more drugs possessing some neuromuscular blocking activity.

Neuromuscular blockers + Clonidine

There is limited evidence to suggest that clonidine modestly increases the duration of action of vecuronium.

Clinical evidence, mechanism, importance and management

In a study of 16 surgical patients, 8 took oral clonidine 4 to 5.5 micrograms/kg 90 minutes before their operation. Anaesthesia was induced by thiopentone, and maintained with nitrous oxide/isoflurane/oxygen supplemented by fentanyl. Clonidine increased the duration of neuromuscular blockade following the use of vecuronium by 26.4%, when compared with the patients not taking clonidine.1

The reasons are not understood. The clinical importance of this interaction would appear to be small.

Neuromuscular blockers + Corticosteroids

Two reports describe antagonism of the neuromuscular blocking effects of pancuronium by high-dose prednisolone, or prednisolone and hydrocortisone. A third report in a patient with adrenocortical insufficiency describes reversal of the pancuronium block by hydrocortisone. Some evidence suggests the dosage of vecuronium may need to be almost doubled in those receiving intramuscular betamethasone. However, prolonged coadministration of high-dose corticosteroids and neuromuscular blockers may increase the risk of myopathy, resulting in prolonged paralysis following the discontinuation of the neuromuscular blocker.

Clinical evidence

(a) Neuromuscular blocking effects

A man undergoing surgery who was taking prednisone 250 mg daily by mouth, had good muscular relaxation in response to intravenous pancuronium 8 mg (100 micrograms/kg) early in the operation, but an hour later he began to show signs of inadequate relaxation, and continued to do so for the next 75 minutes despite being given four additional 2-mg doses of pancuronium.1 Another patient taking large doses of hydrocortisone, prednisolone and aminophylline proved to be resistant to the effects of pancuronium.2 A hypophysectomised man taking cortisone developed profound paralysis when given pancuronium, which was rapidly reversed with 100 mg of hydrocortisone sodium succinate.3

Inadequate neuromuscular blockade with vecuronium (presenting as unexpected movements) occurred in 2 patients during neurosurgery. They had both been given a preoperative course of betamethasone 4 mg four times daily to reduce raised intracranial pressure.4 This prompted a retrospective search of the records of 50 other patients, which revealed that those given intramuscular betamethasone preoperatively had needed almost double the dose of vecuronium (134 compared with 76 micrograms/kg per hour).5

These reports contrast with another,6 in which 25 patients who had no adrenocortical dysfunction or histories of corticosteroid therapy were given pancuronium, metocurine, tubocurarine or vecuronium. They showed no changes in their neuromuscular blockade when given a single intravenous dose of dexamethasone 400 micrograms/kg or hydrocortisone 10 mg/kg.

(b) Increased risk of myopathy

A report describes 3 patients in status asthmaticus who developed acute reversible myopathy after treatment with high-dose intravenous methylprednisolone 320 to 750 mg daily and steroidal neuromuscular blockers (vecuronium or pancuronium), used concurrently for at least 8 days.6 A review of the literature from 1977 to 1995 found over 75 cases of prolonged weakness associated with combined use of neuromuscular blockers and corticosteroids.7 This condition has been referred to as ‘blocking agent–corticosteroid myopathy’ (BACM). Prior to 1994, virtually all cases involved either pancuronium or vecuronium, leading some authors to suggest that atracurium might be safer as it does not have the steroid nucleus of the vecuronium and pancuronium.8 However, there have since been reports of prolonged paralysis associated with extended treatment with high-dose corticosteroids and atracurium9,10 or cisatracurium.10

Mechanism

Not understood. For the partial reversal of neuromuscular blockade, one idea, based on animal studies, is that adrenocortical insufficiency causes a defect in neuromuscular transmission, which is reversed by the corticosteroids.3 Another idea is that the effects seen are connected in some way with the steroid nucleus of the pancuronium and vecuronium, and are mediated presynaptically.4,11

The increased myopathy may be due to an additive effect as both neuromuscular blockers and corticosteroids can cause myopathy. Results of an in vitro study suggested that the combination of vecuronium and methylprednisolone might augment pharmacologic denervation, which may lead to myopathy and contribute to the prolonged weakness observed in some critically ill patients.12

Importance and management

The evidence for antagonism of neuromuscular blocking effects seems to be limited to the reports cited, and involve only pancuronium and vecuronium. Careful monitoring is clearly needed if either is used in patients who have been treated with corticosteroids, being alert for the need to increase the dosage of the neuromuscular blocker. Note that animal studies suggest that atracurium may also possibly be affected by betamethasone to the same extent as vecuronium.11 However, also be aware that prolonged coadministration of competitive neuromuscular blockers and corticosteroids, particularly in patients in intensive care, may result in a marked prolongation of muscle weakness (several months’ rehabilitation have been needed in some cases).8 The complex state of the critically ill patient means that the effects of neuromuscular blockers may be unpredictable.

Neuromuscular blockers + Danazol or Tamoxifen

Two isolated case reports describe prolonged atracurium effects, which were attributed to tamoxifen and danazol.

Clinical evidence, mechanism, importance and management

A case report describes a 67-year-old mastectomy patient taking methyldopa, hydrochlorothiazide, triamterene and long-term tamoxifen 10 mg twice daily who showed prolonged neuromuscular blockade after a single 500-microgram/kg dose of atracurium, which the authors suggest might be due to an interaction between atracurium and tamoxifen.1 The authors also point out an earlier report2 of prolonged atracurium blockade where the patient was taking danazol. These interactions are probably not of general importance.

Neuromuscular blockers + Dantrolene

One patient developed increased vecuronium effects when given dantrolene, whereas two others were unaffected.

Clinical evidence, mechanism, importance and management

A 60-year-old woman, given a total of 350 mg of dantrolene orally during the 28 hours before surgery to prevent malignant hyperthermia, developed increased neuromuscular blockade and a slow recovery rate when vecuronium was subsequently given.3 This report contrasts with another describing two patients taking long-term dantrolene 20 to 50 mg daily who had no changes in vecuronium-induced neuromuscular blockade during or after surgery.4 Dantrolene is a muscle relaxant that acts directly on the muscle by lowering intracellular calcium concentrations in skeletal muscle; it reduces the release of calcium from the sarcoplasmic reticulum. It may also possibly inhibit calcium-dependent pre-synaptic neurotransmitter release.5 Be alert for any increased effects if both drugs are used. These case reports indicate that the effects could be dose-related, and so patients receiving higher doses of dantrolene may be at greater risk, although more study is needed to confirm this.

Neuromuscular blockers + Dexametomidine

Dexametomidine caused a minor increase in plasma rocuronium levels.

Clinical evidence, mechanism, importance and management

A study in 10 healthy subjects under general anaesthesia with alfentanil, propofol and nitrous oxide/oxygen, found that an intravenous infusion of dexametomidine (950 to 990 nanograms/kg) increased plasma rocuronium levels by 7.6%, which was not clinically significant, and decreased the twitch tension from 51% to 44% after 45 minutes. Dexmedetomidine also decreased finger blood flow and increased systemic blood pressure. It was suggested these pharmacokinetic changes occurred due to peripheral vasoconstriction.6 These effects are unlikely to be of clinical significance.

Neuromuscular blockers + Ecothiopate iodide

The neuromuscular blocking effects of suxamethonium (succinylcholine) are markedly increased and prolonged in patients receiving ecothiopate iodide. The dosage of suxamethonium should be reduced appropriately.

Neuromuscular blockers + Disopyramide

An isolated case report suggests that disopyramide may oppose the effects of neostigmine used to reverse neuromuscular blockade with vecuronium.

Clinical evidence, mechanism, importance and management

A case report suggests that the normal antagonism by neostigmine of vecuronium neuromuscular blockade may be opposed by therapeutic serum levels of disopyramide (5 micrograms/mL). Disopyramide has also been shown to decrease the antagonism by neostigmine of the neuromuscular blockade of tubocurarine on the rat phrenic nerve-diaphragm preparation.7 The general clinical importance of these observations is not known.

Neuromuscular blockers + Pantothenic acid

Apart from the single unconfirmed report there seems to be little other reason for avoiding concurrent use or for taking particular precautions. However, the US manufacturer of dexpanthenol recommends that it should not be given within one hour of suxamethonium.2

Neuromuscular blockers + Ecothiopate iodide

In 1965 a study showed that ecothiopate iodide eye drops could markedly lower pseudocholinesterase levels. It was noted that “... within a few days of commencing therapy, levels are reached at which protracted apnoea could occur, should these patients require general anaesthesia in which muscle relaxation is obtained with succinylcholine”. Cases of apnoea due to this interaction were reported the following year and other cases have been subsequently reported.5,6 In one case a woman given suxamethonium (succinylcholine) 200 mg showed apnoea for 5½ hours.2 Other stud-
ies have confirmed that ecotiothiapate given orally or as eye drops markedly reduced the levels of plasma cholinesterase, and can prolong recovery after suxamethonium. On discontinuing ecotiothiapate, it takes several weeks to 2 months for enzyme activity to return to normal.

Mechanism
Suxamethonium is metabolised in the body by plasma cholinesterase. Ecotothiapate iodide depresses the levels of this enzyme so that the metabolism of the suxamethonium is reduced and its effects are thereby enhanced and prolonged. One study in 71 patients found that two drops of ecotothiapate iodide 0.06% three times a week in each eye caused a twofold reduction in plasma cholinesterase (pseudocholinesterase) activity in about one-third of the patients, and a fourfold reduction in 1 in 7 patients.8

Importance and management
An established, adequately documented and clinically important interaction. The dosage of suxamethonium should be reduced appropriately because of the reduced plasma cholinesterase levels caused by ecotothiapate. The study cited above suggests that prolonged apnoea is likely in about 1 in 7 patients. One report describes the successful use of approximately one-fifth of the normal dosage of suxamethonium in a patient receiving ecotothiapate.8 Mivacurium is also metabolised by plasma cholinesterase, and would be expected to interact with ecotothiapate in the same way as suxamethonium.9 Consider also ‘Neuromuscular blockers + Anticholinesterases’, p. 114.

Neuromuscular blockers + Ephedrine
A study in 80 patients found that premedication with ephedrine 10 mg reduced the onset time of rocuronium by roughly 30% but did not significantly affect that of atracurium. The clinical significance of these effects is unclear.

Neuromuscular blockers + Mivacurium
Studies indicate that what happens probably depends on the dosage of rocuronium: 0.1 to 1 micrograms/kg increased the blocking effects of tubocurarine and suxamethonium (succinylcholine) whereas 1 to 4 mg/kg opposed the blockade. One suggestion is that low doses of furosemide may inhibit protein kinase causing a reduction in neuromuscular transmission, whereas higher doses cause inhibition of phosphodiesterase resulting in increased cyclic AMP activity and causing antagonism of neuromuscular blockade. It has also been suggested that large doses of loop diuretics may affect the renal excretion of neuromuscular blockers that are cleared by this route, resulting in more rapid recovery from the blockade.

Neuromuscular blockers + H2-receptor antagonists
One report suggests that recovery from the neuromuscular blocking effects of suxamethonium (succinylcholine) is prolonged by cimetidine, but this may possibly have been due to the presence of metoclopramide. Four other reports say that no interaction occurs between suxamethonium and either cimetidine, famotidine or ranitidine. Cimetidine, but not ranitidine, has been reported to increase the effects of vecuronium. Cimetidine does not alter the effects of atracurium or rocuronium and ranitidine does not alter the effects of atracurium.

Clinical evidence
(a) Evidence of increased neuromuscular blockade
A study in 10 patients given cimetidine 300 mg orally at bedtime and another 300 mg 2 hours before anaesthesia, found that while the onset of action of suxamethonium (succinylcholine) 1.5 mg/kg intravenously was unchanged, when compared with 10 control patients, the time to recover 50% of the twitch height was prolonged 2 to 2.5-fold (from 8.6 to 20.3 minutes). One patient took 57 minutes to recover. His plasma cholinesterase levels were found to be normal.1 It was later reported that some patients were also taking metoclopramide, which is known to interact in this way. See also ‘Neuromuscular blockers + Metoclopramide’, p. 127.

Another study2 in 24 patients found that cimetidine 400 mg significantly prolonged the recovery (T1–25 period) from vecuronium, but few patients had any response to cimetidine 200 mg or ranitidine 100 mg. This slight prolongation of action of vecuronium due to cimetidine 400 mg was confirmed in another placebo-controlled study (mean time to return of T1 was 30 versus 22.5 minutes).4 A study using a rat phrenic nerve dia-
**(b) Evidence of unchanged neuromuscular blockade**

A study in 10 patients given 400 mg of cimetidine orally at bedtime and again 90 minutes before anaesthesia found no evidence of an effect on the neuromuscular blockade caused by suxamethonium, nor on its duration or recovery period when compared with 10 control patients. Another controlled study in patients given cimetidine 300 mg or ranitidine 150 mg, both the night before and 1 to 2 hours before surgery, found no evidence that the duration of action of suxamethonium or the activity of plasma cholinesterase were altered. A study in 15 patients undergoing caesarean section also found no evidence that either cimetidine or ranitidine affected the neuromuscular blocking effects of suxamethonium. A study in 70 patients found no changes in the neuromuscular blocking effects of suxamethonium in those given cimetidine 400 mg, ranitidine 80 mg or famotidine 20 mg.

**Cimetidine and ranitidine** appear not to affect atracurium, cimetidine appears not to affect rocuronium, and ranitidine appears not to affect vecuronium. Another study found that premedication with ranitidine did not affect vecuronium blockade in postpartum patients, but that the neuromuscular blockade was prolonged in these patients compared with non-pregnant controls.

**Mechanism**

Not understood. Studies with human plasma failed to find any evidence that cimetidine in therapeutic concentrations inhibits the metabolism of suxamethonium. However, metoclopramide may do and therefore is possibly the drug responsible for any interaction seen. In vitro studies with very high cimetidine concentrations found inhibition of plasma cholinesterase (pseudocholinesterase) activity. The cimetidine/vecuronium interaction is not understood, but it has been suggested that cimetidine may reduce the hepatic metabolism of vecuronium.

**Importance and management**

Information seems to be limited to the reports cited. The most likely explanation for the discord between the cimetidine/suxamethonium results is that in the one study reporting increased suxamethonium effects some of the patients were also given metoclopramide, which can inhibit plasma cholinesterase and prolong the effects of suxamethonium (see also ‘Neuromuscular blockers + Metoclopramide’, p. 127). In four other studies, cimetidine and other H2-receptor antagonists did not alter suxamethonium effects. Therefore, it seems unlikely that an interaction exists. There is some evidence that cimetidine may slightly prolong the effects of vecuronium, but ranitidine appears not to interact. Atracurium and rocuronium appear not to be affected. Overall these possible interactions seem to be of little clinical significance.

**Neuromuscular blockers + Immunosuppressants**

There is limited evidence to suggest that the neuromuscular blocking effects of atracurium, pancuronium and vecuronium may be increased in some patients taking ciclosporin. There is also some evidence of reduced neuromuscular blockade with azathioprine and antilymphocyte immunoglobulins, but other evidence suggests that there is no clinically relevant interaction with azathioprine.

**Clinical evidence**

(a) Azathioprine or Antilymphocyte immunoglobulins

A retrospective study found that patients taking azathioprine or antilymphocyte immunoglobulins following organ transplantation needed an increased dosage of unspecified muscle relaxants to achieve satisfactory muscle relaxation. A control group of 74 patients not receiving immunosuppression needed 0 to 10 mg of a competitive (non-depolarising) muscle relaxant; 13 patients taking azathioprine needed 12.5 to 25 mg; 11 patients receiving antilymphocyte immunoglobulins (antilymphocyte globulin) needed 10 to 20 mg and two patients taking azathioprine and guanethidine needed 55 and 90 mg. However, a controlled study of 28 patients undergoing renal transplantation, who were receiving atracurium, pancuronium or vecuronium at a constant infusion rate, found that an injection of azathioprine 3 mg/kg given over 3 minutes caused a rapid, but only small and transient decrease of neuromuscular blockade. Ten minutes after the end of the azathioprine injection, a residual interaction was only detectable in those patients who had received pancuronium.

(b) Ciclosporin

A retrospective study found that 4 of 36 patients receiving atracurium and 4 of 29 patients receiving vecuronium experienced prolonged neuromuscular blockade after an aortic operation. Respiratory failure occurred more often in patients who received intravenous ciclosporin during surgery. Extended recovery times after atracurium and vecuronium are described in another report in renal transplant patients who had been taking oral ciclosporin. Similarly, a prolonged duration of action of vecuronium was noted in 7 kidney transplant recipients, when compared with patients with normal renal function, and ciclosporin was considered to be a factor in this. Two case reports describe prolonged neuromuscular blockade attributed to intravenous ciclosporin. In the first report, a woman with a 2-year renal transplant underwent surgery during which pancuronium 5.5 mg was used as the neuromuscular blocker. She was also given intravenous ciclosporin before and after surgery. The surgery lasted for 4 hours and no additional doses of pancuronium were given. Residual paralysis was inadequately reversed with neostigmine and atropine, and so edrophonium was given prior to extubation. However, she had to be re-intubated 20 minutes later because of increased respiratory distress.

In the second report, a 15-year-old girl receiving intravenous ciclosporin with serum levels of 138 micrograms/L was anaesthetised using fentanyl, thiopental and vecuronium 100 micrograms/kg. Anaesthesia was maintained with nitrous oxide, oxygen and isoflurane. Attempts were later made to reverse the blockade with edrophonium, atropine and neostigmine but full neuromuscular function was not restored until 3 hours and 20 minutes after the vecuronium was given. Another report describes a prolongation of the effects of vecuronium in a renal-transplant recipient taking oral ciclosporin, azathioprine, and prednisolone.

**Mechanism**

The reasons for the reduction in neuromuscular blockade with azathioprine and antilymphocyte immunoglobulins are not understood. It has been suggested that azathioprine may inhibit phosphodiesterase at the motor nerve terminal resulting in increased release of acetylcholine. The ciclosporin interaction may be partly due to the vehicle used in intravenous preparations. One idea is that Cremophor, a surfactant which has been used as a solvent for the ciclosporin, may increase the effective concentration of pancuronium at the neuromuscular junction. Both compounds have been observed in animal studies to increase vecuronium blockade, and Cremophor has also been seen to decrease the onset time.
of pancuronium blockade in patients given Cremophor-containing anaesthetics.\(^1\) However, this is not the entire answer because the interaction has also been seen with oral cisclosporin, which does not contain Cremophor.\(^8\)

**Importance and management**

Direct information seems to be limited to the reports cited, and the interactions are not established. Although retrospective data suggest that azathioprine and antilymphocyte immunoglobulins can cause a reduction in the effects of neuromuscular blockers, and in some cases the dosage may need to be increased two- to fourfold,\(^1\) the only prospective study found that the interaction with azathioprine was not clinically significant.\(^2\) The general importance of the cislosporin interaction is also uncertain, but be alert for an increase in the effects of atracurium, pancuronium or vecuronium in any patient receiving cisclosporin. Not all patients appear to develop this interaction.\(^3\) More study is needed.

### Neuromuscular blockers + Lansoprazole

There is some evidence that lansoprazole increases the duration of action of vecuronium.

**Clinical evidence, mechanism, importance and management**

In a study of 50 adult surgical patients, half of whom received lansoprazole 30 mg on the night before their operation, it was found that there was no significant difference between the time of onset of neuromuscular blockade by vecuronium in the two groups, but lansoprazole increased the duration of effect by about 34%.\(^1\) This needs confirmation but be alert for this interaction in any patient treated with lansoprazole.

### Neuromuscular blockers + Lithium

The concurrent use of neuromuscular blockers and lithium is normally safe and uneventful, but four patients taking lithium experienced prolonged blockade and respiratory difficulties after receiving standard doses of pancuronium and/or suxamethonium (succinylcholine).

**Clinical evidence**

A man depressive woman taking lithium carbonate with a lithium level of 1.2 mmol/L, underwent surgery and was given thiopental, 310 mg of suxamethonium (succinylcholine) over a period of 2 hours, and 500 micrograms of pancuronium. Prolonged neuromuscular blockade with apnoea occurred.\(^1\)

Three other patients taking lithium experienced enhanced neuromuscular blockade when given pancuronium alone, with suxamethonium, or both.\(^2\) The authors of one of these reports\(^3\) say that “. . . We have seen potentiation of the neuromuscular blockade produced by succinylcholine in several patients taking lithium carbonate. . .” but give no further details. In contrast, a retrospective analysis of data from 17 patients taking lithium carbonate, who received suxamethonium during a total of 78 ET treatments, failed to reveal any instances of unusually prolonged recovery.\(^4\)

### Neuromuscular blockers + Magnesium compounds

The effects of cisatracurium, mivacurium, pancuronium, rocuronium, tubocurarine, vecuronium, and probably other competitive neuromuscular blockers can be increased and prolonged by magnesium sulfate given parenterally. There is some evidence that magnesium may interact similarly with suxamethonium (succinylcholine), but also evidence from well-controlled trials that it does not.

**Clinical evidence**

(a) Competitive (non-depolarising) neuromuscular blockers

A pregnant 40-year-old with severe pre-eclampsia and receiving magnesium sulfate by infusion, underwent emergency caesarane section during which she was initially anaesthetised with thiopental, maintained with nitrous oxide/oxygen and enflurane, and given firstly suxamethonium and later vecuronium as muscle relaxants. At the end of surgery she rapidly recovered from the anaesthesia but the neuromuscular blockade was very prolonged (an eightfold increase in duration).\(^1\) In a series of randomised studies involving 125 patients, pretreatment with intravenous magnesium sulfate 40 mg/kg reduced the dose requirement of vecuronium by 25%, approximately halved the time to the onset of action, and prolonged the duration of action from 25.2 to 43.3 minutes.\(^2\) Another study found that pretreatment with 40 mg/kg of magnesium sulfate decreased the onset and prolonged the recovery time from vecuronium blockade, but magnesium sulfate 20 mg/kg had no effect.\(^3\) Evidence of enhanced vecuronium neuromuscular blockade by magnesium sulfate is described in one other study,\(^4\) and case report.\(^5\) Another study in 20 patients found that recruration (sufficient to compromise respiration) occurred when magnesium sulfate 60 mg/kg was given in the postoperative period, shortly after recovery from neuromuscular block with vecuronium.\(^6\) Neostigmine-induced recovery from vecuronium block was attenuated by about 30% in interactions between lithium and pancuronium\(^1\) or suxamethonium,\(^6\) have been demonstrated in dogs, and an interaction between lithium and tubocurarine has been demonstrated in cats,\(^6\) but no clear interaction has been demonstrated with any other neuromuscular blocker.\(^7\) A case of lithium toxicity has been described in a woman taking lithium who was given suxamethonium, but it is doubtful if it arose because of an interaction.\(^8\)

**Mechanism**

Uncertain. One suggestion is that, when the interaction occurs, it may be due to changes in the electrolyte balance caused by the lithium, which results in changes in the release of acetylcholine at the neuromuscular junction.\(^9\)

**Importance and management**

Information is limited. There are only four definite reports of this interaction in man, and good evidence that no adverse interaction normally occurs. Concurrent use need not be avoided but it would be prudent to be on the alert for this interaction in any patient taking lithium who is given any neuromuscular blocker.

patients pretreated with magnesium sulfate in a randomised study. The authors demonstrated this was due to slower spontaneous recovery and not decreased response to neostigmine.\(^7\)

In two patients who underwent cardiac surgery, neuromuscular block with either pancuronium, or pancuronium and rocuronium was prolonged by more than 10 hours. This was attributed to the effects of high doses of neuromuscular blockers potentiated by magnesium sulfate 2.5 g; moderate renal impairment may also have been a factor.\(^8\) A fourfold increase in the duration of neuromuscular blockage of rocuronium 0.9 mg/kg was reported in a pregnant woman receiving magnesium sulfate.\(^9\) A further randomised placebo-controlled study confirmed that pretreatment with magnesium sulfate 60 mg/kg increased the duration of neuromuscular block produced by rocuronium (time to initial recovery increased from 25.1 to 42.1 minutes), but the onset time was not affected.\(^10\)

A patient given cisatracurium 14 mg during induction of anaesthesia, which was reversed postoperatively with 2 doses of neostigmine and glycopyrrolate, was then given intravenous magnesium sulfate 2 g over 5 minutes for atrial fibrillation, which had developed about 15 minutes after the end of surgery. Within a few minutes of receiving magnesium, recurrarisation occurred and the patient required re-intubation and artificial ventilation for about 20 minutes.\(^11\) A study in 20 patients undergoing elective cardiac surgery found that magnesium sulfate 70 mg/kg prior to induction followed by 30 mg/kg per hour prolonged the neuromuscular blockade induced with the first maintenance dose of cisatracurium by just over 30 minutes.\(^12\)

The infusion rate of mivacurium required to obtain relaxation in women undergoing a caesarean section was about threefold lower in 12 women who had received magnesium sulfate for pre-eclampsia than in 12 women who had not.\(^13\)

Prolonged neuromuscular block with rapacuronium has also been reported in a patient undergoing emergency caesarean section who received magnesium sulfate and clindamycin, although the clindamycin was thought to be mainly responsible (see also ‘Neuromuscular blockers + Miscellaneous anti-infectives’, p.127).\(^14\)

Prolonged neuromuscular blockade has been described in three women with pre-eclampsia who were given magnesium sulfate and either tubocurarine alone or with succinylcholine.\(^15,16\) Increased blockade by magnesium has been demonstrated with tubocurarine in animals.\(^15,17\)

(b) Depolarising neuromuscular blockers

An early study in 59 women undergoing caesarean section found that those given magnesium sulfate for eclampsia and pre-eclampsia needed less succinylcholine than control patients (4.73 compared with 7.39 mg/kg per hour).\(^18\) A 71-year-old woman given magnesium sulfate and lidocaine for ventricular tachycardia underwent emergency cardioversion and had a delayed onset and prolonged neuromuscular blockade when she was given succinylcholine.\(^19\) Increased blockade by magnesium has been seen with succinylcholine in animals.\(^15,17\)

However, a randomised study involving 20 patients found that pretreatment with a single 60-mg/kg bolus dose of magnesium sulfate did not significantly affect the onset or prolong the block produced by succinylcholine.\(^20\) Similar results were found in a non-randomised study\(^21\) and in a double-blind randomised study.\(^22\) In randomised studies, the use of magnesium sulfate has also been reported to reduce succinylcholine-associated fasciculations\(^21\) and reduce the increase in serum potassium levels produced by succinylcholine.\(^20\)

Mechanism

Not fully understood. Magnesium sulfate has direct neuromuscular blocking activity by inhibiting the normal release of acetylcholine from nerve endings, reducing the sensitivity of the postsynaptic membrane and depressing the excitability of the muscle membranes. These effects are seen when serum magnesium levels rise above the normal range (hypermagnesaemia) and are possibly simply additive (or perhaps more than additive) with the effects of competitive neuromuscular blockers. Be alert for an increase in the effects of any competitive neuromuscular blocker if intravenous magnesium sulfate has been used, and anticipate the need to reduce the dose. Some have suggested that the decreased time to onset with vecuronium may be of use clinically to improve the intubating conditions for rapid sequence induction if suxamethonium is not suitable.\(^2\) Intravenous calcium gluconate was used to assist recovery in one case of prolonged block.\(^2\) Also be aware that recurarisation may occur when intravenous magnesium compounds are used in the postoperative period.\(^6,11\) The authors of one report suggest that magnesium sulfate should be avoided for at least 30 minutes after reversal of residual neuromuscular block, to minimise the risk of recurarisation.\(^11\)

Hypermagnesaemia can occur in patients receiving magnesium in antacids, enemas or parenteral nutrition, especially if there is impaired renal function, but an interaction would not normally be expected, as oral magnesium compounds generally result in lower systemic levels than intravenous magnesium due to poor absorption.\(^2\)

The interaction between magnesium and suxamethonium is not established. Although some animal and clinical evidence suggests potentiation of suxamethonium can occur, well-controlled studies have not confirmed this. Therefore some authors consider that magnesium sulfate does not significantly affect the clinical response to suxamethonium.\(^2,23\)

Neuromuscular blockers + MAOIs

The effects of succinylcholine (suxcinylcholine) were enhanced in 3 patients taking phenelzine.

Clinical evidence, mechanism, importance and management

Two patients, one taking phenelzine and the other who had ceased to do so 6 days previously, developed apnoea following ECT during which succinylcholine (suxcinylcholine) was used. Both responded to injections of nikethamide and positive pressure ventilation with oxygen.\(^1\) A later study observed the same response in another patient taking phenelzine.\(^2\) This would appear to be explained by the finding that phenelzine caused a reduction in the levels of plasma cholinesterase (pseudocholinesterase) in 4
Neuromuscular blockers + Metoclopramide

The neuromuscular blocking effects of suxamethonium (succinylcholine) and mivacurium can be increased and prolonged in patients taking metoclopramide.

Clinical evidence

Metoclopramide 10 mg given intravenously 1 to 2 hours before induction of anaesthesia prolonged the time to 25% recovery after suxamethonium (succinylcholine) by 1.83 minutes (23%) in 19 patients, when compared with 21 control patients. A larger 20-mg dose of metoclopramide prolonged the time to recovery by 56% in a further 10 patients. In another study by the same research group, the recovery from neuromuscular blockade (time from 95% to 25% suppression of the activity of the adductor pollicis muscle) due to suxamethonium was prolonged by 67% in 11 patients who were given metoclopramide 10 mg intravenously during surgery, one minute before the suxamethonium. A randomised, placebo-controlled, double-blind study in 30 patients found that 150 micrograms/kg of intravenous metoclopramide given prior to anaesthetic induction about 10 minutes before mivacurium 150 micrograms/kg prolonged the duration of action of mivacurium by about 30%. Another report found that infusion rates of mivacurium were reduced by up to about 80% in patients given metoclopramide 10 or 20 mg intravenously, 5 minutes before induction, and metoclopramide delayed complete recovery from neuromuscular block after mivacurium by 36% (10 mg dose) and 50% (20 mg dose). Delays in recovery from mivacurium block of 78% after metoclopramide 20 mg were found in another study.

Mechanism

Metoclopramide is postulated to reduce the activity of plasma cholinesterase, which is responsible for the metabolism of suxamethonium and mivacurium. One in vitro study found that a metoclopramide level of 800 nanograms/mL inhibited plasma cholinesterase activity by 50%. However, a 10-mg dose of metoclopramide in adult patients weighing 50 to 70 kg produces peak plasma levels five times less than this (140 nanograms/mL). Further, in an in vivo study, metoclopramide had only minimal inhibitory effects on plasma cholinesterase, and there was no difference in plasma cholinesterase levels in patients who had received metoclopramide and those who had not.

Importance and management

The interaction between metoclopramide and suxamethonium is an established but not extensively documented interaction of only moderate or minor clinical importance. However anaesthetists should be aware that some enhancement of blockade can occur. The interaction between metoclopramide and mivacurium has only more recently been demonstrated. Metoclopramide appears to allow a reduction in the infusion rate of mivacurium and it causes a significant delay in recovery from neuromuscular block. Care is recommended during combined use. The authors of the suxamethonium reports also point out that plasma cholinesterase activity is reduced in pregnancy and so suxamethonium sensitivity is more likely in obstetric patients. Ester-type local anaesthetics also depend on plasma cholinesterase activity for metabolism, and their effects would therefore be expected to be additive with the effects of metoclopramide, see ‘Neuromuscular blockers + Anti-infectives’, p.113.

Colistin, colistimethate sodium, polymyxin B, clindamycin, lincomycin, some penicillins (apicillin, azlocillin, mezlocillin, piperacillin) and vancomycin possess some neuromuscular blocking activity. Increased and prolonged neuromuscular blockade is possible if these antibacterials are used with neuromuscular blocking drugs. In theory amphotericin B might also interact, but the tetracyclines probably do not. No clinically significant interaction has been seen with cefoxitin, cefuroxime, chloramphenicol or metronidazole. See also ‘Neuromuscular blockers + Aminoglycosides’, p.113.

Clinical evidence

(a) Amphotericin B

Amphotericin B can induce hypokalaemia resulting in muscle weakness, which might be expected to enhance the effects of neuromuscular blockers, but there appear to be no reports in the literature confirming that a clinically significant interaction actually occurs.

(b) Cephalosporins

No change in neuromuscular blockade was seen in patients given intravenous cefuroxime shortly before pipecuronium or rocuronium in a controlled study. Similarly, intravenous cefoxitin given before, during and after surgery was not associated with a clinically important prolongation of vecuronium blockade.

(c) Chloramphenicol

No interaction was seen in myasthenic patients given chloramphenicol.

(d) Clindamycin, Lincomycin

Enhanced blockade has been seen in patients given pancuronium and lincomycin, which was reversed by neostigmine. Respiratory paralysis was seen 10 minutes after lincomycin 600 mg was given intramuscularly to a man recovering from neuromuscular blockade with tubocurarine and this interaction was confirmed in another report. Other case reports and clinical studies describe minor to marked increases in neuromuscular blockade in patients receiving pancuronium, pipecuronium, rapacuronium or suxamethonium when they were given clindamycin. One patient developed very prolonged blockade after being unintentionally given clindamycin 2.4 g instead of 600 mg shortly after recovery from suxamethonium and tubocurarine. Prolongation of the neuromuscular blocking effects of vecuronium has also been reported in a patient who received both clindamycin and gentamicin.

(e) Metronidazole

An increase in the neuromuscular blocking effects of vecuronium with metronidazole has been reported in cats, but a later study in patients failed to find any evidence of an interaction, and another study with rocuronium also found no evidence of an interaction with metronidazole. Similarly, no interaction was seen with rocuronium and metronidazole/cefuroxime. Another study found no significant interaction between pipecuronium and metronidazole.
Penicillins

A study in patients found that the neuromuscular blocking effects of **vancomycin** were prolonged by a number of penicillins: *apicillin* 26%, *azlocillin* 55%, *mezlocillin* 38%, and *piperacillin* 46%.19 Reinstatement of neuromuscular blockade and respiratory failure occurred in a patient given **piperacillin** 3 g by intravenous infusion postoperatively, following the reversal of **vecuronium** blockade.21 However, a randomised, double-blind study involving 30 patients found that **piperacillin** or **cefotaxin**, given by intravenous infusion, pre- and intraoperatively, were not associated with clinically important prolongation of the neuromuscular block induced by **vecuronium**. Of 27 patients who could be evaluated, 22 showed a modest overall decrease in recovery time and 5 patients (2 patients after receiving **piperacillin** and 3 patients after **cefotaxin**) exhibited a slight prolongation in recovery time, but these patients all responded readily to neostigmine or other anticholinesterases and subsequent recu arisation did not occur.22 No interaction was seen in a myasthenic patient given **ampicillin**.23

Polymyxins

A literature review of interactions between antibiotics and neuromuscular blockers identified 17 cases over the period 1956 to 1970 period in which **colistin** (polymyxin E) or **colistimethate sodium**, with or without conventional neuromuscular blockers, were responsible for the development of increased blockade and respiratory muscle paralysis. Some of the patients had renal disease.20 A later report describes prolonged respiratory depression in a patient receiving **penciclovir** and **colistin**.21 Calcium gluconate was found to reverse the blockade.21 A placebo-controlled study found that one million units of **colistin** also considerably prolonged the recovery time from **vecuronium** blockade.12 Six cases of enhanced neuromuscular blockade involving **polymyxin B** have also been reported.20 An increase in the blockade due to **vecuronium** by **polymyxin B** and bactracin wound irrigation is described in another report; pyridostigmine, neostigmine and edrophonium were ineffective antagonists of this block and only partial improvement occurred after calcium chloride was given.22 Prolonged and fatal apnoea occurred in another patient given **suxamethonium** when his peritoneal cavity was instilled with a solution containing 100 mg of **polymyxin B** and 100 000 units of bactracin.23

Tetracyclines

Four cases of enhanced neuromuscular blockade with **rotiltertracycline** or **oxytetracycline** in myasthenic patients have been reported20 (2 cases originally reported elsewhere21) but there seem to be no reports of interactions in patients without myasthenia given neuromuscular blocking drugs.

Vancocinycin

A man recovering from neuromuscular blockade with **suxamethonium** (with some evidence of residual Phase II block) developed almost total muscle paralysis and apnoea when given an intravenous infusion of vancomycin. He recovered spontaneously when the vancomycin was stopped, and 100 000 units of bacitracin.23

Mechanism

Not fully understood but several sites of action at the neuromuscular junction (pre and/or post, effects on ion-channels or receptors) have been suggested.

The neuromuscular blocking properties of the polymyxins (polymyxin B, colistin, colistimethate sodium) involve a number of mechanisms, which may explain the difficulty in reversing the blockade.22

Importance and management

The interactions involving polymyxin B, colistin, colistimethate sodium, lincomycin, and clindamycin are established and clinically important. The incidence is uncertain. Concurrent use need not be avoided, but be alert for increased and prolonged neuromuscular blockade. The recovery period should be well monitored because of the risk of recu arisation. Check the outcome of using amphoterin. No interaction would be expected with the tetracyclines, cefuroxime, cefotaxin, metronidazole or metronidazole/cefuroxime, and probably with ampicillin and chloramphenicol, but some caution would seem appropriate with azlocillin, mezlocillin and piperacillin. The situation with vancomycin is less clear. The evidence does suggest a link between vancomycin and increased neuromuscular blockade following the use of suxamethonium, and possibly vecuronium. However, vancomycin is given routinely as antibiotic prophylaxis before surgical procedures. The sparsity of reports therefore suggests that in practice vancomycin rarely causes a clinically significant interaction with neuromuscular blockers.

Clinical evidence, mechanism, importance and management

Neuromuscular blockers are of two types: competitive (non-depolaring) and depolarising.

The competitive or non-depolaring blockers (atracurium and others listed in ‘Table 5.2’, (p.91)) compete with acetylchyle for the receptors

Neuromuscular blockers + Neuromuscular blockers

Combination of competitive neuromuscular blockers may have additive or synergistic effects. However, the sequence of administration may also affect the interaction. Prior administration of a small dose of a competitive neuromuscular blocker (e.g. **vecuronium**) generally reduces the effects of a depolarising blocker (e.g. **suxamethonium**), but if the depolarising blocker is given during recovery from a competitive neuromuscular blocker, antagonism, enhancement or a combination of the two may occur. The effects of a competitive blocker may be increased if it is given after a depolarising blocker.

on the endplate of the neuromuscular junction. Thus the receptors fail to be stimulated and muscular paralysis results. Competitive neuromuscular blockers may be divided by chemical structure into the aminosteroid group (e.g. succinylcholine) and the benzylisoquinolinium group (e.g. decamethonium), see also ‘Table 5.2’, (p.91).

The depolarizing blockers (suxamethonium, succinylcholine) and decamethonium also occupy the receptors on the endplate but they act like acetylcholine to cause depolarisation. However, unlike acetylcholine, they are not immediately removed by cholinesterase so that the depolarisation persists and the muscle remains paralysed.

However, contrary to the prediction, synergism has been reported with the structurally similar combinations of:
- atracurium and cisatracurium
- pancuronium and vecuronium
- tubocurarine and metocurine

Potentiation of neuromuscular blockade or synergism has been reported between the structurally different combinations of:
- cisatracurium and rocuronium
- vecuronium, metocurine and pancuronium
- mivacurium and pancuronium
- tubocurarine and pancuronium

In addition to affecting response, the initial blocker may modify the duration of action of the supplemental blocker.

The combination of a competitive and a depolarising neuromuscular blocker has an intrinsic antagonistic effect. This interaction has been used clinically to reduce muscle fasciculations caused by suxamethonium. A small dose of competitive neuromuscular blocker given shortly before the suxamethonium generally reduces effects and the duration of action of the suxamethonium.

The combination of a competitive neuromuscular blocker and a depolarising muscle relaxant of suxamethonium block has been seen in 5 patients given decamethonium during the recovery from vecuronium block. The neuromuscular blockade would be expected to antagonise the competitive neuromuscular blocker due to their opposite mechanisms of action (suxamethonium and decamethonium act on different receptors on the endplate). However, the depolarising blockers may also reverse a competitive block by enhancing the effect of acetylcholine postsynaptically.

In general, when a competitive blocker is given following suxamethonium, the onset time may be reduced and the potency or duration of the block may be increased, although not always significantly. In a study involving 350 patients, prior administration of suxamethonium 1 mg/kg significantly accelerated the onset of neuromuscular blockade with atracurium, pancuronium, pipecuronium and vecuronium, when these were given after full recovery from the suxamethonium block. However, the duration of blockade was only significantly prolonged with vecuronium. One study found potentiation of vecuronium when it was given up to 30 minutes after full recovery from a single intravenous dose of suxamethonium 1 mg/kg. Another study found the effects of vecuronium or pancuronium were potentiated for at least 2 hours after full recovery from an intubating dose of suxamethonium. Another study showed that the effect of prior administration of suxamethonium on atracurium neuromuscular block appears to depend on the level of recovery from suxamethonium. As with previous studies, the onset of atracurium blockade was shortened when given after full recovery from the suxamethonium. However, this effect was less apparent when the atracurium was given after full suxamethonium recovery. Pretreatment with suxamethonium reduced the time to onset of cisatracurium block, but did not potentiate it or prolong recovery. Pretreatment with suxamethonium decreased the onset time and increased the duration of action or rocuronium although a study in animals suggested rocuronium is not affected by suxamethonium.

Prior administration of decamethonium 100 micrograms/kg caused a sevenfold increase in sensitivity to vecuronium (reducing the ED$_{50}$ from 24 to 3.5 micrograms/kg).

It has been suggested that depolarising neuromuscular blockers such as decamethonium and suxamethonium may have a presynaptic action resulting in reduced acetylcholine output. Although not always clinically significant, be aware that a reduction in the dose of competitive blocker may be necessary following the use of a depolarising neuromuscular blocker.

(a) Competitive neuromuscular blockers + Competitive neuromuscular blockers

Combinations of competitive (non-depolarising) neuromuscular blockers may have additive or synergistic effects. Structural differences between the interacting neuromuscular blockers may have an effect; it has been suggested that structurally similar neuromuscular blockers tend to produce an additive effect whereas structurally different blockers may be synergistic.

For example, additive effects have been found between the structurally similar combinations of:
- atracurium and cisatracurium
- pancuronium and vecuronium
- tubocurarine and metocurine

(b) Competitive then depolarising neuromuscular blockers

The combination of a competitive and a depolarising neuromuscular blocker has an intrinsic antagonistic effect. This interaction has been used clinically to reduce muscle fasciculations caused by suxamethonium. A small dose of competitive neuromuscular blocker given shortly before the suxamethonium generally reduces effects and the duration of action of the suxamethonium. However, following pancuronium pretreatment, the duration of suxamethonium blockade appears to be prolonged, and this is probably due to the inhibition of cholinesterase by pancuronium.

Antagonism of decamethonium has also been seen when it was given after a small dose of vecuronium.
Bradycardia in the presence of vecuronium has been seen during anesthetic induction with other drugs including fentanyl,1,4 and sufentanil (in 3 patients taking beta blockers with or without diltiazem).3 The lack of vagolytic effects associated with vecuronium may mean that opioid-induced bradycardy is unopposed.3,5 The beta blockers and diltiazem may also have played a part in the bradycardia seen in some of these patients3 (see also ‘Neuromuscular blockers + Beta blockers’, p.119). Be alert for this effect if vecuronium is given with any of these drugs. Atropine 500 micrograms given intravenously at the time of induction may prevent the bradycardia.4

For reports of bradycardia occurring with atracurium or suxamethonium used with propofol and fentanyl, see ‘Anaesthetics, general + Neuromuscular blockers’, p.101.

5. Starr NJ, Sethna DH, Estafanos FG. Bradycardia and asystole following the rapid administration of suxamethonium with fentanyl. Anesthesiology (1986) 64, 521–3.

**Neuromuscular blockers + Ondanvron**

Ondansetron does not affect atracurium-induced neuromuscular blockade.

**Clinical evidence, mechanism, importance and management**

A double-blind placebo-controlled study of 30 patients undergoing elective surgery found that intravenous ondansetron 8 or 16 mg given over 5 minutes had no effect on subsequent neuromuscular blockade with atracurium.1 No special precautions would therefore seem necessary. The authors suggest that no interaction is likely with other non-depolarising neuromuscular blockers, but this needs confirmation.

**Neuromuscular blockers + Opioids**

A woman experienced hypertension and tachycardia when she was given pancuronium after induction of anaesthesia with morphine and nitrous oxide/oxygen. Bradycardia has been reported with vecuronium and alfentanil, fentanyl, or sufentanil, sometimes in patients receiving beta blockers and/or calcium channel blockers.

**Clinical evidence, mechanism, importance and management**

(a) Pancuronium

A woman about to receive a coronary by-pass graft was premedicated with morphine 10 mg and hyoscine 400 micrograms, intramuscularly, one hour before the induction of anaesthesia. Morphine 1 mg/kg was then slowly infused while the patient was ventilated with 50% nitrous oxide/oxygen. With the onset of neuromuscular relaxation with pancuronium 150 micrograms/kg, her blood pressure rose sharply from 120/60 to 200/110 mmHg and her pulse rate increased from 54 to 96 bpm, persisting for several minutes but stabilising when 1% halothane was added.1 The suggested reason is that pancuronium can antagonise the vagal tone (heart slowing) induced by the morphine, thus allowing the blood pressure and heart rate to rise. The authors of the report point out the undesirability of this in those with coronary heart disease.

(b) Vecuronium

Two patients, one aged 72 and the other aged 84, undergoing elective cardiac endarterectomy developed extreme bradycardia following induction with alfentanil and vecuronium; both were premedicated with morphine. The first was taking propranolol 20 mg 8-hourly and as the drugs were injected his heart rate fell from 50 to 35 bpm, and his blood pressure fell from 160/70 to 75/35 mmHg. He responded to atropine, ephedrine and phenylephrine. The other patient was taking nifedipine and quinidine. His heart rate fell from 50 to 35 bpm, and his blood pressure fell from 160/70 to 75/35 mmHg. He responded to atropine, ephedrine and phenylephrine. The other patient was taking nifedipine and quinidine. His heart rate fell from 50 to 35 bpm, and his blood pressure dropped from 150/80 to 120/45 mmHg. Both heart rate and blood pressures recovered following skin incision.6

Exposure to organophosphorus insecticides such as malathion and dimpylate (diazinon) can markedly prolong the neuromuscular blocking effects of suxamethonium (succinylcholine).

**Clinical evidence**

A man admitted to hospital for an appendectomy became apnoeic during the early part of the operation when given suxamethonium (succinylcholine) 100 mg to facilitate tracheal intubation, and remained so throughout the 40 minutes of surgery. Restoration of neuromuscular activity occurred about 180 minutes after he had received the suxamethonium. Later studies showed that he had an extremely low plasma cholinesterase activity (3% to 10%), even though he had a normal phenotype. It subsequently turned out that he had been working with malathion for 11 weeks without any protection.1

Another report describes a man whose recovery from neuromuscular blockade with suxamethonium was very prolonged. He had attempted suicide approximately 2 weeks earlier with dimpylate (diazinon), a household insecticide. His pseudocholinesterase was found to be 0.7 units/L (normal values 7 to 19) and his dibucaine number (a measurement of cholinesterase activity) was too low to be measured.3 Other cases of prolonged suxamethonium-induced paralysis associated with organophosphate poisoning have been reported.1,5 These cases have involved accidental ingestion of chlorpyrifos or dichlorvos in children, and one case resulted from subclinical exposure to chlorpyrifos and propetamphos following the treatment of carpets for pests.4 Also, prolonged suxamethonium-induced paralysis has occurred following suicide attempts in adults with chlorpyrifos or Dimazon (dimpylate).4 In one report ECT was performed 2 weeks after attempted suicide with chlorpyrifos and, despite low plasma cholinesterase levels, paralysis with suxamethonium was carried out successfully using one fifth of the normal dose.5

**Mechanism**

Malathion, dimpylate, and other organophosphorus insecticides inhibit the activity of plasma cholinesterase, thereby reducing the metabolism of the suxamethonium and prolonging its effects.

**Importance and management**

An established and well understood interaction. The organophosphorus pesticides are potent anticholinesterases used in agriculture and horticulture to control insects on crops, and in veterinary practice to control various ectoparasites. They are applied as sprays and dips. Anyone who is exposed to these toxic pesticides may therefore show changes in their response to neuromuscular blockers. Widely used organophosphorus pesticides include azamethiphos, bromophos, chlorpyrifos, clofenotins, and others.
Neuromuscular blockers + Quinidine

The effects of both depolarising neuromuscular blockers (e.g. suxamethonium (succinylcholine)) and competitive neuromuscular blockers (e.g. tubocurarine) can be increased by quinidine. Recurarisation and apnoea have been seen in patients when quinidine was given during the recovery period from neuromuscular blockade.

Clinical evidence

A patient given metocurine during surgery regained her motor functions and was able to talk coherently during the recovery period. However, within 15 minutes of additionally being given quinidine sulfate 200 mg by injection she developed muscular weakness and respiratory depression. She needed intubation and assisted respiration for a period of two and a half hours. Edrophonium and neostigmine were used to aid recovery.1

This interaction has also been described in case reports involving tubocurarine2 and suxamethonium (succinylcholine),3,4 and has been confirmed in animal studies.5-7

Mechanism

Not fully understood, but it has been shown that quinidine can inhibit the enzyme (choline acetyltransferase), which is concerned with the synthesis of acetylcholine at nerve endings.8 Neuromuscular transmission would be expected to be reduced if the synthesis of acetylcholine is reduced. Quinidine also inhibits the activity of plasma cholinesterase, which is concerned with the metabolism of suxamethonium.4

Importance and management

The interaction between quinidine and neuromuscular blockers is an established interaction of clinical importance, but the documentation is limited. The incidence is uncertain, but it was seen in one report cited above. A greater or lesser extent in 5 of the 6 patients studied.3 It has only been reported clinically with metocurine, tubocurarine and suxamethonium, but it occurs in animals with gallamine, and it seems possible that it could occur clinically with any depolarising or non-depolarising neuromuscular blocker. Be alert for increased neuromuscular blocking effects during and after surgery.

Neuromuscular blockers + Testosterone

An isolated report describes marked resistance to the effects of suxamethonium (succinylcholine) and vecuronium, apparently due to the long-term use of testosterone. Another case reports resistance to vecuronium in a patient with elevated plasma testosterone levels.

Clinical evidence, mechanism, importance and management

A woman transsexual who had been receiving testosterone enantate 200 mg intramuscularly twice monthly for 10 years was resistant to 100 mg of intravenous suxamethonium (succinylcholine), and needed 100 micrograms/kg of intravenous vecuronium for effective tracheal intubation before surgery. During the surgery it was found necessary to use a total of 22 mg of vecuronium over a 50-minute period to achieve acceptable relaxation of the abdominal muscles for a hysterectomy and salpingo-oophorectomy to be carried out.1 Considerably higher than usual doses of vecuronium were required in a patient with testicular feminisation and elevated plasma testosterone levels.2

The reasons are not understood. However, it has been suggested that the close structural similarity between testosterone and vecuronium, with respect to their common steroidal core, might mean that they share similar metabolic pathways. Chronic elevation of circulating testosterone may up-regulate the hepatic metabolism of steroidal molecules in general, and so enhance the hepatic elimination of vecuronium.2

Neuromuscular blockers + Tobacco

There is some evidence that smokers may need more vecuronium and possibly more rocuronium, but less atracurium to achieve the same effects as non-smokers. However, results are variable and another study found that rocuronium appeared to be unaffected by smoking.

Clinical evidence, mechanism, importance and management

Variable results have been reported on the effect of smoking on neuromuscular blockers. The amount of atracurium required was about 25% lower in smokers, when compared with non-smokers.1 However, in another study, smokers required more vecuronium than non-smokers did (96.8 compared with 72.11 micrograms/kg per hour, respectively; a 34% increase).2 Similarly another study involving patients undergoing minor surgery found that the 20 smokers required about 20% more rocuronium than the 20 non-smokers.3 However, this study has been criticised for having too few patients, which meant that it was unable to properly detect a statistically significant difference between the smokers and non-smokers.4

In yet another study, the onset and recovery times from the neuromuscular blocking effects of rocuronium 600 micrograms/kg were reported to be not significantly affected by smoking more than 10 cigarettes daily.5

Tobacco smoke contains many different compounds and has enzyme-inducing properties, which may affect the dose requirements of neuromuscular blockers. In addition, the time interval in refraining from smoking will affect plasma nicotine concentrations; small doses of nicotine may stimulate the neuromuscular junction, but larger doses may block transmission.6 More studies are needed.

**Neuromuscular blockers + Trimetaphan**

Trimetaphan can increase the effects of suxamethonium (succinylcholine), which may result in prolonged apnoea. This may possibly occur with other neuromuscular blocking drugs, such as alcuronium.

**Clinical evidence**

A man undergoing neurosurgery was given tubocurarine and suxamethonium (succinylcholine). Neuromuscular blockade was prolonged postoperatively, lasting about 2.5 hours, and was attributed to the concurrent use of trimetaphan 4.5 g, given over a 90-minute period. Later when he underwent further surgery using essentially the same anaesthetic techniques and drugs, but with a very much smaller dose of trimetaphan (35 mg over a 10-minute period), the recovery was normal.1

Nine out of 10 patients receiving ECT treatment and given suxamethonium showed an almost 90% prolongation in apnoea (from 142 to 265 seconds) when trimetaphan 10 to 20 mg was used instead of 1.2 mg of atropine.2 Prolonged apnoea has been seen in another patient given suxamethonium and trimetaphan.3 On the basis of an in vitro study it was calculated that a typical dose of trimetaphan would double the duration of paralysis due to suxamethonium.4 Prolonged neuromuscular blockade was also seen in a man given alcuronium and trimetaphan.5

**Mechanism**

Not fully understood. Trimetaphan can inhibit plasma cholinesterase to some extent,2,5 which would reduce the metabolism of the suxamethonium and thereby prolong its activity. Studies in rats6,7 and case reports8 also indicate that trimetaphan has direct neuromuscular blocking activity. Its effects are at least additive with the neuromuscular blocking effects of the aminoglycosides.7

**Importance and management**

Information is limited but the interaction appears to be established. If trimetaphan and suxamethonium are used concurrently, be alert for enhanced and prolonged neuromuscular blockade. This has also been seen with alcuronium, and trimetaphan may interact with other competitive neuromuscular blockers.5 Respiratory arrest has been seen when large doses of trimetaphan were given in the absence of a neuromuscular blocker, so that caution is certainly needed.8 Animal studies suggested that the blockade might not be reversed by neostigmine or calcium chloride,7 but neostigmine and calcium gluconate were successfully used to reverse the effects of alcuronium and trimetaphan in one case.5

**Neuromuscular blockers + Ulinastatin**

Ulinastatin delays the onset and hastens the recovery from vecuronium neuromuscular block.

**Clinical evidence, mechanism, importance and management**

A randomised, placebo-controlled study involving 60 patients found that a 5000 unit/kg intravenous bolus dose of ulinastatin given before induction of anaesthesia, and again 2 minutes before intravenous vecuronium 100 micrograms/kg, delayed the onset of neuromuscular blockade compared with placebo (250 compared with 214 seconds). The recovery from neuromuscular block (measured as return of post-tetanic count) was significantly shorter after ulinastatin than placebo (11 compared with 17.7 minutes). The effects of ulinastatin were thought to be due to an increase in the release of acetylcholine at the neuromuscular junction and enhanced vecuronium elimination due to increases in liver blood flow and urine volume.1

The drugs dealt with in this section include aspirin and other salicylates, NSAIDs, opioid analgesics, and the miscellaneous analgesics, such as nefopam and paracetamol. ‘Table 6.1’, (p.134) contains a listing, with a further classification of the NSAIDs.

**Interactions**

(a) **Aspirin and NSAIDs**

Aspirin and the NSAIDs generally undergo few clinically significant pharmacokinetic interactions. The majority are highly protein bound, and have the potential to interact with other drugs via this mechanism. However, with a few exceptions, most of these interactions are not clinically important (see ‘Protein-binding interactions’, (p.3)).

Of the newer NSAIDs, celecoxib is metabolised by the cytochrome P450 isoenzyme CYP2C9, and inhibits CYP2D6. Rofecoxib, now withdrawn, inhibits CYP1A2, see ‘Tizanidine + CYP1A2 inhibitors’, p.1286. Nevertheless, most of the important interactions with NSAIDs and aspirin are pharmacodynamic. Aspirin and all non-selective NSAIDs inhibit platelet aggregation, and so can increase the risk of bleeding and interact with other drugs that have this effect. NSAIDs that are highly selective for cyclooxygenase-2 (COX-2) do not inhibit platelet aggregation.

Aspirin and all NSAIDs (including COX-2 selective NSAIDs) inhibit the synthesis of renal prostaglandins, and so can cause salt and water retention. This can increase blood pressure and affect antihypertensive therapy. Aspirin and non-selective NSAIDs inhibit the mechanisms that protect the gastrointestinal mucosa and so cause gastrointestinal toxicity. COX-2 selective NSAIDs (coxibs) are less likely to have this effect.

(b) **Opioids**

Morphine is metabolised by glucuronidation by UDP-glucuronyltransferases, mainly to one active and one inactive metabolite. The glucuronidation of morphine can be induced or inhibited by various drugs. Morphine is not significantly affected by the cytochrome P450 isoenzymes. The semi-synthetic morphine analogues, hydromorphone and oxymorphone, are metabolised similarly.

Codeine, dihydrocodeine, and hydrocodone are thought to be pro-drugs, and require metabolic activation, possibly by CYP2D6 or UGT enzymes. Inhibitors of these enzymes may therefore reduce their efficacy. Oxycodone is also metabolised by CYP2D6 and CYP3A4.

Pethidine is metabolised via several cytochrome P450 isoenzymes. If the metabolism of pethidine is increased it can lead to increased production of the toxic metabolite, norpethidine, and increased CNS adverse effects. Methadone is principally metabolised by CYP3A4 and CYP2D6, although CYP2C8 may also play a role. Buprenorphine is metabolised by CYP3A4.

Alfentanil is extensively metabolised by CYP3A4, and has been used as a probe drug for assessing CYP3A4 activity. Fentanyl and sufentanil are also metabolised, but because they are high hepatic-extraction drugs (see ‘Changes in first-pass metabolism’, (p.4)) they are less affected by inhibitors or inducers of CYP3A4, although in some instances this may still lead to clinically significant effects.

(c) **Paracetamol**

Paracetamol is not absorbed from the stomach, and the rate of absorption is well correlated with the gastric emptying rate. Paracetamol has therefore been used as a marker drug in studies of gastric emptying. Paracetamol is primarily metabolised by the liver to a variety of metabolites, principally the glucuronide and sulfate conjugates. Hepatotoxicity of paracetamol is thought to be due to a minor metabolite, N-acetyl-p-benzoquinone imine (NAPQI), which is inactivated with glutathione and excreted as mercapturate and cysteine conjugates. When the liver stores of glutathione are depleted, and the rate of production of NAPQI exceeds the rate of production of glutathione, excess NAPQI attaches to liver proteins and causes liver damage. CYP2E1 may be involved in the formation of this hepatotoxic metabolite.

Aspirin or other Salicylates + Antacids

The serum salicylate levels of patients taking large, anti-inflammatory doses of aspirin or other salicylates can be reduced to subtherapeutic levels by some antacids. The maximum plasma levels of aspirin may be increased by antacids, although the extent of absorption is unaltered.

Clinical evidence

A child with rheumatic fever taking aspirin 600 mg five times daily had a serum salicylate level of between 82 and 118 mg/L while taking 30 mL of Maalox (aluminium/magnesium hydroxide suspension). When the Maalox was withdrawn, the urinary pH fell from a range of 7 to 8 down to a range of 5 to 6.4, whereupon the serum salicylate level rose three- to fourfold to about 380 mg/L, which required a dosage reduction.1 An associated study in 13 healthy subjects taking aspirin 4 g daily for a week found that sodium bicarbonate 4 g daily reduced serum salicylate levels by 44%, from 270 to 150 mg/L. This reflected a rise in the urinary pH from a range of 5.6 to 6.1 up to around 6.2 to 6.9.1,2 Similar changes have been reported in other studies with aspirin or choline salicylate and aluminium/magnesium hydroxide: and aspirin or sodium salicylate and sodium bicarbonate.3,4,5 There is some evidence to suggest that this effect does not occur at low serum salicylate levels,4,5 or if the pH of the urine is unchanged by the antacid.6

A study in 10 healthy subjects found that the mean maximum plasma level of a single 650-mg dose of aspirin was about 70% higher when it was given 10 minutes after an antacid (aluminium/magnesium hydroxide), when compared with aspirin alone. However, there was no change in the time to reach the peak level or the AUC. There were also no significant changes in the pharmacokinetics of the metabolites, salicylic acid and salicyluric acid.3

Mechanism

Aspirin and other salicylates are acidic compounds that are excreted by the kidney tubules and are ionised in solution. In alkaline solution, much of the drug exists in the ionised form, which is not readily reabsorbed, and therefore is lost in the urine. If the urine is made more acidic (e.g. with ammonium chloride), much more of the drug exists in the un-ionised form, which is readily reabsorbed, so that less is lost in the urine and the drug is retained in the body.6,7

In vitro data show that magnesium oxide and aluminium hydroxide strongly adsorb aspirin and sodium salicylate.5 However, in three of the studies above sodium salicylate levels if any antacid is started or stopped in patients where the control of salicylate levels is critical.

No important adverse interaction would be expected in those taking occasional doses of aspirin for analgesia. Some aspirin formulations actually include antacids as buffering agents to increase absorption rates and raise peak serum levels,8 which gives more rapid analgesia, and/or in an attempt to decrease gastric irritation. Note that antacids may also increase the extent of absorption of aspirin given as enteric-coated tablets.9

Importance and management

A well established and clinically important interaction for those receiving long-term treatment with large doses of salicylates because the serum salicylate level may become subtherapeutic. This interaction can occur with both ‘systemic’ antacids (e.g. sodium bicarbonate) as well as some ‘non-systemic’ antacids (e.g. aluminium/magnesium hydroxide), but only appears to occur if there is an increase in the urinary pH. Care should be taken to monitor serum salicylate levels if any antacid is started or stopped in patients where the control of salicylate levels is critical.

Aspirin or other Salicylates + Bile-acid binding resins

Colestyramine and colestipol do not appear to have any clinically important effects on the absorption of aspirin.

Clinical evidence, mechanism, importance and management

(a) Colestipol

In 12 healthy subjects the extent of absorption of a single 650-mg dose of aspirin was unaffected by colestipol 10 g. However, the rate of aspirin absorption was increased by colestipol: at 60 minutes after the dose the plasma level was increased by about 40%.1 No particular precautions seem to be necessary during concurrent use.

(b) Colestyramine

A study in 3 healthy subjects and 3 patients, and a later study in 7 healthy subjects, found that colestyramine 4 g delayed the absorption of a single 500-mg dose of aspirin (time to peak levels extended from 30 to 60 minutes) but the total amount absorbed was only reduced by 5 to 6%. Some of the subjects had slightly higher serum aspirin levels while taking colestyramine.2 Similar results were reported in another study (a 31% lower plasma aspirin level at 60 minutes, but no difference in total absorption).3 There would seem to be little reason for avoiding concurrent use unless rapid analgesia is needed.

Aspirin or other Salicylates + Carbonic anhydrase inhibitors

A severe and even life-threatening toxic reaction can occur in patients taking high-dose salicylates if they are given carbonic anhydrase inhibitors (acetazolamide, dicyfenamide).

Clinical evidence

An 8-year-old boy with chronic juvenile arthritis, taking prednisolone, indometacin and alopixiprin, was admitted to hospital with drowsiness, vomiting and hyperventilation (diagnosed as metabolic acidosis) within a month of the alopixiprin dosage being increased from 3 to 3.6 g daily and starting to take dicyfenamide 25 mg three times daily for glaucoma.1 Other cases of toxicity (metabolic acidosis) have included a 22-year-old woman taking salsalate with acetazolamide 250 mg four times daily,1 and 2 elderly women taking large doses of aspirin with acetazolamide or dicyfenamide.2 A 50-year-old woman taking acetazolamide for glaucoma was admitted to hospital with confusion and cerebellar ataxia, associated with hyperchloremic acidosis, 14 days after starting to take aspirin for acute pericarditis.3 A man taking dicyfenamide developed salicylate poisoning within 10 days of starting to take aspirin 3.9 g daily.4 Coma developed in an 85-year-old woman taking aspirin 3.9 g daily when her dosage of acetazolamide was increased from 500 mg to 1 g daily.5,6 and toxicity was seen in a very elderly man given both drugs: levels of unbound acetazolamide were found to be unusually high.6 An elderly man became confused, lethargic, incontinent and anorexic while taking acetazolamide and salsalate. He needed intravenous hydration.7

Mechanism
Not fully established. One idea is that these carbonic anhydrase inhibitors (acetazolamide, diclofenamide) affect the plasma pH, so that more of the salicylate is present in the un-ionized (lipid-soluble) form, which can enter the CNS and other tissues more easily, leading to salicylate toxicity.2 However, carbonic anhydrase inhibitors also make the urine more alkaline, which increases the loss of salicylate3 (see also ‘Aspirin or other Salicylates + Antacids’, p.135). Animal studies confirm that carbonic anhydrase inhibitors increase the lethality of aspirin.4 An alternative suggestion is that because salicylate inhibits the plasma protein binding of acetazolamide and its excretion by the kidney, acetazolamide toxicity, which mimics salicylate toxicity, may occur.5

Importance and management
Although there are a few clinical reports on this interaction, the interaction between carbonic anhydrase inhibitors and salicylates is established, well confirmed by animal studies, and potentially serious. One study recommended that carbonic anhydrase inhibitors should probably be avoided in those receiving high-dose salicylate treatment.6 If they are used, the patient should be well monitored for any evidence of toxicity (confusion, lethargy, hyperventilation, tinnitus) because the interaction may develop slowly and insidiously.2 In this context NSAIDs may be a safer alternative. Naproxen proved to be a satisfactory substitute in one case.2 The authors of one study suggest that methazolamide may possibly be a safer alternative to acetazolamide because it is minimally bound to plasma proteins. They also suggest paracetamol (acetaminophen) as an alternative to salicylate in patients taking acetazolamide.3 The reports cited here concern carbonic anhydrase inhibitors given orally, not as eye drops. It is not known whether the latter interact similarly, but there appear to be no reports.

Aspirin or other Salicylates + Corticosteroids or Corticotropin

Serum salicylate levels are reduced by corticosteroids and therefore salicylate levels may rise, possibly to toxic concentrations, if the corticosteroid is withdrawn without first reducing the salicylate dosage. Concurrent use increases the risk of gastrointestinal bleeding and ulceration.

Clinical evidence
A 5-year-old boy taking long-term prednisolone in doses of at least 20 mg daily, was given choline salicylate 3.6 g daily, and the prednisolone was gradually tapered off to 3 mg daily over a 3-month period. Severe salicylate toxicity developed, and in a retrospective investigation of the cause, using frozen serum samples drawn for other purposes, it was found that the serum salicylate levels had risen from less than 100 mg/L up to 880 mg/L during the withdrawal of the prednisolone.1 Later studies in 3 other patients taking choline salicylate or aspirin and either prednisolone or another un-named corticosteroid, found about a threefold rise in salicylate levels during corticosteroid withdrawal.1 Hydrocortisone was also found to increase the clearance of sodium salicylate in 4 other patients.1

1. When prednisolone was withdrawn.2 Other studies in both adults and children show that prednisone, methylprednisolone, betamethasone and corticotropin reduce serum salicylate levels.3–5 Two studies also found that intra-articular dexamethasone, methylprednisolone, and triamcinolone transiently reduced serum salicylate levels in patients given enteric-coated aspirin.5 However one study in patients found that prednisolone 12 to 60 mg daily had no effect on the clearance of single doses of sodium salicylate.8

Mechanism
Uncertain. One idea is that the presence of the corticosteroid increases the glomerular filtration rate, which increases salicylate clearance. When the corticosteroid is withdrawn, the clearance returns to normal and the salicylate accumulates. Another suggestion is that the corticosteroids increase the metabolism of the salicylate.3

Importance and management
Well established interactions. Patients should be monitored to ensure that salicylate levels remain adequate when corticosteroids are added and do not become excessive if they are withdrawn. It should also be remembered that concurrent use may increase the incidence of gastrointestinal bleeding and ulceration. See also ‘Corticosteroids + NSAIDs’, p.1058.

Aspirin + Dapsone

Dapsone does not significantly affect the pharmacokinetics of aspirin.

Clinical evidence, mechanism, importance and management
A comparison of the pharmacokinetics of aspirin in 8 healthy subjects and 8 patients with uncomplicated lepromatous leprosy found that the pharmacokinetics of a single 600-mg dose of aspirin was not affected by either leprosy, or by treatment with dapsone 100 mg daily for 8 days.1 No special precautions would seem likely to be needed on concurrent use.

Aspirin + Food

Food delays the absorption of aspirin.

Clinical evidence, mechanism, importance and management
A study in 25 subjects given aspirin 650 mg in five different preparations showed that food roughly halved their serum salicylate levels (measured 10 and 20 minutes later), compared with those seen when the same dose of aspirin was taken while fasting.1 Similar results were found in subjects given calcium aspirin 1.5 g.2 In another study in 8 healthy subjects who were given effervescent aspirin 900 mg, serum salicylate levels at 15 minutes were roughly halved by food, but were more or less unchanged after one hour.3

A further study in 16 healthy subjects showed that the extent of absorption of a single 900-mg dose of soluble aspirin was not significantly affected by a high-fat meal. The rate of absorption was reduced by food and the maximum plasma level was reduced by 18%, which was not considered to be clinically significant. Furthermore, there was no statistically significant
change in the time to maximum plasma levels (20 minutes fasted; 30 minutes fed).  

A possible reason for the reduced rate of absorption is that food delays gastric emptying. Thus if rapid analgesia is needed, aspirin should be taken without food, but if aspirin is needed long-term, giving it with food is thought to help to protect the gastric mucosa.

Aspirin + Griseofulvin

An isolated report describes a marked fall in serum salicylate levels in a child given aspirin and griseofulvin.

Clinical evidence, mechanism, importance and management

An 8-year-old boy with rheumatic fever taking aspirin 110 mg/kg daily and furosemide, digoxin, captopril, potassium, aluminium/magnesium hydroxide and iron, had a very marked fall in his serum salicylate levels (from a range of 18.3 to 30.6 mg/dL to less than 0.2 mg/dL) within 2 days of starting griseofulvin 10 mg/kg daily. Two days after the griseofulvin was stopped, the salicylate levels were back to their former levels. The reasons for this effect are not known, but it was suggested that the salicylate absorption was impaired in some way.  

Aspirin + Kaolin-pectin

Kaolin-pectin causes a small reduction in the absorption of aspirin, which is not clinically relevant.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects the absorption of aspirin 975 mg was reduced by 5 to 10% by 30 or 60 mL of kaolin-pectin. A likely explanation is that the aspirin becomes adsorbed by the kaolin so that the amount available for absorption through the gut wall is reduced. However, this small reduction in absorption is unlikely to be of clinical importance.

Aspirin + Laxatives

Sodium sulfate and castor oil used as laxatives can cause a modest, but probably clinically unimportant, reduction in aspirin absorption.

Clinical evidence, mechanism, importance and management

In an experimental study of the possible effects of laxatives on drug absorption, healthy subjects were given 10 to 20 g of oral sodium sulfate and 20 g of castor oil (doses sufficient to provoke diarrhoea). Absorption, measured by the amount of drug excreted in the urine, was decreased at 4 hours. The reduction was 21% for castor oil and aspirin, and 27% for sodium sulfate and aspirin. However, serum levels of aspirin were relatively unchanged. The overall picture was that while these laxatives can alter the pattern of absorption, they do not seriously impair the total amount of drug absorbed.

Aspirin + Levamisole

The salicylate levels of a patient taking aspirin rose when levamisole was given, but this effect was not confirmed in a subsequent controlled study.

Clinical evidence, mechanism, importance and management

A preliminary report of a patient who had an increase in salicylate levels when levamisole was given with aspirin prompted a study in 9 healthy subjects of this possible interaction. Sustained-release aspirin 3.9 g daily in two divided doses was given over a period of 3 weeks, with levamisole 50 mg three times a day for a week, each subject acting as his own control. No significant changes in plasma salicylate levels were found.

Aspirin + Pentazocine

A man regularly taking large doses of aspirin developed renal papillary necrosis when he was given pentazocine.

Clinical evidence, mechanism, importance and management

An isolated report describes a man, regularly taking aspirin 1.8 to 2.4 g daily, who developed renal papillary necrosis within 6 months of also starting to take pentazocine 800 to 850 mg daily. He developed abdominal pain, nausea and vomiting, and passed tissue via his urethra. Before starting the pentazocine and after it was stopped, no necrosis was apparent. The postulated reason for this reaction is that a pentazocine-induced reduction in blood flow through the kidney potentiated the adverse effects of chronic aspirin use.

1. The general importance of this case is uncertain, but it emphasises the risks of long-term use (possibly abuse) of aspirin with pentazocine.

Aspirin + Phenylbutazone

Phenylbutazone reduces the uricosuric effects of high-dose aspirin. Concurrent use is likely to be associated with an increased risk of gastrointestinal damage.

Clinical evidence

The observation that several patients given aspirin and phenylbutazone developed elevated serum urate levels, prompted a study in 4 patients without gout. This found that aspirin 2 g daily had little effect on the excretion of uric acid in the urine, but marked uricosuria occurred with aspirin 5 g daily. When phenylbutazone 200, 400 and then 600 mg daily (over 3 days) was also given the uricosuria was abolished. Serum uric acid levels rose from an average of about 40 mg/L to 60 mg/L. The interaction was confirmed in a patient with tophaceous gout. The retention of uric acid also occurs if the phenylbutazone is given first.

Mechanism

Not understood. Phenylbutazone is structurally related to sulfinpyrazone, which interacts similarly, see ‘Aspirin or other Salicylates + Sulfinpyrazone’, p.138.

Importance and management

An established but sparsely documented interaction. The potential problems arising from this interaction should be recognised in any patient given aspirin and phenylbutazone. The concurrent use of aspirin and NSAIDs increases the risk of gastrointestinal damage and is not recommended. Al-
though there does not appear to be any specific evidence for phenylbuta-
zone, it would be expected to interact in the same way as other NSAIDs, see ‘NSAIDs + Aspirin; Anti-inflammatory dose’, p.142.

1. Oyer JH, Wagner SL, Schmid FR. Suppression of salicylate-induced uricosuria by phenylbuta-

## Aspirin or other Salicylates + Probencid

The uricosuric effects of high doses of aspirin or other salicylates and probenecid are not additive as might be expected but are mutu-
ally antagonistic. Low dose, enteric-coated aspirin appears not to inter-
act with probenecid.

### Clinical evidence

A study found that the average urinary uric acid excretion in 24 hours was 673 mg with a single 3-g daily dose of probenecid, 909 mg with a 6-g dail-
ly dose of sodium salicylate, but only 114 mg when both drugs were giv-
en. 1 Similar antagonism has been seen in other studies in patients given aspirin 2.6 to 5.2 g daily. 2,3 No antagonism is seen until serum salicylate levels of 50 to 100 mg/L are reached. 4 Therefore no interaction would be expected with low, antiplatelet dose aspirin. This was confirmed by a crossover study in 11 patients with gouty arthritis, regularly taking probenecid, which found that enteric-coated aspirin 32.5 mg daily, taken either with probenecid or 6 hours after probenecid, had no effect on serum urate levels or on the 24-hour urate excretion. 5

### Mechanism

Not understood. The interaction probably occurs at the site of renal tubular sec-
tretion, but it also seems that both drugs can occupy the same site on plasma albumins.

## Aspirin or other Salicylates + Sulfinpyrazone

The uricosuric effects of the salicylates and sulfinpyrazone are not additive, as might be expected, but are mutually antagonistic.

### Clinical evidence

When sodium salicylate 6 g was given with sulfinpyrazone 600 mg daily to one patient the average urinary uric acid excretion in 24 hours was 30 mg, whereas when each drug was used alone in the same doses the av-

genous 24-hour urinary excretion was 281 mg for sodium salicylate and 527 mg for sulfinpyrazone. 1 A later study in 5 men with gout given a sulfinpyrazone infusion for about an hour (300 mg bolus followed by 10 mg/minute) found that the additional infusion of sodium salicylate (3 g bolus followed by 10 to 20 mg/minute) virtually abolished the urico-
suria. When the drugs were given in the reverse order to 3 other patients the same result was seen. 2

In another study, the uricosuria caused by sulfinpyrazone 400 mg daily was found to be completely abolished by aspirin 3.5 g. 3 The clearance of a single 400-mg dose of sulfinpyrazone was modestly increased by 12 to 27% in 5 healthy subjects given four doses of aspirin 325 mg over 24 hours. 4

### Mechanism

Not fully understood. Sulfinpyrazone competes successfully with sali-
cyate for secretion by the kidney tubules so that salicylate excretion is re-
duced, but the salicylate blocks the inhibitory effect of sulfinpyrazone on the tubular reabsorption of uric acid causing the uric acid to accumulate within the body. 2

## Importance and management

An established and clinically important interaction. Concurrent use for uricosuria should be avoided. Doses of aspirin as low as 700 mg can cause an appreciable fall in uric acid excretion, 3 but the effects of an occasional small dose are probably of little practical importance.

## Nefopam + Miscellaneous

The manufacturer states that nefopam should not be given to pa-
tients taking non-selective MAOIs and caution should be used in those taking tricyclic antidepressants, antimuscarinics and symp-
pathomimetics. The intensity and incidence of adverse effects are som-
ewhat increased when nefopam is given with codeine, penta-
zocine or dextropropoxyphene (propoxyphene), and the CNS de-
pressant effect of dihydrocodeine may have contributed to a fatal
overdose with nefopam. However, a morphine-sparing effect has been reported. Nefopam may also have a synergistic analgesic ef-
fet ketoprofen.

### Clinical evidence, mechanism, importance and management

Detailed information about adverse interactions between nefopam and other drugs does not seem to be available. 1 The manufacturer advises cau-
tion if nefopam is given with a tricyclic antidepressant because they low-
er the convulsive threshold; convulsions have been seen in some patients taking nefopam. In addition, the antimuscarinic adverse effects of ne-

can be additive with those of tricyclics and other drugs with an-
timuscarinic effects. 1 For example, the CSM in the UK has a number of re-
ports of urinary retention caused by nefopam, which would be expected to be worsened by drugs with antimuscarinic activity. Nefopam appears to have sympathomimetic activity and the manufacturer therefore says it should not be given with the MAOIs (see ‘MAOIs or RIMAs + Sym-
pathomimetics; Indirectly-acting’, p.1147).

A controlled study was conducted in 45 healthy subjects divided into nine groups of five, each given oral nefopam 60 mg three times daily for 3 days with either aspirin 650 mg, diazepam 5 mg, phenobarbital 60 mg, dextropropoxyphene (propoxyphene) 65 mg, codeine 60 mg, penta-
zocine 50 mg, indomethacin 25 mg or hydroxyzine 50 mg (all three times daily). The only changes were a possible additive increase in the in-
tensity and incidence of adverse effects with nefopam and codeine, pen-
tazocine or dextropropoxyphene. There was no evidence that the bioavailability of nefopam was change by the other drugs. 1

The incidence of sedation with nefopam is 20 to 30% which, depending on the circumstances, may present a problem if it is given with other sed-
ative drugs. 4 A report describes a fatal overdose with nefopam, which was complicated by the CNS depressant effect of dihydrocodeine. 5

In a study in animals, nefopam enhanced the analgesic potency of mor-
phine, 6 but in a study in patients the effects were found to be less than ad-

teptive. 7 However, another study in patients undergoing orthopaedic surgery found that the concurrent use of intravenous nefopam 20 mg every 4 hours with morphine given as patient-controlled analgesia (PCA) had a significant morphine-sparing effect, without major adverse effects. The amount of morphine used over 24 hours was 22% less for those receiving nefopam compared with placebo; the analgesic effect was particularly
notable for patients with intense preoperative pain who required 35% less morphine with nefopam. A study in 72 surgical patients found that the use of nefopam with ketoprofen had a synergistic analytic effect.  

8. Delage N, Maaliki H, Beloeil H, Benhamou D, Mazoit J-X. Median effective dose of naproxen and amoxicillin. A study in healthy subjects found that diclofenac increased the clearance of amoxicillin, nor an effect on its liver metabolism. These studies therefore suggest that a clinically significant interaction would not be expected.

**NSAIDs + Allopurinol**

Allopurinol does not affect indometacin clearance or phenylbutazone levels.

**Clinical evidence, mechanism, importance and management**

Allopurinol 300 mg each morning was given to 8 patients for 5 days with indometacin 50 mg every 8 hours. The allopurinol had no significant effect on the AUC of indometacin and the amounts of indometacin excreted in the urine were not significantly altered.

Allopurinol 100 mg three times daily for a month had no effect on the elimination of a 200-mg daily dose of phenylbutazone in 6 healthy subjects, and no effect on the steady-state plasma levels of phenylbutazone 200 or 300 mg daily in 3 patients. In another study in 8 patients with acute gouty arthritis it was found that allopurinol 100 mg every 8 hours produced small but clinically unimportant effects on the half-life of phenylbutazone 6 mg/kg.

There seems to be no reason for avoiding the concurrent use of these NSAIDs and allopurinol.

**NSAIDs + Amoxicillin**

A study in healthy subjects found that diclofenac increased the clearance of amoxicillin. An isolated report describes acute interstitial nephritis with nephrotic syndrome after taking naproxen for 4 days (total 4 g) and amoxicillin for 10 days (total 24 g). He appeared to recover when the drugs were stopped, but 3 months later he developed renal failure and needed haemodialysis. Acute interstitial nephritis is not only a rare syndrome (reported to be only 55 cases in the world literature in 1988) but this is the first case involving both of these drugs. No special precautions would normally seem to be necessary.

**NSAIDs + Anabolic steroids**

Serum oxyphenbutazone levels are raised about 40% by the use of methandienone (methandrostrolone). Phenylbutazone appears to be unaffected.

**Clinical evidence**

The serum levels of oxyphenbutazone 300 to 400 mg daily for 2 to 5 weeks were raised by 43% (range 5 to 10×) in 6 subjects given methandienone. Neither prednisone 5 mg nor dexamethasone 1.5 mg daily were found to affect oxyphenbutazone levels.

Two other studies confirm this interaction with oxyphenbutazone. One of them found no interaction with phenylbutazone.

**Mechanism**

Uncertain. One idea is that the anabolic steroids alter the distribution of oxyphenbutazone between the tissues and plasma so that more remains in circulation. There may also possibly be some changes in metabolism.

**Importance and management**

The interaction is established but its importance is uncertain. There seem to be no reports of toxicity arising from concurrent use but the possibility should be borne in mind.

**NSAIDs; Diclofenac + Antacids**

The absorption of diclofenac is not affected by aluminium hydroxide, magnesium hydroxide, or the combination.

**Clinical evidence, mechanism, importance and management**

About 10 mL of a 5.8% suspension of aluminium hydroxide had no effect on the bioavailability of a single 50-mg dose of diclofenac in 7 healthy subjects. In another study, 10 mL of magnesium hydroxide suspension (850 mg) was found to have no significant effect on the rate or extent of absorption of a single 50-mg dose of diclofenac in 6 healthy, fasted subjects. However, there was a tendency to an increased rate of absorption. Aluco Gel (aluminium/magnesium hydroxide) had no effect on the extent of absorption of enteric-coated diclofenac, but may have reduced the rate of absorption. No particular precautions would seem to be needed if these antacids are given with diclofenac.

**NSAIDs; Diflunisal + Antacids**

Antacids containing aluminium with or without magnesium can reduce the absorption of diflunisal by up to 40%, but no important interaction occurs if food is taken at the same time. Magnesium hydroxide can increase the rate of diflunisal absorption.

**Clinical evidence**

A study in 4 healthy, fasted subjects found that when a single 500-mg oral dose of diflunisal was given 2 hours before, together with, and 2 hours after three 15-mL doses of *Aludrox* (aluminium hydroxide), the diflunisal AUC was reduced by about 40%. Another study found that the AUC of a single 500-mg dose of diflunisal was reduced by 13% when given with a single 30-mL dose of *Maalox* (aluminium/magnesium hydroxide) by 21% when given 1 hour after the antacid, and by 32% when the antacid was given four times daily. However, in another study, aluminium/magnesium hydroxide had no effect on the AUC diflunisal when the diflunisal was given 30 minutes after food. This study also found that the AUC of diflunisal was reduced by 26% by 15 mL of aluminium hydroxide gel in fasted subjects, but not when the diflunisal was given after food. Magnesium hydroxide suspension markedly increased the rate of diflunisal absorption in fasted subjects. The plasma diflunisal level was increased by 130% at 30 minutes, and by 64% at one hour but the AUC was only increased by a modest 10%.

**Mechanism**

Just how aluminium antacids reduce the absorption of diflunisal is not clear, but adsorption or formation of insoluble salts has been suggested. Food appears to diminish the effect of antacids on diflunisal absorption. By raising the pH, magnesium hydroxide may promote the dissolution of diflunisal, so increasing its absorption. Consider also ‘NSAIDs; Fenamates + Antacids’, below.

**Importance and management**

Aluminium-containing antacids appear to reduce the absorption of diflunisal in the fasted state, but not if taken with food. Since NSAIDs should be taken with or after food, it appears that this interaction has little clinical relevance. See also ‘NSAIDs; Miscellaneous + Antacids’, p.142. Magnesium hydroxide increases the absorption of diflunisal in the fasted state, which may improve the onset of analgesia. However, note that magnesium hydroxide increased the endoscopically-detected gastric toxicity of ibuprofen in one study, see ‘NSAIDs; Ibuprofen and related drugs + Antacids’, below.

**NSAIDs; Fenamates + Antacids**

The absorption of mefenamic acid and tolfenamic acid is markedly accelerated by magnesium hydroxide in fasted subjects. The rate of tolfenamic acid absorption is reduced by aluminium hydroxide alone or combined with magnesium hydroxide/magnesium carbonate, but is not affected by sodium bicarbonate.

**Clinical evidence**

Studies in 6 healthy, fasted subjects given a single dose of mefenamic acid 500 mg or tolfenamic acid 400 mg found that magnesium hydroxide accelerated the absorption of both drugs (the mefenamic acid AUC after 1 hour was increased threefold and the tolfenamic acid AUC was increased sevenfold) but the total bioavailability was only slightly increased. In contrast, aluminium hydroxide, alone and in combination with magnesium hydroxide/magnesium carbonate (*Medisan Forte*), markedly reduced the rate of absorption of tolfenamic acid without causing a marked change in the total amount absorbed. Sodium bicarbonate 1 g did not significantly alter the absorption of tolfenamic acid.

**Mechanism**

Uncertain. It is suggested that magnesium hydroxide increases the solubility of acidic drugs such as the fenamates, possibly by forming a soluble salt and therefore enhancing their dissolution. In contrast, aluminium antacids may form insoluble salts of the drug. Note that food may reduce these effects, see ‘NSAIDs; Diflunisal + Antacids’, above.

**Importance and management**

Information is very limited but it would appear that if rapid analgesia is needed with either mefenamic acid or tolfenamic acid, magnesium hydroxide can be given concurrently but aluminium hydroxide should be avoided. However, note that this applies to the fasted state, whereas NSAIDs are usually taken with or after food. Also note that magnesium hydroxide increased the endoscopically-detected gastric toxicity of ibuprofen in one study, see ‘NSAIDs; Ibuprofen and related drugs + Antacids’, below. Aluminium hydroxide markedly reduces the speed of absorption. Sodium bicarbonate does not interact. Consider also ‘NSAIDs; Miscellaneous + Antacids’, p.142.

**NSAIDs; Ibuprofen and related drugs + Antacids**

Magnesium hydroxide increased the initial absorption of ibuprofen and flurbiprofen, but had no effect on ketoprofen. Unexpectedly, a pharmacodynamic study showed increased gastric erosions when ibuprofen was formulated with magnesium hydroxide. A small reduction in ketoprofen absorption occurred with aluminium-magnesium hydroxide, but desketoprofen, ibuprofen and flurbiprofen were not affected, and naproxen showed a slight increase in rate and extent of absorption. Aluminium phosphate had no effect on ketoprofen absorption. Sodium bicarbonate increased the rate of naproxen absorption, and aluminium hydroxide and magnesium oxide decreased it. Dimeticone did not affect ketoprofen bioavailability.
Clinical evidence

(a) Dextroprofen
In 24 healthy subjects an aluminium/magnesium hydroxide antacid (Maalox) had no effect on the rate or extent of absorption of a single 25-mg dose of dextroprofen, although the maximum level was slightly (13%) lower.7

(b) Flurbiprofen
Malaxol (aluminium/magnesium hydroxide) 30 mL, taken 30 minutes before a single 100-mg dose of flurbiprofen, was found to affect neither the rate nor extent of flurbiprofen absorption in a group of young and old fasting healthy subjects. Similarly, the antacid had no effect on steady-state flurbiprofen pharmacokinetics when both drugs were given 90 minutes before food.2 Another study found that magnesium hydroxide increased the AUC0–2 by 61%, but the AUC0–8 was not changed in fasted subjects, which demonstrated an increased rate of flurbiprofen absorption.3

(c) Ibuprofen
In 8 healthy, fasted subjects an antacid containing aluminium/magnesium hydroxide, given before, with, and after a single 400-mg dose of ibuprofen, did not alter the pharmacokinetics of ibuprofen.4 In another study, the absorption of ibuprofen formulated with aluminium was delayed and reduced, when compared to that of ibuprofen without aluminium.5 Another study in 6 healthy fasted subjects found that magnesium hydroxide 850 mg increased the AUC0–1 and the peak levels of a single 400-mg dose of ibuprofen by 65% and 31%, respectively. The time to the peak was shortened by about 30 minutes but the total bioavailability was unchanged.4 In a pharmacodynamic study in healthy subjects, a 400-mg ibuprofen tablet buffered with 200 mg of magnesium hydroxide, given at a dose of two tablets three times daily for 5 days resulted in about a threefold increase in number of endoscopically-detected gastric erosions, when compared with the same dose of conventional ibuprofen tablets.7

A sodium/potassium salt (kowa), often taken as an antacid in some West African countries, appeared to reduce the absorption of ibuprofen. The bioavailability of ibuprofen 400 mg given to 6 healthy subjects with a millet meal containing the salt extract (pH of 8.9) was reduced, compared with the millet meal alone (pH 5.3) or following overnight fasting (approximate AUCs 20, 120, 110 micrograms/mL per hour, respectively).12

(d) Ketoprofen
Five healthy, fasted subjects had a 22% reduction in the absorption of a 50-mg dose of ketoprofen (as measured by the amount excreted in the urine) when they were given a 1-g dose of aluminium hydroxide.9 Conversely, aluminium phosphate 11 g (as a single then a daily dose) had no effect on the pharmacokinetics of ketoprofen 100 mg in 10 patients.10 Another study in 12 healthy, fasted subjects showed that dimeticon did not significantly affect the bioavailability of a single 100-mg dose of ketoprofen.11 In another study 10 mL of magnesium hydroxide suspension (equivalent to 850 mg) was found to have no significant effect on the rate or extent of absorption of ketoprofen 50 mg in fasted subjects, although the rate of ketoprofen absorption was already noted to be fast.5

(e) Naproxen
Sodium bicarbonate 700 mg or 1.4 g increased the rate of absorption of a single 300-mg dose of naproxen in 14 healthy fasted subjects, whereas magnesium oxide or aluminium hydroxide 700 mg had the opposite effect, and reduced the rate of absorption. Magnesium carbonate had little effect.10 On the other hand when 15 or 60 mL of aluminium/magnesium hydroxide (Maalox) was given, the rate and extent of absorption of naproxen were slightly increased.12

Mechanism
Magnesium hydroxide appears to improve the rate of absorption of some acidic NSAIDs (which become more soluble as the pH rises) such as ibuprofen and flurbiprofen. Why this increased the gastric toxicity of ibuprofen in the one pharmacodynamic study is unclear.9 Sodium bicarbonate appears to have a similar effect on rate of absorption. Aluminium antacids do not produce soluble salts with these NSAIDs, and may therefore reduce the rate/extent of absorption.

Importance and management
It would appear that the initial absorption of both ibuprofen and flurbiprofen is increased by magnesium hydroxide, but not if aluminium hydroxide is present as well. Thus if rapid analgesia is needed, an antacid containing magnesium hydroxide but without aluminium hydroxide could be used with these NSAIDs. However, the unexpected finding that magnesium hydroxide increased the endoscopically-detected gastric toxicity of ibuprofen9 suggests that caution may be warranted, particularly on long-term use. Further study is needed.

Sodium bicarbonate and aluminium hydroxide appear to have a similar effect on naproxen, namely an increased and decreased effect, respectively, on the rate of absorption. However, note that these effects were seen in the fasted state, and may not apply when the NSAIDs are taken with or after food (as is recommended), as is the case with ‘diflunisal’, (p.140).

No particular precautions would seem to be needed if dimeticon, aluminium phosphate or magnesium hydroxide are given with ketoprofen, and it seems doubtful if the effects of ketoprofen will be reduced to any great extent by aluminium hydroxide.6

NSAIDs; Indometacin or Sulindac + Antacids
Although a variety of different antacids have slightly altered the absorption of indometacin the changes are probably not clinically important. Aluminium/magnesium hydroxide had no effect on sulindac absorption.

Clinical evidence
In 12 healthy, fasted subjects the AUC of a single 50-mg dose of indometacin was reduced by 35% when formulated with 80% Mergel (an antacid formulation of aluminium/magnesium hydroxide, and magnesium carbonate) and by 18% when taken with 90% Mergel.9

In another single-dose study in 6 healthy, fasted subjects, aluminium hydroxide suspension 700 mg reduced the rate of indometacin absorption, and reduced the peak indometacin plasma levels. Conversely, sodium bicarbonate 1.4 g appeared to increase the rate of absorption, but this did not reach significance because of wide inter-individual variation.2 In a further study 30 mL of aluminium/magnesium hydroxide caused only slight changes in the absorption of a 50-mg dose of indometacin in fasted subjects.9

The manufacturer of sulindac notes that an antacid (aluminium/magnesium hydroxide suspension) had no effect on the absorption of sulindac.6

Mechanism
Not known. Aluminium compounds might form insoluble salts with indometacin.2 Food might reduce this effect, see ‘NSAIDs; Diflunisal + Antacids’, p.140.
Importance and management

Adequately but not extensively documented. Some small reduction in plasma indomethacin levels is possible with some aluminium containing antacids. Despite this the manufacturers of indomethacin recommend that it be taken with food, milk or an antacid to minimise gastrointestinal disturbances. Sulindac absorption is not affected.

**NSAIDs; Miscellaneous + Antacids**

The rate and extent of absorption of ketorolac, metamizole and tolmetin was not significantly affected by aluminium/magnesium hydroxide. Nabumetone absorption was not affected by aluminium hydroxide, and an unspecified antacid did not affect etodolac absorption.

**Clinical evidence**

(a) Etodolac

A study in 18 healthy, fasted subjects found that when given a single 400-mg dose of etodolac with 30 mL of an unnamed antacid neither the rate nor the extent of etodolac absorption were altered.

(b) Ketorolac

The AUC of oral ketorolac 10 mg was found to be reduced by 11% (not statistically significant) when taken with an unstated amount of aluminium/magnesium hydroxide suspension. Nabumetone absorption was not affected by aluminium hydroxide, and an unspecified antacid did not affect etodolac absorption.

(c) Metamizole sodium (Dipyrone)

The concurrent use of 20 mL of *Maalox* (aluminium/magnesium hydroxide) did not affect the bioavailability of piroxicam 20 mg daily taken with this type of antacid. The AUC of oral ketorolac 10 mg was found to be reduced by 11% (not statistically significant) when taken with an unstated amount of aluminium/magnesium hydroxide suspension (Maalox) in 12 healthy fasted subjects. The rate of absorption was not affected.

(d) Nabumetone

The absorption of a single 1-g dose of nabumetone (as assessed by AUC and maximum plasma level) was not significantly altered by 160 mL of aluminium hydroxide suspension (Aludrox) in 15 healthy fasted subjects.

(e) Tolmetin

A pharmacokinetic study in 24 healthy, fasted subjects showed that aluminium/magnesium hydroxide suspension (*Maalox*), given as a single 20-mL dose four times daily for 3 days, had no significant effect on the absorption of a single 400-mg dose of tolmetin.

**Mechanism**

None.

Importance and management

Although information is limited, no particular precautions would seem necessary. It was found that antacids have been frequently given with NSAIDs to reduce their gastric irritant effects. Consider also ‘coxibs’, (below) for information about the interaction of other NSAIDs with antacids.

**NSAIDs; Oxicam derivatives + Antacids**

The pharmacokinetics of lornoxicam, meloxicam, piroxicam and tenoxicam were not affected by aluminium/magnesium hydroxide antacids. Lornoxicam pharmacokinetics were also not altered by tripotassium dicitratobismuthate or aluminium hydroxide with calcium carbonate.

**Clinical evidence, mechanism, importance and management**

(a) Lornoxicam

Neither 10 mL of Maalox (aluminium/magnesium hydroxide) nor 10 g of So Leah (aluminium hydroxide with calcium carbonate) had any effect on the pharmacokinetics of a 4-mg lornoxicam film-coated tablet in 18 healthy fasted subjects. A later study similarly found no changes in the absorption or pharmacokinetics of a lornoxicam film-coated tablet given with bismuth chelate (tripotassium dicitratobismuthate) 120 mg twice daily. There would seem to be no reason for avoiding concurrent use.

(b) Meloxicam

In an open, randomised, crossover study 9 healthy, fasted subjects were given meloxicam 30 mg alone or with *Maalox* suspension (aluminium/magnesium hydroxide 900/600 mg) four times daily for 4 days. *Maalox* had no significant effect on the pharmacokinetics of the meloxi cam, and therefore no adjustments of the dosage of meloxicam are needed if given with this type of antacid.

(c) Piroxicam

A multiple-dose study in 20 healthy subjects found that Mylanta (aluminium/magnesium hydroxide) and Amphojel (aluminium hydroxide) did not significantly affect the bioavailability of piroxicam 20 mg daily taken after food. Concurrent use need not be avoided.

(d) Tenoxicam

The bioavailability of tenoxicam 20 mg was found to be unaffected in 12 healthy subjects by aluminium hydroxide (Amphojel) or aluminium/magnesium hydroxide (Mylanta) whether taken before, with, or after the tenoxicam, and in the fasted state or with food. No special precautions seem necessary.

**NSAIDs + Aspirin; Anti-inflammatory dose**

The combined use of aspirin and NSAIDs increases the risk of gastrointestinal damage. There is no clinical rationale for the combined use of anti-inflammatory/analgesic doses of aspirin and NSAIDs, and such use should be avoided. There are numerous early pharmacokinetic studies of aspirin and NSAIDs, many of which showed that aspirin reduced the levels of NSAIDs.

**Clinical evidence**

A. Gastrointestinal damage

In a case-control study of data from 1993 to 1998 in the UK General Practice Research Database the risk of upper gastrointestinal bleeding or perforation was increased by slightly more than an additive effect in patients taking both aspirin and NSAIDs (8.2-fold), when compared with aspirin alone (2.4-fold), or NSAIDs alone (3.6-fold). The specific NSAIDs were not mentioned. Another study provided similar findings, as have studies
specifically looking at low-dose aspirin (325 mg or less daily), see ‘NSAIDs + Aspirin; Antplatelet dose’, p.144. Analysis of Yellow Card reports to the CSM in the UK gastrointestinal perforation/obstruction, ulceration or bleeding with diclofenac, naproxen, and ibuprofen revealed that 28% of the patients were receiving concurrent aspirin (dose not stated).

The one pharmacodynamic study below, that also measured gastrointestinal blood loss, found increased bleeding when anti-inflammatory doses of aspirin were given with sodium meclofenamate.6 A case report described acute ulcerative colitis in a woman taking rofecoxib 25 mg daily who also took aspirin.7 See also gastrointestinal effects, in ‘NSAIDs + Aspirin; Antplatelet dose’, p.144.

B. Pharmacokinetic and pharmacodynamic studies

Early studies evaluating non-aspirin NSAIDs in rheumatoid arthritis commonly permitted the concurrent use of aspirin, which was then in wide use for this condition. The unexpected finding that indometacin was no more effective than placebo in patients taking aspirin in one study led to a number of pharmacokinetic studies with this combination (see Indometacin, below), and subsequently other NSAID/aspirin combinations. These studies generally have little clinical relevance to current clinical practice where anti-inflammatory doses of aspirin should not be used in combination with NSAIDs because of the increased risk of gastrointestinal bleeding (see above) and lack of proven additional benefit. However, the pharmacokinetic studies are briefly summarised below.

(d) Diclofenac

Aspirin 900 mg reduced the AUC of diclofenac 50 mg by about one-third in a single-dose study.6 In a clinical study, there was no significant difference in efficacy between diclofenac 50 mg three times daily alone or with aspirin 900 mg three times daily.7

(b) Fenamates

A study in 20 healthy subjects given aspirin 600 mg and sodium meclofenamate 100 mg both three times daily for 14 days found no significant reductions in plasma salicylate levels, but plasma meclofenamate levels were reduced to some extent. However, gastrointestinal blood loss was approximately doubled compared with either drug alone.4

(c) Ibuprofen and related drugs

Aspirin 1.3 to 3.6 g daily more than halved the serum levels of ibuprofen 800 mg to 2.4 g daily,8,9 without affecting salicylate levels.9 There was little additional clinical benefit from the combination.10 Similarly, aspirin reduced the AUC of flurbiprofen by about two-thirds,10 but without any clear changes in clinical effectiveness.11 The pharmacokinetics of the aspirin were unchanged by flurbiprofen.10 Aspirin 3.9 g daily also virtually halved the AUC of fenoprofen 2.4 g daily,10 and reduced the AUC of ketoprofen 200 mg daily1 by about one-third. The AUC of naproxen was only minimally reduced by aspirin.11,12,13 Omeprazole, a proton pump inhibitor, drugs, salicylates, and salicylate metabolism

(e) Diclofenac

Aspirin 900 mg reduced the AUC of diclofenac 50 mg by about one-third in a single-dose study.6 In a clinical study, there was no significant difference in efficacy between diclofenac 50 mg three times daily alone or with aspirin 900 mg three times daily.7

Mechanism

The damaging effects of aspirin and NSAIDs on the gut appear to be additive. The mechanisms behind the pharmacokinetic changes have not been resolved. Changes in the rates of absorption and renal clearance and competition for plasma protein binding have been proposed.

Importance and management

The additive risk of gastrointestinal damage from combining aspirin and NSAIDs is established and, in addition, the lack of clear benefit from the combination, the use of anti-inflammatory/analgesic doses of aspirin with NSAIDs should be avoided. For information on low-dose aspirin and NSAIDs see ‘NSAIDs + Aspirin; Antplatelet dose’, p.144. Consider also ‘NSAIDs + NSAIDs’, p.151.

NSAIDs + Aspirin; Antiplatelet dose

There is some evidence that non-selective NSAIDs such as ibuprofen antagonise the antiplatelet effects of low-dose aspirin, but that COX-2-selective NSAIDs (coxibs) do not. Some, but not other, epidemiological studies have shown that non-selective NSAIDs reduce the cardioprotective effects of low-dose aspirin. Furthermore, some NSAIDs (particularly coxibs) are associated with increased thrombotic risk. Combined use of NSAIDs and low-dose aspirin increases the risk of gastrointestinal bleedings. This seems to apply equally to coxibs.

Clinical evidence

(a) Cardioprotective effects

A number of pharmacodynamic studies have investigated whether or not NSAIDs affect the antiplatelet effects of aspirin. Celecoxib 200 mg twice daily,1 diclofenac 75 mg twice daily,2 etoricoxib 120 mg daily,3 lumiracoxib 400 mg daily,4 meloxicam 15 mg daily,5 naproxen 500 mg twice daily,6 parecoxib 40 mg twice daily,7 and rofecoxib 25 mg daily8 have all been shown not to alter the antiplatelet effects of aspirin in doses of 75 to 325 mg daily. The effects of ibuprofen are less clear, and may be related to the order of drug administration.

As a consequence of these pharmacodynamic studies, various cohort/case-control studies or sub-group analyses have been conducted to see if ibuprofen and/or other NSAIDs reduce the cardioprotective effect of low-dose aspirin in patients, see ‘Table 6.2’, (below). Because these studies are neither prospective nor randomised, their findings are suggestive only, nevertheless they provide some useful insight.

(b) Gastrointestinal effects

Low-dose aspirin alone (300 mg or less daily) was associated with an increased risk of hospitalisation for bleeding peptic ulcer in a case-control study. The odds ratios were 2.3 for aspirin 75 mg daily, 3.2 for aspirin 140 mg daily, and 2.0 for aspirin 200 mg daily.9

150 mg daily, and 3.9 for aspirin 300 mg daily. Use of NSAIDs combined with low-dose aspirin was associated with a greater risk of bleeding (odds ratio 7.7) than use of either NSAIDs alone (5.4) or low-dose aspirin alone (3.3). Similar findings were reported in a cohort study (rate ratio for gastrointestinal bleed for low-dose aspirin 2.6, and for combined use with NSAIDs 5.5).9 Patients taking low-dose aspirin (325 mg or less daily) with celecoxib had a higher frequency of gastrointestinal complications than those taking celecoxib alone. Moreover, there was no difference in frequency of gastrointestinal complications between those taking low-dose aspirin with celecoxib and those taking low-dose aspirin with ibuprofen or diclofenac alone. This was despite celecoxib alone being associated with a lower frequency of gastrointestinal adverse effects than ibuprofen or diclofenac alone.10 Similar results were found with rofecoxib 25 mg daily, which increased the incidence of ulcers in patients taking enteric-coated aspirin 81 mg per day.11

Mechanism
Aspirin irreversibly blocks the production of thromboxane A2 by binding to cyclooxygenase (COX-1) in platelets, and so inhibits platelet aggregation. The beneficial cardiovascular effects are attributed to this effect. Other NSAIDs that are COX-1 inhibitors also have this effect, but it is more selective since they bind reversibly. These NSAIDs can therefore competitively inhibit the binding of aspirin to platelets (a fact that was shown in vitro as early as the 1980s12). When these NSAIDs are present in sufficient quantities when a daily low-dose of aspirin is given, they therefore reduce its antiplatelet effect. In vitro study confirms that COX-2 selective NSAIDs have less effect on aspirin irreversibly blocks the production of thromboxane A2 by binding to cyclooxygenase (COX-1) in platelets, and so inhibits platelet aggregation. The beneficial cardiovascular effects are attributed to this effect. Other NSAIDs that are COX-1 inhibitors also have this effect, but it is more selective since they bind reversibly. These NSAIDs can therefore competitively inhibit the binding of aspirin to platelets (a fact that was shown in vitro as early as the 1980s12). When these NSAIDs are present in sufficient quantities when a daily low-dose of aspirin is given, they therefore reduce its antiplatelet effect. In vitro study confirms that COX-2 selective NSAIDs have less effect on aspirin-mediated platelet function. A single 60-mg dose of etoricoxib was given to healthy subjects on day 7 (b) Etoricoxib
4. The manufacturer notes that flunacosazole 200 mg daily increased the AUC of a single 200-mg dose of celecoxib by 130% and increased the maximum level by 60%. Conversely, ketocaonazole had no effect on the pharmacokinetics of celecoxib.
5. A single 60-mg dose of etoricoxib was given to healthy subjects on day 7 of an 11-day course of celecoxib 400 mg daily. The AUC of etoricoxib was increased by 43% and the maximum plasma level was increased by 29%.2
6. The manufacturer of parecoxib reports a study in which flunacosazole increased the plasma levels of valdecoxib (the main metabolite of parecoxib) by 19% and raised its AUC by 62%.1 Ketocaonazole had a similar, but more moderate effect on the levels of valdecoxib (maximum plasma levels increased by 24%, AUC increased by 38%).4

Mechanism
Flunacosazole markedly raises celecoxib levels, whereas ketocona- zole has no effect on celecoxib levels. Flunacosazole and ketocaonazole moderately increase the levels of valdecoxib (the main metabolite of parecoxib). Ketocaonazole moderately raises etori- coxib plasma levels, but this is unlikely to be of clinical relevance. Flunacosazole has no clinically relevant effect on limracoxib phar- macokinetics.

Clinical evidence
(a) Celecoxib
The manufacturer notes that flunacosazole 200 mg daily increased the AUC of a single 200-mg dose of celecoxib by 130% and increased the maximum level by 60%. Conversely, ketocaonazole had no effect on the pharmacokinetics of celecoxib.

(b) Etoricoxib
A single 60-mg dose of etoricoxib was given to healthy subjects on day 7 of an 11-day course of celecoxib 400 mg daily. The AUC of etoricoxib was increased by 43% and the maximum plasma level was increased by 29%.2

(c) Lumracoxib
A placebo-controlled, crossover study in 13 healthy subjects found that flunacosazole 400 mg on day 1 and 200 mg on days 2 to 4 had no clinically relevant effect on the pharmacokinetics of a single 400-mg dose of lumracoxib given on day 4.

(d) Parecoxib
The manufacturer of parecoxib reports a study in which flunacosazole increased the plasma levels of valdecoxib (the main metabolite of parecoxib) by 19% and raised its AUC by 62%.1 Ketocaonazole had a similar, but more moderate effect on the levels of valdecoxib (maximum plasma levels increased by 24%, AUC increased by 38%).4

NSAIDs + Azoles
Flunacosazole markedly raises celecoxib levels, whereas ketocona- zole has no effect on celecoxib levels. Flunacosazole and ketocaonazole moderately increase the levels of valdecoxib (the main metabolite of parecoxib). Ketocaonazole moderately raises etori- coxib plasma levels, but this is unlikely to be of clinical relevance. Flunacosazole has no clinically relevant effect on limracoxib phar- macokinetics.

Clinical evidence
(a) Celecoxib
The manufacturer notes that flunacosazole 200 mg daily increased the AUC of a single 200-mg dose of celecoxib by 130% and increased the maximum level by 60%. Conversely, ketocaonazole had no effect on the pharmacokinetics of celecoxib.

(b) Etoricoxib
A single 60-mg dose of etoricoxib was given to healthy subjects on day 7 of an 11-day course of celecoxib 400 mg daily. The AUC of etoricoxib was increased by 43% and the maximum plasma level was increased by 29%.2

(c) Lumracoxib
A placebo-controlled, crossover study in 13 healthy subjects found that flunacosazole 400 mg on day 1 and 200 mg on days 2 to 4 had no clinically relevant effect on the pharmacokinetics of a single 400-mg dose of lumracoxib given on day 4.

(d) Parecoxib
The manufacturer of parecoxib reports a study in which flunacosazole increased the plasma levels of valdecoxib (the main metabolite of parecoxib) by 19% and raised its AUC by 62%.1 Ketocaonazole had a similar, but more moderate effect on the levels of valdecoxib (maximum plasma levels increased by 24%, AUC increased by 38%).4

Mechanism
Flunacosazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP2C9 and ketocaonazole inhibits CYP3A4. Etoricoxib is extensively metabolized by CYP2C9 and therefore shows marked rises in plasma levels when given with flunacosazole but not ketocaonazole. Etoricoxib is partially metabolised by CYP3A4, therefore shows moderate rises in plasma levels with ketocaonazole. Valdecoxib is metabolised by both CYP2C9 and CYP3A4, therefore was modestly affected by both flunacosazole and ketocaonazole. Parecoxib is a valdecoxib prodrug, and interacts similarly. From the study with lumracoxib it appears that its pharmacokinetics are likely to be affected by inhibitors of CYP2C9, because, even though lumracoxib is largely metabolised by CYP2C9, other pathways are also important (e.g. glucuronidation).
Importance and management

These pharmacokinetic interactions are established, although their effect in clinical practice has not been assessed. The marked rise in celecoxib levels with fluconazole could be important, and the UK manufacturer recommends that the dose of celecoxib should be halved in patients receiving fluconazole, whereas the US manufacturer suggests starting with the lowest recommended dose. The rise in valdecoxib levels with fluconazole is less marked, nevertheless the manufacturer recommends that for parecoxib or piroxicam are given with ketoconazole, and if lumiracoxib is given with fluconazole.

NSAIDs + Bile-acid binding resins

Simultaneous celecoxib markedly reduced the absorption of diclofenac and sulindac, modestly reduced the absorption of ibuprofen, but only delayed and did not reduce the extent of absorption of naproxen. Administration of celecoxib three or more hours after oral sulindac, piroxicam, or tenoxicam still markedly reduced their plasma levels. Markedly reduced NSAID levels have also been found when celecoxib is given after intravenous meloxicam or tenoxicam. Simultaneous celecopil modestly reduced the oral absorption of diclofenac, but had no effect on ibuprofen absorption.

Clinical evidence

(a) Diclofenac

A single-dose, crossover study in 6 healthy, fasting subjects found that the simultaneous use of celecoxib 8 g markedly reduced the AUC of a single 100-mg oral dose of enteric-coated diclofenac by 62% and reduced its maximum plasma levels by 75%. Celestol 10 g reduced the diclofenac AUC by 33% and its maximum plasma levels by 58%.1

(b) Ibuprofen and related drugs

A single-dose, crossover study in 6 healthy fasting subjects found that the simultaneous use of celecoxib 8 g modestly reduced the AUC of a single 400-mg oral dose of ibuprofen by 26% and reduced its maximum serum levels by 34%. The rate of absorption was also reduced. Conversely, celestol 10 g had no significant effect on the pharmacokinetics of ibuprofen. The absorption of a single 250-mg dose of naproxen was delayed but not reduced in 8 healthy fasting subjects by the simultaneous use of celecoxib 4 g in 100 mL of orange juice. The amount absorbed after 2 hours was reduced from 96% to 51%, but was complete after 5 hours.2

(c) Oxicams

A study in 12 healthy subjects found that celecoxib 4 g taken 2 hours before a 30 mg intravenous dose of meloxicam increased its clearance by 49% and reduced its mean residence time in the body by 39%.3

Another study in 8 healthy subjects found that celecoxib increased the clearance of a single 20-mg oral dose of piroxicam and a single 20-mg intravenous dose of tenoxicam by 52% and 105%, respectively, and reduced their half-lives by 40% and 52%, respectively. In this study, celecoxib 4 g three times daily was started 2 hours before the intravenous tenoxicam and 3.5 hours after the oral piroxicam. Another multiple-dose study celecoxib, given 4 hours after oral piroxicam or oral tenoxicam, gave similar results.4 was a study starting celecoxib 24 hours after the last dose of a 14-day course of piroxicam 20 mg daily [which has a long half-life].5 The elimination half-life of both analgesics was roughly doubled by celecoxib 24 g daily.6

(d) Sulindac

In 6 healthy subjects celecoxib 4 g twice daily with meals was found to reduce the AUC of a simultaneous single 400-mg dose of sulindac by 78%; the AUC of its sulfide metabolite was reduced by 84%. Even when the sulindac was given 3 hours before the celecoxib, its AUC of celecoxib and its sulfide metabolite were reduced by 44% and 55%, respectively.7

Mechanism

The studies of simultaneous oral use suggest that the anion exchange resin celecoxib, and to a lesser extent celestol, bind anionic NSAIDs (e.g. diclofenac) in the gut, so reducing their absorption. The studies showing reduced plasma levels when celecoxib was given after intravenous oxicsams or separated by at least 3 hours from some oral NSAIDs, suggest that celecoxib can reduce the enterohepatic recirculation of these drugs.

Importance and management

Established interactions. Celecoxib markedly reduces the initial absorption of some NSAIDs (shown for diclofenac), and if these NSAIDs also undergo enterohepatic recirculation, their clearance will also be increased (shown for meloxicam, piroxicam, sulindac, and tenoxicam). This latter interaction cannot be avoided by separating the doses, and it may be best not to use celecoxib with these NSAIDs. Celecoxib can be used to speed the elimination of piroxicam and tenoxicam following overdos.3 Diclofenac has been formulated with celecoxib in an attempt to reduce gastric mucosal damage by reducing direct mucosal contact: 140 mg of diclofenac-celecoxib is considered equivalent to 70 mg of diclofenac.3

The reduction in absorption of ibuprofen with celecoxib is probably not clinically important, and naproxen is not affected. Nevertheless, celecoxib delayed the absorption of both ibuprofen and naproxen, which may be relevant if they are being taken for the management of acute pain. Information on many other NSAIDs appears to be lacking. Animal studies suggest that mefenamic acid, flufenamic acid and phenylbutazone will also be affected by celecoxib.8,9,10 Note that it is usually recommended that other drugs are given 1 hour before or 4 to 6 hours after celecoxib. The reduction in diclofenac absorption with celestol may be clinically relevant; if the combination is required monitor well. Note that it is usually recommended that other drugs are given 1 hour before or 4 hours after celestol.

NSAIDs or Aspirin + Caffeine

Caffeine modestly increases the bioavailability, rate of absorption and plasma levels of aspirin. Adding caffeine to diclofenac may improve its efficacy in the treatment of migraine.
Clinical evidence, mechanism, importance and management

Caffeine citrate 120 mg given to healthy subjects with a single 650-mg dose of aspirin increased the aspirin AUC by 36%, increased the maximum plasma levels by 15%, and increased the rate of absorption by 30%. This confirms the results of previous studies. These studies suggest that caffeine may modestly potentiate the efficacy of aspirin via a pharmacokinetic mechanism.

A meta-analysis of randomised, controlled studies concluded that there was no therapeutic advantage of adding caffeine to analgesic doses of aspirin in patients experiencing postoperative pain. In a placebo-controlled study in patients with migraine, there was a non-significant trend towards improved analgesic effect in patients receiving diclofenac softgel 100 mg and caffeine 100 mg compared with diclofenac alone, although the sample size was too small to provide meaningful results.

In general, food has no clinically significant effect on the absorption of the NSAIDs; however, the delay in absorption that occurs may be important if NSAIDs are given in acute pain management.

Clinical evidence

(a) Coxibs

A study in 50 children showed that a single 250-mg/m² dose of celecoxib, given with high-fat food, increased the maximum plasma concentration by 82% and the AUC by 60%. When steady-state levels were achieved with celecoxib 250 mg/m² twice daily, food increased the maximum plasma concentration by 99% and the AUC by 75%. The manufacturers of celecoxib note that a high-fat meal, when compared with the fasting state, delayed the time to achieve the maximum level or the bioavailability.

(b) Diclofenac

Thirteen healthy subjects were given a single 105-mg dose of diclofenac potassium suspension (Flogox) while fasting and after food. The pharmacokinetics of diclofenac were not changed to a clinically relevant extent by food, except that absorption was delayed (time to maximum level increased by about 30 minutes). Similar findings (an increase in time to maximum level of 1.5 to 3 hours) were reported for single doses of enteric-coated diclofenac tablets. However, there was no difference in steady state levels of diclofenac 50 mg twice daily when given before or after food.

(c) Etodolac

When 18 healthy subjects were given etodolac 400 mg after a high-fat meal, peak serum levels were roughly halved, and delayed, from 1.4 to 3.8 hours, but the total amount absorbed was not markedly changed, when compared to the fasting state.

(d) Ibuprofen and related drugs

1. Aceclofenac. The manufacturer states that the rate, but not the extent, of aceclofenac absorption was affected by food.

2. Dextoketrofen. The absorption of a single 25-mg dose of dextekoprofen was delayed by food (maximum level reduced by 45% and time to maximum level delayed by about 1 hour), but the AUC was not affected.

3. Flurbiprofen. Food slightly increased the maximum plasma level and AUC of sustained-release flurbiprofen (Froben SR) by 15% and 25%, respectively, but delayed the time to achieve the maximum level by about 5 hours. In a study in 14 healthy subjects the pharmacokinetics of flurbiprofen were not affected by cranberry juice, grape juice or tea.

4. Ibuprofen. Food had no effect on the pharmacokinetics of the S- and R-enantiomers of ibuprofen in one study. However, in another study, food significantly delayed the absorption of both enantiomers of ibuprofen, and slightly increased the ratio of the S- to R-enantiomer. A study considering the effect of food on ibuprofen pharmacokinetics also showed that the maximum level of a single 400-mg dose of a standard release ibuprofen tablet and two readily soluble preparations (ibuprofen lysinate and ibuprofen extrudate), was consistently lower and appeared later when the dose was given after a standardised breakfast; the extent of ibuprofen absorption was also reduced by food for all three formulations. However, in a further study, food increased the maximum plasma level of sustained-release ibuprofen (Buften Retard) by 42% without affecting the time to achieve the maximum level or the bioavailability.

5. Ketoprofen. Food significantly decreased the rate and extent of absorption of ketoprofen in both single and multiple dose studies in healthy subjects. The AUC was decreased by about 40% and the time to maximum levels decreased by about 5 hours. A further study found that the rate of absorption and the peak plasma levels of ketoprofen were reduced by food, although the AUC was unaltered. In another study, the absorption of ketoprofen (200 mg daily, as a gastric-juice resistant, sustained-release formulation, given 4 hours before the first meal of the day) was about 15 to 24% greater when 16 healthy subjects were given a low-calorie/low-fat diet rather than a high-calorie/high-fat diet. In a further study in 4 healthy subjects, which measured the urinary excretion of ketoprofen after a single 50-mg dose given with water, whole skimmed milk, or a traditional Egyptian breakfast, it was concluded that the rate and extent of absorption of ketoprofen had been reduced by the presence of food, and the extent of absorption was also reduced by milk.

6. Naproxen. Food did not have any clinically relevant effect on the pharmacokinetics of sustained-release naproxen in two studies. Taking a single 550-mg dose of naproxen sodium with a meal had no effect on its analgesic efficacy in postoperative pain, when compared with the fasted state. However, the rate of absorption of a single 550-mg dose of S-naproxen betaine sodium salt monohydrate was found to be reduced by a high-fat meal, when compared with the fasting state.

(e) Indomethacin

Studies in patients and healthy subjects, given single or multiple oral doses of indomethacin, found that food delayed and reduced peak serum indomethacin levels, but fluctuations in levels were somewhat reduced.

(f) Nabumetone

The absorption of a single 1-g dose of nabumetone was increased by food and milk, as shown by an increase of about 50% in the maximum levels and a 40% increase in the AUC0-24. However, the AUC0-72 was not significantly increased.

(g) Oxicams

Food caused some delay in the time to reach maximum levels of piroxicam in a single-dose study, but had no effect on total absorption. In another study, the steady-state plasma levels of piroxicam 20 mg daily were unaffected by food. The bioavailability of tenoxicam 20 mg was unaffected by food in 12 healthy subjects, although the time taken to reach peak serum levels was delayed by about 4 hours. The rate (time to peak serum levels) and extent of absorption (AUC) of meloxicam 30 mg was not altered by food intake.

(h) Sulindac

The manufacturer of sulindac notes that food delayed the time to achieve peak plasma levels of the active metabolite by 1 to 2 hours.

Mechanism

Food delays gastric emptying, therefore frequently affects the rate, but not the extent, of absorption of the NSAIDs.

Importance and management

Food reduces the rate of absorption, but has little or no effect on the extent of absorption, of most of the NSAIDs studied. This was seen to vary with different formulations of NSAIDs; however, these changes in absorption will have no clinical relevance when these drugs are being used regularly to treat chronic pain and inflammation. If these drugs are being used for the treatment of acute pain, administration on an empty stomach would be preferable in terms of onset of effect, and is suggested by the manufacturers of dextokoprofen and etoricoxib. However, administration with or
A case of fatal intracerebral bleeding has been reported in a 71-year-old patient taking a Ginkgo biloba supplement and rofecoxib for 12 weeks after he started taking ibuprofen 600 mg daily. A 69-year-old man taking a Ginkgo biloba supplement and rofecoxib had a subdural haematoma after a head injury, then recurrent small spontaneous haematomas. He was subsequently found to have a prolonged bleeding time, which returned to normal one week after stopping the Ginkgo biloba supplement and rofecoxib, and remained normal after restarting low-dose rofecoxib. A placebo-controlled study in 11 healthy subjects who were given Ginkgo biloba leaf (Ginkgold) 120 mg twice daily for three doses, followed by a single 100-mg dose of flurbiprofen, found that the pharmacokinetics of flurbiprofen were unchanged.

A study in 12 healthy subjects who were given diclofenac 50 mg twice daily for 14 days, with Ginkgo biloba extract (Ginkgold) 120 mg twice daily on days 8 to 15, found no alteration in the AUC or oral clearance of diclofenac.

Mechanism

The reason for the bleeding is not known, but Ginkgo biloba extract contains ginkgolide B, which is a potent inhibitor of platelet-activating factor that is needed for arachidonate-independent platelet aggregation. On their own, Ginkgo biloba supplements have been associated with prolonged bleeding times, left and bilateral subdural haematomas, a right parietal haematoma, post-laparoscopic cholecystectomy bleeding, and subarachnoid haemorrhage. Ibuprofen is an inhibitor of platelet aggregation, but selective inhibitors of COX-2 such as rofecoxib have no effect on platelets and would not be expected to potentiate any bleeding effect of Ginkgo biloba.

The pharmacokinetic study involving diclofenac was designed to identify whether Ginkgo biloba exerted an inhibitory effect on cytochrome P450 isoenzyme CYP2C9, which is involved in the metabolism of diclofenac. Although an indication that such an effect may occur was noted in studies in vitro using S-warfarin, the in vivo study did not confirm that this interaction would be seen clinically.

Importance and management

The evidence from these reports is too slim to forbid patients to take NSAIDs and Ginkgo biloba concurrently, but some do recommend caution. Medical professionals should be aware of the possibility of increased bleeding tendency with Ginkgo biloba, and report any suspected cases.

Consider also ‘Antiplatelet drugs + Herbal medicines’, p.699.

fenoprofen treatment. These indicators of liver impairment suggest that fenoprofen is safer than aspirin in this context. Combined treatment with gold and NSAIDs was more effective than the NSAIDs alone.\(^1\)

A patient with rheumatoid arthritis taking gold (sodium aurothiomolate) developed pneumonitis soon after naproxen 500 mg twice daily was added. An *in vitro* study suggested the pneumonitis was due to hypersensitivity to gold. However, the patient’s condition continued to deteriorate despite stopping the gold, then showed marked improvement when the naproxen was also stopped. The authors suggest that the naproxen may have altered the patient’s immune system in some way to make them more sensitive to the gold.\(^2\) This appears to be the only report of such an effect, and is therefore unlikely to be of general relevance.

### NSAIDs or Aspirin + H₂-receptor antagonists

The H₂-receptor antagonists have no effect or cause only modest and normally clinically unimportant changes in the serum levels of aspirin and the NSAIDs. More importantly H₂-receptor antagonists may protect the gastric mucosa from the irritant effects of the NSAIDs.

#### Clinical evidence

(a) **Aspirin**

Cimetidine 300 mg, given 1 hour before a single 1.2-g dose of aspirin caused only a modest increase in the serum salicylate levels of 3 out of 6 healthy subjects.\(^3\) When 13 patients with rheumatoid arthritis taking enteric-coated aspirin were given cimetidine 300 mg four times daily for 7 days the total amount of aspirin absorbed was unaltered, but aspirin levels were slightly raised, from 161 to 180 micrograms/mL.\(^7\) The pharmacokinetics of a single 1-g dose of aspirin were largely unchanged in 6 healthy subjects given ranitidine 150 mg twice daily for a week.\(^8\) Famil ticam has been found to cause some small changes in the pharmacokinetics of aspirin, but this is of doubtful clinical importance.\(^4\)

(b) **Azapropazone**

A randomised pharmacokinetic study in 12 healthy subjects found that after taking cimetidine 300 mg every 6 hours for 6 days the AUC of a single 600-mg dose of azapropazone was increased by 25%, and the AUC of cimetidine was altered by less than 20%. No significant changes in laboratory values (blood counts, enzyme levels) were seen, and adverse effects were minor (headaches in 3 subjects).\(^5\)

(c) **Diclofenac**

In 14 healthy subjects famotidine 40 mg raised the peak plasma levels of enteric-coated diclofenac 100 mg from 5.84 to 7.04 mg/L. Peak plasma diclofenac levels also occurred more rapidly (2 versus 2.75 hours). The ex tent of the absorption was unchanged.\(^6\) Diclofenac did not affect the pharmacokinetics of ranitidine nor its ability to suppress gastric pH.\(^7\) Another study also found that the pharmacokinetics of diclofenac were unaffected by ranitidine.\(^8\)

(d) **Dipyrone**

In a study in 12 patients with confirmed duodenal ulcer, but no gastrointestinal bleeding, cimetidine 200 mg was given three times daily with another 400 mg at night for 20 days. A single 1.5-g or 750-mg dose of dipyrone was given on days 8 and 13 of cimetidine treatment. In the presence of cimetidine, the AUC of the active metabolite of dipyrone, 4-methyl-aminono-antipyrine (4-MAA), was significantly increased, by 74%, with dipyrone doses of 1.5 g, but the renal clearance of 4-MAA remained unchanged.\(^9\)

(e) **Flurbiprofen**

In 30 patients with rheumatoid arthritis cimetidine 300 mg three times daily for 2 weeks increased the maximum serum level of flurbiprofen 150 to 300 mg daily, but ranitidine 150 mg twice daily had no effect. The efficacy of the flurbiprofen (assessed by Ritchie score, 50 foot walking time, grip strength) was not altered.\(^10\) Another study in healthy subjects found that cimetidine 300 mg four times daily slightly increased the serum levels of a single 200-mg dose of flurbiprofen, and raised the flurbiprofen AUC by 13%.\(^11\) No statistically significant interaction occurred with ranitidine 150 mg twice daily.\(^12\) Although the activity of flurbiprofen is thought to be related to the S-enantiomer, neither cimetidine nor ranitidine were shown to interact preferentially with one enantiomer over the other.\(^13\)

(f) **Ibuprofen**

Cimetidine 400 mg three times daily raised the peak serum levels and AUC of a 600-mg dose of ibuprofen by 14% and 6%, respectively. No changes were seen with ranitidine 300 mg daily.\(^14\) Another study found that the AUC of R-ibuprofen and S-ibuprofen increased by 37% and 19%, respectively, but these were not statistically significant.\(^14\) However, five other studies with ibuprofen found no interaction with cimetidine or ranitidine.\(^15,19\) or nizatidine.\(^20\) However, analysis of the results of one study showed that peak serum ibuprofen levels in black subjects (USA) were 54% higher and occurred sooner, whereas in white subjects (USA) they were 27% lower and delayed.\(^17,20\)

(g) **Indometacin**

Cimetidine 1 g daily for 2 weeks was given to 10 patients with rheumatoid arthritis taking indometacin 100 to 200 mg daily for over a year. The plasma indometacin levels fell by an average of 18%, but there was no significant change in the clinical effectiveness of the anti-inflammatory treat ment (as measured by articular index, pain, grip strength and erythrocyte sedimentation rate).\(^21\) Another study found no changes in the pharmacokinetics of indometacin in healthy subjects given ranitidine.\(^22\) No marked changes in the bioavailability of either cimetidine or ranitidine were seen when they were given with indometacin in a single-dose study in healthy subjects.\(^23\)

(h) **Ketoprofen**

Cimetidine 600 mg twice daily was found not to affect the pharmacokinetics of enteric-coated ketoprofen 100 mg twice daily in 12 healthy subjects.\(^24\)

(i) **Lornoxicam**

In 12 healthy subjects cimetidine 400 mg twice daily increased the maximum serum levels and AUC of lornoxicam 8 mg twice daily by 28% and 9%, respectively. Ranitidine 150 mg twice daily had no significant effect on lornoxicam pharmacokinetics in these same subjects, except that one subject had a very marked increase in serum lornoxicam levels while tak ing both drugs. He dropped out of the study after 6 days because of severe gastric irritation. It is not clear what part, if any, the ranitidine had to play in this effect.\(^25\)

(j) **Meloxicam**

In an open, randomised, crossover study, a group of 9 healthy subjects was given meloxicam 30 mg either alone, or with cimetidine 200 mg four times daily for 5 days. Cimetidine had no significant effect on the pharmacokinetics of the meloxicam.\(^26\)

(k) **Naproxen**

One study found no adverse interaction between naproxen and cimetidine and no alteration in the beneficial effects of cimetidine on gastric acid secretion,\(^27\) but another study found that cimetidine caused a moderate 39 to 60% decrease in the naproxen half-life,\(^28,29\) and a 20% reduction in the AUC of naproxen.\(^30\) In one of these studies the half-life of naproxen was reduced by about 40% by ranitidine and 50% by famotidine.\(^31\) A further study found that nizatidine does not affect the pharmacokinetics of naproxen.\(^30\)

(l) **Piroxicam**

In 10 healthy subjects cimetidine 300 mg four times daily for 7 days slightly increased the half-life and the AUC of a single 20-mg dose of piroxicam by 8% and 16%, respectively.\(^32\) Another study found that cimetidine caused a 15% rise in the AUC of piroxicam.\(^32\) In 12 healthy subjects the half-life and AUC of a single-dose of piroxicam were increased by 41% and 31%, respectively, by cimetidine 200 mg three times daily, and the plasma levels were raised accordingly.\(^33\) For example, at 4 hours they were raised by almost 25%.\(^33\) Ranitidine was not found to affect the pharmacokinetics of piroxicam.\(^34\) No clinically significant changes occurred in the steady-state serum levels of piroxicam in a further study when either cimetidine or nizatidine were given.\(^35\)

(m) **Tenoxicam**

The pharmacokinetics of a single 20-mg oral dose of tenoxicam was unal tered in 6 healthy subjects after they took cimetidine 1 g daily for 7 days.\(^36\)
Mechanism

Uncertain. Azapropazone, 4-MA (the active metabolite of dipyrone), lornoxicam, and piroxicam serum levels are possibly increased because of the metabolic activities of the cytochrome P450 system is reduced by the cimetidine. 5, 29, 33 There may also be some effects on renal excretion. 5

Importance and management

Most of these interactions between the NSAIDs and cimetidine, famotidine, nizatidine or ranitidine appear to be of no particular clinical importance. Most of these interactions between the NSAIDs and cimetidine, famotidine. 5, 9, 25, 33 There may also be some effects on renal excretion. 5

Kreher J, Bellamy N, Freeman D. Do H2-antagonists alter the kinetics and effects of chronic users of oral contraceptives, but anoth er study did not. Oral contraceptives reduced the levels of aspirin, but not phenylbutazone. There are no clinically relevant changes in the pharmacokinetics of oxa propzin with conjugated oestrogens.

Clinical evidence, mechanism, importance and management

(a) Aspirin

The AUCs of single 300- and 600-mg doses of aspirin were lower in 10 women after they started to take a combined oral contraceptive (ethi nylestradiol/norethisterone 30 micrograms/1 mg). After the oral contrace ptive had been discontinued, the pharmacokinetics of aspirin returned to baseline values. 1

(b) Coxibs

For a report of pulmonary embolism in an patient taking valdecoxib with a combined oral contraceptive, and for the effects of coxibs on contraceptive metabolism, see ‘Hormonal contraceptives or HRT + Coxibs’, p. 994.

c) Diffusals

The clearance of a single 250-mg dose of diffusal was 53% higher in 6 women taking oral contraceptives than in 6 control women, but was simi lar to the clearance in 6 men. 2 This difference is unlikely to be of clinical importance.

(d) Ibuprofen

In one study, the pharmacokinetics of R-ibuprofen did not differ between women taking combined oral contraceptives, control women, and control men. 3 However, in another study, the median AUC0–12 of S-ibuprofen lysi nate was 29% lower in users of oral contraceptives, and pain-intensity was higher (possibly due to reduced pain tolerance). 3

(e) Oxypropzin

There was no difference in the pharmacokinetics of a single 1.2-g dose of oxypropzin in 11 women taking conjugated oestrogens (PREmarin) than in 11 control women, except that the time to peak concentration was shorter (4 versus 8.9 hours). 4 This difference is unlikely to be of clinical importance.

(f) Phenylbutazone

The pharmacokinetics of a single 400-mg dose of phenylbutazone did not change in 10 women after they started to take a combined oral contraceptive containing ethinylestradiol/norethisterone 30 micrograms/1 mg. 1

NSAIDs or Aspirin + Hormonal contraceptives or HRT

Oral contraceptives increase diffusional clearance in women, but only to the level normally seen in men. One study showed modestly reduced levels of ibuprofen with oral contraceptives, but another study did not. Oral contraceptives reduced the levels of aspirin, but not phenylbutazone. There are no clinically relevant changes in the pharmacokinetics of oxa propzin with conjugated oestrogens.

NSAIDs or Salicylates + Mazindol

Mazindol does not appear to interact adversely with indometacin or salicylates.

Clinical evidence, mechanism, importance and management

In an 8-week, placebo-controlled, double-blind study, mazindol was given to 26 patients with obesity and arthritis, 15 of whom were taking sali-
cylates, 11 were taking indomethacin and one was taking dextropropoxyphene (propoxyphene) with paracetamol (acetaminophen). Additional analgesic and anti-inflammatory drugs used were ibuprofen (4 patients), phenylbutazone (1), dextropropoxyphene (7) and paracetamol (3). No symptoms attributable to salicylism or indomethacin toxicity (gastric intolerance, headache) were observed.1

**NSAIDs or Aspirin + Metoclopramide**

Metoclopramide increases the rate of absorption of aspirin and tolfenamic acid. Conversely, metoclopramide reduces the bioavailability of ketoprofen.

**Clinical evidence**

(a) *Aspirin*

In one study, intramuscular metoclopramide given before oral effervescent aspirin increased the rate of aspirin absorption during a migraine attack to that seen when aspirin was given alone to subjects who were headache free.1 Similarly, in another study, intramuscular or oral metoclopramide 10 mg increased the rate of absorption of aspirin in patients with migraine.2 However, in healthy subjects metoclopramide did not alter the pharmacokinetics of aspirin.3 In addition, in one clinical study there was no difference in analgesic efficacy between aspirin with metoclopramide (Migravess) and aspirin alone (Alka-Seltzer) for migraine attacks.4

(b) *Ketoprofen*

In a single-dose study in 4 healthy subjects, metoclopramide 10 mg reduced the AUC of a 50-mg capsule of ketoprofen by 28%. The maximum plasma levels of ketoprofen were almost halved and the time to reach this maximum was prolonged by 30%.5

(c) *Tolfenamic acid*

Rectal metoclopramide 20 mg, given to 8 healthy subjects 30 minutes before oral tolfenamic acid 300 mg, caused a threefold increase in the serum tolfenamic acid levels at 45 minutes. There was no change in the maximum level or the AUC.6 In another study, rectal metoclopramide similarly enhanced the rate of oral absorption of tolfenamic acid when given during a migraine attack.7

**Mechanism**

Metoclopramide speeds up gastric emptying. The relatively poorly soluble ketoprofen spends less time in the stomach where it dissolves, and as a result less is available for absorption in the small intestine. Conversely, the absorption rate of tolfenamic acid is increased, without a change in the extent of absorption.

**Importance and management**

The clinical importance of the reduction in ketoprofen levels is unknown, but the authors of the study recommend that ketoprofen (and possibly other NSAIDs that are poorly soluble) should be taken 1 to 2 hours before metoclopramide. Conversely, for aspirin, tolfenamic acid, and other NSAIDs, metoclopramide can be used to increase the rate of absorption, and therefore possibly speed up the onset of analgesic effect in conditions such as migraine.

**NSAIDs + NSAIDs**

The concurrent use of two or more NSAIDs increases the risk of gastrointestinal damage. Diffusilus raises serum indometacin levels about twofold but does not affect naproxen levels. The concurrent use of indometacin and flurbiprofen does not appear to affect the pharmacokinetics of either drug. Floctafenine does not alter diclofenac levels. Indometacin caused renal impairment in a patient recovering from phenylbutazone-induced acute renal failure.

**Clinical evidence**

(a) *Gastrointestinal effects*

The risk of serious upper gastrointestinal bleeding was increased by the use of more than one NSAID in a meta-analysis of data from three case-controlled studies (odds ratio 4.9 with one NSAID and 10.7 with two).1 Another study provided similar findings: the odds ratio was 7.1 with one NSAID and 12.3 with two or more NSAIDs.2 Similar findings have been reported with aspirin and NSAIDs, see ‘NSAIDs + Aspirin; Anti-inflammatory dose’, p.142. Analysis of yellow card reports to the CSM in the UK, of gastrointestinal perforation, obstruction, ulceration or bleeding with diclofenac, naproxen, and ibuprofen, revealed that 6% of the patients were receiving another non-aspirin NSAID.

One pharmacodynamic study in healthy subjects found that gastric instillation of a solution of diffusilus before an indometacin solution prevented the fall in transmucosal potential difference seen with indometacin alone. This was interpreted as evidence that diffusilus protects the human gastric mucosa against the damaging effects of indometacin.3 However, the relevance of this test to the adverse effects of NSAIDs used clinically is unknown. Note that fatal gastrointestinal haemorrhage has been reported in a patient taking diffusilus and indometacin.5

(b) *Pharmacokinetic studies*

No clinically significant changes in the pharmacokinetics of either indometacin 75 mg daily or flurbiprofen 150 mg daily occurred when both drugs were given together. Diffusilus 250 mg twice daily had no effect on plasma levels or urinary excretion of naproxen 250 mg twice daily.7 A study in 16 healthy subjects showed that diffusilus 500 mg twice daily raised the steady-state plasma levels and the AUC of indometacin 50 mg twice daily about twofold. Combined use was associated with more gastrointestinal and CNS adverse effects, but there was no clear effect on blood loss in the faces.8 Another study produced similar findings.9 No change in free diclofenac levels was seen when 6 healthy subjects were given floctafenine 400 mg with diclofenac 75 mg daily for a week.10

(c) *Renal effects*

An isolated report describes deterioration in renal function in a patient during recovery from phenylbutazone-induced renal failure when indometacin 25 mg three times a day was given. The indometacin was discontinued with improvement of renal function.11

**Mechanism**

The damaging effects of the NSAIDs on the gut appear to be additive. Diffusilus may inhibit the glucuronidation of indometacin, or could compete for renal clearance of unmetabolised indometacin.2 All NSAIDs have the propensity to cause renal impairment.

**Importance and management**

The gastrointestinal toxicity of the NSAIDs is well documented, and it appears that combined use increases this risk. The CSM in the UK state that not more than one NSAID should be used concurrently.3,12 The marked rise in plasma levels of indometacin with diffusilus gives an additional reason why this combination in particular should not be used. Some NSAIDs cause more gastrointestinal toxicity than others, a suggested broad ‘rank order’ of seven NSAIDs is as follows: Highest risk (azapropazone); intermediate risk (diclofenac, indometacin, ketoprofen and naproxen, with piroxicam more risky); lowest risk (ibuprofen),12 which has been borne out in another analysis.3 The ranking was based on epidemiological studies and the yellow card database. Ketonolac may also be
particularly associated with gastrointestinal bleeding, and concurrent use with other NSAIDs has been identified as a risk factor,\textsuperscript{13} therefore the manufacturer consequently specifically contraindicates its use with other NSAIDs.\textsuperscript{14}

**NSAIDs or Aspirin + Paracetamol (Acetaminophen)**

Paracetamol levels are increased by diffusional. Aspirin, diclofenac, nabumetone and sulindac pharmacokinetics do not appear to be affected by paracetamol. There is no pharmacokinetic interaction between ibuprofen and paracetamol. Propacetamol, and possibly paracetamol, increase the antplatelet effects of diclofenac, although the evidence is limited and the clinical relevance of this is uncertain.

One epidemiological study found that paracetamol alone, and particularly when combined with NSAIDs, was associated with an increased risk of gastrointestinal bleeding, but other studies have not found such an effect. Two isolated case reports describe renal toxicity in three patients taking ibuprofen or flurbiprofen in which paracetamol was used as a theoretical contributing factor.

**Clinical evidence, mechanism, importance and management**

(a) Antiplatelet effects

In healthy subjects combining single doses of intravenous propacetamol 30 mg/kg and diclofenac 1.1 mg/kg augmented the platelet inhibitory effect of diclofenac by about one-third at 90 minutes post dose. At 5 minutes, the inhibitory effect of both diclofenac alone and the combination was 100%, and by 22 to 24 hours, neither diclofenac alone nor the combination had any antiplatelet effect.\textsuperscript{1} In a previous study, the authors had shown that propacetamol (which is hydrolysed to paracetamol) also inhibited platelet function, and they suggested that the effects of diclofenac and propacetamol were additive.\textsuperscript{1} The clinical relevance of these findings is unclear, but the authors say it should be considered when assessing the risk of surgical bleeding.\textsuperscript{1} Further study is needed.

An in vitro study suggested that high doses of paracetamol, and a combination of paracetamol and diclofenac, may cause platelet inhibition and may increase the risk of bleeding, particularly post-surgery.\textsuperscript{2} Intravenous parecoxib 40 mg was found not to alter the platelet function in 18 healthy subjects when given with intravenous paracetamol 1 g, when compared with paracetamol alone.\textsuperscript{3}

(b) Gastrointestinal damage

In a case-control study of the UK General Practice Research Database from 1993 to 1998 the risk of upper gastrointestinal bleeding or perforation was slightly increased in those taking both aspirin and paracetamol (relative risk 3.3), when compared with aspirin alone (2.4), or paracetamol alone (2.4). Moreover, the risk was markedly increased in those taking NSAIDs and paracetamol (16.6), when compared with NSAIDs alone (3.6). The paracetamol doses used were at least 2 g daily. Paracetamol in doses of less than 2 g daily was not associated with an increased risk. Other cephalosporins and specific NSAIDs were not mentioned.\textsuperscript{1} However, other epidemiological studies have not found any increased risk of upper gastrointestinal bleeding with paracetamol at any dose.\textsuperscript{2} Paracetamol is usually considered not to increase the risk of upper gastrointestinal adverse effects, and the results of this case-control study are probably insufficient to change prescribing practice. Further studies are needed, controlled for the dose of the NSAID and indication for treatment.

(c) Pharmacokinetic studies

1. Aspirin. In a study in 6 healthy subjects, two doses of dextropropoxyphene with paracetamol 65 mg/650 mg, given one hour before and 3 hours after a single 1.2-g dose of soluble aspirin did not affect the plasma salicylate levels. A reduction in plasma salicylate levels was seen in one subject after a single 1.2-g dose of enteric-coated aspirin was taken with dextropropoxyphene and paracetamol, although the authors suggested that this was related to erratic absorption rather than a pharmacokinetic interaction.\textsuperscript{2}

2. Diclofenac. Diclofenac 25 mg given with paracetamol 500 mg, both three times daily for 14 days, had no effect on the pharmacokinetics of diclofenac in 6 healthy subjects.\textsuperscript{2}

3. Diflunisal. Diffusional significantly raised serum paracetamol levels by 50% but the total bioavailability was unchanged in healthy subjects. Diffusional levels were not affected.\textsuperscript{3} This interaction has not been shown to be clinically important. Nevertheless, the manufacturer of diflunisal recommends that the combination should be used with caution, because of the association of high levels of paracetamol with hepatotoxicity.\textsuperscript{4}

4. Ibuprofen. Ibuprofen 400 mg given with paracetamol 650 mg, both every 6 hours for 2 days, had no effect on the pharmacokinetics of either drug in a crossover study in 20 healthy subjects.\textsuperscript{5}

5. Nabumetone. In a single-dose study, the absorption of nabumetone 1 g was not significantly altered by paracetamol 1.5 g.\textsuperscript{6}

6. Sulindac. The manufacturer of sulindac notes that paracetamol had no effect on the plasma levels of sulindac or its sulphide metabolite.\textsuperscript{7}

(d) Renal effects

Two children (aged 12 and 14 years) developed acute flank pain and reversible renal function impairment during the short-term use of flurbiprofen or ibuprofen. They had also taken paracetamol.\textsuperscript{11} Similarly, a 14-month-old infant with febrile status epilepticus was treated with an alternating regimen of paracetamol and ibuprofen, and subsequently developed acute renal failure.\textsuperscript{14} NSAIDs can cause renal toxicity, whereas paracetamol is less likely to cause renal toxicity, except perhaps in overdose.\textsuperscript{15} The authors of the first case report proposed that tubular toxicity of NSAIDs and paracetamol are theoretically synergistic.\textsuperscript{16} This is because NSAIDs inhibit the production of glutathione (needed to prevent the accumulation of toxic metabolites of paracetamol) and renal ischaemia (possibly induced by NSAIDs, or by dehydration) might lead to the accumulation of paracetamol in the renal medulla.\textsuperscript{17}

A review concluded that the available evidence does not support an increased risk of renal toxicity with the use of combination products of aspirin and paracetamol when compared with either drug alone.\textsuperscript{18} Paracetamol is often combined with NSAIDs in the management of chronic pain. In addition, paracetamol and ibuprofen are often used concurrently (as alternating doses) in the management of fever, particularly in children. This latter practice has become controversial. Opponents cite the lack of efficacy data to support combined use (rather than appropriate doses of single agents), and the theoretical increased risk of overdose and renal toxicity.\textsuperscript{17,18} Others consider that, in the absence of true safety issues, professional judgement should be used for recommending combined treatment.\textsuperscript{19} Further study is clearly needed.

### NSAIDs + Phenoxylfline

A review of bleeding events associated with the use of postoperative ketorolac revealed that a small number of patients were also taking phenoxylfline. The UK manufacturers therefore recommend that this drug combination should be avoided, whereas the US manufacturers make no mention of this tentative interaction. There seems to be no evidence regarding this interaction with other NSAIDs.

### NSAIDs + Pesticides

**Chronic exposure to lindane and other chlorinated pesticides can slightly increase the rate of metabolism of phenaclone (antipyrine) and phenylbutazone.**

**Clinical evidence, mechanism, importance and management**

**a) Phenaclone (Antipyrine)**

A study in 26 men occupationally exposed to a mixture of insecticides, predominantly DDT, chlordane and lindane, found that the half-life of phenaclone 10 or 15 mg/kg was reduced from 13.1 hours, in a group of 33 unexposed subjects, to 7.7 hours in the exposed group. The significance of this is unclear as changes in working practices have reduced occupational exposure to such chemicals.

**b) Phenylbutazone**

The plasma half-life of phenylbutazone in a group of men who regularly used chlorinated insecticide sprays (mainly lindane) as part of their work, was found to be 20% shorter (51 hours) than in a control group (64 hours), due, it is believed, to the enzyme-inducing effects of the pes-

---

**NSAIDs + Phenobarbital**

Phenobarbital modestly decreases the AUC of fenoprofen and the clearance of phenylbutazone.

**Clinical evidence, mechanism, importance and management**

In 6 healthy subjects pretreatment with phenobarbital 15 or 60 mg every 6 hours for 10 days reduced the AUC of a single 200-mg dose of fenoprofen by 23% and 37%, respectively.

In 5 healthy subjects the half-life of a single 6-mg/kg dose of phenylbutazone was reduced by 38% after pretreatment with phenobarbital 2 to 3 mg/kg daily for 3 days. Other studies confirm that phenobarbital increases the clearance of phenylbutazone.

The probable reason is that the phenobarbital increases the metabolism of these NSAIDs by the liver, thereby hastening their clearance. Phenylbutazone is metabolised by mixed function oxidase enzymes in the liver, for which reason it is extensively used as a model drug for studying whether other drugs induce or inhibit liver enzymes. In one study phenobarbital caused about a 40% reduction thereby demonstrating that the liver enzymes were being stimulated to metabolise the phenylbutazone more rapidly. The clinical importance of these interactions is uncertain (probably small) but be alert for any evidence of reduced NSAIDs effects if phenobarbital is added.

### NSAIDs + Probencid

Probencid reduces the clearance of dextroketoprofen, diflunisal, indometacin (toxicity seen), ketoprofen, ketorolac, naproxen, sodium meclofenamate, tenoxicam and tiaprofenic acid and raises their levels. Ketorolac and probencid are specifically contraindicated. The uricosuric effects of probencid are not affected by indometacin but may be slightly reduced by sulindac.

**Clinical evidence**

**a) Difluisal**

In 8 healthy subjects probencid 500 mg twice daily increased the steady-state plasma levels of diflunisal 250 mg twice daily by 65%, and reduced the clearances of the glucuronide metabolites.

**b) Indometacin**

A study in 28 patients with osteoarthritis, taking indometacin 50 to 150 mg daily orally or rectally, showed that probencid 500 mg to 1 g daily roughly doubled their indometacin plasma levels and this paralleled the increased effectiveness (relief of morning stiffness, joint tenderness and raised grip strength indices). However, 4 patients developed indometacin toxicity.

Other studies have also demonstrated the marked rise in plasma indometacin levels caused by probencid. Clear signs of indometacin toxicity (nausea, headache, tinnitus, confusion and a rise in blood urea) occurred when a woman with stable mild renal impairment was given probencid. The uricosuric effects of probencid were not altered.
Misoprostol increases the incidence of abdominal pain and diarrhoea when used with diclofenac or indometacin. Isolated cases of neurological adverse effects have been seen with naproxen or pethlybutazone given with misoprostol. However, no important pharmacokinetic interactions seem to occur between aspirin, diclofenac, ibuprofen or indometacin and misoprostol. NSAIDs are reported not to affect the abortive effects of intravaginal misoprostol.

Clinical evidence, mechanism, importance and management

(A) Oral misoprostol

(a) Gastrointestinal adverse effects

A higher incidence of abdominal pain, diarrhoea, nausea and dyspepsia occurred when diclofenac was combined with misoprostol.1,2 Concurrent use of indometacin and misoprostol also resulted in an increase in frequency and severity of abdominal symptoms, frequency of bowel movements and a decrease in faecal consistency.3 The most frequent adverse effect of misoprostol alone is diarrhoea, and this may limit the dose tolerability. When using misoprostol with NSAIDs, warn patients about the possibility of increased stomach pain and diarrhoea. Preparations combining diclofenac or naproxen with misoprostol are available.

(b) Neurological adverse effects

A man with rheumatoid arthritis taking long-term naproxen developed ataxic symptoms a few hours after starting to take misoprostol. He said he felt like a drunk person, staggering about and vomiting. He rapidly improved when he stopped the misoprostol but the adverse symptoms recurred on two further occasions when he restarted misoprostol.4 Adverse effects developed in 3 patients taking phenylbutazone 200 to 400 mg daily when they took misoprostol 400 to 800 micrograms daily.5 One had headaches, dizziness and ambulatory instability that disappeared and then reappeared when the misoprostol was stopped and then restarted. No problems occurred when the phenylbutazone was replaced by etodolac 400 mg daily. The other 2 patients developed symptoms including headache, tingles, dizziness, hot flushes and transient diplopia.6,7 No problems developed when one of them was given naproxen and misoprostol.6 The reasons for this reaction are not understood but theoretically it could possibly be due to a potentiation of the adverse effects of phenylbutazone. The general relevance of these few reports is unclear, but bear them in mind should unexpected neurological effects occur.

(c) Pharmacokinetic studies

No clinically important pharmacokinetic interactions have been found to occur between aspirin 975 mg and misoprostol 200 micrograms,8 or between ibuprofen and misoprostol.1 One study found that misoprostol 800 micrograms daily decreased the AUC of a single 100-mg dose of diclofenac by a modest 20%.9 However, other studies have found that misoprostol had no effect on steady-state diclofenac pharmacokinetics.9 One study found that misoprostol 200 micrograms raised the steady-state levels of indometacin 50 mg three times daily by about 30%,10 whereas another found that misoprostol 400 micrograms twice daily reduced the AUC of indometacin 50 mg twice daily by 13% after one dose and reduced the maximum steady-state plasma concentration by 24%.11 These modest changes in serum indometacin levels are unlikely to be clinically important.
Safe Use of Omeprazole with Other Drugs

NSAIDs and aspirin are frequently avoided before the use of prostaglandins for induction of uterine contractions, because of the theoretical concern that they may inhibit efficacy. For example, the UK manufacturer of dinoprostone says that NSAIDs including aspirin should be stopped before giving intravaginal dinoprostone for induction of labour. However, a study involving 416 women given intravaginal misoprostol to induce early abortion found that the concurrent use of oral NSAIDs did not interact with the efficacy of misoprostol, and the US manufacturer of dinoprostone does not list NSAIDs or aspirin as possible interacting drugs. Further study is needed. Consider also ‘Mifepristone + Aspirin or NSAIDs’, p.1265.

In a preliminary study in 11 healthy subjects, clofenac 100 mg (as enteric-coated tablets) in another study, although it increased the rate of absorption did not significantly affect the plasma levels of either aspirin or salicylic acid. Conversely, enteric-coated salicylate tablets increased plasma levels of aspirin. The antiplatelet activity and the pharmacokinetics of aspirin do not appear to be affected by omeprazole. There was no clinically relevant pharmacokinetic interaction between omeprazole and diclofenac, enteric-coated ketoprofen, naproxen or piroxicam, or between pantoprazole and diclofenac or naproxen, or between omeprazole and naproxen or rofecoxib.

Clinical evidence

(a) Aspirin

In a preliminary study in 11 healthy subjects, omeprazole 20 mg daily for 2 days reduced the serum levels of the salicylic acid metabolite of aspirin at 30 and 90 minutes after a single 650-mg dose of aspirin by 40% and 42%, respectively. However, another study in 14 healthy subjects given omeprazole 20 mg daily for 4 days with a final dose one hour before a single 125-mg dose of aspirin found that omeprazole did not significantly affect the plasma levels of either aspirin or salicylic acid. Omeprazole also did not affect the platelet activity of aspirin. Similarly, omeprazole had no effect on the bioavailability of aspirin (uncoated or enteric-coated tablets) in another study, although it increased the rate of absorption of aspirin from enteric-coated tablets.

(b) Diclofenac

A single 105-mg dose of diclofenac potassium suspension (Flogason) was given to 13 healthy subjects while fasting and after gastric acid secretion blockade with omeprazole. The pharmacokinetics of the diclofenac were not changed to a clinically relevant extent by omeprazole. Similarly, omeprazole 20 mg daily given with diclofenac 50 mg twice daily for one week had no effect on the pharmacokinetics of either drug in 24 healthy subjects.

In another study a single 40-mg oral dose of pantoprazole and diclofenac 100 mg (as enteric-coated Voltarol) were given to 24 healthy subjects together and separately. Neither drug affected the pharmacokinetics of the other.

(c) Ketoprofen

There were no significant changes in the pharmacokinetics of enteric-coated ketoprofen, given with or without omeprazole, although a trend towards higher plasma concentrations with omeprazole was noted, indicating the possibility of increased drug release in the stomach in the presence of an elevated pH.

(d) Naproxen

Naproxen 250 mg twice daily given to healthy subjects with omeprazole 20 mg daily, pantoprazole 40 mg daily, or esomeprazole 40 mg daily for one week had no effect on the pharmacokinetics of either naproxen or the proton pump inhibitor.

(e) Phenoxy (Antipyrine)

The pharmacokinetics of pantoprazole 40 mg orally daily for 8 days was not altered to a clinically relevant extent by a single 5-mg/kg oral dose of phenoxy given on day 8 of the study. Pantoprazole did not affect the pharmacokinetics of phenoxy.

(f) Piroxicam

Omeprazole 20 mg daily given to 24 healthy subjects with piroxicam 10 mg daily for one week had no effect on the pharmacokinetics of either drug.

(g) Rofecoxib

Esomeprazole 40 mg daily given to 30 healthy subjects with rofecoxib 12.5 mg daily for one week had no effect on the pharmacokinetics of either drug from a slight increase in the maximum level and AUC of rofecoxib, which was not thought to be clinically relevant.

Mechanism

Data from animal studies suggest that the absorption and thus the effects of aspirin and NSAIDs can be reduced by omeprazole and H2-receptor antagonists via a pH dependent mechanism. However, note that clinical studies have not found H2-receptor antagonists to have any important effect on the pharmacokinetics of aspirin or NSAIDs, see ‘NSAIDs or Aspirin + H2-receptor antagonists’, p.149. It has been suggested that reducing gastric acidity with omeprazole results in the earlier disruption of enteric-coated tablets, and an increased absorption rate.

Importance and management

The interaction between aspirin and omeprazole is not established. The balance of evidence suggests that omeprazole is unlikely to have an important effect on the pharmacokinetics and efficacy of aspirin. However, because of the uncertainty generated by the animal and preliminary clinical data, it would be of benefit to confirm this in further studies. No clinically significant pharmacokinetic interactions have been identified between any of the other NSAIDs and PPIs cited here, and no drug - drug precautions are needed during concurrent use. For mention that valdecoxib raises plasma levels of omeprazole see ‘NSAIDs; Parecoxib + Miscellaneous’, p.160. Note that omeprazole and other proton pump inhibitors are widely used in the management of gastrointestinal complications of aspirin and NSAIDs.

NSAIDs or Aspirin + Proton pump inhibitors

The platelet activity and the pharmacokinetics of aspirin do not appear to be affected by omeprazole. There was no clinically relevant pharmacokinetic interaction between omeprazole and diclofenac, enteric-coated ketoprofen, naproxen or piroxicam, or between pantoprazole and diclofenac or naproxen, or between omeprazole and naproxen or rofecoxib.

Analgesics and NSAIDs 155
The plasma levels of celecoxib, diclofenac, and etoricoxib are reduced by rifampicin. Metamizole (dipyrone) increased the maximum level of rifampicin. Piroxicam appears unaffected by rifampicin.

**Clinical evidence**

(a) Celecoxib

In 12 healthy subjects pretreatment with rifampicin 600 mg daily for 5 days reduced the AUC of a single 200-mg dose of celecoxib by 64% and increased the clearance by 185%. A preliminary report of another study found broadly similar results.

(b) Diclofenac

A study in 6 healthy subjects found that after taking rifampicin 450 mg daily for 6 days, the maximum serum level of diclofenac, measured 8 hours after a single 100-mg dose of an enteric-coated tablet, was reduced by 43% and the AUC was reduced by 67%.

(c) Etoricoxib

The AUC of a single 60-mg dose of etoricoxib has been found to be reduced by 65% when given on day 8 of a 12-day course of rifampicin 600 mg daily. The maximum plasma concentration of etoricoxib was reduced by 40%.

(d) Metamizole sodium (Dipyrone)

A study in untreated patients with leprosy showed that the pharmacokinetics of a single 600-mg dose of rifampicin were not markedly changed by 1 g of metamizole sodium (dipyrone), but peak serum rifampicin levels increased sooner (at 3 instead of 4 hours) and were about 50% higher.

(e) Phenazone (Antipyrine)

Plasma concentrations following treatment with single 1.2-g oral doses of phenazone were lower after a 13-day course of rifampicin 600 mg daily. The mean AUC of phenazone was reduced by 59% and had not returned to the pre-rifampicin level 13 days after the final rifampicin dose.

(f) Piroxicam

A study in 6 healthy subjects given a single 40-mg dose of piroxicam before and after a 7-day course of rifampicin 600 mg daily found that rifampicin did not significantly alter the pharmacokinetics of piroxicam.

**Mechanism**

Rifampicin is a potent inducer of hepatic enzymes, and it is likely that it increased the metabolism of these NSAIDs.

**Importance and management**

Although information is limited, these pharmacokinetic interactions appear to be established. Their clinical relevance remains to be determined, but it seems likely that the efficacy of these NSAIDs will be reduced by rifampicin. Combined use should be well monitored, and the NSAID dosage increased if necessary. See also ‘NSAIDs; Parecoxib + Miscellaneous’, p.160.

**NSAIDs or Aspirin + SSRRs**

SSRIs may increase the risk of bleeding, including upper gastrointestinal bleeding, and the risk appears to be further increased by concurrent use of NSAIDs and/or aspirin (including low-dose aspirin).

**Clinical evidence**

A retrospective study of the UK general practice research database identified 1651 cases of upper gastrointestinal bleeding diagnosed between 1993 and 1997. Concurrent use of an SSRI significantly increased the risk of bleeding threefold when compared with 10,000 controls. In addition, the concurrent use of an SSRI with an NSAID greatly increased the risk of upper gastrointestinal bleeding (relative risk of bleeding compared with non-use of either drug: 15.6 for SSRIs with NSAIDs, 3.7 for NSAIDs alone, and 2.6 for SSRIs alone); the use of SSRIs with low-dose aspirin was associated with a relative risk of 7.2. Another study found a significant association between the degree of serotonin reuptake inhibition by antidepressants and risk of hospital admission for abnormal bleeding. A retrospective cohort study in elderly patients taking antidepressants found a trend towards an increased risk of upper gastrointestinal bleeding for patients taking antidepressants with greater inhibition of serotonin reuptake. This association was statistically significant when controlled for previous upper gastrointestinal bleeding or age, and octogenarians, in particular, were at high risk. Other studies or case reports have also found that SSRIs increase the risk of upper gastrointestinal bleeding, and this effect is potentiated by the concurrent use of NSAIDs or low-dose aspirin.

In contrast, some workers have disagreed with these results and found no evidence to suggest that SSRIs are more likely to cause gastrointestinal bleeding than other drugs. Another study reported both SSRIs and NSAIDs were associated with a twofold increase in risk of gastrointestinal bleeding, but that the risk of bleeding was not substantially increased when both drugs were taken together (odds ratio for NSAIDs was 2.19, SSRRs was 2.63 and combined use was 2.93).

**Mechanism**

Serotonin is not synthesised by platelets but is taken up into platelets from the bloodstream. Serotonin released from platelets has an important role in regulating the haemostatic response to injury as it potentiates platelet aggregation. At therapeutic doses SSRRs may block this reuptake of serotonin or aspirin (including low-dose aspirin).

**Importance and management**

Serotonin released by platelets plays an important role in haemostasis and there appears to be an association between the use of antidepressant drugs that interfere with serotonin reuptake and the occurrence of bleeding, including gastrointestinal bleeding. In addition, the concurrent use of an SSRI or aspirin (including low-dose aspirin) may potentiate the risk of bleeding. Therefore, the manufacturers of SSRIs advise caution in patients taking SSRIs with NSAIDs, aspirin or other drugs that affect coagulation or platelet function. Alternatives such as paracetamol (acetaminophen) or less gastrotoxic NSAIDs such as ibuprofen may be considered, but if the combination of an SSRI and NSAID cannot be avoided, prescribing of gastroprotective drugs such as proton pump inhibitors, H2-receptor antagonists, or proton pump blockers may be considered, especially in elderly patients or those with a history of gastrointestinal bleeding. Patients,
particularly those taking multiple drugs that may cause bleeding, should be advised to seek informed medical opinion before using non-prescription drugs such as ibuprofen on a regular basis.

7. Dunn NR, Pearce GL, Shaker SA. Association between SSRIs and upper gastrointestinal bleeding. SSRIs are no more likely than other drugs to cause such bleeding. *BMJ* (2000) 320, 1465.

**NSAIDs or Aspirin + Tamarindus indica**

Sucralfate appears not to have a clinically important effect on the pharmacokinetics of aspirin, choline-magnesium trisalicylate, diclofenac, ibuprofen, indomethacin, ketoprofen, naproxen or piroxicam.

**Clinical evidence, mechanism, importance and management**

Sucralfate 2 g was given to 18 healthy subjects 30 minutes before single-doses of ketoprofen 50 mg, indomethacin 50 mg, or naproxen 500 mg. Some statistically significant changes were seen (modestly reduced maximum serum levels of ketoprofen, indomethacin, and naproxen, reduced the NSAIA absorption and increased the indomethacin AUC, and increased the time to achieve maximal serum levels with indomethacin) but no alterations in bioavailability occurred.1 A delay, but no reduction in the total absorption of naproxen is described in two studies.2,3 It is unlikely that its clinical importance of these large increases been evaluated, but this interaction should be borne in mind if high (analgesic or anti-inflammatory) doses of aspirin are taken with this fruit extract. There would seem to be the possible risk of aspirin toxicity.

**NSAIDs or Aspirin + Tamarindus indica**

Tamarindus indica fruit extract markedly increases the absorption and plasma levels of aspirin and ibuprofen.

**Clinical evidence, mechanism, importance and management**

(a) Aspirin

A study in 6 healthy subjects found that the bioavailability of a single 600-mg dose of aspirin was increased when it was taken with a millet meal containing Tamarindus indica fruit extract, compared with the millet meal alone or following overnight fasting. The aspirin AUC rose sixfold, the maximum plasma levels rose almost threefold (from about 10 micrograms/mL with the meal or fasting to about 29 micrograms/mL with the Tamarindus indica extract) and the half-life increased moderately (from about 1.04 to 1.5 hours).2 The reasons are not known, nor has the clinical importance of these large increases been evaluated, but this interaction should be borne in mind if high (analgesic or anti-inflammatory) doses of aspirin are taken with this fruit extract. There would seem to be the possible risk of aspirin toxicity.

(b) Ibuprofen

A study in 6 healthy subjects found that the bioavailability of a single 400-mg dose of ibuprofen was increased when it was taken with a millet meal containing Tamarindus indica fruit extract compared with the millet meal alone, or following overnight fasting. The ibuprofen AUC rose approximately twofold and the maximum plasma levels rose from about 38 micrograms/mL to 45 micrograms/mL. There was also an increase in the plasma levels of the metabolites of ibuprofen. Ingestion of the meal containing Tamarindus indica was thought to favour the absorption of ibuprofen. This might result in an increased risk of toxicity.3

**NSAIDs + Tobacco**

The clearance of diflunisal, phenazone (antipyrine) and phenylbutazone is greater in smokers than in non-smokers.

**Clinical evidence, mechanism, importance and management**

(a) Diflunisal

The clearance of a single 250-mg dose of diflunisal was 35% higher in 6 women who smoked 10 to 20 cigarettes a day than in 6 non-smoking women.4 This change does not appear to be large enough to be of clinical importance.

(b) Phenazone (Antipyrine)

The clearance of phenazone was increased by 63% and the half-life reduced from 13.2 to 8 hours when a single 1-g dose of phenazone was given intravenously to 10 healthy women who smoked cigarettes, when compared with a control group of 26 non-smoking women.5 Similar results were reported in another study.3 This is likely to be as a result of cigarette smoking causing induction of CYPIA2, the enzyme involved in the metabolism of phenazone.2

(c) Phenylbutazone

The half-life of a single 6-mg/kg dose of phenylbutazone was 37 hours in a group of smokers (10 or more cigarettes daily for 2 years) compared with 64 hours in a group of non-smokers. The metabolic clearance was roughly

doubled. The conclusion to be drawn is that those who smoke may possibly need larger or more frequent doses of phenylbutazone to achieve the same therapeutic response, but this needs confirmation.

NSAIDs + Tricyclic antidepressants

The tricyclic antidepressants can delay the absorption of phenylbutazone and oxyphenbutazone from the gut, but their antihypertensive effects are probably not affected.

Clinical evidence, mechanism, importance and management

The absorption of a single 400-mg dose of phenylbutazone in 4 depressed women was considerably delayed (time to maximum level, 4 to 10 hours compared with 2 hours), but the total amount absorbed (measured by the urinary excretion of oxyphenbutazone) remained unchanged when they were pretreated with desipramine 75 mg daily for 7 days. In another study, depressed women in a half-life of oxyphenbutazone was found to be unaltered by 75 mg of desipramine or nortriptyline daily. Animal studies have confirmed that the absorption of phenylbutazone and oxyphenbutazone are delayed by the tricyclic antidepressants, probably because their antimuscarinic effects reduce the motility of the gut, but there seems to be no direct clinical evidence that the antihypertensive effects of either drug are reduced by this interaction. No particular precautions appear to be needed.

NSAIDs; Acemetacin + Miscellaneous

Acemetacin is a glycolic acid ester of indomethacin, and its major metabolite is indometacin. Therefore the interactions of indomethacin would be expected.

NSAIDs; Azapropazone + Chloroquine

The plasma levels of azapropazone are not significantly altered by chloroquine.

Clinical evidence, mechanism, importance and management

A study in 12 subjects given azapropazone 300 mg three times daily found that the plasma levels of azapropazone, measured at 4 hours, were not affected by chloroquine 250 mg daily for 7 days. No special precautions would seem to be needed if these drugs are given together.

NSAIDs; Celecoxib + Selenium

Selenium enriched baker’s yeast does not appear to affect the pharmacokinetics of celecoxib.

Clinical evidence, mechanism, importance and management

In a study in 73 healthy subjects, celecoxib 400 mg was given daily for 2 weeks, then selenium enriched baker’s yeast (Sacharomyces cerevisiae) 200 micrograms daily or matched placebo were added for 30 days. Following blood chemistry analysis (urea and electrolytes, full blood count etc), there were no clinically significant changes from baseline, nor were there any changes in celecoxib steady-state plasma levels.

NSAIDs; Diclofenac + Cefadroxil

Cefadroxil does not alter the pharmacokinetics of diclofenac. The biliary excretion of ceftriaxone is increased by diclofenac.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of diclofenac 100 mg daily were unaffected by either cefadroxil 2 g daily (8 patients) or doxycycline 100 mg daily (7) for one week. No special precautions are needed while taking either of these drugs and diclofenac.

A pharmacokinetic study in 8 patients who had undergone cholecystectomy and who had a T-drain in the common bile duct, found that diclofenac 50 mg every 12 hours increased the excretion of intravenous ceftriaxone 2 g in the bile by about fourfold and roughly halved the urinary excretion. The clinical importance of this is uncertain, but probably small.

Animal studies have shown that diclofenac may alter the pharmacokinetics of some cephalosporins (the AUCs of cefotiam and ceftriaxone were increased by diclofenac, although the pharmacokinetics of cefmenoxime were not affected). The significance of these findings in humans is unknown and further studies are required before any valid conclusions can be drawn from this data.

NSAIDs; Diclofenac topical + Miscellaneous

Topical diclofenac intended for use on the skin is very unlikely to interact adversely with any of the drugs known to interact with diclofenac given orally.

Clinical evidence, mechanism, importance and management

The manufacturer of Pennsaid (a topical solution containing diclofenac 16 mg/mL in dimethyl sulfoxide) says that when the maximum dosage of 1 mL is used on the skin, the maximum plasma levels of diclofenac achieved are less than 10 nanograms/mL. This is 50 times lower than the maximum plasma levels achieved with oral diclofenac 25 mg. Despite these very low concentrations, the manufacturer lists all the interactions that have been observed after systemic administration of diclofenac sodium (aspirin, digoxin, lithium, oral hypoglycaemic agents, diuretics, NSAIDs including other diclofenac preparations, methotrexate, ciclosporin, quinolones and antihypertensives). They note that the risk of these interactions in association with topical use is not known, but is probably low. None of the drugs listed have yet been reported to interact with topical diclofenac.

The manufacturers of other topical preparations (Solaraze 3% w/w gel and Voltarol 1% w/w gel patch) state that interactions are not anticipated due to the low level of systemic absorption, although one manufacturer still warns not to administer concurrently, by either the topical or systemic route, any medicinal product containing diclofenac or other NSAIDs.

Clinical evidence, mechanism, importance and management

An isolated report describes temporary acute renal failure and gastrointestinal bleeding following the use of ketorolac and vancomycin.

Clinical evidence, mechanism, importance and management

A previously healthy middle-aged man developed complete kidney shut down and subsequent gastrointestinal bleeding following uncomplicated surgery and treatment with ketorolac trometamol and vancomycin. The reason for the temporary kidney failure is not known, but the authors of the report suggest that the ketorolac inhibited the normal production of the vasodilatory renal prostaglandins so that renal blood flow was reduced. This would seem to have been additive with nephrotoxic effects of the vancomycin. Note that a vancomycin level taken on postoperative day 3 was found to be above the normal therapeutic range (although the timing of the sample was not stated). Ketorolac alone can cause dose-related and transient renal impairment. It has also been suggested that the trometamol component may be associated with hyperkalaemia. The gastrointestinal bleeding appeared to be due to the direct irritant effects of the ketorolac, possibly made worse by the previous use of piroxicam (see also ‘NSAIDs + NSAIDs’, p.151). The general importance of this interaction is uncertain, but it may be prudent to monitor renal function during concurrent use.

NSAIDs; Ketorolac + Vancomycin

An isolated report describes temporary acute renal failure and gastrointestinal bleeding following the use of ketorolac and vancomycin.

Clinical evidence, mechanism, importance and management

A previously healthy middle-aged man developed complete kidney shut down and subsequent gastrointestinal bleeding following uncomplicated surgery and treatment with ketorolac trometamol and vancomycin. The reason for the temporary kidney failure is not known, but the authors of the report suggest that the ketorolac inhibited the normal production of the vasodilatory renal prostaglandins so that renal blood flow was reduced. This would seem to have been additive with nephrotoxic effects of the vancomycin. Note that a vancomycin level taken on postoperative day 3 was found to be above the normal therapeutic range (although the timing of the sample was not stated). Ketorolac alone can cause dose-related and transient renal impairment. It has also been suggested that the trometamol component may be associated with hyperkalaemia. The gastrointestinal bleeding appeared to be due to the direct irritant effects of the ketorolac, possibly made worse by the previous use of piroxicam (see also ‘NSAIDs + NSAIDs’, p.151). The general importance of this interaction is uncertain, but it may be prudent to monitor renal function during concurrent use.

NSAIDs; Naproxen + Diphenhydramine

There appears to be no significant pharmacokinetic interaction between diphenhydramine and naproxen.

Clinical evidence, mechanism, importance and management

Diphenhydramine hydrochloride 50 mg had no clinically significant effects on the pharmacokinetics of a single 220-mg dose of naproxen sodium in 27 healthy subjects. The pharmacokinetics of diphenhydramine were similarly unaffected by naproxen. No special precautions appear to be necessary.

NSAIDs; Naproxen + Sulglicotide

Sulglicotide does not affect the absorption of naproxen.

Clinical evidence, mechanism, importance and management

Sulglicotide 200 mg had no significant effects on the pharmacokinetics of a single 500-mg dose of naproxen in 12 healthy subjects.

may therefore be used to protect the gastric mucosa from possible injury by naproxen without altering its absorption.

NSAIDs; Naproxen + Zileuton

There appears to be no clinically significant pharmacokinetic or pharmacodynamic interaction between naproxen and zileuton.

Clinical evidence, mechanism, importance and management

In a randomised, placebo-controlled study in 24 healthy subjects zileuton 800 mg every 12 hours was given with naproxen 500 mg every 12 hours for 5 days. No clinically significant change was found in the pharmacokinetics of either drug. Naproxen did not affect the inhibitory effect of zileuton on leukotriene B4 levels and similarly zileuton did not affect the inhibitory effect of naproxen on thromboxane B2. The inhibition of the 5-lipoxygenase pathway by zileuton did not appear to worsen the gastrointestinal effects associated with naproxen. No special precautions would seem necessary.

NSAIDs; Parecoxib + Miscellaneous

As parecoxib is rapidly metabolised to valdecoxib, the interactions are usually considered to be due to the effects of valdecoxib. The manufacturer of parecoxib cautions the concurrent use with carbamazepine, dexamethasone and rifampicin as their effects on parecoxib have not been studied. Valdecoxib increases the levels of dextromethorphan and omeprazole. Because of these interactions, caution is advised with drugs that are metabolised by the same isoenzymes, namely flecainide, metoprolol, propafenone, omeprazole, diazepam, imipramine and phenytoin. No interaction appears to occur between parecoxib and midazolam.

Clinical evidence, mechanism, importance and management

Parecoxib is a parenteral drug that is rapidly metabolised in the liver to the active COX-2 inhibitor valdecoxib. Valdecoxib is predominantly metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP2C9. The interactions therefore are usually considered to be due to the effects of valdecoxib. The manufacturers have done several interaction studies to find out whether parecoxib or valdecoxib can inhibit or induce the cytochrome P450 isoenzymes CYP2C9, CYP2D6, CYP2C19, and CYP3A4 and thereby determine their potential to interact with drugs metabolised by these isoenzymes.

1. CYP2C19. The manufacturers say that the AUC of omeprazole 40 mg was increased by 46% by valdecoxib 40 mg twice daily for a week. This indicates that valdecoxib is an inhibitor of CYP2C19 and although the manufacturers consider it to be a weak inhibitor they suggest that caution should be observed with drugs that have a narrow therapeutic margin and are known to be metabolised by CYP2C19. They list diazepam, imipramine and phenytoin.1 The implication is that the serum levels of these drugs and their effects may possibly be increased by the use of parecoxib, but so far there appears to be no direct clinical reports of any problems with concurrent use.

2. CYP2D6. The manufacturers say that treatment with 40 mg of valdecoxib twice daily for a week caused a threefold increase in the serum levels of dextromethorphan. This indicates that valdecoxib is an inhibitor of CYP2D6, and therefore the manufacturers suggest that caution should be observed with drugs that have a narrow therapeutic margin and are known to be predominantly metabolised by CYP2D6. They list flecainide, metoprolol and propafenone.2 The implication is that the serum levels of these drugs and their effects may possibly be increased by the use of parecoxib, but so far there appears to be no direct clinical reports of any problems with concurrent use.

3. CYP3A4. A study in 12 healthy adults found no significant changes in the pharmacokinetics of midazolam 70 micrograms/kg given an hour after a 40-mg dose of intravenous parecoxib.3 This suggests that parecoxib and valdecoxib are unlikely to inhibit or induce the activity of CYP3A4. This means that parecoxib would not be expected to affect other drugs that are metabolised by CYP3A4.

4. Enzyme inducers. The effects of the enzyme inducers carbamazepine, dexamethasone, phenytoin and rifampicin have not been studied with parecoxib. Nevertheless, the manufacturer of parecoxib warns that they may increase the metabolism of valdecoxib.2

1. Farmacia Ltd. Personal communication, May 2002.

NSAIDs; Phenylbutazone + Methylphenidate

Methylphenidate significantly increased the serum levels of phenylbutazone 200 to 400 mg daily in 5 out of 6 patients, due, it is suggested, to inhibition of liver metabolising enzymes.1 The clinical importance of this is uncertain, especially as the report does not indicate the magnitude of the interaction.

NSAIDs; Sulindac + Dimethyl sulfoxide (DMSO)

Isolated case reports describe serious peripheral neuropathy, which occurred when DMSO was applied to the skin of two patients taking sulindac.

Clinical evidence, mechanism, importance and management

A man with a long history of degenerative arthritis took sulindac 400 mg daily uneventfully for 6 months until, without his doctor’s knowledge, he began regularly to apply a topical preparation containing DMSO 90% to his upper and lower extremities. Soon afterwards he began to experience pain, weakness in all his extremities, and difficulty in standing or walking. He was found to have both segmental demyelination and axonal neuropathy. He made a partial recovery but was unable to walk without an artificial aid.

A second case describes a 68-year-old man with a history of mild osteoarthritis of the knees who was taking sulindac 150 mg twice daily. He later started to apply aqueous solutions of DMSO to his lower extremities, whilst continuing to take sulindac. Within 3 months he reported difficulty in climbing stairs, and myalgia of the thighs and legs. Over the next 5 months he experienced a progressive loss of gait, wasting of thigh and leg muscles, and more intense myalgia, cramps and fasciculations. Nerve conduction studies revealed damage to the nerves. During the year after discontinuing the DMSO, and supplementing his diet with vitamins B6 and B12, the patient showed improvement in the myalgia and physical disabilities, and a return to normal muscle strength. He continued to take the sulindac at a dose of 200 mg twice daily.

The reason for this reaction is not known, but studies in rats have shown that DMSO can inhibit a reductase enzyme by which sulindac is metabolised,2 and it may be that the high concentrations of unmetabolised sulindac increased the neurotoxic activity of the DMSO. Although there are only these two cases on record, its seriousness suggests that patients should not use sulindac and DMSO-containing preparations concurrently.

Opioids + Amphetamines and related drugs

Dexamfetamine and methylphenidate increase the analgesic effects of morphine and other opioids and reduce their sedative and respiratory depressant effects.

Clinical evidence, mechanism, importance and management

Dexamfetamine increased the analgesic effect of morphine and reduced its respiratory depressant effects to some extent in studies during postoperative analgesia and in healthy subjects.

Metoclopramide increases the rate of absorption of oral morphine and increases its rate of onset and sedative effects. However, opioids may antagonise the effects of metoclopramide on gastrointestinal motility. As a reduction in gastric emptying occurs with all opioids they may reduce the rate of absorption of oral opioids.

Clinical evidence

(a) Alizapride

Intravenous alizapride 100 mg given to 60 women undergoing caesarean section under spinal anaesthesia, reduced morphine-induced pruritus, and the amount of sedation (8.3% both peri- and postoperatively) was less than with droperidol, see below.

(b) Droperidol

1. Fentanyl. Epidural droperidol given with epidural fentanyl improved postsurgical analgesia following anorectal surgery and there was less nausea compared with fentanyl alone.

2. Hydromorphone. Early respiratory depression has been reported when droperidol was given 10 minutes before epidural hydromorphone.

3. Morphine. In a double-blind study in 179 patients following abdominal hysterecmy, droperidol 50 micrograms given with morphine 1 mg on demand via patient-controlled analgesia (PCA) provided a morphine-sparing effect and reduced the frequency of postoperative nausea and vomiting, when compared with morphine PCA alone. However, in a study of 107 patients undergoing caesarean section, intravenous droperidol 2.5 mg given just after delivery, reduced the incidence and severity of epidural morphine-induced pruritus, but the incidence of nausea and vomiting was not affected. Furthermore, somnolence was greater in the droperidol-treated patients (17% versus 2% in the control group) but it was never incapacitating. Similar sedative effects were seen with spinal morphine and intravenous droperidol in another study.

(c) Metoclopramide

1. Butorphanol. The pharmacokinetics of a single 1-mg intranasal dose of butorphanol were unaffected by a single 10-mg oral dose of metoclopramide in 24 healthy women. The pharmacokinetics of metoclopramide were also not affected, except for a delay in the time to reach maximum plasma levels (increased from 1 to 2 hours), which was probably due to redistribution of gastrointestinal motility by butorphanol. Metoclopramide reduced the nausea associated with butorphanol, probably by antagonism of central and peripheral dopamine receptors.

2. Morphine. A single 10-mg dose of oral metoclopramide, given to 10 patients before surgery, markedly increased the extent and speed of sedation due to a 20-mg oral dose of modified-release morphine (MST Continus Tablets) in the first 1.5 hours after the dose. The time to peak plasma levels of morphine was almost halved, but peak plasma morphine levels and the total absorption remained unaltered. A study involving 40 patients found that intravenous metoclopramide 10 mg antagonised the reduction in gastric emptying caused by premedication with intramuscular morphine 10 mg given 20 minutes earlier. However, intramuscular metoclopramide given at the same time as the morphine had no effect on the reduced gastric emptying.

Mechanism

Metoclopramide increases the rate of gastric emptying so that the rate of morphine absorption from the small intestine is increased. An alternative idea is that both drugs act additively on opioid receptors to increase sedation.

Importance and management

The effect of metoclopramide on oral morphine absorption is an established interaction that can be usefully exploited in anaesthetic practice, but the increased sedation may also represent a problem if the morphine is being given long-term. The morphine-sparing effect of droperidol is also a useful interaction, but the increased sedation and possible respiratory depression and hypotension should be borne in mind. One manufacturer of fentanyl specifically warns that concurrent use with droperidol can result in a higher incidence of hypotension.

Morphine appears to antagonise the effects of metoclopramide on gastric emptying. As a reduction in gastric motility occurs with all opioids they would all be expected to interact with metoclopramide, and other motility stimulants such as domperidone. However, these drugs are commonly used together and the clinical significance of such effects is not clear.

Consider also ‘Opioids + Antiemetics; Ondansetron’, below.

Opioids + Antiemetics

Ondansetron reduces the analgesic efficacy of tramadol and at least double the dose was required in one clinical study. This resulted in more vomiting despite the ondansetron. In contrast, in studies in healthy subjects, ondansetron had no effect on the analgesic effects of morphine and alfentanil.

Clinical evidence

(a) Alfentanil

In a study in healthy subjects single doses of intravenous ondansetron 8 or 16 mg were found to have no effect on the sedation or ventilatory depression due to alfentanil (a continuous infusion of 0.25 to 0.75 micrograms/kg following a 5 microgram/kg bolus dose) and had no effect on the rate of recovery. Similarly, in another study, intravenous ondansetron 8 mg had no effect on the reaction of 8 healthy subjects to pres-
sure, cold, or electrical stimulation, nor did it oppose the analgesic effect of intramuscular alfentanil 30 micrograms/kg.

(b) **Morphine**

A double-blind, placebo-controlled study in 12 healthy subjects found that a single 16-mg intravenous dose of ondansetron given 30 minutes after a single 10-mg intravenous dose of morphine did not alter the pharmacokinetics of morphine or its metabolites, morphine-3- and morphine-6-glucuronides. The analgesic effect of morphine (as measured by a contact thermode system) was also unaffected by ondansetron.

(c) **Tramadol**

Patients who were given a single 4-mg dose of ondansetron one minute before induction of anaesthesia required 26 to 35% more tramadol by patient-controlled analgesia (PCA) from 1 to 4 hours postoperatively than those who received placebo. Similarly, a 1-mg/hour ondansetron infusion increased the dose of postoperative tramadol used during PCA by two- to threefold in 30 patients, when compared with 29 patients who received placebo. Moreover, in this study the group receiving ondansetron actually experienced more vomiting, probably because they used more tramadol, which caused an emetic effect not well controlled by the ondansetron.

**Mechanism**

On theoretical grounds ondansetron (a 5-HT3-receptor antagonist) might be expected to decrease the effects of drugs that reduce pain transmission because serotonin (5-HT) is thought to affect pain responses via presynaptic 5-HT3 receptors in the spinal dorsal horn. This has been demonstrated for tramadol, which is not a pure opioid and also acts by enhancing the effects of serotonin and noradrenaline (norepinephrine). However, ondansetron had no effect on alfentanil or morphine analgesia in healthy subjects.

**Importance and management**

The interaction between ondansetron and tramadol appears to be established and of clinical importance. Ondansetron may double the dose requirement of tramadol, and so result in increased emetic effects, consequently ondansetron does not appear to be the best antiemetic to use with tramadol. Although not tested, other 5-HT3-receptor antagonists would be expected to interact similarly. Ondansetron appears to have no effect on alfentanil or morphine.

---

**Opioids + Antiepileptics; Enzyme-inducing**

Patients taking enzyme-inducing antiepileptics appear to need more fentanyl than those not taking antiepileptics. Similarly, the efficacy of buprenorphine may be reduced by carbamazepine, phenobarbital and phenytoin. Carbamazepine appears to increase the production of a more potent metabolite of codeine, normorphine. The plasma levels of tramadol are reduced by carbamazepine, and the analgesic efficacy would be expected to be reduced. There is also an increased risk of seizures with tramadol. An isolated report describes pethidine toxicity in a man taking phenytoin. A pharmacokinetic study confirms that phenytoin increases the production of the toxic metabolite of pethidine.

**Clinical evidence, mechanism, importance and management**

(a) **Buprenorphine**

Although interaction studies have not been performed, the metabolism of buprenorphine is mediated by the cytochrome P450 isoenzyme CYP3A4 and therefore drugs that induce this enzyme such as carbamazepine, phenobarbital and phenytoin may induce the metabolism and increase clearance of buprenorphine. The manufacturers of buprenorphine comment that inducers of CYP3A4 may reduce the efficacy of buprenorphine and, if necessary, dose adjustments should be considered, or the combination avoided.

(b) **Codeine**

An experimental study in 7 epileptic patients to find out if carbamazepine induces the enzymes concerned with the metabolism of codeine found that it increased N-demethylation (to norcodeine and normorphine) by two- to threefold, but did not affect O-demethylation (to morphine). The patients were given a single 25-mg dose of codeine before and 3 weeks after starting to take carbamazepine 400 to 600 mg daily. Similarly, an in vitro study found that carbamazepine and phenytoin did not alter the O-demethylation of codeine (methylmorphine) into morphine.

Normorphine is an active metabolite, so that the authors of the first study suggest those taking both codeine and carbamazepine may possibly experience a stronger analgesic effect. However, this needs further study. There would seem to be no reason for avoiding concurrent use.

(c) **Dextropropoxyphene (Propoxyphene)**

Dextropropoxyphene may increase the plasma levels of antiepileptics, particularly carbamazepine, see ‘Carbamazepine or Oxcarbazepine + Dextropropoxyphene (Propoxyphene)’, p.527.

(d) **Fentanyl**

Twenty-eight patients, undergoing craniootomy for seizure focus excision and receiving long-term treatment with antiepileptics in various combinations, needed 48 to 144% more fentanyl during anaesthesia than a control group of 22 patients who were not taking antiepileptics. The fentanyl maintenance requirements in micrograms/kg per hour were:

- 2.7 in the control group,
- 4.0 in patients taking carbamazepine,
- 4.7 in patients taking carbamazepine and phenytoin or valproate,
- 6.3 in patients taking carbamazepine, valproate and either phenytoin or primidone.

Similar results were reported by the same authors in a study involving 61 patients. The increased opioid requirement probably occurs because these antiepileptics are potent enzyme inducers (with the exception of valproate), which increase the metabolism of fentanyl by the liver, so that its levels are reduced. Changes in the state of opiate receptors induced by chronic antiepileptic exposure may also be involved. A marked increase in the fentanyl requirements should therefore be anticipated in any patient receiving long-term treatment with these interacting antiepileptics, but not valproate.

(e) **Methadone**

Methadone levels can be reduced by carbamazepine, phenobarbital or phenytoin. See ‘Opioids; Methadone + Antiepileptics’, p.163.

(f) **Pethidine (Meperidine)**

A 61-year-old man who was addicted to pethidine, taking 5 to 10 g weekly, developed repeated seizures and myoclonus when he also took phenytoin. The problem resolved when both drugs were stopped.

It is known that phenytoin increases the metabolism of pethidine with increased production of norpethidine, the metabolic product of pethidine that is believed to be responsible for its neurotoxicity (seizures, myoclonus, tremors etc). A study found that phenytoin 300 mg daily for 9 days decreased the elimination half-life of pethidine (100 mg orally and 50 mg intravenously) from 6.4 to 4.3 hours, and the systemic clearance increased by 27%. This seems to be the only report of an adverse interaction between phenytoin and pethidine so its general importance is uncertain. Since the study cited found that pethidine given orally produced more of the toxic metabolite (norpethidine) than when given intravenously, it may be preferable to give pethidine intravenously in patients taking phenytoin, or use an alternative opioid. Consider also ‘Opioids + Barbiturates’, p.165.

(g) **Tramadol**

An unpublished study by the manufacturers found that the maximum plasma levels and the elimination half-life of a single 50-mg dose of tramadol were reduced by 50% by carbamazepine 400 mg twice daily for 9 days. It is likely that carbamazepine increases the metabolism of tramadol. On the basis of this study the manufacturers say that the analgesic effectiveness of tramadol, and its duration of action would be expected to be reduced. The US manufacturer recommends avoidance of concurrent use.
use because of the increased metabolism and also the seizure risk associated with tramadol. The UK manufacturer says that patients with a history of epilepsy or those susceptible to seizures should only be given tramadol if there are compelling reasons. Monitor carefully if tramadol and antiepileptics, particularly carbamazepine, are required.

**Clinical evidence, mechanism, importance and management**

A single-dose, placebo-controlled study in 12 healthy subjects given controlled-release morphine 60 mg found that gabapentin 600 mg given after an interval of 2 hours had no effect on the pharmacokinetics of morphine, morphine-6-glucuronide and morphine-6-glucoconuride. In the presence of morphine the gabapentin AUC increased by 44% and its oral clearance and apparent renal clearance decreased by 23% and 16%, respectively. Analytic effect was evaluated by changes in the area under the curve of pain tolerance. Gabapentin plus placebo had no significant analytic effect, but a significant increase in the pain threshold and pain tolerance was found when gabapentin was given with morphine, when compared with placebo. The opioid adverse effects were similar in the gabapentin/morphine and gabapentin/placebo groups. Other clinical studies have reported that gabapentin used in conjunction with opioids has an analgesic and opioid-sparing effect in acute postoperative pain management and neuropathic pain. The manufacturer of gabapentin warns that patients should be carefully observed for signs of CNS depression, such as somnolence, and the dose of gabapentin or morphine should be reduced appropriately.

A study in animals reported a synergistic anticonvulsive interaction between tramadol and gabapentin.

- Neurontin (Gabapentin). Pfizer Ltd. UK Summary of product characteristics, August 2006.

**Clinical evidence**

**(a) Enzyme-inducing antiepileptics**

A study in 37 patients taking methadone maintenance found that those receiving enzyme-inducing drugs (10 patients: taking carbamazepine, phenobarbital or phenytoin) had low trough methadone levels of less than 100 nanograms/mL. One patient taking carbamazepine complained of daily withdrawal symptoms and had signs of opioid withdrawal. Withdrawal symptoms have been seen in other patients taking carbamazepine, phenobarbital, and phenytoin. Similarly, methadone withdrawal symptoms developed in 5 patients within 3 to 4 days of starting to take phenytoin 300 to 500 mg daily. Methadone plasma levels were reduced about 60%. The symptoms disappeared within 2 to 3 days of stopping the phenytoin and the plasma methadone levels rapidly climbed to their former values.

A further patient experienced methadone-induced respiratory depression after discontinuing carbamazepine.

**(b) Lamotrigine**

Lamotrigine-associated rash and blood dyscrasias occurred in a 40-year-old opioid-dependent woman with hepatitis C. Lamotrigine was considered to be the causal factor as haematological values returned to normal 53 days after discontinuation. However, the woman was also receiving methadone maintenance treatment and it was thought that the methadone together with liver impairment might possibly have caused elevated levels of lamotrigine [not measured].

**(c) Valproate**

Two patients who had methadone withdrawal symptoms while taking phenytoin 300 to 400 mg daily, and one of them later when taking carbamazepine 600 mg daily, became free from withdrawal symptoms when they were given valproate instead. It was also found possible to virtually halve their daily methadone dosage.

**Mechanism**

Not fully established, but all of these antiepileptics (except lamotrigine and valproate) are recognised enzyme-inducers that can increase the metabolism of other drugs by the liver, thereby hastening their loss from the body. In one study it was found that phenytoin increased the urinary excretion of the main metabolite of methadone.

**Importance and management**

Information is limited but the interaction between methadone and these enzyme-inducing antiepileptics appears to be established and of clinical importance. Anticipate the need to increase the methadone dosage in patients taking carbamazepine, phenytoin or phenobarbital. It may be necessary to give the methadone twice daily to prevent withdrawal symptoms appearing towards the end of the day. It seems probable that primidone will interact similarly because it is metabolised to phenobarbital. Also be aware of the need to reduce the methadone dose if any enzyme-inducing antiepileptic is stopped. Valproate appears not to interact.

It is unclear whether the methadone or the liver injury contributed to the lamotrigine-associated rash and blood dyscrasias and therefore this isolated cases is of unknown significance.

ids and particularly pethidine (meperidine). A reduction in dosage may be necessary. All sedating antihistamines (see ‘Table 15.1’, (p.582)) would be expected to have additive CNS depressant effects with opioids. This may lead to increased sedation and respiratory depression, and therefore some caution is warranted when both drugs are given.

**Opioids + Azoles**

Several of the opioids (buprenorphine, hydromorphone, methadone) are metabolised by CYP3A, at least in part, and their metabolism is expected to be reduced by the azoles, which, to varying extents, inhibit CYP3A4. This has been seen when fluconazole and voriconazole are given with methadone, and when ketoconazole is given with buprenorphine. It has been suggested that ketoconazole inhibits the metabolism of morphine and oxycodone, but evidence for this is sparse.

**Clinical evidence**

**(a) Buprenorphine**

**Ketoconazole** increases the AUC of buprenorphine by 50% and increases its maximum level by 70% or more; levels of the metabolite norbuprenorphine are less affected.

**(b) Hydromorphone**

An *in vitro* study found that ketoconazole reduced norhydromorphone formation by about 50%.

**(c) Methadone**

1. **Fluconazole.** A randomised, double-blind, placebo-controlled study in 25 patients taking methadone found that fluconazole 200 mg daily for 2 weeks increased the steady-state serum methadone levels and AUC by about 30%, but no signs of methadone overdose were seen and no changes in the methadone dosage were needed. However, a case report describes a man with advanced cancer who had received regular methadone 20 mg every 8 hours and one to three 5-mg rescue doses daily for 10 days, and who rapidly developed respiratory depression of 4 breaths per minute and became unresponsive 4 days after starting fluconazole 100 mg daily, initially orally, then intravenously. Within a few minutes of receiving naloxone he regained consciousness and his respiratory rate increased.

2. **Ketoconazole.** An *in vitro* study suggests that clinically relevant concentrations of ketoconazole decreased the hepatic metabolism of methadone by about 50 to 70%.

3. **Voriconazole.** In a double-blind, placebo-controlled study in 23 patients taking methadone, voriconazole 400 mg twice daily for one day then 200 mg twice daily for 4 days increased the AUC of R-methadone (active) by 47% and S-methadone (inactive) by 103%. Methadone appeared to have no effect on voriconazole pharmacokinetics when compared with a reference study in healthy subjects. There were no signs or symptoms of significant opioid withdrawal or overdose and the combination was generally well tolerated.

**(d) Morphine**

In an *in vitro* study ketoconazole inhibited morphine glucuronidation to morphine-3-glucuronide and morphine-6-glucuronide. The clinical relevance of this is unknown.

**(e) Oxycodone**

The UK manufacturer of oxycodone suggests that inhibitors of CYP3A enzymes such as ketoconazole may inhibit the metabolism of oxycodone, although oxycodone is also metabolised via CYP2D6.

**Mechanism**

Since the metabolism of methadone is mainly mediated by the cytochrome P450 3A4/isoenzyme CYP3A4, methadone clearance can be decreased by drugs that inhibit CYP3A4 activity such as azole antifungals. Buprenorphine is also metabolised by CYP3A4 and may therefore be similarly affected. Most azoles inhibit CYP3A4 to a greater or lesser extent.

**Importance and management**

It has been suggested that although a statistically significant pharmacokinetic interaction occurs between methadone and fluconazole, it is unlikely to be clinically important in patients taking methadone. However, the case report introduces a note of caution. The authors of the second study suggest caution should be exercised if voriconazole is given with methadone and a dose reduction of methadone may be required. Caution may also be warranted with ketoconazole. Further study is needed.

One manufacturer recommends that the dose of buprenorphine should be halved when starting treatment with ketoconazole, and then further titrated as clinically indicated. Other manufacturers recommend close monitoring and possibly a dose reduction if buprenorphine is given with inhibitors of CYP3A4 including azole antifungals such as ketoconazole. The clinical significance of the potential effects of azoles on other opioids, such as hydromorphone, morphine and oxycodone is unclear.

Consider also ‘Opioids; Fentanyl and related drugs + Azoles’, below.

**Opioids; Fentanyl and related drugs + Azoles**

Some patients may experience prolonged and increased alfentanil effects if they are given fluconazole or voriconazole. *In vitro* data suggest iraconazole and ketoconazole may interact similarly. Intravenous fentanyl does not appear to interact with itraconazole in healthy subjects, but one case of possible opioid toxicity from transdermal fentanyl has been reported.

**Clinical evidence**

**(a) Alfentanil**

A double-blind, randomised, crossover study in 9 healthy subjects given intravenous alfentanil 20 micrograms/kg after receiving fluconazole 400 mg, orally or by infusion, found that fluconazole reduced alfentanil clearance by about 60%. Both the alfentanil-induced ventilatory depression and its subjective effects were increased.

A randomised, crossover study in 12 healthy subjects found that oral voriconazole (400 mg twice daily on the first day and 200 mg twice daily on the second day) caused an approximately fivefold increase in the mean AUC of alfentanil 20 micrograms/kg, given intravenously one hour after the last dose of the antifungal. The mean plasma clearance of alfentanil was decreased by 85% and its elimination half-life was prolonged from 1.5 to 6.6 hours. Nausea occurred in 5 subjects and vomiting in 4 subjects.
In a crossover study in 10 healthy subjects the pharmacokinetics and pharmacodynamics of a single 3-micrograms/kg intravenous dose of fentanyl were not altered by itraconazole 200 mg once daily for 4 days. However, the manufacturer says that increased fentanyl plasma concentrations have been observed in individual subjects taking itraconazole, and a case report describes a man with cancer and severe oropharyngeal candidiasis receiving transdermal fentanyl 50 micrograms/hour who developed signs of opioid toxicity (agitated delirium, bilateral myoclonus of muscles in the hand) the day after starting oral itraconazole 200 mg twice daily.

Mechanism
Fluconazole, itraconazole, and voriconazole inhibit the cytochrome P450 isoenzyme CYP3A4 in the liver, which is concerned with the metabolism of alfentanil and fentanyl. However, fentanyl has a high hepatic extraction, and so is more affected by changes in hepatic blood flow than changes in the isoenzymes responsible for its metabolism; it is therefore less affected by CYP3A inhibitors than alfentanil. Sufentanil also has a high hepatic extraction, see ‘Opioids; Fentanyl and related drugs + Macrolides’, p.174.

Importance and management
The interaction of alfentanil with fluconazole and voriconazole appears to be established and clinically important. In vitro data indicate that ketoc- nazole and itraconazole may interact in a similar way. Alfentanil should be given with care to those who have recently received these drugs, and it may be necessary to use a lower alfentanil dose. Be alert for evidence of prolonged alfentanil effects and respiratory depression.

Intravenous fentanyl was not affected by itraconazole in healthy subjects, but the single case report involving transdermal fentanyl introduces a note of caution, particularly in those with unstable advanced disease. Further study is needed. The manufacturers comment that concurrent use of potent CYP3A4 inhibitors including azole antifungals (e.g. flucona- zole, itraconazole, ketoconazole) with oral or transdermal fentanyl may result in increased plasma concentrations of fentanyl. This may increase or prolong both the therapeutic effects and the adverse reactions, which may cause severe respiratory depression. Careful monitoring is re- quired, with dosage adjustment if necessary.

Opioids + Barbiturates
A single case report describes greatly increased sedation with severe CNS toxicity in a woman given pethidine after she took phenobarbital for two weeks. The analogous effects of pethidine can be reduced by barbiturates. Secobarbital increases the respiratory depressant effects of morphine. Other barbiturates would also be expected to increase the CNS depressant effects of opioids.

Clinical evidence
(a) Codeine
A study found that codeine 60 mg increased the hypnotic actions of secobarbital 100 mg resulting in synergism in the sedative effects in pain-free patients.

(b) Morphine
In 30 healthy subjects it was found that both intravenous secobarbital and intravenous morphine depressed respiration when given alone, and a much greater and more prolonged respiratory depression occurred when they were given together. The combination should be used with caution.

(c) Pethidine (Meperidine)
1. Increased pethidine toxicity. A woman whose pain had been satisfactorily controlled with pethidine without particular CNS depression. Good prolonged sedation with severe CNS toxicity when she was given pethidine after taking phenobarbital 30 mg four times daily for 2 weeks.

2. Pethidine effects reduced. Studies in women undergoing dilatation and curettage found that thiopental and phenobarbital increased their sensitivi- ty to pain, and opposed the analgesic effects of pethidine.

(d) Miscellaneous
Increased CNS depression may occur with opioids and other CNS depressants such as hypnotics and manufacturers of several opiates specifically mention that barbiturates can potentiate sedation, respiratory depression, and hypotension. A reduction in dosage may be required. One manufac- turer of methadone contraindicates the use of the injection, but not the oral solution, with other CNS depressants including barbiturates; however, other manufacturers warn of the potential for increased CNS depression, but do not contraindicate barbiturates.

For comment on the effect of enzyme inducers such as phenobarbital on opioid metabolism, see ‘Opioids + Antiepileptics; Enzyme-inducing’, p.162 and ‘Opioids; Methadone + Antiepileptics’, p.163.
Mechanism

Studies suggest that phenobarbital stimulates the liver enzymes concerned with the metabolism (N-demethylation) of pethidine so that the production of its more toxic metabolite (norpethidine) is increased. The toxicity seen appears to be the combined effects of this compound and the directly sedative effects of the barbiturate.8,11

Importance and management

There is only one report of toxicity when phenobarbital was given with pethidine, but metabolic changes have been seen in other patients and subjects. The general clinical importance is uncertain but concurrent use should be undertaken with care. It has also been suggested that if the pethidine is continued but the barbiturate suddenly withdrawn, the toxic levels of norpethidine might lead to convulsions in the absence of antiepileptic.8 Be aware that the barbiturates may reduce analgesia. The metabolic product of pethidine is a less effective analgesic than the parent compound. Both the barbiturates and the opioids have CNS depressant effects, which would be expected to be additive. Therefore care is warranted on concurrent use.

Opioids + Benzodiazepines

In general the concurrent use of opioids and benzodiazepines results in both beneficial analgesic effects, and enhanced sedation and respiratory depression; however, in some cases benzodiazepines have antagonised the respiratory depressant effects of opioids, and, rarely, have antagonised their analgesic effects.

Clinical evidence, mechanism, importance and management

(a) Analgesia

In one study, low-dose midazolam (given to achieve levels of 50 nanograms/mL) reduced the dose of morphine required for postoperative analgesia in the first 12 hours.1 However, in another study postoperative pain scores were higher in patients premedicated with oral diazepam 10 mg than with placebo, although morphine consumption did not differ.2 Similarly, in another study, the benzodiazepine antagonist flumazenil enhanced morphine analgesia in patients who had been premedicated with diazepam.3 It is suggested that benzodiazepines antagonise the analgesic effect of opioids via their effect on supraspinal GABA receptors. Why this has been shown in some studies, but not others, is unclear. Benzodiazepines and opioids are commonly used in surgical anaesthesia, and the relevance of these findings to clinical practice is uncertain.

(b) Overdose

Sudden deaths in patients who abuse opioids are frequently associated with ingestion of other CNS depressants, particularly benzodiazepines. Cases have been reported with buprenorphine,14 15 oxycodone,16 and tramadol17 taken with various benzodiazepines. It has not been established exactly why this occurs, but both pharmacodynamic and pharmacokinetic mechanisms are possible. The deleterious interaction of benzodiazepines and opioids on respiration is possibly due to central effects and/or additive actions on the different neuromuscular components of respiration.8 For buprenorphine, it is considered most likely that excessive CNS depression is solely due to combined pharmacological effects, and not to any pharmacokinetic interaction.9,11 See also Pharmacokinetics, below.

(c) Pharmacokinetics

Intramuscular pethidine 100 mg and intramuscular morphine 10 mg delayed the absorption of oral diazepam 10 mg. Diazepam levels were found to be lower and peak levels were not reached in the 90-minute study period, when compared with the peak level at 60 minutes in the control group.12 The underlying mechanism is that the opioid analgesics delay gastric emptying so that the rate of absorption of the diazepam is reduced. The maximal effect of diazepam would be expected to be delayed in patients receiving these opioids.

Another study in healthy subjects found that dextropropoxyphene 65 mg every 6 hours prolonged the alprazolam half-life from 11.6 to 18.3 hours, and decreased the clearance from 1.3 to 0.8 mL/minute per kg. The pharmacokinetics of single doses of diazepam andlorazepam were not significantly affected.13 It would seem that dextropropoxyphene inhibits the metabolism (hydroxylation) of the alprazolam by the liver, thereby reducing its loss from the body, but has little or no effect on the N-demethylation or glucuronidation of the other two benzodiazepines.

The clinical importance of this is uncertain, but the inference to be drawn is that the CNS depressant effects of alprazolam will be increased, over and above that of simple additive CNS depressant effects likely when other benzodiazepines and dextropropoxyphene are taken together. More study is needed.

Extended-release oxymorphone did not affect the metabolism of midazolam in healthy subjects.14 An in vitro study found that buprenorphine metabolism to norbuprenorphine was only weakly or negligibly inhibited by benzodiazepines, but midazolam had some modest effects and it was suggested that it may possibly cause some clinically relevant inhibition of buprenorphine metabolism.15

(d) Respiratory depression

A 14-year-old boy with staphylococcal pneumonia secondary to influenza developed adult respiratory distress syndrome. It was decided to suppress his voluntary breathing with opioids and use assisted ventilation and he was therefore given pheneridine and diazepam for 11 days, and later diamorphine with lorazepam. Despite receiving diamorphine 19.2 mg in 24 hours his respiratory drive was not suppressed. On day 17, despite serum morphine and lorazepam levels of 320 and 5.3 micrograms/mL respectively, the remained conscious and the pupils were not constricted. Later animal studies confirmed that lorazepam opposed the respiratory depressant effects of morphine.16

In contrast, intravenous diazepam 150 micrograms/kg did not alter the respiratory depressant effect of intravenous pethidine 1.5 mg/kg in a study in healthy subjects17 or in patients with chronic obstructive pulmonary disease.18 Moreover, in the setting of overdose (see (b) above), benzodiazepines might increase the respiratory depressant effects of opioids.

(e) Sedation

The sedative effects of midazolam and morphine were additive in a study in patients given these drugs intravenously prior to surgery. A prospective study of 80 patients undergoing elective endoscopic found that deep sedation occurred frequently (68% of patients) with pethidine and midazolam used with the intent of moderate sedation.20 Another study found that single oral doses of diazepam 10 or 20 mg given to 8 buprenorphine—maintained patients increased subjective effects such as sedation and strength of drug effects, and also caused a deterioration in performance measures such as cancellation time, compared with placebo.21

References

Acute hypotension occurred in a man receiving clonidine, captopril and furosemide who was premedicated with intramuscular midazolam 5 mg and anaesthetised with sufentanil 150 micrograms. This is consistent with another report of sudden hypotension during anaesthetic induction in 4 patients given high-dose sufentanil who had been given lorazepam before induction.13

(d) Pharmacokinetics

A double-blind, placebo-controlled study in 30 patients undergoing orthopaedic surgery found that a single 200-microgram dose of fentanyl given one minute before intravenous midazolam 200 micrograms/kg decreased the systemic clearance of midazolam by 30%. The elimination half-life of midazolam was prolonged by approximately 50%.14

(e) Sedation

A study in patients undergoing an abdominal hysterectomy under alfentanil and midazolam anaesthesia found that although the pharmacokinetics of midazolam were unchanged, postoperative sedation was more pronounced, when compared with a group of patients that did not receive alfentanil.15

Mechanism

Uncertain. The additional use of other CNS depressants may produce additive respiratory depressant and sedative effects. Reduced metabolism of midazolam might also enhance its effects. Why midazolam appeared to increase the analgesic dose requirement for sufentanil is unknown. An in vivo study found that fentanyl competitively inhibited the metabolism of midazolam by the cytochrome P450 isoenzyme CYP3A4.16

Importance and management

Increased sedative and respiratory depressant effects are to be expected when benzodiazepines are used with opioids. The manufacturers of sufentanil17 and alfentanil18 suggest that clinically important hypotension may occur and this may be exacerbated by the use of benzodiazepines: it would seem prudent to be alert for this. The manufacturers of transdermal fentanyl also warn of the possibility of respiratory depression, hypotension, profound sedation and potentially coma with concurrent CNS depressants19 including benzodiazepines.20 When such combined therapy is contemplated, the dose of one or both drugs should be significantly reduced.20

What effect the use of midazolam has on the dose requirement of sufentanil and other opioids in the intensive care setting is unclear, although it would seem that hypotension is a risk.

Opioids; Methadone + Benzodiazepines

Patients taking methadone who are given diazepam may experience increased drowsiness and possibly enhanced opioid effects. Temazepam may have contributed to the sudden death of a patient taking methadone.

Clinical evidence, mechanism, importance and management

A study in patients taking methadone noted that diazepam abuse was prevalent, and that many patients reported that diazepam boosted the effects of methadone.1 The possible reasons for this have been studied. Four addicts, taking methadone for at least 6 months, were given diazepam 300 micrograms/kg for 9 days. The pharmacokinetics of methadone were unaltered and the opioid effects of the methadone remained unchanged, but all 4 subjects were sedated.2 However, another study suggested that the opioid effects of methadone (subjective effects and pupil constriction) may be enhanced by diazepam. This was significant at higher doses (methadone at 150% of the maintenance dose with diazepam 40 mg).3 Later analysis of blood samples from this study confirmed that there is no pharmacokinetic interaction between methadone and diazepam.4 It has been suggested that the absence of increased opioid effects in the earlier study may possibly be explained by the relatively low regular daily doses of diazepam they used, in contrast to the higher more intermittent doses used in the later study, which is the pattern of dosage reportedly used by patients. A further study in patients taking methadone found that single oral doses of diazepam 10 or 20 mg, which are within the usual therapeutic range, increased subjective effects such as sedation, strength of drug effects and euphoria, and also caused a significant deterioration in performance measures such as reaction time, when compared with placebo.5 A 39-year-old man taking methadone 60 mg daily and temazepam 20 mg twice daily was found dead. Blood levels of methadone and temazepam were not particularly high, and revealed that amitryptiline had also been taken. The cause of death was considered to be accidental owing to methadone toxicity enhanced by temazepam and amitryptiline.6 Another case is reported of ventricular arrhythmias associated with high-dose methadone given with CYP3A4 substrates including midazolam.7

Concurrent use involving low-to-moderate diazepam dosage should not be avoided, but patients given both drugs are likely to experience increased drowsiness and reduced psychomotor performance and should be warned against driving or operating machinery under these circumstances. With a high diazepam dose the possibility of opioid enhancement should be borne in mind. Bear in mind that concurrent use of diltiazem and alfentanil requires special patient care and observation; it may be necessary to lower the dose of alfentanil.8

Enhanced analgesia

A double-blind, placebo-controlled study in 26 patients undergoing surgery found that 2 doses of slow-release nifedipine 20 mg given on the day preceding surgery and a further dose given 60 to 90 minutes before surgery increased the analgesic effect of morphine.9 A study in animals found that verapamil potentiated morphine analgesia.10 A further study in animals found that diltiazem, nimodipine and verapamil, given before morphine, potentiated the analgesic effect of morphine and markedly increased morphine serum levels.11

Opioids + Cannabis

Low doses of cannabis enhanced the effect of morphine in three patients. Animal studies have shown that cannabinoids may enhance the potency of opioids.

Clinical evidence, mechanism, importance and management

A report of 3 patients with chronic pain (due to multiple sclerosis, HIV-related peripheral neuropathy, and lumbar spinal damage) found that small doses of smoked cannabis potentiated the antinociceptive effects of morphine. The patients were able to decrease the dose of opioid by 60 to 100%.12 Studies in animals have shown that ∆9-tetrahydrocannabinol, the major psychoactive constituent of cannabis, enhances the potency of opioids such as morphine, codeine, hydromorphone, methadone, oxymorphone and pethidine (meperidine).13-14 It has been suggested that low doses of ∆9-tetrahydrocannabinol given with low doses of morphine may increase opioid potency without increasing adverse effects.15 Cannabis use in methadone-maintained patients did not appear to affect treatment progress, although some psychological difficulties were slightly more prevalent.16 However, other workers have suggested that heavy cannabis use is associated with poorer progress when methadone is given in the treatment of opioid addiction.17

Opioids + Calcium-channel blockers

Bradycardia and hypotension may be enhanced in patients taking opioids with calcium-channel blockers. The analgesic effects of morphine appear to be enhanced by some calcium-channel blockers. Diltiazem prolonged the effects of alfentanil in one study.
Opioids + Carisoprodol

Carisoprodol may enhance the CNS depressant effects of opioids.

Clinical evidence, mechanism, importance and management

A 49-year-old woman who had been taking oxycodone (OxyContin) 40 mg twice daily for more than a year was given carisoprodol 350 mg (one tablet) four times daily because of muscle spasm and uncontrolled pain. After taking this regimen for a week without relief, she increased the dosage to 8 to 10 tablets daily. She was found unconscious, was responsive only to painful stimuli, and her respiration was also depressed. She rapidly returned to full alertness when she was given naloxone 2 mg intravenously, although she had not taken any extra oxycodone tablets. The adverse effects were thought to be due to additive CNS depressant effects of both oxycodone and carisoprodol.1 In a retrospective review of deaths recorded in Jefferson County over a 12-year period, carisoprodol was present in the blood of 24 cases, but was never the sole drug detected; dextropropoxyphene (propoxyphene) was also present in 8 of the 24 cases. Respiratory depression was a major cause of death and as carisoprodol causes respiratory depression, it was considered to be probably responsible, in part, for those deaths.2

The manufacturer of carisoprodol reports that effects of overdose can be additive with other CNS depressants and that concurrent use of other CNS depressants should be avoided. Dependence has occurred with carisoprodol.3

Opioids + Chlorobutanol

Chlorobutanol used as a preservative may possibly contribute to the QT prolongation seen with methadone. Higher maximum trough levels were observed among newborns exposed to morphine that contained chlorobutanol than those exposed to morphine without chlorobutanol. Somnolence in a patient on high-dose morphine may have been due to the effects of morphine and also to a high intake of chlorobutanol preservative.

Clinical evidence, mechanism, importance and management

(a) Methadone

A study in patients receiving intravenous methadone found an approximately linear relationship between the log-dose of methadone and QTc measurements. In addition, methadone and chlorobutanol (a preservative used in intravenous methadone preparations) were both found to block cardiac potassium ion channels in vitro, and chlorobutanol potentiated this effect with methadone.1 High doses of methadone have been reported to cause torsades de pointes, but chlorobutanol used as a preservative in methadone injection may possibly contribute to the QT prolongation.1

(b) Morphine

A report describes a 19-year-old woman who required increasing doses of morphine to control pain, reaching a peak of 275 mg/hour, which was maintained for 4 days. After palliative radiotherapy the rate was reduced to 100 to 150 mg/hour, but only partial pain relief was achieved; however, the patient was somnolent, which was attributed to an effect of the chlorobutol. At doses of morphine 275 mg/hour, chlorobutanol intake was 90 mg/hour, which is in excess of the dose used to aid sleep (150 mg);

Opioids + Food

Food can delay the absorption of dextropropoxyphene (propoxyphene), but the total amount absorbed may be slightly increased. Food increases the bioavailability of oral morphine solution and produces a sustained serum level, however, the absorption of some controlled-release preparations of morphine may be delayed by food. Food may also increase the bioavailability of oxycodone solution, but sustained-release preparations of oxycodone and tramadol and immediate-release hydromorphone appear not to be affected by food.

Clinical evidence, mechanism, importance and management

Studies in animals suggest that ingestion of sucrose for short duration may activate the endogenous opioid system and may modify morphine withdrawal.1,2 Sucrose ingestion has also been shown to alleviate pain and distress in infants and adults.1

Opioids + Cocaine

Cocaine-related torsade de pointes occurred in a patient taking methadone. Ventricular arrhythmias and increased cardiovascular effects have been reported when other patients taking methadone were given cocaine. The cardiovascular effects of cocaine and morphine appear to be similar to those seen with cocaine alone.

Clinical evidence, mechanism, importance and management

A 46-year-old woman who had been taking methadone 80 mg daily for over one year, started abusing cocaine by inhalation and injection and subsequently developed frequent self-limiting episodes of syncpe. These syncopal events consistently occurred within an hour of cocaine use. She was admitted to hospital after collapsing and becoming comatose and was found to have torsade de pointes arrhythmia. She developed irreversible anoxic brain injury secondary to cardiac arrest. Although methadone can cause QT prolongation, the serum methadone level was well within the therapeutic range and it was felt that several factors might have contributed to the arrhythmias including cocaine abuse.1 Another patient taking methadone was withdrawn from a study due to the occurrence of premature ventricular contractions for several minutes after a single 32-mg/70 kg intravenous dose of cocaine.2 Furthermore increased cardiovascular effects (e.g. increased diastolic pressure and heart rate) have been reported when cocaine is given to patients taking methadone.1 Both cocaine and methadone are considered to have effects on the QTc interval and both are potassium-channel blockers. The combination of these two drugs creates a potentially dangerous risk for torsade de pointes.3

In contrast, a study in 9 healthy subjects found that although the combination of morphine and cocaine produced significant cardiovascular and subjective effects, for the most part, the cardiovascular effects were similar to those produced by cocaine alone. Neither cocaine nor morphine altered the plasma levels of the other drug.4

Opioids + Food

Food can delay the absorption of dextropropoxyphene (propoxyphene), but the total amount absorbed may be slightly increased. Food increases the bioavailability of oral morphine solution and produces a sustained serum level, however, the absorption of some controlled-release preparations of morphine may be delayed by food. Food may also increase the bioavailability of oxycodone solution, but sustained-release preparations of oxycodone and tramadol and immediate-release hydromorphone appear not to be affected by food.

Clinical evidence, mechanism, importance and management

Studies in animals suggest that ingestion of sucrose for short duration may activate the endogenous opioid system and may modify morphine withdrawal.1,2 Sucrose ingestion has also been shown to alleviate pain and distress in infants and adults.1

A study in healthy subjects given a single 130-mg dose of dextropropoxyphene (as capsules) found that while fasting, peak plasma dextropropoxyphene levels were reached after about 2 hours. High-fat and high-carbohydrate meals delayed peak serum levels by about 1 hour, and high protein delayed the peak serum levels by about 2 hours. Both the protein and carbohydrate meals caused a small 25 to 30% increase in the total amount of dextropropoxyphene absorbed. The delay in absorption probably occurs because food delays gastric emptying. Avoid food if rapid analgesic effects are needed.

A crossover study in 24 healthy subjects found that food had no clinically relevant effect on the pharmacokinetics of a single 8-mg dose of immediate-release hydromorphone.8

(c) Morphine

Twelve patients with chronic pain were given oral morphine hydrochloride 50 mg in 200 mL of water either while fasting or after a high-fat breakfast (fried eggs and bacon, toast with butter, and milk). The maximum blood morphine levels and the time to achieve these levels were not significantly altered by the presence of the food, but the AUC was increased by 34% and blood morphine levels were maintained at higher levels over the period from 4 to 10 hours after the morphine had been given.2 The reasons are not understood. The inference to be drawn is that pain relief is likely to be increased if the morphine solution is given with food. This appears to be an advantageous interaction. More confirmatory study is needed.

Some differences in pharmacokinetic parameters have also been reported between the fed and fasted states for controlled-release formulations, but these are not necessarily translated into measurable differences in the pharmacodynamic effects of pain relief and adverse effects.9 One single-dose study found that the AUC, maximum plasma level, and time to maximum plasma level were increased by food, when compared with the fasting state for two modified-release morphine tablets available in the United Kingdom (MST Continus; Oramorph SR).2 Whereas in another single-dose study, no difference in these pharmacokinetic parameters was found for MS Contin (Purdue Frederick Company, USA) between the fed and fasted states.2 Yet another single-dose study reported that the rate of absorption of morphine from sustained-release morphine sulfate capsules (Kaplon; Purdue Frederick Company USA) was slower with food; there was a 28% increase in the absorption half-life and a 19% increase in the time to maximum plasma level, but the AUC and maximum plasma level were not significantly affected.2 However, another study reported that sustained-release capsules contained in modified-release capsules in fasted subjects.2

Most of these studies used single doses in healthy subjects and food was given in the form of a high-fat breakfast and although it appears that there might be some delay in the absorption of some sustained-release preparations of morphine with food, the overall effect is unlikely to be clinically significant.

(d) Oxycodone

A study in 22 healthy subjects found that the bioavailability of oxycodone as an immediate-release solution was significantly altered by consumption of a high-fat meal; the AUC was increased by 20% and the maximum plasma level was decreased by 18%, when compared with the fasted state. However, there was no significant effect of food on the bioavailability of oxycodone given as a controlled-release tablet.11

(e) Tramadol

In an open, crossover study in 24 healthy subjects, tramadol sustained-release capsules were found to be bioequivalent with and without concurrent food intake (high-fat breakfast).12

**Opioids + Glutethimide**

A study in animals suggested that glutethimide might potentiate and prolong the analgesic effect of codeine by increasing plasma levels of morphine. Glutethimide combined with codeine can produce a euphoric state and may be addictive; seizures and psychosis have been reported.1

**Opioids + Grapefruit juice**

Grapefruit juice has been associated with a modest increase in oral methadone bioavailability. Grapefruit juice does not appear to affect the bioavailability of intravenous alfentanil or transmucosal fentanyl to a clinically significant extent; the clearance of oral alfentanil may be reduced.

**Clinical evidence, mechanism, importance and management**

(a) Alfentanil

A study in 10 healthy subjects found that grapefruit juice had no effect on the bioavailability of intravenous alfentanil. However, the clearance of oral alfentanil was reduced by about 40% and the maximum plasma level and oral bioavailability were increased by approximately 40% and 60%, respectively. This was thought to be due to selective inhibition of intestinal CYP3A by grapefruit juice. Therefore should alfentanil be given orally its effects would be expected to be increased and prolonged.

(b) Fentanyl

In a study in 12 healthy subjects, grapefruit juice had minimal effect on peak plasma levels or clinical effects of oral transmucosal fentanyl, despite a considerable proportion of the dose being swallowed and absorbed enterally.2

(c) Methadone

A study in 8 patients taking methadone found that 200 mL of grapefruit juice given 30 minutes before and also with their daily dose of methadone was associated with a modest increase in methadone bioavailability. The mean AUC and the maximum plasma levels increased by about 17%. A study in healthy subjects found that grapefruit juice caused a similar modest increase in methadone bioavailability following oral methadone, but had no effect on intravenous methadone bioavailability. The increase in methadone levels were not considered to be clinically significant in the patients studied.2 On the basis of this evidence dosage adjustments of methadone seem unlikely to be necessary in the presence of grapefruit juice.

Opioids + H2-receptor antagonists

No clinically significant interaction appears to occur between cimetidine and butorphanol (intranasal), hydromorphone, morphine, pethidine or tramadol; between famotidine and hydromorphone; or between ranitidine and hydromorphone, morphine, or pethidine. However, isolated reports describe adverse reactions in patients taking methadone, morphine or mixed opium alkaloids with cimetidine, or morphine with ranitidine.

Clinical evidence

(a) Butorphanol

The pharmacokinetics of intranasal butorphanol 1 mg every 6 hours and oral cimetidine 300 mg every 6 hours for 4 days were not significantly altered by concurrent use in 16 healthy subjects, except for a moderate increase in the elimination half-life of cimetidine.1

(b) Hydromorphone

The US manufacturer of hydromorphone says that the concurrent use of H2-receptor antagonists (cimetidine, famotidine, ranitidine) had no significant effect on hydromorphone steady-state pharmacokinetics.2

(c) Methadone

An in vitro study briefly mentions an elderly patient receiving methadone 25 mg daily who developed apnoea 2 days after starting cimetidine 1.2 g daily.3 Another elderly patient taking methadone 5 mg every 8 hours by mouth and subcutaneous morphine 8 mg every 3 hours also developed apnoea (respiratory rate 2 breaths per minute) after receiving intravenous cimetidine 300 mg every 6 hours for 6 days. This was controlled with naloxone. The patient had previously shown no ill effects from the administration of morphine while taking cimetidine and methadone.4

(d) Morphine

1. Cimetidine. In a study in 7 healthy subjects cimetidine 300 mg four times daily for 4 days had no effect on the pharmacokinetics of a single 10-mg dose of intravenous morphine. The extent and duration of the morphine-induced pupillary miosis was also unchanged.5 In other healthy subjects, cimetidine 600 mg, given one hour before a 10-mg dose of intramuscular morphine prolonged the respiratory depression due to morphine, but the extent was small and not considered to be clinically significant.6 Another study in 118 patients undergoing major abdominal surgery found that there were no significant differences between the effects of preoperative or postoperative intravenous cimetidine 4 mg/kg or placebo on postoperative pain intensity, sedation score, cumulative morphine consumption, or the incidence of adverse effects.7

In contrast, an acutely ill patient with grand mal epilepsy, gastrointestinal bleeding and an intertrochanteric fracture who was undergoing haemodialysis three times a week, was taking cimetidine 300 mg three times daily. After being given the sixth dose of intramuscular morphine (15 mg every 4 hours) he became apnoeic (three breaths per minute), which was managed with naloxone. He remained confused and agitated for the next 80 hours with muscular twitching and further periods of apnoea controlled with naloxone. He had received nine 10-mg intramuscular doses of morphine on a previous occasion in the absence of cimetidine without problems. About a month later he experienced the same adverse reactions when given opium alkaloids while still taking cimetidine (see below).8

Apnoea has also been reported in a patient receiving morphine, methadone and cimetidine, see (c) above.

2. Ranitidine. A man with terminal cancer receiving intravenous ranitidine 150 mg every 8 hours became confused, disoriented and agitated when given the ranitidine after an intravenous infusion of morphine 50 mg daily was started. When the ranitidine was stopped his mental state improved but worsened when he was given ranitidine again 8 hours and 16 hours later. He again improved when the ranitidine was stopped.9

Similarly, another report describes hallucinations in a patient receiving ranitidine and sustained-release morphine followed by rectal methadone, but the author discounted the possibility of an interaction.10

Mechanism

Cimetidine inhibits the activity of the liver enzymes concerned with the N-demethylation of methadone11 and pethidine,12 reducing their metabolism, so they accumulate in the body, thereby exaggerating their respiratory depressant effects. A reduction in liver function might possibly have contributed towards, or even been largely responsible for the cases with methadone, because both patients were elderly. The isolated cases of possible interactions between morphine and H2-receptor antagonists remain unexplained.9 In vitro studies have shown that the conjugation of morphine is not affected by cimetidine or ranitidine,16 although one study in 8 healthy subjects suggested that ranitidine might slightly increase the bioavailability of morphine.17

Importance and management

The virtual absence of a generally important interaction between morphine and cimetidine is adequately documented. Concurrent use normally causes only a slight and normally unimportant prolongation of the respiratory depression due to morphine, but it might possibly have some importance in patients with pre-existing respiratory disorders. One manufacturer warns that cimetidine may inhibit the metabolism of morphine,18 and another warns that, because of the isolated report (see (d) above), patients should be monitored for increased respiratory and CNS depression.19 In vitro evidence suggests that ranitidine is unlikely to interact with morphine,20 although one pharmacokinetic study indicated that ranitidine might not affect the pharmacokinetics of pethidine.21

Information about the interaction between pethidine and cimetidine is very limited, and its clinical importance is uncertain, but probably small given the minor changes in pharmacokinetics. However, some manufacturers warn that cimetidine may inhibit the metabolism of pethidine,20,21 and thus caution should be used with concurrent use.22 Ranitidine has been shown not to affect the pharmacokinetics of pethidine.23

It also seems doubtful if the interaction between methadone and cimetidine is of any general importance when the two isolated reports cited here are viewed against the background of the widespread use of both of these two drugs for a good number of years and the lack of other published adverse reports. However, some manufacturers warn that methadone clearance may be decreased when it is given with drugs that inhibit CYP3A4 activity including cimetidine.22,23 There is no clinically important pharmacokinetic interaction between intranasal butorphanol and oral cimetidine, between hydromorphone and H2-receptor antagonists, or between tramadol and cimetidine. Consider also ‘Opioids; Fentanyl and related drugs + H2-receptor antagonists’, p.172.
Opioids + Haloperidol

A patient treated with long-term haloperidol and morphine experienced extrapyramidal symptoms when naloxone was given.

Clinical evidence, mechanism, importance and management

An 18-year-old woman with nasopharyngeal carcinoma who had been treated with long-term haloperidol and morphine developed profound extrapyramidal adverse effects during an attempt to reverse an intrathecal morphine overdose with naloxone. It was suggested that long-term morphine treatment might suppress haloperidol-induced extrapyramidal symptoms through its antiserotonin and dopaminergic effects. Abrupt opioid withdrawal could be potentially hazardous in patients who are also taking haloperidol.1

Opioids + Herbal medicines

St John’s wort reduces the plasma concentrations of methadone and withdrawal symptoms may occur. Some herbal teas may contain opioids.

Clinical evidence, mechanism, importance and management

Some herbal preparations may actually contain opioids; the morphine content of two herbal teas containing Papaveris fruticos was found to be 10.4 micrograms/mL and 31.5 micrograms/mL, respectively. Furthermore, morphine was detected in the urine of 5 healthy subjects one hour after drinking 2 cups of either of the herbal teas and was maximal at 4 to 6 hours: positive urine samples were detected up to 6 to 9 hours after drinking the teas.1 Therefore it may be expected that additive CNS depressive effects will occur if teas such as this are taken with other opioid preparations.

In contrast, a study in 4 patients taking methadone found that St John’s wort (Jarsin) 900 mg daily for 14 to 47 days decreased methadone plasma concentration-to-dose ratios (indicating decreased methadone levels) by 19 to 60%. Two patients reported symptoms that suggested a withdrawal syndrome.2 St John’s wort (Hypericum perforation) is metabolised in the liver and induces the cytochrome P450 enzyme CYP3A4 and P-glycoprotein, and so could affect plasma levels of drugs metabolised in this way including methadone2 and other natural or some synthetic opioids.3

Opioids + Hormonal contraceptives

The clearance of morphine is roughly doubled by combined oral contraceptives. Combined oral contraceptives do not appear to alter the pharmacokinetics of pethidine. The manufacturer of buprenorphine predicts that gestodene may increase plasma levels of buprenorphine.

Clinical evidence, mechanism, importance and management

(a) Buprenorphine

Although no data from clinical studies are available, the manufacturer predicts that inhibitors of the cytochrome P450 isoenzyme CYP3A4 such as gestodene may increase exposure levels to buprenorphine and a dose reduction should be considered when initiating treatment.1 Halving the starting dose of buprenorphine has been suggested for patients taking CYP3A4 inhibitors and receiving buprenorphine as a substitute for opioid depend-

Opioids; Fentanyl and related drugs + H2-receptor antagonists

Cimetidine, but not ranitidine, increases the plasma levels of alfentanil. Some preliminary observations suggest that the effects of fentanyl may be increased by cimetidine.

Clinical evidence, mechanism, importance and management

(a) Alfentanil

In a pharmacokinetic study in 19 intensive care patients, intravenous cimetidine 1.2 g daily for 2 days was given with a single 125-microgram/kg intravenous dose of alfentanil. When compared with an oral aluminum/magnesium hydroxide antacid or intravenous ranitidine 500 mg daily the cimetidine increased the alfentanil half-life by 75 and 61%, respectively, and reduced the clearance by 64 and 54%, respectively. The alfentanil plasma levels were significantly raised by the cimetidine, probably because cimetidine inhibits the metabolism of the alfentanil.1 Whether the alfentanil effects are increased to a clinically important extent awaits assessment. However, be alert for increased alfentanil effects because pharmacokinetic changes of this size are known to be clinically important in some patients (see ‘macrolides’, (p.174) and ‘azoles’, (p.164)). The manufacturer of alfentanil warns that alfentanil is metabolised mainly by CYP3A4, and therefore inhibitors of this enzyme, including cimetidine, could increase the risk of prolonged or delayed respiratory depression. The concurrent use of such drugs requires special patient care and observation; it may be necessary to lower the dose of alfentanil.2,3

Ranitidine does not appear to interact.1

(b) Fentanyl

The terminal half-life of fentanyl 100 micrograms/kg was reported to be more than doubled, from 155 to 340 minutes, by pretreatment with cimetidine (10 mg/kg the night before and 5 mg/kg 90 minutes before the fentanyl dose). This increase in half-life probably occurs because cimetidine inhibits the metabolism of fentanyl by the liver, thereby delaying its clearance from the body.1 The clinical importance of this interaction has not been assessed, but if both drugs are used concurrently, be alert for increased and prolonged fentanyl effects.

ence. However, the same manufacturer suggests that, since the magnitude of an inhibitory effect is unknown, such drug combinations should be avoided when buprenorphine is used parenterally or sublingually as a strong analgesic.2,3 Note that, there appear to be no cases or studies reporting interactions where gestodene is acting as a CYP3A4 inhibitor.

(b) Morphine

The clearance of intravenous morphine 1 mg and oral morphine 10 mg was increased by 75% and 120%, respectively, in 6 young women taking a combined oral contraceptive.4 It is suggested that the oestrogen component of the contraceptive increases the activity of the liver enzyme (glucuronyl transferase) concerned with the metabolism of morphine, which results in an increased clearance. This implies that the dosage of morphine would need to be increased to achieve the same degree of analgesia. Whether this is so in practice requires confirmation.6

(c) Pethidine (Meperidine)

One early study suggested that 4 of 5 women taking a combined oral contraceptive ( mestranol with norethynodrel or norethisterone) excreted more unchanged pethidine in the urine than a control group of 4 women not taking contraceptives, who were found to excrete more of the deacetylated metabolite.5 However a later, well-controlled, comparative study in 24 healthy subjects (8 women taking a combined oral contraceptive containing ethinylestradiol/norgestrel 50/500 micrograms, and 8 women and 8 men not taking contraceptives) found no differences between the plasma levels or excretion patterns of pethidine between the three groups.6 No special precautions appear to be needed if pethidine is given to women taking combined oral contraceptives.

Opioids + Interferons

 Peginterferon alfa does not affect the pharmacokinetics of methadone, but an isolated report describes a patient who relapsed to heroin use following treatment with peginterferon. Methadone maintenance does not appear to affect the pharmacokinetics of peginterferon alfa or the virological response to interferons. Similarly, buprenorphine does not appear to influence the effect of interferon.

Clinical evidence, mechanism, importance and management

A study involving 22 patients with chronic hepatitis C who had been receiving methadone maintenance for a least 3 months found that subcutaneous peginterferon alfa-2a 180 micrograms once weekly for 4 weeks did not influence the pharmacokinetics of methadone to a clinically significant extent. The pharmacokinetics of peginterferon alfa-2a did not appear to be altered by methadone when compared with values from other patients.1 However, a case report describes a patient who stopped taking methadone and then relapsed to heroin use approximately 5 months after completing treatment of chronic hepatitis C with peginterferon and ribavirin.2 Although interferon does not appear to affect methadone levels pharmacokinetically, patients taking methadone may experience increased cravings while receiving antiviral therapy because the adverse effects may mimic opioid withdrawal symptoms. Craving may also be secondary to mood changes caused by antiviral therapy or be related to the use of needles used to deliver interferon.3 It may, therefore, be necessary to increase the dose of methadone during interferon treatment.2,3

Although opioids may possibly facilitate the outbreak of infections through immunomodulating effects on the immune response against a virus, several studies suggest that the use of opioids (buprenorphine,3 methadone1,4) has no effect on the outcome of treatment with interferons4-6 ( peginterferon alfa-2b4) in heroin addicts with chronic hepatitis C.3,5

Opioids + Local anaesthetics

Chloroprocaine can reduce the efficacy of epidural morphine and fentanyl anaesthesia. Bupivacaine may enhance the local anaesthetic effect of fentanyl, but does not appear to affect respiration. Similarly, lidocaine does not appear to increase respiratory depressant effects of morphine. However, two cases of respiratory depression have been reported with lidocaine and opioids. Morphine given as an intravenous bolus does not alter lidocaine serum levels given as a continuous intravenous infusion.

Clinical evidence, mechanism, importance and management

(a) Bupivacaine

A study involving 40 elderly patients undergoing spinal anaesthesia found that bupivacaine 9 mg, with fentanyl 20 micrograms reduced the incidence of hypotension compared with bupivacaine 11 mg alone. Respiratory rate were not depressed in either group. The rate of failed spinal block and discomfort was similar in both groups. The addition of the fentanyl allowed a reduction in the minimum dose of bupivacaine to produce an adequate block, and consequently less hypotension.1

(b) Chloroprocaine

Two studies2,3 have found that chloroprocaine decreases the duration of epidural morphine analgesia (16 hours for chloroprocaine compared with 24 hours for lidocaine).2 Another study found that morphine requirement after caesarean section were much higher in women who had received chloroprocaine for epidural anaesthesia than in those receiving lidocaine.3 The authors of one of the studies suggest that chloroprocaine should be avoided if epidural morphine is used.2 Epidural fentanyl also appears to be antagonised by chloroprocaine.3

(c) Lidocaine

A double-blind study in 10 patients who were receiving continuous lidocaine infusions during suspected myocardial infarction found that a 10-mg intravenous morphine sulfate bolus did not significantly alter the steady-state serum levels of lidocaine.4 In another study, giving lidocaine with exradural morphine did not increase the risk of respiratory depression associated with the morphine.5 However, in one case, respiratory depression occurred within 5 minutes of giving intravenous lidocaine for an episode of ventricular tachycardia in a patient who had previously been given spinal fentanyl and morphine. Naloxone successfully reversed this.6 Similarly, respiratory depression occurred in a 3-year-old boy given lidocaine with adrenaline (epinephrine) about 5 minutes after a subcutaneous injection of the narcotic alphadolpnone. Again naloxone reversed the respiratory depression.7

An isolated report describes a marked increase in the effects of dextromoramide, resulting in coma, in a man treated with trolean-odomycin. Macrodex containing trolean-odomycin and erythro-mycin are predicted to increase buprenorphine bioavailability. Similarly, the metabolism of hydromorphone is reduced by trolean-odomycin in vitro. Some manufacturers have suggested that the metabolism of methadone and oxycodone may be decreased by these macrolides, but there do not appear to be any clinical re-

Clinical evidence (a) Erythromycin

Erythromycin 500 mg twice daily for 7 days increased the mean half-life of alfentanil in 6 subjects from 84 to 131 minutes and decreased the clearance by 26%. The two most sensitive subjects had considerable changes with only one day of erythromycin treatment, and overall showed a marked change. The other 4 subjects had only small or moderate changes.1 A 32-year old man undergoing exploratory laparotomy was given erythromycin 1 g and neomycin 1 g, both three times daily, on the day before surgery. During the induction and maintenance of anaesthesia he received a total of 20.9 mg of alfentanil. An hour after recovery he was found to be unrousable and with a respiratory rate of only 5 breaths per minute. He was successfully treated with naloxone.2 Another patient given alfentanil and erythromycin is said to have developed respiratory arrest during re-

Opioids + Magnesium compounds

Magnesium compounds can potentiate opioid analgesia, although some studies have failed to find an effect. Magnesium sulfate may also reduce opioid requirements during anaesthesia.

Clinical evidence, mechanism, importance and management

Several clinical studies have found that magnesium enhances the analgesic effect of opioids, including intrathecal magnesium with intrathecal fentanyl,1 and intravenous magnesium with intravenous remifentanil,2 or intravenous tramadol. However, one placebo-controlled study found that perioperative administration of intravenous magnesium sulfate did not reduce the pain in patient-controlled pethidine (meperidine) consumption following caesarean delivery. Further, intraoperative blood loss appeared to increase.4 Another study found a similar lack of effect of intravenous magnesium on the amount of morphine used postoperatively.5

Magnesium sulfate infusion also decreased sufentanil requirements for sedation6 and reduced the drug requirements of propofol, droperidol and fentanyl during anaesthesia.1 Intrathecal magnesium sulfate prolonged the period of spinal anaesthesia induced by bupivacaine and fentanyl without additional adverse effects, but the onset of anaesthesia was also significantly delayed.2 Magnesium sulfate may also prolong the effects of the ‘competitive neuromuscular blockers’; (p.125).

Divalent cations appear to be involved in the pain pathway and magnesium sulfate can potentiate the opioid analgesic effect,6 possibly by antagonism of N-methyl-D-aspartate receptor ion channels.3,8 It has been suggested that as magnesium ions do not easily cross the blood brain barrier, the intrathecal use of magnesium may modulate pain relief via central effects, whereas the intravenous route mainly only affects peripheral mechanisms.2

Opioids + NRTIs

Zidovudine had no effect on methadone levels in one study, but there is one report of a patient requiring a modest increase in methadone dose after starting zidovudine. Similarly case reports describe patients requiring a modest increase in methadone dose after starting abacavir. Methadone can increase zidovudine serum levels, and reduce levels of abacavir, stavudine, and didano sine from the tablet formulation, but not the enteric-coated capsule preparation. Tenofovir, and a single dose of zidovudine/lamivudine had no effect on methadone pharmacokinetics.

Clinical evidence

(a) Abacavir

Eleven patients given abacavir had a 23% increase in the rate of methadone clearance but no change in the half-life or renal clearance. In addition, there was a delay, and a 34% decrease in the peak concentration of abacavir, but no change in abacavir clearance or half-life.1 Of 3 patients taking methadone who started taking abacavir, lamivudine and zidovudine, 2 required methadone dosage increases (31% and 46%, respectively). The abacavir was thought to be responsible for this effect.2 A patient receiving methadone experienced oversdes de pointes when receiving abacavir, lamivudine and zidovudine.3

(b) Didanosine

A study in 17 subjects taking methadone found that the AUC and maximum levels of didanosine tablets were 57% and 66% lower, respectively, than when compared with 10 control subjects. Trough levels of methadone were not different from historical controls, suggesting that didanosine had no effect on methadone pharmacokinetics.4 A later study found that there was no reduction in the AUC of didanosine given as enteric-coated capsules.5

(c) Stavudine

A study in 17 subjects taking methadone found that the AUC and maximum levels of stavudine were 23% and 44% lower, respectively, when compared with 10 control subjects. Trough levels of methadone did not differ from historical controls, suggesting that stavudine had no effect on methadone pharmacokinetics.4

(d) Tenofovir

In a study in 13 healthy subjects receiving methadone, tenofovir 300 mg daily for 2 weeks did not alter the pharmacokinetics of methadone, and no symptoms of opioid toxicity or opioid withdrawal were detected.6

(e) Zidovudine

1. Buprenorphine. In one study, there was no difference in the pharmacokinetics of oral zidovudine between patients receiving buprenorphine and placebo. Buprenorphine is not expected to cause zidovudine toxicity.

2. Methadone effects reduced or unaffected. A drug abuser with AIDS needed an increase in his levomethadone (R-methadone) dosage from 40 to 60 mg daily, within a month of starting to take zidovudine 1 g daily.7
In contrast, a study found no evidence of any change in the pharmacokinetics of methadone in HIV-positive patients taking methadone 14 days after they started zidovudine 200 mg every 4 hours. No methadone withdrawal symptoms occurred. Another study in 16 patients taking methadone found that a single-dose of a fixed combination of zidovudine 300 mg with lamivudine 150 mg (Combivir) had no effect on the pharmacokinetics of methadone, and there was no evidence of withdrawal or toxicity.

3. Zidovudine effects increased. In one study the mean AUC of zidovudine was increased by 43% by methadone, and in 4 of 9 patients it was doubled. In another study, 8 HIV-positive patients starting methadone found a 29% increase in the AUC of oral zidovudine and a 41% increase in the AUC of intravenous zidovudine. Three of the 8 patients stopped zidovudine because of adverse effects or haematologic toxicity.13 Decreased zidovudine clearance in patients taking methadone is described in another report.12

Mechanism

Uncertain. It appears that methadone reduces the bioavailability of didanosine, and to a lesser extent, stavudine, possibly because it delays gastric emptying. Thus, the enteric-coated didanosine preparation appears not to be affected.4,5 Conversely, methadone apparently reduces the glucuronidation of the zidovudine by the liver, resulting in an increase in its serum levels.13 Methadone may also reduce renal clearance of zidovudine.11

Importance and management

The increase in zidovudine levels with methadone is established, although the clinical relevance is uncertain. Be alert for any increase in zidovudine adverse effects. The balance of evidence suggests that zidovudine is unlikely to reduce methadone levels, and the one case reported remains unexplained, although note that some of the adverse effects of zidovudine may be mistaken for opioid withdrawal effects. The reduction in didanosine levels with methadone may be clinically relevant, and the authors suggest increasing the dose of the tablet formulation. Monitor virological response. The enteric-coated didanosine preparation is not affected and it may therefore be worth considering using this preparation instead. The reduction in stavudine levels and the changes in abacavir peak levels with methadone are probably not clinically relevant, but again, further data are required. The reports with abacavir suggest that it would be prudent to monitor methadone dose requirements when this drug is prescribed. Tenofovir does not appear to affect methadone levels.

Opioids; Methadone + NNRTIs

Methadone plasma levels can be markedly reduced by efavirenz or nevirapine and withdrawal symptoms have been seen. In contrast, delavirdine slightly increased methadone levels in one study.

Clinical evidence

(a) Delavirdine

The pharmacokinetics of delavirdine 600 mg twice daily did not differ between 16 HIV-negative subjects taking methadone and 15 healthy control subjects. In another study methadone did not affect delavirdine pharmacokinetics. However, delavirdine decreased methadone clearance and increased its AUC by 19%.2

(b) Efavirenz

An HIV-positive woman who had been taking methadone for over a year began to complain of discomfort within 4 weeks of having nelfinavir replaced by efavirenz 600 mg daily, and by 8 weeks typical methadone withdrawal symptoms were occurring late in the afternoon. It was found that the levels of R-methadone (the active enantiomer) had fallen from 168 to 90 nanograms/mL, and those of the S-methadone from 100 to 28 nanograms/mL. The methadone dosage had to be increased from 100 mg to 180 mg daily before the symptoms disappeared.3 A further case is reported in which a man taking methadone stopped taking efavirenz 600 mg daily because of the occurrence of withdrawal symptoms in spite of increased methadone dosage.4 Another report describes a man who required a 133% increase in his methadone dose over 4 weeks after starting efavirenz, and mentions two other patients who complained of opioid withdrawal shortly after starting efavirenz. They also required methadone dose increases.5

In a pharmacokinetic study, 11 patients taking methadone 35 to 100 mg daily were given efavirenz with two nucleoside analogues. Nine of the patients developed methadone withdrawal symptoms and needed dose increases of 15 to 30 mg (mean 22%). A pharmacokinetic study of these patients found that 3 weeks after starting efavirenz their mean methadone AUCs were reduced by 57% and their maximum plasma levels by 48%.5 Similar results were found in another study in 5 HIV-positive patients taking methadone: 4 patients experienced opioid withdrawal symptoms and a mean methadone dose increase of 52% was required.7 In another retrospective study, 6 out of 7 patients needed methadone dosage increases of 8% to 200% within 2 weeks to 8 months of starting an efavirenz-based regimen.8

(c) Nevirapine

A retrospective review revealed 7 cases of patients taking methadone who developed withdrawal symptoms after starting regimens including nevirapine. The symptoms developed within 4 to 8 days, and methadone dose increases of 21% to 186% were required. Despite this, 3 patients did not respond. They elected to discontinue nevirapine, and in 2 of them somnolence developed within 2 weeks, so the methadone dosage was reduced. Methadone plasma levels were available in 2 patients, and these suggested that nevirapine decreased methadone levels by about 90%.9 In a pilot study of a once daily nevirapine-containing regimen, 30% of patients required an increase in methadone dosage.10 In another study 4 of 5 patients taking methadone developed withdrawal symptoms on starting nevirapine-containing regimens and 2 refused further nevirapine, despite increasing their methadone dose. Another 2 patients were successfully treated with increases in their methadone doses of 33% and 100%.11 Three other similar cases have been reported.1,2,13

In a pharmacokinetic study, 8 patients taking methadone 30 to 120 mg daily had methadone levels measured before and 14 days after starting an antiretroviral regimen including nevirapine 200 mg daily. The methadone AUC decreased by 52%, and the maximum level by 36%. Patients complained of symptoms of methadone withdrawal, and required a mean increase in methadone dose of 16%.14

Mechanism

Efavirenz and nevirapine induce the metabolism of methadone (possibly by the cytochrome P450 isoenzyme CYP3A4, or CYP2B6), which results in reduced levels and effects. In contrast, delavirdine is an inhibitor
Importance and management

The interaction between methadone and efavirenz or nevirapine is established and of clinical importance. Some authors have found that the dose increase required is much less than that predicted based on the reduction in methadone levels.5,8,9 Whereas others have questioned this.5,6 It may be important not to confuse the adverse effects of the NNRTIs with withdrawal symptoms. It has been suggested that patients talking methadone who are given these drugs should be screened for opioid withdrawal beginning on the fourth day of the new medication. If symptoms develop, the methadone dose should be increased by 10 mg every 2 to 3 days until symptoms abate.57 However, others have suggested dose increments should be made at one-week intervals to avoid overdose, as methadone has a half-life expected to range from 13 to 72 hours.5 Note that some patients may require an increase in methadone dose frequency to twice daily.11 If efavirenz or nevirapine is stopped, the methadone dose should be gradually reduced to pretreatment levels over the course of 1 to 2 weeks.1

The US manufacturers of delavirdine1 suggest that the methadone dose reduction be reduced; however, the effects in the study reported are small, and would not be expected to be of clinical significance.

Mechanism

Buprenorphine is a substrate for the cytochrome P450 isoenzyme CYP3A4 and inducers of CYP3A enzymes such as efavirenz would be expected to increase buprenorphine clearance, whereas delavirdine, which is an inhibitor of CYP3A, would be expected to reduce the CYP3A-mediated metabolism of buprenorphine to norbuprenorphine.

Importance and management

Despite the magnitude of the changes in buprenorphine levels seen with efavirenz and delavirdine, clinically significant consequences of these interactions on opioid withdrawal symptoms, cognitive effects and adverse effects were not observed and it was suggested that dosage adjustments were not likely to be necessary. However, the study was in HIV-negative subjects and it has been suggested that the interaction may be of significant in HIV-positive individuals.3 More clinical studies in HIV-positive patients are needed. Furthermore, the study showing QT-prolongation with these NNRTIs and buprenorphine suggest that some caution would be prudent.

The manufacturers predict that inhibitors of the cytochrome P450 isoenzyme CYP3A4 [such as delavirdine] may increase the exposure to buprenorphine.1-7 One manufacturer recommends close monitoring and possibly a dose reduction; halving the starting dose of buprenorphine has been suggested by another manufacturer for patients taking CYP3A4 inhibitors and receiving buprenorphine as a substitute for opioid dependence.4 However, the same manufacturer suggests that, since the magnitude of an inhibitory effect is unknown, such drug combinations should be avoided when buprenorphine is used parenterally or sublingually as a strong analogy.5,6

Opioids + Buprenorphine + NNRTIs

Preliminary evidence suggests that buprenorphine does not affect the antiretroviral efficacy or pharmacokinetics of delavirdine and efavirenz. Delavirdine may increase buprenorphine plasma levels and may increase buprenorphine’s clearance in patients with these NNRTIs, but the clinical significance has not been fully investigated. Delavirdine given with buprenophine/naloxone has been shown to slightly prolong the QT interval.

Clinical evidence

A study in 20 opioid-dependent subjects taking buprenorphine with naloxone found that efavirenz 600 mg daily for 15 days decreased the AUC of buprenorphine and its metabolite, norbuprenorphine, by approxi-

Opioids + NSAIDs

Ketoprofen reduced morphine-associated respiratory depression, and did not alter morphine pharmacokinetics. Similarly, diclofenac did not alter morphine pharmacokinetics in one study. Improved pain relief and reduced adverse effects have been found when morphine was given with lornoxicam, ketoprofen, or ketorolac. However, in another, diclofenac slightly increased respiratory depression and reduced morphine use, partly because of persistent levels of an active metabolite of morphine. Diclofenac did not affect the pharmacokinetics or analgesic effects of codeine in healthy subjects. Intramuscular diclofenac did not affect the pharmacokinetics of methadone solution in cancer patients. Ibuprofen did not appear to interact

---

pharmacokinetically with oxycodeone. No pharmacokinetic interaction occurred between meclofenamate and dextropropoxyphene, and dextropropoxyphene did not alter sulindac plasma levels. A single case report describes marked respiratory depression in a man given buprenorphine when ketorolac was added. An isolated report describes grand mal seizures in a patient given diclofenac and pentazocine. For mention of other NSAIDs see ‘coxibs’, (p.179).

Clinical evidence, mechanism, importance and management

NSAIDs are often administered with opioids because they usually reduce the opioid requirements and some of the opioid-induced adverse effects. Enhanced pain relief has been reported with various combinations including dextromethorphan with ketorolac or tenoxicam, oxycodeone with ibuprofen, and tramadol with ketorolac without increased adverse effects. See also ‘coxibs’, (p.179). However, cases of respiratory depression have been reported, see Morphine below. Myoclonus has been reported with high doses of morphine administered with NSAIDs, see ‘Opioids; Morphine + Miscellaneous’, p.190.

(a) Buprenorphine

A man underwent thoracotomy for carcinoma of the middle third of his oesophagus. An hour after transfer to the recovery ward he complained of severe pain at the operative site and was given epidural buprenorphine 150 micrograms (3 micrograms/kg), and 2 hours later intramuscular ketorolac 30 mg because of continued pain. During the next hour he became more drowsy, stopped obeying commands and his respiratory rate dropped to 6 breaths per minute. He recovered after 6 hours of mechanical ventilation. The authors of this report suggest that it may be necessary to use less buprenorphine in the presence of ketorolac to avoid the development of these respiratory depressant effects. This appears to be the only report of this possible interaction.

As with other opioids, NSAIDs such as etodolac have been used with buprenorphine to reduce the postoperative pain score without increasing side effects.

(b) Codeine

A single 50-mg dose of diclofenac sodium did not have an important effect on the pharmacokinetics of a single 100-mg dose of codeine phosphate in a placebo-controlled crossover study in 12 healthy subjects. There was no effect on the metabolic clearance of morphine, and only a slight (about 5% to 10%) increase in the levels of glucuronid metabolites. In addition, diclofenac did not alter the analgesic effects of codeine as assessed in a cold pressor test (a test in which opioids, but not NSAIDs, are effective).

These findings are in contrast to an earlier in vitro study by the same research group, which found that diclofenac markedly inhibited the glucuronidation of codeine in human liver tissue.

Although this interaction perhaps requires confirmation in a multiple-dose study in a clinical setting, the findings in healthy subjects suggest that no special precautions were required during the concurrent use of diclofenac and codeine.

Single oral-dose studies in 24 healthy subjects showed that the bioavailability of both codeine phosphate 25 mg and ibuprofen 200 mg were unaffected by concurrent use.

(c) Dextropropoxyphene (Propoxyphene)

In healthy subjects dextropropoxyphene 260 mg daily and sodium meclofenamate 400 mg daily for a week was found to have no effect on the plasma levels of either drug.

The manufacturer of sulindac notes that dextropropoxyphene had no effect on the plasma levels of sulindac or its sulfide metabolite.

(d) Methadone

Intramuscular diclofenac 75 mg twice daily given for 5 days with oral methadone solution every 8 hours had no effect on the AUC or maximum plasma levels of methadone in 16 patients with cancer pain. No special precautions would appear to be necessary during concurrent use.

(e) Morphine

An infusion of ketorolac 1.5 mg/kg with morphine 100 micrograms/kg reduced the respiratory depression associated with morphine alone in 11 healthy subjects. There was no change in plasma morphine levels. Another study in 6 patients found that intramuscular diclofenac 75 mg twice daily for 5 days did not affect the half-life and AUC of oral morphine solution. Other studies have reported superior pain relief with morphine and NSAIDs e.g. lornoxicam, ketoprofen, and ketorolac, with fewer adverse effects. See also ‘coxibs’, (p.179).

However, in contrast to the reports of a study in 7 patients on the first postoperative day after spinal surgery found that, although diclofenac 100 mg rectally reduced patient-controlled morphine consumption by 20%, respiratory rates were significantly lower after the diclofenac, and minimal at about 200 minutes. Levels of an active metabolite, morphine-6-glucuronide did not significantly decrease until 420 minutes.

NSAIDs are frequently used with opioids because of their lack of respiratory depression and opioid-sparing effects. However, this study demonstrates that there may be a risk of respiratory depression and other adverse effects due to persistently high levels of morphine-6-glucuronide for a number of hours after receiving an NSAID. During this time period, patients should be more closely monitored.

For mention of the suggestion that NSAIDs may increase the incidence of myoclonus with high-dose morphine, see ‘Opioids; Morphine + Miscellaneous’, p.190.

(f) Oxycodeone

A study involving 23 healthy subjects found that the single-dose pharmacokinetics of ibuprofen 400 mg and oxycodeone 5 mg were similar when given as monotherapy or in combination.

(g) Pentazocine

A man with Buerger’s disease had a grand mal seizure while watching television 2 hours after being given a single 50-mg suppository of diclofenac. He was also taking pentazocine 50 mg three times daily. He may possibly have had a previous seizure some months before taking a single 100-mg slow-release diclofenac tablet. The reasons for this reaction are not known, but on rare occasions diclofenac alone has been associated with seizures (incidence said to be 1 in 100 000) and seizures have also been seen with pentazocine alone. It is not clear what part the disease itself, or watching television, had in the development of this adverse reaction.

No interaction between diclofenac and pentazocine is established, but be aware of this case if concurrent use is being considered, particularly in patients who are known to be seizure-prone.

Opioids + NSAIDs; Coxibs

Parecoxib had no effect on the pharmacokinetics of alfentanil or fentanyl, and celecoxib and rofecoxib appeared not to affect the pharmacokinetics of tramadol. Coxibs can reduce the perioperative opioid requirement, but adverse effects are not necessarily reduced.

Clinical evidence, mechanism, importance and management

(a) Pharmacokinetic studies

In a crossover study in 12 healthy subjects intravenous parecoxib 40 mg, given one hour before and 12 hours after an infusion of alfentanil 15 micrograms/kg or fentanyl 5 micrograms/kg, had no effect on the pharmacokinetics of these opioids.1 Pupill diameter versus time curves were not affected by parecoxib. This interaction was investigated because both valdecoxib (the main metabolite of parecoxib) and alfentanil are substrates of the cytochrome P450 isoenzyme CYP3A4. The study suggests there should be no interaction during concurrent use. In a study in patients receiving stable doses of celecoxib or rofecoxib, the pharmacokinetics of tramadol (given with paracetamol) did not appear to be affected by the coxibs. Tramadol is metabolised by CYP2D6 and CYP3A4, but there appeared to be no difference in the clearance of tramadol given with celecoxib (potential to interact with CYP2D6 substrates) and is itself metabolised in part by CYP3A4.2

(b) Pharmacodynamic studies

Many studies have reported reduced opioid requirements and reduced opioid-related adverse effects when coxibs include celecoxib,3 parecoxib,4 and rofecoxib5 are given perioperatively or postoperatively with various opioids including hydrocodone6 and morphine.7 The timing of the coxib administration appears to affect the opioid-induced analgesia and post-infusion increases in sensitivity to pain. One study in healthy subjects found that pretreatment with parecoxib increased the analgesic effects of a remifentanil infusion and significantly diminished the increased sensitivity to pain after remifentanil was withdrawn. Giving parecoxib at the start of the remifentanil infusion did not alter its analgesic effects.8 In another study, patients given preoperative and postoperative rofecoxib, or placebo, found that rofecoxib reduced morphine requirements and pain scores. In another group of patients given placebo preoperatively and rofecoxib postoperatively, rofecoxib did not significantly affect morphine requirements or pain score at 24 hours after the operation compared to those given placebo pre-and postoperatively, but did show improvement at 48 hours and 72 hours after the operation. However, preoperative rofecoxib was considered to provide only moderate benefit and possibly offered little benefit for early postoperative administration.9

In a double-blind, placebo-controlled study in 72 patients undergoing laparoscopic cholecystectomy, oral etoricoxib 120 mg given 1.5 hours before surgery reduced the need for postoperative patient controlled analgesia (PCA) with fentanyl, but opioid-related adverse effects were not reduced.10 Furthermore, the safety of short-term perioperative use of coxibs has been questioned, as some studies have reported more adverse effects (including myocardial infarction, cardiac arrest, stroke, and pulmonary embolism) with parecoxib or valdecoxib compared with placebo.8

Opioids + Opioids

The concurrent use of two opioid agonists may have enhanced effects, although acute opioid tolerance may also occur. Opioids with mixed agonist/antagonist properties (e.g. buprenorphine, butorphanol, nalbuphine, pentazocine) may precipitate opioid withdrawal symptoms in patients taking pure opioid agonists (e.g. fentanyl, methadone, morphine).

Clinical evidence, mechanism, importance and management

Many of the opioids used clinically act primarily at µ receptors including morphine, codeine, fentanyl, methadone and diamorphine, but they often have non-µ pharmacological effects, and patients tolerant to one opioid can frequently be switched to another opioid (opiod rotation) at doses lower than predicted by relative potencies.1 Studies in animals have found synergistic or additive effects between µ-opioids.2 The majority of studies in patients have reported enhanced analgesic effects with opioid combinations,3 although combined opioids are not always beneficial;4 in some cases adverse effects were increased and acute opioid tolerance has also occurred.5 For example, a study in 69 patients who had undergone abdominal surgery and were receiving morphine found that the addition of a tramadol infusion was associated with improved patient-controlled analgesia and smaller morphine requirement with no increase in adverse effects.6 However, another study found that the effects of this combination were less than additive.7 Furthermore, the incidence of opioid withdrawal occurred more frequently and it was concluded that the use of two µ-opioid agonists in combination might only increase the number of adverse effects.8 Other studies have found that transdermal fentanyl reduced morphine requirements after hysterectomy9,10 without affecting sedation scores.11 However, the combination of fentanyl and morphine resulted in more pronounced respiratory depression than morphine alone.12 In contrast, in a study of 49 patients undergoing major abdominal surgery, relatively large doses of intraoperative remifentanil (mean remifentanil infusion rate 300 nanograms/kg per minute) was reported to almost double morphine requirements in the first 24 hours postoperatively. The results suggested that remifentanil caused the development of acute opioid tolerance and excessive sensitivity to pain.13 Therefore, although some opioid combinations are useful, clinical studies are needed to ascertain benefits and safety of specific combinations.4

Opioids with mixed agonist/antagonist properties (e.g. buprenorphine, butorphanol, nalbuphine, pentazocine) may precipitate opioid withdrawal symptoms in patients taking pure opioid agonists such as fentanyl, methadone and morphine (see Table 6.1, p.134, for a classification). An example of this occurred in a 60-year-old woman who was taking slow-release morphine 90 mg twice daily for cancer pain and was additionally given nalbuphine 30 mg intravenously in an ambulance following a fractured femur. She became agitated and experienced involuntary movements, tachycardia, hypertension and sweating (typical of opioid withdrawal). Her management was further complicated by resistance to intravenous morphine, necessitating a femoral nerve block. The agitation, which lasted for about 4 hours after she was given the nalbuphine, was controlled with lorazepam.9

Opioids + Phenothiazines

Chlorpromazine has been reported to increase the analgesic effect of pethidine, but increased respiratory depression, sedation, CNS toxicity and hypotension can also occur. Other phenothiazines such as levomepromazine, promethazine, prochlorperazine, promazine and thioridazine may also interact with pethidine to cause some of these effects. Additive CNS depressant effects would be expected when opioids are given with phenothiazines.

Clinical evidence

(a) Pethidine (Meperidine)

Chlorpromazine 25 mg/70 kg given alone had no consistent effect on respiratory function in 6 healthy subjects but the respiratory depression produced by pethidine 100 mg/70 kg was exacerbated when the two drugs were given together. One subject showed marked respiratory depression, beginning about 30 minutes after both drugs were given and lasting 2 hours.1 No change in the pharmacokinetics of pethidine was found when chlorpromazine was given in a single-dose study in healthy subjects, but the excretion of the metabolites of pethidine was increased. The symptoms of light-headedness, dry mouth and lethargy were significantly increased and 4 subjects experienced such marked debilitation that they required assistance to continue the study. Systolic and diastolic blood pressures were also reduced.2 The respiratory depressant effects of pethidine can be increased by promethazine with pentobarbital,3 promazine4 and levomepromazine,5 but the effects of prochlorperazine6 with pethidine on respiration were not statistically significant. A 12-year-old patient taking long-term thioridazine 50 mg twice daily, given premedication with pethidine, diphenhydramine and glycopyrrolate, was very lethargic after surgery and stopped breathing. He responded to naloxone.8 For the effects of promethazine see below.

(b) Other opioids

There have been conflicting data as to whether or not phenothiazines potentiate narcotic analgesia,9 and it has been suggested that some patients treated with an opioid and a phenothiazine are merely too sedated to report pain.10 However, some studies have shown that promethazine reduces opioid requirements. The maintenance doses of a variety of opioid analogues (morpheine, pethidine, oxymorphone, hydromorphone, fentanyl, pentazocine) required during surgical anaesthesia were reduced by 28% to 46% when 132 patients were premedicated with intramuscular promethazine, 50 mg/70 kg, when compared with control patients. Similarly, on-demand pentazocine requirements post-caesarean section were reduced by 32% in women given promethazine as soon as the cord was clamped.11 In a randomised, placebo-controlled study in 90 patients undergoing abdominal hysterectomy, the preoperative use of intravenous promethazine 100 micrograms/kg (given over 30 minutes, starting 30 minutes before induction), reduced the 24-hour postoperative morphine consumption by about 30%, when compared with placebo or postoperative promethazine use. Postoperative nausea and vomiting was reduced by both pre- and postoperative promethazine compared with placebo.12

Mechanism

There is evidence that chlorpromazine can increase the activity of the liver microsomal enzymes so that the metabolism of pethidine to norpethidine and norphendimethic acid is increased. These metabolites are toxic and probably contribute to the lethargy and hypotension seen in one study.2 The effects of the phenothiazines on pethidine-induced respiratory depression may be related. Both the opioids and the phenothiazines are CNS depressants, and their effects may be additive.

Importance and management

The manufacturers of many opioids note that they can enhance the hypnotic, sedative, and respiratory depressant effects of phenothiazines. Patients should be monitored carefully, and dosage reductions may be necessary. One manufacturer of methadone contradicates the use of the injection, but not the oral solution, with other CNS depressants including phenothiazines.13,14 Although lower analgesic doses of pethidine have been used with chlorpromazine,15 a marked increase in respiratory depression can occur in some susceptible individuals1 and the authors of one study9 suggested that the risks of using the combination of pethidine with chlorpromazine outweighed the advantages. Information about other adverse interactions with pethidine and phenothiazines seems to be very limited: the interaction with thioridazine seems to be the only one reported. Increased analgesia may occur but it may be accompanied by increased respiratory depression, which is undesirable in patients with existing respiratory insufficiency. The US manufacturer suggests that the dose of pethidine should be proportionately reduced (usually by 25 to 50%) when it is given with phenothiazines.16

For mention of myoclonus associated with high doses of morphine and chlorpromazine, see ‘Opioids; Morphine + Miscellaneous’, p.190.

Opioids + Protease inhibitors

Ritonavir decreases pethidine (meperidine) and increases nor- pethidine levels, which may possibly increase toxicity on long-term use. Similarly, ritonavir and other protease inhibitors increase buprenorphine levels. Ritonavir may increase the metabolism of morphine, and decrease the metabolism of dextropropoxyphene (CYP3A4 substrate) and tramadol or other CYP2D6 substrates (such as codeine).

Clinical evidence

(a) Buprenorphine

One report describes 3 HIV-positive patients who experienced increased buprenorphine adverse effects (e.g. daytime sleepiness, dizziness, and reduced mental function) within about 2 days of starting to take azitranavir boosted by low-dose ritonavir. When the dose of buprenorphine was reduced there was a reduction in sedative symptoms within a week.1

In a study in opioid-dependent patients treated with sublingual buprenorphine and naloxone, patients were given an antiretroviral (nelfinavir, lopinavir/ritonavir, or ritonavir) for 5 to 15 days to investigate the effect of these drugs on the QT interval. Buprenorphine/naloxone alone did not significantly alter the QT interval, but when combined with an antiretroviral there was a statistically, but probably not clinically, significant increase in the QT interval. The greatest increase in QTc interval was seen in patients receiving buprenorphine/naloxone with ritonavir 100 mg twice daily (low booster dose).2

Ritonavir 500 mg twice daily for 10 days decreased the AUC of a single 50-mg dose of oral pethidine by 62% and increased the AUC of norpethidine by 47% in 8 healthy subjects. Norpethidine is pharmacologically active, and is possibly less effective as an analgesic than the parent compound, and more likely to cause CNS effects such as seizures.

**Mechanism**

**In vitro and in vivo** studies have demonstrated that ritonavir is a potent inhibi- tor of the cytochrome P450 isoenzyme CYP3A4 and to a lesser extent CYP2D6, and may also induce glucuronidation. An in vitro study sug- gested that buprenorphine metabolism may be inhibited by ritonavir and to a lesser extent by indinavir and saquinavir, which would be expected to lead to increased buprenorphine levels. Other opioids metabolised by CYP3A4 include dextropropoxyphene (propoxyphene), ‘fentanyl and related drugs’, (below), and ‘methylone’, (p.182). Substrates of CYP2D6 include codeine, dihydrocodeine, oxycodone, and tramadol. Morphine undergoes glucuronidation, and the morphine metabolite M6G [morphine-6 beta-glucuronide] is believed to contribute to the analgesic effects of morphine. Buprenorphine, and to some extent, codeine also undergoe glu- curonidation.

**Importance and management**

Most of these interactions remain theoretical, but they are consistent with the way the protease inhibitors and the opioids interact with other drugs. The consequences of inhibition of CYP2D6 are most pronounced for codeine, and CYP2D6 inhibition will lead to decreased levels of the morphine metabolite of codeine and therefore, perhaps contrary to expectation, a reduced effect. The levels of other CYP2D6 substrates dihydrocodeine, oxycodone, and tramadol would be expected to be raised, and dose reductions may be necessary. This has been suggested for tramada- dol. It would seem prudent to monitor for adverse effects such as sedation. However, note that low-dose ritonavir (i.e. the dose used as a pharmacokinetic enhancer with other protease inhibitors) has a less potent effect on CYP2D6 and dose reductions of drugs metabolised by CYP2D6 will not generally be required if this dose of ritonavir is given concur- rently.

Ritonavir is a potent inhibitor of CYP3A4 and therefore the UK manu- facturer of ritonavir contraindicates its use with dextropropoxyphene as extremely raised dextropropoxyphene levels may occur, which would in- crease the risk of serious respiratory depression or other serious adverse events. However, the US manufacturer only suggests that a dose decrease may be required. The outcome of taking ritonavir with morphine is less clear, but it is ex- pected that its levels will be decreased. It would seem prudent to moni- tor closely to ensure morphine is effective in patients taking ritonavir. More study is needed.

It has been suggested that the starting dose of buprenorphine should be halved in patients taking CYP3A4 inhibitors, such as the protease inhibitors, when it is used for opioid dependence. However, it has also been suggested that, since the magnitude of an inhibitory effect is unknown, such drug combinations should be avoided when buprenorphine is used parenterally or sublingually as a strong analgesic.

The manufacturers of pethidine oral preparations and injection contrain- dicate or advise against its use with ritonavir because of the risk of norpethidine toxicity. Long-term use of pethidine with other protease inhibitors e.g. tipranavir, which are given with low-dose ritonavir is also not recommended.

---

**Opioids; Fentanyl and related drugs + Protease inhibitors**

Ritonavir markedly increases the levels of fentanyl, and markedly increases alfentanil-induced miosis. Other protease inhibitors such as nelfinavir may have a similar effect. Care should also be taken if ritonavir is used with other protease inhibitors as a pharmaco- kinetic enhancer.

**Clinical evidence**

(a) **Fentanyl**

The miosis caused by oral and intravenous alfentanil was markedly increased by the short-term (1 to 3 days) and longer-term (14 days) use of ritonavir in healthy subjects.

(b) **Fentanyl**

Ritonavir 200 mg increased to 300 mg three times daily for a total of 7 doses increased the AUC of a single 5-mg/kg intravenous dose of fentanyl by 83%, decreased its clearance by 67%, and increased the elimination half-life twofold in healthy subjects.

**Mechanism**

Both fentanyl and alfentanil are metabolised by the cytochrome P450 isoenzyme CYP3A4. Ritonavir, and other protease inhibitors, are potent inhibitors of CYP3A4 and therefore reduce the metabolism of these opioids, which results in increased levels and effects.

**Importance and management**

The evidence is limited, but is consistent with the way protease inhibitors and fentanyl or alfentanil interact with other drugs. The UK manufacturer of alfentanil warns that potent CYP3A4 inhibitors such as ritonavir could increase the risk of prolonged or delayed respiratory depression, and says the combination should be used with special care, and that a reduced dose of alfentanil may be necessary. Similarly, caution is required in patients taking ritonavir given fentanyl by any route (oral, parenteral, or transder- mal). In particular, the manufacturers suggest avoiding the combination of ritonavir and transdermal fentanyl, unless the patient is closely moni- tored. Fentanyl dose reductions may be needed on long-term treatment to avoid fentanyl accumulation. The US manufacturer also warns that other potent CYP3A4 inhibitors including saquinavir may have a similar effect. In addition, the manufacturers of saquinavir warn that, although specific studies have not been performed, the use of saquinavir or saquinavir with ritonavir may raise the levels of fentanyl and alfentanil and therefore these combinations should be given with caution.

---

---

Opioids; Methadone + Protease inhibitors

Methadone serum levels can be reduced by amprenavir, nelfinavir, lopinavir/ritonavir, saquinavir/ritonavir, tipranavir/ritonavir, and possibly ritonavir. In addition, amprenavir levels may be reduced by methadone. No interaction appears to occur between methadone and indinavir, or possibly atazanavir or saquinavir, alone.

Clinical evidence

(a) Amprenavir

A study involving 16 opioid-dependent subjects found that amprenavir 1.2 g twice daily for 10 days decreased the AUCs for both R-methadone (active enantiomer) and S-methadone (inactive enantiomer) by 13% and 40%, respectively. No clinically significant changes were noted in opioid effects and there was no evidence of opioid withdrawal. However, in another study methadone levels were reduced by 35% (range 28% to 87%) in 5 patients within 17 days of starting to take amprenavir 1.2 g twice daily and abacavir 600 mg twice daily. Two patients reported nausea before their daily methadone dose, which can be a sign of opiate withdrawal. Note that ‘abacavir’, (p.175), may modestly reduce methadone levels, and could therefore have contributed to this effect.

The first study also found that amprenavir and methadone resulted in a 30% decrease in amprenavir AUC compared with non-matched historical controls. Another study in 6 HIV-positive patients taking methadone and two nucleoside analogues similarly found that methadone serum levels remained unchanged when indinavir was added.

There are also clinical reports about 2 patients whose methadone levels appeared to be unaltered while taking indinavir, but who later had reduced levels when treated with nelfinavir or ritonavir (see (c) and (g) below). This would seem to confirm that indinavir does not have a clinically relevant effect on methadone levels.

(b) Lopinavir/ritonavir

A study in healthy subjects found that lopinavir/ritonavir 400 mg/100 mg twice daily for 10 days reduced the AUC of a single 5-mg dose of methadone by about 50%. Similarly, in 15 healthy subjects taking methadone lopinavir/ritonavir 400 mg/100 mg twice daily for 7 days decreased the AUC of methadone by 26% and increased its clearance by 42%. Four of the subjects had clinically important increases in opioid-withdrawal scores, and were all found to have subtherapeutic trough methadone levels. [Note that the same dose of ritonavir alone had no effect on methadone levels, see (f) below]. In another study in 8 HIV-positive patients taking methadone a lopinavir/ritonavir based antiretroviral regimen reduced the AUC of methadone by 36% after 14 days of treatment. However, none of these patients experienced methadone withdrawal during the study or during 6 weeks of follow-up. In yet another study (that did not measure methadone levels), none of 18 patients experienced methadone withdrawal during the 28 days after starting lopinavir/ritonavir.

In a further study, methadone appeared to have no effect on the pharmacokinetics of lopinavir or ritonavir (given as a combined preparation).

(c) Nelfinavir

An HIV-positive man who had been taking methadone 100 mg daily for several years with indinavir 800 mg and zalcitabine 750 micrograms three times daily, developed opioid withdrawal symptoms within 6 weeks of starting to take stavudine and nelfinavir 750 mg three times daily. His methadone dosage was increased to 285 mg daily before therapeutic serum levels were achieved. When his antiretroviral treatment was withdrawn, his methadone dosage was successfully reduced to 125 mg daily. Two other patients taking nucleoside analogues had a 40 to 50% fall in their serum methadone levels when nelfinavir was added. Similarly, in another study, 4 of 6 patients developed symptoms of methadone withdrawal within 5 to 7 days of starting nelfinavir-based therapy. The mean AUC of methadone was reduced by 56% and the subjects required a mean increase in methadone dose of 15%.

The manufacturers of nelfinavir say that in a pharmacokinetic study nelfinavir reduced the concentrations of methadone by 47%. However, despite this reduction none of the subjects developed withdrawal symptoms, although due to the pharmacokinetic changes, it should be expected that some patients might experience withdrawal symptoms.

A patient receiving methadone experienced torsades de pointes after starting treatment with nelfinavir. Raised methadone levels are associated with QT-prolongation, and this case therefore suggests that nelfinavir raises methadone levels.

In a study looking at the levels of nelfinavir and its active metabolite M8, methadone had no significant effect on the AUC of nelfinavir, but the AUC0–12 of M8 was reduced by 48%.

(d) Ritonavir

A patient taking lamivudine and zidovudine had a marked decrease in methadone serum levels when ritonavir was added.

Another patient receiving methadone experienced an opioid withdrawal syndrome when ritonavir was added to a similar antiretroviral regimen. Ritonavir (dose not stated) was given to 11 healthy subjects for 14 days, with a single 3-mg dose of methadone on day 11. Ritonavir reduced the maximum serum levels of methadone by 37.8% and the AUC0–12 of methadone by 48%. However, in another study in 15 healthy subjects receiving methadone, ritonavir 100 mg twice daily for 7 days had no significant effect on methadone pharmacokinetics.

In a further study, methadone apparently increased ritonavir exposure by 60%, when given alone, but had no effect on ritonavir pharmacokinetics when it was given with lopinavir.

In healthy subjects the miosis caused by oral and intravenous methadone was increased by the acute use of ritonavir for 3 days but returned to below baseline after longer-term use for 14 days. It appeared that acute ritonavir inhibited, but chronic ritonavir mildly increased methadone elimination.

(e) Saquinavir

An HIV-positive patient taking methadone 90 mg daily with indinavir, lamivudine and zidovudine, developed withdrawal symptoms and was hospitalised within a week of stopping these HIV drugs and starting ritonavir 400 mg, saquinavir 400 mg and stavudine 40 mg twice daily. The patient was eventually re-stabilised taking methadone 130 mg daily.

A later study in 12 HIV-positive subjects taking methadone maintenance found that ritonavir/saquinavir 400 mg/400 mg twice daily decreased the S-methadone AUC by 40% and the R-methadone AUC by 32%. However, when these decreases were corrected for changes in protein binding, the free R-methadone AUC was decreased by only 19.6%, and the free S-methadone AUC by 24.6%. None of the subjects experienced methadone withdrawal or required a change in their methadone dosage.

In another study ritonavir/saquinavir 100 mg/1600 mg daily for 14 days caused no clinically relevant changes in total or free levels of either enantiomer of methadone in 12 HIV-negative subjects taking methadone. None of the subjects experienced methadone withdrawal.

(f) Tipranavir/ritonavir

The manufacturers of tipranavir state that use of methadone with tipranavir boosted by low-dose ritonavir (200 mg) can result in a decrease in methadone levels of about 50%, which may require dose increase in some patients.

Mechanism

Not known. The findings are the opposite of those originally predicted based on in vitro data showing inhibition of methadone metabolism (principally mediated by the cytochrome P450 isoenzyme CYP3A). One study found a slight increase in methadone elimination, but this was not mediated by CYP3A. It is possible that these protease inhibitors induce the
activity of other isoenzymes or act via other mechanisms (e.g. glucuronyltransferases). The reduction in methadone levels has not always correlated with clinical effects, and it has been suggested that this may be because the pharmacokinetics of the enantiomers (one of which is inactive) are affected differently, and/or altered protein binding occurs.19

Importance and management
Information is limited but the interactions with amprenavir, nelfinavir, lopinavir/ritonavir, saquinavir/ritonavir, tipranavir/ritonavir and probably ritonavir would appear to be established. However the picture seems to be that methadone is not subject to enzyme withdrawal symptoms if given these drugs. Therefore, in methadone-maintained patients, care should be taken if any of these protease inhibitors is started or stopped. It has been suggested that patients taking methadone who are given a protease inhibitor should be screened for opioid withdrawal beginning on the fourth day of the new medication. If symptoms develop, the methadone dose should be increased by 10 mg every 2 to 3 days until symptoms abate.20 However, others have suggested dose increments should be made at one-week intervals to avoid overdose, as methadone has a long half-life (reported to range from 13 to 47 hours).18 If the protease inhibitor is stopped the methadone dose should be gradually reduced to pretreatment levels over the course of 1 to 2 weeks.

Indinavir appears not to interact with methadone, and very limited evidence suggests that atazanavir and saquinavir alone do not interact either. Note that amprenavir plasma levels may also be reduced by methadone. The US manufacturer says that amprenavir may be less effective if taken concurrently with narcotic analgesics and alternative antiretroviral therapy should be considered.20

Clinical evidence, mechanism, importance and management
(a) Fentanyl
Quinidine appears to increase the oral absorption and effects of fentanyl, methadone, and morphine, but does not significantly alter the opioid-induced miosis when these opioids are given intravenously. Care should be taken if high-dose methadone is used with quinidine as cardiac conduction might possibly be affected.

Quinidine sulfate 600 mg given one hour before an infusion of fentanyl 2.5 micrograms/kg did not alter the fentanyl-induced miosis in healthy subjects. However, the same dose of quinidine given before oral fentanyl 2.5 micrograms/kg (with ondansetron as an antiemetic) did increase fentanyl-induced miosis. This increase was considered proportionate to the increase in the AUC of fentanyl (160%). There was no change in the elimination half-life of fentanyl.1 It was suggested that quinidine inhibits the intestinal P-glycoprotein and so allows an increase in oral fentanyl absorption, and a consequent increase in its effects. The miosis on fentanyl indicates that quinidine did not alter brain access of fentanyl.1

The clinical importance of this finding to the use of baccal fentanyl citrate (of which a significant proportion is swallowed) remains to be determined, but be aware that effects may be increased.

(b) Hydromorphone
An in vitro study suggested that quinidine did not significantly affect the metabolism of hydromorphone to norhydromorphone. Hydromorphone appears to be mainly metabolised by CYP3A, and to a lesser extent by CYP2D6. The inhibition of CYP2D6 by quinidine does not appear to affect norhydromorphone formation.2

(c) Methadone
Methadone sulfate 600 mg, given one hour before intravenous methadone 10 mg, did not alter methadone-induced miosis in healthy subjects. However, the same dose of quinidine given before oral methadone hydrochloride 10 mg (with ondansetron as an antiemetic) increased the peak methadone-induced miosis by 34% and increased the plasma levels of oral methadone in the absorption phase, but had no effect on the maximum plasma level or AUC of methadone.3 Methadone is primarily metabolised by CYP3A and quinidine does not affect the hepatic metabolism of methadone. However, quinidine can inhibit P-glycoprotein and this may affect methadone intestinal transport and absorption.4

The absorption of oral methadone may possibly be affected by quinidine, but the clinical relevance is not known. However, note that both high doses of methadone and quinidine can affect the QT interval, see “Drugs that prolong the QT interval + Other drugs that prolong the QT interval”1, p.257.

(d) Morphine
Morphine sulfate 600 mg, given one hour before intravenous morphine sulfate 150 micrograms/kg, did not alter morphine-induced miosis in healthy subjects. However, the same dose of quinidine given before oral morphine sulfate 30 mg (with ondansetron as an antiemetic) increased morphine-induced miosis by 56%. This increase was considered proportionate to the increase in morphine AUC (60%) and maximum level (88%). There was no change in the elimination half-life of morphine.5 Similarly, in another study in healthy subjects, quinidine 800 mg, given one hour before intravenous morphine 7.5 mg did not alter the respiratory depressant or nor mictic effects of morphine, and there was no change in plasma morphine or morphine glucuronide levels.5
It was suggested that quinidine inhibits P-glycoprotein and so allows an increase in oral morphine absorption. In addition, the effects on miosis suggest that quinidine has no effect on the brain distribution of morphine.

The clinical importance of these findings remains to be determined, but it appears that quinidine may increase the effects of oral morphine.

(e) Tramadol

A placebo-controlled study in 12 healthy subjects found that quinidine 50 mg had virtually no effect on the analgesic effects of tramadol 100 mg but it inhibited its effect on pupil size. The manufacturers say that quinidine increases the tramadol AUC and maximum level by 25%, but this is within the normal pharmacokinetic variation seen with tramadol. Tramadol is partially metabolised to the active metabolite O-desmethyltramadol (which affects opioid receptors), by the cytochrome P450 isoform CYPD2D, and it is this enzyme that is inhibited by quinidine. Blockade of the production of this metabolite appears to have little effect on the analgesic effect of tramadol. No special precautions seem to be needed.

Opioids; Codeine and related drugs + Quinidine

The analgesic effects of codeine, and probably also hydrocodone, are reduced or abolished by quinidine. Quinidine alters the pharmacokinetics of dihydrocodeine and oxycodone, but this does not appear to alter their effects.

Clinical evidence

(a) Codeine

Codeine 100 mg was given to 16 extensive metabolisers of the cytochrome P450 isoenzyme CYPD2D with and without a single 200-mg dose of quinidine. The quinidine reduced the peak morphine levels by about 80% (from a mean of 18 nanomol/L to less than 4 nanomol/L). Codeine given alone increased the pain threshold (pin-prick pain test using an aragon laser) but no significant analgesic effects were detectable when quinidine was also present. Another study found that the effects of codeine in extensive metabolisers of CYPD2D who were given quinidine were virtually the same as codeine alone in poor metabolisers of CYPD2D. These studies confirm the preliminary findings of an earlier study using codeine 100 mg and quinidine 50 mg. The quinidine reduced the peak morphine plasma levels by more than 90% (by 92% in 7 extensive metabolisers, and by 97% in one poor metaboliser) and similarly abolished the analgesic effects.

(b) Dihydrocodeine

A study in which 4 extensive metabolisers of the cytochrome P450 isoenzyme CYPD2D were given dihydrocodeine 40 or 60 mg found that when they were pretreated with quinidine 200 mg almost none of the morphinoid metabolites of dihydrocodeine normally present in the serum could be detected. The same authors found essentially the same results in a further study in 10 extensive metabolisers of CYPD2D given dihydrocodeine 60 mg and quinidine 50 mg. However, a single-dose study involving 10 healthy subjects who were extensive metabolisers of CYPD2D investigated the effect of quinidine on the visceral and somatic analgesic effects of dihydrocodeine and its metabolite, dihydromorphine. It was found that quinidine reduced dihydrocodeine plasma levels (by inhibition of CYPD2D reducing the metabolism of dihydrocodeine to dihydromorphine), this did not result in diminished pain tolerance thresholds. This suggested that the metabolism of dihydrocodeine to dihydromorphine may not be clinically important for analgesia. Further study is needed.

(c) Hydrocodeone

In a comparative study, 5 extensive metabolisers and 6 poor metabolisers of the cytochrome P450 isoenzyme CYPD2D were given hydrocodeone, and another 4 extensive metabolisers of CYPD2D were given hydrocodeone after pre-treatment with quinidine. The metabolism of the hydrocodeone to its active metabolite hydromorphone was found to be high in the extensive metabolisers who described ‘good opiate effects’ but poor in the poor metabolisers and the extensive metabolisers pretreated with quinidine who described ‘poor opiate effects’. For the effect of quinidine on hydromorphone metabolism, see ‘Opioids + Quinidine’, p.183.

(d) Oxycodone

Quinidine, given as 200 mg 3 hours before and 100 mg 6 hours after a single 20-mg dose of oxycodone almost completely inhibited the formation of the metabolite, oxymorphone, in 10 healthy extensive metabolisers of the cytochrome P450 isoenzyme CYPD2D. Despite this, the psychomotor and subjective effects of oxycodone were not altered (note that analgesia was not assessed). The AUC of the metabolite noroxycodone was increased about 85%, and the oxycodone AUC was slightly increased by 13%. Similar results were found in the preliminary report of another study.

Mechanism

The evidence available shows that the conversion of codeine, dihydrocodeine and hydrocodeone to their active analgesic metabolites in the body (morphine, morphinoid metabolites and hydromorphone, respectively) probably depends upon the activity of the cytochrome P450 isoenzyme CYPD2D in the liver. If this isoenzyme is inhibited by quinidine, these conversions largely fail to occur and the analgesic effects may be reduced or lost. This interaction is only likely to occur in extensive metabolisers and not in poor metabolisers, who have minimal CYPD2D activity and who therefore may only derive minimal benefit from analgesics such as codeine, whose principal pharmacological effect appears to depend on this metabolism. However, one study in healthy subjects has suggested that the analgesic effect of dihydrocodeone does not necessarily depend on its systemic metabolism to hydromorphone. Similarly, although quinidine also blocks conversion of oxycodone to oxymorphone, it appears that this is not important for the pharmacodynamic effects of this drug.

Importance and management

The interaction between codeine and quinidine is well established and clinically important. Codeine will be virtually ineffective as an analgesic in extensive metabolisers of CYPD2D (most patients) taking quinidine. An alternative analgesic should be used (possibly dihydrocodeine, see below, or tramadol, see ‘Opioids + Quinidine’, p.183). No interaction would be expected in poor metabolisers (about 7% of Caucasians), but codeine is probably unlikely to be effective in these patients in any case. Whether the antitussive effects of codeine are similarly affected is not established, but it seems likely. Note that this interaction has been used clinically in an attempt to treat codeine dependence.

The interaction of hydrocodeine is less well established, but the evidence suggests that the analgesic effect will similarly be reduced or lost if quinidine is given. Further study is needed.

The available evidence suggests that the efficacy of dihydrocodeine, hydromorphone, or oxycodone may not be significantly affected by quinidine, but this needs confirmation.

Opioids + Rifampicin (Rifampin)

Rifampicin markedly increases the metabolism of codeine and morphine, and reduces their effects. Rifampicin dramatically reduced the effects of oxycodone in one patient.

Clinical evidence, mechanism, importance and management

(a) Codeine

A study in 9 extensive metabolisers and 6 poor metabolisers of the cytochrome P450 isoenzyme CYP2D6 found that after taking rifampicin 600 mg daily for 3 weeks, the metabolism of a single 120-mg oral dose of codeine phosphate was markedly increased in both phenotypes. The AUC of codeine was decreased by 79.4% in extensive metabolizers and 83.5% in poor metabolisers and in both the N-demethylation and glucuronidation metabolic pathways were induced. However, the O-demethylation of codeine (mediated by CYP2D6) was induced only in extensive metabolisers, and in these subjects there was a 56% reduction in the AUC of morphine (the main active metabolite of codeine), and a 173% increase in the AUC normorphine (another active metabolite). Note that morphine and its metabolites were not detected in poor metabolisers, either before or after rifampicin was given because the pathway that leads to these metabolites is deficient or absent in these subjects. Rifampicin reduced the respiratory and psychomotor effects of the codeine in extensive metabolisers, but not in poor metabolisers. In contrast, rifampicin did not alter the pupillary effect of codeine in extensive metabolisers, but decreased it in poor metabolisers. The clinically more relevant question of whether, and to what extent, the analgesic effects of the codeine were reduced by this interaction was not addressed by this study. However, some reduction in effect might be expected. Therefore, if these drugs are used concurrently, be alert for the need to raise the codeine dosage. More study is needed.

(b) Morphine

In a randomised study, 10 healthy subjects were given a single 10-mg oral dose of morphine sulphate with rifampicin 600 mg daily. It was found that the rifampicin increased the clearance of the morphine by 49% and its analgesic effects (using a modified cold pressor test) were abolished. The mechanism of this interaction is uncertain since morphine is principally metabolised by glucuronidation (see ‘opioids’, (p.133)), but the findings of this study could not be attributed to rifampicin induction of glucuronosyltransferases (UGTs). Be alert for the need to use an increased dosage of morphine in patients taking rifampicin. More study is needed.

(c) Oxycodone

A 60-year-old man who was taking rifampicin as well as oxycodone had 3 consecutive negative urine oxycodone screens in a 2-month period, which would normally suggest that he was not taking the oxycodone. However, oxycodone metabolites were found in his urine confirming compliance with his medication. An interaction between rifampicin and oxycodone was suspected and his oxycodone dose was increased to optimise his pain control. The dose of oxycodone was increased to 60 mg per day and alfentanil was increased to 200 micrograms/kg after taking rifampicin 600 mg orally for 5 days. Alfentanil clearance was increased almost threefold.

Opioids; Fentanyl and related drugs + Rifampicin (Rifampin)

The serum levels and effects of transdermal fentanyl were decreased when one patient took rifampicin. Studies in healthy subjects have shown that the bioavailability of transmucosal fentanyl is reduced, and the clearance of intravenous alfentanil is markedly increased, by rifampicin.

Clinical evidence, mechanism, importance and management

(a) Alfentanil

A study in 9 healthy subjects found that when they were given intravenous alfentanil 20 micrograms/kg after taking rifampicin 600 mg orally for 5 days, alfentanil clearance was increased almost threefold. This increased clearance probably occurs because rifampicin increases the activity of the cytochrome P450 isoenzyme CYP3A4 in the liver, which is concerned with the metabolism of alfentanil (see ‘opioids’, (p.133)). This study was primarily designed to investigate the role of CYP3A4 in the metabolism of alfentanil, but it also provides good evidence that alfentanil is likely to be much less effective in patients taking rifampicin. A much larger dose of alfentanil will almost certainly be needed.

(b) Fentanyl

A 61-year-old man with lung metastases was given transdermal fentanyl (1.67 mg patch every 3 days). Serum fentanyl levels were measured 48 and 72 hours after the first day of treatment were 0.9 and 0.77 nanograms/mL, respectively (within the reported minimal effective therapeutic range of 0.2 to 1.2 nanograms/mL). On day 5, due to insufficient pain control, the fentanyl patch was increased to 2.5 mg every 3 days. However, on day 7, oral rifampicin 300 mg daily, isoniazid and ethambutol were started for pulmonary tuberculosis. The following day severe pain developed and fentanyl serum levels 48 and 72 hours after treatment on day 8 were 0.53 and 0.21 nanograms/mL, respectively (i.e. in the presence of rifampicin a higher dose of fentanyl had led to lower levels). Even after the dose was titrated up to 7.5 mg every 3 days, the patient still complained of moderate pain and the fentanyl serum level 72 hours after treatment was only 0.69 nanograms/mL (i.e. less than the level achieved with the 1.67 mg dose).

In a study in 12 healthy subjects, peak levels and maximum miosis after oral, transmucosal fentanyl 10 micrograms/kg were minimally affected by oral rifampicin 600 mg daily for 5 days, but the AUC of fentanyl was decreased by 63%; the AUC of its metabolite, norfentanyl, was increased by 73%, and the AUC₉₅ of miosis was decreased by 54%.

Fentanyl is metabolised by the cytochrome P450 isoenzyme CYP3A4 and rifampicin, a potent inducer of CYP3A4, appears to reduce its serum levels and pharmacological efficacy. Thus an increase in fentanyl dosage may be needed in patients taking rifampicin. Consider also ‘Opioids + Rifampicin (Rifampin)’, above.

Opioids; Methadone + Rifamycins

Serum methadone levels can be markedly reduced by rifampicin, and withdrawal symptoms have occurred in some patients. Rifaxutin appears to interact similarly, but to a lesser extent.

Clinical evidence

(a) Rifabutin

A study in 24 HIV-positive patients taking methadone found that after taking rifabutin 300 mg daily for 13 days the pharmacokinetics of the methadone were minimally changed. However 75% of the patients reported at least one mild symptom of methadone withdrawal, but this was not enough for any of them to withdraw from the study. Only 3 of them asked for and received an increase in their methadone dosage. The authors offered the opinion that over-reporting of withdrawal symptoms was likely to be due to the warnings that the patients had received.

(b) Rifampicin

The observation that former diamorphine (heroin) addicts taking methadone complained of withdrawal symptoms when given rifampicin, in a clinical study in 30 patients taking methadone. Withdrawal symptoms developed in 21 of the 30 within 1 to 33 days of starting rifampicin 600 to 900 mg daily and isoniazid daily. In 6 of the 7 most severely affected, the symptoms developed within a week, and their plasma methadone
levels fell by 33 to 68%. Of 56 other patients taking methadone with other anti-tubercular treatment (which included isoniazid but not rifampicin), none developed withdrawal symptoms.\(^\text{2-4}\)

Other cases of this interaction have been reported.\(^\text{5-9}\) Some patients needed two to threefold increases in the methadone dosage while taking rifampicin to control the withdrawal symptoms.\(^\text{6,7,9}\)

**Mechanism**

Rifampicin is a potent enzyme-inducer, which increases the activity of the intestinal and liver enzymes concerned with the metabolism of methadone, resulting in a marked decrease in its levels.\(^\text{10}\) In 4 patients in the study cited, the urinary excretion of the major metabolite of methadone rose by 150%.\(^\text{2}\) Rifabutin has only a small enzyme-inducing effect and therefore the effects are not as great.

**Importance and management**

The interaction between methadone and rifampicin is established, adequately documented and of clinical importance. The incidence is high. Two-thirds (21) of the narcotic-dependent patients in one study\(^\text{2}\) developed this interaction, 14 of whom were able to continue treatment. Withdrawal symptoms may develop within 24 hours. The analgesic effects of methadone would also be expected to be reduced. Concurrent use need not be avoided, but the effects should be monitored and appropriate dosage increases (as much as two to threefold) made where necessary. Rifabutin appears to interact to a very much lesser extent so that fewer, if any, patients are likely to need a methadone dosage increase.

**Opioids + Tobacco**

Smokers who discontinue smoking appear to require more opioid analgesics for postoperative pain control than non-smokers; this has been seen with both fentanyl and morphine patient controlled analgesia. Atmospheric pollution has a similar effect on pentazocine. Codeine metabolism was not affected to a clinically relevant extent by smoking in one study.

**Clinical evidence**

A retrospective study of coronary artery bypass graft patients found that 20 patients who had abruptly discontinued smoking prior to surgery required more postoperative opioid analgesics than 69 non-smokers. The opioid analgesics included dextropropoxyphene (propoxyphene), fentanyl, hydromorphone, oxycodone, morphine, nalbuphine and pethidine (meperidine), but the most commonly used postoperative opioid analgesic was fentanyl (used in approximately two-thirds of the patients) given by patient controlled analgesia (PCA). Smokers deprived of nicotine had an increase in opioid requirement (converted to morphine equivalents), during the first 48 hours after surgery, ranging from 29 to 33% (when normalised for body weight or body mass index).\(^\text{1}\) Similarly, another retrospective study in 171 women found that average postoperative narcotic use (expressed as equivalent doses of morphine) was 10.9 mg/12 hours for patients who had never smoked, 13 mg/12 hours for former smokers, and 13.1 mg/12 hours for current smokers.\(^\text{1}\)

2. Woodside JR. Female smokers have increased postoperative narcotic requirements. J Addict Dis (2000) 19, 1–10.

(a) Codeine

The metabolism of a single 25-mg dose of codeine did not differ between 9 heavy smokers (greater than 20 cigarettes daily) and 9 non-smoking control subjects, except that smokers had a slightly higher rate of codeine glucuronidation.\(^\text{3}\) This is unlikely to be clinically important. Another study found no clinically important differences in the systemic availability of single 60-mg oral or intramuscular doses of codeine between 10 smokers and 12 non-smokers. There was no significant difference in the plasma half-life of codeine or in the conversion of codeine to morphine, however, there was a slightly higher plasma clearance of codeine in smokers than in non-smokers.\(^\text{4}\) No differences in the efficacy of codeine are expected between smokers and non-smokers.

(b) Dextropropoxyphene (Propoxyphene)

A study in 835 patients who were given dextropropoxyphene for mild or moderate pain or headache found that its efficacy as an analgesic was decreased by smoking. The drug was rated as ineffective in about 10% of 335 non-smokers, 15% of 347 patients who smoked up to 20 cigarettes daily, and 20% of 153 patients who smoked more than 20 cigarettes daily.\(^\text{5}\)

(c) Morphine

A study in 7 women during acute post-caesarean recovery found that intravenous morphine use (as patient-controlled analgesia; PCA), was significantly higher in smokers compared with non-smokers: weight-adjusted morphine use was 1.8 mg/kg per 24 hours compared with 0.64 mg/kg per 24 hours, respectively. It was suggested that a history of nicotine use and/or short-term nicotine abstinence could modulate morphine use and analgesia during postoperative recovery.\(^\text{6}\) Similarly, another retrospective study found increased morphine PCA requirements in smokers compared with non-smokers.\(^\text{7}\)

(d) Pentazocine

A study in which pentazocine was used to supplement nitrous oxide relaxant anaesthesia found that patients who came from an urban environment needed about 50% more pentazocine than those who lived in the country (3.6 micrograms/kg per minute compared with 2.4 micrograms/kg per minute). Roughly the same difference was seen between those who smoked and those who did not (3.8 micrograms/kg per minute compared with 2.5 micrograms/kg per minute).\(^\text{8}\) In another study it was found that pentazocine metabolism was 40% higher in smokers than in non-smokers.\(^\text{9}\)

**Mechanism**

It is thought that tobacco smoke contains compounds that increase the activity of the liver enzymes concerned with the metabolism of dextropropoxyphene, pentazocine and other opioids, which increases their metabolism, decreases their levels and diminishes their effectiveness as analgesics. However, former smokers have also been found to have increased opioid requirements and it has been suggested that smoking might have an effect on pain perception and/or opioid response, or that nicotine addiction and opioid requirements may be genetically linked.\(^\text{2}\)

**Importance and management**

The interaction appears to be well established. Prescribers should be aware that smokers may require a greater amount of opioids postoperatively than non-smokers. In contrast, codeine metabolism does not appear to be affected to a clinically important extent by smoking.

2. Woodside JR. Female smokers have increased postoperative narcotic requirements. J Addict Dis (2000) 19, 1–10.
Opioids + Tricyclic and related antidepressants

In general, the concurrent use of most opioids and tricyclics is uneventful, although lethargy, sedation, and respiratory depression have been reported. Tramadol should be used with caution with tricyclic antidepressants because of the possible risk of seizures and the serotonin syndrome. Dextropropoxyphene may cause moderate rises in the serum levels of amitriptyline and nortriptyline, and methadone may moderately raise desipramine levels. The bioavailability and the degree of analgesia of oral morphine is increased by clomipramine, desipramine and possibly amitriptyline.

Clinical evidence

(a) Buprenorphine

A study in 12 healthy subjects found that both sublingual buprenorphine 400 micrograms and oral amitriptyline 50 mg impaired the performance of a number of psychomotor tests (digit symbol substitution, flicker fusion, Maddox wing, hand-to-eye coordination, reactive skills), and the subjects felt drowsy, feeble, mentally slow and muzzy. When amitriptyline 30 mg, increased to 75 mg daily was given for 4 days before a single dose of buprenorphine, the psychomotor effects were not significantly increased, but the respiratory depressant effects of the buprenorphine were enhanced.1

(b) Dextropropoxyphene (Propoxyphene)

An elderly man taking dextin 150 mg daily developed lethargy and daytime somnolence when he started to take dextropropoxyphene 65 mg every 6 hours. His plasma dextin levels rose by almost 150% (from 20 to 48.5 nanograms/mL) and desmethylcodeine levels were similarly increased (from 8.8 to 20.7 nanograms/mL).2

The amitriptyline concentration/dose ratio in 12 patients given amitriptyline and dextropropoxyphene was raised by about 20% (suggesting raised amitriptyline levels), when compared with other patients taking amitriptyline alone. Similarly, the plasma levels of the amitriptyline metabolite nortriptyline was raised by about 30% in 14 patients given dextropropoxyphene;3 and in another study nortriptyline plasma levels were raised by 16% by dextropropoxyphene.4

Fifteen patients with rheumatoid arthritis given a single 25-mg dose of amitriptyline and dextropropoxyphene (up to 65 mg three times daily) experienced some drowsiness and mental slowness. They complained of being clumsier and had more pain, but these effects were said to be mild.4

(c) Methadone

The mean serum levels of desipramine 2.5 mg/kg daily were approximately doubled in 5 men who took methadone 500 micrograms/kg daily for 2 weeks. Previous observations in patients given both drugs had shown that desipramine levels were higher than expected and adverse effects developed at relatively low doses.5 Further evidence of an increase in plasma desipramine levels due to methadone is described in another study.6

(d) Morphine

Clomipramine or amitriptyline, in doses of 20 or 50 mg daily, increased the AUC of oral morphine by 28 to 111% in 24 patients with cancer pain. The half-life of morphine was also prolonged.7 A previous study8 found subjects felt drowsy, but not amitriptyline, increased and prolonged morphine analgesia, and a later study by the same group confirmed the value of desipramine.9

(e) Oxycodone

Pretreatment with amitriptyline 10 mg increased to 50 mg daily for 4 days caused no major changes in the psychomotor effects of a single 280-microgram/kg oral dose of oxycodone in 9 healthy subjects.10 Respiratory effects were not assessed.

(f) Pentazocine

Both pentazocine and amitriptyline given alone caused 11 healthy subjects to feel drowsy, muzzy and clumsy, and reduced the performance of a number of psychomotor tests. However, when the same subjects were given intramuscular pentazocine 30 mg after taking amitriptyline 50 mg daily for a week, the combination of drugs appeared not to impair driving or occupational skills more than either drug given alone.11 Respiratory depression was increased more by the combination than either drug alone. Amitriptyline modestly decreased pentazocine plasma levels by about 20% at 1.5 and 3.5 hours.11

(g) Tramadol

The CSM in the UK has publicised 27 reports of convulsions and one of worsening epilepsy with tramadol, a reporting rate of 1 in 7000 patients. Some of the patients were given doses well in excess of those recommended, and 8 patients were also taking tricyclic antidepressants, which are known to reduce the convulsive threshold.12 Similarly, the FDA in the US has received 124 reports of seizures associated with tramadol, 28 of which included the concurrent use of tricyclic antidepressants,13 and the Australian Adverse Drug Reaction Advisory Committee (ADRAC) has received 26 cases of convulsions associated with tramadol, some of which included the concurrent use of tricyclic antidepressants.14 ADRAC have also received reports of the serotonin syndrome, which were associated with the use of tramadol and tricyclic antidepressants.14 Furthermore two case reports suggest that tramadol may have contributed to the development of the serotonin syndrome, one in a patient abusing tramadol, moclobemide and clomipramine,15 and the other in a 79-year-old patient taking morphine (MST), co-proxamol (dextropropoxyphene with paracetamol) and amitriptyline16 after she started to take tramadol.16.17 In both of these cases the patient died. For this reason tramadol should be used with caution with tricyclic antidepressants.

Similarly, seizures and the serotonin syndrome have been reported in a woman who took mirtazapine with tramadol, but this may have been due to over-use of the tramadol rather than an interaction.18 Lethargy, confusion, hypotension, bronchospasm and hypoxia has also been seen following the use of tramadol and mirtazapine, which resolved within hours of both drugs being stopped.19

Mechanism

The CNS depressant effects of opioids and the tricyclic antidepressants are expected to be additive. The reasons for the increased morphine levels and analgesic effects that occur with some tricyclics are not understood. The increased analgesia may be due not only to the increased serum levels of morphine, but possibly also to some alteration in the way the morphine affects its receptors. Dextropropoxyphene probably inhibits liver metabolism of some tricyclic antidepressants1 by inhibiting the activity of the cytochrome P450 isoenzyme CYP2D6, and as a result the serum levels of the tricyclic antidepressants rise. It is suggested that the methadone may possibly inhibit the hydroxylation of the desipramine, thereby raising its levels.6

Importance and management

The majority of the evidence, and general clinical experience suggests that, in most cases, the use of opioids with tricyclic antidepressants is uneventful. Furthermore, limited evidence suggests that concurrent use may be beneficial in pain management. However, the CNS depressant effects of both these classes of drugs should be considered when prescribing the combination, especially as there is some evidence to suggest that the respiratory depressant effects are increased: this may be clinically important in patients with a restricted respiratory capacity.11 Certain opioids appear to have a greater propensity to interact. Both tramadol and the tricyclics can lower the seizure threshold and cause the serotonin syndrome. Therefore particular caution is warranted with this combination, especially in epileptic patients or those taking other drugs that affect serotonin. Mirtazapine appears to interact in the same way as the tricyclies. Be aware that as dextropropoxyphene and methadone may raise tricyclic levels: however, the general clinical significance of these interactions is uncertain but be alert for any evidence of increased CNS depression and increased tricyclic antidepressant adverse effects. In this context it is worth noting that one study reported that the incidence of hip fractures in the elderly was found to be increased by a factor of 1.6 in those taking dextropropoxyphene, and further increased to 2.6 when antidepressants, benzodiazepines or antipsychotics were added.20
Opioids + Urinary acidifiers or alkalinisers

Urinary methadone clearance is increased if the urine is made acidic (e.g. by giving ammonium chloride) and reduced if it is made alkaline (e.g. by giving sodium bicarbonate). The urinary clearance of dextropropoxyphene (propoxyphene) and pethidine (meperidine) may also be increased by acidification of the urine.

Clinical evidence

(a) Dextropropoxyphene (Propoxyphene)

A study in 6 healthy subjects found that the cumulative 72-hour urinary excretion of unchanged dextropropoxyphene was increased sixfold by acidification of the urine with oral ammonium chloride and reduced by 95% by alkalisation with sodium bicarbonate; the half-life of dextropropoxyphene was also shortened by ammonium chloride. The excretion of the active metabolite norpropoxyphene was much less dependent on urinary pH. However, the cumulative excretion of dextropropoxyphene and norpropoxyphene, even into acidic urine, accounted for less than 25% of the dose during 72 hours.

(b) Methadone

A study in patients taking methadone found that the urinary clearance in those with urinary pHs of less than 6 was greater than those with higher urinary pHs. When the urinary pH of one subject was lowered from 6.2 to 5.5, the loss of unchanged methadone in the urine was nearly doubled.

A pharmacokinetic study in 5 healthy subjects given a 10-mg intramuscular dose of methadone found that the plasma half-life was 19.5 hours when the urine was made acidic (pH 5.2) with ammonium chloride, compared with 42.1 hours when the urine was made alkaline (pH 7.8) with sodium bicarbonate. The clearance of the methadone fell from 134 to 91.9 mL/minute when the urine was changed from acidic to alkaline. For isolated reports of respiratory depression when cinetemazine or ranitidine were given with opioids, see ‘H₂-receptor antagonists’, (p.171).

A study in 6 healthy subjects given intravenous pethidine 21.75 mg found that urinary acidification with ammonium chloride increased the 48-hour urinary recovery of pethidine and norpethidine from about 7% and 12%, respectively, with no control of urinary pH, to about 20% and 24%, respectively. Urinary alkalisation reduced the urinary recovery of pethidine and norpethidine to less than 1% and 7%, respectively. These pronounced effects had negligible effects on the blood concentration/time profiles. A study in 10 healthy Chinese subjects given intravenous pethidine 150 micrograms/kg found large variations in the 48-hour urinary recovery of pethidine and norpethidine depending on urinary pH; mean urinary recovery values under acidic conditions were 24.3% and 33.0%, respectively, and under alkaline conditions were 0.4% and 3.8%, respectively. The bioavailability was slightly lower under acidic urinary conditions than under 48-hour renal clearance of the drug.

Mechanism

Methadone is eliminated from the body both by liver metabolism and excretion of unchanged methadone in the urine. Above pH 6 the excretion is less important, but with urinary pH below 6 the half-life becomes dependent on both excretion (30%) and metabolism (70%). Methadone is a weak base (pKa 8.4) so that in acidic urine little of the drug is in the unionised form and little is reabsorbed by simple passive diffusion. On the other hand, in alkaline solution most of the drug is in the unionised form, which is readily reabsorbed by the kidney tubules, and little is lost in the urine.

Acidification of the urine may also increase the renal clearance of unchanged pethidine and norpethidine again probably due to reduced reabsorption in the renal tubule.

Opioids; Alfentanil + Reserpine

An isolated report describes ventricular arrhythmias when a patient taking reserpine was given alfentanil during anaesthesia.

Clinical evidence, mechanism, importance and management

A hypertensive woman taking reserpine 250 micrograms daily was given intravenous alfentanil 800 micrograms over 5 minutes, before anaesthesia with thiopental and suxamethonium (suxcinyllcholine). During surgery she was given nine 100-microgram doses of alfentanil and 70% N₂O/O₂. Bradycardia developed and frequent unifocal premature ventricular con-
Tobias occurred throughout the surgery, but they disappeared 3 to 4 hours afterwards. The arrhythmia was attributed to an interaction between reserpine and alfentanil, but just why this should occur is not understood.\(^1\)

---

### Opioids; Alfentanil + Terbinafine

Terbinafine 250 mg daily for 3 days had no statistically significant effect on alfentanil pharmacokinetics and no adverse effects were reported.\(^1\)

### Opioids; Codeine + Kaolin

An isolated report describes patients suffering from chronic diarrhoea, who were stabilised taking codeine phosphate, but who experienced a relapse when the codeine was added to Kaolin Mixture. An in vitro study suggested the bioavailability of codeine may be reduced by adsorption onto kaolin.\(^1\)

### Opioids; Codeine + Somatostatin analogues

Lanreotide and octreotide partially inhibit the metabolism of codeine, which may possibly reduce its analgesic effects.

#### Clinical evidence, mechanism, importance and management

A study in 6 patients with gastrointestinal carcinoid tumours found that lanreotide or octreotide 750 micrograms subcutaneously three times daily for 3 days decreased the partial metabolic clearance of codeine by N-demethylation (by the cytochrome P450 isoenzyme CYP3A) by an average of 44% and the O-demethylation (by CYP2D6) by 35%. However, the partial clearance by 6-glucuronidation and the total systemic clearance of codeine were not consistently changed. The effects of the somatostatins were thought to be mediated by a suppression of growth hormone secretion. The reduction in O-demethylation can reduce the active metabolite of codeine, morphine, which could reduce the analgesic effect of the drug.\(^1\)

### Opioids; Dextropropoxyphene (Propoxyphene) + Orphenadrine

An alleged adverse interaction between dextropropoxyphene and orphenadrine, which is said to cause mental confusion, anxiety, and tremors, seems to be very rare, if indeed it ever occurs.

#### Clinical evidence, mechanism, importance and management

The manufacturers of orphenadrine used to state in their package insert that mental confusion, anxiety and tremors have been reported in patients receiving both orphenadrine and dextropropoxyphene. The manufacturers of dextropropoxyphene issued a similar warning. However, in correspondence with both manufacturers, two investigators\(^1\) of this interaction were told that the basis of these statements consisted of 6 anecdotal reports from clinicians to one manufacturer and 7 to the other (some could represent the same cases). Of the 7 cases to one manufacturer, 4 occurred where patients had received twice the recommended dose of orphenadrine. In every case the adverse reactions seen were similar to those reported with either drug alone. A brief study in 5 patients given both drugs to investigate this alleged interaction failed to reveal an adverse interaction.\(^2\) One case has been reported separately.\(^3\)

The documentation is therefore sparse, and no case of interaction has been firmly established. The investigators calculated that the two drugs were probably being used together on 300 000 prescriptions a year, and that these few cases would be less than significant.\(^4\) There seems therefore little reason for avoiding concurrent use.

### Opioids; Diamorphine + Pyrithyldione

A single case report describes a fatality due to the combined CNS depressant effects of diamorphine and pyrithyldione.

#### Clinical evidence, mechanism, importance and management

A diamorphine (heroin) addict was found dead after taking pyrithyldione (a sedative and hypnotic) with diamorphine. His blood pyrithyldione and brain morphine levels were found to be 590 nanograms/mL and 0.06 nanograms/g respectively, suggesting that he had taken only a therapeutic dose of the pyrithyldione and a moderate dose of diamorphine. The presumed cause of death was the combined CNS depressant effects of both drugs. The authors of the report draw the conclusion that the pyrithyldione potentiated the effects of the diamorphine.\(^1\)

### Opioids; Levacetylmethadol + Miscellaneous

Levacetylmethadol has been withdrawn in Europe and the USA because of cases of life-threatening cardiac arrhythmias associated with QT prolongation.\(^1,2\) Its use was contraindicated with MAOIs and drugs that prolong the QT interval.\(^3,4\) In addition, the manufacturers warned about the possible effects of inducers or inhibitors of the cytochrome P450 isoenzyme CYP3A4, which may increase or reduce its activity, respectively;\(^5\) the additive effects of alcohol or other CNS depressants; and the possible risk of oral contraceptive failure.\(^5\) They also advised the avoidance of pethidine (meperidine), dextropropoxyphene (propoxyphene) or naloxone (except when used for overdosage).\(^3\)

### Opioids; Methadone + Ciprofloxacin

An isolated case describes sedation, confusion and respiratory depression, which was attributed to the inhibition of methadone metabolism by ciprofloxacin.

#### Clinical evidence

A woman taking methadone 140 mg daily for 6 years to manage pain due to chronic intestinal pseudo-obstruction was admitted to hospital because of a urinary tract infection and given ciprofloxacin 750 mg twice daily. Two days later she became sedated and confused. Ciprofloxacin was replaced with co-trimoxazole and the patient recovered within 48 hours. She was treated with ciprofloxacin for recurrent urinary-tract infections a further three times and on each occasion the patient became sedated, with her normal alertness regained on discontinuing ciprofloxacin. On the last oc-
casion, when the venlafaxine that she had also been taking was replaced by fluoxetine, she also developed respiratory depression, which was reversed with naloxone.1

**Mechanism**

The cytochrome P450 isoenzymes CYP1A2, CYP2D6 and CYP3A4 are involved in the metabolism of methadone. Ciprofloxacin is a potent inhibitor of CYP1A2 and possibly has some effect on CYP3A4. It is therefore probable that the confusion and sedation seen in the patient were due to the inhibition of methadone metabolism. The use of "fluoxetine", (p. 1221) and the fact that the patient was a smoker, may also have contributed.

**Importance and management**

This seems to be the only report of this interaction but it would appear to be of clinical importance. Care is needed if ciprofloxacin and methadone are given concurrently, especially if there are other factors such as smoking or the use of other enzyme inhibitors, which may also contribute to the interaction. Be alert for the need to change the methadone dosage. Consider also ‘Quinolones + Opioids’, p. 338.

---

**Opioids; Methadone + Fusidic acid**

There is evidence that long-term fusidic acid may modestly reduce the effects of methadone.

**Clinical evidence, mechanism, importance and management**

Seven opioid addicts, without chronic alcoholism or liver disease, and who were receiving methadone maintenance treatment (45 to 65 mg daily) had an increase in the urinary excretion of the major pyrrolidine metabo-lite of methadone (an indicator of increased N-demethylation) when given fusidic acid 500 mg daily for 7 days. However, there was no effect on the degree of opioid intoxication, nor were withdrawal symptoms experienced.1 No special precautions would seem to be necessary if both drugs are given.

---

**Opioids; Methadone + Disulfiram**

No adverse interaction was seen when patients taking methadone were given disulfiram.

**Clinical evidence, mechanism, importance and management**

In 19 patients with malignant disease taking high doses of morphine (daily doses of 500 mg or more orally or 250 mg or more parenterally), an analysis was made of the relationship between myoclonus and the use of supplemental drugs. In the 12 patients with myoclonus, 8 patients were taking antidepressants (amitriptyline, doxepin) or antipsychotics (chlorpromazine, haloperidol) compared with none of 6 patients without myoclonus. In addition, there was a higher use of NSAIDs (indometacin, naproxen, piroxicam, aspirin) and an antiemetic (thiethylperazine).1 The reasons are not understood, and the findings of this paper have been questioned.2

---

**Opioids; Methadone + Aciclovir**

An isolated report describes pethidine toxicity associated with the use of high-dose aciclovir.

**Clinical evidence, mechanism, importance and management**

A man with Hodgkin’s disease was treated with high-dose intravenous aciclovir for localised herpes zoster, and with intramuscular pethidine, oral methadone and carbipoda-levodopa. On the second day he experienced nausea, vomiting and confusion, and later dysarthria, lethargy and ataxia. Despite vigorous treatment he later died. It was concluded that some of the adverse effects were due to pethidine toxicity arising from norpethidine accumulation, associated with renal impairment caused by the aciclovir.1 The US manufacturer of pethidine says that plasma concentrations of pethidine, and its metabolite norpethidine may be increased by aciclovir, thus caution should be used if both drugs are given.2

---

**Opioids; Tramadol + Pseudoephedrine**

An isolated report describes ischaemic colitis when a patient taking tramadol took a decongestant containing pseudoephedrine.

**Clinical evidence, mechanism, importance and management**

Acute, self-limiting ischaemic colitis occurred in a 46-year-old patient taking regular tramadol, celecoxib and diazepam for back pain, who had self-medicating with an oral decongestant containing pseudoephedrine. He had taken the maximum recommended dose of pseudoephedrine (240 mg daily) for 7 days. A similar, but milder abdominal discomfort had occurred 3 months earlier when he had used the same medication for one week. The colitis was thought to be due to the pseudoephedrine, but the concurrent use of the tramadol might possibly have contributed by increasing adrenergic vasoconstriction.1 The general significance of this isolated case is unclear.

---

**Paracetamol (Acetaminophen) + Amantadine**

Amantadine had no clinically significant effect on the pharmacokinetics of paracetamol.

**Clinical evidence, mechanism, importance and management**

A single 650-mg dose of paracetamol was given to 5 healthy subjects who had taken amantadine 200 mg daily for 42 days, and also after a single dose of amantadine. Although the apparent volume of distribution of paracetamol was very slightly larger following long-term amantadine use, no
other pharmacokinetic parameters were altered. Therefore, from this limited information it appears that no change in paracetamol dose is necessary if these two drugs are given together.1

Paracetamol (Acetaminophen) + Antiemetics

Metoclopramide increases the rate of absorption of paracetamol and raises its maximum plasma levels. Similarly, domperidone may increase the rate of absorption of paracetamol.

Clinical evidence, mechanism, importance and management

Intravenous metoclopramide 10 mg increased the peak plasma levels of a single 1.5-g dose of paracetamol by 64% in 5 healthy subjects (slow absorbers of paracetamol), and increased its rate of absorption (peak levels reached in 48 minutes instead of 120 minutes), but the total amount absorbed remained virtually unaltered.1 Oral metoclopramide also increases the rate of paracetamol absorption,2 probably because the rate of gastric emptying is increased. Similarly, the speed of absorption of paracetamol may also be increased by domperidone.3 This interaction is exploited in Paramax (a proprietary oral preparation containing both paracetamol and metoclopramide) to increase the effectiveness and onset of analgesia for the treatment of migraine. This is obviously an advantageous interaction in this situation.

Paracetamol (Acetaminophen) + Antiepileptics

The metabolism of paracetamol is increased in patients taking enzyme-inducing antiepileptics (carbamazepine, phenytoin, phenobarbital, primidone). Isolated reports describe unexpected hepatotoxicity in patients taking phenobarbital, phenytoin, or carbamazepine after taking paracetamol. Valproate does not appear to affect paracetamol metabolism. Paracetamol modestly reduces the AUC of lamotrigine but appears not to affect phenytoin or carbamazepine.

Clinical evidence

(a) Enzyme-inducing antiepileptics

The AUC of oral paracetamol 1 g was found to be 40% lower (and when given intravenously, 31% lower) in 6 epileptic subjects than in 6 healthy subjects. Five of the epileptic patients were taking at least two of the following drugs: carbamazepine, phenobarbital, primidone, phenytoin, and one was taking phenytoin alone.4 Similar findings (a 38% decrease in AUC) were reported in another study in 13 patients taking enzyme-inducing antiepileptics and 2 patients taking rifampicin. In these patients, the amount of glucuronide, but not sulfate, metabolites of paracetamol were higher than controls, but the potentially hepatotoxic metabolite (assessed by mercapturic acid and cysteine conjugates) was not raised.5 Similar changes in paracetamol metabolites were reported in Chinese patients taking phenytoin alone. However, in those taking carbamazepine alone there was no change in the paracetamol metabolites, when compared with control subjects.6 Other studies have also reported a greater rate of paracetamol glucuronidation and unchanged sulfation in patients taking phenytoin alone7 and patients taking phenytoin and/or carbamazepine.8

In contrast, this latter study also found an increase in clearance of the glutathione-derived conjugates (mercapturic and cysteine conjugates), which may indicate an increased risk of paracetamol hepatotoxicity.9

An epileptic woman taking phenobarbital 100 mg daily developed hepatic failure after taking paracetamol 1 g daily for 3 months for headaches. With in 2 weeks of stopping the paracetamol her serum transaminase levels had fallen within the normal range, which implied drug-induced liver damage.6 Another patient taking phenobarbital developed liver and kidney toxicity after taking only 9 g of paracetamol over 48 hours.7 Phenobarbital also appeared to have increased the toxic effects of paracetamol in an adolescent who took an overdose of both drugs, which resulted in fatal hepatic encephalopathy.8

Other case reports describe unexpected paracetamol hepatotoxicity in three patients taking phenytoin,9,10 three patients taking carbamazepine,12–14 and a patient taking phenytoin and primidone.15 Another analysis of patients with paracetamol-induced fulminant hepatic failure suggested that mortality was higher in the group of patients receiving antiepileptics (including phenytoin, phenobarbital, carbamazepine, primidone and valproate alone or in combination).15

The serum levels of phenytoin and carbamazepine in 10 epileptics were not significantly affected by paracetamol 1.5 g daily for 3 days.16

(b) Lamotrigine

A study in 8 healthy subjects found that paracetamol 2.7 g daily reduced the AUC of a 300-mg dose of lamotrigine by 20% and reduced its half-life by 15%.17

(c) Valproate

Valproate is extensively metabolised in man and a significant proportion of the metabolism occurs via glucuronide conjugation. A study designed to determine whether valproate affected the disposition of drugs that are largely dependent on conjugation found that it did not affect the pharmacokinetics of paracetamol in 3 epileptic patients.19

Mechanism

The increased paracetamol clearance is due to the well-recognised enzyme inducing effects of the antiepileptics, which increase its metabolism (glucuronidation and oxidation) and loss from the body. It has been suggested that this could result in an increase in the production of the hepatoxidative metabolite of paracetamol, N-acetyl-p-benzoquinone imine. If this toxic metabolite then exceeds the normal glutathione binding capacity, liver damage may occur (see ‘paracetamol’, p 133). The production of the toxic metabolite in vitro in animals and humans seems to depend on several isoenzymes, but the available evidence indicates that the cytochrome P450 isoenzyme CYP2E1 is the primary enzyme in humans.20 Therefore, since these enzyme-inducing antiepileptics do not induce this isoenzyme, some consider the few possible cases described merely represent idiosyncratic effects.15 However, others have suggested that, when several drugs, including phenobarbital or phenytoin are taken, inhibition of uridine diphosphate glucuronosyltransferase (UGT) enzymes by one of these drugs can lead to decreased glucuronidation and increased systemic exposure and toxicity of the paracetamol.21

Importance and management

Information is limited. The clinical importance of these interactions is not established and further study is needed. However, paracetamol is possibly a less effective analgesic in patients taking enzyme-inducing antiepileptics as plasma-paracetamol levels may be reduced. Levels of the potentially hepatotoxic metabolites may be increased. Some believe that the evidence indicates that the risk of liver damage after paracetamol overdose is increased, and they suggest that patients taking enzyme-inducing antiepileptics should be treated with antidotes at lower plasma levels of paracetamol.14,13,12,15 In addition, some suggest that therapeutic doses of paracetamol should be used with caution in patients receiving these drugs.10,11,16 Conversely, others consider that therapeutic doses of paracetamol are not associated with an increased risk of toxicity when used with enzyme-inducers. Moreover, phenytoin, by increasing glucuronida tion, may actually have some hepato-protective effects.20,22 The differences stem from different understandings of which mechanism and other factors are important in the interplay of the hepatoxic metabolite of paracetamol (see Mechanism, above).

It is unlikely that the interaction between lamotrigine and paracetamol is of practical importance, but this needs confirmation.

Paracetamol (Acetaminophen) + Caffeine

Caffeine has been variably reported to increase, decrease, and have no effect on the absorption of paracetamol.

Clinical evidence, mechanism, importance and management

Caffeine citrate 120 mg increased the AUC of a single 500-mg dose of paracetamol in 10 healthy subjects by 29%, increased the maximum plasma levels by 15% and decreased the total body clearance by 32%. The decrease in time to maximum level and increase in absorption rate did not reach statistical significance.1 However, in another study, although caffeine slightly increased the rate of absorption of paracetamol, it had no effect on the extent of absorption.2 Moreover, a third study states that caffeine decreased plasma paracetamol levels and AUC and increased paracetamol elimination in healthy men.3 Caffeine is commonly included in paracetamol preparations as an analgesic adjuvant. Its potential benefit and the mechanisms behind its possible effects remain unclear.

Paracetamol (Acetaminophen) + Chloroquine

Although modest pharmacokinetic effects occur when paracetamol and chloroquine are given together this is not thought to be clinically significant.

Clinical evidence, mechanism, importance and management

In a single-dose study, intravenous chloroquine increased the peak plasma paracetamol levels and the AUC by 47% and 22%, respectively.1 Another single-dose study in 8 healthy subjects found that paracetamol 500 mg increased the maximum plasma level and AUC of chloroquine 600 mg by 17% and 24%, respectively.2 These changes were thought unlikely to be clinically significant in therapeutic doses.3 A further study in 5 healthy subjects found that the pharmacokinetics of a single 300-mg dose of chloroquine were not affected by a single 1-g dose of paracetamol.4 This evidence therefore suggests that no dosage adjustments would be expected to be necessary when paracetamol is given with chloroquine.

Paracetamol (Acetaminophen) + Colestyramine

The absorption of paracetamol may be reduced if colestyramine is given at the same time, but the reduction in absorption is small if colestyramine is given an hour later.

Paracetamol (Acetaminophen) + Antimuscarinics

Propantheline reduced the rate, but not the extent, of paracetamol absorption. This would be expected to reduce the rate of onset of analgesia. Other antimuscarinic drugs that delay gastric emptying would be expected to interact similarly. In one case, the diphenhydramine component of a paracetamol product delayed paracetamol absorption after an overdose, and complicated the evaluation of the risk of toxicity.

Clinical evidence, mechanism, importance and management

Propantheline 30 mg intravenously delayed the peak serum levels of paracetamol 1.5 g in 6 convalescent patients from about 1 hour to 3 hours. Peak levels were lowered by about one-third, but the total amount of paracetamol absorbed was unchanged. This effect occurs because propantheline is an antimuscarinic drug that slows the rate at which the stomach empties, so that the rate of absorption in the gut is reduced. The practical consequence of this is likely to be that rapid pain relief with single doses of paracetamol may be delayed and reduced by antimuscarinics (see ‘Table 18.1’, (p.672), and ‘Table 18.2’, (p.674) for a list) but this needs clinical confirmation. If the paracetamol is being taken in repeated doses over extended periods this seems unlikely to be an important interaction because the total amount absorbed is unchanged.

One study in 10 healthy subjects reported that diphenhydramine 250 mg taken with paracetamol 5 g (simulated paracetamol overdose) had little effect on the absorption of paracetamol. However, a case has been described where the diphenhydramine component of a paracetamol product (Tylenol PM) taken in overdose (paracetamol 7.5 g and diphenhydramine 375 mg) delayed the absorption of paracetamol, so that the peak serum-paracetamol level did not occur until 8 hours after ingestion
Clinical evidence
When 4 healthy subjects took colestyramine 12 g and paracetamol 2 g together, the absorption of the paracetamol was reduced by 60% (range 30 to 98%) at 2 hours, but the results were said not to be statistically significant. When the colestyramine was given 1 hour after the paracetamol, the absorption was reduced by only 16%.1

Mechanism
Colestyramine reduces absorption, presumably because it binds with the paracetamol in the gut. Separating the dosages minimises mixing in the gut.

Importance and management
Although information is limited, it suggests that colestyramine should not be given within 1 hour of paracetamol if maximal analgesia is to be achieved. It is normally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine.

Paracetamol (Acetaminophen) + Disulfiram
Disulfiram had no important effect on the metabolism of paracetamol in one study, but decreased the production of the glutathione (hepatotoxic) metabolites in another.

Clinical evidence, mechanism, importance and management
After taking disulfiram 200 mg daily for 5 days, the clearance of a single 500-mg intravenous dose of paracetamol was slightly reduced (by about 10%) in 5 healthy subjects without liver disease and 5 others with alcoholic liver cirrhosis. The fractional clearance of paracetamol to its glucuronide, sulfate and glutathione metabolites was not altered.1 In contrast, another study found that pretreatment of healthy subjects with a single 500-mg dose of disulfiram 10 hours before a single 500-mg oral dose of paracetamol reduced the recovery of glutathione metabolites (a measure of the production of the hepatotoxic metabolite, see ‘paracetamol’, (p.133)) by 69%.2

Disulfiram is an inhibitor of the cytochrome P450 isoenzyme CYP2E1, which is involved in the metabolism of paracetamol. Previously, the authors of the first study1 had shown that in rats, high doses of disulfiram protected against the hepatotoxicity of paracetamol. Therefore, it was suggested that disulfiram might be useful in reducing the risks of paracetamol overdose. However, the authors of the first study concluded that disulfiram at doses used clinically is unlikely to have any beneficial (or adverse) effect on paracetamol metabolism.1 In contrast, the authors of the second study consider that disulfiram may be useful in reducing the formation of the hepatotoxic metabolite of paracetamol in some situations. Further study is needed.

Paracetamol (Acetaminophen) + Erythromycin
Erythromycin accelerates gastric emptying and increases paracetamol absorption but this does not appear to result in a clinically significant interaction.

Clinical evidence, mechanism, importance and management
In a study in healthy subjects, intravenous erythromycin 0.75 to 3 mg/kg accelerated gastric emptying in a dose-dependent manner and increased paracetamol absorption.1 However, another study found that erythromycin 200 mg intravenously, given to promote gastrointestinal motility, did not alter the pharmacokinetics of an extended-release oral dose of paracetamol.2 A further study in 7 healthy subjects reported that the pharmacokinetics of a single 1-g oral dose of paracetamol were not significantly affected by pretreatment with oral erythromycin 250 mg four times daily for 7 days.3 It was suggested that the concurrent use of erythromycin and paracetamol is unlikely to result in a clinically significant interaction.4

Clinical evidence, mechanism, importance and management
(a) Absorption of paracetamol (acetaminophen)
Several studies have demonstrated that food slows the rate of absorption of paracetamol, but the overall bioavailability is not usually affected. However, in some individuals food may delay and reduce peak paracetamol-plasma levels. A high fat meal may slightly reduce the extent of paracetamol absorption and certain foods, such as cabbage and brussels sprouts, may affect the metabolism of paracetamol, but this is unlikely to be clinically significant. Consider also the food preservative ‘sodium nitrate’, (p.198).

(b) Fasting and hepatotoxicity of paracetamol
A prospective study found that, of 49 patients with paracetamol hepatotoxicity, all had taken more than the recommended limit of 4 g of paracetamol daily. Paracetamol hepatotoxicity after a dose of 4 to 10 g daily was associated with fasting and less commonly with alcohol use, and it was suggested that paracetamol hepatotoxicity after an overdose appears to be enhanced by fasting in addition to alcohol ingestion.10 The metabolism of a lower 2-g dose of paracetamol was not, however, affected by food restriction or these patients had previously may ingest paracetamol hepatotoxicity by shunting paracetamol detoxification from the conjugative to the potentially toxic oxidative pathways.11 See also, ‘Alcohol + Paracetamol (Acetaminophen)’, p.73.

(c) Metabolism of paracetamol
In a crossover study in 10 healthy subjects, a 10-day balanced diet including cabbage 100 g and brussels sprouts 150 g at lunch and dinner was found to stimulate the metabolism of paracetamol, at least in part by en-
hanced glucuronidation. Compared with a control diet (which included instead, lettuce, cucumber, green beans and peas), cabbage and brussels sprouts induced a 16% decrease in the mean AUC of paracetamol, a 17% increase in the mean metabolic clearance rate, and an 8% increase in the mean 24-hour urinary recovery of the glucuronide metabolite.12 Consumption of watercress caused a decrease in the levels of plasma and urinary oxidative metabolites of paracetamol, but the urinary excretion of paracetamol, or its glucuronide and sulfate were not significantly altered.13 However, charcoal-brused beef (which accelerates the oxidative metabolism of some drugs) did not affect paracetamol metabolism.4 It seems unlikely that these foods would have a significant clinical effect, except perhaps cabbage and brussels sprouts if eaten to excess.

**Paracetamol (Acetaminophen) + H₂-receptor antagonists**

Cimetidine, nizatidine, and ranitidine do not appear to alter the pharmacokinetics of paracetamol to a clinically relevant extent.

### Clinical evidence

**a) Cimetidine**

Cimetidine (given as a single 200-mg dose or as 1 g daily in divided doses for 7 days) had no statistically significant effect on the pharmacokinetics of a single 750-mg dose of paracetamol in 4 healthy subjects.1 Similarly, in another study, a single 800-mg dose of cimetidine given one hour before paracetamol 1 g had no effect on paracetamol half-life or plasma clearance, and no effect on urinary excretion of its principal metabolite (glucuronide, sulfate, mercapturate) in 10 healthy subjects.2 Furthermore, the pharmacokinetics of a single 1-g dose of paracetamol were not altered by 2 months of treatment with cimetidine 400 mg twice daily in 10 patients. The only difference in urinary metabolites was a modest 37% decrease in paracetamol mercapturate (indicating a reduction in the hepatotoxic metabolite).3 Other studies have shown that cimetidine does not alter the clearance4 or metabolic pathways of paracetamol.5

In contrast, one study reported that cimetidine 300 mg every 6 hours decreased the fractional clearance of the oxidised metabolites (mercapturate and cysteine conjugates) of paracetamol in healthy subjects.6 Another study showed that a single 400-mg dose of cimetidine given one hour be-
A study in 6 healthy subjects found that (b) Hibiscus would therefore be expected if paracetamol is taken with garlic. There was a very slight increase in glucuronidation after the long-term use of garlic, and some evidence that sulfate conjugation was enhanced, but no effect on oxidative metabolism. No clinically significant interaction would therefore be expected if paracetamol is taken with garlic.

A study in 6 healthy subjects found that Zobo drink (Hibiscus sabdariffa water extract), given 78 minutes before a single 1-g dose of paracetamol did not affect the absorption or AUC of paracetamol, but the total body clearance increased by 12%. This is not expected to be clinically significant.

(c) Kakkonto Studies in healthy subjects found that 5 g of Kakkonto extract, a Chinese herbal medicine containing extracts of Puerariae, Ephedrae, Zingiberis, Cinnamomi, Glycyrrhizae, Paoniae and Ziziphi spp. had no effects on the pharmacokinetics of a single 12-mg/kg dose of paracetamol. A further study in 19 healthy subjects found that 1.25 g of Kakkonto had no effect on the pharmacokinetics of paracetamol 150 mg (from a preparation also containing salicylamide, caffeine and promethazine methylene disalicylate). Because in animal studies high doses of Kakkonto for 7 days were found to significantly increase serum levels of paracetamol, the authors concluded that further investigations were required to assess safety and efficacy of concurrent use.

**Paracetamol (Acetaminophen) + 5-HT3-receptor antagonists**

A placebo-controlled, crossover study in 26 healthy subjects found that both intravenous griseofulvin 3 mg and tropisetron 5 mg blocked the analgesic effect of a single 1-g oral dose of paracetamol given 90 minutes later. The pharmacokinetics of paracetamol were unaffected by the two drugs. The interaction was thought to involve the serotoninergic system, see Mechanism, in 'Opioids + Antiemetics; Ondansetron', p.161.

**Paracetamol (Acetaminophen) + Hormonal contraceptives or HRT**

Paracetamol clearance is increased in women taking oral contraceptives, although the clinical relevance of this is uncertain. Paracetamol also increases the absorption of ethinylestradiol from the gut by about 20%. HRT appears not to interact with paracetamol.

**Clinical evidence**

(a) Effect on paracetamol

In 7 healthy women taking combined oral contraceptives (containing ethinylestradiol), the plasma clearance of a single 1.5-g dose of paracetamol was 64% higher and the elimination half-life 30% lower, when compared with 7 healthy women not taking oral contraceptives. The fractional clearance by glucuronidation and of the cysteine conjugate increased, but that of sulfation and the mercapturic acid conjugate were unchanged. Similarly, other studies have found higher paracetamol clearances of 30 to 49%, and corresponding lower paracetamol half-lives, in women taking oral contraceptives, when compared with control subjects.

One study found that the pharmacokinetics of a single 650-mg intravenous dose of paracetamol did not differ between women who had taken conjugated oestrogens for at least 3 months and control subjects.

(b) Effect on oral contraceptives

A single 1-g oral dose of paracetamol increased the AUC of ethinylestradiol by 22% in 6 healthy women, and decreased the AUC of ethinylestradiol sulfate by 41%. Plasma levels of levonorgestrel were not affected.

**Mechanism**

The evidence suggests that oral contraceptives increase the metabolism (both oxidation and glucuronidation) of paracetamol by the liver so that it is cleared from the body more quickly. The increased absorption of the ethinylestradiol probably occurs because the paracetamol reduces its metabolism by the gut wall during absorption. It has been suggested that the difference between the effects of oral contraceptives and conjugated oestrogens on paracetamol may be attributable to the influence of progestogens on glucuronide and sulfate conjugation. This needs confirmation.

**Importance and management**

The modest pharmacokinetic interaction between the oral contraceptives and paracetamol appears to be established, but its clinical importance has not been directly studied. The clinical importance of the modest increased ethinylestradiol absorption is also uncertain, but likely to be minor. HRT appears not to interact with paracetamol.

**Paracetamol (Acetaminophen) + Isoniazid**

A number of reports suggest that the toxicity of paracetamol may be increased by isoniazid so that normal analgesic dosages (4 g daily) may not be safe in some individuals. Pharmacokinetic studies suggest that isoniazid usually inhibits the metabolism of paracetamol, but that metabolism to toxic metabolites may be induced shortly after stopping isoniazid, or late in the isoniazid dose-interval in fast acetylators of isoniazid.

**Clinical evidence**

A 21-year-old woman who had been taking isoniazid 300 mg for 6 months took 3.25 g of paracetamol for abdominal cramping. Within about 6 hours she developed marked evidence of liver damage (prolonged prothrombin time, elevated ammonia, transaminases, hyperbilirubinemia).

A young woman taking isoniazid who had taken up to 1.5 g of paracetamol in a suicide gesture, developed life-threatening hepatic and renal toxicity despite the fact that her serum paracetamol levels 13 hours later were only 15 micromol/L (toxicity normally associated with levels above 26 micromol/L).
Three other similar cases were reported in patients taking isoniazid, rifampicin and pyrazinamide who had taken only 2 to 6 g of paracetamol daily. Three other possible cases of this toxic interaction have been described. In a pharmacokinetic study in 10 healthy subjects of both slow and fast acetylator status, isoniazid 300 mg daily for 7 days moderately decreased the total clearance of a single 500-mg dose of paracetamol by 15%. Moreover, the clearance of paracetamol to oxidative metabolites was decreased. Similarly, in a further study in 10 healthy slow acetylators of isoniazid, the formation of paracetamol thioether metabolites and oxidative metabolites was reduced by 63% and 49%, respectively, by isoniazid 300 mg daily. However, one day after stopping isoniazid, the formation of thioether metabolites was increased by 56%, and this returned to pretreatment values 3 days after the discontinuation of isoniazid. In yet another study in 10 healthy subjects taking isoniazid prophylaxis, the formation clearance of paracetamol to N-acetyl-p-benzoquinone imine (NAPQI) was inhibited by 56% when the paracetamol was given simultaneously with the daily isoniazid dose, but when the paracetamol was taken 12 hours after the isoniazid, there was no difference in NAPQI formation clearance, compared with the control phase (1 to 2 weeks after isoniazid had been discontinued). However, when the results were analysed by acetylator status, it appeared that the NAPQI formation clearance was increased in fast acetylators taking paracetamol 12 hours after the isoniazid dose.

Mechanism
Not established. A possible reason that isoniazid induces the cytochrome P450 isoenzyme CYP2E1 by stabilisation. This means that while the isoniazid is still present, the metabolism of substrates such as paracetamol is inhibited. However, when isoniazid levels drop sufficiently (as may be the case late in the dosing interval in fast acetyators), metabolism may be induced resulting in a greater proportion of the paracetamol being converted into toxic metabolites than would normally occur.

Importance and management
Information is limited, but it would now seem prudent to consider warning patients taking isoniazid to limit their use of paracetamol because it seems that some individuals risk possible paracetamol-induced liver toxicity, even with normal recommended doses. Pharmacokinetic studies suggest that it is possible that the risk is greatest shortly after stopping isoniazid. The risk may also be higher if paracetamol is taken late in the isoniazid dosing interval, particularly in fast acetylators of isoniazid. More study is needed to clarify the situation.

Clinical evidence
(a) Codeine
In 6 healthy subjects paracetamol 1 g every 8 hours for 7 doses had no effect on the pharmacokinetics of a single 30-mg oral dose of codeine, or its metabolites. Similarly in other studies, codeine had no effect on the pharmacokinetics of paracetamol. Paracetamol and codeine are often combined because the combination is more effective than either drug given alone. However, note that not all studies have found this. For example, in one clinical study of surgical removal of impacted third molar teeth, there was no difference in analgesic efficacy between patients given paracetamol alone (800 mg given 3, 6, and 9 hours after surgery, then 400 mg four times daily for 2 days) and those given the same dose of paracetamol with the addition of codeine phosphate 30 mg. Moreover, patients given codeine experienced more adverse effects (nausea, dizziness, drowsiness).

(b) Diamorphine, Pethidine (Meperidine) and Pentazocine
In 8 healthy subjects the absorption of a single 20-mg/kg oral dose of paracetamol solution given 30 minutes after an intramuscular injection of either pethidine 150 mg or diamorphine 10 mg was markedly delayed and reduced. Peak plasma paracetamol levels were reduced by 31% and 74%, respectively, and delayed from 22 minutes to 114 minutes and 142 minutes, respectively. This interaction was also observed, by the same study group, in women in labour who had been given paracetamol tablets after receiving pethidine, diamorphine or pentazocine.

(c) Fentanyl
An in vitro study found that paracetamol inhibited the oxidation of fentanyl to norfentanyl, but the concentrations of paracetamol used were greater than those found therapeutically. A potential interaction was thought possible because fentanyl is metabolised by the cytochrome P450 isoenzyme CYP3A4 and paracetamol is also partially metabolised by the CYP3A family.

(d) Morphine
A study in healthy subjects, who remained in the supine position, investigated the effect of morphine syrup (4 doses of 10 mg given every 4 hours) on the absorption of paracetamol. The time to the maximum plasma paracetamol level, for conventional tablets, was increased from 51 minutes to 160 minutes by morphine, whereas the time to the maximum plasma paracetamol level for dispersible tablets was only increased from 14 to 15 minutes.

(e) Oxycodone
A crossover study in 10 healthy subjects investigated the effect of oxycodone 500 micrograms/kg on the absorption kinetics of a simulated paracetamol overdose (5 g). The maximum serum paracetamol level was reduced by 40%, the time to maximum level was increased by 68%, and the AUC0-∞ was 27% lower, when compared with paracetamol alone.

Mechanism, importance and management
The underlying mechanism of these interactions is that the opioid analgesics delay gastric emptying so that the rate of absorption of paracetamol is reduced, but the total amount absorbed is not affected. These were largely investigational studies in healthy subjects, where paracetamol was used as a measure of gastric emptying, and any clinical relevance has not been determined. Reducing the rate of paracetamol absorption would be expected to reduce the onset of analgesic effect, but this is probably not relevant in patients who are receiving regular doses of paracetamol. However, if speed of onset of action is important, one study suggested that the use of dispersible paracetamol might help to reduce the delay in reaching therapeutic plasma levels.

In paracetamol overdose, it has been suggested that when an opioid is present there may be a potential role for the use of activated charcoal beyond the one-hour post ingestion, because of the delay in the absorption of paracetamol. It is also worth noting that maximum plasma levels may be delayed when assessing treatment options.

Paracetamol (Acetaminophen) + Opioids
Diamorphine, morphine, oxycodone, pentazocine and pethidine delay gastric emptying so that the rate of absorption of paracetamol given orally is reduced. There is no pharmacokinetic interaction between codeine and paracetamol, but the combination may not always result in increased analgesia.

Paracetamol (Acetaminophen) + Probenecid

Probenecid reduces the clearance of paracetamol.

Clinical evidence, mechanism, importance and management

A metabolic study in 10 healthy subjects found that the clearance of paracetamol 1.5 g was almost halved (from 6.23 to 3.42 ml/minute per kg) when it was taken 1 hour after a 1-g dose of probenecid. The amount of unchanged paracetamol in the urine stayed the same, but the glucuronide metabolite fell sharply. Another study in 11 subjects also found that probenecid 500 mg every 6 hours almost halved (from 329 to 178 ml/minute) the clearance of a 650-mg intravenous dose of paracetamol. The urinary excretion of the glucuronide metabolite was decreased by 68% and the excretion of the sulfate metabolite increased by 49%. These studies suggest that probenecid inhibits paracetamol glucuronidation, possibly by inhibiting glucuronyltransferase. See also "paracetamol", p.133. The practical consequences of this interaction are uncertain but there seem to be no adverse reports.

Propanolol may slightly increase the bioavailability of paracetamol, but this is unlikely to be clinically significant.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects, propanolol 80 mg twice daily for 4 days increased the half-life of a single 1.5-g dose of paracetamol by 25% and lowered its clearance by 14%. The partial clearance of paracetamol to its cysteine and mercapturate derivatives was decreased by 16% and 32%, respectively, and the clearance to the glucuronide conjugate was decreased by 27%, but the sulfate was not significantly affected. Similarly, an earlier study found that propanolol 40 mg four times daily for one week increased the maximum plasma level of a single 1.5-g dose of paracetamol and reduced the time to peak plasma level. However, the increased rate of absorption of paracetamol was not thought to be clinically important. In contrast, a study in 6 subjects found that a relatively small dose of propanolol (80 mg daily for 6 days) did not affect the pharmacokinetics of paracetamol. Another study found that long-term propanolol use in patients with chronic liver disease did not influence the clearance of total or unconjugated paracetamol.

The changes described here appear to be small, and therefore unlikely to be clinically significant. Note that, it has been postulated, based on studies in animals, that propanolol may have a protective effect on paracetamol hepatic toxicity by inhibiting the oxidative metabolism of paracetamol to toxic metabolites.

Paracetamol (Acetaminophen) + Proton pump inhibitors

Lansoprazole modestly increased the rate, but not the extent, of absorption of paracetamol solution. Omeprazole does not appear to have any effect on the metabolism of phenacetin or paracetamol.

Clinical evidence

(a) Lansoprazole

In a study in 6 healthy subjects, lansoprazole 30 mg once daily for 3 days increased the peak level of paracetamol (given as a single 1-g dose in solution) by 43%, and decreased the time to peak paracetamol levels by half (from about 35 to 17.5 minutes). However, lansoprazole had no effect on the AUC and elimination half-life of paracetamol.

(b) Omeprazole

Omeprazole 20 mg daily for 8 days had no effect on the pharmacokinetics of phenacetin, or paracetamol derived from phenacetin, in 10 healthy subjects, except that the peak plasma level of phenacetin was higher. There was no change in the metabolism (oxidative and conjugative) of phenacetin or derived paracetamol. In another study, omeprazole 40 mg daily for 7 days had no effect on the formation of thioether metabolites of paracetamol in 5 rapid and 5 slow metabolisers of S-mephenytoin [a probe drug for CYP2C19 activity, see 'Genetic factors in drug metabolism', (p.4)].

Mechanism

Lansoprazole may increase the absorption of paracetamol by indirectly increasing the rate of gastric emptying. Phenacetin is metabolised to paracetamol by the cytochrome P450 isoenzyme CYP1A2, and it has been suggested that omeprazole can induce CYP1A2, and possibly increase the formation of hepatotoxic metabolites of paracetamol. However, the findings here suggest that omeprazole has no important effect on CYP1A2, or on phenacetin or paracetamol metabolism.

Importance and management

The findings from these studies suggest that neither lansoprazole nor omeprazole cause any clinically important changes in the pharmacokinetics of paracetamol. No special precautions appear to be needed on concurrent use.

Paracetamol (Acetaminophen) + Rifampicin (Rifampin)

Rifampicin increases the metabolism of paracetamol. An isolated report describes hepatic failure, which may have been due to an interaction between paracetamol and rifampicin.

Clinical evidence, mechanism, importance and management

The metabolite to paracetamol ratio for glucuronides was twice as high in 10 patients treated with rifampicin 600 mg daily than in 14 healthy control subjects. In contrast the ratio for sulfates did not differ between the two groups. In a crossover study in healthy subjects, rifampicin 600 mg daily for 1 week, given before paracetamol 500 mg, had no effect on the formation of N-acetyl-p-benzoquinone imine (NAPQI) or the recovery of thiol
metabolites formed by conjugation of NAPQI with glutathione. These studies suggest that rifampicin induces the glucuronidation of paracetamol, but that it does not increase the formation of hepatotoxic metabolites of ‘paracetamol’, (p.133).

However, a 32-year-old woman, who had taken paracetamol 2 to 4 g daily for several weeks, and who had not responded to doxycycline or clarithromycin for suspected cat scratch fever, became confused and agitated 2 days after starting to take rifampicin 600 mg twice daily. Her INR increased from 1.1 to 5.2 and her liver enzymes became raised. Rifampicin and paracetamol were stopped, and she was treated with vitamin K and acetylcysteine, and liver function returned to normal. Paracetamol hepatotoxicity, in doses not normally associated with such effects, occurred only after the addition of rifampicin. It was suggested that rifampicin, which alone may cause hepatitis, had in this case induced the metabolism of paracetamol to hepatotoxic metabolites.3

The clinical importance of the studies awaits further study, but they suggest that rifampicin may reduce the efficacy of paracetamol.

---

**Paracetamol (Acetaminophen) + Sodium nitrate**

An isolated report describes severe methaemoglobinemia in a patient who had taken paracetamol after a meal consisting of ‘yuke’ (raw beef preserved with sodium nitrate). Both paracetamol and sodium nitrate may cause methaemoglobinemia, so an interaction resulting in additive effects may have occurred, but a genetic cause was also considered to be a possibility.1

---

**Paracetamol (Acetaminophen) + Sucralfate**

The bioavailability of paracetamol 1 g (using salivary paracetamol levels over 4 hours as a measure of paracetamol absorption) was found to be unchanged in 6 healthy subjects given sucralfate 1 g.1

---

**Paracetamol (Acetaminophen) + Sulfipyrazone**

Sulfipyrazone modestly increases the clearance of paracetamol.

**Clinical evidence, mechanism, importance and management**

In 12 healthy subjects, sulfipyrazone 200 mg given every 6 hours for one week, increased the clearance of a single 1-g dose of paracetamol by 23%. There was a 26% increase in metabolic clearance of the glucuronide conjugate, and a 43% increase in the glutathione-derived conjugates (indicating an increased production of the hepatotoxic metabolite), but no change in sulfation.1 It has therefore been suggested that, in patients taking sulfipyrazone, the risk of liver damage may be increased after paracetamol overdosage and perhaps during prolonged consumption, (see also ‘paracetamol’, (p.133)) but there seem to be no adverse reports. The clinical importance of these findings awaits further study.

---

**Paracetamol (Acetaminophen) + Tobacco**

Heavy, but not moderate, smoking may increase the metabolism of paracetamol. The clearance of phenacetin is also increased in smokers. There is some evidence that smokers are at risk of a poorer outcome after paracetamol overdose.

**Clinical evidence, mechanism, importance and management**

There was no difference in the clearance of a single 1-g dose of paracetamol in 6 healthy smokers (more than 15 cigarettes per day) and 6 healthy non-smokers in one study, and no difference in the paracetamol metabolites.1 Similarly, another study found no difference in the pharmacokinetics of a single 650-mg intravenous dose of paracetamol in 14 healthy smokers (range 8 to 35 cigarettes per day) and 15 non-smokers.2 In contrast, in another study, the metabolite to paracetamol ratio for glucuronides was 53% higher in 9 heavy smokers (about 40 cigarettes daily), suggesting increased paracetamol metabolism, than in 14 healthy non-smokers. However, it was not higher in moderate smokers (about 10 cigarettes daily).3

A further study in 36 healthy Chinese subjects given a single 900-mg dose of phenacetin found that subjects who smoked cigarettes (7 to 40 daily; mean 20) had a 2.5-fold higher phenacetin apparent oral clearance, compared with non-smokers. Paracetamol plasma levels were also moderately lower in the smokers (phenacetin is metabolised to paracetamol). Cigarette smoke appears to induce the metabolism of phenacetin by the cytochrome P450 isoenzyme CYP1A2, and also appears to increase the metabolism of paracetamol either by stimulating a minor pathway involving CYP1A2 oxidation or by stimulating the conversion of phenacetin to compounds other than paracetamol.4

A retrospective study of patients treated for paracetamol poisoning found that there was a much higher proportion of smokers than in the general population (70% versus 31%). Moreover, smoking was independently associated with an increased risk of hepatic encephalopathy (odds ratio 2.68) and death (odds ratio 3.64) following paracetamol overdose.5

No interaction is established, but the above studies suggest that heavy smoking may increase the metabolism of paracetamol. The retrospective study also suggests that smoking is associated with a poorer outcome after paracetamol overdose. Further study is needed.

This section covers the drugs used in the management of obesity (such as orlistat and sibutramine) as well as the older drugs, such as the amphetamines, which are now no longer widely indicated for this condition, and are now more generally considered as drugs of abuse. However, it should not be forgotten that the amphetamines (largely dexamfetamine) still have a limited therapeutic role in the management of narcolepsy. Ecstasy (MDMA, methylenedioxymethamphetamine), a drug of abuse that is structurally related to amphetamine, is also included in this section. The amphetamines are sympathomimetics, a diverse group, which have a number of interactions. The mechanism of action and classification of sympathomimetics is discussed in ‘Cardiovascular drugs, miscellaneous’, (p.878). Other stimulant drugs (such as atomoxetine; and methylphenidate, another sympathomimetic) have a role in attention deficit hyperactivity disorder (ADHD) and are also discussed in this section.
Amfetamines + Cocaine

An ischaemic stroke occurred in a patient who was abusing amfetamine and cocaine. In vitro, cocaine inhibits the demethylation of ecstasy (MDMA, methylenedioxymethamphetamine), but the clinical significance of this is unknown.

Clinical evidence, mechanism, importance and management

A 16-year-old boy developed unsteadiness and double vision 5 minutes after intranasal inhalation of a small amount of amfetamine ‘cut’ with cocaine. Cranial MRI (magnetic resonance imaging) revealed a mesencephalic lesion that was seen to have decreased 12 days later, and he became symptom-free after 3 weeks. The ischaemic lesion was thought to be due to vasospasm caused by synergistic stimulation of the sympathetic nervous system: amfetamine causes the release of adrenaline (epinephrine) and noradrenaline (norepinephrine), while cocaine prevents their reuptake.1

An in vitro study showed that cocaine (a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6) inhibited the CYP2D6-mediated demethylation of ecstasy (MDMA, methylenedioxymethamphetamine). Therefore, theoretically, the use of cocaine would be expected to increase plasma and CNS concentrations of ecstasy,2 but it is not known if this is significant in practice.

Amfetamines and related drugs + Lithium

The stimulant and/or cardiovascular effects of the amfetamines have been shown to be opposed by lithium in some, but not other studies.

Clinical evidence, mechanism, importance and management

Two depressed patients stopped abusing metamfetamine and cannabis, or phenmetrazine and ‘other diet pills’ because, while taking lithium carbonate, they were unable to get ‘high’. Another patient complained that she felt no effects from amfetamines taken for weight reduction, including no decrease in appetite, until lithium carbonate was withdrawn.1 A controlled study in 9 depressed patients confirmed that lithium carbonate taken for 10 days attenuated the subjective stimulant effects of dexamfetamine or L-amphetamine.2 Another study found similar results with dexamfetamine in schizophrenic patients.3 However, in a further study, only 4 of 8 subjects had an attenuation of the stimulant effects of amfetamine.4 In this study, lithium attenuated the increase in systolic blood pressure caused by amfetamine (from an average increase of 31/15 mmHg down to 20/9 mmHg).5 In contrast, in a controlled study in healthy subjects, there was no difference in subjective or cardiovascular effects of a single 20-mg dose of dexamfetamine between those receiving lithium 1.2 g daily for 7 days and those receiving placebo.6 In yet another controlled study, in 9 subjects, the only significant effect of pretreatment with lithium 900 mg for 14 days was to attenuate the feeling of happiness after dexamfetamine.6

The reasons for these reactions, when they occur, are not known, but one suggestion is that amfetamines and lithium have mutually opposing pharmacological actions on noradrenaline (norepinephrine) release and uptake at adrenergic neurones.1

Information is contradictory, therefore an interaction is not established. Nevertheless, it may be prudent to be alert for evidence of reduced amfetamine effects in the presence of lithium.

Amfetamines and related drugs + Phenothiazines

The appetite suppressant and other effects of amfetamines, chlorpromazine and phenmetrazine are opposed by chlorpromazine. It seems possible that other phenothiazines will interact similarly. The antipsychotic effects of chlorpromazine can be opposed by dexamfetamine.

Clinical evidence

In a placebo-controlled study 10 obese schizophrenic patients who were taking drugs including chlorpromazine, thioridazine, imipramine and chlor Diazepoxide did not respond to treatment with dexamfetamine for obesity. The expected sleep disturbance in response to dexamfetamine was also not seen.1 In a double-blind, placebo-controlled study in 76 patients, chlorpromazine was found to diminish the weight-reducing effect of phenmetrazine,2 and, in another study, patients taking chlorpromazine did not experience the expected weight loss when they were given phenmetrazine or chlorphenetermine.3 Similarly, antagonism of the effects of amfetamines by chlorpromazine has been described in other reports.4

A study in 462 patients taking chlorpromazine 200 to 600 mg daily indicated that the addition of dexamfetamine 10 to 60 mg daily had a detrimental effect on the control of their schizophrenic symptoms.5

This interaction has been deliberately exploited, with success, in the treatment of 22 children poisoned with various amfetamines or related compounds (amfetamine, dexamfetamine, metamfetamine, phenmetrazine).6

Mechanism

Not understood. It is known that chlorpromazine can inhibit adrenergic and dopaminergic activity, which could explain some part of the antagonism of the amfetamines, the euphoriant effects of which are said to be mediated by central dopamine receptors.

Importance and management

Established interactions. These reports suggest that it is not beneficial to attempt to treat patients taking chlorpromazine with amfetamines, such as dexamfetamine, or other central stimulants such as phenmetrazine. In one study, thioridazine also appeared to interact. However, it is not clear whether this interaction takes place with antipsychotics other than chlorpromazine, but it seems possible with the phenothiazines, especially if the suggested mechanism is correct. Note that central stimulants are no longer recommended for the treatment of obesity.

Amfetamines + Phenylpropanolamine

The effects of levamfetamine were attenuated in a hyperactive child by a nasal decongestant containing chlorphenamine and phenylpropanolamine.
Amphetamines and related drugs + Protease inhibitors

A man taking ritonavir suffered a fatal serotonergic reaction after taking ecstasy (MDMA, methylenedioxymethamphetamine). A similar fatal reaction occurred with metamfetamine and ritonavir.

Clinical evidence

(a) Ecstasy (MDMA, Methylenedioxymethamphetamine)

An HIV-positive man taking lamivudine and zidovudine was additionally given ritonavir 600 mg twice daily. About a fortnight later he went to a club and took ecstasy, in a dose estimated to be about 180 mg. He soon became unwell, and when seen by a nurse in the club was hypertonic, tachypnoeic (45 breaths per minute), tachycardic (more than 140 bpm), cyanosed and diaphoretic. He had a tonic-clonic seizure, his pulse rose to 200 bpm, he then vomited, had a cardiorespiratory arrest and died. A post-mortem showed blood-alcohol concentrations of 24 mg% and an ecstasy level of 500 nanograms/mL in the blood (considered to be in the fatal range, especially a case report describes 2 patients taking ritonavir 20 mg daily or paroxetine 20 mg daily who did not experience any effects from ecstasy after starting the SSI. One patient continued to experience a ‘high’ from amphetamines. However, an account of 4 ecstasy users who had taken fluoxetine 20 mg before taking ecstasy 100 to 250 mg, reported that they still experienced the subjective effects of euphoria, but one commented that the overall acute experience was “slightly calmer”. Some of the adverse effects such as jaw clenching and insomnia were also attenuated and recovery was more rapid.

(b) Metamfetamine

A 49-year-old HIV-positive man taking protease inhibitors was found dead after injecting himself twice with metamfetamine as well as sniffing amyl nitrate. He had been taking an antiretroviral regimen of ritonavir 400 mg twice daily, soft gel saquinavir 400 mg twice daily and stavudine 40 mg twice daily for 4 months. Toxicology detected metamfetamine 500 nanograms/mL in the blood (considered to be in the fatal range, especially when used with other unnamed drugs). Cannabinoids and traces of diazepam and nordiazepam were also found in this patient.

Mechanism

Ritonavir inhibits the cytochrome P450 isoenzyme CYP2D6, which is responsible for the demethylation of ecstasy, so concurrent use leads to a sharp rise in ecstasy plasma levels. Poor liver function (due to alcoholism) may have been a contributory factor in one patient, and further CYP inhibition by nitric oxide (the metabolite of amyl nitrate) may have contributed to another case. An additional factor is that ecstasy may show non-linear pharmacokinetics. Metamfetamine is also metabolised by CYP2D6 and its levels would therefore similarly be raised by ritonavir.

Importance and management

Although there are few reported cases, what happens is consistent with the known toxic effects and pharmacology of the drugs concerned. In addition, protease inhibitors may theoretically inhibit the metabolism of ecstasy via other isoenzymes (CYP3A4, CYP2B6), which could therefore also lead to increased levels.

It has been suggested that patients who are prescribed any protease inhibitor should be made aware of the potential risks of using any form of recreational drugs metabolised by CYP2D6. In particular, some authors recommend that patients taking ritonavir should avoid using ecstasy, metamfetamine and other amphetamines. Open discussions of illicit drug use would enable carers to warn patients that the use of these drugs may be even more dangerous while taking protease inhibitors. Appropriate precautions, apart from avoidance, include a reduction of the usual dose of ecstasy to about 25%, taking breaks from dancing, checking that a medical team are on site, maintaining adequate hydration by avoiding alcohol, and replenishing fluids regularly.

Amphetamines and related drugs + SSRIs

The psychological effects of ecstasy (MDMA, methylenedioxymethamphetamine) may be reduced if citalopram has previously been given. It seems likely that other SSRIs will also reduce or block some of the effects of ecstasy, but increased serotonin effects may, in theory, also be possible. An isolated report describes a neurotoxic reaction in a man taking citalopram when he took unknown amounts of ecstasy. Fluoxetine and paroxetine may decrease the metabolism of ecstasy.

Clinical evidence

A double-blind, placebo-controlled psychometric study in 16 healthy subjects found that ecstasy (MDMA, methylenedioxymethamphetamine) 1.5 mg/kg produced an emotional state with heightened mood, increased self-confidence and extraversion, moderate derealisation and an intensification of sensory perception. Most of these effects were found to be markedly reduced by pretreatment with citalopram 40 mg by intravenous infusion, although their duration was prolonged by up to 2 hours. Similarly, a case report describes 2 patients taking citalopram 20 mg daily or paroxetine 20 mg daily who did not experience any effects from ecstasy after starting the SSI. One patient continued to experience a ‘high’ from amphetamines. However, an account of 4 ecstasy users who had taken fluoxetine 20 mg before taking ecstasy 100 to 250 mg, reported that they still experienced the subjective effects of euphoria, but one commented that the overall acute experience was “slightly calmer”. Some of the adverse effects such as jaw clenching and insomnia were also attenuated and recovery was more rapid.

When a man taking citalopram 60 mg daily additionally took unknown amounts of ecstasy he became aggressive, agitated, severely grandiose, restless and performed compulsive movements in a peculiar and Joyce-like manner. He lacked normal movement control and said he could see little bugs. He was treated with haloperidol and chlor Diazepoxide, and improved within 2 days of replacing the citalopram with promazine.

In a placebo-controlled, randomised, crossover study, 7 healthy subjects were given ecstasy 100 mg on the last day of taking paroxetine 20 mg daily for 3 days. Paroxetine raised the maximum serum levels and AUC of ecstasy by 17% and 27%, respectively.

Mechanism

Complex. It has been suggested that the psychological and neurotoxic effects of ecstasy may be caused by serotonin release in the brain. This could potentially be blocked by serotonin reuptake inhibitors (such as citalopram) resulting in reduced ecstasy effects. However, ecstasy is also thought to inhibit serotonin reuptake, so its use with the SSRIs could increase serotonin effects, which could result in neurotoxicity. Furthermore, the SSRIs (to varying degrees) inhibit the cytochrome P450 isoenzyme CYP2D6, by which ecstasy is metabolised, so concurrent use could result in increased ecstasy levels.
Amfetamines + Urinary acidifiers or alkalinisers

The urinary excretion of amfetamines is increased by urinary acidifiers (ammonium chloride) and reduced by urinary alkalinisers (sodium bicarbonate).

Clinical evidence
A study in 6 healthy subjects given dexamfetamine 10 to 15 mg found that when the urine was made alkaline (pH of about 8) by giving sodium bicarbonate, only 3% of the original dose of amfetamine was excreted over a 16-hour period, compared with 55% when the urine was made acidic (pH of about 5) by taking ammonium chloride. Similar results have been reported elsewhere for amfetamine, dexamfetamine and metamphetamine. A further study found that the effects of amfetamine were increased and prolonged in subjects with alkaline urine. Psychoses resulting from amfetamine retention in patients with alkaline urine have been described.

Mechanism
Amfetamines are bases, which are excreted by the kidneys. If the urine is alkaline most of the drug exists in the unionised form, which is readily reabsorbed by the kidney tubules so that little is lost. In acid urine, little of the drug is in the unionised form so that little can be reabsorbed and much of it is lost. For more detail on this mechanism see ‘Changes in urinary pH’, (p.7).

Importance and management
A well established and well understood interaction but reports of problems in practice seem rare. The interaction has been exploited to increase the clearance of amfetamines in cases of overdose by acidifying the urine with ammonium chloride. Conversely it can represent an undesirable interaction if therapeutic doses of amfetamines are excreted too rapidly. Care is needed to ensure that amfetamine toxicity does not develop if the urine is made alkaline with sodium bicarbonate or another urinary alkaliniser, acetazolamide.

Paroxetine markedly increases amfetamine levels in extensive metabolisers of CYP2D6. Fluoxetine also raises amfetamine levels. There is a possibility that this may increase adverse effects, and a slower titration of amfetamine dose is suggested for patients taking paroxetine and other CYP2D6 inhibitors.

Clinical evidence
Paroxetine 20 mg daily for 17 days, with amfetamine 20 mg twice daily on days 12 to 17, was given to 22 healthy subjects who were extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6 (most common phenotype). Paroxetine increased the AUC of amfetamine 6.5-fold, increased the maximum plasma level by 3.5-fold, and increased the elimination half-life by 2.5-fold, when compared with amfetamine alone. No changes in paroxetine pharmacokinetics were seen. The pharmacokinetics of amfetamine with paroxetine in these subjects was similar to that previously seen with amfetamine alone in poor metaboliser subjects.

Following a small-scale study in which amfetamine was given with fluoxetine without any adverse effects, 127 children with attention deficit hyperactivity disorder were randomised to receive fluoxetine 20 mg daily and 46 to placebo. After 3 weeks amfetamine (starting at 0.5 mg/kg daily, increasing over 5 weeks to a maximum of 1.8 mg/kg daily) was also given to both groups. The fluoxetine group had 3.3-fold higher peak amfetamine levels than the placebo group (1177 nanograms/mL compared with 351 nanograms/mL). However, despite a trend towards a greater incidence of decreased appetite with the combination (20% versus 6.8%), there was no significant difference in adverse events between the two groups.

Mechanism
Amfetamine is extensively metabolised by CYP2D6, an isoenzyme that shows polymorphism, with up to 10% of the population lacking an active form (poor metabolisers). Paroxetine inhibits CYP2D6, and thereby increases amfetamine levels in those with an extensive metaboliser phenotype. It would not be expected to have any effect in poor metabolisers. Fluoxetine can similarly inhibit CYP2D6.

Importance and management
An established pharmacokinetic interaction. Paroxetine effectively changes patients from an extensive metaboliser phenotype to a poor metaboliser phenotype, markedly raising amfetamine levels. Although the clinical relevance has not been directly assessed, the manufacturer notes that adverse effects of amfetamine were up to twice as frequent in poor metaboliser patients in clinical studies. Because of this, they suggest that patients already taking CYP2D6 inhibitors should undergo a slower titration of amfetamine dose than usual, with the dose only increased if symptoms fail to improve and if the initial dose is well tolerated. This seems a sensible precaution. Note that in the fluoxetine study, which found that the concurrent use of amfetamine was generally well-tolerated, dosage increases were made on a weekly basis, with a dose of 1.2 mg/kg daily achieved in 2 weeks. The US manufacturers suggest a starting dose of amfetamine 0.5 mg/kg daily and only increasing the dose to 1.2 mg/kg daily if symptoms fail to improve over 4 weeks and the initial dose is well tolerated. The UK manufacturers say that the initial dose should be maintained for a minimum of 7 days before increasing it, if necessary, and that slower titration may be necessary in patients taking CYP2D6 inhibitors. It would also seem prudent to be alert to the possibility of an increase in adverse effects if CYP2D6 inhibitors are added to established amfetamine
The manufacturer contraindicates the concurrent use of atomoxetine and MAOIs on theoretical grounds. Atomoxetine is predicted to have additive effects with pressor drugs and other sympathomimetics and has been seen to potentiate the increase in heart rate and blood pressure seen with intravenous salbutamol. However, no increase in cardiovascular effects was seen when atomoxetine was given with methylphenidate. Atomoxetine did not alter desipramine pharmacokinetics and would therefore not be expected to affect other substrates of CYP2D6. Atomoxetine did not alter midazolam pharmacokinetics and would therefore not be expected to affect other substrates of CYP3A4. Antacids and omeprazole do not alter atomoxetine bioavailability.

Clinical evidence, mechanism, importance and management

Atomoxetine is a sympathomimetic that acts as a noradrenaline reuptake inhibitor. As such, it causes a modest increase in pulse and/or blood pressure in many patients. It can also cause hypotension.

(a) Antacids or Omeprazole

In a study in 20 extensive metabolisers of atomoxetine, aluminium/magnesium hydroxide (Maalox) and omeprazole did not affect the bioavailability of atomoxetine 40 mg. No special precautions appear to be necessary on concurrent use.

(b) CYP2D6 substrates

Atomoxetine 40 or 60 mg twice daily for 13 days was given to 21 subjects who were extensive metabolisers of CYP2D6 (most common phenotype) with a single 50-mg dose of desipramine on day 4. Atomoxetine had no effect on desipramine pharmacokinetics.

Desipramine is extensively metabolised by CYP2D6, and can be used as a probe drug for assessment of the effect of drugs on this isozyme in extensive metabolisers (see ‘Genetic factors’, p.4). It was concluded that atomoxetine, even at the maximum recommended dose, does not cause clinically relevant inhibition of CYP2D6 in vivo, and so will not affect the pharmacokinetics of other CYP2D6 substrates. For a list of CYP2D6 substrates, see ‘Table 1.3’, (p.6).

(c) CYP3A4 substrates

Atomoxetine 60 mg twice daily for 12 days was given to 6 subjects who were poor metabolisers of CYP2D6, with a single 5-mg oral dose of midazolam on days 6 and 12. Atomoxetine increased the maximum level and AUC of midazolam by about 16%, which was not statistically or clinically significant.

Midazolam is extensively metabolised by CYP3A4, and can be used as a probe drug for assessment of the effect of drugs on this isozyme. Poor metabolisers of CYP2D6 were chosen for this study, because they have much higher levels of atomoxetine than extensive metabolisers of CYP2D6. It was concluded that atomoxetine, even at the maximum recommended dose, does not cause clinically relevant inhibition of CYP3A4 in vivo, and so will not affect the pharmacokinetics of other CYP3A4 substrates. For a list of CYP3A4 substrates, see ‘Table 1.4’, (p.6).
Gross-Tsur V. Carbamazepine and methylphenidate. One child died from ventricular fibrillation due to cardiac abnormality, and the case was largely a media-inspired scare story built on inconclusive evidence.2,3

Carbamazepine may reduce methylphenidate levels.

Clinical evidence, mechanism, importance and management

A 7-year-old boy with attention deficit disorder taking carbamazepine 1 g daily for grand mal epilepsy was referred because of unmanageable behaviour. He failed to respond to methylphenidate in doses of up to 30 mg every 4 hours, and his blood levels of both methylphenidate and its metabolites were undetectable. The authors of the report attributed this to an interaction with the carbamazepine.1 Similarly, symptoms of attention deficit hyperactivity disorder worsened in a 13-year-old girl taking methylphenidate after she also took carbamazepine. Methylphenidate serum levels decreased markedly and the dose of methylphenidate had to be increased from 20 to 60 mg three times daily to regain a benefit similar to that achieved before the addition of carbamazepine.2 However, another report describes 4 out of 7 children taking methylphenidate and carbamazepine in whom the combination was successful. Blood levels of methylphenidate were apparently not measured.3 Despite the sparsity of the information, and the cases of apparently successful use, it would seem wise to consider carbamazepine as a possible cause if patients do not respond adequately to methylphenidate. If this occurs, consider increasing the methylphenidate dose.

Methylphenidate + Clonidine

Much publicised fears about the serious consequences of using methylphenidate with clonidine appear to be unfounded. There is limited evidence to suggest that concurrent use can be both safe and effective.

Clinical evidence, mechanism, importance and management

There have been fears about serious adverse events when methylphenidate is taken with clonidine,1 due to reports of 3 deaths in children taking both drugs. One child died from ventricular fibrillation due to cardiac abnormalities, one from cardiac arrest attributed to an overdose of fluoxetine, and the third death was unexplained. Studies of these 3 cases and one other failed to establish any link between the use of methylphenidate with clonidine and these deaths, the final broad conclusion being that the event was largely a media-inspired scare story built on inconclusive evidence.2,3 A small scale pilot study in 24 patients suggested that the combination is both safe and effective for the treatment of attention deficit hyperactivity disorder,4 and the manufacturers of one formulation of methylphenidate4 said that, as of 2002, they were not aware of any reports describing adverse events when Concerta XL (methylphenidate) was used with clonidine.

Modafinil + Dexamfetamine

No pharmacokinetic interaction appears to occur between modafinil and dexamfetamine.

Clinical evidence, mechanism, importance and management

In a steady-state study, 23 healthy subjects were given modafinil 200 mg daily for 7 days, followed by 400 mg daily for 3 weeks. During the last week, 10 of the subjects were also given dexamfetamine 20 mg daily, 7 hours after their modafinil dose. Dexamfetamine caused no significant change in the pharmacokinetics of modafinil and the combination was well tolerated. In addition, the pharmacokinetics of dexamfetamine did not appear to be affected by modafinil, when compared with values reported in the literature.2 Similar results were found in a single dose study.2 No additional precautions appear to be necessary on concurrent use.

Modafinil + Methylphenidate

No pharmacokinetic interaction appears to occur between modafinil and methylphenidate.

Clinical evidence, mechanism, importance and management

In a single-dose study in healthy subjects, modafinil 200 mg and methylphenidate 40 mg were given together without any clinically relevant changes in the pharmacokinetics of either drug.1 In a steady-state study, 30 healthy subjects were given modafinil 200 mg daily for 7 days, followed by 400 mg daily for 3 weeks. During the last week, 16 of the subjects were also given methylphenidate 20 mg daily, taken 8 hours after their modafinil dose. Methylphenidate caused no significant change in the pharmacokinetics of modafinil. In addition, the pharmacokinetics of methylphenidate did not appear to be affected by modafinil, when compared with values reported in the literature.2 No special precautions would appear to be necessary on concurrent use.

Modafinil + Miscellaneous

The manufacturers caution if enzyme-inducing anticonvulsants, particularly phenytoin, are used with modafinil. There is speculation, based on in vitro studies, about some possible interactions with other drugs, such as warfarin. Modafinil is an inducer of CYP3A4 and therefore may be expected to interact with substrates of this isoenzyme.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers and inhibitors

Animal studies suggest that phenobarbital reduces the serum levels of modafinil; both drugs are inducers of the cytochrome P450 isoenzyme CYP3A4.1 The manufacturers similarly suggest that this is a possibility.2,3 There is no clinical evidence of interactions with other potent enzyme inducers, but the manufacturers suggest that carbamazepine1,2 and rifampicin (rifampin)1 may reduce modafinil levels. Also, inhibitors of CYP3A4 (itraconazole, ketoconazole are specifically named) are predicted to possibly increase modafinil levels. However, clinically relevant interactions with either CYP3A4 inducers or inhibitors seem unlikely because CYP3A4 is not the only cytochrome P450 isoenzyme that is involved in the metabolism of modafinil.

(b) CYP3A4 substrates

Modafinil is an inducer of the cytochrome P450 isoenzyme CYP3A4. The manufacturers therefore predict that it may reduce the levels of drugs that are CYP3A4 substrates. They specifically name the protease inhibitors, buspirone, calcium-channel blockers, ciclosporin, midazolam, and the statins [note that only some statins, namely atorvastatin, lovastatin and
sinvastatin, are CYP3A4 substrates], and triazolam. Interactions have been seen with ‘ciclosporin’, (p.1039), and ‘triazolam’, (p.732).

(c) Phenytion

Due to the enzyme inhibiting potential of modafinil, the manufacturers say that care should be taken if phenytion is also given. There is in vitro evidence to indicate that modafinil may possibly inhibit the metabolism of phenytion by the cytochrome P450 isoenzymes CYP2C9 and CYP2C19, and so there is some reason for monitoring concurrent use for evidence of increased phenytion effects and toxicity.

(d) Warfarin

There is no clinical evidence of an interaction between warfarin and modafinil, but because warfarin is, in part, metabolised by the cytochrome P450 isoform CYP2C9 (which is inhibited by modafinil) the manufacturers suggest that concurrent use should be monitored for the first 2 months of concurrent use.

Orlistat + Sucrose polyesters

A single case report suggests that the concurrent use of orlistat and sucrose polyesters (Olestra – used in some foods as a fat substitute) can result in additive gastrointestinal adverse effects (soft, fatty/oily stools, increased flatus and abdominal pain). In the case in question, symptoms resolved when the patient stopped eating Olestra-containing food while continuing to take orlistat.

Phenmetrazine + Barbiturates

The CNS adverse effects and the weight-reducing effects of phenmetrazine are reduced by amobarbital.

Clinical evidence, mechanism, importance and management

A comparative study in 50 overweight adults, of the effects of phenmetrazine 25 mg three times daily with or without amobarbital 30 mg three times daily, found that although the adverse CNS effects, particularly insomnia, headache and nervousness, were decreased by the presence of the barbiturate, the weight-reducing effects were also decreased (by 65%).

Phentermine + Fluoxetine

An isolated report describes phentermine toxicity, which occurred in a woman several days after she stopped taking fluoxetine.

Clinical evidence, mechanism, importance and management

A 22-year-old woman who had successfully and uneventfully taken fluoxetine 20 mg daily for 3 months, stopped the fluoxetine and then 8 days later took a single 30-mg tablet of phentermine. Within a few hours she experienced racing thoughts, stomach cramps, palpitations (pulse 84 bpm), tremors, dry eyes and diffuse hyper-reflexia. The problems had all resolved the following day after she took lorazepam 1.5 mg. The authors of this report suggested that the residual inhibitory effects of the fluoxetine on liver cytochrome P450 enzymes led to decreased phentermine metabolism, resulting in increased phentermine levels and sympathomimetic hyperstimulation. It is known that fluoxetine and its active metabolite are have a long half-life and can persist for weeks. The authors also alternatively wondered whether some of the symptoms might have fitted those of the serotonin syndrome.

Although this is an isolated case and its general importance is unknown, the authors of the report draw attention to the possible risks of taking SSRIs and sympathomimetic drugs used for controlling diet.

A neurotoxic reaction has also been reported with ecstasy and citalopram, see ‘Amfetamines and related drugs + SSRIs’, p.201.

Rimonabant + Miscellaneous

Ketoconazole doubled the AUC of rimonabant, and other potent CYP3A4 inhibitors are also expected to raise rimonabant levels. Potent CYP3A4 inducers are expected to lower rimonabant levels. Due to a lack of information the manufacturers suggest that rimonabant should not be taken with antidepressants. Rimonabant does not appear to affect the levels of oral contraceptives, digoxin, midazolam or warfarin, and alcohol, lorazepam, and orlistat do not appear to alter rimonabant levels.

Clinical evidence, mechanism, importance and management

(a) Antidepressants

Depressive disorders and mood alterations are common in patients taking rimonabant. The manufacturers say that as there is limited experience in using rimonabant with antidepressants, and concurrent use is not recommended.

(b) CYP3A4 inducers and inhibitors

Rimonabant is partly metabolised by the cytochrome P450 isoenzyme CYP3A4. Ketoconazole, a potent CYP3A4 inhibitor, doubles the AUC of rimonabant. The manufacturers therefore expect that other potent CYP3A4 inhibitors (they name clarithromycin, itraconazole, nefazodone, ritonavir, and telithromycin) will also raise rimonabant levels, and they therefore advise caution on concurrent use. They similarly suggest that potent CYP3A4 inducers (such as carbamazepine, phenobarbital, phenytion, rifampicin (rifampin) and St John’s wort) may lower rimonabant levels. If concurrent use is necessary monitor to ensure that rimonabant remains effective.

Sibutramine + Azoles

Ketoconazole modestly increases steady-state levels of sibutramine and its active metabolites. The UK manufacturers recommend caution when sibutramine is used with itraconazole or ketoconazole.

Clinical evidence, mechanism, importance and management

Twelve obese patients were given sibutramine hydrochloride monohydrate 20 mg daily for 14 days, with ketoconazole 200 mg twice daily for the last 7 days. Ketoconazole caused moderate increases in the serum levels of sibutramine and its two metabolites (AUC and maximum serum level) increases of 58% and 36%, respectively, for metabolites M1, and 20% and 19%, respectively, for M2, probably through inhibition of the cytochrome P450 isoform CYP3A4). Small increases in heart rates were seen (2.5 bpm at 4 hours and 1.4 bpm at 8 hours), while ECG parameters were unchanged. Sibutramine alone can cause an increase in heart rate, and a rate increase of 10 bpm is an indication to withdraw the drug.
fore, the manufacturers in the UK suggest caution should be exercised when sibutramine is used with ketoconazole. They also suggest that due to its ability to inhibit CYP3A4, italy should also be used with caution.

### Sibutramine + Macrolides

Although no interaction appears to occur between sibutramine and erythromycin, the UK manufacturers still caution the use of sibutramine with clarithromycin, erythromycin and troleandomycin.

**Clinical evidence, mechanism, importance and management**

Twelve obese patients were given sibutramine 20 mg daily for 14 days, with erythromycin 500 mg three times daily for the last 7 days. It was found that, apart from some slight and unimportant changes in the pharmacokinetics of the metabolites of sibutramine (probably caused by some inhibition of the cytochrome P450 isoform CYP3A4), the pharmacokinetics of sibutramine were not significantly altered by erythromycin. No blood pressure changes were seen and only very small and clinically irrelevant increases in the QTc interval and heart rate occurred. The extent of any interaction appears to be too small to matter, and there would seem to be no reason for avoiding the concurrent use of these two drugs. Despite this, the UK manufacturers still say that caution should be exercised, probably because sibutramine is principally metabolised by CYP3A4. They also extrapolate their caution to the CYP3A4 inhibitors clarithromycin and troleandomycin.

### Sibutramine + Miscellaneous

On theoretical grounds the manufacturers contraindicate the concurrent use of sibutramine with MAOIs, and they say that it should not be given with serotonergic drugs because of the risk of the serious serotonin syndrome. The manufacturers say that the use of sibutramine with other centrally acting appetite suppressants is contraindicated and they caution the use of cold and flu remedies. No clinically relevant interactions have been seen between sibutramine and cimetidine, and no interaction occurs with oral contraceptives.

**Clinical evidence, mechanism, importance and management**

(a) Cimetidine

When cimetidine 400 mg twice daily was given with sibutramine 15 mg once daily to 12 healthy subjects the maximum serum levels and AUCs of the combined sibutramine metabolites were increased by 3.4% and 7.3%, respectively. These changes are too small to be of clinical significance, and there is no reason for avoiding the concurrent use of these two drugs.

(b) Centrally acting appetite suppressants, and drugs that raise blood pressure or heart rate

The UK manufacturers say that the concurrent use of sibutramine and other centrally acting appetite suppressants is contraindicated. No work appears to have been done to see what happens if sibutramine is given with decongestants, cough, cold and allergy medications, but the manufacturers advise caution because of the risk of raised blood pressure or heart rate. The manufacturers in the UK and US both list ephedrine and pseudoephedrine, while in the UK xylometazoline is also specifically named.

(c) CYP3A4 inducers

The UK manufacturers point out that carbamazepine, dexamethasone, phenobarbital, phenytoin and rifampicin are all inducers of CYP3A4, an isoenzyme involved in the metabolism of sibutramine. These drugs might therefore increase the metabolism of sibutramine resulting in a fall in its serum levels. However, this has not been studied experimentally and, at the present time, the existence, the extent and the possible clinical relevance of any such interaction is unknown.

(d) MAOIs

There are no reports of adverse reactions between sibutramine and the MAOIs. However, sibutramine inhibits serotonin reuptake, and because the serious serotonin syndrome can occur when MAOIs and SSRIs are used together, the manufacturers warn that concurrent use of sibutramine and MAOIs is contraindicated. They say that 14 days should elapse between stopping either drug and starting the other. The US manufacturers included selegiline in this warning.

(e) Oral contraceptives

A crossover study in 12 subjects found that sibutramine 15 mg daily, given for 8 weeks, had no clinically significant effect on the inhibition of ovulation caused by an oral contraceptive, and it was concluded that there is no need to use alternative contraceptive methods while taking sibutramine.

(f) Serotonergic drugs

Because sibutramine inhibits serotonin uptake, and because the serious serotonin syndrome has been seen when serotonergic drugs were taken with SSRIs, the manufacturers say that sibutramine should not be taken with any serotonergic drugs. They name dextromethorphan, dihydroergotamine, fenbutyl, pentazocine, pethidine (meperidine), SSRIs, sumatriptan, and tryptophan. Possible cases have been reported for sibutramine and ‘SSRIs’, below. The US manufacturers also include lithium in their list. Note that this list is not exhaustive (see MAOIs under (d) above) and a case of the serotonin syndrome has been seen when venlafaxine was given with sibutramine. The extent of the risk with these serotonergic drugs is not known, but because of the potential severity of the reaction this warning would seem to be a prudent precaution. For more information on the serotonin syndrome, see ‘Additive or synergistic interactions’.

Two case reports suggest that the concurrent use of sertraline or citalopram with sibutramine may cause the serotonin syndrome.

**Clinical evidence, mechanism, importance and management**

A 43-year-old woman taking citalopram 40 mg daily was also given sibutramine hydrochloride monohydrate 10 mg daily. Within a few hours of taking the first dose of sibutramine she developed racing thoughts, hyperactivity, psychomotor agitation, shivering and diaphoresis, which continued for the 3 days that she continued to take sibutramine. The authors suggested that one of the reasons for the hypomania may have been the serotonin syndrome, which could have been caused by the use of two drugs with serotonergic action. A letter briefly mentions another possible case of the serotonin syndrome, following the use of sibutramine and sertraline. The manufacturers of sibutramine say that concurrent use of any other drug that has serotonergic actions should be avoided where possible, or only undertaken with appropriate monitoring. For more information about the serotonin syndrome, see ‘Additive or synergistic interactions’.

Anthelmintics, Antifungals and Antiprotozoals

‘Table 8.1’, (p.208) lists the drugs covered in this section by therapeutic group and drug class. If the anti-infective is the drug causing the interaction, the interaction is generally dealt with under the affected drug. Also note that drugs such as the 5-nitroimidazoles (e.g. metronidazole), which have actions against more than one type of organism (e.g. bacteria and protozoa) are covered under Antibacterials.

(a) Amphotericin B

Intravenous amphotericin B causes important pharmacodynamic interactions via additive nephrotoxicity and myelotoxicity, and may increase the cardiotoxicity of other drugs because of amphotericin-induced hypokalaemia. No important pharmacokinetic interactions are known. Lipid formulations such as liposomal amphotericin are less nephrotoxic than conventional amphotericin, and would therefore be expected to interact less frequently. Orally administered amphotericin is not absorbed systematically, and no interactions are known.

(b) Azole antifungals

The most important interactions affecting and caused by theazole antifungals are those resulting from inhibition and induction of cytochrome P450 isoenzymes.

**Fluconazole** is principally (80%) excreted unchanged in the urine, so is less affected by enzyme inducers and inhibitors than some other azoles. Fluconazole is a potent inhibitor of CYP2C9 and CYP2C19, and generally only inhibits CYP3A4 at high doses (greater than 200 mg daily). Interactions are less likely with single doses used for genital candidiasis than with longer term use.

**Itraconazole** is extensively metabolised by CYP3A4, and its metabolism may become saturated with multiple dosing. Itraconazole and its major metabolite, hydroxyitraconazole are potent inhibitors of CYP3A4.

**Ketoconazole** is extensively metabolised, particularly by CYP3A4. It is also a potent inhibitor of CYP3A4.

**Miconazole** is a potent inhibitor of CYP2C9. Because this azole is generally used topically as pessaries, skin cream, or an oral gel, it is less likely to cause interactions, although it should be noted that interactions with warfarin, (p.388), have been reported, particularly for the oral gel.

**Posaconazole** is metabolised via UDP glucuronidation, and may also be a substrate for P-glycoprotein. Posaconazole is an inhibitor of CYP3A4.

**Voriconazole** is metabolised by CYP2C19, CYP2C9, and to a lesser extent by CYP3A4. Voriconazole is an inhibitor of CYP2C9, CYP2C19 and CYP3A4.

An number of other azole antifungals are only used topically in the form of skin creams or intravaginal preparations, and have not been associated with drug interactions, presumably since their systemic absorption is so low, see ‘Azoles; Topical + Miscellaneous’, p.222.

Fluconazole, ketoconazole and voriconazole have been associated with prolongation of the QT interval, although generally not to a clinically relevant extent. However, they may also raise the levels of other drugs that prolong the QT interval, and these combinations are often contraindicated, see ‘Antihistamines + Azoles’, p.584.

Albendazole or Mebendazole + Antiepileptics

Phenytoin, carbamazepine and phenobarbital lower the plasma levels of albendazole and mebendazole, and they therefore might reduce their efficacy for systemic infections. Valproate does not lower plasma mebendazole levels.

Clinical evidence

(a) Albendazole

In one study, 32 patients with intraparenchymatous neurocysticercosis were given albendazole 7.5 mg/kg every 12 hours for 8 days. These patients were also taking either phenytoin 200 to 300 mg daily (9 patients), carbamazepine 600 to 1200 mg daily (9 patients), or phenobarbital 100 to 300 mg daily (9 patients) all for at least 3 months, and a control group consisting of 9 patients who did not receive any antiepileptics. The AUCs for (+)-albendazole sulfoxide were 66%, 49%, and 61% lower than the control group for the phenytoin, carbamazepine, and phenobarbital groups respectively. The maximum plasma levels of (+)-albendazole sulfoxide were 50 to 63% lower and the half lives about 3 to 4 hours shorter. The AUCs, peak plasma levels and half-life of (-)-albendazole sulfoxide (present in much lower levels than the (+)-isomer) were similarly reduced by the antiepileptics.

(b) Mebendazole

A retrospective analysis found that patients with echinococcosis taking mebendazole and phenytoin or carbamazepine tended to have lower plasma mebendazole levels than patients not taking these antiepileptics. Valproic acid tended to increase mebendazole levels, and some patients had a clinically important rise in mebendazole levels when they were switched from phenytoin or carbamazepine to valproic acid.

Mechanism

Phenytoin, carbamazepine and phenobarbital appear to induce the oxidative metabolism of albendazole by the cytochrome P450 isozyme CYP3A to roughly the same extent, resulting in significantly reduced levels of albendazole sulfoxide. Phenytoin, and to a lesser extent carbamazepine, may also induce the metabolism of albendazole sulfone by CYP2C. Mebendazole is similarly affected.

Importance and management

These pharmacokinetic interactions are established, and are likely to be clinically important when these anthelmintics are used to treat systemic worm infections. For these infections it may be necessary to increase the albendazole or mebendazole dosage in patients taking phenytoin, carbamazepine or phenobarbital. Monitor the outcome of concurrent use. The interactions are of no importance when these anthelmintics are used for intestinal worm infections (where their action is a local effect on the worms in the gut), which is the most common use of mebendazole in particular.

Albendazole or Mebendazole + Cimetidine

Cimetidine raises serum mebendazole levels, and prolongs the half-life of albendazole sulfoxide. In some cases cimetidine appeared to increase the effectiveness of these anthelmintics against systemic infection.

Clinical evidence

(a) Albendazole

A study in 6 healthy subjects given albendazole 20 mg/kg and cimetidine 10 mg/kg twice daily found that cimetidine significantly inhibited the metabolism of albendazole sulfoxide as indicated by an increase in its elimination half-life from 7.4 to 19 hours. Cimetidine also reduced individual variability in plasma albendazole levels. Another study in patients with cystic echinococcosis given albendazole 20 mg/kg daily, for three 4-week courses separated by intervals of 10 days, found that levels of the active metabolite albendazole sulfoxide were higher in bile and hydatid cyst fluid in 7 patients who also received cimetidine 10 mg/kg daily. The therapeutic benefit of the combined treatment was reported to be greater than that with albendazole alone.

(b) Mebendazole

A study in 8 patients (5 with peptic ulcers and 3 with hydatid cysts) taking mebendazole 1.5 g three times daily found that cimetidine 400 mg three times daily for 30 days raised the maximum plasma mebendazole levels by 48%. The previously unresponsive hepatic hydatid cysts resolved totally. However, a previous study had found smaller increases in serum mebendazole levels with cimetidine 1 g daily in divided doses, which were considered too small to be clinically useful.

Mechanism

It is suggested that the interaction is caused by the enzyme inhibitory actions of cimetidine, which result in a reduction in the metabolism of albendazole and mebendazole. Cimetidine may also reduce albendazole absorption and minimise inter-patient variability by reducing gastric acidity, but the reduction in absorption appears to be outweighed by the enzyme-inhibitory effects.

Importance and management

These pharmacokinetic interactions would appear to be established, but their clinical relevance is uncertain. Increased efficacy has been shown in some studies for systemic worm infections. There would seem to be no reason for avoiding concurrent use, but increased monitoring for efficacy and toxicity might be prudent.

Albendazole + Corticosteroids

Dexamethasone can raise levels of albendazole sulfoxide by 50%, which might increase its efficacy in systemic worm infections.

Clinical evidence

In one study albendazole 15 mg/kg daily in three divided doses was given to 8 patients with cysticercosis. The plasma levels of the active metabolite of albendazole (albendazole sulfoxide) were found to be increased by about 50% by the use of dexamethasone 8 mg every 8 hours. Another study did not detect significantly increased maximum plasma levels of albendazole sulfoxide, when dexamethasone was given, but the AUC was increased twofold, and there was a decrease in its clearance.

Mechanism

Albendazole + Diethylcarbamazine

There appears to be no pharmacokinetic interaction between albendazole and diethylcarbamazine.

Clinical evidence, mechanism, importance and management

There was no difference in the pharmacokinetics of single doses of diethylcarbamazine 6 mg/kg or albendazole 400 mg between groups of 14 microfilaric subjects given either drug alone and another group of 14 subjects given both drugs. This study suggests there is no pharmacokinetic interaction between these two anthelmintic drugs, and the lack of adverse events suggests that concurrent use is safe.1

Albendazole + Food

Giving albendazole with a fatty meal markedly increases the levels of its active metabolite. Albendazole should be taken with a meal.

Clinical evidence, mechanism, importance and management

A study in Sudanese men found that giving a single 400-mg dose of albendazole with a meal resulted in a 7.9-fold higher level of the active metabolite, albendazole sulfoxide, than when albendazole was given in the fasted state. Similarly, a further study in healthy subjects found that when albendazole 10 mg/kg was given with a fatty meal, rather than with water, the peak plasma levels of the active metabolite were increased by more than sixfold and the half-life decreased from 8.8 to 8.2 hours. Albendazole absorption is poor, and if it is being used for systemic infections, it is advisable to take it with a meal.

Albendazole + Grapefruit juice

Grapefruit juice increases the plasma levels of albendazole.

Clinical evidence, mechanism, importance and management

Grapefruit juice increased albendazole sulfoxide levels by about threefold and shortened its half-life by 46%.1 When albendazole was given with grapefruit juice and cimetidine the peak plasma level was reduced from 760 to 410 micrograms/L. However, the level achieved with cimetidine and grapefruit juice was still greater than that achieved when albendazole was given with water.

It was suggested that grapefruit juice inhibits the metabolism of albendazole by the cytochrome P450 isozyme CYP3A4 in the intestinal mucosa, and so albendazole levels are raised. The addition of cimetidine may decrease this effect by reducing albendazole absorption by affecting gastric pH.1 (See also ‘Albendazole + Praziquantel’, p.209.) The clinical relevance of the change with grapefruit juice is uncertain. For systemic infections, increased absorption might be beneficial, but the decrease in half-life might be detrimental.1

Albendazole + Ivermectin

No pharmacokinetic interaction occurs between albendazole and ivermectin.

Clinical evidence, mechanism, importance and management

In a double-blind placebo-controlled study, 42 patients with onchocerciasis were given single doses of either ivermectin 200 micrograms/kg. albendazole 400 mg or both drugs together. There was no significant pharmacokinetic interaction, and although the combination seemed to offer no advantage over ivermectin alone for the treatment on onchocerciasis, the combination appeared safe. No dosage adjustments would be required during concurrent use.1

Albendazole + Levamisole

Levamisole may markedly decrease the bioavailability of albendazole sulfoxide, but albendazole has no clinically significant effects on levamisole pharmacokinetics.

Clinical evidence, mechanism, importance and management

A study in 28 healthy subjects given levamisole 2.5 mg/kg alone or with albendazole 400 mg found that albendazole produced a modest reduction in the AUC of levamisole but no other pharmacokinetic parameters were affected. However, the AUC of albendazole sulfoxide (the active metabolite) was 75% lower when given with levamisole than historical values in subjects who had received levamisole alone.1 An associated study in 44 patients found that levamisole with or without albendazole was not effective against Onchocerca volvulus infections. Both treatments caused a similar number of adverse effects.1 The clinical relevance of these findings is unclear, but they suggest that caution is needed if both drugs are to be given for systemic worm infections.

Albendazole + Praziquantel

Albendazole does not alter the bioavailability of praziquantel. Praziquantel markedly increases the bioavailability of albendazole sulfoxide in fasted subjects, but much less so when albendazole is given with a meal, as recommended. None of these changes appears to have adverse consequences.

Clinical evidence, mechanism, importance and management

(a) Effect on albendazole

In a study in Sudanese men, the AUC of albendazole sulfoxide (the active metabolite of albendazole), was increased 4.5-fold when a single 400-mg dose of albendazole was given with praziquantel 40 mg/kg to fasting subjects. However, this difference was much less marked (only a 1.5-fold increase) when the drugs were given with food.1 The reasons for these changes and their practical consequences are not known, but the increases in albendazole sulfoxide levels seemed not to cause any problems.1 If both drugs are given with food, as may be advisable (see ‘Albendazole + Food’, above), any interaction is modest. On the basis of these studies there do not seem to be any obvious reasons why the concurrent use of these two drugs should be avoided.

(b) Effect on praziquantel

In a study, 21 children treated for giardiasis were given a single 400-mg dose of albendazole either alone or with a single 20-mg/kg dose of praziquantel. It was found that the pharmacokinetics of albendazole were not significantly affected by praziquantel when the drugs were given with 200 mL of milk, one hour after breakfast. There were wide inter-individ-
Amphotericin B + Antineoplastics

Use of conventional amphotericin B with nephrotoxic antineoplastics such as cisplatin and ifosfamide may increase the risk of renal impairment, and should generally be avoided. Liposomal amphotericin B may be an alternative, but renal function should still be closely monitored.

Clinical evidence, mechanism, importance and management

A multivariate analysis in patients receiving high-dose cisplatin with saline hydration and mannitol diuresis found that the concurrent use of amphotericin B was a predictor of renal failure.2 Both cisplatin and amphotericin B are nephrotoxic, and their effects might be expected to be additive.

The manufacturer of conventional amphotericin B states that nephrotoxic antineoplastics should not be given concurrently except with great caution.2 Of the antineoplastics, cisplatin, ifosfamide and methotrexate are well known for their nephrotoxicity. Amphotericin also reduces the renal clearance of methotrexate. (p.642).

Liposomal amphotericin B is licensed for use in the empirical treatment of presumed fungal infections in febrile neutropenic patients. It is therefore likely to be used in patients who have received antineoplastics and who may have antineoplastic-induced renal impairment. The manufacturer notes that it has been used successfully in a large number of patients with pre-existing renal impairment. Nevertheless, renal function should be closely monitored in these patients.3

Amphotericin B + Azoles

The effects of amphotericin B and azole antifungals would be expected to be antagonistic, and there is some clinical evidence to support this suggestion of reduced efficacy, and even increased adverse effects. However, other studies suggest that the combination of amphotericin B and fluconazole may be beneficial.

Clinical evidence

Studies in a few patients and in vitro experiments suggest that the antifungal effects of amphotericin B and miconazole used together may be antagonistic.1,2 In another study, 4 out of 6 patients did not respond to amphotericin B treatment while also taking ketoconazole, whereas treatment was successful in 6 others.5 Of whom had stopped taking prophylactic miconazole or ketoconazole. The authors suggested that the numbers are too small to draw any definite conclusions, but antagonism is certainly a possibility.3 A comparative study found that patients given itraconazole and amphotericin B had serum itraconazole levels of less than 1 microgram/mL, whereas those given itraconazole alone had serum itraconazole levels of 3.75 micrograms/mL, which suggests that amphotericin B may reduce itraconazole levels.4 There are numerous in vitro and animal studies of the potential interaction of azoles with amphotericin B, which show conflicting results from antagonism to additive or synergistic effects, some of which have been the subject of a review.5 In a recent large randomised study in 219 patients with candidaemia who were not neutropenic, high-dose fluconazole plus amphotericin B tended to be more effective than fluconazole plus placebo (69% versus 56% success rate). The combination was not antagonistic compared with fluconazole alone.6 Similarly, in a randomised study in HIV-positive patients with cryptococcal meningitis, fluconazole plus amphotericin B was found to be more effective in reducing CSF fungal levels than amphotericin B alone. However, it was not as effective as amphotericin B plus flucytosine. All treatments were well tolerated.7

A retrospective study of itraconazole use found that 11 of 12 leukemic patients given amphotericin B and itraconazole had raised liver enzymes. These abnormalities resolved in 7 patients when the amphotericin B was discontinued. Itraconazole alone, given to another 8 patients did not cause liver enzyme abnormalities, even though it was used in high doses.8 Amphotericin B has only rarely been associated with adverse effects on the liver and increases in liver enzymes may occur in patients treated with itraconazole.

Mechanism

Uncertain. In theory, the combination of an antifungal that binds to ergosterol in fungal cell membranes (amphotericin B) with one that inhibits the synthesis of ergosterol (azoles) would be expected to exert antagonistic effects.9,10 In vitro studies with Candida albicans found that azole exposure may allow the generation of cells that are unaffected by subsequent exposure to amphotericin B. The degree of resistance appears to depend on concentration and the azole involved, with itraconazole causing more resistance than fluconazole.11 Resistance of Candida species to amphotericin B appears to depend on the duration of pre-exposure to fluconazole and is also greater when amphotericin B is subsequently used in combination with fluconazole rather than alone.10,12 Resistance may also depend on the organism involved and its sensitivity to azoles.13,14

Importance and management

Despite extensive in vitro and animal data, it is not entirely clear whether or not azoles inhibit the efficacy of amphotericin B.9,15,16 The emergence of resistant strains of fungi and the fact that antifungal therapy for invasive fungal infections remains suboptimal, has meant that combinations of antifungals have continued to be tried. Critically ill patients are often given empirical treatment with amphotericin B, with a subsequent change to fluconazole if the organism is sensitive. The Infectious Disease Society of America advises that a combination of amphotericin B and fluconazole may be an option in selected patients.17 However, combinations of azoles and amphotericin B should not be considered as routine practice, and until more is known it may be better to limit concurrent use to specific cases. The outcome of combined use should be well monitored for both a reduced antifungal response and an increase in adverse effects, such as a worsening of liver function tests.8 Some recent reviews have usefully discussed the topic of antifungals combinations.18-20

5. Sugar AM. Use of amphotericin B with azole antifungal drugs: what are we doing? Antimi-
6. The degree of resistance appears to depend on concentration and the azole involved, with itraconazole causing more resistance than fluconazole. Resistance of Candida species to amphotericin B appears to depend on the duration of pre-exposure to fluconazole and is also greater when amphotericin B is subsequently used in combination with fluconazole rather than alone. Resistance may also depend on the organism involved and its sensitivity to azoles.
**Amphotericin B + Corticosteroids**

Both amphotericin B and corticosteroids can cause potassium loss and salt and water retention, which can have adverse effects on cardiac function.

**Clinical evidence**

Four patients treated with amphotericin B and hydrocortisone 25 to 40 mg daily developed cardiac enlargement and congestive heart failure. The cardiac size decreased and the heart failure disappeared within 2 weeks of stopping the hydrocortisone. The amphotericin B was continued successfully with the addition of potassium supplements.1

**Mechanism**

Amphotericin B causes potassium to be lost in the urine. Hydrocortisone can cause potassium to be lost, and salt and water to be retained, and occasional instances of hypernatraemia with amphotericin B have also been seen. Working in concert these could account for the hypokalaemic cardiocirculatory overload that was seen.

**Importance and management**

Information is limited but the interaction would seem to be established. Monitor electrolytes (especially potassium, which should be closely monitored in patients receiving amphotericin B in any case) and fluid balance if amphotericin B is given with corticosteroids. The elderly would seem to be particularly at risk. Note that hypokalaemia increases the risk of adverse interactions with ‘digitalis glycosides’, (p.923) and ‘QT-interval prolonging drugs’, (p.257). The manufacturer of conventional amphotericin B advises that corticosteroids should not be used concurrently unless necessary to control drug reactions.2 However, in clinical practice, it is sometimes deemed necessary to use both drugs together. In this situation, close monitoring of the patient’s fluid balance, potassium level and cardiovascular parameters is required.

**Amphotericin B + Low salt diet**

The renal toxicity of amphotericin B can be associated with sodium depletion. When the sodium is replaced the renal function improves.1

**Amphotericin B + Pentamidine**

There is some evidence to suggest that acute renal failure may develop in patients taking amphotericin B if they are also given parenteral pentamidine.

**Clinical evidence, mechanism, importance and management**

A retrospective study between 1985 and 1988 identified 101 patients with AIDS who had been given amphotericin B for various systemic mycoses. The patients were given amphotericin B 0.6 to 0.8 mg/kg daily for 7 to 10 days, then a dose three times a week for about 9 weeks. Nine patients were concurrently treated for *Pneumocystis carinii* pneumonia, and of these the 4 who had been given pentamidine parenterally developed acute and rapid reversible renal failure. In all 4 cases, renal function returned to normal when the drugs were withdrawn. No renal failure was seen in 2 others given pentamidine by inhalation or 3 given intravenous co-trimoxazole.1

Both amphotericin B and pentamidine are known to be nephrotoxic and the renal impairment was attributed to additive effects of these drugs. The reason no toxicity occurred when the pentamidine was given by inhalation is probably because the serum levels achieved were low.

In general, conventional amphotericin B should not be used with other nephrotoxic drugs such as parental pentamidine. Renal function should be monitored closely with either drug (daily in the case of parenteral pentamidine), and it is essential that this recommendation is adhered to if both drugs are given. Anticipate the likelihood of renal failure and the need to withdraw the drugs.

**Amphotericin B; Oral + Miscellaneous**

The manufacturer of amphotericin B1 notes that its absorption from the gastrointestinal tract is negligible, and that no interactions have been noted with amphotericin B lozenges, or other oral formulations. For a theoretical interaction with sucralfate, see ‘sucralfate’, (below).

**Amphotericin B; Oral + Sucralfate**

An *in vitro* study with amphotericin B found that it became markedly and irreversibly bound to sucralfate at the pH values found in the gut. This suggests that efficacy for intestinal candidiasis or gut decontamination might be decreased, but no study appears to have been conducted to establish this.

**Clinical evidence, mechanism, importance and management**

To simulate what might happen in the gut, amphotericin B 25 mg/L was mixed with sucralfate 500 mg in 40 mL of water at pH 3.5 and allowed to stand for 90 minutes at 25°C. Analysis of the solution found that the amphotericin B concentration fell rapidly and progressively over 90 minutes to about 20%. When the pH of the mixture was then raised to about 6.5 to 7 for 90 minutes, there was no change in the concentration of amphotericin
Atovaquone + Co-trimoxazole

In one small study co-trimoxazole did not alter atovaquone levels, and atovaquone caused a minor decrease in co-trimoxazole levels, which was not considered clinically relevant.

Clinical evidence, mechanism, importance and management

As part of a larger study, 6 HIV-positive subjects received atovaquone 500 mg once daily, co-trimoxazole 960 mg (trimethoprim/sulfamethoxazole 160/800 mg) twice daily, or the combination, taken with food. There was no change in steady-state atovaquone levels but there was a minor 17% decrease in steady-state trimethoprim levels and a minor 8% decrease in sulfamethoxazole levels when both drugs were given together.1

This study shows there is no important pharmacokinetic interaction between atovaquone and co-trimoxazole. No dosage adjustments of either drug would be required on concurrent use.

Mechanism

Atovaquone is a highly lipophilic compound, which shows considerable inter-individual variability in absorption. Dietary fat increases the rate and extent of atovaquone absorption from both the suspension and the tablets, probably by increasing its solubility in the gut. The suspension has about a twofold higher oral bioavailability than the tablets when given with food or when fasting.

Importance and management

Established interactions of clinical importance. Atovaquone suspension used for the treatment or prevention of Pneumocystis pneumonia must be taken with food, since this is likely to increase the likelihood of successful treatment and survival.5,6 Alternatively, an enteral nutritional supplement with a high-fat content appears to be suitable.4 In the US, the manufacturer says that, for patients who have difficulty taking atovaquone suspension with food, parenteral therapy for Pneumocystis pneumonia should be considered.4

Similarly, atovaquone/proguanil tablets used for the treatment or prophylaxis of malaria should be taken with a milk drink or with food to maximise absorption.7,8 Be aware that if patients are unable to tolerate food, the systemic exposure to atovaquone will be reduced.7,8 In this situation, monitoring of parasitaemia to ensure efficacy would seem prudent.

Atovaquone + Food

Taking atovaquone with fatty food markedly increases its AUC by two to threefold. Atovaquone/proguanil tablets should be taken with food or a milky drink, and atovaquone suspension should be taken with food, to maximise absorption and efficacy.

Clinical evidence

(a) Suspension

In a pharmacokinetic study in HIV-positive subjects designed to determine the dose of atovaquone suspension that would achieve specific steady-state plasma levels, administration with high-fat food increased the bioavailability of atovaquone by 1.4-fold when compared with the fasted state.1 In another similar study, administration of atovaquone suspension with food (23 g of fat) increased average steady-state levels by 1.3-fold to 1.7-fold with different dosage regimens (using 500 mg to 1.5 g of atovaquone).2

In a single-dose study in healthy subjects, a high-fat breakfast (21 g of fat) increased the AUC of atovaquone by 2.4-fold, and an enteral nutrition supplement (Sustacal Plus, containing 28 g of fat) increased the AUC by 2.7-fold compared with the fasted state.5

(b) Tablets

In a crossover study in 18 healthy subjects after an overnight fast, administration of atovaquone 500 mg after a high-fat standard breakfast (23 g of fat) increased the AUC by 3.3-fold when compared with the fasted state.5 In a further study of similar design, 2 slices of toast alone had no effect on atovaquone AUC, 2 slices of toast with 23 g of butter increased the AUC by threefold, and 2 slices of toast with 56 g of butter increased the AUC by 3.9-fold.4

Atovaquone + Miscellaneous

Preliminary evidence suggested that, of a number of drugs given with atovaquone in clinical trials, only metoclopramide caused any marked change (decreases) in the atovaquone serum levels. Until more is known, it may be prudent to monitor efficacy if metoclopramide is used with atovaquone.

Clinical evidence, mechanism, importance and management

An analysis of 191 patients with AIDS, given atovaquone as part of efficacy studies, found that when normalised for plasma albumin, bodyweight, and the absence of other drugs, the expected steady-state plasma levels of atovaquone were 14.8 micrograms/mL. Steady-state atovaquone plasma levels achieved in the presence of other drugs were examined in an attempt to identify possible interactions. Fluconazole and prednisone were associated with increases of 2.5 and 2.3 micrograms/mL, respectively, whereas paracetamol (acetaminophen), aciclovir, opioids, antiinflammatory drugs, benzodiazepines and laxatives were associated with decreases of greater than 3.4 micrograms/mL. Metoclopramide was associated with a decrease of 7.2 micrograms/mL. U plasma binders [not defined], erythromycin, clofazimine, antacids, clotrimazole, NSAIDs, ketoconazole, hydroxyzine, megestrol, antidiabetics (other than metoclopramide), other systemic steroids, and H2-receptor antagonists were not associated with any change in steady-state atovaquone serum levels. U plasma binders, erythromycin and clofazimine were re- presented by fewer than 5 subjects.1,2

The kind of analysis described above1-2 provides only the very broadest indication that interactions might or might not occur between atovaquone and these drugs, but it highlights the need to be vigilant if an apparently interacting drug is used concurrently. Only the changes caused by metoclopramide seem likely to have any potential clinical importance and the manufacturers recommend caution in its use with atovaquone/pro-
If an antiemetic is required in patients taking atovaquone/proguanil, they suggest that **metoclopramide** should be given only if other antiemetics are unavailable, and that parasitaemia should be closely monitored. In the UK, the manufacturers also say that **metoclopramide** should be given with caution to patients taking atovaquone suspension for Pneumocystis pneumonia, until the interaction has been further studied, whereas the US manufacturers of atovaquone suspension do not mention metoclopramide.

There appears to be no clinically relevant pharmacokinetic interaction between atovaquone and proguanil.

**Clinical evidence, mechanism, importance and management**

Atovaquone did not affect the pharmacokinetics of proguanil in a comparative study of 4 patients taking proguanil 200 mg twice daily for 3 days and 12 patients taking proguanil 200 mg twice daily with atovaquone 500 mg twice daily for 3 days. A similar lack of interaction was seen in 18 healthy subjects given proguanil 400 mg daily with atovaquone 1 g daily for 3 days.

In contrast, in a longer study 13 healthy subjects were given a single 250/100-mg dose of atovaquone/proguanil, then after an interval of one week they were given daily doses for 13 days. There was no change in the AUC of atovaquone from single dose to steady state, indicating that accumulation did not occur. However, the AUC of proguanil was modestly increased at steady state, and the AUC of the active metabolite cycloguaniol was modestly decreased, in the 9 subjects who were extensive metabolisers for the cytochrome P450 isoenzyme CYP2C19 (see ‘Genetic factors’, p.4)). It was suggested that atovaquone may have inhibited the production of cycloguaniol by CYP3A4. However, since this study had no arm with each drug alone, it is impossible to determine whether these changes in pharmacokinetics were due to an interaction or not.

A pharmacokinetic interaction is not established, and is anyway of little clinical relevance, since the efficacy of the combination product for malaria prophylaxis up to 12 weeks is established. The enhanced activity of the combination may, in part, be due to proguanil lowering the effective concentration at which atovaquone collapses the mitochondrial potential in malaria parasites.

**Atovaquone + Proguanil**

**Clinical evidence**

(a) **Rifabutin**

In 24 healthy subjects given atovaquone 750 mg twice daily and rifabutin 300 mg once daily for 14 days, there was a modest 34% decrease in the AUC of atovaquone and a small 19% decrease in the rifabutin levels.

(b) **Rifampicin (Rifampin)**

A steady-state study in 13 HIV-positive subjects found that the use of atovaquone 750 mg twice daily with rifampicin 600 mg four times daily for 14 days resulted in a more than 50% reduction in the atovaquone AUC and serum levels, but a more than 30% rise in rifampicin AUC and serum levels.

**Mechanism**

Uncertain. Atovaquone is predominantly excreted (greater than 90%) as unchanged drug in the faeces, and would not therefore be expected to be affected by cytochrome P450 enzyme induction.

**Importance and management**

Information is limited but these pharmacokinetic interactions appear to be established. Their clinical importance is unknown, but it seems highly likely that the efficacy of atovaquone will be reduced in the presence of rifampicin. The combination should therefore be avoided.

The effect of rifabutin is less than rifampicin, and the authors of the above report suggested that no atovaquone dosage adjustment is needed. However, in the UK, the manufacturer of atovaquone still considers that rifabutin use could result in subtherapeutic atovaquone levels in some patients, and they also advise against the concurrent use of this combination.

**Atovaquone + Tetracyclines**

Tetracycline reduces the plasma levels of atovaquone by about 40%. The effect of doxycycline does not appear to have been studied.

**Clinical evidence, mechanism, importance and management**

The manufacturer of atovaquone/proguanil notes that tetracycline may reduce plasma levels of atovaquone by about 40%

An *in vitro* study found that doxycycline potentiated the antimalarial activity of atovaquone, but there appears to be no information on the effect of doxycycline on the absorption of atovaquone. A study looking at the population pharmacokinetics of atovaquone in 24 Thai patients found that neither the oral clearance nor the volume of distribution of atovaquone were significantly affected by the concurrent use of tetracycline.

The manufacturers suggest that parasitaemia should be closely monitored in patients taking atovaquone/proguanil tablets with tetracycline. In the UK, they also say that tetracycline should be given with caution to patients taking atovaquone suspension for Pneumocystis pneumonia, until the interaction has been further studied, whereas the US manufacturers of atovaquone suspension do not mention tetracycline.

Atovaquone/Proguanil + Artesunate

Artesunate does not appear to affect the pharmacokinetics of atovaquone/proguanil.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, a single dose of atovaquone/proguanil 1 g/400 mg was given to 12 healthy subjects with and without artesunate 250 mg. No change was noted in the pharmacokinetics of either atovaquone or proguanil and no unexpected adverse events were seen. Although artemisinin does not therefore appear to interact pharmacokinetically with atovaquone/proguanil, this needs confirmation in a multiple-dose study. A study to investigate whether the addition of artemisinin to atovaquone/proguanil increased the risk of cardiotoxicity found that the QTc interval was not significantly altered in those taking the cocktail with atovaquone and proguanil compared to those receiving atovaquone/proguanil alone.1

Azoles + Antacids

The gastrointestinal absorption of ketoconazole is markedly reduced by antacids. Itraconazole may also be modestly affected. However, the absorption of fluconazole and posaconazole appears not to be significantly affected by antacids. Similarly, voriconazole is not expected to be affected.

Clinical evidence

(a) Fluconazole

Maalox forte (aluminium/magnesium hydroxide) 20 mL did not affect the absorption of a single 100-mg dose of fluconazole in 14 healthy subjects.1

(b) Itraconazole

For mention of a study in which some patients needed an increase in itraconazole dose when treated with ranitidine and an antacid [not named], see ‘Azoles + H₃-receptor antagonists’, p.217.

(c) Ketoconazole

A haemodialysis patient did not respond to treatment with ketoconazole 200 mg daily while taking cimetidine, sodium bicarbonate 2 g daily and aluminium oxide 2.5 g daily. Only when the ketoconazole dosage was increased to 200 mg four times daily did her serum levels rise. A later study in 3 healthy subjects found that when ketoconazole 200 mg was taken 2 hours after cimetidine 400 mg, the absorption was considerably reduced (AUC reduced by about 60%). When this was then repeated with the addition of sodium bicarbonate 500 mg, the absorption was reduced by about 95%. In contrast, when this was again repeated, but with the ketoconazole in an acidic solution, the absorption was increased by about 50%.2 A study in 4 patients found that the concurrent use of Maalox reduced the absorption of ketoconazole but this was not statistically significant.3 An anecdotal report suggested that giving ketoconazole 2 hours before a stomatis cocktail containing Maalox seemed to prevent the cocktail reducing ketoconazole effectiveness.4

(d) Posaconazole

A study in 12 healthy subjects found that Mylanta (aluminium/magnesium hydroxide) 20 mL did not significantly affect the bioavailability of a single 200-mg dose of posaconazole, either when taken with food or when fasting.5

Mechanism

Ketoconazole is a poorly soluble base, which must be transformed by the acid in the stomach into the soluble hydrochloride salt. Agents that reduce gastric acidity, such as antacids, H₃-receptor antagonists, (p.217), and proton pump inhibitors, (p.218), raise the pH in the stomach so that the dissolution of the ketoconazole and its absorption are reduced. Conversely, anything that increases the gastric acidity (e.g. ‘cola drinks’, (p.215)) increases the dissolution and the absorption of ketoconazole. The absorption of itraconazole is also affected by changes in gastric pH, but fluconazole and posaconazole are minimally affected.

Importance and management

The interaction of antacids with ketoconazole is clinically important, but not extensively documented. Advise patients to take antacids not less than 2 to 3 hours before or after the ketoconazole so that absorption can take place with minimal changes in the pH of the gastric contents.2 Monitor the effects to confirm that the ketoconazole is effective. The situation with itraconazole is not entirely clear, but based on the data with H₃-receptor antagonists, (p.217), some reduction in its absorption might be expected with antacids, and it would therefore be prudent to separate administration.

Antacids do not significantly affect posaconazole or fluconazole levels, and, based on the data with H₃-receptor antagonists, (p.217), would not be expected to affect voriconazole levels.

Azoles + Cola drinks

Some cola drinks can temporarily lower the stomach pH of patients with achlorhydria or hypochlorhydria due to disease or acid-suppressing drugs. This improves the bioavailability of itraconazole and ketoconazole.

Clinical evidence

Eight healthy subjects were given itraconazole 100 mg with either 325 mL of water or Coca-Cola (pH 2.5). Their peak serum itraconazole levels were more than doubled by the Coca-Cola and the itraconazole AUC was increased by 80%. Two of the subjects did not show this effect.1 Another study in 18 fasted AIDS patients who absorbed itraconazole poorly, found that the absorption was restored to that of fasted healthy subjects when the itraconazole was given with a cola drink.2 A study in 30 healthy subjects compared the bioavailability of itraconazole alone or after ranitidine, both with and without a cola drink. Ranitidine reduced the absorption of itraconazole but this effect was countered by the cola drink.3 Yet another study used omeprazole to raise the pH and Coca-Cola Classic to lower it. Absorption was greatest when ketoconazole was given alone, and least when given with omeprazole. However, Coca-Cola increased the absorption of ketoconazole in the presence of omeprazole to 65% of that seen with ketoconazole alone.4

Mechanism

Itraconazole and ketoconazole are poorly soluble bases, which must be transformed by the acid in the stomach into a soluble hydrochloride salt. Therefore any condition that reduces gastric acidity (or any drug that raises stomach pH, see ‘H₃-receptor antagonists’, (p.217) and ‘proton pump inhibitors’, (p.218)) can reduce the dissolution and the absorption of these antifungals. Acidic drinks, which lower the pH, can increase the absorption.

Importance and management

The interactions of itraconazole and ketoconazole with cola drinks that lower the gastric pH are established. The interaction can be exploited to improve the absorption of these antifungals in patients with achlorhydria or hypochlorhydria, and those taking gastric acid suppressants (see ‘H₃-receptor antagonists’, (p.217) and ‘proton pump inhibitors’, (p.218)), and this is recommended by some manufacturers of ketoconazole and itraconazole.6,7 For a brief mention of the use of cola to increase ketoconazole
levels and thereby increase cicrosorin levels, see ‘Cicloropin + Azoles’, p.1023. Coca-Cola Classic, Pepsi and Canada Dry Ginger Ale can be used because they can achieve stomach pH levels of less than 3, but none of the other beverages examined in one study produced such a low pH. The authors suggest that these would be less effective, although they were not actually studied. They included Diet Coca-Cola, Diet Pepsi, Diet 7-Up, Diet Canada Dry Ginger Ale. Diet Canada Dry Orange juice, 7-Up and Canada Dry Orange juice. For mention that glutamic acid did not increase the absorption of itraconazole in fasted or fed subjects, or ketoconazole in subjects pre-treated with cimetidine, see ‘Azoles + Food’, below, and ‘Azoles + H₂-receptor antagonists’, p.217, respectively.

Azoles + Food

Itraconazole capsules should be taken with or after food to improve absorption, whereas itraconazole solution should be taken at least one hour before food. Food increases the absorption of posaconazole suspension, and this should be taken with a meal or nutritional supplement. Some manufacturers advise taking ketoconazole with food, but two studies have shown little effect of food on absorption, and one actually showed a decrease. The bioavailability of voriconazole is modestly reduced by food, and the manufacturer recommends it be taken at least one hour before or after a meal. Food does not appear to affect the bioavailability of fluconazole capsules.

Clinical evidence

(a) Fluconazole

A study in 12 healthy subjects found that food had no therapeutically relevant effect on the pharmacokinetics of a single 100-mg dose of fluconazole in capsule form.1

(b) Itraconazole

A study in 24 patients with superficial dermatophyte, Candida albicans and pityriasis versicolor infections, given itraconazole 50 or 100 mg daily, found that taking the drug with either breakfast produced higher serum levels and gave much better treatment results than taking it before breakfast.2 A later study found that the relative bioavailability of itraconazole was 54% on an empty stomach, 86% after a light meal and 100% after a full meal.1 Similar results were found in other studies.3,4

In contrast, studies with itraconazole oral solution give different results. A study in 30 healthy males given itraconazole solution 200 mg daily, either on an empty stomach or with a standard breakfast, found that the bioavailability was 29% higher when itraconazole was taken in the fasted state.5

In another study of 20 HIV positive patients, glutamic acid 1360 mg, given to acidify the stomach, either with or without food did not enhance itraconazole absorption.3

(c) Ketoconazole

One study found that the AUC and peak serum concentrations of a single 200-mg dose of ketoconazole tablets were reduced by about 40% (levels reduced from 4.1 to 2.3 micrograms/mL) when given to 10 healthy subjects after a standardised meal.6

In contrast, another study found that high carbohydrate and fat diets tended to reduce the rate, but not the overall amount of ketoconazole absorbed from tablets.7 Similarly, a third study found that the absorption of single 200- or 800-mg doses of ketoconazole in 8 healthy subjects was not altered when they were taken after a standardised breakfast, although the peak serum levels were delayed. The absorption of single 400- and 600-mg doses were increased by about up to 50% with food, but this was not statistically significant.8

(d) Posaconazole

A study in 24 healthy subjects found that the maximum plasma levels and AUC of a single 400-mg dose of posaconazole oral suspension were increased 3.4- and 2.6-fold, respectively, when given with a nutritional supplement (Boost Plus) rather than in the fasting state.9 In a further study in 20 healthy subjects, single 200-mg doses of posaconazole (as oral suspension) were given with either a high-fat meal, a non-fat breakfast or after a 10-hour fast. The AUC of the suspension was increased fourfold when given with a high-fat meal, and 2.7-fold when given with a non-fat breakfast when compared with fasting.10

(e) Voriconazole

In a study 12 healthy subjects were given voriconazole capsules 200 mg twice daily either with food or in the fasted state (2 hours before or after food). Food delayed the oral absorption of voriconazole by about one hour and reduced the AUC by 22%.11

Mechanism

Not understood.

Importance and management

Itraconazole absorption from the capsule formulation is best when it is taken with or after food, whereas absorption from the acidic liquid formulation appears to be better when it is taken at least one hour before food. Similarly, posaconazole absorption from the oral suspension is improved by food, and the manufacturer recommends that posaconazole should be taken with food.

A confusing and conflicting picture is presented by the studies with ketoconazole, two showing no significant change in absorption with food, and one showing a decrease. However, one manufacturer of ketoconazole says that the absorption of ketoconazole is maximal when it is taken during a meal, as it depends on stomach acidity, and it should therefore always be taken with meals.12

The manufacturers of voriconazole tablets and the US manufacturers of voriconazole suspension recommend that it should be taken at least 1 hour before or at least 1 hour after a meal. The UK manufacturers of voriconazole suspension suggest that it should be taken at least 1 hour before or at least 2 hours after a meal.13,14

There appears to be no relevant interaction between food and fluconazole capsules.

Aazoles + H₂-receptor antagonists

The gastrointestinal absorption of ketoconazole is markedly reduced by cimetidine and ranitidine. The absorption of itraconazole is reduced (possibly halved) by H₂-receptor antagonists, and, similarly, the absorption of posaconazole is reduced by about 40% by cimetidine. The absorption of fluconazole and voriconazole is not significantly affected by H₂-receptor antagonists.

Clinical evidence

(a) Fluconazole

The AUC₀₋₄₈ of fluconazole 100 mg was reduced by only 13% when it was given to 6 healthy subjects with a single 400-mg dose of cimetidine. Two other studies found that cimetidine and famotidine did not affect fluconazole absorption.

(b) Itraconazole

Twelve healthy subjects were given cimetidine 400 mg twice daily or ranitidine 150 mg twice daily for 3 days and after a single 200-mg dose of itraconazole. The AUC and maximum serum levels of the itraconazole were reduced, but not significantly. The largest changes were 20% reductions in the AUC and maximum serum levels with ranitidine. In contrast, another study in 30 healthy subjects found that itraconazole 150 mg twice daily for 3 days reduced the AUC of a single 200-mg dose of itraconazole by 44%, and reduced the maximum serum levels by 52%. A study of the bioavailability of itraconazole in 12 lung transplant patients also given ranitidine 150 mg twice daily and an antacid four times daily found that the serum levels of itraconazole were highly variable. Half of the patients required the dose of itraconazole to be increased from 200 to 400 mg daily to achieve satisfactory serum levels.

Famotidine 40 mg was found to reduce the serum levels of a 200-mg dose of itraconazole by about 50% in 12 healthy subjects. Famotidine 20 mg twice daily was given with itraconazole 200 mg daily for 10 days to 16 patients undergoing chemotherapy for haematological malignancies. The minimum plasma levels of itraconazole were reduced by about 39%, and 8 patients did not achieve the levels considered necessary to protect neutropenic patients from fungal infections.

A study in 8 healthy subjects found that itraconazole 200 mg twice daily for 3 days increased the AUC of intravenous cimetidine (loading dose 0.2 mg/kg followed by an infusion of 36 mg/hour for 4 hours) by 25%.

(c) Ketoconazole

A haemodialysis patient did not respond to treatment with ketoconazole 200 mg daily while taking cimetidine, sodium bicarbonate 2 g daily and aluminium oxide 2.5 g daily. Only when the ketoconazole dosage was increased to 200 mg four times daily did her serum levels rise. A later study in 3 healthy subjects found that when ketoconazole 200 mg was taken 2 hours after cimetidine 400 mg, the absorption was considerably reduced (AUC reduced by about 60%). When this was repeated with the addition of sodium bicarbonate 500 mg, the absorption was reduced by about 95%. In contrast, when this was again repeated but with the ketoconazole in an acidic solution, the absorption was increased by about 50%.

The AUC of a single 200-mg oral dose of ketoconazole was reduced by 91% in 12 fasting subjects who received cimetidine 300 mg two hours prior to ketoconazole, followed by sodium bicarbonate 2 g one hour prior to the ketoconazole. This effect was only slightly reversed by the use of glutamic acid. Another study in 24 healthy subjects found that intravenous cimetidine titrated to give a gastric pH of 6 or more reduced the absorption of ketoconazole by 95%. A study in 6 healthy subjects found that ranitidine 150 mg given 2 hours before ketoconazole 400 mg reduced its AUC by about 95%.

(d) Posaconazole

A placebo-controlled study in 12 healthy subjects found that cimetidine 400 mg every 12 hours, given with posaconazole 200 mg once daily for 10 days, reduced the AUC and maximum plasma levels of posaconazole by about 40%. A study in 12 healthy subjects found that cimetidine 400 mg twice daily given with voriconazole 200 mg twice daily increased the maximum plasma levels and AUC of voriconazole by about 20%, but this is not considered sufficient to warrant a dosage adjustment. Ranitidine 150 mg twice daily had no significant effect on the AUC and maximum plasma levels of voriconazole.

Mechanism

Ketoconazole is a poorly soluble base, which must be transformed by the acid in the stomach into the soluble hydrochloride salt. Agents that reduce gastric acidity, such as H₂-receptor antagonists, ‘proton pump inhibitors’, (p.218) or ‘antacids’, (p.215), raise the pH in the stomach so that the dissolution of the ketoconazole and its absorption are reduced. Conversely, anything that increases the gastric acidity increases the dissolution and the absorption (e.g. ‘cola drinks’,(p.215)). The absorption of itraconazole is also affected by changes in gastric pH, but fluconazole is minimally affected. The manufacturer of posaconazole says that the reduced absorption is possibly secondary to a reduction in gastric acid. The slight increase in cimetidine levels in the presence of itraconazole may be due to inhibition of P-glycoprotein mediated renal tubular secretion of cimetidine.

Importance and management

The interactions with ketoconazole are clinically important but not extensively documented. Monitor the effects to confirm that the ketoconazole is effective. The situation with itraconazole is not entirely clear, but some reduction in its absorption apparently occurs and it would also therefore be prudent to confirm that it remains effective in the presence of H₂-receptor antagonists. It has been suggested that the reduction in bioavailability due to H₂-receptor antagonists can be minimised by giving itraconazole and ketoconazole with an acidic drink such as ‘cola’, (p.215), and this is recommended by some manufacturers.

The bioavailability of posaconazole also appears to be reduced by cimetidine. If this is due to the reduction in gastric acid, it could minimised by taking posaconazole with a cola drink, as for ketoconazole and itraconazole. However, the manufacturer currently recommends that the use of posaconazole with cimetidine or other H₂-receptor antagonists be avoided if possible, unless the benefit to the patient outweighs the risk.

Further study is needed.

Fluconazole only interacts to a small and clinically irrelevant extent with H₂-receptor antagonists and is therefore a possible alternative to ketoconazole and itraconazole. Similarly, no dosage adjustments are necessary if voriconazole is used with any of the H₂-receptor antagonists.

Azoles + Proton pump inhibitors

The bioavailability of ketoconazole is reduced by both omeprazole and rabeprazole. Other proton pump inhibitors are expected to behave similarly. Omeprazole also markedly reduces the absorption of itraconazole capsules, but not the oral solution. Proton pump inhibitors are predicted to reduce the bioavailability of posaconazole. The bioavailabilities of fluconazole and voriconazole are not significantly affected by omeprazole. Esomeprazole levels may also be increased by voriconazole. Omeprazole levels are increased by ketoconazole, and markedly increased by fluconazole and voriconazole.

Clinical evidence

(a) Esomeprazole

Based on data for omeprazole (see below), and the known acid-lowering effect of esomeprazole, the manufacturers predict that esomeprazole might reduce the absorption of itraconazole and ketoconazole, which depend on a low pH for optimal dissolution and absorption. Voriconazole may or may not involve the same levels of esomeprazole.

(b) Omeprazole

1. Fluconazole. A study in 12 healthy subjects found that omeprazole 20 mg daily for 7 days did not affect the pharmacokinetics of a single 100-mg dose of fluconazole given after a standard breakfast. In another study in 18 healthy subjects, fluconazole 100 mg daily for 5 days markedly increased the peak plasma levels and AUC of a single 20-mg dose of omeprazole by 2.4- and 6.3-fold, respectively.

2. Itraconazole. Itraconazole 200 mg (capsule) was given after a standard breakfast to 11 healthy subjects after 14 days pre-treatment with omeprazole 40 mg daily. The AUC and maximum serum level of itraconazole were both reduced by about 65%. In contrast, another study in 15 healthy subjects found that omeprazole 40 mg daily did not significantly affect the pharmacokinetics of single 400-mg doses of itraconazole or its metabolite hydroxyitraconazole when given as an oral solution. However, there was a large interpatient variation in mean serum levels. Another study similarly reported that omeprazole had little effect on the pharmacokinetics of itraconazole oral solution.

3. Ketoconazole. A three-way crossover study in 9 healthy fasting subjects found that omeprazole 60 mg reduced the AUC of ketoconazole 200 mg by about 80%.

Another study was carried out in 10 healthy subjects (both ‘extensive’ and ‘poor’ metabolisers) to find the extent to which cytochrome P450 isoenzymes are affected by ketoconazole. This revealed that ketoconazole 100 to 200 mg, a known inhibitor of CYP3A4, reduced the formation of the ketoconazole sulfoxide in both groups, and doubled the serum omeprazole levels in the poor metabolisers.

4. Posaconazole. Based on the 40% reduction in posaconazole AUC when given with ‘cola’, the manufacturers consider that proton pump inhibitors might interact similarly. Voriconazole interaction with posaconazole is established and of clinical importance. Direct evidence seems to be limited and of clinical importance. Importance and management

The interaction between ketoconazole and omeprazole appears to be established and of clinical importance. Voriconazole is not affected by omeprazole, and is unlikely to be affected by proton pump inhibitors. However, esomeprazole does not routinely require a dose adjustment. The clinical importance of the marked rise in serum omeprazole levels caused by voriconazole is not established, but the manufacturers recommend that the omeprazole dose be halved, although US manufacturers restrict this to patients taking omeprazole 40 mg or more. The increase in levels of esomeprazole by voriconazole does not routinely require a dose adjustment. Voriconazole interaction with omeprazole is unknown, but it might be expected to increase omeprazole levels similarly to ketoconazole.

The interaction between voriconazole and omeprazole is established but no adjustment to the dose of voriconazole is required. The clinical importance of the marked rise in serum omeprazole levels caused by voriconazole is not established, but the manufacturers recommend that the omeprazole dose be halved, although US manufacturers restrict this to patients taking omeprazole 40 mg or more. The increase in levels of esomeprazole by voriconazole does not routinely require a dose adjustment. Voriconazole interaction with omeprazole is unknown, but it might be expected to increase omeprazole levels similarly to ketoconazole.

The interaction between voriconazole and omeprazole is established but no adjustment to the dose of voriconazole is required. The clinical importance of the marked rise in serum omeprazole levels caused by voriconazole is not established, but the manufacturers recommend that the omeprazole dose be halved, although US manufacturers restrict this to patients taking omeprazole 40 mg or more. The increase in levels of esomeprazole by voriconazole does not routinely require a dose adjustment. Voriconazole interaction with omeprazole is unknown, but it might be expected to increase omeprazole levels similarly to ketoconazole.

The increase in levels of esomeprazole by voriconazole does not routinely require a dose adjustment. Voriconazole interaction with omeprazole is unknown, but it might be expected to increase omeprazole levels similarly to ketoconazole.
Rifabutin levels are increased by fluconazole, posaconazole, voriconazole, and possibly itraconazole. Patients taking this combination are at increased risk of rifabutin toxicity, specifically uveitis, and should be closely monitored. Rifabutin markedly reduces the plasma levels of itraconazole, posaconazole, and voriconazole. These azoles should be used cautiously with rifabutin, if at all. Rifabutin does not affect the metabolism of fluconazole.

Clinical evidence

(a) Fluconazole

Twelve HIV positive patients were given zidovudine 500 mg daily from day 1 to 44, fluconazole 200 mg daily from days 3 to 30 and rifabutin 300 mg daily from days 17 to 44. Rifabutin did not significantly affect the pharmacokinetics of fluconazole, but fluconazole increased the AUC of rifabutin by 82%, and the AUC of the rifabutin metabolite, LMS65 was increased by 216%. In another study in 10 patients with HIV infection, fluconazole 200 mg daily increased the AUC of rifabutin 300 mg daily by 76% and the maximum level by 91%. When the patients were also given clarithromycin 500 mg daily, the AUC of rifabutin was further increased to 152%. There is some evidence that fluconazole increases the prophylactic efficacy of rifabutin against M. avium complex disease, although there was an incidence in leucopenia. Uveitis developed in 6 HIV positive patients taking rifabutin 450 to 600 mg daily and fluconazole, 5 of whom were also taking clarithromycin, which is also known to increase rifabutin levels, see ‘Macrolides + Rifamycins’ p.316. Uveitis has been attributed to the concurrent use of rifabutin and fluconazole in other reports. Rifabutin does not appear to significantly affect the metabolism of fluconazole.

(b) Itraconazole

1. Itraconazole serum levels reduced. In a three-period study, 6 HIV positive patients were given itraconazole 200 mg daily for 14 days, rifabutin 300 mg daily for 10 days, and then both drugs for 14 days. It was found that the rifabutin reduced the peak plasma levels of the itraconazole by 71% and reduced its AUC by 74%. Rifabutin serum levels raised. A 49-year-old HIV positive man taking rifabutin 300 mg daily was also given itraconazole 600 mg daily. Because of low plasma levels after 3 weeks the itraconazole dose was increased to 900 mg daily. A week later the patient developed anterior uveitis. It was found that the itraconazole trough serum levels were normal but rifabutin trough serum levels were raised to 153 nanograms/mL (expected to be less than 50 nanograms/mL after 24 hours). Rifabutin was stopped and the uveitis was treated. Symptoms resolved after 5 days.

(c) Posaconazole

In a study in healthy subjects the concurrent use of posaconazole 200 mg once daily and rifabutin 300 mg once daily for 10 days increased the AUC of rifabutin by 72% and decreased the AUC of posaconazole by 51% when compared with either drug alone.

(d) Voriconazole

Rifabutin 300 mg daily decreased the AUC and maximum plasma levels of voriconazole 200 mg twice daily by 79% and 67%, respectively. Increasing the dose of voriconazole to 350 mg twice daily in the presence of rifabutin gave an AUC of 68% of that achieved with voriconazole 200 mg twice daily alone while maximum plasma levels were more or less the same. At a dose of 400 mg twice daily, voriconazole increased the maximum plasma level and AUC of rifabutin 300 mg twice daily by about threefold and fourfold, respectively.

Mechanism

Rifabutin increases the metabolism of itraconazole, posaconazole and voriconazole, probably, at least in part, by inducing their metabolism by the cytochrome P450 CYP3A subfamily. Fluconazole is largely excreted unchanged in the urine and so it is not affected. The azoles apparently increase rifabutin levels by inhibiting its metabolism, probably by CYP3A4. Raised rifabutin levels can cause uveitis.

Importance and management

The interaction between rifabutin and fluconazole is established, the general picture being that concurrent use can be advantageous. However, because of the increased risk of uveitis, the UK Committee on Safety of Medicines says that full consideration should be given to reducing the dosage of rifabutin to 300 mg daily. The rifabutin should be stopped if uveitis develops and the patient referred to an ophthalmologist. A later review suggests this 300 mg dose is associated with a reduced risk of uveitis and maintains efficacy. The combination should be well monitored. Note that the effects of ‘clarithromycin’, p.316, are additive with those of fluconazole.

Information on the interaction between itraconazole and rifabutin is very limited, but monitor for reduced antifungal activity, raising the itraconazole dosage as necessary, and watch for increased rifabutin levels and toxicity (in particular uveitis). More study is needed. Note that the manufacturers recommend that the combination should be avoided.

The manufacturer of ketoconazole suggests that the levels of both drugs may be affected if rifabutin is also taken. They suggest that the rifabutin dose may need to be reduced. On the basis of the interaction between rifabutin and posaconazole, the manufacturer suggests that the combination be avoided unless the benefit to the patient outweighs the risk. If the combination is used, monitor the efficacy of posaconazole and the toxicity of rifabutin, particularly full blood counts and uveitis.

The manufacturer in the US contraindicates the combination of voriconazole and rifabutin. However, the UK manufacturer permits concurrent use if the benefits outweigh the risks. If used together, it is recommended that the oral dose of voriconazole be increased from 200 mg twice daily to 350 mg twice daily (and from 100 to 200 mg twice daily in patients under 40 kg). The intravenous dose should also be increased from 4 to 5 mg/kg twice daily. Importantly, the manufacturer advises careful monitoring for rifabutin adverse effects (e.g. check full blood counts, monitor for uveitis).

Azoles + Rifampicin (Rifampin) and/or Isoniazid

Although rifampicin causes only a modest increase in fluconazole clearance, the reduction in its effects may possibly be clinically important. Fluconazole does not appear to affect rifampicin pharmacokinetics. There is an isolated report of hypercalcaemia in a patient taking both fluconazole and rifampicin. Rifampicin very markedly reduces serum itraconazole levels. This can reduce or abolish the antifungal effects of the itraconazole, possibly depending on the infection being treated.

The serum levels of ketoconazole can be reduced by 50 to 90% by rifampicin and/or isoniazid. Serum rifampicin levels can also be halved by ketoconazole, but are possibly unaffected if the drugs are given 12 hours apart.

Rifampicin markedly reduces voriconazole levels, and the combination should be avoided. Posaconazole is predicted to be similarly affected.

Clinical evidence

(a) Fluconazole

1. Fluconazole levels reduced. In a study in healthy subjects, rifampicin 600 mg daily for 19 days reduced the AUC of a single 200-mg dose of oral fluconazole by 23% and decreased the half-life by 19%. Similarly, a study in two groups of 12 patients with AIDS found that the AUC and peak plasma level of fluconazole 400 mg daily given for cryptococcal meningitis were reduced by 22% and 17% by rifampicin 600 mg daily when compared with the 12 patients not given rifampicin. The elimination rate constant of fluconazole was increased by 39% and the elimination half-life was reduced by 28%. There were no significant changes in clinical outcome although the subsequent use of a lower prophylactic dose of fluconazole 200 mg with rifampicin was found to result in levels of fluconazole 400 mg daily relapsed when rifampicin was added. Another report briefly states that one of 5 patients taking fluconazole needed an increased dosage or a replacement antifungal when given rifampicin.

In yet another study, the AUC of intravenous fluconazole was 52% lower in 2 patients also taking rifampicin than in 3 other patients not taking rifampicin.5

2. Rifampicin (Rifampin) levels unchanged. A study in 11 AIDS patients with cryptococcal meningitis found that fluconazole 200 mg twice daily for 14 days had no effect on the pharmacokinetics of rifampicin 300 mg daily.5 Five patients with tuberculosis, taking rifampicin and fluconazole, had normal rifampicin levels compared with 14 similar patients taking rifampicin alone, but in both groups rifampicin levels were only about 28% of those predicted.

3. Hypercalcaemia. There is an isolated report of severe hypercalcaemia attributed to the use of rifampicin and fluconazole in a patient with tuberculosis and pneumocystis. The clinical relevance of this case is uncertain.

(b) Itraconazole

A patient receiving antitubercular treatment including rifampicin 600 mg and isoniazid 300 mg daily was also given itraconazole 200 mg daily. After 2 weeks his serum itraconazole levels were negligible (0.011 mg/L). Even when the dosage was doubled the levels only reached a maximum of 0.056 mg/L. When the antitubercular drugs were stopped his serum itraconazole level was 3.23 mg/L with a 300 mg daily dose, and 2.35 to 2.6 mg/L with a 200 mg daily dose.

A later study in 8 other patients confirmed that itraconazole levels were reduced by rifampicin but the clinical outcome depended on the mycosis being treated. Four out of 5 patients responded to treatment for a Cryptococcus neoformans infection, despite undetectable itraconazole levels, apparently because in vitro there is synergy between the two drugs. In contrast, 2 patients with coccidioidomycosis failed to respond, and 2 others with cryptococcosis suffered a relapse or persistence of seborrhoic dermatitis (possibly due to M. furfur) while taking both drugs. In a patient with AIDS the serum levels of itraconazole 400 to 600 mg daily in divided doses were undetectable in the presence of rifampicin, and took 3 to 5 days to recover after the rifampicin was stopped.11 Undetectable itraconazole levels occurred in another patient given rifampicin who was treated for histoplasmosis. In contrast, a study found that the AUC of a single 100-mg dose of itraconazole was reduced by 80% after 6 healthy subjects took rifampicin 600 mg daily for 3 days.13 Very markedly reduced serum itraconazole levels (undetectable in some instances) have been seen in other healthy subjects and AIDS patients when given rifampicin.12 Retrospective review of the medical records of 2 patients given itraconazole and rifampicin indicated that itraconazole was not effective until rifampicin was stopped, based on the finding of continued weight loss while on the combination, and a clear weight gain after rifampicin was stopped.13

(c) Ketoconazole

1. Ketoconazole levels reduced. The addition of ketoconazole 200 mg twice daily for one day then 200 mg once daily for 2 days to rifampicin 600 mg daily had little effect on the peak level and AUC of rifampicin in a study in 6 healthy subjects. In contrast, the rifampicin serum levels of a child who had responded poorly to treatment found that peak serum levels and AUC of ketoconazole were reduced by about 65 to 80% by rifampicin and/or isoniazid. The interaction also occurred when the dosages were separated by 12 hours. When all three drugs were given together the ketoconazole serum levels were undetectable. Other reports confirm these reports of decreased ketoconazole levels with rifampicin.

2. Rifampicin levels. The addition of ketoconazole 200 mg twice daily for one day then 200 mg once daily for 2 days to rifampicin 600 mg daily had little effect on the peak level and AUC of rifampicin in a study in 6 healthy subjects. In contrast, the rifampicin serum levels of a child were roughly halved by ketoconazole, but when the rifampicin was given 12 hours after the ketoconazole, the serum levels of rifampicin were unaffected. Other studies also show a reduction in rifampicin levels caused by ketoconazole, one confirming that separation of the drugs by 12 hours minimised the interaction.

(d) Voriconazole

The manufacturer notes that rifampicin 600 mg once daily decreased the maximum plasma levels and AUC of voriconazole 200 mg twice daily by about 95%. Even doubling the dose of voriconazole did not give adequate exposure. The concurrent use of voriconazole and rifampicin is therefore contraindicated.

Mechanism

Rifampicin increases the metabolism of the azole antifungals by the liver. However, as fluconazole (unlike ketoconazole, itraconazole and voriconazole) is mainly excreted unchanged in the urine, changes to its metabolism would not be expected to have as marked an effect as on these other azoles. The absorption of antitubercular drugs may be reduced in patients with AIDS and an increase in rifampicin levels may be due to increased absorption in the presence of fluconazole. In contrast, it is suggested that ketoconazole impairs the absorption of rifampicin from the gut. Just how isoniazid interacts is uncertain.

Importance and management

The interaction between rifampicin and fluconazole appears to be established and of clinical importance. Although rifampicin has only a modest effect on fluconazole, the cases of relapse cited above and the need for an increased dosage indicate that this interaction can be clinically important. Monitor concurrent use and increase the fluconazole dosage if necessary. One study suggests a 30% increase in fluconazole dose may be considered for serious infections during concurrent rifampicin therapy. This may be especially important during prophylaxis of cryptococcal meningitis with lower doses of fluconazole, such as 200 mg daily.

The interaction between itraconazole and rifampicin is established and clinically important. Monitor the effects of concurrent use, being alert for the need to increase the itraconazole dosage. The effect on serum itraconazole levels can be very marked indeed. The clinical importance of this interaction can apparently depend on the mycosis being treated. Note that the manufacturer considers that itraconazole should not be used with rifampicin, since its levels are so markedly reduced.

The interactions between ketoconazole and rifampicin appear to be established and of clinical importance, but there is very much less information about the interaction with isoniazid. The effects on rifampicin can apparently be avoided by giving the ketoconazole at a different time (12 hours apart seems to be effective) but this does not solve the problem of the effects on ketoconazole. The dosage of at least one of the drugs will need to be increased to achieve both good antituberculous and antifungal responses. Concurrent use should be well monitored and dosage increases made if necessary. One manufacturer suggests that the combination should be avoided.28

The manufacturer predicts that posaconazole levels may be significantly lowered when used with rifampicin. They suggest that the combination be avoided unless the benefit to the patient outweighs the risk.29

Voriconazole levels are very markedly reduced by rifampicin and concurrent use is contraindicated.24,25

Clinical evidence
(a) Fluconazole
Sucralfate 2 g was found to have no significant effect on the pharmacokinetics of a single 200-mg dose of fluconazole in 10 healthy subjects, confirming the results of an in vitro study.1

(b) Ketoconazole
A study2 in 6 fasting healthy subjects found that sucralfate 1 g given 2 hours before ketoconazole 400 mg reduced its AUC by about 20%. Another study in fasting healthy subjects found that sucralfate 1 g given with glutamic acid hydrochloride reduced the AUC and maximum serum levels of a single 100-mg dose of ketoconazole by about 25%, but no significant changes were seen when the ketoconazole was given 2 hours after the sucralfate.3

Mechanism
There is an in vitro evidence that an electrostatic interaction occurs between ketoconazole and sucralfate to form an ion pair that cannot pass through the gut wall.4

Importance and management
The interaction of sucralfate with ketoconazole is modest and of uncertain clinical importance. Any interaction may be minimised by taking sucralfate at least 2 to 3 hours before or after the ketoconazole. Fluconazole does not interact with sucralfate.

Azoles; Fluconazole + Hydrochlorothiazide
Hydrochlorothiazide modestly increases the levels of fluconazole, but this is unlikely to be clinically relevant.

Azoles; Itraconazole + Grapefruit and other fruit juices
Grapefruit juice impaired the absorption of itraconazole capsules in one study, but not in another. Grapefruit juice had no effect on the absorption of itraconazole oral solution. Orange juice impaired the absorption of itraconazole capsules in one study.

H. Novafil (Posaconazole). Schering-Plough Ltd. UK Summary of product characteristics, October 2006.
similar study found that grapefruit juice had no effect on the pharmacokinetics of itraconazole capsules (Itrizole, Janssen). The only apparent differences in this study were that itraconazole was given at the lower dose of 100 mg, and that 350 mL of single-strength grapefruit juice was used. Furthermore, in this study, orange juice reduced the AUC of itraconazole by an average of 41%.

(b) Oral solution

A small 17% increase in the AUC of itraconazole was seen in 20 healthy subjects when given grapefruit juice. In this study, regular strength grapefruit juice 240 mL was given three times daily for 2 days, then together with itraconazole oral solution 200 mg on the morning of the third day in the fasted state, then again 2 hours later.

Mechanism

As grapefruit juice is an inhibitor of intestinal cytochrome P450 iso-enzyme CYP3A4, the major enzyme involved in itraconazole metabolism, it was predicted that it would enhance itraconazole absorption. Appearing to confirm this, a small increase in itraconazole levels was seen with itraconazole oral solution. However, with itraconazole capsules, one study showed decreased levels and one no change. The mechanism is not known, but grapefruit juice may impair the absorption of itraconazole capsules either by affecting P-glycoprotein or lowering the duodenal pH.

Importance and management

The 40% reduction in itraconazole levels from itraconazole capsules seen with grapefruit juice would be anticipated to be clinically relevant in some situations, but it was seen in only one of two single-dose studies. Similarly, the reduction in levels with orange juice might be clinically relevant. However, at present, there is insufficient evidence to recommend avoiding concurrent use. Until more is known, in the event of unexpected inefficacy or low levels of itraconazole, bear the possibility in mind that grapefruit juice or orange juice may be a factor. Itraconazole oral solution, which is better absorbed than the capsules, did not appear to be affected by grapefruit juice.

Azoles; Voriconazole + St John’s wort (Hypericum perforatum)

St John’s wort, taken for two weeks, halved the levels of a single dose of voriconazole, which may be clinically relevant.

Clinical evidence, mechanism, importance and management

A single 400-mg dose of oral voriconazole was given alone and on the first and last day of St John’s wort (Jarsin, Lichtwer Pharma) given at a dose of 300 mg three times daily for 15 days to 17 healthy subjects. One day of St John’s wort had no effect on the voriconazole AUC0-∞, but slightly increased the maximum serum level and AUC0-10 by 22%. However, when voriconazole was given on day 15, the AUC of voriconazole was decreased by 59% and there was a 2.4-fold increase in oral clearance. These results suggest that the short-term effect of St John’s wort is to slightly enhance the absorption of voriconazole, whereas the longer-term effect is to induce absorption-limiting transport proteins and intestinal metabolism via cytochrome P450 isoenzymes.

The slight increase in voriconazole absorption with a single dose of St John’s wort is not clinically relevant. However, the reduction in voriconazole levels after 15 days of St John’s wort could impact on clinical efficacy. This suggests that patients requiring voriconazole should be asked about current or recent use of St John’s wort, since this may indicate the need to use an increased voriconazole dose, at least initially. Patients taking voriconazole should be advised not to take St John’s wort.

Chloroquine or Hydroxychloroquine + Antacids or Kaolin

The absorption of chloroquine is moderately reduced by magnesium trisilicate and kaolin. Hydroxychloroquine is predicted to be similarly affected.

Clinical evidence

Six healthy subjects were given chloroquine phosphate 1 g (equivalent to 620 mg of chloroquine base) with either magnesium trisilicate 1 g or
kaolin 1 g after an overnight fast. The magnesium trisilicate reduced the AUC of the chloroquine by 18.2% and the kaolin reduced it by 28.6%. Related in vitro studies by the same authors using segments of rat intestine found that the absorption of chloroquine was decreased as follows: magnesium trisilicate 31.3%, kaolin 46.5%, calcium carbonate 52%, and gerdiga 36.1%. Gerdiga is a clay containing hydrated silicates with sodium and potassium carbonates and bicarbonates. It is used as an antacid and is similar to attapulgite.

Mechanism
These antacid and antidiarrhoal compounds adsorb chloroquine thereby reducing the amount available for absorption by the gut. Dissolution of chloroquine from tablets may also be delayed by adsorbent antacids.

Importance and management
The modest pharmacokinetic interactions between chloroquine and magnesium trisilicate or kaolin are established, but their clinical importance does not seem to have been assessed. One way to minimise any interaction is to separate the dosages of the antimalarials and magnesium trisilicate or kaolin as much as possible (at least 2 to 3 hours) to reduce admixture in the gut. There do not appear to be any studies to see if other antacids behave similarly.

The manufacturer of hydroxychloroquine predicts that, as with chloroquine, antacids might decrease hydroxychloroquine absorption, and they recommend separating administration by 4 hours.

Chloroquine + Colestyramine
Colestyramine can modestly reduce the absorption of chloroquine, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management
Colestyramine 4 g reduced the absorption of chloroquine 10 mg/kg by about 30% in 5 children aged 6 to 13. Considerable inter-individual differences were seen. This reduced absorption is consistent with the way colestyramine interacts with other drugs by binding to them in the gut. The clinical importance is uncertain but separating the dosages is effective in minimising this interaction with other drugs. It is generally advised that other drugs are given 1 hour before or 4 to 6 hours after colestyramine.

Chloroquine or Hydroxychloroquine + H₂-receptor antagonists
Cimetidine reduces the metabolism and clearance of chloroquine, but the clinical importance of this is uncertain. Hydroxychloroquine is predicted to interact in the same way as chloroquine. Ranitidine appears not to interact with chloroquine.

Clinical evidence, mechanism, importance and management
Cimetidine 400 mg daily for 4 days approximately halved the clearance of a single 600-mg dose of chloroquine base in 10 healthy subjects. The elimination half-life was prolonged from 3.11 to 4.62 days. It was suggested that these effects occurred because cimetidine inhibits the metabolism of chloroquine by the liver. The clinical importance of this interaction is uncertain, but it would seem prudent to be alert for any signs of chloroquine toxicity during concurrent use. A similar study by the same authors found that ranitidine does not interact with chloroquine.

On the basis of these data for chloroquine and cimetidine, the manufacturer of hydroxychloroquine states that, even though specific reports have not appeared, cimetidine might inhibit hydroxychloroquine metabolism.

Chloroquine + Imipramine
No pharmacokinetic interaction was seen in 6 healthy subjects given single doses of chloroquine 300 mg and imipramine 50 mg. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Chloroquine + Methylthioninium chloride (Methylene blue)
Methylthioninium chloride caused a small 20% reduction in exposure to chloroquine, which was not considered to be clinically relevant.

Clinical evidence, mechanism, importance and management
Methylthioninium chloride 130 mg twice daily given orally to 12 healthy subjects with a 3-day course of chloroquine tended to decrease the AUC of chloroquine (by 20%), without affecting renal clearance when compared with a control group of 12 patients receiving chloroquine alone. This small reduction would not be expected to be clinically relevant.

Chloroquine + Promethazine
Promethazine appears to increase the levels of intramuscular chloroquine and its metabolites.

Clinical evidence, mechanism, importance and management
A study in healthy subjects found that intramuscular promethazine hydrochloride 25 mg, given with intramuscular chloroquine phosphate 200 mg increased the AUC of chloroquine and its metabolites by 85%. This may be due to promethazine enhancing the absorption of chloroquine from the injection site or displacing it and its metabolites from binding sites in the blood. The initial rate of excretion of chloroquine and the total drug excretion in urine were increased within 3 hours was unaffected by promethazine. The increased bioavailability of chloroquine may improve its therapeutic effects but could also increase toxicity. In vitro and animal studies suggest the combination may be effective in the treatment of uncomplicated chloroquine-resistant malaria. More study is needed. For mention that chloroquine may increase chlorpromazine levels, see ‘Phenothiazines + Antimalarials’, p.739.

Co-artemether + CYP2D6 substrates

The manufacturer of co-artemether notes that in vitro data indicate that lumefantrine significantly inhibits CYP2D6. As a consequence, they contraindicate the use of co-artemether in patients taking any drug that is metabolised by CYP2D6, and they give food, metoprolol, imipramine, amitriptyline, clomipramine as examples (for a list of CYP2D6 substrates, see ‘Table I.3’, (p.6)). These contraindications seem unnecessarily restrictive, especially since none of the drugs they give as examples are contraindicated with other established inhibitors of CYP2D6. Until more is known, it would be prudent to closely monitor the effects of any CYP2D6 substrate in patients for whom co-artemether is considered the antimalarial drug of choice.

Co-artemether + CYP3A4 inhibitors

Ketoconazole doubles the AUC of artemether and lumefantrine, and other potent inhibitors of CYP3A4 are predicted to interact similarly. Although the clinical relevance of this is uncertain, the manufacturers of co-artemether currently advise against concurrent use.

Clinical evidence, mechanism, importance and management

In one study, 16 healthy subjects were given ketoconazole 400 mg on day one then 200 mg daily for 4 days increased the AUC of artemether 2.4-fold, its metabolite dihydroartemisinin 1.7-fold and lumefantrine 1.7-fold after a single dose of co-artemether 80/480 mg given with a high-fat breakfast. The maximum levels of the drugs were increased to a similar extent. No changes in ECG parameters or increases in adverse events were noted.

It was suggested that ketoconazole probably increases the levels of artemether and lumefantrine via its effects on intestinal and/or hepatic cytochrome P450 isoenzyme CYP3A4. A pharmacokinetic interaction with ketoconazole seems to be established, and would be predicted for other similar potent CYP3A4 inhibitors. However, the clinical relevance of a twofold increase in artemether and lumefantrine levels is unclear. The authors suggest that no dosage adjustment would appear necessary. Nevertheless, the manufacturer of co-artemether contraindicates the use of co-artemether in patients who are taking any drug that inhibits CYP3A4, and they give erythromycin, ketoconazole, itraconazole, cimetidine and protease inhibitors as examples. They base this advice on the lack of clinical data and unknown effects on safety. Given the data with ketoconazole, in the setting of acute Plasmodium falciparum malaria, when co-artemether is considered the appropriate treatment, this advice seems unnecessarily restrictive. If it is deemed necessary to use co-artemether in a patient on a CYP3A4 inhibitor, it may be prudent to closely monitor the ECG and potassium levels, since artemether may prolong the QT interval. Further study is needed.

Co-artemether + Food

High-fat food markedly increases the absorption of lumefantrine and moderately increases the absorption of artemether. As soon as patients can tolerate food they should be encouraged to take co-artemether with meals.

Co-artemether + Grapefruit juice

Grapefruit juice doubles the AUC of artemether. Although the clinical relevance of this is uncertain, the manufacturers of co-artemether advise against concurrent use.

Clinical evidence, mechanism, importance and management

In a crossover study, healthy subjects were given a single 100-mg dose of artemether after breakfast with water, then after a 7-day washout period the study was repeated with 350 mL of double-strength grapefruit juice. Grapefruit juice increased the AUC of artemether by almost twofold, and the maximum level by more than twofold. The pharmacokinetics of the metabolite dihydroartemisinin were unaffected. In a further multiple-dose study, artemether 100 mg was taken with water or 350 mL of double-strength grapefruit juice once daily for 5 days. Grapefruit juice increased the AUC and maximum level of artemether twofold on both day one and day 5, but the AUC of artemether was markedly lower on day 5, due to autoinduction of its metabolism. This suggests that grapefruit juice might increase the levels of artemether via inhibition of intestinal CYP3A4, but that autoinduction does not affect this process.

The clinical relevance of a twofold increase in artemether levels is unclear. The authors suggest that the use of grapefruit juice might improve clinical efficacy in malaria, and might theoretically reduce the recrudescence (the reappearance of a disease after a period of inactivity) rate of artemether monotherapy. However, artemether is used with lumefantrine to limit recrudescence. Further study is needed.

Co-artemether + Mefloquine

The levels of lumefantrine were modestly reduced by mefloquine pretreatment, but the levels of artemether and of mefloquine were not affected. No adverse effects on the QT interval were seen. These data indicate that co-artemether may be used after mefloquine prophylaxis or treatment.
Clinical evidence, mechanism, importance and management

In a study, 6 doses of co-artemether 80/480 mg were given over 60 hours to 42 healthy subjects, starting 12 hours after a short course of mefloquine (3 doses totalling 1 g given over 12 hours). The pharmacokinetics of the mefloquine and the artemether were unaffected by sequential use, but the lumefantrine maximum plasma concentrations and AUC were reduced by 29 and 41% respectively. However, given that the plasma levels of lumefantrine are usually highly variable, these changes were not thought large enough to affect the efficacy of treatment.1

In another study, similar sequential use of these drugs did not affect the QT interval, and drug levels were also considered adequate for treatment.2

The authors considered that adverse effects on the QT interval are unlikely to occur if co-artemether is used after mefloquine prophylaxis or treatment.

These data indicate that sequential use of mefloquine then co-artemether is unlikely to require any special precautions. The manufacturer of co-artemether notes that prolongation of the QT interval was seen in about 5% of patients in clinical trials (although they say this could be disease related). They state that, due to the limited data on safety and efficacy, co-artemether should not be given concurrently with any other antimalarial.3 For mention of a study where artemether pretreatment modestly reduced mefloquine levels, see ‘Mefloquine + Artemisinin derivatives’, p.231.

Co-artemether + Quinine

No clinically significant pharmacokinetic interaction appears to occur between quinine and co-artemether. Quinine-induced QTc prolongation may be enhanced by artemether.

Clinical evidence, mechanism, importance and management

In a double-blind placebo-controlled study in healthy subjects, 6 doses of co-artemether 80/480 mg were given to 14 subjects, over a period of 60 hours, followed 2 hours after the last dose by intravenous quinine 10 mg/kg (to a maximum of 600 mg) over 2 hours. Another two groups, each containing 14 subjects, received quinine or co-artemether, with placebo. The pharmacokinetics of lumefantrine and quinine were unaffected by combined use but the AUC and plasma levels of artemether and its active metabolite dihydroartemisinin appeared to be lower when co-artemether was given with quinine. However, the levels prior to quinine use in this group were also lower and the reduction in the presence of quinine was not considered clinically significant. The transient prolongation of the QTc interval noted with quinine (average and peak increase of 3 and 6 milliseconds, respectively) was slightly greater when quinine was given after co-artemether (average and peak increases 7 and 15 milliseconds respectively).1 Both quinine and artemether are known to prolong the QT interval. In general, it is advised that the concurrent use of drugs that prolong the QT interval should be avoided (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257). However, the authors of this study considered that the modest increased risk of QTc prolongation was outweighed by the potential benefit of the combined treatment in complicated or multidrug-resistant falciparum malaria.1 If the combination is used, careful cardiac monitoring is recommended.

Clinical evidence

Two studies, one in healthy subjects1 and the other in patients with onchocerciasis,2 found that making the urine alkaline with sodium bicarbonate markedly increased the retention of the diethylcarbamazine. The urinary excretion of a 50-mg dose of diethylcarbamazine was 62.3% and its elimination half-life 4 hours when the urine was made acidic (pH less than 5.5) by giving ammonium chloride, compared with 5.1% and 9.6 hours respectively when the urine was made alkaline (pH more than 7.5) using sodium bicarbonate.1

Mechanism

In alkaline urine most of the diethylcarbamazine is non-ionised and is therefore easily reabsorbed in the kidney by simple diffusion through the lipid membrane. However, the conclusion was reached that in practice there is no advantage in making the urine alkaline in order to be able to use smaller doses of diethylcarbamazine because the severity of the adverse reactions (the Mazzotti reaction) is not reduced, and the microfilarial counts at the end of a month are not significantly different.2

Importance and management

The clinical importance of any unsought for changes in the urinary pH brought about by the use of other drugs during diethylcarbamazine treatment has not been assessed, but be aware that its pharmacokinetics and possibly the severity of its adverse effects can be changed.

Echinocandins + Amphotericin B

Limited evidence suggests that amphotericin B does not alter the pharmacokinetics of anidulafungin. The pharmacokinetics of caspofungin and amphotericin B are not altered by concurrent use.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

The manufacturer notes that population pharmacokinetic analysis showed no difference in the pharmacokinetics of anidulafungin in 27 patients who were also given liposomal amphotericin B when compared with data from patients receiving anidulafungin alone. This suggests that no dosage adjustment of anidulafungin is required if it is given with amphotericin B.1

(b) Caspofungin

The manufacturers of caspofungin say there were no pharmacokinetic interactions between caspofungin and amphotericin B in a study in healthy subjects.2

Echinocandins + Azoles

No pharmacokinetic interaction appears to occur between anidulafungin and voriconazole or between caspofungin and itraconazole. No dosage adjustment of these drugs is necessary if they are used in combination.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

In a crossover study in 17 healthy subjects the steady state maximum level and AUC of both anidulafungin and voriconazole were not significantly altered by concurrent use, when compared with either drug given with placebo. Intravenous anidulafungin was given at a dose of 200 mg on the first
Ciclosporin appears to modestly increase caspofungin levels, and concurrent use can apparently result in raised liver enzymes. Ciclosporin slightly raised anidulafungin levels in one study, without any serious adverse events.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

Intravenous anidulafungin 200 mg on day one, then 100 mg daily for 7 days was given to 12 healthy subjects with concurrent oral ciclosporin solution (Neoral) 1.25 mg/kg twice daily on the last 4 days. Cyclosporin caused a small 22% increase in the steady-state AUC of anidulafungin, which was not considered to be clinically relevant. No dose-limiting toxicities or serious adverse events were noted. One patient had a mild increase in liver enzymes on day 6 (after 2 days of concurrent use), and the study drugs were withdrawn at this point.1

Anidulafungin is not expected to alter ciclosporin levels based on an in vitro study where anidulafungin had no effect on the metabolism of ciclosporin.2 The manufacturer states that no dosage adjustment of either drug is needed on concurrent use.2

(b) Caspofungin

The manufacturers report that in two studies in healthy subjects, ciclosporin (a single 4-mg/kg dose, or two 3-mg/kg doses 12 hours apart) increased the AUC of caspofungin by 35%. Moreover, 5 of 12 subjects (43%) had increases in AST and ALT of up to threefold. The liver enzymes returned to normal on discontinuation of both drugs, and during concurrent use the levels of ciclosporin were not affected.3,4 These findings led to the exclusion of patients receiving ciclosporin from phase II/III studies of caspofungin.5 Note that elevated liver enzymes (typically mild and rarely leading to discontinuation) are a common adverse effect of caspofungin alone.6,7 More recently, 3 studies have reported retrospective analyses of the clinical use of caspofungin in a total of 68 patients taking ciclosporin.8-10 All three found no serious hepatic adverse events. Two reported no clinically significant elevations of liver enzymes,6,9 but one found 2 of 40 patients had discontinued therapy because of abnormalities in hepatic enzymes, possibly related to caspofungin and/or ciclosporin.7 The manufacturers say that ciclosporin and caspofungin can be used together if the potential benefit outweighs the risk. If they are used together, close monitoring of liver enzymes is recommended.3,4

Echinocandins + Ciclosporin

Ciclosporin appears to modestly increase caspofungin levels, and concurrent use can apparently result in raised liver enzymes. Ciclosporin slightly raised anidulafungin levels in one study, without any serious adverse events.

Clinical evidence

(a) Anidulafungin

A population pharmacokinetic analysis of anidulafungin in patients with serious fungal infections found that the clearance of anidulafungin did not differ between 27 patients also taking rifampicin (rifampin) and 77 patients taking no known interacting drugs.1 Similarly, anidulafungin clearance was not different in 40 patients given inducers of cytochrome P450 (including rifampin, but others not specifically named).2 These findings suggest that no dosage adjustment of anidulafungin is needed in patients taking rifampicin or other enzyme inducers.1,2

(b) Caspofungin

A parallel-group study in healthy subjects looked at the effects of rifampicin on the pharmacokinetics of caspofungin. In the first group, rifampicin 600 mg daily was given with intravenous caspofungin 50 mg daily, started on the same day. It was found that the trough levels and AUC of caspofungin were increased by 170 and 61%, respectively, on day one. However, after 2 weeks the AUC had returned to normal, and, when compared to subjects not taking rifampicin, there was a trend to lower trough levels of caspofungin. In the second group of healthy subjects in this study, rifampicin 600 mg daily was given for 14 days alone and then for a further 14 days combined with caspofungin. In this study, no significant increase in the caspofungin AUC was seen on day one of concurrent use. On both day one and day 14, the trough levels of caspofungin were reduced by about 30%, without any change in the AUC, similar to the findings on day 14 in the first group. In this second group, caspofungin did not alter the pharmacokinetics of rifampicin.3 A case report describes a neutropenic patient with fungaemia who did not respond to intravenous caspofungin (70 mg on the first day then 50 mg daily) whilst taking rifampicin 600 mg daily. However, susceptibility testing showed that the isolate was not resistant to caspofungin and she was successfully treated with amphotericin B. Although this patient was treated with standard dose caspofungin, the authors note she weighed just 47 kg and showed not even an initial response. They suggest that caspofungin doses of more than 70 mg daily would have been required for efficacy in their patient.4

Mechanism

Caspofungin is a poor substrate for cytochrome P450 and is not a substrate for P-glycoprotein, therefore these mechanisms are not thought to be involved in the interaction with rifampicin. It is possible that the modest effect of rifampicin on caspofungin is due to induction of tissue uptake transport proteins at steady-state.5

Importance and management

The manufacturers recommend that consideration should be given to increasing the dose of caspofungin from 50 to 70 mg daily in patients taking rifampicin.6,7 This dose has been generally well tolerated in clinical studies.8 However, bear in mind the case report of possible caspofungin failure, even at this dose. The manufacturers also say that a population pharmacokinetic analysis suggested that the concurrent use of other met-

abolic inducers (carbamazepine, dexamethasone, efavirenz, nevirapine or phenytoin) may result in clinically meaningful reductions in caspofungin AUC.\(^5\)\(^6\) They suggest considering increasing the dose of caspofungin from 50 to 70 mg daily if it is used with enzyme inducers such as these. Further study is needed.

### Echinocandins; Anidulafungin + Miscellaneous

A population pharmacokinetic analysis of anidulafungin in patients with serious fungal infections found that the clearance of anidulafungin did not differ between 140 patients taking drugs classified as cytochrome P450 isoenzyme inhibitors (none specifically named) and 77 patients who received no known interacting drugs.\(^1\) For the lack of a pharmacokinetic interaction between anidulafungin and voriconazole, see ‘Echinocandins + Azoles’, p.225.

### Echinocandins; Caspofungin + Mycophenolate

The manufacturers of caspofungin say that the pharmacokinetics of caspofungin and mycophenolate are not altered by concurrent use.\(^1\)\(^2\)

### Echinocandins; Caspofungin + Nelfinavir

Nelfinavir does not have a clinically relevant effect on the pharmacokinetics of caspofungin.

**Clinical evidence, mechanism, importance and management**

In a parallel-group study healthy subjects were given nelfinavir 1250 mg every 12 hours, with intravenous caspofungin 50 mg daily, started on the same day. The AUC of caspofungin and the trough level were increased by 16 and 58%, respectively, on the first day when compared with subjects receiving caspofungin alone. However, after 2 weeks of combined use, there was no difference in the AUC or trough level of caspofungin.\(^1\) The authors note that their previous population pharmacokinetic analysis had shown that nelfinavir might decrease the AUC and trough level of caspofungin, which in the light of the controlled study, they consider to be a spurious finding.

It appears that nelfinavir does not have a clinically significant effect on the pharmacokinetics of caspofungin, and no dosage adjustment of caspofungin is required on combined use.

### Flucytosine + Amphotericin B

The combination of flucytosine with amphotericin B may be more effective than flucytosine alone for some fungal infections, but amphotericin B increases the toxicity of flucytosine. Close monitoring of flucytosine levels and renal function is required. Other drugs that impair glomerular filtration might also decrease flucytosine elimination and increase toxicity.

**Clinical evidence, mechanism, importance and management**

The combined use of flucytosine and amphotericin B is more effective than flucytosine alone in the treatment of cryptococcal meningitis, as demonstrated in an early study,\(^1\) and is still the recommended treatment.\(^2\)\(^3\) However, amphotericin B can cause deterioration in renal function, which reduces flucytosine elimination, and may result in raised flucytosine blood levels. In addition, amphotericin may increase the cellular uptake of flucytosine.\(^4\) Whatever the exact mechanism, combined use increases flucytosine bone marrow toxicity. A study of 194 patients randomised to either a 4 or 6-week course of low-dose amphotericin B (initially 0.3 mg/kg daily) and maximal dose flucytosine (150 mg/kg daily, adjusted for renal function) found that severe adverse effects were common. These included azotaemia (51 patients), blood dyscrasias (52 patients), and hepatitis (13 patients).\(^5\)

Flucytosine levels and renal function should be very closely monitored when the drugs are used concurrently. One manufacturer of flucytosine says that any drug that impairs glomerular filtration may prolong the half-life of flucytosine, which would increase the risk of toxicity.\(^6\)\(^6\)

### Flucytosine + Antacids

Aluminium/magnesium hydroxide delays the absorption of flucytosine from the gut, but the total amount absorbed remains unaffected.\(^1\) No special precautions appear to be needed if this antacid is given with oral flucytosine.

### Flucytosine + Cytarabine

Some very limited evidence suggests that cytarabine may oppose the antifungal effects of flucytosine, or reduce flucytosine levels. Theoretically, their bone marrow suppressant effects might be additive.

**Clinical evidence, mechanism, importance and management**

A man with Hodgkin’s disease treated for cryptococcal meningitis with flucytosine 100 mg/kg daily had reduced flucytosine serum and CSF levels, from a range of 30 to 40 mg/L down to undetectable levels, when given cytarabine intravenously. When the cytarabine was replaced by procarbazine, the flucytosine levels returned to their former values. In vitro tests found that cytarabine 1 mg/L completely abolished the activity of up to 50 mg/L of flucytosine against the patient’s strain of Cryptococcus, whereas procarbazine did not.\(^1\) In another study in a patient with acute myeloid leukaemia, the predose flucytosine level fell from 65 to 42 mg/L and...
the post-dose flucytosine level fell from and 80 to 53 mg/L when cytarabine and daunorubicin were given. However, these levels were still within the therapeutic range. The drop in levels was attributed to an improvement in renal function rather than antagonism between the two drugs. In an in vitro study the antifungal effects of flucytosine against 14 out of 16 wild isolates of Cryptococcus were not changed in the presence of cytarabine. In the remaining two isolates, an increase in effect was seen in one and a decrease was seen in the other. The evidence for any interaction is therefore very limited indeed and its general clinical importance remains uncertain. The manufacturers of flucytosine advise that strict monitoring of flucytosine levels is required if both drugs are given. Of equal concern is the fact that both drugs are bone marrow suppressants, and this effect might be additive.

Furazolidone + Omeprazole

Omeprazole modestly reduces the serum levels of furazolidone. Note that the two drugs have been successfully combined in H. pylori eradication regimens.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects found that omeprazole 20 mg twice daily for 5 days reduced the peak serum level of a single 200-mg dose of furazolidone by about 30%. The clinical relevance of this modest change is uncertain. Omeprazole may alter the bioavailability of furazolidone by reducing its dissolution or increasing its degradation before it reaches the intestine and/or inducing its first-pass metabolism. Note that there are now a large number of clinical trials describing the successful combination of furazolidone with omeprazole in regimens to eradicate H. pylori. However, there is some evidence that success rates are unacceptable if low-dose furazolidone (100 mg twice daily) rather than standard dose (200 mg twice daily) is used. It is possible that pharmacokinetic interaction could play a part in this finding.

Grisofulvin + Food

The rate and probably extent of griseofulvin absorption is markedly increased if it is taken with a high-fat meal.

Clinical evidence, mechanism, importance and management

A study in 5 healthy subjects found that the absorption of micronised griseofulvin 125 mg (Fulcin) was enhanced if it was given with a fatty meal rather than in the fasting state, as assessed by a 37% increase in urinary excretion. Other studies similarly found that the absorption of griseofulvin at 4 and 8 hours was about doubled when it was taken with a high-fat meal. A further study in 12 healthy subjects found that the higher the fat content of the meal the higher the bioavailability of griseofulvin (70% increase in bioavailability with a low-fat meal and 120% increase with a high-fat meal, when compared with fasting state absorption). However, another study found that although food increased the rate of absorption of micronised and PEG-ultramicrocrystalline griseofulvin, the extent of absorption was not changed. Another report suggested that giving griseofulvin with food tended to reduce the differences in the bioavailability of griseofulvin from micronised and ultramicrocrystalline tablets. Enhanced absorption was also found with a formulation of griseofulvin in a corn oil emulsion, when compared with tablets or an aqueous suspension.

This interaction is established and of clinical importance. Some manufacturers advise that griseofulvin should be given after meals, otherwise absorption is likely to be inadequate.

Grisofulvin + Phenobarbital

The antifungal effects of griseofulvin can be reduced or even abolished by phenobarbital.
**Clinical evidence**

Two epileptic children taking phenobarbital 40 mg daily did not respond to long-term treatment for tinea capitis with griseofulvin 125 mg three times daily until the barbiturate was withdrawn.\(^1\)

Five other patients (3 also taking phenoxytoin) similarly did not respond to griseofulvin while taking phenobarbital.\(^2\) Two studies, in a total of 14 healthy subjects, found that phenobarbital 30 mg three times daily reduced the serum levels of oral griseofulvin by about one-third,\(^3\) and the absorption was reduced from 58.1% without phenobarbital to 40.6% in the presence of phenobarbital.\(^4\)

**Mechanism**

Not fully understood. Initially it was thought that the phenobarbital increased the metabolism and clearance of the griseofulvin,\(^5\) but it has also been suggested that it reduces the absorption of griseofulvin from the gut.\(^6\)

One idea is that the phenobarbital increases peristalsis reducing the opportunity for absorption.\(^6\) Another suggestion is that phenobarbital forms a complex with griseofulvin, which makes an already poorly soluble drug even less soluble, and therefore less readily absorbed.\(^7\) A further suggestion is that phenobarbital may reduce the level of intestinal bile salts, which in turn may reduce the solubility and absorption of griseofulvin.\(^8\)

**Importance and management**

An established interaction of clinical importance, although the evidence seems to be limited to the reports cited. If phenobarbital must be given, it has been suggested that the griseofulvin should be given in divided doses three times a day to give it a better chance of being absorbed.\(^9\) However, divided doses were used in one of the reports describing an interaction.\(^1\)

The effect of increasing the dosage of griseofulvin appears not to have been studied. An alternative, where possible, is to use a non-interacting anticonvulsant such as sodium valproate. This proved to be successful in one of the cases cited.\(^1\)

---

**Halofantrine + Miscellaneous**

Halofantrine prolongs the QT interval and therefore should not be used with other drugs that can prolong the QT interval because of the increased risk of cardiac arrhythmias. The concurrent and sequential use of halofantrine and mefloquine markedly increased the risk of clinically important increases in the QT interval. Pyrimethamine/sulfadoxine and tetracycline have been shown to increase halofantrine levels, and may therefore increase its toxicity. Diltiazem, erythromycin, ketoconazole, mefloquine, quinine, and quinidine might also increase the toxicity of halofantrine because they have been shown to inhibit its metabolism in vitro. The manufacturer has therefore recommended caution with the concurrent use of potent CYP3A4 inhibitors. Fatty food markedly increases halofantrine levels, consequently it is recommended that halofantrine is taken on an empty stomach. Grapefruit juice has a similar effect. Note that halofantrine is no longer widely marketed.

---

**Halofantrine + Antacids**

Magnesium carbonate halves the maximum plasma levels of halofantrine, which may be clinically relevant. Aluminium hydroxide and magnesium trisilicate seem less likely to interact.

**Clinical evidence**

Magnesium carbonate 1 g reduced the maximum plasma levels of halofantrine 500 mg by almost 50% in a single-dose study in healthy subjects. The AUC was also reduced by 28%, but this was not statistically significant. The active metabolite of halofantrine, which is equally potent, was similarly affected.\(^1\)

**Mechanism**

Magnesium carbonate might decrease the absorption of halofantrine. In vitro study showed that the halofantrine absorptive capacity of various antacids was highest for magnesium carbonate, intermediate for aluminium hydroxide, and least for magnesium trisilicate.\(^1\)

**Importance and management**

The pharmacokinetic interaction between halofantrine and magnesium carbonate appears to be established. Its clinical importance does not seem to have been assessed, but the authors note that the clinical efficacy of halofantrine is related to peak levels, and therefore they consider that magnesium carbonate might affect antimalarial efficacy.\(^1\) One way to minimize the interaction is to separate the dosages of halofantrine and magnesium carbonate as much as possible (at least 2 to 3 hours) to reduce admixture in the gut. There do not appear to be any studies to see if other antacids behave similarly, but the in vitro data with aluminium hydroxide and magnesium trisilicate (see Mechanism, above) suggest they are less likely to interact.\(^1\)

---

8. Abouage BA, Bigford DJ, McGregor GA, Grant DJW. Complex formation and other physico-chemical interactions between griseofulvin and phenobarbionte. J Pharm Pharmacol (1976) 28, 44P.
treatment (18 of 51 patients). However, the authors note that their population had longer baseline QT intervals than the average population, which may have made them more susceptible to the effects of halofantrine. The manufacturers of mefloquine and halofantrine, therefore contraindicated concurrent use, and the use of halofantrine after mefloquine.

(c) Food
A study in 6 healthy subjects found that the maximum plasma levels and AUC of a single 250-mg dose of halofantrine were increased by about 6.6-fold and 2.9-fold, respectively, when given with a fatty meal rather than in a fasting state. The AUC of the metabolite desbutylhalofantrine was also increased. Animal data suggest that fats may reduce the presystemic metabolism of halofantrine. As this is likely to increase the risk of halofantrine-induced arrhythmias, halofantrine should not be taken with meals, but should be taken on an empty stomach.

(d) Grapefruit juice or Orange juice
A crossover study in 12 healthy subjects given halofantrine 500 mg with 250 mL of either water, orange juice or grapefruit juice (standard strength), found that grapefruit juice increased the AUC and peak plasma levels of halofantrine by 2.8-fold and 3.2-fold, respectively. The QTc interval increased by 17 milliseconds with halofantrine, and by 31 milliseconds when grapefruit juice was also given. Orange juice did not affect the pharmacokinetics or pharmacodynamics of halofantrine. These data suggest that grapefruit juice should be avoided by patients taking halofantrine due to the increased risk of arrhythmias.

(e) Pyrimethamine/Sulfadoxine (Fansidar)
In a preliminary study in healthy subjects, pyrimethamine/sulfadoxine (Fansidar) raised the AUC,0.6, and peak plasma levels of halofantrine by about 1.6-fold, without changing the overall AUC. This might lead to an increased incidence of arrhythmias, see also (b) above.

(f) Tetracyclines
A study in 8 healthy subjects found that tetracycline 500 mg twice daily for 7 days increased the maximum plasma levels, AUC and elimination half-life of a single 500-mg dose of halofantrine by 146%, 99%, and 73%, respectively. Increases in the major metabolite of halofantrine also occurred in the presence of tetracycline. As both halofantrine and tetracycline are excreted into the bile, competition for this elimination route may result in increased plasma levels. There may be an increased risk of halofantrine toxicity if it is used with higher doses of tetracycline. In contrast, in vitro studies found that doxycycline does not inhibit the metabolism of halofantrine.

Clinical evidence, mechanism, importance and management
A woman with discoid lupus, which was controlled by hydroxychloroquine 200 mg daily, was also given rifampicin, isoniazid and pyrazinamide for tuberculosis. Within 1 to 2 weeks the discoid lupus flared-up again but it rapidly responded when the hydroxychloroquine dosage was doubled. The reason for this reaction is not known for certain but the authors of the report suggest that the rifampicin (a recognised and potent cytochrome P450 enzyme inducer) increased the metabolism and clearance of the hydroxychloroquine so that it was no longer effective. It is already known that discoid lupus flare-ups can occur within 2 weeks of stopping hydroxychloroquine, which gives support to this suggested mechanism. Neither isoniazid nor pyrazinamide is likely to have been responsible for what happened.

This seems to be the first and only report of this interaction, but what happened is consistent with the way rifampicin interacts with many other drugs. If rifampicin is added to hydroxychloroquine, the outcome should be well monitored. Be alert for the need to increase the hydroxychloroquine dosage.

Hydroxyquinoline (Oxyquinoline) + Zinc oxide

The presence of zinc oxide inhibits the therapeutic effects of hydroxyquinoline in ointments.

Clinical evidence
The observation that a patient had an allergic reaction to hydroxyquinoline in ointments with a paraffin base, but not a zinc oxide base, prompted further study of a possible incompatibility. The subsequent study in 13 patients confirmed that zinc oxide reduces the eczematogenic (allergic) properties of the hydroxyquinoline. However, it also inhibits its antibacterial and antimitic effects, and appears to stimulate the growth of Candida albicans.

Mechanism
It seems almost certain that the zinc ions form chelates with hydroxyquinoline, which have little or no antibacterial properties.

Importance and management
The documentation is limited but the reaction appears to be established. There is no point in using zinc oxide to reduce the allergic properties of hydroxyquinoline if, at the same time, the therapeutic effects disappear.

Ivermectin + Food

The manufacturer notes that the bioavailability of ivermectin 30 mg was increased by about 2.5-fold when it was taken after a high-fat meal (48.6 g of fat) when compared with the fasted state. They recommend that ivermectin is taken on an empty stomach with water.

Ivermectin + Levamisole

Levamisole may markedly increase the bioavailability of ivermectin. Ivermectin does not alter the pharmacokinetics of levamisole.
Clinical evidence, mechanism, importance and management

A study in 28 healthy subjects given levamisole 2.5 mg/kg, alone or with ivermectin 200 micrograms/kg, found that ivermectin had no effect on the AUC or maximum level of levamisole. However, the AUC of ivermectin was twofold higher when given with levamisole compared with historical values in subjects who had received ivermectin alone. An associated study in 44 patients with *Onchocerca volvulus* infections found that levamisole given with ivermectin was neither macrofilaricidal nor more effective against microfilariae and adult worms than ivermectin alone. In addition, patients taking both drugs had a higher incidence of pruritus, arthralgia and fever than those on ivermectin alone. Caution is recommended on concurrent use.

### Ivermectin + Orange juice

Orange juice modestly reduces the bioavailability of ivermectin.

### Levamisole + Miscellaneous

There is some evidence that levamisole, taken with fluorouracil, can increase the effects of phenytoin, and that a disulfiram-like reaction can occur if patients taking levamisole drink alcohol.

### Mefloquine + Ampicillin

Although ampicillin modestly increases the plasma levels of mefloquine and reduces its half-life, these effects are probably not clinically relevant.

Clinical evidence, mechanism, importance and management

In a study, 8 healthy subjects were given ampicillin 250 mg four times daily for 5 days, with a single 750-mg dose of mefloquine on day 2. The maximum plasma level and 5-day AUC of mefloquine were increased by 36% and 39%, respectively, when the ivermectin was given with orange juice (750 mL over 4 hours) rather than with water. The mechanism for the reduced bioavailability is not known but it does not seem related to P-glycoprotein activity. The clinical relevance of these changes is uncertain.

### Mefloquine + Artemisinin derivatives

Artemether pretreatment appears to modestly reduce mefloquine levels, whereas artemisinin and dihydroartemisinin do not affect the pharmacokinetics of mefloquine. If mefloquine is given shortly after artesunate its levels are lowered, but giving mefloquine two days in to artesunate treatment appears to raise mefloquine levels. The combined use of mefloquine with artemisinin derivatives might improve antimalarial activity. See also 'Co-artemether + Mefloquine', p.224

**Clinical evidence, mechanism, importance and management**

(a) Artemether

In a study in patients with acute uncomplicated falciparum malaria 15 patients were given a single 300-mg dose of artemether, with a single 750-mg dose of mefloquine 24 hours later. The AUC of mefloquine in these patients was found to be 27% lower than the AUC of 7 patients receiving mefloquine alone. However, the addition of artemether improved the rate of parasite clearance, and cure rates were similar between the groups. For discussion of a study that found mefloquine pharmacokinetics did not appear to be altered when artemether/lumefantrine was given 12 hours after mefloquine treatment, see ‘Co-artemether + Mefloquine’, p.224. Note that co-administration (artemether with lumefantrine) is one of the recommended treatment options in the WHO guidelines for the treatment of uncomplicated falciparum malaria.

(b) Artemisinin or Dihydroartemisinin

In a single-dose three-way crossover study, 10 healthy subjects were given either mefloquine 750 mg, dihydroartemisinin 300 mg or both drugs together. The pharmacokinetics of the drugs were unchanged on concurrent use, except for the rate of absorption of mefloquine, which was increased. Also the activity of these drugs against *Plasmodium falciparum* was synergistic, rather than additive. Another study in patients with falciparum malaria found no significant pharmacokinetic interaction between artemisinin and mefloquine. In this study, patients received mefloquine 750 mg alone or artemisinin 500 mg daily for 3 days with a single 750-mg dose of mefloquine either on day 1 or day 4. There was no difference in overall efficacy between treatments, although those treated with artemisinin together with mefloquine on the first day of treatment had the fastest parasite clearance rates.

(c) Artesunate

A study in 20 patients with acute uncomplicated falciparum malaria given mefloquine (750 mg followed after 6 hours by 500 mg) found that the levels of mefloquine were reduced by 27% and its clearance rate was increased 2.6-fold when the doses of mefloquine were given 6 and 12 hours after artesunate 200 mg. However, the patients who received the combination had shorter fever clearance and parasite clearance times than those given mefloquine alone, but the cure rate was lower for combined treatment than for mefloquine alone (66% versus 75%). To prevent the pharmacokinetic interaction resulting in a reduction in its efficacy, mefloquine should be given when artesunate and its metabolites have cleared the circulation (the authors suggest possibly 24 hours after a dose). This suggestion is supported by a study looking at the efficacy of mefloquine with artesunate. This study found that the AUC of mefloquine was about 30% higher in 22 children given mefloquine on day 2 of artesunate treatment, when compared with 24 children given mefloquine on day 0 (before artesunate was started). Both groups were given mefloquine without food.

The combined use of artesunate and mefloquine is one of the recommended treatment options in the WHO guidelines for the treatment of uncomplicated falciparum malaria, and for uncomplicated vivax malaria in selected areas. They say that mefloquine is usually given on day 2 of combined treatment.

Clinical evidence, mechanism, importance and management

A single 500-mg dose of mefloquine was given to 10 healthy subjects before and after they took cimetidine 400 mg twice daily for 28 days. The cimetidine had no effect on the AUC or serum levels of mefloquine, but its half-life increased by 50% (from 9.6 to 14.4 days) and the oral clearance decreased by almost 40%. In another study mefloquine was given to 6 healthy subjects and 6 patients with peptic ulcers, before and after cimetidine 400 mg twice daily for 3 days. In contrast to the first study, cimetidine increased the maximum plasma levels of mefloquine by about 42% and 20% and increased the AUC by about 37% and 32% in the healthy subjects and patients, respectively. The elimination half-life was increased, but not to a significant extent.

The findings of the first study suggest that cimetidine (a recognised enzyme inhibitor) reduces the metabolism of the mefloquine by the liver. However, the second study suggests that cimetidine may increase the rate of mefloquine absorption without significantly inhibiting its elimination.

These two studies produced different findings, and an interaction is not therefore established. Nevertheless, the changes seen in both studies were modest, and unlikely to be clinically relevant in most patients taking lower doses of chloroquine for malaria prophylaxis. With higher doses of mefloquine used to treat malaria, to be on the safe side, prescribers should be alert for any evidence of increased mefloquine adverse effects (dizziness, nausea, vomiting, abdominal pain) and psychiatric or neurological reactions during concurrent use. Note that the UK Committee on Safety of Medicines say that any patient given mefloquine [for malaria prophylaxis] should be informed about its adverse effects, and advised that, if these occur, they should seek medical advice on alternative antimalarials before the next dose is due.

Mefloquine + Cardioactive drugs

An isolated report describes cardiopulmonary arrest in a patient taking mefloquine with propranolol. The WHO have issued a warning about the concurrent use of mefloquine with antiarrhythmics, beta blockers, calcium-channel blockers, antihistamines, phenothiazines, and some related antimalarials. For mention that halofantrine should not be used with or after mefloquine, because of a clinically significant lengthening of the QT interval, see ‘Halofantrine + Miscellaneous’, p.229.

Clinical evidence, mechanism, importance and management

The WHO warn that the use of mefloquine with antiarrhythmics, beta blockers, calcium-channel blockers, antihistamines and phenothiazines may contribute to the prolongation of the QTc interval, but do not specifically contraindicate the use of mefloquine with these drugs. Note that, of the classes mentioned, class II and class III antiarrhythmics, sotalol, astemizole and terfenadine are most frequently associated with QT-prolongation, and these drugs are therefore likely to present the greatest risk. It is also suggested that mefloquine and related drugs (e.g. quinine or quinidine) should only be given together under close medical supervision because of possible additive cardiotoxicity. The manufacturers of mefloquine also give these warnings, pointing out that the interactions are theoretical, and that clinically significant QTc prolongation has not been found with mefloquine alone. Apart from ‘quinine’, (p.233) where two studies found minor QTc prolongation, no formal studies on the possible adverse effects of combining any of the above drugs with mefloquine seem to have been done. It remains to be confirmed whether the effects of mefloquine and these other drugs on cardiac function are normally additive, and whether the outcome is clinically important. However, until more is known it would seem prudent to err on the side of caution and to follow this precautionary advice. Drugs that prolong the QT interval are listed in ‘Table 9.2’, (p.257). There is also a theoretical interaction with QT-prolonging ‘quinolones’ (p.233). For mention that halofantrine should not be used with or after mefloquine, because of a clinically significant lengthening of the QT interval, which may be due to a pharmacokinetic interaction, see ‘Halofantrine + Miscellaneous’, p.229. One 1990 review and the US prescribing information briefly mention a single case of cardiopulmonary arrest (with full recovery) when a patient taking propranolol was given a single dose of mefloquine. It has been suggested that the concurrent use of beta blockers and mefloquine may lead to bradycardia, which is an uncommon adverse effect of mefloquine, and a known effect of the beta blockers. However, there do not appear to be any reports of an adverse interaction in the literature.

Mefloquine + Cardiac effects

Mefloquine levels may be modestly increased and/or its elimination modestly reduced by cimetidine. The clinical importance of this is uncertain.
son for these changes is that metoclopramide increases gastric emptying causing mefloquine to reach the small intestine more quickly, which would increase the rate of absorption. Despite these changes, the toxicity of mefloquine (dizziness, nausea, vomiting, abdominal pain) was noted to be reduced. The modest increase in peak levels is probably not clinically relevant, especially with prophylactic mefloquine doses. More study is needed.

### Mefloquine + Primquine

Although one study suggested that primquina can increase both the peak serum levels and adverse effects of mefloquine, other studies have generally found no important interaction. Primquina may be used after mefloquine to effect a radical cure of *P. vivax* malaria without any special precautions.

#### Clinical evidence

A preliminary report of a randomised crossover study in 14 healthy subjects given mefloquine 1 g found that the addition of primquina 15 or 30 mg raised the peak serum levels of mefloquine by 48% and 29%, respectively. Those taking the larger dose of primquina had a transient increase in peak primquina serum levels, and its conversion to its inactive carboxy metabolite was also increased. Significant CNS symptoms were also experienced by those taking the larger dose of primquina. However, these results contrast with another single dose study in 8 healthy subjects, who were given mefloquine 750 mg with primquina 45 mg. No increased adverse effects attributable to concurrent use were seen, and mefloquine pharmacokinetics (including the peak level) were not altered by primquina. Similarly, in a study in patients with malaria, there was no change in mefloquine pharmacokinetics when it was given with primquina. In another group in this study, the only difference in mefloquine pharmacokinetics was an 11% shorter terminal elimination half-life in those taking primquina with mefloquine and sulfadoxine/pyrimethamine, when compared with those taking mefloquine with sulfadoxine/pyrimethamine. Similarly, in another study in children given mefloquine with sulfadoxine/pyrimethamine, the addition of primquina had no effect on the pharmacokinetics of mefloquine, and there was no serious adverse effects.

The pharmacokinetics of a single 45-mg dose of primquina were not altered by a single 10-mg/kg oral dose of mefloquine in healthy subjects.

#### Mechanism

*In vitro* studies suggest that primquina is a potent inhibitor of mefloquine metabolism.

### Importance and management

The bulk of the evidence suggests there is no important alteration in the pharmacokinetics or effect of mefloquine when it is given with primquina. After treatment of *vivax* malaria, primquina is used to eradicate hepatic parasites, so producing a radical cure, and the manufacturer of mefloquine specifically advises this.

#### Clinical evidence, mechanism, importance and management

Mefloquine 750 mg was given to 7 healthy subjects either alone, or followed 24 hours later by quinine 600 mg. The combination did not affect the pharmacokinetics of either drug, but the number of adverse effects and the period of prolongation of the QT interval was greater with the combination, although no symptomatic cardio toxicity was seen. This absence of a change in pharmacokinetics is contrary to earlier *in vitro* data and unpublished clinical observations, which suggested that quinine may inhibit the metabolism of mefloquine, thereby raising its serum levels. Another study in 13 patients with uncomplicated falciparum malaria given quinine dihydrochloride 10 mg/kg as a one-hour infusion and simultaneous oral mefloquine 15 mg/kg found no evidence of a pharmacokinetic interaction, but postural hypotension was common. The QTc interval was prolonged by 12%, although a clinically significant cardiovascular interaction was not reported.

The manufacturers of mefloquine say that it should not be given with quinine or related compounds (e.g. *quinidine*, *chloroquine*) since this could increase the risk of ECG abnormalities and convulsions. They suggest that patients initially given intravenous quinine for 2 to 3 days should delay mefloquine until at least 12 hours after the last dosing of quinine to minimise interactions leading to adverse events. However, there seem to be no documented adverse reports of this interaction leading to convulsions. Consider also ‘Mefloquine + Cardioactive drugs’ p.232, for further discussion of the potential for cardiotoxicity with these drugs.

### Mefloquine + Quinolones

Three non-epileptic patients had convulsions when they were treated for fever with mefloquine and a quinolone. Also, some quinolones, such as moxifloxacin, prolong the QT interval and concurrent use with mefloquine might theoretically result in additive effects.

#### Clinical evidence, mechanism, importance and management

A large scale survey in India of the adverse effects of mefloquine identified 3 cases of convulsions out of a total of 150 patients also taking *ciprofloxacin*, *ofloxacin* or *sparfloxacin*. All 3 patients were not epileptic, and had no family history of epilepsy. All were being treated for fever, which was due to *Plasmodium vivax* in one case, *F. falciparum* in the second, and was not established in the third. None of the patients had severe or complicated malaria. The *ofloxacin* was given 2 days before the mefloquine, and the other two quinolones were given together with the mefloquine.

The reason for the seizures is not known, but seizures are among the recognised adverse effects of both mefloquine and these quinolones. These adverse, apparently additive, effects are rare, but prescribing should be
aware of the potential increased risk of convulsions when prescribing these drugs together.

(b) Prolongation of the QT interval

Gatifloxacin, moxifloxacin, and sparfloxacin may cause clinically relevant prolongation of the QT interval. Although mefloquine alone has not been shown to cause a clinically relevant lengthening of the QT interval, caution has still been recommended when it is combined with some other drugs that prolong the QT interval, see ‘Mefloquine + Cardioactive drugs’, p.232, and it may be prudent to extend this caution to these quinolones. The manufacturers of moxifloxacin note that an additive effect on QT prolongation between moxifloxacin and antimalarials cannot be excluded, and therefore contraindicates concurrent use, although they specifically mention only halofantrine.1

Mefloquine + Rifampicin (Rifampin)

Rifampicin significantly reduces the plasma concentrations of mefloquine. Until more is known, it may be prudent to avoid the combination.

Clinical evidence, mechanism, importance and management

Rifampicin 600 mg daily was given to 7 healthy subjects for 7 days with a single 500-mg dose of mefloquine on day 7. The maximum plasma level of mefloquine decreased by 19% and the AUC decreased by 68%. Rifampicin, a potent enzyme-inducer, increases the metabolism of mefloquine by the cytochrome P450 isoenzyme CYP3A4 in the liver and gut wall. The clinical relevance of this reduction in mefloquine levels uncertain, but the authors suggest that simultaneous use of rifampicin and mefloquine should be avoided to prevent treatment failure and the risk of Plasmodium falciparum resistance to mefloquine.1 Until more is known, this would seem a sensible precaution.

Mefloquine + Sulfadoxine/Primaquine

Sulfadoxine/primaquine caused a modest increase in exposure to mefloquine in healthy subjects, but not in a study in patients. Any changes seem unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

In healthy subjects, a comparison of the pharmacokinetic parameters of a single 750-mg dose of mefloquine given alone or in combination with sulfadoxine/primaquine found that the only difference was a 33% increase in mean residence time and 27% increase in the half-life of mefloquine.1 However, in a further study in patients with malaria, there was no difference in any pharmacokinetic parameter of mefloquine 750 mg between 15 patients taking mefloquine alone and 16 taking mefloquine with sulfadoxine/primaquine.2 In both of these studies there was considerable inter-individual variability in the pharmacokinetics of mefloquine.1,2,3 In another study in healthy subjects, the mefloquine AUC was increased by a non-significant 13% when mefloquine was given as a combination tablet containing mefloquine, sulfadoxine and primaquine when compared with mefloquine given alone.3 These studies suggest that, at the most, a small increase in exposure to mefloquine may occur when it is given with sulfadoxine/primaquine. It would seem that this is unlikely to be clinically relevant, especially in view of the inter-individual variability in mefloquine pharmacokinetics. No special precautions appear to be needed.

Mefloquine + Tetracycline

Mefloquine serum levels are modestly increased by tetracycline.

Clinical evidence, mechanism, importance and management

The maximum serum levels of a single 750-mg dose of mefloquine were increased by 38% (from 1.16 to 1.6 mg/mL) in 20 healthy Thai men who took tetracycline 250 mg four times daily for a week. The AUC was increased by 30% and the half-life reduced from 19.3 to 14.4 days, without any evidence of an increase in adverse effects. The suggested reason for the increased mefloquine levels is that its enterohepatic recycling is reduced because of competition with tetracycline for biliary excretion.1 The authors of the report conclude that concurrent use may be valuable for treating multi-drug resistant falciparum malaria because higher mefloquine levels are associated with a more effective response. However, more study is needed to confirm these findings. There seems to be no reason for avoiding concurrent use.

Mefloquine + Typhoid vaccine; Oral

Some sources suggest that mefloquine should not be given at the same time as oral attenuated live typhoid vaccine, whereas others suggest that concurrent administration is acceptable. Note that this advice does not apply to the capsular polysaccharide typhoid vaccine for injection.

Clinical evidence

An in vitro study found that mefloquine killed a significant amount of Salmonella typhi (Ty21a vaccine strain), which suggested that concurrent administration could possibly reduce the efficacy of the vaccine.1 A study in healthy subjects investigated the use of mefloquine with a combination of cholera and oral typhoid vaccine (Ty21a vaccine strain). Cholera and typhoid vaccines had previously been shown not to affect each other, and the addition of mefloquine did not significantly reduce the serum antibody response to these vaccines. The authors therefore concluded that mefloquine could be given at the same time as oral typhoid vaccine without reducing its efficacy.2

Mechanism

Oral typhoid vaccine requires active replication of the attenuated Salmonella typhi strain in the ileum for the development of immunity. Mefloquine is thought to have some antibacterial effect, which may diminish the amount of S. typhi present, and therefore reduce the immune response produced by the vaccine.3

Importance and Management

As mefloquine is rapidly absorbed it has been suggested that by 8 hours after a dose, the levels of mefloquine will be insufficient to inhibit live oral typhoid vaccine.4 Based on the results of the above study the US manufacturers note that mefloquine can be given at the same time as oral typhoid vaccine.2,5 The UK manufacturers of the oral typhoid vaccine recommend separating the dose of oral typhoid vaccine and mefloquine by at least 12 hours.6 However, the manufacturers of mefloquine say that immunisation with vaccines such as oral typhoid should be completed at least 3 days before the first dose of mefloquine.7,8 The UK Department of Health say that mefloquine can be given 12 hours before or after vaccination with oral typhoid vaccine.6 It would therefore seem acceptable to separate administration by 12 hours. Note that this advice does not apply to the capsular polysaccharide typhoid vaccine for injection.

Praziquantel + Chloroquine

Metrifonate + Antacids or H2-receptor antagonists

The pharmacokinetics of a single dose of metrifonate were not altered by an antacid containing aluminium/magnesium hydroxide, nor by pretreatment with cimetidine or ranitidine.

Clinical evidence, mechanism, importance and management

(a) Antacids

The AUC and maximum level of metrifonate and its pharmacologically active metabolite were not altered by concurrent use of an aluminium/magnesium hydroxide-containing antacid in a single-dose study in healthy subjects.1

(b) H2-receptor antagonists

The AUC and maximum level of metrifonate and its pharmacologically active metabolite were not altered by pretreatment with either cimetidine or ranitidine in a study in healthy subjects.1 Based on these results it seems unlikely that other H2-receptor antagonists will interact with metrifonate.

Piperazine + Chlorpromazine

An isolated case of convulsions in a child was attributed to the use of piperazine followed by chlorpromazine.

Clinical evidence, mechanism, importance and management

A child given piperazine for pin worms developed convulsions when treated with chlorpromazine several days later.1 In a subsequent animal study using chlorpromazine 4.5 or 10 mg/kg, many of the animals died from respiratory arrest after severe clonic convulsions.1 However, a later study did not confirm these findings2 and it is by no means certain whether the ad- 

vantage reaction in the child was due to an interaction or not. Given that both drugs may cause convulsions, there is probably enough evidence to warrant caution if they are used concurrently.

Praziquantel + Antiepileptics

Phenytoin, phenobarbital and carbamazepine markedly reduce the serum levels of praziquantel, but whether this results in neurocysticercosis treatment failures is unclear. A case report suggests that the addition of ‘cimetidine’, (p.236) may control this interaction.

Clinical evidence

(a) Carbamazepine, Phenobarbital or Phenytoin

A comparative study of patients, taking long-term phenytoin or carbamazepine, and healthy subjects (10 in each group), both given a single 25-mg/kg oral dose of praziquantel, found that phenytoin and carbamazepine reduced the AUC of praziquantel by about 74% and 90%, respectively, and reduced the maximum serum levels by 76% and 92%, respectively, when compared with the controls.1 Another study also reported low praziquantel levels (maximum levels of 42 to 540 nanograms/mL with undetectable trough levels) in 4 patients taking phenytoin and 8 patients taking phenobarbital. However, in this study praziquantel 45 mg/kg daily in 3 divided doses for 15 days was very effective for neurocysticercosis, with all patients showing a marked improvement.2

(b) Phenytoin/Phenobarbital and Cimetidine

A patient with neurocysticercosis taking phenytoin and phenobarbital for a seizure disorder had no response to praziquantel (four courses in doses of up to 50 mg/kg daily). Praziquantel 50 mg/kg daily and dexamethasone 12 mg daily were started and, after one week, cimetidine 400 mg four times daily was added. The patient’s serum praziquantel levels more than doubled with the addition of cimetidine (maximum serum levels raised from 350 to 826 nanograms/mL) and the AUC rose about fourfold, and became similar to that found in control subjects taking praziquantel alone. The patient showed marginal improvement, and continued to slowly improve over the following 4 months.3

Mechanism

Not established, but the probable reason is that these anticonvulsants and ‘dexamethasone’, (p.236) have enzyme-inducing effects and can therefore increase the metabolism of praziquantel. ‘Cimetidine’, (p.236) (an enzyme inhibitor) appears to oppose this effect. However, the fact that prazi-

quantel was still effective in one study suggests that metabolites of praziquantel might be active.2

Importance and management

Direct information appears to be limited to the reports cited, but the phar-

macokinetic interactions appear to be established. However, the clinical relevance of the interaction is uncertain. When treating systemic worm infec-

tions such as neurocysticercosis some authors advise increasing the praziquantel dosage from 25 to 50 mg/kg if potent enzyme inducers such as carbamazepine or phenytoin are being used, in order to reduce the risk of treatment failure.1 A 45 mg/kg daily dose was effective in one study in 11 patients taking antiepileptics, despite low praziquantel levels,2 but a 50 mg/kg daily dose was not effective in another case.3 Note that the manu-

facturer recommends giving praziquantel 50 mg/kg daily in 3 divided doses for neurocysticercosis, and they suggest that the use of drugs to pre-

vent or alleviate convulsions should be decided on a case to case basis.4 Adding cimetidine may reduce the effect of enzyme-inducing anticonvulsants. However, the authors of the case above4 were not sure whether the improvement they saw was in fact due to the cimetidine or simply part of the natural history of the disease. It is clear that ‘cimetidine’, (p.236), alone can markedly increase praziquantel levels. The interaction with anticonvulsants is of no importance when praziquantel is used for intestinal worm infections (where its action is a local effect on the worms in the gut).

3. Buchanan WD, Adubofour KO, Bikin DS, Johnson CH, Mullin PD, Winograd M. Cimetidine-induced rise in praziquantel levels in a patient with neurocysticercosis being treated with anti-

Praziquantel + Chloroquine

Chloroquine reduces the bioavailability of praziquantel, which would be expected to reduce its efficacy in systemic worm infec-

tions such as schistosomiasis.

Clinical evidence, mechanism, importance and management

A single 40-mg/kg oral dose of praziquantel was given to 8 healthy sub-
jects alone, and 2 hours after chloroquine 600 mg. The chloroquine re-
duced the praziquantel AUC by 65% and the maximum serum levels by 59%. The reasons for this effect are not understood. There were large in-

dividual variations in levels, and one subject was not affected. The effect of this interaction could be that some patients will not achieve high enough
serum praziquantel levels to treat systemic worm infections such as schis-
mosomiasis. After taking the chloroquine, the praziquantel serum levels of 4
out of the 8 subjects (50%) did not reach the threshold of 0.3 micrograms/mL
for about 6 hours (which is required to effectively kill schistosomes), compared with only 2 of 8 (25%) during the control period.

The authors conclude that an increased dosage of praziquantel should be
considered if chloroquine is given (they do not suggest how much), particu-
larly in anyone who does not respond to initial treatment with praziquan-
tel.1 More study of this interaction is needed.

The interaction is of no importance when praziquantel is used for intesti-
nal worm infections (where its action is a local effect on the worms in the
gut).

Praziquantel + Cimetidine

Cimetidine can double the serum levels of praziquantel, and may
improve its efficacy in neurocysticercosis.

Clinical evidence

In a randomised crossover study 8 healthy subjects were given three
25-mg/kg oral doses of praziquantel at 2-hourly intervals with cimetidine
400 mg given 1 hour before each dose of praziquantel. Cimetidine was
found to have roughly doubled the praziquantel serum levels and AUC.1,2
A further study in patients with neurocysticercosis found that this short
regimen of praziquantel with cimetidine (which increased plasma levels of
praziquantel by about threefold), had similar efficacy to the traditional
regimen of 50 mg/kg daily in divided doses for 15 days.3 Of 6 patients re-
ceiving praziquantel with cimetidine, the clinical cure rate was 83% com-
pared with only 50% in 6 patients receiving praziquantel while fasting.1

Mechanism

Cimetidine probably inhibits the metabolism of praziquantel.

Importance and management

Direct information appears to be limited to the reports cited, but the inter-
action does appear to be established. It is clear that cimetidine can markedly
increase praziquantel levels, and the authors say that concurrent use can
reduce treatment for neurocysticercosis from 2 weeks to 1 day.1,3 Cimet-
dine has been tried to reverse the effects of ‘antiepileptics’, (p.235) and
‘corticosteroids’, (below) on praziquantel.

1. Praziquantel + Cimetidine

1. Na-Bangchang K, Vanijanonta S, Karbwang J. Plasma concentrations of praziquantel during
administration with cimetidine in rats and in humans. Biofarm Drug Dispos (1994) 15, 33–
43.

Praziquantel + Corticosteroids

The continuous use of dexamethasone can halve serum praziqu-
antel levels. Two case reports suggest that this may reduce its ef-
cacy in systemic worm infections, whereas another study
suggests that efficacy is not affected.

Clinical evidence

Eight patients with parenchymal brain cysticercosis taking praziquantel
50 mg/kg (in three divided doses, taken every 8 hours) had a 50% redu-
tion in steady-state serum levels, from 3.13 to 1.55 micrograms/mL, when
given dexamethasone 8 mg every 8 hours.1 Another patient with recur-
rent neurocysticercosis, who did not respond to praziquantel 50 mg/kg
daily, was successfully treated with high-dose praziquantel 100 mg/kg
daily, dexamethasone 12 mg daily and cimetidine 800 mg daily. As dex-
amethasone was thought to reduce the plasma levels of praziquantel, ci-
metidine was added to try to reverse this effect, as it has been reported to
increase the bioavailability of praziquantel.2 However, some patients have
responded well to praziquantel, despite low serum levels.3

Mechanism

Uncertain. Dexamethasone is an inducer of the cytochrome P450 isoen-
zyme CYP3A4, and might therefore be expected to reduce levels of prazi-
quantel. ‘Cimetidine’, (above) may reverse this effect.

Importance and management

Information seems to be limited but the pharmacokinetic interaction
would appear to be established. Just how much it affects the outcome of
treatment for systemic worm infections such as cysticercosis is unknown
because the optimum praziquantel levels are still uncertain, and it is pos-
sible that the metabolites of praziquantel might be active.3 The authors of
one report suggest that dexamethasone should not be given continuously
with praziquantel but only used transiently to resolve inflammatory re-
actions to praziquantel treatment.1 Alternatively, limited information sug-
gests the addition of cimetidine may allow dexamethasone to be used.2
Intravenous methylprednisolone has also been used for acute corticos-
teroid therapy with praziquantel, and oral prednisone has been used long-
term to prevent further tissue damage associated with inflammation4,5 but
the effect of these corticosteroids on the plasma levels of praziquantel
do not appear to have been studied.

The interaction with dexamethasone is of no importance when prazi-
quantel is used for intestinal worm infections (where its action is a local ef-
cacy on the worms in the gut).

ment of schistosomal myeloradiculopathy with praziquantel and corticosteroids and evaluation

Food increases the bioavailability of praziquantel.

Clinical evidence, mechanism, importance and management

The maximum plasma levels and AUC of a single 1.8-g dose of prazi-
quantel were increased by 243% and 180% when it was given following a
high-fat diet and by 515% and 271% after a high-carbohydrate diet, re-
spectively.1 In another study in healthy Sudanese men, when praziquantel
was given with food the AUC was 2.6-fold higher than when it was given
in the fasted state.2

A further study in patients with neurocysticercosis found that treatment
with a short regimen of praziquantel 25 mg/kg every 2 hours for 3 doses
with a high-carbohydrate diet, which increased plasma levels of prazi-
quantel, provided an adequate clinical alternative to the traditional regimen
of 50 mg/kg daily in divided doses for 15 days.3 In 6 patients who took
praziquantel with food, the clinical cure rate was 83%, compared with
only 50% in 6 patients who took praziquantel while fasting.3

On the basis of the above studies, if praziquantel is used for systemic
worm infections, administration with food is advisable, and this is recom-
med by the manufacturers.4,5

**Praziquantel + Grapefruit juice**

Grapefruit juice increases the AUC of praziquantel.

**Clinical evidence, mechanism, importance and management**

In a study in healthy subjects the maximum plasma level of a single 1.8-g dose of praziquantel was increased by about 63% and the AUC by 90% when given with 250 mL of grapefruit juice rather than with water. The authors suggested that grapefruit juice probably increased the absorption of praziquantel. The clinical effect of this interaction has not been assessed, but it may lead to improved efficacy. When compared with other studies, the authors noted that the effect of grapefruit juice was comparable to that of "cimetidine", but it may lead to improved efficacy. When compared with other studies, the authors noted that the effect of grapefruit juice was comparable to that of "food".

**Praziquantel + Rifampicin (Rifampin)**

The plasma levels of praziquantel were markedly reduced by rifampicin pretreatment, to undetectable levels in over half of the subjects in one study. It is predicted that rifampicin will reduce the efficacy of praziquantel.

**Clinical evidence, mechanism, importance and management**

Pretreatment with rifampicin 600 mg once daily for 5 days markedly reduced the AUC and maximum level of a single 40-mg/kg dose of praziquantel in 10 subjects. Seven of the subjects had undetectable praziquantel levels (less than 12.5 nanograms/mL), and the other 3 had an 85% reduction in the AUC of praziquantel. The same subjects were then given three doses of praziquantel 25 mg/kg at intervals of 8 hours, alone, and after pretreatment with rifampicin. In this multiple-dose study, 5 of the 10 subjects had undetectable praziquantel levels, and the remainder had an 80% reduction in AUC. It was suggested that rifampicin induced the metabolism of praziquantel via cytochrome P450 isoenzyme CYP3A4. Although efficacy has not been assessed, the authors concluded that the levels of praziquantel after rifampicin pretreatment were less than those considered necessary for anthelminthic activity. They therefore recommend that the combination should be avoided, a stance which is also taken by one of the manufacturers of praziquantel.

**Primaquine + Quinine**

Quinine does not appear to affect the pharmacokinetics of primaquine.

**Clinical evidence, mechanism, importance and management**

Quinine 10 mg/kg three times daily had no effect on the pharmacokinetics of a single 45-mg dose of primaquine in 7 subjects, except for a 50% increase in the AUC of the carboxyprimaquine metabolite. The combination was effective for the treatment of malaria with no complications and no adverse effects reported.

Usually quinine is used only for the treatment of falciparum malaria, and primaquine is used only to eliminate the liver stages of vivax and ovale malarial species, and therefore the drugs are generally unlikely to be taken together. However, primaquine may be used in the treatment of vivax or ovale malarial species, and therefore the drugs are generally unlikely to be taken together when given with 250 mL of grapefruit juice, rather than with water.

**Proguanil + Antacids**

The absorption of proguanil is markedly reduced by magnesium trisilicate, and therefore the efficacy of proguanil may be reduced.

**Clinical evidence**

**Magnesium trisilicate** reduced the AUC of a 200-mg dose of proguanil by about 65% in 8 healthy subjects, as assessed by salivary proguanil levels.

**Mechanism**

In vitro tests showed that magnesium trisilicate adsorbed proguanil. Two other antacids, aluminium hydroxide and light magnesium carbonate, had lesser effects.

**Importance and management**

The interaction between proguanil and magnesium trisilicate appears to be established, but its clinical importance does not seem to have been assessed. Given the extent of reduction in levels, the antimalarial effects of proguanil might be expected to be reduced. One way to minimise the interaction is to separate the dosage of proguanil and magnesium trisilicate as much as possible (2 to 3 hours) to reduce admixture in the gut. There do not appear to be any studies to see if other antacids behave similarly. The manufacturers of proguanil recommend taking proguanil and antacids at least 2 to 3 hours apart.

1. Onyeji CO, Babalola CP. The effect of magnesium trisilicate, and therefore the efficacy of proguanil may be reduced.

**Proguanil + Chloroquine**

Chloroquine appears to increase the incidence of mouth ulcers by 1.5-fold in those taking prophylactic proguanil.

**Clinical evidence, mechanism, importance and management**

Following the observation that mouth ulcers appeared to be common in those taking prophylactic antimalarials, an extensive study was undertaken in 628 servicemen in Belize. Of those taking proguanil 200 mg daily, 24% developed mouth ulcers, and in those also taking chloroquine base 150 to 300 mg weekly, 37% developed mouth ulcers. The incidence of diarrhea was also increased from 63% among those who did not develop ulcers to 83% in those that did develop ulcers (any treatment). The reasons are not understood. The authors of the study suggested that these two
drugs should not be given together unnecessarily for prophylaxis against *Plasmodium falciparum*. Nevertheless, chloroquine plus proguanil is an established prophylactic regimen that is commonly recommended in regions where there is some chloroquine resistance.

**Proguanil + Cimetidine or Omeprazole**

There is some evidence that omeprazole and cimetidine can moderately reduce the production of the active metabolite of proguanil, but also some evidence to suggest that this may not be clinically relevant.

**Clinical evidence**

(a) Cimetidine

In one study, 4 patients with peptic ulcer disease and 6 healthy subjects were given a single 200-mg dose of proguanil on the last day of a 3-day course of cimetidine 400 mg twice daily. In both groups the half-life and AUC of proguanil were significantly increased, but only the healthy subjects had an increase in the maximum serum concentration of 89%. In both groups these pharmacokinetic changes resulted in lower levels of the active metabolite, cycloguanil. This decrease in cycloguanil supported the findings of an earlier study, which had found a 30% decrease in the urinary recovery of cycloguanil when proguanil and cimetidine were given together.

(b) Omeprazole

In a steady-state study in 12 healthy subjects taking proguanil 200 mg daily it was found that omeprazole 20 mg daily roughly halved the AUC of the active metabolite of proguanil, cycloguanil. However, an earlier study found that omeprazole 20 mg had no effect on the urinary recovery of cycloguanil (or proguanil) following a single 200-mg dose of proguanil.

**Mechanism**

Cimetidine and omeprazole increase the gastric pH, which may lead to an increase in the absorption of proguanil. Cimetidine and omeprazole are also thought to inhibit the metabolism of proguanil, due to their inhibitory effects on cytochrome P450 isoenzyme CYP2C19.

**Importance and management**

The differences between the healthy subjects and patients with peptic ulcer disease seen in one study may have been because the disease itself alters the effects of the cimetidine in some way. Patients with peptic ulcer disease are also likely to have an increased gastric pH, which will lead to altered proguanil absorption. The clinical relevance of all these findings is still unclear, although the implication is that decreased cycloguanil levels may lead to inadequate malaria prophylaxis. However, a subsequent clinical study reported that subjects who were poor metabolisers of proguanil (who had relatively low cycloguanil levels) did not have an increased risk of failure of proguanil prophylaxis. Similarly, treatment of malaria with proguanil was as effective in 62 patients with CYP2C19 poor metaboliser genotype as in 33 patients with extensive metaboliser genotype, independent of cycloguanil levels. This suggests any interaction with fluvoxamine, or other CYP2C19 inhibitors, may not be clinically relevant.

**Proguanil + Fluvoxamine**

The conversion of proguanil to its active metabolite is markedly inhibited by fluvoxamine in those who are CYP2C19 extensive metabolisers. However, there is some evidence this may not be of any clinical relevance.

**Clinical evidence**

Twelve healthy subjects, 6 of whom were of CYP2C19 extensive metaboliser genotype and 6 of whom were CYP2C19 poor metabolisers, were given proguanil 200 mg daily for 8 days. This was followed by fluvoxamine 100 mg for 8 days, with a single 200-mg dose of proguanil on day 6. In the group of extensive metabolisers it was found that fluvoxamine reduced the total clearance of proguanil by about 40%. The partial clearance of proguanil via its two metabolites was reduced, by 85% for cycloguanil, and by 79% for 4-chlorophenybiguanide. The concentrations of these two metabolites in the plasma were hardly detectable while fluvoxamine was being taken. No pharmacokinetic interaction occurred in the poor metabolisers.

**Mechanism**

Proguanil, which is thought to be a prodrug, is metabolised to its active metabolite, cycloguanil by the cytochrome P450 isoenzyme CYP2C19. This isoenzyme is inhibited by fluvoxamine and so proguanil does not become activated. Note that subjects with decreased CYP2C19 activity show slower metabolism of proguanil to cycloguanil, but they may still respond to proguanil.

**Importance and management**

Information appears to be limited to the studies cited, the purpose of which was to confirm that fluvoxamine is an inhibitor of CYP2C19. However, they also demonstrate that proguanil, which is a prodrug, will not be effectively converted into its active form in patients who are extensive metabolisers if fluvoxamine is also being taken, making them effectively poor metabolisers. There are as yet no reports of treatment failures due to this interaction, but if the activity of proguanil is virtually abolished by fluvoxamine, as the authors suggest, then proguanil would also be expected to be ineffective in the proportion of the population that are poor metabolisers. However, a subsequent clinical study reported that subjects who were poor metabolisers of proguanil did not have an increased risk of failure of proguanil prophylaxis. Similarly, treatment of malaria with proguanil was as effective in 62 patients with CYP2C19 poor metaboliser genotype as in 33 patients with extensive metaboliser genotype, independent of cycloguanil levels. This suggests any interaction with fluvoxamine, or other CYP2C19 inhibitors, may not be clinically relevant.

**Pyrantel + Piperazine**

Piperazine opposes the anthelmintic actions of pyrantel.

**Clinical evidence, mechanism, importance and management**

Pyrantel acts as an anthelmintic because it depolarises the neuromuscular junctions of some intestinal nematodes causing the worms to contract. This paralyses the worms so that they are dislodged by peristalsis and expelled in the faeces. Piperazine also paralyses nematodes but it does so by causing hyperpolarisation of the neuromuscular junctions. These two pharmacological actions oppose one another, as was shown in two *in vitro* pharmacological studies. Strips of whole *Ascaris lumbricoides*, which
contracted when exposed to pyrantel failed to do so when also exposed to piperazine.1 Parallel electrophysiological studies using Ascaris cells confirmed that the depolarisation due to pyrantel (which causes the paralysis) was opposed by piperazine.1

In practical terms this means that piperazine does not add to the anthelmintic effect of pyrantel on Ascaris as might be expected, but opposes it. For this reason it is usually recommended that concurrent use should be avoided, but direct clinical evidence confirming that combined use is ineffective seems to be lacking. It seems reasonable to extrapolate the results of these studies on Ascaris lumbricoides (roundworm) to the other gastrointestinal parasites for which pyrantel is used, i.e. Enterobius vermicularis (threadworm or pinworm), Angiostrongylus duodenale, Necator americanus (hookworm) and Trichostrongylus spp. However, no one seems to have studied this.

**Pyrimethamine + Artemether**

Artemether raises pyrimethamine plasma levels, but this does not appear to cause an increase in adverse effects.

**Clinical evidence, mechanism, importance and management**

In a three-way single-dose crossover study, 8 healthy subjects were given either artemether 300 mg, pyrimethamine 100 mg, or both drugs together. Although there was large inter-individual variation in the pharmacokinetics of pyrimethamine, its maximum plasma levels were raised by 44%. As there was no corresponding increase in adverse effects the authors suggest that the interaction may be of benefit.1 More study is warranted to confirm this result.

**Pyrimethamine + Co-trimoxazole or Sulfonamides**

Serious pancytopenia and megaloblastic anaemia have occasionally occurred in patients given pyrimethamine and either co-trimoxazole or other sulfonamides.

**Clinical evidence**

A woman taking pyrimethamine 50 mg weekly as malaria prophylaxis, developed petechial haemorrhages and widespread bruising within 10 days of starting to take co-trimoxazole (trimethoprim 320 mg with sulfamethoxazole 800 mg) daily for a urinary-tract infection. She was found to have gross megaloblastic changes and pancytopenia in addition to being obviously pale and ill. After withdrawal of the two drugs she responded rapidly and both selectively inhibit the actions of the enzyme dihydrofolate reductase, which is concerned with the eventual synthesis of the nucleic acids needed for the production of new cells. The sulfonamides inhibit another part of the same synthetic chain. The adverse reactions seen would seem to reflect a gross reduction of the normal folate metabolism caused by the combined actions of both drugs. Megaloblastic anaemia and pancytopenia are among the adverse reactions of pyrimethamine and, more rarely, of co-trimoxazole taken alone.

**Importance and management**

Information seems to be limited to the reports cited, but the interaction appears to be established. Its incidence is unknown. Pyrimethamine is usu-

ally given with a sulfonamide for toxoplasmosis and malaria. Caution should be used in prescribing these combinations, especially in the presence of other drugs, such as folate antagonists, or disease states that may predispose to folate deficiency. Note that the manufacturer of sulfadoxine/pyrimethamine (Fansidar), which is indicated for the prophylaxis and treatment of malaria, recommends that concomitant treatment with folate antagonists such as other sulfonamides, trimethoprim, co-trimoxazole and some antiepileptics should be avoided.2,3 When high-dose pyrimethamine is used for the treatment of toxoplasmosis, the manufacturer recommends that all patients should receive a folate supplement, preferably calcium folinate, to reduce the risk of bone marrow depression.4,5

**Pyrimethamine + Sulfadoxine + Zidovudine**

Pyrimethamine does not appear to alter zidovudine pharmacokinetics, and zidovudine does not appear to alter the prophylactic efficacy of sulfadoxine/pyrimethamine for toxoplasmosis. The combination of pyrimethamine and zidovudine may increase the risk of myelosuppression.

**Clinical evidence, mechanism, importance and management**

The addition of pyrimethamine (200 mg loading dose then 50 mg daily) and folinic acid 10 mg daily to zidovudine had no effect on zidovudine pharmacokinetics, based on data from 10 HIV positive patients for whom zidovudine pharmacokinetics were available before and after starting pyrimethamine. Of 26 patients receiving the combination, 5 developed leucopenia and one discontinued treatment because of anaemia.1

A study in patients with AIDS found that zidovudine 250 mg four times daily did not adversely affect the prevention of toxoplasma encephalitis with pyrimethamine/sulfadoxine (Fansidar), one tablet twice weekly for up to 8 months.2 In vitro and animal data have shown that the combination of zidovudine and pyrimethamine caused synergistic decreases in lymphocyte and neutrophil numbers.3

The manufacturers of pyrimethamine note that the concurrent use of zidovudine may increase the risk of bone marrow depression.4,5 They say that if signs of folate deficiency develop, then pyrimethamine should be discontinued and folinic acid given. Note that the prophylactic use of a folate supplement, preferably folinic acid, is recommended for all patients with toxoplasmosis taking high-dose pyrimethamine, to reduce the risk of bone marrow suppression.4,5 See also ‘NRTIs; Zidovudine + Myelosuppressive drugs’, p.809

**Quinine + Colestyramine**

Colestyramine does not appear to alter the pharmacokinetics of quinine.
Clinical evidence, mechanism, importance and management

Colestyramine 8 g did not alter the pharmacokinetics of quinine 600 mg, given concurrently to 8 healthy subjects. The authors warn that this lack of interaction may have been because only single doses were used, and suggest continuing to separate the administration of the two drugs until a lack of interaction is demonstrated in a multiple dose study.1 It is usually recommended that other drugs are taken 1 hour before or 4 to 6 hours after colestyramine.

### Quinine + Fluvoxamine

Fluvoxamine had no effect on the pharmacokinetics of quinine.

#### Clinical evidence, mechanism, importance and management

In a study in healthy subjects, fluvoxamine 25 mg was given both 12-hours and 1-hour before a single 500-mg dose of quinine hydrochloride, followed by a further 4 doses of fluvoxamine, given every 12 hours. Fluvoxamine had no effect on the apparent oral clearance of quinine and caused a minor 6% increase in the AUC of 3-hydroxyquinine, with no effect on the AUC of various other metabolites.1,2 Fluvoxamine is a known inhibitor of the cytochrome P450 isoenzyme CYP2C19, and it appears that this has little effect on the pharmacokinetics of quinine and therefore no dose adjustments would be necessary on concurrent use.

### Quinine + Grapefruit juice

Grapefruit juice had no effect on the pharmacokinetics of quinine.

#### Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects 200 mL full-strength grapefruit juice, half-strength grapefruit juice, or orange juice was given twice daily for 11 doses with a single 600-mg dose of quinine sulfate, given on day 6 with the last dose of grapefruit juice. There were no significant differences in the pharmacokinetics of quinine between the three treatments, although the maximum level of the 3-hydroxymetabolite was slightly reduced (by 19%) with full-strength grapefruit juice compared with orange juice or half-strength grapefruit juice.1

### Quinine + H2-receptor antagonists

Quinine clearance is reduced by cimetidine, but not ranitidine.

#### Clinical evidence, mechanism, importance and management

In a study in 6 healthy subjects cimetidine 200 mg three times daily and 400 mg at night for one week reduced the clearance of quinine by 27%, increased the half-life by 49% (from 7.6 to 11.3 hours), and increased the AUC by 42%. Peak levels were unchanged. No interaction was seen when cimetidine was replaced by ranitidine 150 mg twice daily.1 The probable reason for this effect is that cimetidine (a recognised enzyme inhibitor) reduces the metabolism of the quinine by the liver, whereas ranitidine does not. It therefore seems likely that other H2-receptor antagonists will not interact, although this needs confirmation. The clinical importance of this is uncertain, but prescribers should be alert for any evidence of quinine toxicity if cimetidine is also given.

### Quinine + Miscellaneous

Urinary alkalinisers can increase the retention of quinine in man, and antacids can reduce the absorption of quinine in *animals*. None of these interactions appears to be of general clinical importance.

#### Clinical evidence, mechanism, importance and management

(a) Antacids

Aluminium/magnesium hydroxide gel reduces the absorption of quinine from the gut of rats and reduces quinine blood levels by 50 to 70%.1 This appears to occur because aluminium hydroxide slows gastric emptying, which reduces absorption, and also because magnesium hydroxide forms an insoluble precipitate with quinine. However, there seem to be no clinical reports of a reduction in the therapeutic effectiveness of quinine due to the concurrent use of antacids.

(b) Urinary alkalinisers and acidifiers

The excretion of unchanged quinine is virtually halved (from 17.4 to 8.9%) if the urine is alkalinised. This is because in alkaline urine more of the quinine exists in the non-ionised (lipid soluble) form, which is more
Quinine + Rifampicin (Rifampin)

Rifampicin induces the metabolism of quinine, which may result in subtherapeutic quinine levels.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects found that the clearance of a single 600-mg dose of quinine sulfate was increased more than sixfold by pretreatment with rifampicin 600 mg daily for 2 weeks. The elimination half-life of quinine was decreased from about 11 hours to 5.5 hours.

A report describes a patient with myotonia, controlled with quinine, whose symptoms worsened within 3 weeks of starting to take rifampicin for the treatment of tuberculosis. Peak quinine levels were found to be low, but rose again when the rifampicin was stopped. Control of the myotonia was regained 6 weeks later.

The effect of adding rifampicin to quinine was investigated in patients with uncomplicated falciparum malaria. They were taking quinine sulfate 10 mg/kg three times daily either alone (30 patients) or with rifampicin 15 mg/kg daily (29 patients) for 7 days. Peak plasma levels of quinine during monotherapy were attained within 2 days of treatment and remained within the therapeutic range for the 7-day treatment period. Levels of the main metabolite of quinine, 3-hydroxyquinine, followed a similar pattern. In patients taking quinine with rifampicin, quinine was more extensively metabolised and, after the second day of treatment, quinine levels were sharply reduced to below therapeutic levels. Acute malaria reduces the metabolic clearance of quinine (by a reduction in hepatic mixed function oxidase activity, mainly by the cytochrome P450 isoenzyme CYP3A4) and recovery is associated with a sharp decline in quinine levels. Rifampicin induces the cytochrome P450 isoenzymes and this probably more than counteracted their inhibition during acute malaria and resulted in increased metabolism of quinine. Although patients who received rifampicin with quinine had shorter parasite clearance times than those who received quinine alone, suggesting rifampicin may enhance the antimalarial activity of quinine, recrudescence rates were 5 times, higher suggesting increased resistance. [Note, recrudescence is the reappearance of the disease after a period of inactivity.] The authors suggest that rifampicin should not be given with quinine for the treatment of malaria. Patients receiving rifampicin who also require quinine for malaria may need increased doses of quinine.

Quinine + Tetracyclines

Doxycycline does not appear to alter the pharmacokinetics of quinine. Tetracycline increases quinine levels and has been found to improve efficacy.

Clinical evidence, mechanism, importance and management

(a) Doxycycline

In a study in 13 patients with acute falciparum malaria, the addition of intravenous doxycycline to treatment with intravenous quinine did not affect quinine pharmacokinetics, when compared with 13 patients taking quinine alone. In contrast, in vitro, doxycycline appears to be a potent inhibitor of quinine metabolism. However, given the above evidence from their use in patients, no special precautions would seem to be necessary on concurrent use.

(b) Tetracycline

A study in patients with acute falciparum malaria found that quinine levels were about doubled in those taking quinine 600 mg every 8 hours with tetracycline 250 mg every 6 hours, when compared with those taking quinine alone. Quinine levels were lower for Malaria with the combination but not for quinine alone. Two of 8 patients treated with quinine alone had malaria recrudescence (the reappearance of the disease after a period of inactivity) compared with none of 8 patients receiving the combination. In vitro tetracycline is also a potent inhibitor of quinine metabolism. The authors considered that this pharmacokinetic interaction might be part of the explanation why the combination has been found to be more effective.

Quinine + Tobaccco

Smokers cleared quinine from the body much more quickly than non-smokers in a single-dose study in healthy subjects. However, quinine metabolism is reduced in patients with falciparum malaria, which may negate this effect. Quinine pharmacokinetics and efficacy were unchanged by smoking in one study.

Clinical evidence

A comparative study in 10 smokers (averaging 17 cigarettes daily) and 10 non-smokers found that the AUC of a single 600-mg dose of quinine sulphate was reduced by 44%, the clearance was increased by 77% and the half-life was shortened (from 12 to 7.5 hours), when compared with the non-smokers. In contrast, in a study in patients with uncomplicated falciparum malaria taking quinine sulfate 10 mg/kg three times daily for 7 days, there was no significant difference in fever clearance time, parasite clearance time, and cure rate between 10 regular smokers and 12 non-smokers. In addition pharmacokinetic parameters did not differ significantly between the smokers and non-smokers.

Mechanism

Tobacco smoke contains polycyclic aromatic compounds and other substances, which are potent inducers of the liver enzymes that metabolise quinine. It is not yet clear which cytochrome P450 isoenzymes are affected. Smoking induces CYP1A1, but the formation of the major metabolite of quinine, 3-hydroxyquinine, is catalysed by CYP3A4, which suggests that other metabolic pathways of quinine are affected by smoking.

Importance and management

Information seems to be limited but the pharmacokinetic interaction would appear to be established in healthy subjects. However, the clinical study in patients with falciparum malaria suggests that any pharmacokinetic differences are more limited probably due to the additional effect the disease has on quinine metabolism, and that smoking status does not appear to affect the clinical outcome of quinine treatment for malaria. The systemic clearance of quinine in acute falciparum malaria may be reduced by up to two-thirds, when compared to healthy subjects as malaria reduces hepatic microsomal enzyme activity. The authors say that this reduction in the clearance of quinine outweighs the possible effects of smoking-induced clearance.

Cimetidine modestly increases the AUC of terbinafine. However, no clinically relevant interactions appear to have been reported between terbinafine and cimetidine or ranitidine.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects cimetidine 400 mg twice daily for 5 days increased the AUC of a single 250-mg dose of terbinafine by 34% and reduced its clearance by 30%. The likely reason is that cimetidine (a known enzyme inhibitor) reduces the metabolism of terbinafine by the liver. However, it seems that this modest increase in the serum levels of terbinafine is of little or no clinical relevance, because in a large scale post-marketing survey of patients taking terbinafine no interactions were reported in patients also taking cimetidine or ranitidine [number unknown].

Nevertheless, the manufacturer of terbinafine recommends that the dosage of terbinafine may need adjusting (presumably reduced) if cimetidine is given.

The serum levels of terbinafine are reduced by rifampicin.

Clinical evidence, mechanism, importance and management

In 12 subjects, rifampicin 600 mg daily for 6 days halved the AUC of terbinafine and roughly doubled its clearance. Rifampicin is a potent enzyme inducer, which increases the metabolism of many drugs. Be alert, therefore, for the need to increase the dosage of terbinafine if rifampicin is given.

This section is mainly concerned with the class I antiarrhythmics, which also possess some local anaesthetic properties, and with class III antiarrhythmics. Antiarrhythmics that fall into other classes are dealt with under ‘beta blockers’, (p.833), ‘digitalis glycosides’, (p.903), and ‘calcium-channel blockers’, (p.860). Some antiarrhythmics that do not fit into the Vaughan Williams classification (see ‘Table 9.1’, (below)) are also included in this section (e.g. adenosine). Interactions in which the antiarrhythmic drug is the affecting substance, rather than the drug whose activity is altered, are dealt with elsewhere.

Predicting interactions between two antiarrhythmics

It is difficult to know exactly what is likely to happen if two antiarrhythmics are used together. The hope is always that a combination will work better than just one drug, and many drug trials have confirmed that hope, but sometimes the combinations are unsafe. Predicting unsafe combinations is difficult, but there are some very broad general rules that can be applied if the general pharmacology of the drugs is understood.

If drugs with similar effects are used together, whether they act on the myocardium itself or on the conducting tissues, the total effect is likely to be increased (additive). The classification of the antiarrhythmics in ‘Table 9.1’, (see below) helps to predict what is likely to happen, but remember that the classification is not rigid so drugs in one class can share some characteristics with others. The following sections deal with some examples.

(a) Combinations of antiarrhythmics from the same class

The drugs in class Ia can prolong the QT interval so combining drugs from this class would be expected to show an increased effect on the QT interval. This prolongation carries the risk of causing torsade de pointes arrhythmias (see the monograph, ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257). It would also be expected that the negative inotropic effects of quinidine would be additive with procainamide or any of the other drugs within class Ia. For safety therefore it is sometimes considered best to avoid drugs that fall into the same subclass or only to use them together with caution.

(b) Combinations of antiarrhythmics from different classes

Class III antiarrhythmics such as amiodarone can also prolong the QT interval, so they would also be expected to interact with drugs in other classes that do the same, namely class Ia drugs (see ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257). Verapamil comes into class IV and has negative inotropic effects, so it can interact with other drugs with similar effects, such as the beta blockers, which fall into class III. For safety you should always look at the whole drug profile and take care with any two drugs, from any class, that share a common pharmacological action.

†Bretylium has class II and III activity
**Adenosine + Dipyridamole**

Dipyridamole reduces the bolus dose of adenosine necessary to convert supraventricular tachycardia to sinus rhythm by about fourfold. Profound bradycardia occurred in one patient taking dipyridamole when an adenosine infusion was given for myocardial stress testing.

**Clinical evidence**

**(a) Adenosine bolus for supraventricular tachycardia**

Adenosine by rapid intravenous bolus (10 to 200 micrograms/kg in stepwise doses) was found to restore sinus rhythm in 10 of 14 episodes of tachycardia in 7 patients with supraventricular tachycardia (SVT). The mean dose was 8.5 mg compared with only 1 mg in two patients also taking oral dipyridamole.1 Another study in 6 patients found that dipyridamole (560 microgram/kg intravenous bolus, followed by a continuous infusion of 5 micrograms/kg/minute) reduced the minimum effective bolus dose of intravenous adenosine required to stop the SVT from 6.8 to 17 micrograms/kg in 5 patients. In the other patient, dipyridamole alone stopped the SVT.2

Other studies in healthy subjects have clearly shown that dipyridamole reduces the dose of adenosine required to produce an equivalent cardiovascular effect by fourfold or six- to sixteenfold.4 A brief report describes a woman with paroxysmal SVT who lost ventricular activity for 18 seconds when given adenosine 6 mg intravenously. She was also taking dipyridamole (dose unstated), which was considered to have contributed to the loss of ventricular function.3 Another report describes 3 of 4 patients who had heart block of 3, 9 and 21-second duration respectively when given adenosine 3 to 6 mg by central venous bolus. The patient with the most profound heart block was also being treated with dipyridamole, which was thought to have contributed to the reaction.5

**(b) Adenosine infusion for myocardial stress testing**

A 79-year-old woman taking a combination of low-dose aspirin and extended-release dipyridamole (Aggrenox) became profoundly bradycardic (36 bpm), dizzy and almost fainted 2 minutes after the start of an adenosine infusion for radionuclide myocardial imaging. Adenosine was stopped, and she recovered within 2 minutes. The last dose of Aggrenox had been taken 12 hours previously.2 However, note that bradycardia is a known adverse effect of adenosine.5,9

**Mechanism**

Not fully understood. Part of the explanation is that dipyridamole increases plasma levels of endogenous adenosine by inhibiting its uptake into cells.2,4,10

**Importance and management**

An established interaction.

**(a) Patients will need much less adenosine to treat arrhythmias while taking dipyridamole**

It has been suggested that the initial dose of adenosine should be reduced by twofold or fourfold. The UK manufacturers actually advise the avoidance of adenosine in patients taking dipyridamole. If it must be used for supraventricular tachycardia in a patient taking dipyridamole, they recommend that the adenosine dose should be reduced about fourfold.5

**(b) The UK manufacturers advise the avoidance of adenosine in patients taking dipyridamole**

If adenosine is considered necessary for myocardial imaging in a patient taking dipyridamole, they suggest that the dipyridamole should be stopped 24 hours before, or the dose of adenosine should be greatly reduced.9 This may be insufficient for extended-release dipyridamole preparations: the authors of the above report recommend several days.7 Xanthines, such as intravenous aminophylline, have been used to terminate persistent adverse effects of adenosine infusion given for myocardial imaging.8 Consider also ‘Adenosine + Xanthines’, below.

**Adenosine + Nicotine**

Nicotine appears to enhance the effects of adenosine, but the clinical relevance of this is unclear.

**Clinical evidence, mechanism, importance and management**

Nicotine chewing gum 2 mg (approximately equal to one cigarette) increased the circulatory effects of a 70 microgram/kg/minute infusion of adenosine in 10 healthy subjects. The increase in heart rate due to nicotine (5.5 bpm) was further increased to 14.9 bpm by the adenosine, and the diastolic blood pressure rise due to nicotine (7 mmHg) was reduced to 1.1 mmHg.1 In another study, nicotine chewing gum 2 mg increased chest pain and the duration of AV block when it was given to 7 healthy subjects with intravenous bolus doses of adenosine.2 What this means in practical terms is uncertain, but be aware that the effects of adenosine may be modified to some extent by nicotine-containing products (tobacco smoking, nicotine gum, etc).

**Adenosine + Xanthines**

Caffeine and theophylline can inhibit the effects of adenosine infusions used in conjunction with radionuclide myocardial imaging. Xanthines should be withheld 12 to 24 hours prior to the procedure or they will interfere with test results. Aminophylline has been used to terminate persistent adverse effects of adenosine infusions. Adenosine may still be effective for terminating supraventricular tachycardia in patients taking xanthines.

**Clinical evidence**

**(a) Adenosine bolus for supraventricular tachycardia**

It is usually considered that an adenosine bolus for the termination of paroxysmal supraventricular tachycardia will be ineffective in patients taking xanthines. However, one case describes a man taking theophylline (serum level 8 nanograms/mL) in whom adenosine 9 mg terminated supraventricular tachycardia. Two previous adenosine doses, of 400 to 800 micrograms/kg (usual dose 50 to 200 micrograms/kg), were required to revert supraventricular tachycardia in a preterm infant receiving theophylline.7

**(b) Adenosine infusion**

Experimental studies in healthy subjects, on the way xanthine drugs possibly interact with adenosine, have shown that caffeine and theophylline (but not enprofylline) reduced the increased heart rate and the changes in blood pressure caused by infusions of adenosine.8,9 and attenuated adenosine-induced vasodilatation. Theophylline also attenuated adenosine-induced respiratory effects and chest pain.5,6 Similarly, an adenosine infusion antagonised the haemodynamic effects of a single dose of theophylline in healthy subjects, but did not reduce the metabolic effects (reductions in plasma potassium and magnesium).5

**Mechanism**

Caffeine and theophylline have an antagonistic effect on adenosine receptors.9 They appear to have opposite effects on the circulatory system: caf-
feine and theophylline cause vasoconstriction whereas adenosine infusions generally cause vasodilatation. Consequently their concurrent use is likely to result in an interaction.

Importance and management

(a) Adenosine bolus injection for the termination of paroxysmal supraventricular tachycardia may still be effective in patients on xanthines. The usual dose schedule should be followed. However, note that adenosine has induced bronchospasm. The US manufacturers[10,11] state that adenosine preparations, whether used for supraventricular tachycardia or myocardial imaging, should be avoided in patients with bronchoconstriction or bronchospasm (e.g. asthma), and used cautiously in those with obstructive pulmonary disease not associated with bronchospasm (e.g. emphysema or bronchitis). The UK manufacturers similarly recommend that the product used for supraventricular tachycardia[12] should be avoided in asthma, and warn that adenosine may precipitate or aggravate bronchospasm. They also contraindicate the use of adenosine for diagnostic imaging[13] in both asthma and other obstructive pulmonary disease associated with bronchospasm. Whether an adenosine bolus can stop theophylline-induced supraventricular tachycardia appears not to have been studied.

(b) The manufacturers of adenosine state that theophylline, aminophylline and other xanthines should be avoided for 24 hours before using an adenosine infusion for radionuclide myocardial imaging, and that xanthine-containing drinks (tea, coffee, chocolate, cola drinks etc.) should be avoided for at least 12 hours before imaging.[13] In a recent study in 70 patients, measurable caffeine serum levels were found in 74% of patients after 12 hours of self-reported abstention from caffeine-containing products. Patients with caffeine serum levels of at least 2.9 mg/L had significantly fewer stress symptoms (chest tightness, chest pain, headache, dyspnoea, nausea, dizziness) than those with lower serum levels. The authors suggest that a 12-hour abstention from caffeine-containing products may be insufficient, and cause false-negative results.[14] Xanthines, such as intravenous aminophylline, have been used to terminate persistent adverse effects of adenosine infusion given for myocardial imaging.[13]

Clinical evidence, mechanism, importance and management

There is some evidence that the presence of amiodarone possibly increases the risk of complications (atropine-resistant bradycardia, hypotension, decreased cardiac output) during general anaesthesia. All cases were with fentanyl-based anaesthesia, but some other studies have shown no problems with fentanyl-based anaesthesia.

Clinical evidence

(a) Evidence for complications

Several case reports[15] and two studies[6,7] suggest that severe intra-operative complications (atropine-resistant bradycardia, myocardial depression, hypotension) may occur in patients receiving amiodarone. One of the studies, a comparative retrospective review of patients (16 receiving amiodarone, 300 to 800 mg daily and 30 controls) having operations under anaesthesia (mainly open-heart surgery), showed that the incidence of slow nodal rhythm, complete heart block or pacemaker dependency rose from 17% in controls to 66% in amiodarone-treated patients. Intra-aortic balloon pump augmentation (reflecting poor cardiac output) was 50% in the amiodarone group compared with 7% in the control group, and a state of low systemic vascular resistance with normal to high cardiac output occurred in 13% of the amiodarone-treated patients, but none of the controls. Overall there were 3 fatalities; all of these patients had received amiodarone and had been on cardiopulmonary bypass during surgery. Fentanyl was used for all of the patients, often combined with diazepam, and sometimes also isoflurane, enflurane or halothane.[5]

Another study of 37 patients receiving amiodarone (mean dose about 250 mg daily) found no problems in 8 undergoing non-cardiac surgery. Of the 29 undergoing cardiac surgery, 52% had postoperative arrhythmias and 24% required a pacemaker, which was not considered exceptional for the type of surgery. However, one patient having coronary artery bypass surgery had fatal vasoplegia (a hypotensive syndrome), which was considered to be amiodarone-related. This occurred shortly after he was taken off of cardiopulmonary bypass. Anaesthesia in all patients was fentanyl-based. It was suggested in one case report that serious hypotension in two patients on amiodarone undergoing surgery may have been further compounded by ACE inhibitor therapy.[7] For the interactions of ACE inhibitors and anaesthetics see ‘Anaesthetics, general + Antihypertensives’, p.94.

(b) Evidence for no complications

The preliminary report of one study in 21 patients taking amiodarone (mean dose 538 mg daily) and undergoing defibrillator implantation suggested that haemodynamic changes during surgery were not significantly different from those in matched controls not taking amiodarone.[6] Similarly, another study found no difference in haemodynamic status or pacemaker dependency between patients on short-term amiodarone 600 mg daily for 1 week then 400 mg daily for 2 weeks prior to surgery and a control group during valve replacement surgery with thiopental-fentanyl anaesthesia.[8] In a double-blind trial, there was no significant difference in haemodynamic instability during fentanyl-isoflurane anaesthesia between patients randomised to receive short-term amiodarone (3.4 g over 5 days or 2.2 g over 24 hours) or placebo before cardiac surgery. In this study in 5 healthy subjects found that the metabolism of ajmaline was inhibited by quinidine, possibly because the quinidine becomes competitively bound to the enzymes that metabolise ajmaline.[3] The clearance of intravenous ajmaline was almost twice as high in 3 patients also taking phenobarbital when compared with 5 patients who were not taking phenobarbital. Therefore the clinical effects of ajmaline would be expected to be markedly diminished in those taking phenobarbital.[1]

The clinical importance of all of these interactions is uncertain but concurrent use should be well monitored.

Amiodarone + Anaesthesia

An isolated report describes cardiac failure in a patient given ajmaline with lidocaine. Quinidine causes a very considerable increase in the plasma levels of ajmaline, and phenobarbital appears to cause a marked reduction.

Clinical evidence, mechanism, importance and management

A woman had a marked aggravation of her existing cardiac failure when she was given ajmaline orally and lidocaine intravenously for repeated ventricular tachycardias.1

A study[2] in 4 healthy subjects found that if a single 200-mg oral dose of quinidine was given with a single 50-mg oral dose of ajmaline, the AUC of ajmaline was increased 10- to 30-fold and the maximum plasma concentrations increased from 18 to 141 nanograms/mL. Another single-dose
study, haemodynamic instability was assessed by fluid balance, use of dopamine or other vasopressors, and use of a phosphodiesterase inhibitor or intra-aortic balloon pump. A case report describes the successful use of epidural anaesthesia with fentanyl then chloroprocaine during labour and caesarean section in a woman who had been taking amiodarone long-term for arrhythmia control. The only haemodynamic change of possible note was that the patient had a drop in systemic vascular resistance from high to almost normal levels shortly after receiving fentanyl during the first stage of labour, and again when fentanyl was given for postoperative pain relief.

Mechanism

In vitro and in vivo studies in animals suggest that amiodarone has additional cardiodepressant and vasodilator effects with volatile anaesthetics such as halothane, enflurane and isoflurane. The manufacturer notes that fentanyl is a substrate for the cytochrome P450 isoenzyme CYP3A4, and that amiodarone might inhibit CYP3A4, thereby increasing the toxicity of fentanyl.

Importance and management

The assessment of this interaction is complicated by the problem of conducting studies in anaesthesia, most being retrospective and using matched controls. The only randomised study used short-term amiodarone to assess its safety in the prevention of post-operative atrial fibrillation, and its findings may not be relevant to patients taking long-term amiodarone. It appears that potentially severe complications may occur in some patients taking amiodarone undergoing general anaesthesia, including bradycardia unresponsive to atropine, hypotension, conduction disturbances, and decreased cardiac output. Anaesthetists should take particular care in patients taking amiodarone who undergo surgery on cardiopulmonary bypass. Amiodarone persists in the body for many weeks, which usually means it cannot be withdrawn before surgery, especially if there are risks in delaying surgery, or the amiodarone is being used for serious arrhythmias. A possible pharmacokinetic interaction exists between fentanyl and amiodarone, which could contribute to the interactions seen, and further study is needed on this.

Clinical evidence, mechanism, importance and management

A 73-year-old woman taking amiodarone for atrial fibrillation was given loratadine and developed syncpe and multiple episodes of torsade de points arrhythmia.

Amiodarone alone is known to cause QT prolongation and torsade de points arrhythmia, but loratadine is not usually considered to have a clinically relevant effect on the QT interval, see ‘Table 15.2’, (p.583). Amiodarone may have inhibited the metabolism of loratadine by the cytochrome P450 isoenzyme CYP3A4.

The general clinical relevance of this one case is uncertain, but the authors consider that the QT interval should be monitored if loratadine is given with other drugs that may potentially prolong the QT interval. Note that it is recommended that antihistamines with known potential for QT prolongation such as terfenadine and astemizole (see ‘Table 15.2’, (p.583)) should not be used with amiodarone, and although there appear to be no cases of clinically relevant QT-prolongation with mizolastine, the manufacturers contraindicate concurrent amiodarone.

Amiodarone + Antihistamines

Hypotension, bradycardia, ventricular fibrillation and asystole have been seen in a few patients given amiodarone with propranolol, metoprolol or sotalol (for sotalol, see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257). However, analysis of clinical trials suggests that the combination can be beneficial. Amiodarone may inhibit the metabolism of beta blockers metabolised by CYP2D6, such as metoprolol, which might be a factor in the interaction.

Clorinde evidence

(a) Case reports of problems

A 64-year-old woman was treated for hypertrophic cardiomyopathy with amiodarone 1.2 g daily and atenolol 50 mg daily. Five days later the atenolol was replaced by metoprolol 100 mg daily. Within 3 hours she complained of dizziness, weakness and blurred vision. On examination she was found to be pale and sweating with a pulse rate of 20 bpm. Her systolic blood pressure was 60 mmHg. Atropine 2 mg did not produce chronotropic or haemodynamic improvement. She responded to isoprenaline (isoprotanol). Severe hypotension has been reported in another patient taking sotalol when intravenous amiodarone (total dose 250 mg) was given. Another report describes cardiac arrest in one patient on amiodarone and metoprolol; severe bradycardia and ventricular fibrillation (requiring defibrillation) in another, within 1.5 and 2 hours of starting to take propranolol.

(b) Clinical studies showing benefits

In contrast to the above case reports, an analysis of data from two large clinical studies of the use of amiodarone for post-myocardial infarction arrhythmias found that the combination of beta blockers [unamed] and amiodarone was beneficial (reduced cardiac deaths, arrhythmic deaths and resuscitated cardiac arrest) compared with either drug alone, or neither drug. Discontinuation of amiodarone because of excessive bradycardia was no more frequent when beta blockers were also given, although more patients taking amiodarone discontinued beta blockers than those taking placebo. Similarly, in the analysis of another study in ischaemic heart failure, the benefits of carvedilol were still apparent in those patients already receiving amiodarone, and the combination was not associated with a greater incidence of adverse effects (worsened heart failure, hypotension/dizziness, bradycardia/atrophic ventricular block) than either drug alone.

(c) Pharmacokinetics

In one study, 10 elderly patients (9 with symptomatic atrial fibrillation and one with an implanted defibrillator and frequent ventricular tachycardia) taking metoprolol (mean daily dose 119 mg) were also given amiodarone 1.2 g daily for 6 days. The metoprolol AUC and plasma levels were increased by about 80% and 75%, respectively, by the amiodarone, the extent varying by CYP2D6 genotype. None of the patients included in the study were poor metabolisers.
Mechanism
Not understood. The clinical picture is that of excessive beta-blockade, and additive pharmacodynamic effects are possible. In addition, amiodarone increases the levels of metoprolol via inhibition of the cytochrome P450 isoenzyme CYP2D6, and this may be significant in fast metabolisers.6 See ‘Genetic factors’, (p.4), for more information about fast metabolisers. Other beta blockers that are also substrates of CYP2D6, and which could therefore be similarly affected, include carvedilol and propranolol.

Importance and management
The isolated reports of adverse reactions cited here (they seem to be the only ones so far documented) emphasise the need for caution when amiodarone is used with beta blockers. The manufacturers of amiodarone recommend that the combination should not be used1 or used with caution2 because potentiation of negative chronotropic properties and conduction-slowing effects may occur. However, the concurrent use of beta blockers and amiodarone is uncommon and may be therapeutically useful. The authors of one of the analyses suggest that post-myocardial infarction, if possible, beta blockers should be continued in patients for whom amiodarone is indicated.4 A pharmacokinetic interaction between amiodarone and beta blockers that are substrates of CYP2D6, such as metoprolol, also appears to be established. Although this interaction with other inhibitors of CYP2D6 is generally not thought to be clinically relevant (e.g. see ‘Beta blockers + SSRIs’, p.855), it is possible that this pharmacokinetic interaction plays some part in the adverse reactions sometimes seen, or even in the clinical benefits.6 See also ‘Drugs that prolong the QT interval’ + Other drugs that prolong the QT interval’, p.257, which deals with the possible risks of using amiodarone with sotalol.

Cimetidine possibly causes a modest rise in the serum levels of amiodarone in some patients.

Clinical evidence, mechanism, importance and management
The preliminary report of one study in 12 patients notes that the mean serum levels of amiodarone 200 mg twice daily rose by an average of 38%, from 1.4 to 1.93 micrograms/mL, when cimetidine 1.2 g daily was given for a week. The desethyl-amiodarone levels rose by 54%. However, these increases were not statistically significant, and only 8 of the 12 patients had any rise.1 It is possible that cimetidine may inhibit the metabolism of amiodarone. Information seems to be limited to this study but this interaction may be clinically important in some patients. Monitor the effects when cimetidine is started, being alert for amiodarone adverse effects. Remember that amiodarone has a very long half-life of 25 to 100 days, so that the results of the one-week study cited here may possibly not adequately reflect the magnitude of this interaction. There does not appear to have been anything further published on this.

Amiodarone + Calcium-channel blockers
Increased cardiac depressant effects would be expected if amiodarone is used with diltiazem or verapamil. One case of sinus arrest and serious hypotension occurred in a woman taking diltiazem when she was given amiodarone.

Clinical evidence, mechanism, importance and management
A woman with compensated congestive heart failure, paroxysmal atrial fibrillation and ventricular arrhythmias was treated with furosemide and diltiazem 90 mg every 6 hours. Four days after amiodarone, 600 mg every 12 hours was added, she developed sinus arrest and a life-threatening low cardiac output state (systolic blood pressure 80 mmHg) with oliguria. Diltiazem and amiodarone were stopped and she was treated with pressor drugs and ventricular pacing. She had previously had no problems when taking diltiazem or verapamil alone, and later she took amiodarone 400 mg daily alone without incident. This reaction is thought to be caused by the additive effects of both drugs on myocardial contractility, and on sinus and atrioventricular nodal function. Before this isolated case report was published, another author predicted this interaction with diltiazem or verapamil on theoretical grounds, and warned of the risks if dysfunction of the sinus node (bradycardia or sick sinus syndrome) is suspected, or if partial AV block exists.2 The manufacturers state that amiodarone should not be used,3 or used with caution,4 with certain calcium-channel blockers (diltiazem, verapamil) because potentiation of negative chronotropic properties and conduction-slowing effects may occur. Note that diltiazem has been used for rate control in patients developing postoperative atrial fibrillation despite the use of prophylactic amiodarone.3 There do not appear to be any reports of adverse effects attributed to the use of amiodarone with the dihydropyridine class of calcium-channel blockers (e.g. nifedipine), which typically have little or no negative inotropic activity at usual doses.

Amiodarone + Cimetidine

Cimetidine responds to the serum levels of amiodarone.

Clinical evidence
When 4 doses of cimetidine 4 g were given to patients at 1-hour intervals starting 1.5 hours after a single 400-mg dose of amiodarone, the serum amiodarone levels 7.5 hours later were reduced by about 50%.1 In a further study, the amiodarone half-life was shorter in 3 patients given cimetidine 4 g daily after discontinuing long-term amiodarone (23.5, 29 and 32 days, respectively) compared with that in 8 patients discontinuing amiodarone and not given cimetidine (35 to 58 days).1

Amiodarone + Colestyramine

Colestyramine appears to reduce the serum levels of amiodarone.

Clinical evidence
When 4 doses of colestyramine 4 g were given to patients at 1-hour intervals starting 1.5 hours after a single 400-mg dose of amiodarone, the serum amiodarone levels 7.5 hours later were reduced by about 50%.1 In a further study, the amiodarone half-life was shorter in 3 patients given colestyramine 4 g daily after discontinuing long-term amiodarone (23.5, 29 and 32 days, respectively) compared with that in 8 patients discontinuing amiodarone and not given cimetidine (35 to 58 days).1
Amiodarone + Disopyramide

The risk of QT interval prolongation and torsade de points is increased if amiodarone is given with disopyramide.

Clinical evidence
A brief report describes 2 patients who developed torsade de points when they were given amiodarone with disopyramide. Their QT intervals became markedly prolonged to somewhere between 500 and 600 milliseconds. In another study, 2 patients who had been taking disopyramide 300 mg daily for a number of months developed prolonged QT intervals from 450 to 640 milliseconds and from 390 to 680 milliseconds respectively, and developed torsade de points 2 and 5 days respectively, after starting amiodarone 800 mg daily. However, one early report also described the successful and apparently safe use of amiodarone 100 to 600 mg daily with disopyramide 300 to 500 mg daily, although the results on long-term follow-up were not reported in all cases.

Mechanism
Amiodarone is a class III antiarrhythmic and can prolong the QT interval. Disopyramide is a class Ia antiarrhythmic and also prolongs the QT interval. Their additive effects can result in the development of torsade de points arrhythmias.

Importance and management
An established and potentially serious interaction. In general, class Ia antiarrhythmics such as disopyramide (see ‘Table 9.2’, p.257) should be avoided or used with great caution with amiodarone because of their additive effects in delaying conduction. The manufacturers of amiodarone contraindicate or urge caution if it is used with class Ia antiarrhythmics. If amiodarone is started in a patient taking disopyramide, they suggest the dose of disopyramide should be reduced by 30 to 50% several days after the addition of amiodarone, and that the continued need for disopyramide should be monitored, and withdrawal attempted. If disopyramide is added to amiodarone, the initial dose of disopyramide should be about half of the usual recommended dose. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257, and for the interactions of other class Ia antiarrhythmics see ‘Procainamide + Amiodarone’, p.271, and ‘Quinidine + Amiodarone’, p.276.

Amiodarone + Grapefruit juice

Grapefruit juice inhibited the metabolism of oral amiodarone, and decreased its effects on the PR and QTc interval.

Clinical evidence, mechanism, importance and management
A single 17-mg/kg oral dose of amiodarone was given to 11 healthy subjects on two occasions, once with water and once with grapefruit juice (300 mL taken three times on the same day). Grapefruit juice completely inhibited the metabolism of amiodarone to its major metabolite N-deethylamiodarone (N-DEA) and increased the amiodarone AUC by 50% and the peak serum level by 84%. The effect of amiodarone on the PR and QTc intervals was decreased. It is likely that grapefruit juice inhibits the cytochrome P450 isoenzyme CYP3A4 in the intestinal mucosa, thus inhibiting the formation of N-DEA from oral, but probably not intravenous, amiodarone.

This interaction appears to be established, but its clinical consequences remain to be determined. N-DEA is known to be active, so this could possibly result in increased activity, high amiodarone concentrations may increase toxicity. Conversely, a reduction in QT prolongation is potentially beneficial. Further study is needed. However, the US manufacturer recommends that grapefruit juice should not be taken during treatment with oral amiodarone.

Amiodarone + Lithium

Hypothyroidism developed very rapidly in two patients taking amiodarone when lithium was added.

Clinical evidence, mechanism, importance and management
A patient who had taken amiodarone 400 mg daily for more than a year developed acute manic depression. He was started on 600 mg of lithium daily [salt unknown], but within 2 weeks he developed clinical signs of hypothyroidism, which were confirmed by clinical tests. He made a complete recovery within 3 weeks of stopping amiodarone while continuing lithium. Similarly, another patient rapidly developed hypothyroidism, when taking amiodarone with lithium [dose and salt unknown]. It resolved when the amiodarone was stopped. Both lithium and amiodarone on their own can cause hypothyroidism, (note that amiodarone can also cause hyperthyroidism). In these two cases the effects appear to have been additive, and very rapid.

These two cases appear to be the first and only reports of this interaction. Its general importance is therefore still uncertain. Note that lithium has been tried for the treatment of amiodarone-induced hyperthyroidism, and regular monitoring of thyroid status is recommended throughout amiodarone treatment. It would therefore seem prudent to be extra vigilant for any signs of hypothyroidism (lethargy, weakness, depression, weight gain, hoarseness) in any patient given both drugs.

Lithium therapy has rarely been associated with cardiac QT prolongation, and consequently the UK manufacturer of amiodarone contraindicates combined use. However, note that QT-prolongation associated with lithium is usually as a result of lithium toxicity. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Amiodarone + Macrolides

Torsade de pointes occurred in a man taking amiodarone when he was also given intravenous erythromycin. QT prolongation occurred in another patient when azithromycin was added to established amiodarone therapy.

Clinical evidence
A 76-year-old man taking amiodarone 200 mg daily had a prolonged QT interval and a syncopal episode with torsade de pointes 24 hours after starting a course of intravenous erythromycin lactobionate. This occurred on rechallenge. Marked QT prolongation and increased QT dispersion occurred when azithromycin was started in a patient on long-term amiodarone therapy, and resolved when it was stopped.

Mechanism
Amiodarone alone can prolong the QT interval and increase the risk of torsade de pointes. Of the macrolides, intravenous erythromycin is known to prolong the QT interval, and there is also some evidence that clarithromycin may prolong the QT interval. Amiodarone and these macrolides may therefore have additive effects on the QT interval.

Importance and management
In general the concurrent use of two or more drugs that prolong the QT interval should be avoided, because this increases the risk of torsade de pointes.
pointes arrhythmias (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257). For this reason, the UK manufacturer of amiodarone contraindicates the concurrent use of intravenous erythromycin,3 The authors of the above report suggest that the combination of azithromycin and amiodarone should be used with caution,4 and this should probably also apply to clarithromycin until more is known.

The US manufacturer recommends that a careful risk assessment should be done if amiodarone is to be given with a macrolide.5

### Amiodarone + Orlistat

Orlistat modestly reduces the absorption of amiodarone, but this is unlikely to be clinically important.

#### Clinical evidence, mechanism, importance and management

A randomised placebo-controlled study in 16 healthy subjects found that orlistat 120 mg three times daily reduced the AUC and peak serum level of a single 1.2-g dose of amiodarone by 23% and 27%, respectively. Levels of its active metabolite, desethylamiodarone, were similarly reduced. The half-life and time to maximum serum level were not significantly altered. It was suggested that orlistat, which inhibits dietary fat absorption, may also reduce the absorption of amiodarone, which is a lipophilic drug. Although the clinical effect of this modest reduction in amiodarone levels is not known, it is almost certainly unlikely to be clinically relevant.

### Amiodarone + Oxygen

High-dose oxygen may increase the risks of amiodarone-induced postoperative adult respiratory distress syndrome.

#### Clinical evidence, mechanism, importance and management

A retrospective review of 20 patients who underwent cardiac surgery found that orlistat 120 mg three times daily reduced the AUC and peak serum level of a single 1.2-g dose of amiodarone by 23% and 27%, respectively. Levels of its active metabolite, desethylamiodarone, were similarly reduced. The half-life and time to maximum serum level were not significantly altered. It was suggested that orlistat, which inhibits dietary fat absorption, may also reduce the absorption of amiodarone, which is a lipophilic drug. Although the clinical effect of this modest reduction in amiodarone levels is not known, it is almost certainly unlikely to be clinically relevant.

The UK manufacturer of amiodarone suggests caution in patients receiving high-dose oxygen therapy.6 Others have suggested that the concentration of oxygen should be maintained at the lowest possible level consistent with adequate oxygenation.1,3,4,6

#### Amiodarone + Protease inhibitors

A case report describes increased amiodarone levels in a patient given indinavir. Other protease inhibitors are predicted to act similarly.

#### Clinical evidence

A patient taking amiodarone 200 mg daily was also given zidovudine, lamivudine, and indinavir for 4 weeks, as post HIV-exposure prophylaxis after a needlestick injury. Amiodarone serum levels increased, from 0.9 mg/L before antiretroviral prophylaxis, to 1.3 mg/L during therapy, and gradually decreased to 0.8 mg/L during the 77 days after stopping prophylaxis. Although the reference range for amiodarone levels is not established, these levels were not outside those usually considered to achieve good antiarrhythmic control.

#### Mechanism

Protease inhibitors such as indinavir are inhibitors of cytochrome P450 enzymes and pharmacokinetic interactions are therefore possible. It was considered that the increase in serum amiodarone in this case was due to decreased metabolism of amiodarone, although no decrease in the serum levels of desethylamiodarone were observed.

#### Importance and management

Although in the case cited the interaction was not clinically relevant, the authors considered that it could be in patients with higher initial amiodarone levels. They recommend monitoring amiodarone therapy if indinavir is also given.3 In general the UK manufacturers of protease inhibitors suggest that they may increase amiodarone levels, and contraindicate concurrent use. The exception is atazanavir,6 where caution is recommended. Similarly the US manufacturers of the protease inhibitors generally contraindicate concurrent use. The exceptions are amprenavir,4 atazanavir,4 fosamprenavir4 and lopinavir,5 where the manufacturers recommend increased monitoring, including taking amiodarone levels, where possible.

#### Amiodarone + Quinolones

Torsade de pointes has been reported in two patients taking amiodarone and levofloxacin. Post-marketing surveillance identified two cases with amiodarone andsparfloxacin. An increased risk of this arrhythmia would also be expected if amiodarone is used with gatifloxacin or moxifloxacin.
Clinical evidence, mechanism, importance and management

Torsade de pointes arrhythmia occurred in a patient taking levofloxacin and amiodarone. The same authors subsequently encountered a second case of this reaction. The FDA Adverse Events Reporting System database up to May 2001 was reviewed for cases of torsade de pointes associated with quinolones. Four cases (possibly including the two mentioned above) were noted in patients taking amiodarone and a quinolone (unspecified, but ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, and ofloxacin were assessed). In total, 37 cases of torsade de pointes were identified, and 19 occurred in patients also taking other drugs known to prolong the QT interval.

During post-marketing surveillance of sparfloxacin in France over a period of 8 months (about 750,000 patients) serious adverse cardiovascular effects were reported in 7 patients. All 7 patients had underlying risk factors including 3 patients who were also receiving amiodarone. Of these, 2 patients had documented QT prolongation and ventricular tachycardia. Amiodarone can prolong the QT interval and increase the risk of torsade de pointes. Of the quinolones used clinically, gatifloxacin, moxifloxacin, and sparfloxacin are known to prolong the QT interval (see ‘Table 9.2’, p.257). There is also evidence that levofloxacin may prolong the QT interval.

In general the concurrent use of two or more drugs that prolong the QT interval should be avoided, because this increases the risk of torsade de pointes arrhythmias (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257). The above quinolones should probably be avoided in patients on amiodarone. Ciprofloxacin appears to have less effect on the QT interval.

Amiodarone + Sertraline

In an isolated report, a slight to moderate rise in plasma amiodarone levels was attributed to the concurrent use of sertraline.

Clinical evidence, mechanism, importance and management

A depressed patient taking amiodarone 200 mg twice daily had his treatment with carbamazepine 200 mg twice daily and sertraline 100 mg daily stopped, just before ECT treatment. After 4 days it was noted that his plasma amiodarone levels had fallen by nearly 20%. The authors of the report drew the conclusion that while taking all three drugs, the amiodarone levels had become slightly raised due to the enzyme inhibitory effects of the sertraline, despite the potential enzyme-inducing activity of the carbamazepine. The patient had no changes in his cardiac status while amiodarone levels were reduced, suggesting that this interaction (if such it is) is of limited clinical importance.

Amiodarone + Trazodone

An isolated report describes the development of torsade de pointes when a woman taking amiodarone was also given trazodone.

Clinical evidence, mechanism, importance and management

A 74-year-old woman with a pacemaker, taking nifedipine, furosemide, aspirin and amiodarone 200 mg daily, began to have dizzy spells but no loss of consciousness soon after starting trazodone (initially 50 mg and eventually 150 mg daily by the end of 2 weeks). Both the amiodarone and trazodone were stopped when she was hospitalised. She had prolonged QT, QTc and JTc intervals on the ECG and recurrent episodes of torsade de pointes arrhythmias, which were controlled by increasing the ventricular pacing rate. The QTc and other ECG intervals shortened and she was later discharged on amiodarone without the trazodone, with an ECG similar to that seen 4 months before hospitalisation. No general conclusions can be drawn from this apparent interaction, but prescribers should be aware of this case. The manufacturer notes that trazodone does have the potential to be arrhythmogenic. See also, ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Amiodarone + Rifampicin (Rifampin)

An isolated case report suggests that rifampicin may decrease the serum levels of amiodarone and its metabolite N-desethylamiodarone.

Clinical evidence, mechanism, importance and management

A woman with congenital heart disease and atrial and ventricular arrhythmias managed by an implanted cardioverter defibrillator, epicardial pacing and amiodarone 400 mg daily, experienced deterioration in the control of her condition. She developed palpitations and experienced a shock from the defibrillator. Her amiodarone serum levels were 40% lower than 2 months previously, and her N-desethylamiodarone levels were undetectable. It was noted that 5 weeks earlier rifampicin 600 mg daily had been started to treat an infection of the pacing system. The amiodarone dose was doubled, but the palpitations continued. Amiodarone and N-desethylamiodarone levels increased after rifampicin was discontinued. Rifampicin is a potent enzyme inducer and it may have increased the metabolism and clearance of amiodarone. This case suggests that combined use of amiodarone and rifampicin should be well monitored.

Amiodarone + Sertraline

In an isolated report, a slight to moderate rise in plasma amiodarone levels was attributed to the concurrent use of sertraline.

Clinical evidence, mechanism, importance and management

A depressed patient taking amiodarone 200 mg twice daily had his treatment with carbamazepine 200 mg twice daily and sertraline 100 mg daily stopped, just before ECT treatment. After 4 days it was noted that his plasma amiodarone levels had fallen by nearly 20%. The authors of the report drew the conclusion that while taking all three drugs, the amiodarone levels had become slightly raised due to the enzyme inhibitory effects of the sertraline, despite the potential enzyme-inducing activity of the carbamazepine. The patient had no changes in his cardiac status while amiodarone levels were reduced, suggesting that this interaction (if such it is) is of limited clinical importance.

In vitro studies suggest pharmacokinetic interactions between azimilide and drugs metabolised by CYP1A2, CYP2C9 and CYP2D6 are also unlikely. Azimilide was found to maintain its class III antiarrhythmic effect in the presence of isoprenaline.

Clinical evidence, mechanism, importance and management

(a) Digoxin

A study in 18 healthy subjects found that, except for an increase in renal clearance of 36%, azimilide pharmacokinetics were not affected by digoxin. The pharmacokinetics of digoxin were unaffected by azimilide except for a 21% increase in maximum serum levels and a 10% increase in the AUC. In this study, azimilide dihydrochloride 175 mg was given orally once daily for 4 days then 100 mg on day 5 and digoxin was given as a loading dose of 750 micrograms on day one then as 250 micrograms daily for 4 days. Drugs were given alone, and then combined. Azimilide alone increased the QTc, whereas digoxin did not. The combination showed that digoxin caused about a 2 to 4% decrease in QTc when compared with azimilide alone. Neither the pharmacokinetic changes nor the effect of digoxin on the azimilide-induced QTc prolongation are likely to be clinically important.

(b) Isoprenaline (Isoproterenol)

In a study, patients with cardiovascular disorders were given isoprenaline infusion titrated from 0.5 micrograms/minute up to a maximum of 4 micrograms/minute until the heart rate reached 125% of baseline (up to a maximum 120 bpm). Patients were then given azimilide infusion as a loading dose of 4.5 mg/kg over 15 minutes followed by a continuous infusion of 0.625 mg/kg per hour plus either a second dose of isoprenaline at the same final dose as the first then a saline infusion or vice versa. In the presence of isoprenaline, azimilide prolonged the action potential duration at 90% repolarisation by a mean of 8.7 milliseconds (isoprenaline alone shortened action potential duration by 2.6 milliseconds). Isoprenaline at 90% repolarisation by a mean of 8.7 milliseconds (isoprenaline alone shortened the right ventricular effective period by 13.6 seconds, but shortened action potential duration by 2.6 milliseconds). Isoprenaline

(c) Ketoconazole and other CYP3A4 inhibitors

In a randomised placebo-controlled study in 21 healthy subjects, ketoconazole 200 mg daily slightly increased the AUC and maximum blood levels of a single 125-mg dose of azimilide dihydrochloride given on day 8 by 16% and 12%, respectively. Azimilide half-life was prolonged by 13% and clearance was decreased by 14%. Azimilide is partly metabolised by the cytochrome P450 isoenzyme CYP3A4, which is inhibited by ketoconazole. The minor changes in azimilide pharmacokinetics with ketoconazole are not considered to be clinically important, and clinically significant pharmacokinetic interactions with other inhibitors of CYP3A4 are not expected.

(d) Omeprazole

A randomised placebo-controlled study in 40 healthy subjects (extensive metabolisers of the cytochrome P450 isoenzyme CYP2C19) given azimilide dihydrochloride 125 mg every 12 hours for 3 days, then daily for 5 days found that the AUC of a single 20-mg dose of omeprazole given on day 8 was reduced by 12%. There were no significant changes in the pharmacokinetics of 5-hydroxomeprazole. There was no change in the metabolite-to-parent AUC suggesting that azimilide had no effect on the CYP2C19-mediated metabolism of omeprazole. The change in omeprazole AUC described would not be clinically significant.

The authors note that in vitro studies suggested that of the cytochrome P450 isoenzymes, azimilide had the lowest inhibitory concentration against CYP2C19. On this basis they suggest that azimilide is also unlikely to interact with drugs metabolised by CYP1A2, CYP2C9, CYP2D6 and CYP3A4.

Bretlyium + Sympathomimetics

The pressor effects of adrenaline (epinephrine) and noradrenaline (norepinephrine) are increased in the presence of bretlyium. Amfetamine and protriptyline antagonise the blood pressure lowering effect of bretlyium.

Clinical evidence

(a) Adrenaline (epinephrine) or Noradrenaline (norepinephrine)

A dose of bretlyium sufficient to produce postural hypotension enhanced the pressor effect of noradrenaline in 4 healthy subjects. A similar effect was found with adrenaline.

(b) Amfetamine

When 7 patients with hypertension, taking bretlyium 600 mg to 4 g daily were given a single 25-mg dose of amfetamine, 6 patients had a rise in blood pressure.

(c) Protriptyline

An experimental study found that protriptyline can return the blood pressure to normal in patients taking bretlyium, without reducing its antiarrhythmic efficacy.

Mechanism

Animal studies have shown that bretlyium reduces blood pressure via its blocking effects on adrenergic neurones similar to guanethidine. Bretlyium therefore enhances the effects of directly-acting sympathomimetics such as noradrenaline, and is antagonised by drugs with indirect sympathomimetic activity such as the amfetamines and tricyclic antidepressants.

Importance and management

Although documentation is limited, based on the known pharmacology of bretlyium, these interactions would appear to be established. The use of bretlyium is now limited to the short-term control of ventricular arrhythmias. In this situation, if directly-acting sympathomimetics such as noradrenaline are required to reverse bretlyium-induced hypotension, this should be undertaken with caution since their effects may be enhanced.

Bretlyium is no longer used for the treatment of hypertension, therefore the interactions with amfetamines and tricyclics described above are unlikely to be of much clinical relevance.

Cibenzoline (Cifenline) + H₂-receptor antagonists

Cimetidine increases the plasma levels of cibenzoline, but ranitidine does not interact.

Clinical evidence, mechanism, importance and management

Cimetidine 1.2 g daily raised the maximum plasma levels of a single 160-mg dose of cibenzoline in 12 healthy subjects by 27%, increased the AUC by 44%, and prolonged its half-life by 30%. Ranitidine 300 mg daily had no effect. The probable reason is that cimetidine, an enzyme inhibitor, reduces the metabolism of the cibenzoline by the liver, whereas ranitidine, which has little enzyme inhibiting effects, does not. The clinical importance of this interaction is not known but be alert for increased cibenzoline effects.

Disopyramide + Antacids

There is some inconclusive evidence that aluminium phosphate may possibly cause a small reduction in the absorption of disopyramide.

Clinical evidence, mechanism, importance and management

A single 11-g dose of an aluminium phosphate antacid had no statistically significant effect on the pharmacokinetics of a single 200-mg oral dose of disopyramide in 10 patients. However the antacid appeared to reduce the absorption of disopyramide to some extent in individual subjects. The clinical importance of this interaction is uncertain, but probably small.

Disopyramide + Beta blockers

Severe bradycardia has been described after the use of disopyramide with beta blockers including practolol (3 cases, 1 fatal) pindolol (1 case, fatal) and metoprolol (1 case). Another patient given disopyramide and intravenous sotalol developed asystole (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257). Atenolol modestly decreased disopyramide clearance in one study. Oral propranolol and disopyramide have been combined without any increase in negative inotropic effects or pharmacokinetic effects in healthy subjects.

Clinical evidence

Two patients with supraventricular tachycardia (180 bpm) were treated, firstly with intravenous practolol (20 and 10 mg respectively) and shortly afterwards with disopyramide (150 and 80 mg respectively). The first patient rapidly developed sinus bradycardia of 25 bpm, lost consciousness and became profoundly hypotensive. He did not respond to atropine. He was resuscitated with adrenaline (epinephrine) but later died. He was successfully treated with disopyramide 150 mg alone for a later episode of tachycardia. The second patient also developed severe bradycardia and asystole, despite the use of atropine. He was resuscitated with adrenaline (epinephrine) but later died.

Severe bradycardia has been reported in another patient, similarly treated with intravenous practolol and then disopyramide. Another patient developed severe bradycardia and died when treated for supraventricular tachycardia with pindolol 5 mg and disopyramide 250 mg (both orally). Another patient taking oral disopyramide 250 mg twice daily developed asystole when given a total of 60 mg of intravenous sotalol.

A patient with hypertrophic obstructive cardiomyopathy and paroxysmal atrial fibrillation taking disopyramide 450 mg daily developed hypotension, bradycardia and cardiac conduction disturbances 5 days after starting metoprolol 50 mg daily.

Atenolol 100 mg daily has been shown to increase the serum disopyramide steady-state levels from 3.46 to 4.25 micrograms/mL and reduce the clearance of disopyramide by 16% in healthy subjects and patients with ischaemic heart disease. None of the subjects developed any adverse reactions or symptoms of heart failure, apart from one of the subjects who had transient first degree heart block.

In contrast, studies in healthy subjects have shown that the negative inotropic effect was no greater when oral propranolol and disopyramide were used concurrently, nor were the pharmacokinetics of either drug affected.

Mechanism

Not understood. Both disopyramide and the beta blockers can depress the contractility and conductivity of the heart muscle.

Importance and management

The general clinical importance of this interaction is uncertain. A clear risk seemed to exist in patients who were treated with disopyramide and practolol. Considerable caution should be exercised in patients treated with disopyramide and intravenous sotalol. More study is needed to find out what contributes to the development of this potentially serious interaction. The US manufacturers of disopyramide suggest that the combination of disopyramide and beta blockers should generally be avoided, except in the case of life-threatening arrhythmias unresponsive to a single drug.

The UK manufacturer of sotalol also warns that both sotalol and disopyramide can prolong the QT interval, which may increase the risk of torsade de points arrhythmia if both are used together. The US manufacturer recommends that this combination should be avoided. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Disopyramide + H2-receptor antagonists

A single-dose study has shown that cimetidine can slightly increase the serum levels of oral disopyramide. Cimetidine did not affect the pharmacokinetics of intravenous disopyramide. Ranitidine appears not to interact with disopyramide.

Clinical evidence, mechanism, importance and management

Oral cimetidine 400 mg twice daily for 14 days did not alter the pharmacokinetics of a single 150-mg intravenous dose of disopyramide in 7 healthy subjects. Another study in 6 healthy subjects found that a single 400-mg dose of cimetidine increased the AUC of a single 300-mg oral dose of disopyramide by 8.5% and increased the maximum serum levels by 18.5%, but did not significantly affect the metabolism of disopyramide. Ranitidine 150 mg was found not to interact significantly. The reasons are not known, but the authors of the report suggest that cimetidine may have increased disopyramide absorption. Cimetidine is only a weak inhibitor of disopyramide metabolism in vitro. The changes described are unlikely to be clinically important, but this should probably be confirmed in a more clinically realistic situation, using multiple oral doses of both drugs.

Disopyramide + Macrolides

The serum disopyramide levels of two patients rose when they were given erythromycin, and QT prolongation and cardiac arrhythmias developed. Another patient given both drugs developed heart block. One patient developed ventricular fibrillation and two patients developed torsade de points when given clarithromycin with disopyramide. Two other patients developed severe hypoglycaemia. Ventricular fibrillation occurred in a patient given azithromycin with disopyramide. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Clinical evidence

(a) Azithromycin

A patient taking disopyramide 150 mg three times daily developed ventricular tachycardia requiring cardioversion 11 days after starting azithromycin 250 mg daily.1 Her disopyramide level was found to have risen from 2.6 to 11.1 micrograms/mL.

(b) Clarithromycin

A 74-year-old woman who had been taking disopyramide 200 mg twice daily for 7 years collapsed with ventricular fibrillation 6 days after starting to take omeprazole 40 mg, metronidazole 800 mg and clarithromycin 500 mg daily. After successful resuscitation, her QTc interval, which had never previously been above 440 milliseconds, was found to have risen to 625 milliseconds. Her disopyramide plasma level was also elevated (4.6 micrograms/mL) and the half-life was markedly prolonged (40 hours). The QTc interval returned to normal when clarithromycin was stopped and disopyramide 5 days later.4 An episode of torsade de pointes occurred in another elderly woman taking disopyramide 50 mg daily because of paroxysmal atrial fibrillation, which was hospitalised with hypoglycaemic coma after also taking clarithromycin 600 mg daily. Serum disopyramide levels increased from 1.5 to 8 micrograms/mL during treatment with clarithromycin.5 QT and QTc intervals were prolonged, but torsade de pointes did not occur.3 Hypoglycaemic coma has also been reported in another patient taking disopyramide with clarithromycin.6

(c) Erythromycin

A woman with ventricular ectopy taking disopyramide (300 mg alternating with 150 mg every 6 hours) developed new arrhythmias (ventricular asystoles and later torsade de pointes) within 36 hours of starting erythromycin lactobionate 1 g intravenously every 6 hours, and cefamandole. Her QTc interval had increased from 390 to 600 milliseconds and her serum disopyramide level was found to be 16 micromol/L. The problem resolved when the disopyramide was stopped and bretylam given, but it returned when the disopyramide was restarted. It resolved again when the erythromycin was stopped.7 Another patient with ventricular tachycardia, well controlled over 5 years with disopyramide 200 mg four times daily, developed polymorphic ventricular tachycardia within a few days of starting erythromycin 500 mg four times daily. His QTc interval had increased from 430 to 630 milliseconds and serum disopyramide levels were found to be elevated at 30 micromol/L. The problem resolved when both drugs were withdrawn and antiarrhythmics given.7 Heart block is said to have developed in another patient treated with both drugs.8

Mechanism

Not fully established. An in vitro study using human liver microsomes indicated that erythromycin inhibits the metabolism (mono-N-dealkylation) of disopyramide which, in vivo, would be expected to reduce its loss from the body and increase its serum levels.7 Clarithromycin and azithromycin probably do the same. The increased serum levels of disopyramide can result in adverse effects such as QT prolongation and torsade de pointes, and may result in enhanced insulin secretion and hypoglycaemia.8,9 Both intravenous erythromycin10 and clarithromycin11 alone have been associated with prolongation of the QT interval and torsade de pointes. Therefore, disopyramide and macrolides may have additive effects on the QT interval in addition to the pharmacokinetic interaction.

Importance and management

An established interaction, although it is probably rare. Even so the effects of concurrent use should be well monitored if azithromycin, clarithromycin or erythromycin is added to disopyramide, being alert for the development of raised plasma disopyramide levels and prolongation of the QT interval. The manufacturer of disopyramide recommends12 avoiding the combination of disopyramide and macrolides that inhibit the cytochrome P450 isoenzyme CYP3A, and this would certainly be prudent in situations where close monitoring is not possible. Although direct clinical information is lacking, in vitro studies with human liver microsomes indicate that josamycin is likely to interact similarly, and telithromycin (an erythromycin derivative) might also be expected to interact in the same way. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

Disopyramide + Phenobarbital

Serum disopyramide levels are reduced by phenobarbital.

Clinical evidence

After taking phenobarbital 100 mg daily for 21 days, the half-life and AUC of a single 200-mg dose of disopyramide were reduced by about 35%. The apparent metabolic clearance more than doubled, and the fraction recovered in the urine as metabolite increased. Sixteen healthy subjects took part in the study and no significant differences were seen between those who smoked and those who did not.1

Mechanism

It seems probable that phenobarbital (a known enzyme inducer) increases the metabolism of disopyramide by the liver, and thereby increases its loss from the body.

Importance and management

This interaction appears to be established, but its clinical importance is uncertain. The extent to which it would reduce the control of arrhythmias by disopyramide is unknown, but monitor the effects and the serum levels of disopyramide if phenobarbital is added or withdrawn. The manufacturer of disopyramide12 recommends avoiding using it in combination with inducers of the cytochrome P450 isoenzyme CYP3A, such as phenobarbital. Other barbiturates would be expected to interact similarly.

Disopyramide + Phenyoctin

Serum disopyramide levels are reduced by phenytoin and may fall below therapeutic levels. Loss of arrhythmic control may occur.

Clinical evidence

Eight patients with ventricular tachycardia treated with disopyramide 600 mg to 2 g daily had a 54% fall in their serum disopyramide levels (from a mean of 3.99 to 1.82 micrograms/mL) when they were also given phenytoin 200 to 600 mg daily for a week. Two of the patients who responded to disopyramide and underwent Holter monitoring showed a 53- and 2000-fold increase in ventricular premature beat frequency as a result of this interaction.1

In other reports, 3 patients who had low levels of disopyramide and high levels of its metabolite were noted to be taking phenytoin,2 and one patient

References

receiving both drugs required an unusually high dose of disopyramide. A marked fall in serum disopyramide levels (75% in one case) was seen in 2 patients who took phenytoin 300 to 400 mg daily for up to 2 weeks. Pharmacokinetic studies in a total of 12 healthy subjects confirm this interaction. In addition, one healthy epileptic taking phenytoin had a disopyramide AUC and elimination half-life that were 50% lower than those in control subjects.

**Mechanism**

Phenytoin, which is a known enzyme-inducer, increases the metabolism of the disopyramide by the liver. Although, the major metabolite (N-dealkyldisopyramide) also possesses antiarrhythmic activity the net effect is a reduction in arrhythmic control.

**Importance and management**

An established interaction of clinical importance. Some loss of arrhythmic control can occur during concurrent use. Disopyramide adverse effects (because of the potential for high metabolite levels) and the antiarrhythmic response should be well monitored. An increase in the dosage of disopyramide may be necessary. The interaction appears to resolve fully within 2 weeks of withdrawing the phenytoin. Note that the manufacturer of disopyramide recommends avoiding using it in combination with inducers of the cytochrome P450 isoenzyme CYP3A, such as phenytoin.

### Disopyramide + Verapamil

Disopyramide serum levels may be slightly raised by verapamil. Both drugs prolong the QT interval, and this effect may be additive on combined use.

**Clinical evidence, mechanism, importance and management**

After taking verapamil 200 mg four times daily, the peak serum levels of disopyramide, given as a single 150-mg dose to 16 healthy subjects, were raised by 20% from 2.68 to 3.32 micrograms/mL, and by 14% when given long-term, as 150 mg four times a day. Serum quinidine levels were decreased by 26%. However, there was no change in the half-life of either drug. Both quinidine and disopyramide caused a slight shortening of the QTc interval, and when quinidine was added to disopyramide therapy additional lengthening of the QT interval occurred. The frequency of adverse effects such as dry mouth, blurred vision, urinary retention and nausea were also somewhat increased. The mechanism of the effect on serum levels is not understood. The antimuscarinic adverse effects of disopyramide may be increased. Disopyramide and quinidine are both class la antiarrhythmics that prolong the QT interval, and, in general, such combinations should be avoided (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257).

### Disopyramide + Antacids

Disopyramide + Antacids

**The plasma levels of disopyramide can be reduced by rifampicin.**

**Clinical evidence**

After taking rifampicin for 14 days the plasma levels of disopyramide were approximately halved in 11 patients with tuberculosis who had taken a single 200- or 300-mg dose of disopyramide. The disopyramide AUC was reduced by about two-thirds and the half-life was reduced from 5.9 to 3.25 hours by rifampicin. A woman who had been receiving rifampicin for 2 weeks started taking disopyramide 100 mg every 8 hours but only achieved subtherapeutic levels of 0.9 micromol/L. The dosage of disopyramide was increased to 300 mg every 8 hours, and the rifampicin was discontinued. Three days after discontinuing rifampicin the disopyramide level was 3.6 micromol/L and after 5 days it was 8.1 micromol/L. The patient was eventually maintained on disopyramide 250 mg every 8 hours.

**Mechanism**

The most probable explanation is that rifampicin (a well-known enzyme inducer) increases the metabolism of the disopyramide by the liver so that it is cleared from the body much more quickly.

### Disopyramide + Quinidine

Disopyramide serum levels may be slightly raised by quinidine. Both drugs prolong the QT interval, and this effect may be additive on combined use.

**Clinical evidence, mechanism, importance and management**

After taking quinidine 200 mg four times daily, the peak serum levels of disopyramide, given as a single 150-mg dose to 16 healthy subjects, were raised by 20% from 2.68 to 3.32 micrograms/mL, and by 14% when given long-term, as 150 mg four times a day. Serum quinidine levels were decreased by 26%. However, there was no change in the half-life of either drug. Both quinidine and disopyramide caused a slight lengthening of the QT interval, and when quinidine was added to disopyramide therapy additional lengthening of the QT interval occurred. The frequency of adverse effects such as dry mouth, blurred vision, urinary retention and nausea were also somewhat increased. The mechanism of the effect on serum levels is not understood. The antimuscarinic adverse effects of disopyramide may be increased. Disopyramide and quinidine are both class la antiarrhythmics that prolong the QT interval, and, in general, such combinations should be avoided (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257).

### Dofetilide + Antacids

**Antacids (aluminium/magnesium hydroxide) appear not to interact with dofetilide.**

**Clinical evidence, mechanism, importance and management**

A study in 12 healthy subjects found that pretreatment with aluminium/magnesium hydroxide (Maalox) 30 mL (10, 2 and 0.5 hours before dofetilide) did not affect the pharmacokinetics of a single 500-microgram dose of dofetilide, nor the dofetilide-induced change in QTc interval. No special precautions appear to be necessary.

Hydrochlorothiazide and hydrochlorothiazide/triamterene modestly increased dofetilide plasma levels, and caused a marked increase in the QT interval.

Clinical evidence

The manufacturer notes that the concurrent use of dofetilide 500 micrograms twice daily with hydrochlorothiazide 50 mg daily for 7 days increased the dofetilide AUC by 14% and increased the QTc interval by 47.6 milliseconds. Similar results were seen with the same dose of dofetilide combined with hydrochlorothiazide/triamterene 50/100 mg daily (18% increase in AUC, and 38.1 millisecond increase in QTc).

Mechanism

Triamterene might be expected to increase dofetilide plasma levels by competing for its renal tubular secretion (see ‘Dofetilide + Miscellaneous’, p.255), but the effect of its combination with hydrochlorothiazide was no greater than with hydrochlorothiazide alone. Why hydrochlorothiazide should increase dofetilide levels is unclear. An increase in dofetilide levels would be expected to increase the QT interval, but the increase seen here was much greater than expected by the change in plasma levels. The manufacturer suggests that a reduction in serum potassium could have contributed to the extent of QT prolongation. This makes sense for hydrochlorothiazide (a potassium-depleting diuretic), but the combination with triamterene (a potassium-sparing diuretic) might therefore have been expected to have less effect on the QT interval.

Importance and management

On the basis of the above findings, the manufacturer contraindicates the concurrent use of hydrochlorothiazide and hydrochlorothiazide/triamterene with dofetilide, and serum potassium should be monitored.2

Dofetilide + Diuretics

Dofetilide + Ketoconazole

Ketoconazole markedly increases the plasma levels of dofetilide. This is likely to be associated with an increased risk of dofetilide-induced QT prolongation and torsade de points arrhythmias.

Clinical evidence

The manufacturer of dofetilide notes that ketoconazole 400 mg daily, given with dofetilide 500 micrograms twice daily for 7 days, increased the dofetilide peak levels by 53% in men and 97% in women, and the AUC by 41% in men and 69% in women.1 Ketoconazole decreased the renal clearance of dofetilide by 31.3% and the non-renal clearance by 40.3%, resulting in a reduction in total clearance of 34.7%.2

Mechanism

Ketoconazole may inhibit the active renal tubular secretion mechanism by which dofetilide is eliminated, so reducing its loss from the body (see also ‘Dofetilide + H2-receptor antagonists’, above).1,2 Ketoconazole also inhibits the metabolism of dofetilide by the cytochrome P450 isoenzyme CYP3A4. Both of these mechanisms contribute to the increase in dofetilide plasma levels. There is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which increases the risk for torsade de points.1

Importance and management

An established interaction. Because of the likely increased risk of torsade de points, the manufacturer contraindicates the use of ketoconazole in patients on dofetilide. This would seem to be a prudent precaution.

Dofetilide + H2-receptor antagonists

Cimetidine markedly increases plasma dofetilide levels, and hence increases dofetilide-induced QT prolongation and the risk of torsade de points arrhythmias. Its combined use with dofetilide should be avoided. Dofetilide appears not to interact with ranitidine.

Clinical evidence

A placebo-controlled study in 24 healthy subjects indicated that cimetidine 400 mg twice daily given with dofetilide 500 micrograms twice daily for 7 days significantly decreased the renal clearance of dofetilide by 44%, increased its AUC by 58%, and increased its peak blood levels by 50%, without significantly altering the QTc interval.1 In a further study it was found that cimetidine 100 mg twice daily (non-prescription dose) or 400 mg twice daily (a common prescription dose) for 4 days reduced the renal clearance of a single 500-microgram dose of dofetilide by 13 and 33%, respectively. In addition, the respective cimetidine doses increased the QTc interval by 22 and 33%. Conversely, ranitidine 150 mg twice daily did not significantly affect the pharmacokinetics or pharmacodynamics of dofetilide.2

Mechanism

At least 50% of a dofetilide dose is eliminated unchanged in the urine by an active renal tubular secretion mechanism.3,4 Drugs that inhibit this mechanism, such as cimetidine, increase dofetilide plasma levels.2,3 There is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which increases the risk of torsade de points arrhythmias.3

Importance and management

An established interaction. Because of the likely increased risk of torsade de points, the manufacturer contraindicates the use of cimetidine in patients on dofetilide. This would seem to be a prudent precaution. This applies equally to cimetidine at over-the-counter doses, and patients on dofetilide should be warned to avoid this. No special precautions appear to be necessary with ranitidine. Note that ‘omeprazole’, (p.256) and ‘antacids’, (p.254) also appear not to interact with dofetilide.

Dofetilide + Miscellaneous

The manufacturer of dofetilide cautions about the use of various drugs that may have the potential to increase dofetilide plasma levels, so increasing the risk of QT prolongation and arrhythmias. Use with other drugs that prolong the QT interval should be avoided.

Clinical evidence, mechanism, importance and management

(a) Inhibitors/substrates for renal secretion

At least 50% of a dofetilide dose is eliminated unchanged in the urine by an active renal tubular secretion mechanism.1,2 Some drugs that inhibit this mechanism have been shown to increase dofetilide plasma levels (e.g. see ‘Dofetilide + H2-receptor antagonists’, above). The manufacturer contraindicates their concurrent use since there is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval.

Dofetilide is a class III antiarrhythmic that prolongs the QT interval and can cause torsade de points arrhythmia. In general, use of two or more drugs that prolong the QT interval should be avoided. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’.1

### Clinical evidence, mechanism, importance and management

**Clinical evidence, mechanism, importance and management**

Studies in healthy subjects found that the concurrent use of theophylline 450 mg every 12 hours and dofetilide 500 micrograms every 12 hours did not alter the steady-state pharmacokinetics of either drug.1,2 In addition, the increase in the QTc interval was no greater with the combination than with dofetilide alone.1 No special precautions appear to be necessary.

### Dofetilide + Theophylline

There does not appear to be any interaction between theophylline and dofetilide.

**Clinical evidence, mechanism, importance and management**

Verapamil transiently increases dofetilide plasma levels and QTc prolongation, and has been associated with an increased risk of torsade de points arrhythmia. Its use with dofetilide is contraindicated.

**Clinical evidence**

A study in 12 healthy subjects found that verapamil 80 mg three times daily given with dofetilide 500 micrograms twice daily for 3 days caused a 42% increase in the peak plasma levels of dofetilide from 2.4 to 3.43 nanograms/mL.1 There was a 26% increase in the AUC0–24, which was associated with a transient simultaneous increase in QTc of 20 milliseconds for dofetilide alone and 26 milliseconds for the combination. However, the AUC0–8 was not significantly different.1 The manufacturer notes that an analysis of clinical trial data for dofetilide revealed a higher occurrence of torsade de points when verapamil was used with dofetilide.2

**Mechanism**

Verapamil is postulated to interact with dofetilide by increasing its rate of absorption by increasing hepatic blood flow.1 There is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which is a risk factor for torsade de points.1

The combined use of drugs that can cause hypokalaemia (e.g. amphotericin B, corticosteroids, thiazide and loop diuretics, and stimulant laxatives) and drugs that prolong the QT interval (e.g. class Ia and class III antiarrhythmics; see ‘Table 9.2’, (above)) should be well monitored because hypokalaemia increases the risk of torsade de pointes arrhythmias. There appear to be only a few reports of this interaction, for example, see ‘Beta blockers + Potassium-depleting drugs’, p.852.

The consensus of opinion is that the concurrent use of drugs that have a high risk of prolonging the QTc interval should be avoided because of the risk of additive effects, leading to the possible development of serious and potentially life-threatening torsade de pointes cardiac arrhythmias. With drugs that have some risk of prolonging the QTc interval, some caution is appropriate, particularly in patients with other risk factors for QTc prolongation.

Clinical evidence, mechanism, importance and management

If the QT interval on the ECG becomes excessively prolonged, ventricular arrhythmias can develop, in particular a type of polymorphic tachycardia known as ‘torsade de pointes’. On the ECG this arrhythmia can appear as an intermittent series of rapid spikes during which the heart fails to pump effectively, the blood pressure falls and the patient will feel dizzy and may possibly lose consciousness. Usually the condition is self-limiting but it may progress and degenerate into ventricular fibrillation, which can cause sudden death.

There are a number of reasons why QT interval prolongation can occur. These include:

- increasing age
- female sex
- congenital long QT syndrome
- cardiac disease
- thyroid disease
- some metabolic disturbances (hypocalcaemia, hypokalaemia, hypomagnesaemia)

Another important cause is the use of various QT-prolonging drugs including some antiarrhythmics, antipsychotics, antihistamines, antimalarials and others.1,2 These drugs all appear to cause this effect by blocking the rapid component of the delayed rectifier (repolarisation) potassium channel.

This list is not exhaustive

Drugs that prolong the QT interval + Drugs that lower potassium levels

The combined use of drugs that can cause hypokalaemia (e.g. amphotericin B, corticosteroids, thiazide and loop diuretics, and stimulant laxatives) and drugs that prolong the QT interval (e.g. class Ia and class III antiarrhythmics; see ‘Table 9.2’, (above)) should be well monitored because hypokalaemia increases the risk of torsade de pointes arrhythmias. There appear to be only a few reports of this interaction, for example, see ‘Beta blockers + Potassium-depleting drugs’, p.852.
At what degree of prolongation of corrected QT (QTc) interval the torsade de pointes arrhythmia is likely to develop is uncertain. However, a QTc interval exceeding 500 milliseconds is generally considered of particular concern, but this is not an exact figure. In addition, there is uncertainty about what constitutes an important change in QTc interval from baseline, although, in general, increases of 30 to 60 milliseconds should raise concern, and increases of 60 milliseconds raise clear concerns about the potential for arrhythmias. Because of these uncertainties, many drug manufacturers and regulatory agencies contraindicated the concurrent use of drugs known to prolong the QT interval, and a ‘blanket’ warning was often issued because the QT prolonging effects of the drugs are expected to be additive. Regulatory guidance for the assessment of risk of a non-antiarrhythmic drug states that drugs causing an increase in mean QT/QTc interval of around 5 milliseconds or less do not appear to cause torsade de pointes. Data on drugs causing mean increases of around 5 and less than 20 are inconclusive, and some drugs causing this have been associated with proarhythmic risk. Drugs with an increase of more than 20 milliseconds have a substantially increased likelihood of being proarrhythmic.\(^3\)\(^,\)\(^4\) The extent of the drug-induced prolongation usually depends on the dosing of the drug and the particular drugs in question.

‘Table 9.2’, (p.257) is a list of drugs that are known to prolong the QT interval and cause torsade de pointes. Note that this list is not exhaustive of all the drugs that have been reported to be associated with QT interval prolongation and torsade de pointes. For some of the drugs listed, QT prolongation is a fairly frequent effect when the drug is used alone, and it is well accepted that use of these drugs requires careful monitoring (e.g. a number of the antiarrhythmics). For other drugs, QT prolongation is rare, but because of the relatively benign indications for these drugs, the risk-benefit ratio is considered poor, and use of these drugs has been severely restricted or discontinued (e.g. astemizole, terfenadine, cisapride). For others there is less clear evidence of the risk of QT prolongation (e.g. clarithromycin, chlorpromazine). Specific reports of additive QT prolonging effects with or without torsade de pointes are covered in individual monographs.

Drugs that do not themselves prolong the QT interval, but potentiate the effect of drugs that do (e.g. by pharmacokinetic mechanisms, lowering serum potassium, or by causing bradycardia) are not included in ‘Table 9.2’, (p.257). The interactions of these drugs (e.g. azole antifungals with cis-tiamycin, chlorpromazine). Specific reports of additive QT prolonging effects with or without torsade de pointes are covered in individual monographs.

General references discussing the problems of QT prolongation are given below.\(^6\)--\(^14\)

### Flecainide + Amiodarone

**Serum flecainide levels are increased by amiodarone. The flecainide dosage should be reduced by between one-third and one-half.**

An isolated report describes a patient on amiodarone who developed torsade de pointes when given flecainide.

#### Clinical evidence

Amiodarone 1.2 g daily for 10 to 14 days then 600 mg daily was given to 7 patients taking oral flecainide 200 to 500 mg daily. The trough plasma levels of flecainide were increased by about 50%, and the flecainide dosage was reduced by one-third (averaging a reduction from 325 to 225 mg daily) to keep the flecainide levels constant. Observations in two patients suggest that the interaction begins soon after the amiodarone is added, and it takes 2 weeks or more to develop fully.\(^1\)

Other authors have reported this interaction, and suggest reducing the flecainide dosage by one-third to one-half when amiodarone is added.\(^2\)--\(^5\) Another study found that amiodarone raised steady-state flecainide plasma levels by 37% in extensive metabolisers, and 55% in poor metabolisers of dextromethorphan (a probe drug for CYP2D6 activity).\(^9\) In a later report of this study the authors concluded that these differences were not clinically important, and that CYP2D6 phenotype does not affect the extent of the flecainide-amiodarone interaction.\(^7\) An isolated report describes torsade de pointes in a patient on amiodarone when given flecainide.\(^8\)

#### Mechanism

Amiodarone inhibits the cytochrome P450 isoenzyme CYP2D6, so that the flecainide is metabolised by the liver more slowly. Amiodarone also inhibits CYP2D6-independent mechanisms of flecainide elimination.\(^1\)

#### Importance and management

An established interaction, but the documentation is limited. Reduce the flecainide dosage by one-third to one-half if amiodarone is added.\(^1\)--\(^5\) The manufacturer of flecainide recommend a 50% reduction in dose if amiodarone is given, and advise that adverse effects and plasma flecainide levels should be monitored.\(^8\)--\(^10\) There seems to be no need to treat extensive metabolisers differently from poor metabolisers.\(^7\) Remember that the interaction may take 2 weeks or more to develop fully, and also that amiodarone is cleared from the body exceptionally slowly so that this interaction may persist for some weeks after it has been withdrawn.

### Flecainide + Antacids or Food

The absorption of flecainide is not significantly altered if it is taken with food or an aluminum hydroxide antacid in adults, but it may possibly be reduced by milk in infants.
Clinical evidence, mechanism, importance and management

Neither food nor three 15-mL doses of Alroax (280 mg of aluminium hydroxide per 5 mL) had any significant effect on the rate or extent of absorption of a single 200-mg dose of flecainide in healthy adult subjects.1 No special precautions seem necessary if they are taken together.

A premature baby being treated for refractory atrio-ventricular tachycardia with high doses of flecainide (40 mg/kg daily or 25 mg every 6 hours) developed flecainide toxicity (seen as ventricular tachycardia) when his milk feed was replaced by dextrose 5%. His serum flecainide levels approximately doubled, the conclusion being that the milk had reduced the absorption.2 Milk-fed infants on high doses of flecainide may therefore possibly need a reduced dosage if milk is reduced or stopped. Monitor the effects.

Flecainide + Antiepileptics

Limited data suggests that phenytoin or phenobarbital may modestly increase flecainide clearance, but this may not be clinically important.

Flecainide + Benziodarone

A single case report describes ECG changes in a patient taking flecainide with benziodarone.

Clinical evidence, mechanism, importance and management

A 71-year-old woman who had undergone kidney transplantation 7 years earlier and who was taking amloidipine, losartan, furosemide, chloralidone, calcitriol, aspirin, prednisone, ciclosporin, cyclophosphamide and insulin was also treated with flecainide, which controlled her paroxysmal atrial fibrillation. Atrorvastatin was then restarted for hypercholesterolaemia and benziodarone 100 mg daily (because of intolerance to allopurinol) was added to treat hyperuricaemia. Three days later she presented with asthenia and poor overall condition and later an ECG showed QRS prolongation of 169 milliseconds (21% increase) caused by complete right bundle branch block with a previous anterior hemiblock, QTc interval prolongation of 482 milliseconds (22% increase) and PR interval prolongation of 203 milliseconds (18% increase). Creatinine levels were about 127 micromol/L, creatine phosphokinase 354 units/L and urea 155 mg/dL. Atrorvastatin was stopped because of mild rhabdomyolysis. Flecainide and benziodarone were discontinued because an interaction was also suspected and symptoms resolved within 48 hours, with the ECG then showing values close to baseline. Flecainide was restarted and the dose gradually increased to 100 mg daily.

It was suggested that benziodarone may inhibit the cytochrome P450 isoenzyme CYP2D6 which is concerned with the metabolism of flecainide.1 Note that benziodarone is chemically related to amiodarone, which has a similar effect, see ‘Flecainide + Amiodarone’, p.258. Mild renal insufficiency in the patient may also have contributed to reduced flecainide elimination. More study is needed.

Flecainide + Cimetidine

Cimetidine can increase flecainide plasma levels.

Clinical evidence

After taking cimetidine 1 g daily for a week, the AUC of a single 200-mg dose of flecainide was increased by 28% in 8 healthy subjects. The fraction of flecainide excreted unchanged in the urine was increased by 20%, but the total renal clearance was not altered.1 In another study in 11 patients, cimetidine 1 g daily for 5 days almost doubled the plasma levels of flecainide 200 mg daily measured 2 hours after the morning dose.2

Mechanism

Uncertain, but it is thought that the cimetidine reduces the hepatic metabolism of flecainide.1,2

Importance and management

An established but not extensively documented interaction. The clinical importance appears not to have been assessed, but be aware for the need to reduce the flecainide dosage if cimetidine is added. Caution is recommended in patients with impaired renal function, as the interaction is likely to be enhanced.1

Flecainide + Colestyramine

An isolated report describes reduced plasma flecainide levels in a patient given colestyramine. However, studies in other subjects have not found an interaction.

Clinical evidence, mechanism, importance and management

A patient taking flecainide 100 mg twice daily had unusually low trough plasma levels (100 nanograms/mL) while taking colestyramine 4 g three times daily. When he stopped taking the colestyramine his plasma flecainide levels rose. However, a later study in 3 healthy subjects given flecainide 100 mg once daily and colestyramine 4 g three times daily, found little or no evidence of an interaction (steady-state flecainide levels of 63.1 and 59.1 nanograms/mL without and with colestyramine respectively. In vitro studies also did not find any binding between flecainide and colestyramine that might result in reduced absorption from the gut.1 The authors however postulate that the citric acid contained in the colestyramine formulation might have altered the urinary pH, which could have increased the renal clearance of the flecainide.1 Information seems to be limited to this preliminary report. Its general importance seems to be minor, nevertheless the outcome of concurrent use should be monitored so that any unusual cases can be identified.

Flecainide + Quinidine or Quinine

Quinidine and quinine cause a modest reduction in the clearance of flecainide.

Clinical evidence, mechanism, importance and management

(a) Quinidine

A single 50-mg oral dose of quinidine given to 6 healthy subjects the night before a single 150-mg intravenous dose of flecainide decreased the flecainide clearance by 23%. The flecainide half-life was increased by 22%
Flecainide + SSRIs

Paroxetine is an inhibitor of CYP2D6 and may, therefore, increase the plasma levels of flecainide, which is metabolised via this isoenzyme. The manufacturers suggest that escitalopram may have similar effects.

Clinical evidence, mechanism, importance and management

(a) Escitalopram

Although studies in vitro did not reveal an inhibitory effect of escitalopram on CYP2D6, limited in vivo data with ‘desipramine’, (p.1241) and ‘metoprolol’, (p.855) suggest a modest inhibitory effect. The UK manufacturer recommends caution if escitalopram is given with drugs that are metabolised via this enzyme, such as flecainide. Several similarly metabolised drugs have been shown to interact (e.g. ‘metoprolol’, (p.855), and ‘propafenone’, (p.275)).

(b) Paroxetine

The manufacturer states that paroxetine is an inhibitor of CYP2D6 and it may increase the plasma levels of drugs that are metabolised via this enzyme, such as flecainide. Several similarly metabolised drugs have been shown to interact (e.g. ‘metoprolol’, (p.855), and ‘propafenone’, (p.275)).

Flecainide + Tobacco

Tobacco smokers need larger doses of flecainide than non-smokers to achieve the same therapeutic effects.

Clinical evidence

Prompted by the chance observation that smokers appeared to have a reduced pharmacodynamic response to flecainide than non-smokers, a meta-analysis was undertaken of the findings of 7 premarketing pharmacokinetic studies and 5 multicentre efficacy trials in which flecainide had been studied and in which the smoking habits of the subjects/patients had been also been recorded. In the pharmacokinetic studies, the clearance of flecainide was found to be about 50% higher in smokers than in non-smokers. In the efficacy studies, average clinically effective flecainide doses were found to be 338 mg daily for smokers and 288 mg daily for non-smokers, while trough plasma concentrations of flecainide were 1.74 and 2.18 nanograms/mL per mg dose for the smokers and non-smokers, respectively. This confirmed that smokers needed higher doses of flecainide to achieve the same steady-state serum levels.

Mechanism

The probable reason for this interaction is that some components of the tobacco smoke stimulate the cytochrome P450 enzymes in the liver concerned with the O-dealkylation of flecainide, so that it is cleared from the body more quickly.

Importance and management

An established interaction. Smokers seem likely to need higher doses of flecainide than non-smokers, but the way in which this interaction was identified suggests that in practice no specific action needs to be taken to accommodate it.

Flecainide + Urinary acidifiers or alkalisers

The excretion of flecainide is increased if the urine is made acidic (e.g. with ammonium chloride) and reduced if the urine is made alkaline (e.g. with sodium bicarbonate). The clinical importance of these changes is not known.

Clinical evidence

Six healthy subjects were given single 300-mg oral doses of flecainide on two occasions. On the first occasion flecainide was taken after ammonium chloride 1 g orally every 3 hours, and 2 g at bedtime, for a total of 21 hours to make the urine acidic (pH range 4.4 to 5.4). On the second occasion flecainide was taken after sodium bicarbonate 4 g every 4 hours for a total of 21 hours (including night periods) to make the urine alkaline (pH range 7.4 to 8.3). Over the next 32 hours, 44.7% of unchanged flecainide appeared in the acidic urine, but only 7.4% in alkaline urine. This compares with 25% found by other researchers when urinary pH was not controlled. A later similar study from the same research group broadly confirmed these findings; the elimination half-life of the flecainide was 10.7 hours in acidic urine and 17.6 hours in alkaline urine. Another study also confirmed the effect of urinary pH on the excretion of flecainide, and found that the fluid load and the urinary flow rate had little effect on flecainide excretion.

Mechanism

In alkaline urine at pH 8, much of the flecainide exists in the kidney tubules in the non-ionised form (non-ionised fraction 0.04), which is therefore more readily reabsorbed. In acidic urine at pH 5 more exists in the ionised form (non-ionised fraction 0.0001), which is less readily reabsorbed and is therefore lost in the urine.

Importance and management

Established interactions, but their clinical importance is still uncertain. The effects of these changes on the subsequent control of arrhythmias by flecainide in patients seem not to have been studied, but the outcome should be well monitored if patients are given drugs that alter urinary pH to a significant extent (such as ammonium chloride, sodium bicarbonate). Large doses of some antacids may possibly do the same, but nobody seems to have studied this.

Although flecainide and verapamil have been used together successfully, serious and potentially life-threatening cardiogenic shock and asystole have been seen in a few patients, because the cardiac depressant effects of the two drugs can be additive.

Clinical evidence
A man with triple coronary vessel disease and taking flecainide 200 mg daily for recurrent ventricular tachycardia, developed severe cardiogenic shock within 2 days of increasing the flecainide dosage to 300 mg daily and one day of starting verapamil 80 mg daily. His blood pressure fell to 60/40 mmHg and he had an idioventricular rhythm of 88 bpm. Another patient with atrial flutter and fibrillation was given digitalis and verapamil 120 mg three times daily. He was also given flecainide 150 mg daily for 10 days, but 3 days after the dosage was raised to 200 mg daily he fainted, and later developed severe bradycardia (15 bpm) and asystoles of up to 14 seconds. He later died.1

Another report describes atrioventricular block in a patient with a pacemaker when treated with digoxin, flecainide and verapamil.2

Two earlier studies in patients3 and healthy subjects4 had found that the pharmacokinetics of flecainide and verapamil were only minimally affected by concurrent use, but the PR interval was increased by both drugs and additive depressant effects were seen on heart contractility and AV conduction. No serious adverse responses occurred.

Mechanism
Flecainide and verapamil have little or no effects on the pharmacokinetics of each other,5,6 but they can apparently have additive depressant effects on the heart (negative inotropic and chronotropic) in both patients and healthy subjects.3,4 Verapamil alone5,6 and flecainide alone7,8 have been responsible for asystole and cardiogenic shock in a few patients. In the cases cited above3,7 the cardiac depressant effects were particularly serious because the patients already had compromised cardiac function.

Importance and management
An established interaction, but the incidence of serious adverse effects is probably not great. The additive cardiac depressant effects are probably of little importance in many patients, but may represent ‘the last straw’ in a few who have seriously compromised cardiac function. The authors of one of the reports cited1 advise careful monitoring if both drugs are used and emphasise the potential hazards of combining class Ic antiarrhythmics and verapamil.

Clinical evidence, mechanism, importance and management
When intravenous ibutilide 2 mg was used for cardioversion of atrial fibrillation or flutter in 70 patients taking long-term amiodarone the QT interval was further prolonged (from 371 to 479 milliseconds). However, only one patient had an episode of non-sustained torsade de pointes. Ibutilide was effective within 30 minutes of infusion in 39% of patients with atrial flutter, and 54% of patients with fibrillation.1 Both amiodarone and ibutilide are class III antiarrhythmics and prolong the QT interval, with the consequent risk of torsade de pointes. The manufacturer recommends that they should not be used concurrently.2 However, the authors of the above report suggest that ibutilide may be useful for cardioversion in those already taking amiodarone. Combined use should be very well monitored.

Ibutilide + Calcium-channel blockers
Calcium-channel blockers (predominantly non-dihydropyridine type) have not altered the safety or efficacy of ibutilide in clinical trials.

Clinical evidence, mechanism, importance and management
Retrospective analysis of three clinical trials showed that calcium-channel blockers did not alter the ECG effects (QT prolongation) or the efficacy of ibutilide. In these three studies, 68 of the 130 patients treated with ibutilide were also taking calcium-channel blockers. The report did not specify which calcium-channel blockers were used, except to say that only 12 of the 68 (19%) were taking a dihydropyridine-type.1

In vitro studies have shown that nifedipine (a dihydropyridine) attenuated the effects of ibutilide. The findings of the above report1 suggest that this may not be clinically important. However, since so few patients were taking a dihydropyridine, an effect specific to dihydropyridines cannot be excluded. Further study is needed.

Ibutilide + Class Ic antiarrhythmics
Some evidence suggests that patients taking ibutilide have a less marked increase in QT interval, without a change in efficacy, when they are also given propafenone or flecainide.

Clinical evidence, mechanism, importance and management
The increase in QTc interval after intravenous ibutilide 2 mg was less in patients treated with propafenone (5 patients) or flecainide (1 patient) than in 85 other patients who had taken ibutilide alone (34 versus 65 milliseconds). The effect appeared to be dose-related, with higher propafenone doses causing the largest attenuation in the ibutilide-induced QT prolongation. The efficacy of ibutilide was unaltered.1 In a further study, 71 patients with atrial fibrillation or atrial flutter receiving either propafenone 300 to 900 mg daily or flecainide 100 to 300 mg daily underwent cardioversion with a single intravenous dose of ibutilide 1 mg over 10 minutes, followed if necessary by a further dose after an interval of 10 minutes. Torsade de pointes occurred in one patient with profound sinus node suppression after cardioversion, but the mean ibutilide-induced QTc interval was attenuated (20 ± 54 milliseconds compared to reported range of 47 to 90 milliseconds) without a decrease in efficacy. However, the authors note that the risk of sustained torsade de pointes in this study appears to be similar to that seen in other studies of ibutilide.6

Ibutilide, a class III antiarrhythmic, is known to increase the QT interval, so increasing the risk of torsade de pointes arrhythmia. Class Ic antiarrhythmics such as propafenone and flecainide generally shorten the QT interval. It is possible that class Ic antiarrhythmics may usefully attenuate the risk of torsade de pointes with ibutilide,1 and ibutilide may be
useful in restoring sinus rhythm in patients taking class Ic antiarrhythmics,² but further study is needed.

Ibutilide + Miscellaneous

Ibutilide can prolong the QT interval, therefore caution has been advised about the concurrent use of other drugs that can do the same. Ibutilide is reported not to interact with beta blockers or digoxin.

Clinical evidence, mechanism, importance and management

No specific drug interaction studies appear to have been undertaken with ibutilide, which is a class III antiarrhythmic, but because it can prolong the QT interval it has been recommended that other drugs that can do the same should be administered with caution, because of the potential additive effects.¹ The manufacturer of ibutilide specifically recommends that class Ia and other class III antiarrhythmics should not be given within 4 hours of an ibutilide infusion, and that ibutilide should not be given within five half-lives of these antiarrhythmics (but see also, ‘Ibutilide + Amiodarone’, p.261).² The concern is that a prolongation of the QT interval is associated with an increased risk of torsade de pointes arrhythmia, which is potentially life-threatening. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.²

The concurrent use of beta blockers and digoxin during clinical trials is reported not to affect the safety or efficacy of ibutilide.¹,² Ibutilide is said not to affect the cytochrome P450 isoforms CYP3A4 or CYP2D6 and so metabolic interactions with drugs affected by these enzymes would not be expected.¹ Study is needed to confirm all of these predictions and findings.

Lidocaine + Amiodarone

One man receiving intravenous lidocaine had a seizure about two days after starting treatment with amiodarone, and another man with sick sinus syndrome taking amiodarone had a sinoatrial arrest during placement of a pacemaker under local anaesthesia with lidocaine. There is conflicting evidence as to whether or not amiodarone affects the pharmacokinetics of intravenous lido-
caine.

Clinical evidence

(a) Effects on lidocaine levels, seizure

An elderly man taking digoxin, enalapril, amitriptyline and temazepam was treated for monomorphic ventricular tachycardia, firstly with procain-
amide, later replaced by a 2-mg/minute infusion of lidocaine, to which oral amiodarone 600 mg twice daily was added. After 12 hours his lidocaine level was 5.4 mg/L (therapeutic levels 1.5 to 5 mg/L), but 53 hours later he developed a seizure and his lidocaine level was found to have risen to 12.6 mg/L. A tomography brain scan showed no abnormalities that could have caused the seizure and it was therefore attributed to the toxic lidocaine levels.³

Six patients with symptomatic cardiac arrhythmias took part in a two-phase study. Initially, lidocaine 1 mg/kg was given intravenously over 2 minutes. In phase I, loading doses of amiodarone 500 mg daily for 6 days were given, followed by the same lidocaine dose. After 19 to 21 days, when the total cumulative amiodarone dose was 13 g, the same lidocaine dose was given again (phase II). The lidocaine AUC increased by about 20% and the systemic clearance decreased by about 20%.³ The elimination half-life and distribution volume at steady-state were unchanged. The pharmacokinetic parameters of lidocaine in phase II were the same as those in phase I, indicating that the interaction occurs early in the loading phase of amiodarone use.² This is in contrast to an earlier study, in which the pharmacokinetics of a bolus dose of lidocaine 1 mg/kg over 2 minutes were not altered in 10 patients who had taken amiodarone 200 to 400 mg daily (following an loading dose of 800 or 1200 mg) for 4 to 5 weeks.³

(b) Sinoatrial arrest

An elderly man with long standing brady-tachycardia was successfully treated for atrial flutter firstly with a temporary pacemaker (later withdrawn) and 600 mg amiodarone daily. Ten days later, and 25 minutes after a permanent pacemaker was inserted under local anaesthesia with 15 mL of 2% lidocaine, severe sinus bradyarrhythmia and long sinoatrial arrest developed. He was effectively treated with atropine plus isoprenaline, and card-
diac massage.⁴

Mechanism

An in vitro study has demonstrated that amiodarone may inhibit lidocaine metabolism competitively and vice versa. The interaction in vivo may be due to inhibition of the cytochrome P450 isoenzyme CYP3A4 by amio-
darone and/or its main metabolite desethylamiodarone.³ CYP3A4 is par-
tially involved in the metabolism of lidocaine.

The authors of the report describing the sinoatrial arrest suggest a syner-
gistic depression by both drugs of the sinus node.

Importance and management

Evidence of a pharmacokinetic interaction between lidocaine and amio-
darone is conflicting. However, the two reports of adverse interactions and the study in patients with arrhythmias illustrate the importance of good monitoring if both drugs are used.

4. Keidar S, Grenadier E, Palant A. Sinoatrial arrest due to lidocaine injection in sick sinus syn-

Lidocaine + Barbiturates

Plasma lidocaine levels following slow intravenous injection may be modestly lower in patients who are taking barbiturates.

Clinical evidence

A single 2-mg/kg dose of lidocaine was given by slow intravenous injec-
tion (rate about 100 mg over 15 minutes) to 7 epileptic patients, firstly while taking their usual antiepileptic drugs and sedatives (including phenytoin, barbiturates, phenothiazines, benzodiazepines) and secondly after taking only phenobarbital 300 mg daily for 4 weeks. The same lido-
caine dose was also given to 6 control subjects who had not received any other drugs. When compared with the levels in the 6 control subjects, plasma lidocaine levels were somewhat lower when the patients took their standard antiepileptic treatment they were found to be 10 to 25% higher, respectively. When plasma lidocaine levels achieved during the phenobarbital phase were compared with those achieved during the standard antiepileptic treatment they were found to be 10 to 25% higher, suggesting that the effect of combined treatment caused a greater reduc-
tion in lidocaine levels than phenobarbital.¹

Mechanism

Not fully understood. One suggestion is that the barbiturates increase the activity of the liver microsomal enzymes, thereby increasing the rate of metabolism of the lidocaine.³

Importance and management

Direct information is very limited. It may be necessary to increase the dos-
age of lidocaine to achieve the desired therapeutic response in patients on phenobarbital or other barbiturates.

The plasma levels of lidocaine after intravenous, and possibly oral, use can be increased by propranolol. Isolated cases of toxicity attributed to this interaction have been reported. Nadolol and penbutolol possibly interact similarly, but there is uncertainty about metoprolol. Atenolol and pindolol appear not to interact.

**Clinical evidence**

(a) Atenolol

A study with oral atenolol 50 mg daily found that it did not affect the clearance of lidocaine after oral or intravenous use.1

(b) Metoprolol

In 6 healthy subjects, metoprolol 100 mg twice daily for 2 days did not affect the pharmacokinetics of a single intravenous dose of lidocaine.2 Similarly, another study in 7 healthy subjects failed to find any changes in the pharmacokinetics of a single oral or intravenous dose of lidocaine after treatment with metoprolol 100 mg every 12 hours for a week.3 In contrast, another study found that the clearance of a single intravenous dose of lidocaine was reduced by 31% by pretreatment with metoprolol 50 mg every 6 hours for a day.3

(c) Nadolol

A study in 6 healthy subjects receiving 30-hour infusions of lidocaine at a rate of 2 mg/minute found that pretreatment with nadolol 160 mg daily for 3 days raised the steady-state plasma lidocaine levels by 28% (from 2.1 to 2.7 micrograms/mL) and reduced the plasma clearance by 17%.4

(d) Penbutolol

In 7 healthy subjects, penbutolol 60 mg daily significantly increased the volume of distribution of a single 100-mg intravenous dose of lidocaine, thus prolonging its elimination half-life. However, the reduction in clearance of lidocaine did not reach significance.5

(e) Pindolol

A study with intravenous pindolol 23 micrograms/kg found that it did not affect the clearance of intravenous lidocaine.6

(f) Propranolol

A study in 6 healthy subjects receiving 30-hour infusions of lidocaine at a rate of 2 mg/minute found that pretreatment with propranolol 80 mg every 8 hours for 3 days raised the steady-state plasma lidocaine levels by 19% (from 2.1 to 2.5 micrograms/mL) and reduced the plasma clearance by 16%.4 Other similar studies have found a 22.5 to 30% increase in steady-state serum lidocaine levels and a 14.7 to 46% fall in plasma clearance due to the concurrent use of propranolol.6,7 Two cases of lidocaine toxicity attributed to a lidocaine-propranolol interaction were revealed by a search of the FDA adverse drug reaction file in 1981. A further case of lidocaine toxicity (seizures) has been described in a man on propranolol after accidental oral ingestion of lidocaine for oesophageal anaesthesia. High serum levels of lidocaine were detected.9

(g) Unnamed beta blockers

A matched study in 51 cardiac patients taking a variety of beta blockers (including propranolol, metoprolol, timolol, and pindolol) found no significant differences in either total or free concentrations of lidocaine during a lidocaine infusion, but there was a trend towards an increase in the adverse effects of lidocaine (bradycardia) with concurrent beta blocker treatment.10

**Mechanism**

Not fully agreed. There is some debate about whether the increased serum lidocaine levels largely occur because of the decreased cardiac output caused by the beta blockers, which decreases the flow of blood through the liver thereby reducing the metabolism of the lidocaine,4 or because of direct liver enzyme inhibition.11 There may also be a pharmacodynamic interaction, with an increased risk of myocardial depression.10

**Importance and management**

The lidocaine/propranolol interaction is established and of clinical importance. Monitor the effects of concurrent use and reduce the intravenous lidocaine dosage if necessary to avoid toxicity. The situation with other beta blockers is less clear. Nadolol appears to interact like propranolol, but it is uncertain whether metoprolol interacts or not. Atenolol and pindolol are reported not to interact pharmacokinetically. It has been suggested that a higher intravenous loading dose (but not a higher maintenance dose) of lidocaine may be needed if penbutolol is used.3 The suggestion has been made that a significant pharmacokinetic interaction is only likely to occur with non-selective beta blockers without intrinsic sympathomimetic activity11 e.g. nadolol or propranolol. Aside from the pharmacokinetic interactions, a pharmacodynamic interaction is possible, and so it would be prudent to monitor the effects of concurrent use with any beta blocker.

Note that local anaesthetic preparations of lidocaine often contain adrenaline (epinephrine), which may interact with beta blockers, see ‘Beta blockers + Inotropes and Vasopressors’, p.848.

**Lidocaine + Cocaine**

Limited evidence suggests intravenous lidocaine use in patients with cocaine-associated myocardial infarction is not associated with significant toxicity.

**Clinical evidence, mechanism, importance and management**

A retrospective study, covering a 6-year period in 29 hospitals, identified 29 patients (27 available for review) who received lidocaine for prophylaxis or treatment of cocaine-associated myocardial infarction. No patient exhibited bradycardia, sustained ventricular tachycardia or ventricular fibrillation, and no patients died.1 In contrast, another study in 7 healthy subjects failed to find any changes in the clearance of lidocaine during a lidocaine infusion of 3 days raised the steady-state plasma lidocaine levels by 28% (from 2.1 to 2.7 micrograms/mL) and reduced the plasma clearance by 17%.4

Both lidocaine and cocaine exhibit class I antiarrhythmic effects and are proconvulsants. Lidocaine may potentiate the cardiac and CNS adverse effects of cocaine. Therefore the use of lidocaine for cocaine-associated myocardial infarction is controversial. The lack of adverse effects in this study may have been due to delays of more than 5 hours between last exposure to cocaine and lidocaine therapy. These authors3 and others3,4 consider that the cautious use of lidocaine does not appear to be contraindicated in patients with cocaine-associated myocardial infarction who require antiarrhythmic therapy. However, extra care should be taken in patients who receive lidocaine shortly after cocaine.1

References

**Lidocaine + Dextromethorphan**

Intravenous lidocaine does not inhibit the activity of CYP2D6, as assessed by its lack of effect on dextromethorphan pharmacokinetics, and is therefore unlikely to interact with drugs that are metabolised by this isoenzyme.

**Clinical evidence, mechanism, importance and management**

Although in vitro data suggested that lidocaine inhibited oxidative metabolism reactions mediated by the cytochrome P450 isoenzyme CYP2D6, a
later in vivo study in 16 patients found that, while being given an infusion of lidocaine (serum level range 3.2 to 55.9 microM/L), the metabolism of a single 30-mg dose of dextromethorphan remained unchanged. All of the patients were of the extensive metaboliser phenotype. Since dextromethorphan is a well-established marker of CYP2D6 activity, it was concluded that lidocaine is unlikely to interact with drugs that are extensively metabolised by this isoenzyme.1

**Clinical evidence, mechanism, importance and management**

In an in vitro study using serum taken from 9 patients receiving intravenous lidocaine for severe ventricular arrhythmias showed that there was an average 20% increase in its free (unbound) fraction when disopyramide in a concentration of 14.7 microM/L was added.1 This appears to occur because disopyramide can displace lidocaine from its binding sites on plasma proteins (alpha-1-acid glycoprotein).

The importance of this possible displacement interaction in clinical practice is uncertain. The suggestion made by the authors1 is that, although lidocaine has only a minor cardiac depressant effect, a transient 20% increase in levels of free and active lidocaine plus the negative inotropic effects of the disopyramide might possibly be hazardous in patients with reduced cardiac function.

**Lidocaine + Disopyramide**

**In vitro studies show that disopyramide can increase the levels of unbound lidocaine, but it is not known whether their combined effects have a clinically important cardiac depressant effect in practice.**

**Lidocaine + Fluvoxamine**

Fluvoxamine reduces the clearance of intravenous lidocaine.

Clinical evidence, mechanism, importance and management

In a study, 9 healthy subjects were given fluvoxamine 100 mg daily alone or with erythromycin 500 mg three times daily for 5 days before the administration of a single intravenous dose of lidocaine 1.5 mg/kg on day 6. The clearance of lidocaine was reduced 41% by fluvoxamine and 53% by concurrent fluvoxamine and erythromycin.1

The study found lidocaine clearance was reduced by fluvoxamine and further decreased by concurrent erythromycin. The cytochrome P450 isoenzymes CYP1A2 and CYP3A4 are involved in lidocaine metabolism. An in vitro study found that fluvoxamine (a CYP1A2 inhibitor) was a more potent inhibitor of lidocaine metabolism than erythromycin (a CYP3A4 inhibitor).2 See also ‘Lidocaine + Erythromycin’, above and ‘Anaesthetics, local + Fluvoxamine’, p.110.

**Lidocaine + H₂-receptor antagonists**

Cimetidine modestly reduces the clearance of intravenous and possibly oral lidocaine, and raises its serum levels in some patients. Lidocaine toxicity may occur if the dosage is not reduced. Ranitidine appears to interact minimally. See also ‘Anaesthetics, local + H₂-receptor antagonists’, p.111.

**Clinical evidence**

(a) Cimetidine in cardiac patients

In one study, 15 patients were given a 1-mg/kg intravenous loading dose of lidocaine followed by a continuous infusion of 2 or 3 mg/minute over 26 hours. At 6 hours the patients were started on cimetidine (initial dose 300 mg intravenously, then 300 mg every 6 hours by mouth). After 26 hours (20 hours after cimetidine was started) the serum levels of lidocaine were 30% higher (5.6 micrograms/mL) than in a control group of 6 patients (4.3 micrograms/mL). The most substantial rise in levels occurred in the first 6 hours after cimetidine was started. Six patients developed toxic serum levels (over 5 micrograms/mL) and two (with levels of 10 and 11 micrograms/mL) experienced lethargy and confusion attributed to lidocaine toxicity, which disappeared when the lidocaine was stopped.1

**Lidocaine + Erythromycin**

Erythromycin may markedly increase plasma levels of oral lidocaine, but causes only a minor increase after intravenous lidocaine.

Clinical evidence

In a randomised double-blind crossover study 9 healthy subjects were given erythromycin 500 mg three times daily or placebo daily for 4 days. Erythromycin increased the AUC and peak plasma levels of a single 1-mg/kg oral dose of lidocaine by 50 and 40% respectively. Erythromycin also markedly increased the AUC of the metabolite of lidocaine, monoethylgycynexyridide (MEGX) by 60%.1 In a similar study,2 erythromycin had no effect on the AUC or peak plasma level of a single 1.5-mg/kg intravenous dose of lidocaine, but still increased the AUC of MEGX by 70%. In yet another study, erythromycin ethylsuccinate 600 mg three times daily for 5 doses had a minor effect on the pharmacokinetics of a single 1-mg/kg intravenous dose of lidocaine (an 18% decrease in clearance), and caused a 33% increase in the AUC of MEGX. There was no difference in the results from the 10 healthy subjects and the 20 patients with biopsy proven cirrhosis.3 In another study, 9 healthy subjects were given fluvoxamine 100 mg daily alone or with erythromycin 500 mg three times daily for 5 days before the administration of a single intravenous dose of lidocaine 1.5 mg/kg on day 6. The clearance of lidocaine was reduced 41% by fluvoxamine and 53% by concurrent fluvoxamine and erythromycin.4

**Mechanism**

Erythromycin is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, the isoenzyme partially involved in the metabolism of lidocaine. Erythromycin appears to markedly reduce the first-pass metabolism of oral lidocaine so that its plasma levels rise.1 The increase in MEGX could be due to either an increase in the production of this metabolite, or the inhibition of its further metabolism. Fluvoxamine, is an inhibitor of CYP1A2 which is also involved in lidocaine metabolism. Lidocaine clearance is reduced by fluvoxamine and further decreased by concurrent erythromycin.

serum levels of 24% and 9% occurred by 24 hours. In contrast, a study in 6 patients with suspected myocardial infarction given lidocaine infusions, followed later by a cimetidine infusion, failed to find a significant increase in the plasma accumulation of lidocaine. An 89-year-old man with congestive heart failure taking oral cimetidine had two seizures 10 to 15 minutes after accidental oral ingestion of lidocaine solution for oesophageal anaesthesia. He had a high serum lidocaine level of 7.8 micrograms/mL.

An increase in the clearance of lidocaine is reversed 4 days after the discontinuation of cimetidine. The mechanism of this increase is largely related to the reduced plasma protein binding of lidocaine with cimetidine. However, the degree of plasma protein binding of lidocaine is decreased if the liver is damaged. Excess lidocaine that is not metabolised quickly can accumulate in the brain and cause convulsions. This effect can be decreased by the administration of a drug that blocks the metabolic pathway of lidocaine.

In a study of 6 healthy subjects cimetidine 300 mg every 6 hours for one day raised the peak serum levels of intravenous lidocaine by 50%. Systemic clearance fell by about 25% (from 766 to 576 mL/minute) and 5 of the 6 experienced toxicity (light-headedness, paraesthesia). Similarly, in another study, oral cimetidine 300 mg four times daily caused a 30% fall in the clearance of intravenous lidocaine. In contrast, in other studies, oral cimetidine 150 mg four times daily caused only 18% and 15% falls in the clearance of intravenous lidocaine under both single-dose and steady-state conditions, which did not reach statistical significance. In one study, the effect of intravenous cimetidine 300 mg four times daily was less than that of the oral cimetidine.

Cimetidine pretreatment increased the oral bioavailability of lidocaine by 35% in healthy subjects, and reduced the apparent oral clearance by 42%. Another study showed that 2 days of cimetidine pretreatment increased the AUC of lidocaine by 52% after aerosol application of lidocaine 120 mg (12 sprays of Xylocaine 10%) to the oropharynx.

The mechanism of the increased oral bioavailability of lidocaine by cimetidine is not clear. However, it is known that cimetidine decreases the activities of the liver microsomal enzymes. As a result, its clearance is reduced and its serum levels rise.

Importance and management

The lidocaine/cimetidine interaction is well studied but controversial. It is confused by the differences between the studies (healthy subjects, patients with different diseases, different modes of drug administration, etc.). A fall in the clearance of lidocaine (15% or more) and a resultant rise in the serum levels should be looked for if cimetidine is used, but a clinically significant alteration may not occur in every patient. It may possibly be of less importance in patients following a myocardial infarction because of the increased amounts of alpha-1-acid glycoprotein, which alters the levels of bound and free lidocaine. Monitor all patients closely for evidence of toxicity and, where possible, check serum lidocaine levels regularly. A reduced infusion rate may be needed. Ranitidine would appear to be a suitable alternative to cimetidine. See also ‘Anaesthetics, local + H2-receptor antagonists’.

Lidocaine + Itraconazole

Itraconazole may markedly increase the plasma levels of lidocaine after oral administration, but not after intravenous administration or inhalation via a nebuliser.

Clinical evidence

Nine healthy subjects were given either itraconazole 200 mg once daily or placebo for 4 days, in a randomised double-blind crossover study. Itraconazole increased the AUC and peak plasma levels of a single 1-mg/kg oral dose of lidocaine by 75% and 55% respectively. Itraconazole did not affect the concentration of the lidocaine metabolite, monoethylglycinexylidide (MEGX). In similar studies, itraconazole had no effect on the AUC and peak plasma levels of lidocaine or MEGX after 1.5-mg/kg intravenous or nebulised doses of lidocaine.

Mechanism

Itraconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, which is partially involved in the metabolism of lidocaine. Itraconazole appears to markedly reduce the first-pass metabolism of orally administered lidocaine so that its plasma levels rise.

Importance and management

Information seems to be limited, and since lidocaine is not usually given orally the practical importance is minor. However, lidocaine is used for oro-pharyngeal topical anaesthesia, and there have been cases of toxicity after accidental ingestion. There is also a possibility of accidental oral ingestion during inhalation of lidocaine. In patients on itraconazole, the toxicity of oral lidocaine may be markedly increased.

Lidocaine + Mexiletine

Mexiletine may increase the toxicity of lidocaine.

Clinical evidence, mechanism, importance and management

A patient with cardiomyopathy taking mexiletine 300 mg twice daily developed lidocaine CNS toxicity within one hour of receiving a total of 600 mg of oral lidocaine for oesophageal burning. Her lidocaine concentration was raised at 26.9 micrograms/mL. Similarly, involuntary movement and muscular stiffness occurred in a man treated with oral mexiletine and an intravenous infusion of lidocaine for one day. Studies in animals have shown that the concurrent use of mexiletine and intravenous lidocaine resulted in a decrease in the total clearance of lidocaine and an increase in plasma levels. It appeared that this was due to mexiletine displacing the tissue binding of lidocaine and reducing its distribution. Mexiletine is an oral lidocaine analogue, so it is perhaps not surprising the two drugs may interact. The combination should be used with caution, especially during the initial stages of treatment. Where possible, lidocaine levels should be closely monitored.

References

**Lidocaine + Omeprazole**

Omeprazole does not appear to alter the pharmacokinetics of intravenous lidocaine.

**Clinical evidence, mechanism, importance and management**

Omeprazole 40 mg daily for one week did not affect the AUC or half-life of lidocaine or its metabolite methylglycinexylidine when a single 1-kg/mg intravenous dose of lidocaine was given to 10 healthy subjects. This study suggests that no special precautions are required during concurrent use.

---

**Lidocaine + Phenytoin**

The incidence of central toxic adverse effects may be increased following the concurrent intravenous infusion of lidocaine and phenytoin. Sinoatrial arrest has been reported in one patient. In patients taking phenytoin, serum lidocaine levels may be slightly reduced when given intravenously, but markedly reduced if given orally.

**Clinical evidence**

(a) Cardiac depression and increased adverse effects

A study in 5 patients with suspected myocardial infarction, given lidocaine 0.5 to 3 mg/minute intravenously for at least 24 hours, followed by additional intravenous injections or infusions of phenytoin, found that plasma levels of both drugs remained unchanged but the incidence of adverse effects (vertigo, nausea, nystagmus, diplopia, impaired hearing) were unusually high.1

Sinoatrial arrest occurred in a man with heart block following a suspected myocardial infarction, after he received intravenous lidocaine 1 mg/kg over 1 minute, followed 3 minutes later by phenytoin 250 mg given over 5 minutes. The patient lost consciousness and his blood pressure could not be measured, but he responded to a 200-microgram dose of isoprenaline (isoprotrenol).2

(b) Serum lidocaine levels

In the study described above,1 intravenous phenytoin had no effect on plasma lidocaine levels during continuous infusion. However, in another study, lidocaine 2 mg/kg was given intravenously to 7 epileptic patients taking their usual anticonvulsants (including phenytoin, barbiturates, pentothersinates, benzodiazepines), and to 6 control subjects. Plasma lidocaine levels were 27 and 43% lower in the epileptic patients at 30 and 60 minutes, respectively.3 Another study found that the clearance of intravenous lidocaine was slightly greater in patients taking anticonvulsants than in healthy subjects (850 compared with 770 mL/minute) but this difference was not statistically significant.4 Other studies in epileptic patients and healthy subjects have shown that phenytoin halves the bioavailability of oral lidocaine.5

**Mechanism**

Phenytoin and lidocaine appear to have additive cardiac depressant actions. The reduced lidocaine serum levels are possibly due to liver enzyme induction; when lidocaine is given orally the marked reduction in levels results from the stimulation of hepatic first-pass metabolism by phenytoin.6,7 In addition, patients taking antiepileptics including phenytoin had higher plasma concentrations of alpha-1-acid glycoprotein, which may result in a lower free fraction of lidocaine in the plasma.8

**Importance and management**

Information is limited and the importance of this interaction is not well established. The case of sinoatrial arrest emphasizes the need to exercise caution when giving two drugs that have cardiac depressant actions.

---

**Lidocaine + Procainamide**

An isolated case of delirium has been described in a patient given intravenous lidocaine with procainamide.

**Clinical evidence, mechanism, importance and management**

A man with paroxysmal tachycardia, treated with oral procainamide 1 g every 5 hours and increasing doses of lidocaine by intravenous infusion (550 mg within 3.5 hours), became restless, noisy and delirious when given a further 250 mg intravenous dose of procainamide. The symptoms disappeared within 20 minutes of discontinuing the lidocaine. The reason is not understood but the symptoms suggest that the neurotoxic effects of the two drugs might be additive. Other studies in patients have shown that lidocaine plasma levels are unaffected by intravenous or oral procainamide.2

---

**Lidocaine + Propafenone**

Propafenone has minimal effects on the pharmacokinetics of intravenous lidocaine, but the severity and duration of the CNS adverse effects of lidocaine are increased.

**Clinical evidence, mechanism, importance and management**

Twelve healthy subjects, who had been taking 225 mg propafenone every 8 hours for 4 days, were given a continuous infusion of lidocaine 2 mg/kg/hour for 22 hours. Propafenone increased the AUC of lidocaine by 7% and reduced the clearance by 7%. One poor metaboliser of propafenone had an increase in lidocaine clearance. Increases in the PR and QRS intervals of 10 to 20% were also seen. Combined use increased the severity and duration of adverse effects (lightheadedness, dizziness, paraesthesia, lethargy, somnolence). One subject withdrew from the study as a result.1 Another study, the combined infusion of lidocaine (100 mg bolus then a 2 mg/minute infusion) and propafenone (1 or 2 mg/kg) produced a minor additional negative inotropic effect (which was not statistically significant) and reversed the prolongation in atrial and ventricular refractoriness produced by propafenone alone.2

There would therefore appear to be no marked or important pharmacokinetic interaction between these two drugs, but the increased CNS adverse effects may be poorly tolerated by some individuals, and cardiac depressive effects may be additive.

Lidocaine + Rifampicin (Rifampin)

Rifampicin may reduce the serum levels of lidocaine given intravenously.

Clinical evidence, mechanism, importance and management

Rifampicin 600 mg daily for 6 days increased the clearance of a 50-mg intravenous dose of lidocaine by 15% in 10 healthy subjects. In addition, plasma concentrations of the lidocaine metabolite monoethylglycinexylidide (MEGX) increased by 34%, although this did not reach statistical significance. Using cultured human hepatocytes it was found that rifampicin increases the metabolism of lidocaine, probably because it induces the cytochrome P450 isoenzyme CYP3A4, which is partially concerned with the metabolism of lidocaine to MEGX. These modest changes in lidocaine pharmacokinetics are unlikely to be of much importance, particularly as the intravenous lidocaine dose is usually titrated to effect.

Lidocaine + Tobacco

Tobacco smoking reduces the bioavailability of oral but not intravenous lidocaine.

Clinical evidence, mechanism, importance and management

A study in healthy subjects found that the bioavailability of oral lidocaine was markedly lower in smokers (mean AUCs of 15.2 and 47.9 micrograms/mL per minute in 4 smokers and 5 non-smokers respectively), but when the lidocaine was given intravenously only moderate differences were seen. The reason for the differences is probably due to liver enzyme induction caused by components of tobacco smoke. With oral lidocaine this could result in increased first-pass hepatic clearance. In the case of intravenous lidocaine, first-pass clearance is bypassed, and the enzyme induction was opposed by a smoking-related decrease in hepatic flow. In practical terms this interaction is unlikely to be of much importance since lidocaine is not usually given orally.

Lidocaine + Tocainide

A report describes a tonic-clonic seizure in a man during the period when his treatment was being changed from intravenous lidocaine to oral tocainide.

Clinical evidence, mechanism, importance and management

An elderly man taking furosemide and co-trimoxazole experienced a tonic-clonic seizure while his treatment with intravenous lidocaine was being changed to oral tocainide, although the serum levels of both antiarrhythmics remained within their therapeutic ranges. The patient became progressively agitated and disorientated about 8 hours after starting oral tocainide 600 mg every 6 hours while still receiving lidocaine 2 mg/minute intravenously. About 1 hour later he had a seizure. The patient subsequently tolerated each drug separately, at concentrations similar to those that preceded the seizure, without problems. A study in animals showed that tocainide reduces the lidocaine serum levels at which seizures occur by about 45%. Tocainide is no longer widely available, but the manufacturer previously noted that concurrent use of lidocaine and tocainide may cause an increased incidence of adverse effects, including CNS adverse reactions such as seizure, since the two drugs have similar pharmacodynamic effects. Great care must therefore be exercised if tocainide is given during lidocaine use.

1. Forrence E, Covinsky JO, Mullen C. A seizure induced by concurrent lidocaine-tocainide therapy — Is it just a case of additive toxicity? Drug Intell Clin Pharm (1986) 20, 56–9.

Mexiletine + Amiodarone

Amiodarone does not affect the clearance of mexiletine. The concurrent use of mexiletine and amiodarone can be clinically useful.

Clinical evidence, mechanism, importance and management

The clearance of mexiletine in 10 patients did not differ before and after 1, 3 and 5 months concurrent use of amiodarone. In addition, the clearance of mexiletine did not differ between these patients and 155 other patients not taking amiodarone. Torsade de points has been described in a patient taking amiodarone and mexiletine (a class Ib antiarrhythmic). The manufacturers of mexiletine say that this seems to be an isolated case.

Class Ib antiarrhythmics are usually associated with shortening of the QT interval, and could therefore be expected to reduce the QT prolongation and risk of torsade de points seen with amiodarone alone. For examples of this effect of mexiletine see also ‘Mexiletine + Beta blockers’, p.268 and ‘Mexiletine + Quinidine’, p.269. However, note that the UK manufacturer of mexiletine says that it may exacerbate arrhythmias as all antiarrhythmics may, but also that it may be used concurrently with amiodarone. The two drugs have been used together successfully.

Mexiletine + Antacids, Atropine or Metoclopramide

The rate of absorption of mexiletine is slowed by the antacid almasilate and atropine or hastened by metoclopramide, but the extent of the absorption in healthy subjects.

Mexiletine + Amiodarone

Amiodarone does not affect the clearance of mexiletine. The concurrent use of mexiletine and amiodarone can be clinically useful.

Clinical evidence, mechanism, importance and management

The clearance of mexiletine in 10 patients did not differ before and after 1, 3 and 5 months concurrent use of amiodarone. In addition, the clearance of mexiletine did not differ between these patients and 155 other patients not taking amiodarone. Torsade de points has been described in a patient taking amiodarone and mexiletine (a class Ib antiarrhythmic). The manufacturers of mexiletine say that this seems to be an isolated case.

Class Ib antiarrhythmics are usually associated with shortening of the QT interval, and could therefore be expected to reduce the QT prolongation and risk of torsade de points seen with amiodarone alone. For examples of this effect of mexiletine see also ‘Mexiletine + Beta blockers’, p.268 and ‘Mexiletine + Quinidine’, p.269. However, note that the UK manufacturer of mexiletine says that it may exacerbate arrhythmias as all antiarrhythmics may, but also that it may be used concurrently with amiodarone. The two drugs have been used together successfully.

Mexiletine + Beta blockers

The concurrent use of mexiletine and beta blockers can be clinically useful. Mexiletine may reduce the QT prolonging effects of sotalol.

Clinical evidence, mechanism, importance and management

A study in 4 patients found that a combination of mexiletine and propranolol 240 mg daily was more effective in blocking ventricular premature depolarisation (VPD) and ventricular tachycardia than mexiletine alone, and did not increase adverse effects. Plasma mexiletine concentrations were not changed significantly by propranolol.1 Similar efficacy was reported for metoprolol with mexiletine.2 Success in decreasing VPDs was noted in 30% of 44 patients taking mexiletine plus a beta blocker (unspecified) compared with only 14% of 185 subjects taking mexiletine alone.3 The UK manufacturer of mexiletine states that it may be used concurrently with beta blockers.4

A study in animals showed that mexiletine reduced the QT prolonging effect of sotalol and reduced the risk of torsade de points.5

Mexiletine + Ciprofloxacin

Ciprofloxacin slightly reduces the clearance of mexiletine, but this is unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

A study in healthy subjects found that the oral clearance of mexiletine was reduced by about 8 to 20% when a single dose was given on day 3 of a 5-day course of ciprofloxacin 750 mg twice daily. This was due to a decrease in the metabolic clearance of mexiletine, presumed to occur as a result of ciprofloxacin-induced inhibition of the cytochrome P450 isoenzyme CYP1A2, which is involved in the metabolism of mexiletine.1 It is unlikely that changes of this magnitude would be clinically relevant.

Mexiletine + Fluconazole

Fluconazole does not affect the pharmacokinetics of mexiletine.

Clinical evidence, mechanism, importance and management

Six healthy subjects were given a single 200-mg dose of mexiletine before and after taking fluconazole 200 mg daily for 7 days. Two of the subjects were given fluconazole 400 mg daily for a further 7 days. No significant changes in the pharmacokinetics of mexiletine were seen.1 The clinical outcome of concurrent use in patients was not studied, but there appear to be no adverse reports in the literature. No special precautions appear to be necessary if these drugs are used concurrently.

Mexiletine + H₂-receptor antagonists

The pharmacokinetics of mexiletine were not altered by cimetidine or ranitidine. Cimetidine can reduce the gastric adverse effects of mexiletine.

Clinical evidence, mechanism, importance and management

The peak and trough plasma mexiletine levels of 11 patients were unaltered when they were given cimetidine 300 mg four times daily for a week, and the frequency and severity of the ventricular arrhythmias for which they were being treated remained unchanged. Moreover the gastric adverse effects of mexiletine were reduced in half of the patients.1 This study in patients confirms the findings of two other studies using cimetidine or ranitidine in healthy subjects.2,3 There would seem to be no problems associated with giving these drugs concurrently, and some advantages.

Mexiletine + Omeprazole

Omeprazole does not appear to affect the pharmacokinetics of mexiletine.

Clinical evidence, mechanism, importance and management

A crossover study in 9 healthy Japanese men found that when they were given mexiletine 200 mg after taking omeprazole 40 mg daily for 8 days, the mexiletine serum concentrations and its AUCs remained unchanged. It was concluded that omeprazole does not affect the metabolism of mexiletine,1 and no special precautions would seem to be needed if these drugs are used concurrently.

Mexiletine + Opioids

The absorption of mexiletine is reduced following myocardial infarction, and very markedly reduced and delayed if diamorphine or morphine is used concurrently. A higher loading dose may be needed if oral mexiletine is required during the first few hours following a myocardial infarction.

Clinical evidence

A pharmacokinetic study showed that the mean plasma levels of mexiletine (400 mg orally followed by 200 mg 2 hours later) in the first 3 hours were more than 50% lower in 6 patients who had suffered a myocardial infarction and who had been given diamorphine 10 to 15 mg than in 4 patients who had not been given opioids. In addition, the AUC₉₀₈ was 38.6% lower in those who had received opioids.1

In a further study about the prophylactic use of mexiletine, the same authors found that plasma mexiletine levels 3 hours after the first oral dose were 31% lower in 10 patients who had received opioids than in 6 patients who had not. These patients were from a subset who were subsequently shown not to have had a myocardial infarction.1 In another similar trial of mexiletine in acute myocardial infarction, use of diamorphine was associated with low plasma mexiletine levels at 3 hours, and possible reduced efficacy of mexiletine. In this study, pretreatment with intravenous metoclopramide tended to reduce the effect of diamorphine on mexiletine absorption,2 although this was not noted in the other report.1

Mechanism

The reduced absorption of mexiletine would seem to result from inhibition of gastric emptying by the opioids. Other mechanisms probably contribute to the delayed clearance of mexiletine.

Importance and management

An established interaction although information is limited. The delay and reduction in the absorption would seem to limit the value of oral mexiletine during the first few hours after a myocardial infarction, particularly if opioid analgesics are used. The manufacturer suggests that a higher load-
ing dose of oral mexiletine may be preferable in this situation. Alternatively, an intravenous dose of mexiletine may be given. In addition, they note that it may be necessary to titrate the dose against therapeutic effects and adverse effects.1

### Mexiletine + Quinidine

The concurrent use of mexiletine and quinidine can be clinically useful. Mexiletine appears to limit the quinidine-induced increase in QT interval. Quinidine raises mexiletine serum levels in extensive metabolisers of cytochrome P450 isoenzyme CYP2D6.

#### Clinical evidence, mechanism, importance and management

Mexiletine and quinidine given concurrently were reported to be more effective than either drug alone, and the incidence of adverse effects was reduced. Mexiletine limited the quinidine-induced increase in QT interval.1 A study in animals concluded that the benefit of combined use may be due to prolonged refractoriness and conduction time in the peri-infarct zone.2 Two studies3,4 in healthy subjects have shown that quinidine reduces the metabolism and excretion of mexiletine in extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6 (total clearance reduced by 24%), but not poor metabolisers. Quinidine is an inhibitor of CYP2D6, and inhibits the metabolism of mexiletine by this pathway. Thus, a pharmacokinetic mechanism may also contribute to the increased efficacy of the combination.4 The UK manufacturer of mexiletine states that it may be used concurrently with quinidine.5 They also note that it may be necessary to reduce the dose of mexiletine when used concurrently with drugs causing inhibition of hepatic enzymes, particularly the cytochrome P450 isoenzymes CYP1A2 and CYP2D6.5

### Mexiletine + Rifampicin (Rifampin)

The clearance of mexiletine is increased by rifampicin. An increase in the dosage of mexiletine may be necessary.

#### Clinical evidence, mechanism, importance and management

After taking rifampicin 600 mg daily for 10 days, the half-life of a single 400-mg dose of mexiletine was reduced by 40% (from 8.5 to 5 hours) and the AUC fell by 39% in 8 healthy subjects.1 The probable reason is that the rifampicin (a known, potent enzyme-inducer) increases the metabolism and clearance of mexiletine. It seems likely that the mexiletine dosage will need to be increased during concurrent use. Monitor concurrent use well.

Mexiletine is also metabolised by CYP2D6 (e.g. see ‘Mexiletine + Propafenone’, p.269). In an in vitro study using human liver microsomes, paroxetine, fluoxetine, and sertraline extensively inhibited the metabolism of mexiletine. Using a model to predict in vivo interactions, it was suggested that both fluoxetine and paroxetine may interact with mexiletine to a clinically relevant extent, whereas sertraline is less likely to interact.2

The UK manufacturer notes that it may be necessary to reduce the dose of mexiletine when used concurrently with drugs causing inhibition of hepatic enzymes, in particular the cytochrome P450 isoenzymes CYP1A2 and CYP2D6,3 which is consistent with the proposed mechanism of the interaction.

Mexiletine + Urinary acidifiers or alkalinisers

Large changes in urinary pH caused by acidifying or alkalinising drugs can have a marked effect on the plasma levels of mexiletine in some patients.

Clinical evidence

In 4 healthy subjects, a single 200-mg intravenous dose of mexiletine was given, once when the urine was acidic (pH 5) after administration of amnomium chloride, and once when the urine was alkaline (pH 8) after administration of sodium bicarbonate. The plasma elimination half-life was significantly shorter when the urine was acidic (2.8 hours) compared with when it was alkaline (8.6 hours). In addition, the percentage of mexiletine excreted unchanged in the urine was 57.5% when acidic and just 0.6% when alkaline.1 Similar results were found in another study.2 A further study in patients with uncontrolled urine pH (range 5.04 to 7.86) given mexiletine orally for 5 days found that the plasma concentration of mexiletine correlated with urine pH. In addition, it was predicted that a normal variation in pH could cause more than a 50% variation in plasma mexiletine levels.3 A later comprehensive pharmacokinetic study in 5 healthy subjects confirmed that renal clearance of mexiletine was 4 mL/minute in alkaline urine (pH 8) compared with 168 mL/minute in acidic urine (pH 5.2). In two subjects, this resulted in an increase in plasma concentrations of 61% and 96%, but in the other three the increase was less than 20%. Non-renal clearance (metabolic clearance) increased in the three subjects with little change in plasma concentrations, but was unaffected in the two with marked changes.4

Mechanism

Mexiletine is a basic drug, and undergoes greater reabsorption by the kidneys when in the non-ionised form in alkaline urine. Mexiletine is also extensively cleared from the body by liver metabolism and only about 10% is excreted unchanged in the urine at physiological pH, although this is variable. Any changes in the renal clearance of mexiletine that occur as a result of urinary pH changes might therefore be expected to be compensated for by an increase in metabolic clearance, but this does not seem to occur in all patients.4

Importance and management

Although changes in urinary pH can affect the amount of mexiletine lost in the urine, the effect of diet or the concurrent use of alkalinisers (sodium bicarbonate, acetazolamide) or acidifiers (ammonium chloride etc.) on the plasma concentrations of mexiletine does not appear to be predictable. There appear to be no reports of adverse interactions but concurrent use should be monitored. The UK manufacturer of mexiletine recommends that the concomitant use of drugs that markedly acidify or alkalinise the urine should be avoided.5

Moracizine + Cimetidine

Cimetidine increases the plasma levels of moracizine but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects cimetidine 300 mg four times daily for 7 days, halved the clearance of a single 500-mg dose of moracizine and increased both its half-life and AUC by 39%. It is believed that this is because the cimetidine reduces moracizine metabolism by the liver.1 Despite the increase in plasma moracizine levels, the PR and QRS intervals were not further prolonged. One possible explanation (so it is postulated) is that some of the metabolites of moracizine, whose production is inhibited by cimetidine, could also be pharmacologically active. Concurrent use should be well monitored, but measuring plasma moracizine levels may be of limited value because of the potential effects of the moracizine metabolites.

Moracizine + Diltiazem

A pharmacokinetic interaction occurs between moracizine and diltiazem resulting in increased systemic availability of moracizine and decreased systemic availability of diltiazem.

Clinical evidence, mechanism, importance and management

After 16 healthy subjects took both diltiazem 60 mg and moracizine 250 mg every 8 hours for 7 days, the maximum plasma concentration of moracizine was increased by 89%, the AUC was increased by 121%, and clearance was decreased by 54%. In contrast, the maximum plasma concentration and AUC of diltiazem decreased by 36% and clearance was increased by 52%. The AUCs for the diltiazem metabolites were not significantly affected. No clinically significant changes in ECG parameters were seen. However, the frequency of adverse events (e.g. headache, dizziness, paraesthesia) was greater on concurrent use (76%) than with either drug alone (54 and 45% for moracizine and diltiazem respectively).1 Diltiazem probably inhibits the hepatic metabolism of moracizine while moracizine increases that of diltiazem. The clinical significance of this interaction is not known. However, particular caution is advised if diltiazem and moracizine are given concurrently, in light of the increase in adverse events. Dose adjustments may also be required to obtain optimum therapeutic responses.1

Moracizine + Propranolol

Moracizine appears not to interact adversely with propranolol.

Clinical evidence, mechanism, importance and management

The efficacy and tolerability of the combination of propranolol and moracizine was compared with either drug alone in patients with ventricular arhythmias in controlled trials. The combination was well tolerated, with no evidence of any adverse interactions, nor any beneficial interactions.
However, the dose of propranolol used was fairly low at 120 mg daily. Further study is needed.

Pirmenol + Cimetidine

Cimetidine 300 mg four times daily for 8 days had no significant effect on the pharmacokinetics of single 150-mg oral doses of pirmenol in 8 healthy subjects. No clinically important interaction would therefore be expected in patients given both drugs.

Pirmenol + Rifampicin (Rifampin)

Rifampicin markedly increases the loss of pirmenol from the body. A reduction in its antiarrhythmic effects is likely to occur.

Clinical evidence, mechanism, importance and management

Treatment with rifampicin 600 mg daily for 14 days markedly affected the pharmacokinetics of a single 150-mg dose of pirmenol in 12 healthy subjects. The apparent plasma clearance increased sevenfold and the AUC decreased by 83%. The probable reason is that rifampicin increases the hepatic metabolism of pirmenol. Monitor well and anticipate the need to increase the dosage of pirmenol if rifampicin is used concurrently.

Procainamide + Amiodarone

When procainamide and amiodarone are used together the QT interval prolonging effects are increased, therefore the combination should generally be avoided. Serum procainamide levels are increased by about 60% and N-acetylprocainamide levels by about 30% by amiodarone. If the combination is used, the dosage of procainamide will need to be reduced to avoid toxicity.

Clinical evidence

Twelve patients were stabilised on procainamide (2 to 6 g daily, or about 900 mg every 6 hours). When amiodarone (600 mg loading dose every 12 hours for 5 to 7 days, then 600 mg daily) was also given their mean serum procainamide levels rose by 57% (from 6.8 to 10.6 micrograms/mL) and their serum levels of the metabolite N-acetylprocainamide (NAPA) rose by 32% (from 6.9 to 9.1 micrograms/mL). Procainamide levels increased by more than 3 micrograms/mL in 6 patients. The increases usually occurred within 24 hours, but in other patients they occurred as late as 4 or 5 days. Toxicity was seen in 2 patients. Despite lowering the procainamide dosages by 20%, serum procainamide levels were still higher (at 7.7 micrograms/mL) than before the amiodarone was started.

In another study, intravenous procainamide was given once before (at a mean dose of 13 mg/kg), and once during (at a 30% reduced dose: mean 9.2 mg/kg) the use of amiodarone 1.6 g daily for 7 to 14 days. Amiodarone decreased the clearance of procainamide by 23% and increased its elimination half-life by 38%. Both drugs prolonged the QRS and QTc intervals, and the extent of prolongation was significantly greater with the combination than either drug alone.

Mechanism

The mechanism behind the pharmacokinetic interaction is not understood. The QT prolonging effects of the two drugs would be expected to be additive.

Importance and management

Information appears to be limited to these studies, but the interaction would seem to be established and clinically important. The use of amiodarone with procainamide further prolongs the QTc interval, which can increase the risk of torsade de pointes. Therefore, the combination should generally be avoided. The UK manufacturers of amiodarone contraindicate its use with class la antiarrhythmics such as procainamide, whereas the US manufacturers of amiodarone recommend that such combined therapy should be reserved for life-threatening ventricular arrhythmias incompletely responsive to either drug alone and recommend that the procainamide dosage should be reduced by one-third. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257. This is similar to the recommendation made by the authors of the pharmacokinetic studies, who suggest that the dosage of procainamide may need to be reduced by 20 to 50%. They also suggest that serum levels should be monitored and patients observed for adverse effects. Remember that the interaction can develop within 24 hours.

Procainamide + Antacids or Antidiarrhoeals

There is some inconclusive evidence that aluminium phosphate may possibly cause a small reduction in the absorption of procainamide. Kaolin-pectin appears to reduce the bioavailability of procainamide.

Clinical evidence, mechanism, importance and management

A single 11-g dose of an aluminium phosphate antacid modestly reduced the AUC of a single 750-mg oral dose of procainamide by 14.6%. The clinical importance of this interaction is uncertain, but probably small. Kaolin-pectin was found to reduce the peak salvia concentrations and AUC of a single 250-mg dose of procainamide by about 30% in 4 healthy subjects. Kaolin-pectin and a variety of antacids (Pepto-bismol, Simec® and magnesium trisilicate) absorbed procainamide in vitro. The clinical importance of this is also uncertain.

Procainamide + Beta blockers

The pharmacokinetics of procainamide are little changed by either propranolol or metoprolol. Both sotalol and procainamide have QT-interval prolonging effects, which may be additive if they are used together.

Clinical evidence, mechanism, importance and management

Preliminary results of a study in 6 healthy subjects found that long-term treatment with propranolol [period and dosage not stated] increased the procainamide half-life from 1.71 to 2.66 hours and reduced the plasma clearance by 16%. However, a later study in 8 healthy subjects found that the pharmacokinetics of a single 500-mg dose of procainamide were only slightly altered by propranolol 80 mg three times daily or metoprolol 100 mg twice daily. The procainamide half-life of 1.9 hours increased to 2.2 hours with propranolol, and to 2.3 hours with metoprolol, but no significant changes in total clearance occurred. No changes in the AUC of the metabolite N-acetylprocainamide were seen. It seems unlikely that a clinically important adverse interaction normally occurs between these drugs.

A clinical study describes the successful use of procainamide with sotalol. However, both sotalol and procainamide can prolong the QT interval, and there may be an increased risk of torsade de pointes arrhythmias if...
they are used together. See also ‘Drugs that prolong the QT interval’ or Other drugs that prolong the QT interval’, p.257.

**Procainamide + H2-receptor antagonists**

**Serum procainamide levels can be increased by cimetidine and toxicity may develop, particularly in those who have a reduced renal clearance, such as the elderly. Ranitidine and famotidine appear to interact only minimally or not at all.**

**Clinical evidence**

(a) Cimetidine

In one study, 36 elderly patients (65 to 90 years old) taking sustained-release oral procainamide every 6 hours had rises in mean steady-state serum levels of procainamide and its metabolite N-acetylprocainamide of 55 and 36% respectively, after taking cimetidine 300 mg every 6 hours for 3 days. This was tolerated in 24 patients without adverse effects (se- rum procainamide and N-acetylprocainamide less than 12 mg/L and less than 15 mg/L respectively) but the other 12 had some adverse effects (nausea, weakness, malaise PR interval increases of less than 20%), which was dealt with by stopping one or both drugs. Another report describes an elderly man who developed procainamide toxicity when given cimetidine 1.2 g daily. His procainamide dosage was roughly halved (from 937.5 to 500 mg every 6 hours) to bring his serum procainamide and N-acetylprocainamide levels into the accepted therapeutic range.

Four studies in healthy subjects have found that cimetidine increased the procainamide AUC by 24 to 43%, and decreased the renal clearance by 55 and 36% respectively, after taking cimetidine 300 mg every 6 hours for 3 days. This was tolerated in 24 patients without adverse effects (serum procainamide and N-acetylprocainamide less than 12 mg/L and less than 15 mg/L respectively) but the other 12 had some adverse effects (nausea, weakness, malaise PR interval increases of less than 20%), which was dealt with by stopping one or both drugs. Another report describes an elderly man who developed procainamide toxicity when given cimetidine 1.2 g daily. His procainamide dosage was roughly halved (from 937.5 to 500 mg every 6 hours) to bring his serum procainamide and N-acetylprocainamide levels into the accepted therapeutic range. They found that PABA may in fact not be useful for increasing the efficacy and safety of procainamide.

(b) Famotidine

Famotidine 40 mg daily for 5 days did not affect the pharmacokinetics or pharmacodynamics of a single 5-mg/kg intravenous dose of procainamide in 8 healthy subjects.

(c) Ranitidine

One study found that ranitidine 150 mg twice daily for one day reduced the absorption of procainamide from the gut by 10% and reduced its renal excretion by 19%, increasing the procainamide and N-acetylprocainamide AUC by about 14%. However, no change in the steady-state pharmacokinetics of procainamide was found with ranitidine 150 mg twice daily in another study, except that ranitidine delayed the time to maximum plasma concentration (from 1.4 to 2.7 hours). In a further study, ranitidine 150 mg twice daily for 4 days caused no significant changes in the mean pharmacokinetics of oral procainamide 1 g in 13 healthy subjects. However, it appeared that subjects had either a modest 20% increase or decrease in procainamide clearance, with the direction of change related to their baseline procainamide clearance: the higher the baseline clearance the greater the decrease caused by ranitidine.

**Mechanism**

Procainamide levels in the body are increased because cimetidine reduces its renal excretion by about one-third or more, but the precise mechanism is uncertain. One suggestion is that it interferes with the active secretion of procainamide by the kidney tubules.

**Importance and management**

The interaction between procainamide and cimetidine is established. Concurrent use should be undertaken with care because the safety margin of procainamide is low. Reduce the procainamide dosage as necessary. This is particularly important in the elderly because they have a reduced ability to clear both drugs. Ranitidine and famotidine appear not to interact to a clinically important extent, but it should be appreciated that what is known is based on studies in healthy subjects rather than patients.

**Procainamide + Para-aminobenzoic acid (PABA)**

A single case report found that para-aminobenzoic acid (PABA) increased the serum levels of procainamide and reduced the serum levels of the procainamide metabolite N-acetylprocainamide. In contrast, a later pharmacokinetic study in healthy subjects found that PABA had no effect on serum procainamide levels, and increased serum N-acetylprocainamide levels.

**Clinical evidence, mechanism, importance and management**

A 61-year-old man who had sustained ventricular tachycardia, which did not respond adequately to oral procainamide, was found to be a fast N-acetylator of procainamide, which resulted in particularly high serum levels of the procainamide metabolite N-acetylprocainamide when compared with the procainamide levels. When he was also given para-aminobenzoic acid (PABA) 1.5 g every 6 hours for 30 hours, to suppress the production of this metabolite, the serum level of procainamide increased, that of N-acetylprocainamide decreased, and control of his arrhythmia improved. However, a later study in 10 healthy subjects, who were also fast acetylators, found that PABA did not significantly affect the pharmacokinetics of procainamide. In addition, although PABA inhibited the production of N-acetylprocainamide, it also inhibited renal excretion, so that the AUC and elimination half-life were increased. This suggests that PABA may in fact not be useful for increasing the efficacy and safety of procainamide.

These contradictory findings are difficult to explain, but neither report suggests that concurrent use need be avoided.

**Procainamide + Probenecid**

The pharmacokinetics of a single 750-mg intravenous dose of procainamide and its effects on the QT interval were not altered by the prior administration of probenecid 2 g in 6 healthy subjects. No special precautions appear to be necessary.

**Procainamide + Quinidine**

A single case report describes a marked increase in the plasma procainamide levels of a patient when he was also given quinidine. The combination prolongs the QT interval, and should generally be avoided because of the increased risk of torsade de points.
Clinical evidence

A man with sustained ventricular tachycardia taking high-dose intravenous procainamide 2 g every 8 hours had a 70% increase in his steady-state plasma procainamide levels, from 9.1 to 15.4 nanograms/mL, when he also took quinidine gluconate 324 mg every 8 hours. The procainamide half-life increased from 3.7 to 7.2 hours and its clearance fell from 27 to 16 L/hour. His QTc interval increased from 648 to 678 milliseconds.1 In another study in patients with ventricular arrhythmias, quinidine was combined with procainamide. The doses were adjusted based in part on the QT interval. The QTc interval was longer with the combination (499 milliseconds) than each drug alone (quinidine 470 milliseconds, procainamide 460 milliseconds) despite using reduced doses in the combination (mean quinidine dose reduced by 28%; mean procainamide dose reduced by 32%).

Mechanism

It has been suggested that the quinidine interferes with one or more of the renal pathways by which procainamide is cleared from the body.1

Importance and management

Information on the possible pharmacokinetic interaction seems to be limited to this report. Both quinidine and procainamide are class la antiarrhythmics and prolong the QT interval, an effect that is increased with the combination. Such combinations should generally be avoided because of the increased risk of torsade de pointes. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.237.

### Procainamide + Quinolones

**Ofloxacin and levofloxacin cause moderate increases in the serum levels of procainamide, whereas ciprofloxacin has a lesser effect. However, the ECG appears to be unaltered in studies in healthy subjects given these quinolones with procainamide. An increased risk of torsade de pointes would be expected if procainamide is used with gatifloxacin, moxifloxacin, or sparfloxacin, and possibly levofloxacin.**

**Clinical evidence**

Nine healthy subjects were given a single 1-g oral dose of procainamide alone, then again with the fifth dose of ofloxacin (400 mg given twice daily for five doses). Ofloxacin increased the AUC of procainamide by 27%, increased the maximum plasma levels by 21% (from 4.8 to 5.8 micrograms/L) and reduced the total clearance by 22%, whereas the pharmacokinetics of the active metabolite of procainamide (N-acetylpicainamide) were not significantly altered.1 In another study 10 healthy subjects were given levofloxacin 500 mg once daily or ciprofloxacin 500 mg twice daily and a single 15-mg/kg intravenous dose of procainamide on day 5. Levofloxacin increased the AUC of procainamide by 21% and prolonged the half-life by about 19% (from 2.7 to 3.2 hours). The clearance of procainamide was reduced by 17% (range 4 to 46%) with renal clearance reduced by 26% (range 11 to 58%) by levofloxacin. The pharmacokinetics of N-acetylpicainamide were similarly affected. Ciprofloxacin caused only minor changes in procainamide and N-acetylpicainamide pharmacokinetics, although the renal clearance of procainamide was reduced by 15% (range 3 to 26%).

Despite the pharmacokinetic changes, no ECG changes were detected. However, these studies1,2 involved only single doses of procainamide with average maximum serum levels (about 4 to 6 micrograms/mL) in the lower end of the therapeutic range for procainamide, although in one study individual levels of up to 8.5 micrograms/mL were found.

One case of torsade de pointes was noted in a patient taking procainamide with a quinolone [unspecified] in an analysis of cases of torsade de pointes associated with quinolones on the FDA Adverse Events Reporting System database up to May 2001. The quinolones included were ciprofloxacin, ofloxacin, levofloxacin, gatifloxacin, and moxifloxacin, and in total there were 37 cases identified, of which 19 occurred in patients also taking other drugs known to prolong the QT interval.2

**Mechanism**

The probable reason for the interaction is that levofloxacin, ofloxacin and to a lesser extent ciprofloxacin, inhibit the secretion of unchanged procainamide by the kidney tubules via renal drug transporters. Levofloxacin also appears to inhibit the secretion of N-acetylpicainamide.

**Importance and management**

These results suggest that ofloxacin and levofloxacin interact to a modest extent and ciprofloxacin to a lesser extent with procainamide. The large interpatient variation found in these studies suggests it is possible that many patients will not experience a clinically significant interaction. However, in slow acetylators, in whom renal clearance contributes to a larger fraction of total clearance, and those on higher doses of procainamide (serum levels greater than 10 micrograms/mL), the use of quinolones could result in pharmacodynamic changes. Therefore, it would be prudent to monitor the outcome if procainamide and ofloxacin or ciprofloxacin are given together in patients. Monitoring has been recommended if procainamide is given with levofloxacin.2 However, as there is also evidence that levofloxacin may prolong the QT interval (see ‘Amiodarone + Quinolones’, p.249) it may be best to avoid concurrent use of this quinolone and procainamide.

Of the quinolones used clinically, gatifloxacin, moxifloxacin, and sparfloxacin are known to prolong the QT interval (see ‘Table 9.2’, (p.257)) and would be expected to increase the risk of torsade de pointes arrhythmias when used with procainamide. These quinolones should probably be avoided in patients on procainamide (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257).

**Procainamide + Sucralfate**

Sucralfate does not appear to affect the absorption of procainamide.

**Clinical evidence, mechanism, importance and management**

In 4 healthy subjects sucralfate 1 g taken 30 minutes before a single 250-mg dose of procainamide reduced the mean maximum salivary level of procainamide by 5.3%, but did not significantly affect either the AUC or the rate of absorption.1 These results suggest that a clinically significant interaction is unlikely.

**Procainamide + Trimethoprim**

Trimethoprim causes a marked increase in the plasma levels of procainamide and its active metabolite, N-acetylpicainamide, which increases the risk of toxicity.

**Clinical evidence**

Eight healthy subjects were given procainamide 500 mg every 6 hours for 3 days. The concurrent use of trimethoprim 200 mg daily increased the AUC0-12 of procainamide and its active metabolite, N-acetylpicainamide (NAPA), by 63% and 51%, respectively. The renal clearance of procainamide and NAPA decreased by 47% and 13%, respectively. The QTc prolonging effects of procainamide were increased to a significant, but slight, extent by trimethoprim.1 Another study found that trimethoprim 200 mg
daily reduced the renal clearance of a single 1-g dose of procainamide by 45% and of NAPA by 26%. The QTc interval was increased from 400 to 430 milliseconds.  

Mechanism

Trimethoprim decreases the renal clearance of both procainamide and its active metabolite by competing for active tubular secretion. It may also cause a small increase in the conversion of procainamide to N-acetyprocainamide.  

Importance and management

An established interaction but its documentation is limited. The need to reduce the procainamide dosage should be anticipated if trimethoprim is given to patients already controlled on procainamide. In practice the effects may be greater than the studies cited suggest because the elderly lose procainamide through the kidneys more slowly than young healthy subjects. Remember too that the daily dosage of trimethoprim in co-trimoxazole (trimethoprim 160 mg with sulfamethoxazole 800 mg) may equal or exceed the dosages used in the studies cited.  

Propafenone + Barbiturates

Phenobarbital increases the metabolism of propafenone and reduces its serum levels.  

Clinical evidence, mechanism, importance and management

In a preliminary report of a study in 7 non-smoking subjects who were fast metabolisers of propafenone, phenobarbital 100 mg daily for 3 weeks reduced the levels of a single 300-mg dose of propafenone by 26 to 87% and the AUC by 10 to 89%. The intrinsic clearance increased by 11 to 84%. The results in a further 4 heavy smokers were similar.  

Propafenone + Cimetidine

Cimetidine appears to interact minimally with propafenone.  

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects (10 extensive metabolisers and 2 poor metabolisers of propafenone) given propafenone 225 mg every 8 hours found that the concurrent use of cimetidine 400 mg every 8 hours caused some changes in the pharmacokinetics and pharmacodynamics of the propafenone, with wide intersubject variability. Raised mean peak and steady-state plasma levels were seen (24 and 22%, respectively), but these did not reach statistical significance. A slight increase in the QRS duration also occurred. However, none of the changes were considered clinically important.  

Propafenone + Erythromycin

Limited evidence suggests that erythromycin may inhibit the metabolism of propafenone.  

Clinical evidence, mechanism, importance and management

The preliminary results of a study in 12 healthy subjects given a single 300-mg dose of propafenone with or without erythromycin 250 mg showed that the increase in propafenone AUC with erythromycin was greater in those with lower cytochrome P450 isoenzyme CYP2D6 activity. It was suggested that low CYP2D6 activity shifts propafenone metabolism to the CYP3A4/1A2-mediated N-depropylpropafenone pathway increasing the interaction with erythromycin, which is an inhibitor of CYP3A4. This appears to be the only documentation of a possible interaction with erythromycin and its clinical significance is not certain. More study is needed.  

Propafenone + Grapefruit juice

Limited evidence suggests that grapefruit juice may inhibit the metabolism of propafenone.  

Clinical evidence, mechanism, importance and management

Preliminary results of a study in 12 healthy subjects given a single 300-mg dose of propafenone with or without 250 mL of grapefruit juice showed that the increase in propafenone AUC with grapefruit juice was greater in those with lower cytochrome P450 isoenzyme CYP2D6 activity. It was suggested that in the presence of low CYP2D6 activity a greater proportion of propafenone is eliminated by metabolism by CYP3A4 and CYP1A2 and the effect of grapefruit juice is increased since it is an inhibitor of CYP3A4. The clinical significance of this finding is not certain. Further study is needed.  

Propafenone + Ketoconazole

An isolated case report describes a man taking propafenone who had a seizure two days after taking a dose of ketoconazole. Limited evidence suggests ketoconazole may inhibit the metabolism of propafenone.  

Clinical evidence

A man who had been taking captopril and hydrochlorothiazide for 6 years and propafenone 300 mg daily for 4 years, without problems, and without any history of convulsive episodes, experienced a tonic-clonic seizure while watching television. It was later found that he had started to take two capsules of ketoconazole daily 2 days previously for the treatment of a candidal infection. The preliminary results of another study in 12 healthy subjects given a single 300-mg dose of propafenone with or without ketoconazole 200 mg found that the increase in propafenone AUC with ketoconazole was greater in those with lower cytochrome P450 isoenzyme CYP2D6 activity.  

Mechanism

The authors of the case report postulate that the ketoconazole may have inhibited the metabolism of the propafenone so that this patient, in effect, may have developed an overdose. However, convulsions with propafenone, even in overdose, are extremely rare. Ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which propafenone is metabolised to N-depropylpropafenone. Propafenone is also extensively metabolised by CYP2D6 to 5-hydroxypropafenone but it was suggested that if CYP2D6 activity is low, propafenone metabolism may be shifted to the CYP3A4 pathway increasing the possibility of an interaction with ketoconazole. The manufacturer states that drugs that inhibit CYP2D6 and CYP3A4, such as ketoconazole, might lead to increased levels of propafenone.  

Importance and management

The general importance of this interaction is uncertain. As of 2006, there had been no other cases reported to the manufacturer of propafenone.  

References

available data suggest that an interaction can occur, it would seem prudent to keep this interaction in mind during concurrent use. There seems to be nothing documented about the effects of other azole antifungals.

Propafenone + Quinidine

Quinidine doubles the plasma levels of propafenone and halves the levels of its active metabolite in CYP2D6 extensive metabolisers. This interaction has been utilised clinically.

Clinical evidence

Nine patients taking propafenone for frequent isolated ventricular ectopic beats, firstly had their dosage reduced to 150 mg every 8 hours and then 4 days later the steady-state pharmacokinetics of propafenone were determined at this new dose. Quinidine was then added at a dose of 50 mg every 8 hours, and after a further 4 days the steady-state plasma propafenone levels in 7 CYP2D6 extensive metabolisers had more than doubled from 408 to 1100 nanograms/mL, and 5-hydroxypropafenone concentrations had approximately halved, but the ECG intervals and arrhythmia frequency were unaltered. The steady-state plasma propafenone levels remained unchanged in the other 2 patients with low levels of CYP2D6 (‘poor’ metabolisers).1 Consider ‘Genetic factors’, (p.4), for more information on metaboliser status. The same research group conducted a similar study in healthy subjects, which confirmed that quinidine increased the plasma levels of propafenone in ‘extensive’ but not ‘poor’ metabolisers. In addition, it was found that quinidine increased the extent of the beta-blockade caused by the propafenone in ‘extensive’ metabolisers to approach that seen in ‘poor’ metabolisers.2 Another study has shown that the inhibition of propafenone metabolism by low-dose quinidine also occurs in Chinese as well as Caucasian patients.3 [CYP2D6 shows pronounced interethnic differences in expression.] A further study showed that combining low-dose quinidine (150 mg daily) with standard dose propafenone in patients with atrial fibrillation resulted in a similar control of the arrhythmia as increasing the propafenone dose, but caused less gastrointestinal adverse effects.4

Mechanism

Quinidine inhibits the CYP2D6-dependent 5-hydroxylolation of propafenone by the liver in those who are ‘extensive’ metabolisers so that it is cleared more slowly. Its plasma levels are doubled as a result, but the over-all antiarrhythmic effects remain effectively unchanged, possibly because the production of its active antiarrhythmic metabolite (5-hydroxypropafenone) is simultaneously halved.1 Quinidine increases the beta-blocking effects of propafenone in extensive metabolisers because only the parent drug, and not the metabolites, has beta-blocking activity.2

Importance and management

Quinidine appears to raise propafenone levels, and may also affect the beta-blocking properties of propafenone in some patients. In one study the concurrent use of propafenone and quinidine was said to have an effect similar to increasing the propafenone dose.4 The importance of CYP2D6 metaboliser status is unclear, and more study is needed to clarify this.

Propafenone + Rifampicin (Rifampin)

Propafenone serum levels and therapeutic effects can be markedly reduced by rifampicin.

Clinical evidence

A man with ventricular arrhythmias successfully treated with propafenone had a marked fall in his plasma propafenone level from 993 to 176 nanograms/mL within 12 days of starting to take rifampicin 450 mg twice daily. Levels of the two active metabolites of propafenone, 5-hydroxypropafenone and N-depropylpropafenone, changed from 195 to 64 nanograms/mL and from 110 to 192 nanograms/mL, respectively. His arrhythmias returned, but 2 weeks after stopping the rifampicin his arrhythmias had disappeared and the propafenone and its 5-hydroxy and N-depropyl metabolites had returned to unreatable levels (1411, 78 and 158 nanograms/mL respectively).1 In a study in young healthy subjects, rifampicin 600 mg daily for 9 days reduced the bioavailability of a single 300-mg oral dose of propafenone from 30 to 10% in CYP2D6 extensive metabolisers, and from 81 to 48% in those with low levels of CYP2D6 (‘poor’ metabolisers). Consider ‘Genetic factors’, (p.4), for more information on metaboliser status. QRS prolongation decreased during enzyme induction. In contrast, in this study, rifampicin had no substantial effect on the pharmacokinetics of propafenone given intravenously.2 Similar findings were reported in a further study by the same research group in healthy elderly subjects.3

Mechanism

Rifampicin induces the CYP3A4/1A2-mediated metabolism and phase II glucuronidation of propafenone. The effect of rifampicin on gastrointestinal clearance of propafenone was greater than that of its hepatic clearance. Rifampicin had no effect on CYP2D6-mediated metabolism of propafenone (the usual main metabolic route in ‘extensive’ metabolisers).1,2,3

Importance and management

An established and clinically relevant metabolic drug interaction. The dosage of oral propafenone will need increasing during concurrent use of rifampicin.4 Alternatively, if possible, the authors of the case report1 advise the use of another antibacterial, where possible, because of the probable difficulty in adjusting the propafenone dosage.

Propafenone + SSRIs

Fluoxetine markedly inhibits the metabolism of propafenone by 5-hydroxylation, and paroxetine would be expected to behave similarly, but the clinical consequences of this are unknown. Fluvoxamine would be expected to inhibit the metabolism of propafenone by N-dealkylation. Sertraline, citalopram (and probably escitalopram) would not be expected to interact to a significant extent.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects fluoxetine 20 mg daily for 10 days decreased the oral clearance of a single 400-mg dose of propafenone by 34% for both the R- and S-enantiomers. The peak plasma levels increased by 39% for S-propafenone and by 71% for R-propafenone. However, there were no differences in the changes to the PR and QRS intervals.1 Fluoxetine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, which is responsible for the metabolism of propafenone to its primary active metabolite 5-hydroxypropafenone (for more detail see mechanism under ‘Propafenone + Quinidine’, above). In vitro data have shown that, of the SSRIs, fluoxetine is the most potent inhibitor of propafenone 5-hydroxylation, and that paroxetine would also be expected to interact.2 As with
'quinidine', (p.275), inhibition of 5-hydroxylation would be expected to increase the beta-blocking effects of propafenone.\textsuperscript{2} Until more is known, it would be prudent to use caution when giving fluoxetine or paroxetine with propafenone. Sertraline and citalopram did not interact in vitro.\textsuperscript{2} Similarly, escitalopram would not be expected to interact significantly because evidence with other drugs (‘desipramine’, (p.1241) and ‘metoprolol’, (p.855)) suggest that escitalopram has only a modest inhibitory effect on CYP2D6. However, the manufacturers\textsuperscript{3} still warn about a possible interaction with propafenone.

Although fluvoxamine had no effect on propafenone 5-hydroxylation \textit{in vitro};\textsuperscript{2} it did inhibit propafenone N-dealkylation\textsuperscript{2} via its inhibitory effects on the cytochrome P450 isoenzyme CYP1A2. This isoenzyme has only a minor role in the metabolism of propafenone, but it may assume greater importance in those who have low levels of CYP2D6 (‘poor’ metabolisers).\textsuperscript{2} Further study is needed.

The QT interval prolonging effects of quinidine and amiodarone

\section*{Clinical evidence}

Eleven patients were stabilised on quinidine (daily doses of 1.2 to 4.2 g). When they were also given amiodarone (600 mg every 12 hours for 5 to 7 days, then 600 mg daily) their mean serum quinidine levels rose by an average of 32\%, from 4.4 to 5.8 micrograms/mL and 3 of them had a substantial increase of 2 micrograms/mL. Signs of toxicity (diarrhoea, nausea, vomiting, hypotension) were seen in some, and the quinidine dosage was reduced in 9 of the patients by an average of 37\%. Despite the dose reduction, the quinidine serum levels were still higher at 5.2 micrograms/mL than before the amiodarone was started.\textsuperscript{1}

A test in a healthy subject showed that 3 days after amiodarone 600 mg was added to quinidine 1.2 g daily, the serum quinidine levels doubled and the relative QT interval was prolonged from 1 (no drugs) to 1.2 (quinidine alone) to 1.4 (quinidine plus amiodarone).\textsuperscript{2} This report also described two patients with minor cardiac arrhythmias who developed QT prolongation and torsade de points when given both drugs.\textsuperscript{2} A Russian study of the use of the combination in atrial fibrillation reported that one of 52 patients had a 50\% increase in the QT interval resulting in torsade de pointes and subsequently ventricular fibrillation, which required repeated defibrillation over 6 hours.\textsuperscript{1} A 76-year-old man taking quinidine and amiodarone had a number of episodes of loss of consciousness, and subsequently QT prolongation and torsade de points, which stopped when the quinidine was discontinued.\textsuperscript{4}

\section*{Mechanism}

The mechanism behind the pharmacokinetic interaction is not understood. The QT prolonging effects of the two drugs would be expected to be additive.

\section*{Importance and management}

An established and clinically important pharmacokinetic and pharmacodynamic interaction. The use of amiodarone with quinidine further prolongs the QT interval and increases the risk of torsade de pointes. Therefore, the combination should generally be avoided. The UK manufacturer of amiodarone contraindicates its use with class Ia antiarrhythmics such as quinidine.\textsuperscript{3} See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257. The pharmacokinetic component appears to occur in most patients, and to develop rapidly. The US manufacturer\textsuperscript{4} of amiodarone considers such combination therapy should be reserved for life-threatening ventricular arrhythmias incompletely responsive to either drug alone and recommend that the dose of quinidine should be reduced by one-third. Others suggest that if the two drugs are considered essential, the dosage of quinidine should be reduced by about 30 to 50\% and the serum levels should be monitored.\textsuperscript{1} The ECG should also be monitored for evidence of changes in the QT interval when combined therapy is started or stopped.\textsuperscript{4} Successful and uneventful continued use has been described in a report of 4 patients taking quinidine [dose not stated] and amiodarone 200 mg five times weekly.\textsuperscript{5} Another describes the successful use of a short course of quinidine to convert chronic atrial fibrillation to sinus rhythm in 9 of 15 patients on long-term amiodarone therapy. Patients were hospitalised and continuously monitored. No proarrhythmias occurred and the QT interval remained within acceptable limits.\textsuperscript{3}

\section*{Quinidine + Amiloride}

A single study has shown that the antiarrhythmic activity of quinidine can be opposed by amiloride.

\section*{Clinical evidence}

A study in 10 patients with inducible sustained ventricular tachycardia was carried out to see whether a beneficial interaction occurred between quinidine and amiloride. Patients were given oral quinidine until their trough serum levels reached 10 micromol/L, or the maximum well-tolerated dose was reached. After electrophysiological studies, oral amiloride was added at a dosage of 5 mg twice daily, increased up to 10 mg twice daily (if serum potassium levels remained normal) for 3 days. The electrophysiological studies were then repeated. Unexpectedly, 7 of the 10 patients demonstrated adverse responses while taking both drugs. Three developed sustained ventricular tachycardia and 3 others had somatic adverse effects (hypotension, nausea, diarrhoea), which prevented further studies being carried out. One patient had 12 episodes of sustained ventricular tachycardia while taking both drugs. Amiloride had no effect on quinidine levels.\textsuperscript{1}

\section*{Mechanism}

Not understood. The combination of quinidine and amiloride increased the QRS interval, but did not prolong the QT interval more than quinidine alone.

\section*{Importance and management}

So far the evidence seems to be limited to this single study but it suggests that amiloride can oppose the antiarrhythmic activity of quinidine. The full clinical implications of this interaction are not yet known, but it would now clearly be prudent to consider monitoring to confirm that the quinidine continues to be effective if amiloride is present.

\section*{Quinidine + Amiodarone}

The QT interval prolonging effects of quinidine and amiodarone are increased when they are used together, and torsade de pointes has occurred. Therefore the combination should generally be avoided. However, if the combination is used, note that amiodarone increases quinidine levels and dosage reductions are likely to be needed.
Quinidine + Antacids or Urinary alkalinisers

Large rises in urinary pH due to the concurrent use of some antacids, diuretics or alkaline salts can cause quinidine retention, which could lead to quinidine toxicity, but there seems to be only one case on record of an adverse interaction (with an aluminium/magnesium hydroxide antacid). Aluminium hydroxide alone appears not to interact.

Clinical evidence

The renal clearance of oral quinidine in 4 subjects taking 200 mg every 6 hours was reduced by an average of 50% (from 53 to 26 mL/minute) when their urine was made alkaline (i.e. changed from pH 6 to 7, up to pH 7 to 8) with sodium bicarbonate and acetazolamide 500 mg twice daily. Below pH 6 their urinary quinidine level averaged 115 mg/L, whereas when urinary pH values rose above 7.5 the average quinidine level fell to 13 mg/L. The quinidine urinary excretion rate decreased from 103 to 31 micrograms/minute. In 6 other subjects the rise in quinidine levels was reflected in a prolongation of the QT interval. Raising the urinary pH from about 6 to 7.5 in one individual increased serum quinidine levels from about 1.6 to 2.6 micrograms/mL.1

A patient on quinidine who took eight Mylanta tablets daily (aluminium hydroxide gel 200 mg, magnesium hydroxide 200 mg and simeticone 20 mg) for a week and a little over 1 litre of fruit juice (orange and grapefruit) each day developed a threefold increase in serum quinidine levels (from 8 to 25 mg/L) and toxicity. However, note that the ‘grapefruit juice’, (p.280) may have contributed. In 6 healthy subjects, this dose of Mylanta for 3 days produced consistently alkaline urine in 4 subjects, and in 5 subjects when combined with fruit juice.2

In 4 healthy subjects, 30 mL of aluminium hydroxide gel (Amphogel) given with, and one hour after, a single 200-mg dose of quinidine sulphate had no effect on serum quinidine levels, AUC or excretion (urine pH ranged from 5 to 6.2).3 Two similar single-dose studies in healthy subjects found that the absorption and elimination of 400 mg of quinidine sulphate4 or 648 mg of quinidine gluconate5 was unaffected by 30 mL aluminium hydroxide gel, although the change in quinidine AUC did vary from a decrease of 18% to an increase of 35% in one study.6 Urinary pH was unaffected in both studies.4,5

Mechanism

Quinidine is excreted unchanged in the urine. In acid urine much of the quinidine excreted by the kidney tubules is in the ionised (lipid-insoluble) form, which is unable to diffuse freely back into the cells and so is lost in the urine. In alkaline urine more of the quinidine is in the non-ionised (lipid-soluble) form, which freely diffuses back into the cells and is retained. In this way the pH of the urine determines how much quinidine is lost or retained and thereby governs the serum levels. In vitro data suggest that changes in pH and adsorption effects within the gut due to antacids could also affect the absorption of quinidine.5,7

Importance and management

An established interaction, but with the exception of the one isolated case cited,2 there seem to be no reports of problems in patients given quinidine and antacids or urinary alkalinisers. However, in this case quinidine was given with grapefruit juice, which may potentially have had an effect of its own, see ‘Quinidine + Grapefruit juice’, p.280. Nevertheless you should monitor the effects if drugs that can markedly change urinary pH are started or stopped. Reduce the quinidine dosage as necessary.

It is difficult to predict which antacids, if any, are likely to increase the serum levels of quinidine. As noted above, aluminium hydroxide gel and magnesium hydroxide (Mylanta) alkalinises urine and can interact. Similarly, magnesium and aluminium hydroxide (Maalox) can raise the urinary pH by about 0.9 and possibly interact.8 Magnesium hydroxide (Milk of magnesia) and calcium carbonate-glycine (Titralac) in normal doses raise the urinary pH by about 0.5, so that a smaller effect is likely.8 Aluminium hydroxide gel (Amphogel) and dihydroxylaluminium glycinate (Rosalate) are reported to have no effect on urinary pH,9 and the studies above confirm aluminium hydroxide gel does not generally interact.

Quinidine + Antiepileptics

Serum quinidine levels can be reduced by phenytoin, phenobarbital or primidone. Loss of arrhythmia control is possible if the quinidine dosage is not increased.

Clinical evidence

A man taking long-term primidone 500 mg daily was given quinidine 300 mg every 4 hours, but only attained a plasma quinidine level of 0.8 micrograms/mL with an estimated half-life of 5 hours. When primidone was discontinued, his quinidine level rose to 2.4 micrograms/mL and the half-life was 12 hours. Phenobarbital 90 mg daily was then started, and the quinidine level fell to 1.6 micrograms/mL with a half-life of 7.6 hours. In another case, a woman required doses of quinidine sulfate of up to 800 mg every 4 hours to achieve therapeutic levels while taking phenytoin. When the phenytoin was stopped, quinidine toxicity occurred, and the dose was eventually halved. Further study was then made in 4 healthy subjects. After 4 weeks of treatment with either phenytoin (in dosages adjusted to give levels of 10 to 20 micrograms/mL) or phenobarbital, the elimination half-life of a single 300-mg dose of quinidine sulphate was reduced by about 50% and the total AUC was reduced by about 60%.1

Similar results were found with phenytoin in another study in 3 healthy subjects.2 Other cases have also been reported with phenytoin, primidone, pentobarbital and phenobarbital.3-5 In one case, quinidine levels fell by 44% when phenytoin was given with quinidine to a patient with a recurrent ventricular tachycardia.4 In another report quinidine levels increased from a mean of 0.8 to 2.2 micrograms/mL 15 days after pentobarbital was discontinued.4 Interestingly, in this case the patient was also on digoxin, and stopping phenobarbital precipitated digoxin toxicity by causing an increase in quinidine levels.

A 3-year-old child taking both phenobarbital and phenytoin required quinidine 300 mg every 4 hours to achieve therapeutic serum quinidine levels, and had an estimated quinidine half-life of only 1.4 hours.5 Difficultly in achieving adequate serum quinidine levels was also reported in a woman taking phenytoin and primidone.6 Her quinidine half-life was 2.7 hours, about half that usually seen in adults.6 Quinidine 200 mg had no effect on the metabolism (4-hydroxylation) of mephenytoin 100 mg in 10 healthy subjects.7

Mechanism

The evidence suggests that phenytoin, primidone or phenobarbital (all known enzyme-inducers) increase the hepatic metabolism of quinidine and thereby reduce its levels.2

Importance and management

Established interactions of clinical importance although the documentation is limited. The concurrent use of phenytoin, primidone, phenobarbital or any other barbiturate need not be avoided, but be alert for the need to increase the quinidine dosage. If the anticonvulsants are withdrawn the quinidine dosage may need to be reduced to avoid quinidine toxicity. Where possible, quinidine serum levels should be monitored.

Quinidine + Aspirin

A patient and two healthy subjects given quinidine and aspirin had a two- to threefold increase in bleeding times. The patient developed petechiae and gastrointestinal bleeding.

Clinical evidence, mechanism, importance and management

A patient with a prolonged history of paroxysmal atrial tachycardia was given quinidine 800 mg daily and aspirin 325 mg twice daily. After a week he developed generalised petechiae and blood in his faeces. His prothrombin and partial prothrombin times were normal but the template bleeding time was more than 35 minutes (normal 2 to 10 minutes). Further study in two healthy subjects showed that quinidine 975 mg daily given alone for 5 days and aspirin 650 mg three times a day given alone for 5 days prolonged bleeding times by 125% and 163% respectively; given together for 5 days the bleeding times were prolonged by 288%.1 The underlying mechanism is not totally understood but it is believed to be the outcome of the additive effects of two drugs, both of which can reduce underlying mechanism is not totally understood but it is believed to be the

(c) Nifedipine

1. Quinidine serum levels. The quinidine serum levels of 2 patients taking quinidine sulfate 300 or 400 mg every 6 hours and nifedipine 10 or 20 mg every 6 or 8 hours doubled (from a range of 2 to 2.5 up to 4.6 micrograms/mL and from 1.6 to 1.8 up to 3.5 micrograms/mL respectively) when the nifedipine was withdrawn. The increased serum quinidine levels were reflected in a prolongation of the QTc interval. However, in the first patient there had been no change in quinidine levels when nifedipine was initially added to his existing quinidine therapy. Further, 4 other patients did not develop this interaction.2

2. Two other reports5,6 describe a similar response: the quinidine serum level doubled in one patient when the nifedipine was stopped,5 and in the other it was found difficult to achieve adequate serum quinidine levels when nifedipine was added, even when the quinidine dosage was increased threefold. When the nifedipine was withdrawn, the quinidine levels rose once again.6 A study in 12 patients found no significant change in serum quinidine levels in the group as a whole when given nifedipine, but one patient had a 41% decrease in quinidine levels.7 Two other studies in healthy subjects found that the quinidine AUC was unchanged by nifedipine.8

2. Nifedipine serum levels. In a study in 10 healthy subjects quinidine sulfate 200 mg every 8 hours increased the AUC of nifedipine by 37%, and heart rates were significantly increased. Quinidine levels were unchanged.8 Another study found that quinidine had a modest inhibitory effect on the metabolism of nifedipine (half-life prolonged by 40%).10 A further study in 12 healthy subjects found that the AUC of a single 20-mg dose of nifedipine was increased 16% by quinidine 200 mg and its clearance was reduced by 17%, but these modest changes were not considered clinically relevant.9

(d) Nisoldipine

An open crossover study in 20 healthy subjects found that nisoldipine 20 mg had no effect on the bioavailability of quinidine gluconate 648 mg.11

(e) Verapamil

After taking verapamil 80 mg three times daily for 3 days, the clearance of a single 400-mg dose of quinidine sulphate in 6 healthy subjects was decreased by 32% and the half-life was increased by 35% from 6.87 to 9.29 hours.12

A patient given quinidine gluconate 648 mg every 6 hours had an increase in serum quinidine levels from 2.6 to 5.7 micrograms/mL when given verapamil 80 mg every 8 hours for a week. He became dizzy and had blurred vision and was found to have atrioventricular block (heart rate 38 bpm) and a systolic blood pressure of 50 mmHg. In a subsequent study in this patient it was found that the verapamil halved the quinidine clearance and almost doubled the serum half-life.13

Three other patients given quinidine orally developed marked hypotension when given intravenous verapamil 2.5 or 5 mg (blood pressure fall from 130/70 to 80/50 mmHg, systolic pressure fall from 140 to 85 mmHg and a mean arterial pressure fall from 100 to 60 mmHg, in the 3 patients respectively). In two of the patients, after quinidine was discontinued, the same dose of verapamil did not cause a drop in blood pressure.14

Mechanism

Suggestions for how nifedipine could alter quinidine levels include changes in cardiovascular haemodynamics,9 and effects on metabolism.7 Quinidine probably inhibits the metabolism of nifedipine by competing for metabolism by the cytochrome P450 isozyme CYP3A4.10 The interaction with verapamil is probably due to an inhibitory effect of verapamil on the metabolism of quinidine (inhibition of cytochrome P450 isozyme CYP3A).12,15 The marked hypotension observed may be related to the antagonistic effects of the two drugs on catecholamine-induced alpha-receptor induced vasoconstriction.14

Importance and management

The results of studies of the interaction between quinidine and nifedipine are inconsistent and contradictory, so that the outcome of concurrent use is uncertain. Monitor the response, being alert for the need to modify the
dosage. More study of this interaction is needed. Quinidine appears to increase nifedipine levels, but the importance of this is uncertain.

What is known about the interaction between quinidine and verapamil suggests that a reduction in the dosage of the quinidine may be needed to avoid toxicity. If the verapamil is given intravenously, use with caution and be alert for evidence of acute hypotension. Monitor the effects of concurrent use closely. There is actually a fixed dose preparation containing verapamil and quinidine (Coridichin) available in Germany, which is used for the management of atrial fibrillation. No interaction apparently occurs between quinidine and felodipine or nisoldipine. The situation with diltiazem is as yet uncertain but be alert for the need to reduce the quinidine dosage.

Quinidine + Diazepam

A single 4.5-g dose of colesvealam had no significant effect on the pharmacokinetics of a single 324-mg dose of quinidine in 25 healthy subjects.1 This suggests that colesvealam does not reduce the absorption of quinidine. No special precautions appear to be needed during concurrent use.

Quinidine + Co-phenotrope (Atropine/Diphenoxylate)

Co-phenotrope slightly reduced the rate, but not the extent, of absorption of a single dose of quinidine.

Clinical evidence, mechanism, importance and management

In one study, 8 healthy subjects were given a single 300-mg dose of quinidine sulfate alone and after taking two tablets of co-phenotrope (atropine sulfate 25 micrograms, diphenoxylate 2.5 mg; Lomotil) at midnight on the morning before and after two tablets the next morning an hour before the quinidine.1 It was found that the maximum plasma quinidine levels were reduced by 21% from 2.1 to 1.65 micrograms/mL by the co-phenotrope, the time to maximum level was prolonged from 0.89 to 1.21 hours, and there was a slight increase in elimination half-life from 5.7 to 6.8 hours. While these results were statistically significant, the changes were relatively small and it seems doubtful if they are clinically relevant, particularly as the extent of absorption was unchanged. However it needs to be emphasised that because the quinidine formulation used was an immediate-release preparation, these results may not necessarily apply to sustained-release preparations, and also may not apply if multiple doses of quinidine are used.

Quinidine + Disulfiram

Disulfiram does not affect the pharmacokinetics of quinidine.

Clinical evidence, mechanism, importance and management

In an open study, 6 healthy subjects were given a single 200-mg dose of quinidine sulfate before and on day 5 of a 6-day course of disulfiram 200 mg daily. There were no changes in quinidine pharmacokinetics during disulfiram administration.1 Disulfiram is thought to be an inhibitor of the cytochrome P450 isoenzyme CYP2E1, but this isoenzyme does not
appear to have a major role in quinidine metabolism.\(^1\) Clinically relevant pharmacokinetic interactions between quinidine and disulfiram therefore seem unlikely. Concurrent use need not be avoided.

**Quinidine + Erythromycin**

Erythromycin can increase quinidine levels and cause a small further increase in the QTc interval. An isolated report describes a moderate rise in serum quinidine levels in an elderly man attributed to the concurrent use of intravenous erythromycin, which was possibly a factor in an episode of torsade de pointes. Another isolated report describes the development of torsade de pointes arrhythmia in a very elderly man when he was given quinidine and erythromycin orally. See also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257.

**Clinical evidence**

A 74-year-old man with a history of cardiac disease (coronary artery bypass graft surgery, ventricular tachycardia) treated with quinidine sulfate 200 mg every 6 hours and several other drugs (mexiletine, hyalurazine, dipryramidone, aspirin and paracetamol (acetaminophen)), was hospitalised with suspected implantable cardioverter defibrillator infection. Within 2 days of starting to take erythromycin lactobionate 500 mg every 6 hours and ceftriaxone 1 g daily, both given intravenously, his trough serum quinidine levels had risen by about one-third from about 2.8 to 4.2 mg/L. On day 7 metronidazole 500 mg every 8 hours was added and the erythromycin dosage was doubled, and the patient experienced an episode of torsade de pointes. By day 12 his serum quinidine levels had further risen to 5.8 mg/L, whereupon the quinidine dosage was reduced by 25%. Because an interaction between quinidine and erythromycin had by then been suspected, the antibacterials were replaced by doxycycline and ciprofloxacin. By day 21 the quinidine serum levels had fallen to their former levels. The patient had a prolonged QTc interval of 504 milliseconds on admission, and this did not change.\(^1\)

A 95-year-old man developed QT interval prolongation, torsade de pointes arrhythmia and subsequent cardiac arrest when given quinidine and erythromycin, both orally.\(^2\)

Preliminary results of a randomised, placebo-controlled crossover study in 12 subjects found that when a single 400-mg dose of quinidine was given after oral erythromycin 500 mg three times daily or a placebo for 5 days, the total QTc AUC was significantly prolonged by about 6% during the erythromycin phase.\(^3\) In a parallel study by the same group, peak levels of quinidine were increased by 39%, from 587 to 829–38. 6 therefore, quinidine and erythromycin may have additive effects on the QT interval in addition to the pharmacokinetic interaction.

**Mechanism**

Not fully understood, but erythromycin inhibits the metabolism of quinidine,\(^4\) possibly by inhibition of the cytochrome P450 isoenzyme CYP3A4,\(^4\) thereby reducing its clearance from the body and increasing its effects. There are also a number of cases on record of prolongation of the QT interval and torsade de pointes associated with the use of intravenous erythromycin alone.\(^6\) Therefore, quinidine and erythromycin may have additive effects on the QT interval in addition to the pharmacokinetic interaction.

**Importance and management**

Information about this interaction appears to be limited to these reports, but it would appear to be established. If erythromycin is essential in a patient taking quinidine, the effects of concurrent use should be well monitored, being alert for the development of raised plasma quinidine levels and prolongation of the QT interval (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257).

**Quinidine + Fluvoxamine**

Fluvoxamine appears to inhibit the metabolism and clearance of quinidine.

**Clinical evidence, mechanism, importance and management**

Six healthy subjects were given a single 250-mg dose of quinidine sulfate before and on day 5 of a 6-day course of fluvoxamine 100 mg daily.\(^1\) The total apparent oral clearance of quinidine was reduced by 29%, and N-oxidation and 3-hydroxylation were reduced by 33 and 44% respectively. Renal clearance and the elimination half-life were unchanged. It was concluded that fluvoxamine inhibited the metabolism of quinidine by the cytochrome P450 isoenzyme CYP3A4, although a role for CYP1A2 and CYP2C19 was not excluded. The clinical relevance of these findings is unclear. However, it would seem prudent to monitor the concurrent use of quinidine with fluvoxamine. More study is needed to assess the effect of multiple dosing and to establish the clinical significance of this interaction.

**Quinidine + Grapefruit juice**

Grapefruit juice delays the absorption of quinidine and reduces its metabolism to some extent, but no clinically relevant adverse interaction seems to occur.

**Clinical evidence, mechanism, importance and management**

In one study, 12 healthy subjects were given quinidine sulfate 400 mg orally on two occasions, once with 240 mL of water and once with grapefruit juice. The pharmacokinetics of the quinidine were unchanged, except that its absorption was delayed (the time to reach maximum plasma concentrations was doubled from 1.6 to 3.3 hours), for reasons that are not understood. The AUC of its metabolite (3-hydroxyquinidine) was significantly reduced.\(^3\) Another study in 6 healthy subjects found the total clearance of a single 200-mg dose of quinidine sulfate was reduced by 15% by 250 mL of grapefruit juice, with no change in maximum level. There was a small reduction in metabolic formation suggesting only minor inhibition of metabolism.\(^2\) Grapefruit is known to inhibit the cytochrome P450 isoenzyme CYP3A4, which is involved with the metabolism of quinidine, so it seems likely that any interaction would occur via this pathway.\(^1,2\) These studies suggest that it is not necessary for patients on quinidine to avoid grapefruit juice. Nevertheless, grapefruit juice may have contributed to raised quinidine levels and toxicity in a woman who took an antacid and one litre of fruit juice daily for a week, see ‘Quinidine + Antacids or Urinary alkalinisers’, p.277.

Quinidine + H₂-receptor antagonists

Quinidine serum levels can rise and toxicity may develop in some patients when they take cimetidine. An isolated case of ventricular bigeminy (a form of arrhythmia) occurred in a patient taking quinidine and ranitidine.

Clinical evidence

Cimetidine 300 mg four times daily for 7 days prolonged the elimination half-life of a single 400-mg dose of quinidine sulfate by 55%, from 5.8 to 9 hours, and decreased its clearance by 37% in 6 healthy subjects. Peak plasma levels were raised by 21%. These changes were reflected in ECG changes, with 51% and 28% increases in the mean areas under the QT and QTc time curves, respectively, but these were not considered to be statistically significant. ¹

A later study in healthy subjects, prompted by the observation of two patients who developed toxic quinidine levels when given cimetidine, found essentially the same effects. The AUC and half-life of quinidine were increased by 14.5 and 22.6%, respectively, and the clearance was decreased by 25% by cimetidine 300 mg four times daily. ² A further study in 4 healthy subjects found that cimetidine 300 mg four times daily for 5 days prolonged the elimination half-life of quinidine by 54% and decreased its total clearance by 36%.³ ⁴ Cimetidine prolonged the QT interval by 30% more than the effect of quinidine alone. ⁴ A case report describes marked increases in both quinidine and digitoxin concentrations in a woman also given cimetidine. ⁵ Similarly, quinidine levels increased by up to 50%, without causing any adverse effects, when a man taking quinidine was given cimetidine. ⁶

Ventricular bigeminy (a form of arrhythmia) occurred when a man taking quinidine was given ranitidine. His serum quinidine levels remained unchanged.⁷

Mechanism

It was originally suggested that the cimetidine inhibits the metabolism of the quinidine by the liver so that it is cleared more slowly.² However, further data suggest that cimetidine successfully competes with quinidine for its excretion by the kidneys.⁸

Importance and management

The interaction between quinidine and cimetidine is established and of clinical importance. The incidence is unknown. Be alert for changes in the response to quinidine if cimetidine is started or stopped. Ideally the quinidine serum levels should be monitored and the dosage reduced as necessary. Reductions of 25% (oral) and 35% (intravenous) have been suggested.³ Those at greatest risk are likely to be patients with impaired renal function, patients with impaired liver function, the elderly, and those with serum quinidine levels already at the top end of the therapeutic range.² The situation with ranitidine is uncertain.

Quinidine + Itraconazole

Itraconazole increases the plasma levels of quinidine.

Clinical evidence

In a double-blind, randomised, two-phase crossover study, 9 healthy subjects were given a single 100-mg dose of quinidine sulfate on the final day of a 4-day course of either itraconazole 200 mg daily or placebo. The itraconazole caused a 1.6-fold increase in the peak plasma quinidine levels, a 2.4-fold increase in its AUC, a 1.6-fold increase in its elimination half-life and a 50% decrease in its renal clearance.¹ Similarly, another study in 6 healthy subjects found that itraconazole 100 mg daily for 6 days reduced the total clearance of a single 200-mg dose of quinidine sulfate by 61%, increased its elimination half-life by 35%, and decreased its renal clearance by 60%.²

Mechanism

The most likely explanation is that itraconazole not only inhibits the metabolism of quinidine by the cytochrome P450 isoenzyme CYP3A4 in the gut wall and liver, but possibly also inhibits the active secretion of quinidine by the kidney tubules.¹³

Importance and management

Direct information appears to be limited to these studies, but the evidence suggests that this interaction is clinically important. What happens is consistent with the way that itraconazole interacts with other drugs. If larger doses of itraconazole were to be used and for longer periods, it seems likely that the effects would be even greater. The concurrent use of these drugs should therefore be well monitored and the dosage of quinidine reduced accordingly. More study is needed. Consider also ‘Quinidine + Ketoconazole’, below.

Quinidine + Kaolin-pectin

There is some evidence that kaolin-pectin can reduce the absorption of quinidine and lower its serum levels.

Clinical evidence, mechanism, importance and management

When 4 patients were given 30 mL of kaolin-pectin (Kaopectate), after a single 100-mg oral dose of quinidine, the maximal salivary quinidine concentration was reduced by 54% and the AUC by 58%, without any effect on absorption rate.³ There is a correlation between salivary and serum concentrations after a single (but not repeated) doses of quinidine.² This is consistent with in vitro data showing quinidine is adsorbed onto kaolin,¹ pectin,³ and kaolin-pectin.¹ Documentation appears to be limited to these two studies, but be alert for the need to increase the quinidine dosage if kaolin-pectin is used concurrently.

Quinidine + Ketoconazole

An isolated report describes a temporary marked increase in plasma quinidine levels in man when he was also given ketoconazole.

Clinical evidence, mechanism, importance and management

An elderly man with chronic atrial fibrillation, treated with quinidine sulfate 300 mg four times daily, was also given ketoconazole 200 mg daily, for candidal oesophagitis after antineoplastic therapy. Within 7 days his plasma quinidine levels had risen from a range of 1.4 to 2.7 mg/L up to 6.9 mg/L (normal range 2 to 5 mg/L) but he showed no evidence of toxicity. The elimination half-life of quinidine was found to be 25 hours (normal values in healthy subjects 6 to 7 hours). The quinidine dosage was reduced to 200 mg twice daily, but it needed to be increased to the former
dose by the end of a month, even though ketoconazole was continued at the same dosage. The reasons for this reaction are not understood, but may be that the ketoconazole initially inhibits the metabolism of quinidine, causing the plasma levels to rise, and then later induces the metabolism of quinidine, causing the levels to fall. This is an isolated case so that its general importance is uncertain. See also ‘Quinidine + Itraconazole’, p.281.

Quinidine + Laxatives

Quinidine plasma levels can be reduced by the anthraquinone laxative senna.

Clinical evidence, mechanism, importance and management

A study in 7 patients with cardiac arrhythmias taking quinidine bisulfate 500 mg every 12 hours found that the anthraquinone laxative senna (Liquedepur) reduced plasma quinidine levels, measured 12 hours after the last dose of quinidine, by about 25%. This might be of clinical importance in patients whose plasma levels are barely adequate to control their arrhythmia.

Quinidine + Lidocaine

A single case report describes a man taking quinidine who had sinoatrial arrest when he was given intravenous lidocaine.

Clinical evidence, mechanism, importance and management

A man with Parkinson’s disease was given quinidine 300 mg every 6 hours for the control of ventricular ectopic beats. After receiving two doses he was given lidocaine as well, initially as a bolus of 80 mg, followed by an infusion of 4 mg/minute because persistent premature ventricular beats developed. Within 2.5 hours the patient complained of dizziness and weakness, and was found to have sinus bradycardia, sinoatrial arrest and atrioventricular escape rhythm. Normal sinus rhythm resumed when the lidocaine was stopped. Whether quinidine was a contributing factor in this reaction is uncertain. However, this case emphasises the need to exercise caution when giving two drugs that have cardiac depressant actions.

Quinidine + Metoclopramide

Metoclopramide slightly reduced the absorption of quinidine from a sustained-release formulation in one study, but modestly increased quinidine levels in another.

Clinical evidence

A study of this interaction was prompted by the case of a patient who was taking sustained-release quinidine (Quinidex) and whose arrhythmia became uncontrolled when metoclopramide was added. In a crossover study, 9 healthy subjects were given either metoclopramide 10 mg every 6 hours for 24 hours before, and 48 hours after, a single 600- or 900-mg oral dose of quinidine sulfate or quinidine alone. It was found that metoclopramide caused a mean 10% decrease in the AUC of quinidine, although two subjects had decreases of 22.5 and 28.1%, respectively. The elimination rate constant was unaffected. Another study in patients taking a sustained-release formulation of quinidine bisulfate 500 mg every 12 hours found that metoclopramide 10 mg three times daily increased the mean plasma levels measured 3.5 hours after the last dose of quinidine by almost 20%, from 1.6 to 1.9 micrograms/mL, and at 12 hours by about 16%, from 2.4 to 2.8 micrograms/mL.

Mechanism

Not understood. Metoclopramide alters both the gastric emptying time and gastrointestinal motility, which can affect quinidine absorption.

Importance and management

Direct information seems to be limited to these studies using different quinidine preparations. The outcome of concurrent use is uncertain, but generally seems small.

Quinidine + Omeprazole

Omeprazole does not appear to alter the pharmacokinetics or QT-interval prolonging effects of quinidine.

Clinical evidence, mechanism, importance and management

Omeprazole 40 mg daily for one week had no effect on the pharmacokinetics of a single 400-mg dose of quinidine sulfate in 8 healthy subjects. In addition, the corrected QT interval was not significantly changed. There would not appear to be the need for any special precautions during concurrent use.

Quinidine + Quinolones

Ciprofloxacin normally appears not to interact with quinidine to a clinically relevant extent. An increased risk of torsade de points might be expected if quinidine is used with gatifloxacin, moxifloxacin, or sparfloxacin, and possibly levofloxacin.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of a single 400-mg oral dose of quinidine sulfate and QRS and QTc prolongation were not significantly changed in 7 healthy subjects after they took ciprofloxacin 750 mg daily for 6 days. The decrease in clearance ranged from a decrease of 10% to an increase of 20%, with a mean 1% increase, which is unlikely to be clinically relevant. However an isolated case report describes a woman who started taking quinidine gluconate 324 mg every 8 hours while she was taking ciprofloxacin and metronidazole. Her first trough serum quinidine levels was raised a little above normal at 6.3 micrograms/mL compared with the normal range of 2 to 5 micrograms/mL, without evidence of toxicity. Quinidine therapy was continued unchanged, and her next trough serum quinidine level was only 2.3 micrograms/mL, 3 days after finishing the course of antibacterials. This was tentatively attributed to the possible enzyme inhibitory effects of ciprofloxacin and metronidazole. This case is far from clear and so no firm conclusions can be reached. There would seem to be little reason for avoiding concurrent use.

Some quinolones can prolong the QT interval, and would be expected to increase the risk of torsade de points arrhythmias when used with quinidine. Of the quinolones used clinically, gatifloxacin, moxifloxacin, and sparfloxacin are known to prolong the QT interval (see ‘Table 9.2’ (p.257)). There is also evidence that levofloxacin may prolong the QT interval (see ‘Amiodarone + Quinolones’, p.249). These quinolones should...
probably be avoided in patients taking quinidine (see also ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.257).

**Quinidine + Rifamycins**

The serum levels and therapeutic effects of quinidine can be markedly reduced by rifampicin.

**Clinical evidence**

It was noted that the control of ventricular arrhythmia deteriorated in a patient taking quinidine sulfate 800 mg daily within a week of starting to take rifampicin 600 mg daily. His serum quinidine level fell from 4 to 0.5 microgram/mL, and remained low despite doubling the quinidine dose to 1.6 g daily. The rifampicin was discontinued, and quinidine levels gradually increased over a week. Some signs of quinidine toxicity then occurred, and the quinidine dose was reduced back to 800 mg daily. Further study in 4 healthy subjects found that treatment with rifampicin 600 mg daily for 7 days reduced the mean half-life of a single 6 mg/kg oral dose of quinidine sulfate by about 62% (from 6.1 to 2.3 hours) and the AUC by 83%. Similar findings were reported in 4 other subjects receiving the same dose of quinidine intravenously. Another case report describes a patient taking rifampicin who did not achieve adequate serum quinidine levels despite large daily doses of up to 3.2 g of quinidine. When the rifampicin was stopped, ultimately, a reduced quinidine dosage of 1.8 g daily achieved a serum level of 2 micrograms/mL, reflecting a 44% decrease in dose and a 43% increase in level. In a further case, a ‘double interaction’ was seen when a patient taking quinidine and digoxin was given rifampicin: the quinidine levels fell, resulting in a fall in digoxin levels.

**Mechanism**

Rifampicin is a potent enzyme-inducer, which markedly increases the metabolism of the quinidine by 3-hydroxylation and N-oxidation, thereby reducing its levels and effects. It has been suggested that two of the quinidine metabolites (3-hydroxyquinidine and 2-oxoquinidinone) may be active, which might, to some extent, offset the effects of this interaction.

**Importance and management**

An established interaction of uncertain but probably limited clinical importance. There seem to be no reports of adverse reactions in patients as a result of this interaction, but be alert for any evidence of increased tocainide effects if other drugs are given that can raise the urinary pH significantly (e.g., sodium bicarbonate and acetazolamide). Reduce the tocainide dosage if necessary. Of the antacids, cimetidine can reduce the bioavailability of tocainide, but ranitidine appears not to have any effect on urinary pH.

**Quinidine + Antacids or Urinary alkalinisers**

Raising the pH of the urine (e.g. with some antacids, diuretics or alkaline salts) can modestly reduce the loss of tocainide from the body.

**Clinical evidence**

Preliminary findings of a study found that when 5 healthy subjects took 30 mL of an unnamed antacid four times a day for 48 hours before and 58 hours after a single 600 mg dose of tocainide, the urinary pH rose from 5.9 to 6.9, the total clearance of tocainide fell by 28%, the peak serum levels fell by 19% from 4.2 to 3.4 micrograms/mL, the AUC rose by 33% and the half-life was prolonged from 13.2 to 15.4 hours.

**Mechanism**

Tocainide is a weak base so that its loss in the urine will be affected by the pH of the urine. Alkalisation of the urine increases the number of non-ionised molecules available for passive reabsorption, thereby reducing the urinary loss and raising the serum levels.

**Importance and management**

An established interaction of uncertain but probably limited clinical importance. There seem to be no reports of adverse reactions in patients as a result of this interaction, but be alert for any evidence of increased tocainide effects if other drugs are given that can raise the urinary pH significantly (e.g., sodium bicarbonate and acetazolamide). Reduce the tocainide dosage if necessary. Of the antacids, aluminium/magnesium hydroxide (Maalox) can raise urinary pH by about 0.9 whereas magnesium hydroxide (Milk of magnesia) and calcium carbonate-glycine (Tiritacal) in normal doses raise the pH by about 0.5. Aluminium hydroxide (Amphogel) and dihydroxyaluminium glycinate (Robalate) are reported to have no effect on urinary pH.

**Tocainide + H₂-receptor antagonists**

There is some evidence that cimetidine can reduce the bioavailability and serum levels of tocainide, but ranitidine appears not to interact.

**Clinical evidence, mechanism, importance and management**

In a preliminary report of a study, 4 days of treatment with cimetidine [dose not stated] in 11 healthy subjects had a small effect on the pharmacokinetics of tocainide 500 mg given intravenously over 15 minutes, which was not considered clinically important.
serum levels were also reduced, from 2.81 to 1.7 micrograms/mL, but no changes in the half-life or renal clearance occurred. The reasons for this, and its clinical importance are uncertain, but be alert for evidence of a reduced response to tocainide in the presence of cimetidine. Ranitidine 150 mg twice daily has been found not to interact.

Phenobarbital does not appear to alter the pharmacokinetics of tocainide.

Clinical evidence, mechanism, importance and management

Phenobarbital 100 mg daily for 15 days did not alter the AUC of a single 600-mg dose of tocainide in 6 healthy subjects. In addition, the percentage of the dose excreted unchanged in the urine and as the glucuronide metabolite did not differ. Phenobarbital at this dosage does not appear to alter the metabolism of tocainide. No special precautions appear to be necessary.

The loss of tocainide from the body is increased by rifampicin.

Clinical evidence, mechanism, importance and management

The AUC of a single 600-mg oral dose of tocainide was reduced by almost 30% and the half-life was also reduced by about 30%, from 13.2 to 9.4 hours, in 8 healthy subjects given rifampicin 300 mg twice daily for 5 days.

This response is consistent with the well-recognised enzyme inducing effects of rifampicin. Information is limited to this single dose study, but the interaction would seem to be established and may be of clinical importance. Monitor any patients given rifampicin for evidence of reduced tocainide serum levels and reduced effects. Increase the dosage as necessary. Reduce the tocainide dosage if the rifampicin is withdrawn. More study is needed.

This section deals with interactions where the effects of the antibacterial are altered. In many cases the antibacterial drugs interact by affecting other drugs, and these interactions are dealt with elsewhere in this publication. Some of the macrolides and the quinolones are potent enzyme inhibitors; the macrolides exert their effects on the cytochrome P450 isoenzyme CYP3A4, whereas many quinolones inhibit CYP1A2. Rifampicin (rifampin) is a potent non-specific enzyme inducer and therefore lowers the levels of many drugs.

Many of the interactions covered in this section concern absorption interactions, such as the ability of the tetracyclines and quinolones to chelate with divalent cations. More information on the mechanism of these interactions can be found in ‘Drug absorption interactions’, (p.3).

Many monographs concern the use of multiple antibacterials. One of the great difficulties with these interactions is the often poor correlation between in vitro and in vivo studies, so that it is difficult to get a thoroughly reliable indication of how antibacterial drugs will behave together in clinical practice. Two antibacterials may actually be less effective than one on its own, because, in theory, the effects of a bactericidal drug, which requires actively dividing cells for it to be effective, may be reduced by a bacteriostatic drug. However, in practice this seems to be less important than might be supposed and there are relatively few well-authenticated clinical examples.

The antibacterials covered in this section are listed in ‘Table 10.1’, (see below).

Aminoglycosides + Amphotericin B

One study suggested that amphotericin B decreased the clearance of amikacin and gentamicin. The concurrent use of aminoglycosides and amphotericin B can result in nephrotoxicity.

Clinical evidence, mechanism, importance and management

A study found that amikacin or gentamicin clearance was impaired in 12 of 17 children given amphotericin B. Serum creatinine increased by 50% or more in 3 of them, but there was no significant increase in creatinine levels in 7 others. As a result, the aminoglycoside dose was decreased or the dose interval lengthened in 7 children.1

The renal function of 4 patients receiving moderate doses of gentamicin deteriorated when they were given amphotericin B. Both drugs are known to be nephrotoxic and it is suggested, on the basis of what was seen, that combined use may have had additive nephrotoxic effects.2 A further retrospective analysis found that the use of amikacin tended to increase amphotericin B-related nephrotoxicity.3

A study assessing the risk factors for nephrotoxicity with aminoglycosides (tobramycin and gentamicin) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of amphotericin B significantly increased the risk of nephrotoxicity.4

The nephrotoxicity of various combinations of antibiotics was assessed in 171 cancer patients (139 treated with a combination of aminoglycoside with penicillin or cephalosporin; 32 treated with amphotericin B or vancomycin with other antibacterials). The highest nephrotoxicity (based on changes in urea and electrolytes) was found in patients treated with amphotericin B with an aminoglycoside and a cephalosporin.5 Two other studies did not find aminoglycosides increased the risk of amphotericin B-associated toxicity (defined as a 100% or greater increase in serum creatinine),6,7 although in one of the studies7 the frequency of concurrent aminoglycoside use may have been too low to identify any evidence of increased nephrotoxic risk.

As aminoglycosides are generally considered to be nephrotoxic, avoidance of use with other nephrotoxic drugs (such as amphotericin B) is generally recommended. However, concurrent use may be essential. Renal function and drug levels should be routinely monitored during aminoglycoside therapy, and it may be prudent to increase the frequency of such monitoring in the presence of amphotericin B. Lipid formulations of amphotericin B are less nephrotoxic than the conventional formulation.8 One manufacturer notes there was significantly less nephrotoxicity in patients receiving concurrent aminoglycosides and liposomal amphotericin B (Ambisome) compared to aminoglycosides and conventional amphotericin B.9

Clinical evidence

(a) Gentamicin and Cefalotin

Acute renal failure has been reported in a patient given gentamicin and cefalotin.1 One study reported an increase in the incidence of nephrotoxicity when cefaloridine was given with gentamicin (or other unnamed aminoglycosides), although other factors such as excessive dosage or pre-existing renal impairment were also associated with the increase in cephalosporin nephrotoxicity in most cases.2

(b) Gentamicin or Tobramycin and Cefalotin

A randomised, double-blind study3 in patients with sepsis showed the following incidence of definite nephrotoxicity:

- gentamicin with cefalotin 30.4% (7 of 23 patients),
- tobramycin with cefalotin 20.8% (5 of 24),
- gentamicin with meticillin 10% (2 of 20),
- tobramycin with meticillin 4.3% (1 of 23).

A very considerable number of studies and case reports confirm an increase in the incidence of nephrotoxicity when gentamicin4,14 or tobramycin5,16 are used with cefalotin. However, some other studies have found no increase in nephrotoxicity with the combination.7,12

(c) Aminoglycosides and other Cephalosporins

The nephrotoxicity of various combinations of antibiotics was assessed in 171 cancer patients. In those receiving an aminoglycoside with a third generation cephalosporin, the most nephrotoxic combinations were found to be gentamicin with cefotaxime (although another study did not find this combination to be nephrotoxic20) and amikacin with ceftriaxone, where 5 of 20 and 5 of 13 patients, respectively, had increased serum creatinine. The following combinations were found to be safer: amikacin with cefoxitin or cefadizime, gentamicin with cefoxitin, and netilmicin with cefotaxime.22

Another study assessing the risk factors for nephrotoxicity with aminoglycosides (tobramycin and gentamicin) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of cefalotin nephrotoxicity in most cases.2

Mechanism

Uncertain. The nephrotoxic effects of gentamicin and tobramycin are well documented, and some (mostly older) cephalosporins are known to be nephrotoxic, especially in high dose. However, it appears that doses that are well tolerated separately can be nephrotoxic when given together.11

Importance and management

The interaction between gentamicin and cefalotin is very well documented and potentially serious, but there is less information about tobramycin and cefalotin. The risk of nephrotoxicity is probably greatest if high doses of antibacterial are used in those with some existing renal impairment. One study suggests that short courses of treatment are sometimes justified,12 but renal function should be very closely monitored and dosages kept to a minimum. The combination of gentamicin or tobramycin and cefalotin is probably best avoided in high-risk patients wherever possible.

Whether other aminoglycosides or cephalosporins interact similarly is uncertain, but the possibility should be borne in mind. Risk factors for this interaction are said to include raised aminoglycoside trough levels, decreased albumin, male gender, advanced age, increased length of treatment, liver disease or ascites, and some other diseases, including

Aminoglycosides + Cephalosporins

The nephrotoxic effects of gentamicin and tobramycin can be increased by cefalotin. This may also occur with other aminoglycosides and cephalosporins.
leukæmia,23,31 although their significance in practice has been questioned.23

Aminoglycosides + Loop diuretics

The concurrent use of aminoglycosides and etacrylic acid should be avoided because their damaging actions on the ear can be additive. Even sequential use may not be safe. Bumetanide and pirenzepine have been shown to interact similarly in animals. Although some patients have developed nephrotoxicity and/or ototoxicity while taking furosemide and an aminoglycoside, it has been established that this was as a result of an interaction.

Clinical evidence

(a) Bumetanide

There seem to be no clinical reports of an interaction between aminoglycosides and bumetanide, but ototoxicity has been described in animals given kanamycin and bumetanide.1,2

(b) Etacrylic acid

Four patients with renal impairment became deaf after they were given intramuscular kanamycin 1 to 1.5 g and intravenous etacrylic acid 50 to 150 mg. One patient also received streptomycin, and another also received oral neomycin. Deafness took between 30 minutes and almost 2 weeks to develop. In some cases deafness developed despite the doses being given on separate days, and in all cases it appeared irreversible.3 A patient receiving gentamicin rapidly developed deafness when furosemide was replaced by intravenous etacrylic acid.4

There are other reports describing temporary, partial or total permanent deafness as a result of giving intravenous etacrylic acid with gentamicin,5 intramuscular kanamycin,6 oral neomycin,8 or streptomycin.6 This interaction has been extensively demonstrated in animals.

(c) Furosemide

An analysis of three, controlled, randomised, studies found that furosemide did not increase either aminoglycoside-induced nephrotoxicity, or otoxicity when the aminoglycosides used were amikacin, gentamicin, and tobramycin.10 Nephrotoxicity developed in 20% (10 of 50 patients) given furosemide and 17% (38 of 222) not given furosemide. Auditory toxicity developed in 22% (5 of 23) given furosemide and 24% (28 of 119) not given furosemide.9 A study assessing the risk factors for nephrotoxicity with aminoglycosides (tobramycin and gentamicin) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of clindamycin was not significantly associated with increased risk of nephrotoxicity. This suggests that treatment of the combination is without nephrotoxic risk above and beyond that seen with aminoglycoside alone. A short report has also indicated that the combination of tobramycin and clindamycin is not nephrotoxic.4

As renal function should be routinely monitored during the use of aminoglycosides, no additional precautions should be necessary if clindamycin is also given.

Aminoglycosides + Clindamycin

Three cases of acute renal failure have been tentatively attributed to the use of gentamicin with clindamycin, and another report identified the combination as a risk factor for nephrotoxicity. However, other reports note no increased nephrotoxicity when gentamicin or tobramycin was given with clindamycin.

Clinical evidence, mechanism, importance and management

Acute renal failure has been reported in 3 patients with normal renal function when they were given gentamicin 3.9 to 4.9 mg/kg daily and clindamycin 0.9 to 1.8 mg/kg daily for 13 to 18 days. They recovered within 3 to 5 days of discontinuing the antibiotics1 but in one patient acute renal failure only developed after the clindamycin was stopped. The reasons for the renal failure are not known, but given the long courses of gen-

Antibacterials 287
induced renal damage,\textsuperscript{11} whereas two other clinical studies found no interaction.\textsuperscript{12,13} There are clinical reports claiming that concurrent use results in otoxicity, but usually only small numbers of patients were involved and control groups were not included.\textsuperscript{14–16} A retrospective study of neonates suggested the possibility of increased otoxicity but no firm conclusions could be drawn.\textsuperscript{17} Studies in patients and healthy subjects have shown that furosemide reduces the renal clearance of gentamicin\textsuperscript{20,21} and can cause a rise in both serum gentamicin\textsuperscript{1} and tobramycin levels.\textsuperscript{22} Otoxicity has been described in animals given kanamycin and furosemide.\textsuperscript{1,2}

Mechanism

Aminoglycosides or etacrynic acid alone can damage the ear and cause deafness, the site of action of the aminoglycosides being the hair cell and that of etacrynic acid the stria vascularis. Other loop diuretics may similarly damage hearing.

Animal studies have shown that intramuscular neomycin can cause a fivefold increase in the concentration of etacrynate in cochlear tissues, and it is possible that the aminoglycoside has some effect on the tissues, which allows the etacrynic acid to penetrate more easily.\textsuperscript{23} Similar results have been found with gentamicin.\textsuperscript{24}

Importance and management

The interaction between etacrynic acid and aminoglycoside is well established and well documented. The concurrent or sequential use of etacrynic acid with parenteral aminoglycosides should be avoided because permanent deafness may result. Patients with renal impairment seem to be particularly at risk, most likely because the drugs are less rapidly cleared. Most of the reports describe deafness after intravenous use, but it has also been seen when etacrynic acid is given orally alone.\textsuperscript{25} If it is deemed absolutely necessary to use etacrynic acid and intravenous aminoglycosides, minimal doses should be used and the effects on hearing should be monitored continuously. Not every aminoglycoside has been implicated, but their otoxicity is clearly established and they may be expected to interact in a similar way. For this reason the same precautions should be used.

Although there is ample evidence of an adverse interaction between furosemide and aminoglycosides in animals,\textsuperscript{2–7} the weight of clinical evidence suggests that furosemide does not normally increase either the nephrotoxicity or ototoxicity of the aminoglycosides. Nevertheless as there is still some uncertainty about the safety of concurrent use it would be prudent to monitor for any evidence of changes in aminoglycoside serum levels, and renal or hearing impairment. The authors of the major study cited\textsuperscript{4} suggest that an interaction may possibly exist if high dose infusions of furosemide are used. The same precautions would seem to be appropriate with bumetanide and piretanide.

Note that it is generally advised that aminoglycosides should not be used with other drugs that may cause ototoxicity or nephrotoxicity, such as etacrynic acid and furosemide.

Aminoglycosides + Magnesium compounds

A neonate with elevated serum magnesium levels had a respiratory arrest when given gentamicin.

Clinical evidence

An infant born to a woman whose pre-eclampsia had been treated with magnesium sulfate was found to have muscle weakness and a serum magnesium concentration of 1.77 mmol/L. The neonate was given ampicillin 100 mg/kg intravenously and gentamicin 2.5 mg/kg intramuscularly every 12 hours, starting 12 hours after birth. Soon after the second dose of gentamicin she stopped breathing and needed intubation. The gentamicin was stopped and the child improved.\textsuperscript{1} Animal studies confirmed this interaction.

Mechanism

Magnesium ions and the aminoglycosides have neuromuscular blocking activity, which can be additive (see also ‘Neuromuscular blockers + Magnesium compounds’, p.125 and ‘Neuromuscular blockers + Aminoglycosides’, p.113). In the case cited here it seems that it was enough to block the actions of the respiratory muscles.

Importance and management

Direct information about this interaction is very limited, but it is well supported by the recognised pharmacological actions of magnesium and the aminoglycosides, and their interactions with conventional neuromuscular blockers. The aminoglycosides as a group should be avoided in hypermagnesaemic infants needing antibacterial treatment. If this is not possible, the effects on respiration should be closely monitored.

Aminoglycosides + Miconazole

A report describes a reduction in serum tobramycin levels, which was attributed to the use of miconazole.

Clinical evidence, mechanism, importance and management

Intravenous miconazole significantly lowered the peak serum tobramycin levels from 9.1 to 6.7 micrograms/mL in 9 patients undergoing bone marrow transplantation. Six of them needed tobramycin dosage adjustment.\textsuperscript{1} Miconazole was stopped in 4 patients, and tobramycin pharmacokinetic patterns returned to normal 4 to 8 days later. The reasons for this interaction are not understood. Although the use of tobramycin should be well monitored it would be prudent to increase the frequency in patients also given systemic miconazole (note that miconazole oral gel can have significant systemic absorption). There does not appear to be any information about other aminoglycosides and azole antifungals.

Aminoglycosides + NSAIDs

There are conflicting reports as to whether or not serum gentamicin and amikacin levels are raised by indomethacin or ibuprofen in premature infants.

Clinical evidence

(a) Amikacin

A study in 10 preterm infants with gestational ages ranging from 25 to 34 weeks, who were given amikacin, found that the use of indomethacin 200 micrograms/kg every 8 hours, for up to 3 doses, caused a rise in the serum levels of amikacin. Trough and peak levels of amikacin were raised by 28% and 17%, respectively.1

In another study, preterm infants were given amikacin 20 mg/kg every 36 hours (gestational age less than 30 weeks) or every 24 hours (gestational age 30 to 31 weeks) with either ibuprofen lysine 10 mg/kg within 6 hours of birth, then a further 5 mg/kg dose 24 and 48 hours later, or placebo. The half-life of amikacin was increased from 12.4 to 16.4 hours and its clearance was reduced by 40% in infants who also received intravenous ibuprofen lysine.2 Reductions in amikacin clearance, independent of gestational age were found by the same authors in another study in which preterm infants with gestational ages of between 24 and 34 weeks were given amikacin and ibuprofen.3

In contrast, another study in preterm infants given amikacin found no changes in its pharmacokinetics when ibuprofen or indomethacin were given.4

(b) Gentamicin

A study in 10 preterm infants with gestational ages ranging from 25 to 34 weeks, who were given gentamicin, found that the use of indomethacin 200 micrograms/kg every 8 hours, for up to 3 doses, caused a rise in the serum levels of gentamicin. Trough and peak levels of gentamicin were raised by 48% and 33%, respectively.1 A later study confirmed that indomethacin (200 micrograms/kg given intravenously at 0 hours, then 100 micrograms/kg given at 12 and then 36 hours) decreased the clearance of 3-mg/kg daily doses of gentamicin by 23% in preterm infants weighing less than 1250 g.

In contrast, 8 out of 13 infants had no increase in their serum gentamicin levels when they were given indomethacin 200 to 250 micrograms/kg every 12 hours for 3 doses. Of the remaining 5, slight to moderate rises occurred in 4, and a substantial rise occurred in just one.6 In another study no significant changes in serum gentamicin levels were seen in 31 preterm newborns given parenteral indomethacin 200 micrograms/kg every 12 hours for 3 doses.7

Mechanism

Aminoglycosides are excreted by renal filtration, which can be inhibited by indomethacin or ibuprofen. This may result in the retention of the aminoglycoside.

Importance and management

Information seems to be limited to these conflicting studies, although supporting evidence for indomethacin comes from the fact that it also causes the retention of digoxin in premature infants. The authors of one of the studies suggest that the different results may be because aminoglycoside serum levels were lower in their study before the indomethacin was given, and also because they measured the new steady-state levels after 40 to 60 hours instead of 24 hours. Whatever the explanation, concurrent use should be very closely monitored because toxicity is associated with raised aminoglycoside serum levels. It has been suggested that the aminoglycoside dosage should be reduced before giving indomethacin and the serum levels and renal function well monitored during concurrent use.1

It has also been suggested that the dose interval of amikacin should be increased by at least 6 to 8 hours if ibuprofen lysine is also given during the first days of life.2 Other aminoglycosides possibly behave similarly. This interaction does not seem to have been studied in adults.

Aminoglycosides + Penicillins or Carbapenems

The use of piperacillin is reported to be a risk factor for aminoglycoside-associated nephrotoxicity. A reduction in serum aminoglycoside levels can occur if aminoglycosides and penicillins are given together to patients with severe renal impairment. No pharmacokinetic interaction of importance appears to occur with intravenous aminoglycoside and penicillins in those with normal renal function or between aminoglycosides and carbapenems. The serum levels of oral phenoxymethylpenicillin can be halved by oral neomycin.

Clinical evidence

A. Intravenous or intramuscular aminoglycosides

(a) With carbapenems

The suspicion that low tobramycin levels in one patient might have been due to an interaction with imipenem-cilastatin was not confirmed in a later in vitro study.1 It has also been suggested that the nephrotoxic effects of imipenem and the aminoglycosides might possibly be additive but this awaits confirmation.2 A study in healthy subjects given single intravenous doses of imipenem and amikacin found there was a transient increase in imipenem levels but no effects on other pharmacokinetic parameters of either drug.3 In a study in 12 healthy subjects the concurrent use of tobramycin and biapenem did not alter the pharmacokinetics of either drug.4 No inactivation occurred in an in vitro assay, one of these two drugs in urine.5

(b) With penicillins in patients with renal impairment

A study in 6 patients with renal failure requiring dialysis, who were receiving intravenous carbenicillin 8 to 15 g daily in 3 to 6 divided doses, found that in the presence of the penicillin serum gentamicin levels did not exceed 4 micrograms/mL. When the carbenicillin was stopped, serum gentamicin levels rose.6

Other reports similarly describe unusually low gentamicin levels in patients with impaired renal function, given carbenicillin,7-10 piperacillin,11 or ticarcillin.8,10,12 The half-life of gentamicin has been reported to be reduced by carbenicillin or piperacillin by about one-half or one-third.8,11,12 Similarly, unusually low tobramycin levels have been reported in patients with impaired renal function, who were given carbenicillin,7 piperacillin14 or ticarcillin.12

In 3 patients receiving long-term haemodialysis piperacillin doubled the clearance of tobramycin 2 mg/kg, and reduced its half-life from 73 to 22 hours.13 A patient showed a reduction in the half-life of tobramycin from an expected 70 hours to 10.5 hours after being given piperacillin.14 In contrast one study found that piperacillin or piperacillin/tazobactam did not change the pharmacokinetics of tobramycin in subjects with renal impairment.15

Piperacillin 4 g every 12 hours did not affect the pharmacokinetics of netilmicin 2 mg/kg in 3 patients receiving long-term haemodialysis.15

(c) With penicillins in patients with normal renal function

A patient with normal renal function was given gentamicin 80 mg intravenously, with and without carbenicillin 4 g. The serum gentamicin concentration profiles in both cases were very similar.7 No interaction was seen in 10 patients given tobramycin with piperacillin,18 or in another 10 healthy subjects given once daily gentamicin with piperacillin/tazobactam.19 Only minimal pharmacokinetic changes were seen in 9 healthy subjects given tobramycin with piperacillin/tazobactam,20 and 18 cystic fibrosis patients (adults and children) given tobramycin with ticarcillin.21

However, a study assessing the risk factors for nephrotoxicity with aminoglycosides (tobramycin and gentamicin) enrolled 1489 patients,
157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of piperacillin, but not ticarcillin or carbenicillin significantly increased the risk of nephrotoxicity.22

B. Oral aminoglycosides

The serum concentrations of a 250-mg oral dose of phenoxymethylpenicillin were reduced by more than 50% in 5 healthy subjects after they took neomycin 3 g four times daily for 7 days. Normal penicillin pharmacokinetics were not seen until 6 days after the neomycin was withdrawn.23

Mechanism

The nephrotoxic effects of gentamicin and tobramycin are well documented. The reason why piperacillin but not carbenicillin or ticarcillin should increase the risk of nephrotoxicity is not clear. One suggestion is that sodium loading may protect the kidney from tobramycin toxicity and piperacillin has only 40% as much sodium as ticarcillin.22

In vitro, the amino groups on the aminoglycosides and the beta-lactam ring on the penicillins interact chemically to form biologically inactive amides.24 It has been suggested that this reaction may also occur in the plasma, causing a drop in the levels of active antibacterial.13 The interaction occurs in those with poor renal function as the drugs persist in the plasma for longer, allowing a greater time for inactivation. This therefore means the drug is lost more rapidly than has been accounted for by the renal function, and consequently lower than expected levels of the antibacterial result. However, the lack of interaction found in one study led to the conclusion that reported interactions in renal impairment may be due to in vitro inactivation after sample collection.17

In the case of phenoxymethylpenicillin, the levels are probably lowered because oral neomycin can cause a reversible malabsorption syndrome (histologically similar to nontropical sprue).19

Importance and management

The concurrent use of piperacillin and aminoglycosides is reported to be a risk factor for nephrotoxicity.22,25 The nephrotoxic effects of gentamicin and tobramycin are well documented. Risk factors for nephrotoxicity include raised aminoglycoside trough levels, decreased albumin, male gender, advanced age, increased length of treatment, liver disease or ascites, and some other diseases, including leukemias.22,25 Although their significance in practice has been questioned.25 Renal function and antibacterial serum levels should be monitored if piperacillin is given with an aminoglycoside.

Other reports suggest that a pharmacokinetic interaction between parenteral aminoglycosides and piperacillin or other penicillins, resulting in reduced levels of aminoglycoside, seems to occur in patients with renal impairment.

In those cases where concurrent use is thought necessary, it has been recommended that the serum levels of both antibacterials closely monitored.6 However, note that antibacterial inactivation can continue in the assay bypass circuit.1 However, the lack of interaction found in one study led to the conclusion that reported interactions in renal impairment may be due to in vitro inactivation after sample collection.17

Evidence for the oral neomycin/penicillin interaction seems limited to this one report and its clinical significance is unclear. It seems possible that oral kanamycin and paromomycin might interact similarly, but this needs confirmation.

Aminoglycosides + Polygeline (Haemaccel)

The incidence of acute renal failure appears to increase in cardiac surgical patients given polygeline (Haemaccel) with gentamicin.

Clinical evidence

The observation of a differing incidence of acute renal failure in patients undergoing coronary artery bypass surgery in two similar units, prompted a retrospective review of patient records. This showed that the only management differences were related to antibacterial prophylaxis and the by-pass prime content (i.e. the solution used to prime the cardiopulmonary bypass circuit).

Acute renal failure was defined as a more than 50% rise in serum creatinine on the first postoperative day in those patients whose creatinine was also greater than 120 micromol/L.

Four groups of patients were identified, and the incidence of renal failure was as follows:

- A (polygeline plus gentamicin and flucloxacillin) 31% (28 of 91 patients); B (polygeline plus cefalotin) 12% (9 of 72 patients);
- C (crystalloid plus gentamicin and flucloxacillin) 7% (4 of 57 patients);
- D (crystalloid plus cefalotin) 2% (1 of 47 patients).

Polygeline (Haemaccel) 1 litre, which is a urea linked gelatin colloid with a calcium concentration of 6.25 micromol/L, was used for groups A and B, with crystalloid - Hartmann’s solution or Ringer’s injection (calcium concentration 2 mmol/L) to make up the rest of the prime volume of 2 litres. Groups C and D received only crystalloid (no polygeline) in the prime. Albumin 100 mL was used in groups B and D.2 However, the study has been criticized because other drugs affecting renal function (such as ACE inhibitors, cimetidine, NSAIDs or clonidine) which may have been taken by the patients were not considered.2 This criticism has been refuted because of the large sample size involved.3
Mechanism
Not fully understood. It is thought that the relatively high calcium content of the polygeline may have potentiated gentamicin-associated nephrotoxicity. Hypercalcaemia has been shown in animals to increase aminoglycoside-induced nephrotoxicity.4

Importance and management
Information appears to be limited to this clinical study and animal studies, but the evidence available suggests that a clinically important adverse interaction occurs between these drugs. The incidence of acute renal failure in cardiac surgery patients is normally about 3 to 5%2 which is low compared with the 31% shown by those given polygeline and gentamicin. The authors of the study advise avoidance of these two drugs. More study is needed.

Aminoglycosides + Vancomycin
The nephrotoxicity of the aminoglycosides appears to be potenti-ated by vancomycin.

Clinical evidence, mechanism, importance and management
A retrospective review of 105 patients who had received an aminoglyco-side with vancomycin for at least 5 days found that nephrotoxicity occurred in 27% of the patients. Of these, 6 had no other identifiable cause for nephrotoxicity.1 A study assessing the risks factors for nephrotoxicity with aminoglycosides (tobramycin and gentamicin) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of vancomycin significantly increased the risk of nephrotoxicity.2

A number of other studies,3,4,5 including those where patients have had individualised pharmacokinetic monitoring,6 and those using both once daily and multiple daily dosing,4 have all found that vancomycin independently increases the risk of nephrotoxicity in patients receiving aminoglycosides. In one meta-analysis of 8 studies, the incidence of nephrotoxicity with the combination was 4.3% greater than with aminoglycosides alone and 13.3% greater than with vancomycin alone.6

Risk factors are said to include vancomycin peak and trough levels,1,6 aminoglycoside peak and trough levels,1,6 reduced albumin concentrations,2 male gender,1,6 advanced age,1,6 increased length of treatment,1,6 liver disease or ascites,1,2 as well as a large number of other disease states (such as leukaemia,2 peritonitis1 or neutropenia),1 although their significance in practice has been questioned.2

Concurrent use of these antibacterials is therapeutically useful, but the risk of increased nephrotoxicity should be borne in mind. Therapeutic drug monitoring and regular assessment of renal function is warranted, as is recommended with the use of either drug alone.

Aminoglycosides + Verapamil
Verapamil appears to protect the kidney from damage caused by gentamicin.

Clinical evidence, mechanism, importance and management
In a comparative study, 9 healthy subjects were given gentamicin alone (2 mg/kg loading dose, followed by doses every 8 hours to achieve a peak concentration of 5.5 mg/L and a trough concentration of 0.5 mg/L), and 6 other subjects were given the same dosage of gentamicin with sustained-release verapamil 180 mg twice daily. The gentamicin AUCs of the two groups were virtually the same but the 24-hour urinary excretion of alamine aminopeptidase (AAP) was modestly reduced, by 18%, in the group given verapamil. The reduction in AAP excretion was particularly marked during the first 6 days.7 The significance of urinary AAP is that this enzyme is found primarily in the brush border membranes of the proximal renal tubules, and its excretion is an early and sensitive marker of renal damage. Thus it seems that verapamil may modestly protect the kidneys from damage by gentamicin, but using a drug as potentially toxic as verapamil to provide this protection, when the risks of renal toxicity can be minimised by carefully controlling the gentamicin dosage, is unwarranted. Information about other aminoglycosides and other calcium-channel blockers seems to be lacking.

1. Kazerud DJ, Wojcik GJ, Nix DE, Goldfarb AL, Schentag JJ. The effect of verapamil on the nephrotoxic potential of gentamicin as measured by urinary enzyme excretion in healthy vol-

Aminoglycosides; Tobramycin + Sucralfate
An in vitro study with tobramycin found that it became markedly and irreversibly bound to sucralfate at the pH values found in the gut. This suggests that the efficacy of tobramycin in gut decon-tamination might be decreased.

Clinical evidence, mechanism, importance and management
To simulate what might happen in the gut, tobramycin 50 mg/ml was mixed with sucralfate 500 mg in 40 mL of water at pH 3.5 and allowed to stand for 90 minutes at 25°C. Analysis of the solution showed that the tobra-mycin concentration fell rapidly and progressively over 90 minutes to about 1%. When the pH of the mixture was then raised to 6.5 to 7 for 90 minutes, there was no change in the concentration of tobramycin, suggesting that the interaction was irreversible.8 The reason for this change is not known, but the suggestion is that sucralfate forms insoluble chelates with tobramycin.1

It is not known how important this interaction is likely to be in practice, but the efficacy of tobramycin in gut decontamination may be decreased. Separating the dosages might not be effective in some postoperative patients because their gastric function may not return to normal for up to 5 days, and some sucralfate might still be present when the next dose is given.9 More study is needed to find out whether this interaction is clinically important, but in the meanwhile it would seem prudent to monitor concurrent use carefully, being alert for any evidence of reduced effects.

Aminosalicylic acid + Diphenhydramine
Diphenhydramine can cause a small reduction in the absorption of aminosalicylic acid from the gut.

Clinical evidence, mechanism, importance and management
A study in 9 healthy subjects1 showed that diphenhydramine 50 mg given intramuscularly 10 minutes before a 2-g oral dose of aminosalicylic acid, reduced the mean peak serum aminosalicylic acid levels by about 15%.

This effect may occur because diphenhydramine reduces peristalsis in the gut, which in some way reduces aminosalicylic acid absorption. The extent to which diphenhydramine or any other anticholinergic drug diminishes the therapeutic response to long-term treatment with aminosalicylic acid is uncertain, but it is probably small.

---

### Aminosalicylic acid + Probenecid

The plasma levels of aminosalicylic acid can be raised up to fourfold by probenecid.

**Clinical evidence, mechanism, importance and management**

In a study in 7 patients, probenecid 500 mg every 6 hours increased the plasma levels of aminosalicylic acid 4 g by as much as fourfold. Similar results are described in another report. The reasons for this effect are uncertain but it seems probable that probenecid successfully competes with aminosalicylic acid for active excretion by the kidney tubules, which results in the increased aminosalicylic acid levels.

The documentation of this interaction is limited but it appears to be established. Such large increases in plasma aminosalicylic acid levels would be expected to lead to toxicity. It also seems possible that the dosage of aminosalicylic acid could be reduced without losing the required therapeutic response. This needs confirmation. Monitoring aminosalicylic acid levels, where possible, would probably be useful. Concurrent use should be undertaken with caution.

---

### Antibacterials + Immunoglobulins

One animal study found that for severe infections antibacterials were less effective in the presence of high-dose immunoglobulin, but this was not seen in less severe infections. The clinical relevance of this is uncertain.

**Clinical evidence, mechanism, importance and management**

A study in an animal model of severe group B streptococcal infection found the following mortalities: 51% with benzylpenicillin 200 mg/kg alone, 88% with immunoglobulin and benzylpenicillin, and 100% with immunoglobulin 2 g/kg alone. A smaller dose of immunoglobulin 0.5 g/kg was not associated with an increase in mortality. Roughly similar results were found when the penicillin was replaced by ceftriaxone. In another study using a 1000-fold smaller inoculum of group B streptococci, there was no difference in mortality between benzylpenicillin 200 mg/kg daily alone and benzylpenicillin with immunoglobulin 0.25 to 2 g/kg, and there was some evidence of a lower incidence of bacteremia with the combination.

Immunoglobulins are used with antibacterials in the successful prevention of infections in clinical practice, and no special precautions appear to be needed in this situation. However, their clinical use for treating established infection is unclear, and the above findings suggest some caution is warranted.

---

### Aztreonam + Other antibacterials

There appear to be no clinically significant pharmacokinetic interactions between aztreonam and amikacin, cefradine, clindamycin, gentamicin, metronidazole or nafcillin.

**Clinical evidence, mechanism, importance and management**

A study in healthy subjects given a single 1-g intravenous dose of aztreonam found that maximum levels were reduced by 12.6% and 9.8% when it was given with gentamicin 80 mg and metronidazole 500 mg, respectively. Serum bound aztreonam fell by 5% when it was given with nafcillin 500 mg and increased by 5.1% when given with cefradine 1 g. When aztreonam 1 g and clindamycin 600 mg were given together, their renal excretion increased by 5.2% and 10.9%, respectively. None of these changes was statistically significant. Another study in healthy subjects found that the AUC of a 1-g intravenous dose of aztreonam was reduced by 22% by amikacin 500 mg, and the AUC of amikacin was increased by 27% by aztreonam.

---

### Carbapenems + Probenecid

Probenecid increases the serum levels of meropenem, but does not appear to interact with ertapenem to a clinically relevant extent.

**Clinical evidence, mechanism, importance and management**

(a) **Erta penem**

The use of probenecid with ertapenem is reported to decrease the renal clearance of unbound ertapenem by about 50%, probably because probenecid inhibits the renal tubular secretion of ertapenem. Probenecid slightly increased the elimination half-life and AUC of ertapenem and therefore concurrent use is considered unlikely to increase the effects of ertapenem.

(b) **Meropenem**

In 6 healthy subjects probenecid (1 g given orally 2 hours before meropenem and 500 mg given orally 1.5 hours after meropenem) increased the AUC of meropenem 500 mg by 43%. Another study in 6 healthy subjects found that probenecid (1.5 g in divided doses the day before and 500 mg one hour before meropenem) increased the AUC of meropenem 1 g by up to 55% and increased its half-life by 33% (from 0.98 to 1.3 hours). In both studies the serum levels of meropenem were modestly increased. This is possibly because meropenem and probenecid compete for active kidney tubular secretion.

The manufacturers say that because the potency and duration of meropenem are adequate without probenecid, they do not recommend concurrent use.

---

### Cephalosporins + Antacids

No clinically significant interactions appear to occur between an aluminium/magnesium hydroxide antacid and cefaclor AF, cefalexin, cefetamet pivoxil, cefixime or cefprozil; between Alka-Seltzer and cefixime; or between cefdinir and Mylanta. In contrast, antacids reduce the bioavailability of cefpodoxime proxetil.

**Clinical evidence, mechanism, importance and management**

(a) **Cefaclor**

A study with cefaclor AF (a formulation with a slow rate of release) found that an aluminium/magnesium hydroxide antacid (Maulox) given one hour after the cefaclor AF to fed subjects reduced the AUC by 18%. This reduction is small and unlikely to be clinically important.
Nifedipine increases the serum levels of cefixime but this is unlikely to be clinically important. Neither nifedipine nor diltiazem affect the pharmacokinetics of cefpodoxime proxetil.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects the AUC and peak serum levels of a single 200-mg dose of cefixime were increased by about 70% and 50%, respectively, when cefixime was taken 30 minutes after a 20-mg dose of nifedipine. The rate of absorption was also increased. One suggested reason for this interaction is that the nifedipine increases the absorption of the cefixime by affecting the carrier system across the epithelial wall of the gut.1 It seems doubtful if this increased cefixime bioavailability is clinically important (the combination was well-tolerated) and no particular precautions would seem to be necessary on concurrent use.

The pharmacokinetics of a single 200-mg dose of cefpodoxime proxetil were found to be unchanged by single doses of either diltiazem 60 mg or nifedipine 20 mg in 12 healthy subjects.2 No special precautions would seem necessary during concurrent use.

Cephalosporins + Colestyramine

Cefotaxime binds with cefadroxil and cefalexin in the gut, which delays their absorption. The importance of this is probably small.

Clinical evidence

The peak serum levels of a 500-mg oral dose of cefadroxil were reduced and delayed in 4 subjects when it was taken with 10 g of cefotaxime, but the total amount absorbed was not affected.1 Similar results were found in a study involving cefalexin and cefotaxime.2

Mechanism

Cefotaxime is an ion-exchange resin, which binds with these two cephalosporins in the gut. This prevents the early and rapid absorption of the antibacterial, but as the cefotaxime/cephalosporin complex passes along the gastrointestinal tract, the antibacterial is progressively released and eventually virtually all of it becomes available for absorption.1

Importance and management

Direct information seems to be limited to the studies cited. The clinical significance is uncertain, but as the total amount of antibacterial absorbed is not reduced this interaction is probably of little importance. This needs confirmation. Information about other cephalosporins seems to be lacking.1

3. Cefpodoxime + Food

The bioavailabilities of cefadroxil, cefalexin, cefixime, cefprozil, and ceftadine are not affected by food. Cefadroxil may be given without regard to food but absorption of an extended-release preparation may be increased by food. The bioavailabilities of cefetamet pivoxil and cefuroxime axetil may be increased by administration with food.

Clinical evidence, mechanism, importance and management

(a) Cefadroxil

A study in 18 healthy subjects given a single 250-mg capsule of cefadroxil after an overnight fast or within 30 minutes of different meals found the bioavailability was not significantly affected by food.1 The rate of absorption and maximum plasma levels were decreased: a low-fat vegetarian diet decreased by food but compared to the fasting state, the maximum levels were increased; by 52% for rice-based diets, by 33% for low-fat-vegetarian diet, by 30% for low-fat-vegetarian diet, by 7% for low-fat-vegetarian diet. Compared with the fasting state, all the diets increased the time above MIC50 with significant increase of almost 42% with low-fat-vegetarian (wheat-based) food.2 The manufacturers of immediate-release cefadroxil capsules state that total absorption is the same whether the drug is given with or without

food, but for the extended-release preparation since absorption is enhanced by administration with food, the manufacturers recommend that this preparation should be taken with meals.4

(b) Cefadroxil

The manufacturers of cefadroxil state that the bioavailability of cefadroxil is unaffected by food so it may be taken either with meals or on an empty stomach.5

(c) Cefalexin

The manufacturers of cefalexin state that it is acid stable and may be given without regard to meals.6

(d) Cefetamet pivoxil

A study found that the bioavailability of cefetamet pivoxil was up to 25% higher when it was given 10 minutes after a standard breakfast rather than in the fasting state.13 However, in another study, healthy subjects were given oral cefetamet pivoxil hydrochloride 1 g (equivalent to 693 mg of cefetamet free acid) either: 1 hour before food with 200 mL of water; with a standard breakfast and a cup of tea or coffee; or 1 hour after breakfast with 200 mL of water. The cefetamet maximum plasma levels were 5.5, 5.47, and 6.57 micrograms/mL, respectively, and the AUCs were 38, 35.7, and 42.8 micrograms.hour/mL, respectively, suggesting that bioavailability of cefetamet pivoxil is lowest when taken with food. The time to reach maximum plasma levels was increased from 3.3 hours when given before food to 4.3 hours when given with food, and 4.1 hours when given one hour after food.9 It was thought possible that the amount of fluid taken with cefetamet may have affected absorption, but a study in which cefetamet 1 g was given under fasting conditions with either 250 or 450 mL of water found that increasing fluid intake did not affect absorption. Further, the absorption when taken with food, with or without 200 mL of water was similar. It was recommended that cefetamet pivoxil should be taken within an hour of a meal to improve absorption. The delay in absorption was not considered to be of significance, especially during multiple dose therapy.5

(e) Cefixime

A study in healthy subjects given a single 400-mg dose of cefixime, either in the fasting state or immediately after a standard breakfast found that the time to peak serum levels was increased from about 3.8 to 4.8 hours when cefixime was given with food, probably because of delayed gastric emptying. Serum levels, AUC and 24 hour urinary recovery were similar for fasted and fed states.10 Cefixime may be given without regard to meals.10,11

(f) Cefprozil

In a study in healthy subjects, cefprozil proxetil 400 mg tablets were given with 180 mL of water after an overnight fast, or either 1 hour before, with, or 2 hours after the start of a high-fat meal. Dosing 1 hour before the meal was similar to dosing in the fasting state. However, when cefprozil was taken with, or 2 hours after the meal its peak plasma levels were increased by about 45% and 46%, respectively, when compared with the peak levels achieved in the fasting state. The AUC was also increased, by 40%. The rate of cefprozil absorption was not greatly affected by food.8 Studies with a 200-mg dose of cefprozil have also found that food increases the extent, but not the rate, of cefprozil absorption.13 However, the extent of the food effect appears to be greater with the 400 mg dose. This is possibly because the bioavailability of the 400-mg tablets is less than that of the 200-mg tablets, so food may have a greater effect on the higher strength preparation.12 In another study by the same authors the AUC and urinary excretion of cefprozil proxetil 200 mg given as a suspension were higher (11% and 14%, respectively) when taken with a high-fat meal rather than in the fasting state. Maximum plasma levels were not affected by a high-fat meal but the time to achieve maximum levels was prolonged.14 The manufacturers state that the bioavailability of cefprozil proxetil 100 mg tablets and suspension is increased by food.15,16 The studies12-14 suggest the increased bioavailability of the tablets, but possibly not that of the suspension, when given with food may be clinically significant.

(g) Cefpodoxime proxetil

A study in healthy subjects found that, although food caused slight changes in the rate of absorption of a 1-g dose of cefpodoxime its pharmacokinetics (including total absorption) were not significantly affected.17

(h) Cefradine

A study in healthy subjects given cefradine 500 mg in the fasting state or immediately after a meal found the time to peak levels was increased from 0.8 hours to 2 hours by food. Peak serum levels of cefradine were reduced by 45% when it was given after food. However, the half-life and AUC were not affected.18 The manufacturers state that cefradine may be given without regard to meals.19

(i) Cefuroxime axetil

A study in healthy subjects given cefuroxime axetil 500 mg intravenously or oral doses of 125 mg to 1 g with or without food found that 36% and 52% of a 500-mg oral dose was absorbed in the fasting and fed states respectively.20 In another study in healthy subjects, a single 1-g dose of cefuroxime axetil was given 2 hours before or 35 minutes after a standard cooked breakfast. The bioavailability of cefuroxime was markedly enhanced by food.21 The manufacturer notes that optimum absorption of cefuroxime axetil occurs when it is given after a meal.22 This is probably because of delayed gastric emptying and transit which allowed more complete dissolution and absorption.21

Cephalosporins + Furosemide

The nephrotoxic effects of cefaloridine and possibly cefalotin or cefazolin appear to be increased by furosemide. Cefadroxil brain levels are reduced by furosemide. No important interactions appear to occur between furosemide and cefotin, ceftazidime, ceftriaxone, or cefuroxime.

Clinical evidence

(a) Nephrotoxicity

Nine out of 36 patients who developed acute renal failure while taking cefaloridine had also been taking a diuretic: furosemide was used in 7 cases. Other factors such as patient age and drug dosage may also have been involved. The authors of this report related their observations to previous animal studies, which showed that potent diuretics such as furosemide and etacrynic acid enhanced the incidence and extent of tubular necrosis.1 Several other reports describe nephrotoxicity in patients given both cefalor-

294 Chapter 10
Cephalosporins + H₂-receptor antagonists

Ranitidine and famotidine reduce the bioavailability of cefpodoxime proxetil. Ranitidine with sodium bicarbonate reduces the bioavailability of cefuroxime axetil, but not to an important extent if cefuroxime is taken with food. No clinically significant pharmacokinetic interactions appear to occur between cefaclor AF and cimetidine, or between cefetamet pivoxil, cefalexin or ceftibuten and ranitidine.

Clinical evidence
(a) Cefaclor
A study using cefaclor AF (a formulation with a slow rate of release) found that cimetidine 800 mg taken the previous night reduced its maximum plasma concentration by 12%.

(b) Cefalexin
Ranitidine 150 mg for 3 doses had only small and therapeutically unimportant effects on the pharmacokinetics of cefalexin 1 g. In another study in healthy subjects ranitidine 150 mg for 3 doses prolonged the time to attain peak serum levels of a single 500-mg dose of cefalexin from 1.19 to 1.48 hours. Other pharmacokinetic parameters were not significantly affected. Similar results were found when omeprazole was given instead of ranitidine.

(c) Cefetamet pivoxil
Ranitidine 150 mg twice daily for 4 days did not affect the pharmacokinetics of cefetamet pivoxil 1 g given to 18 healthy subjects after breakfast.

(d) Cefpodoxime proxetil
A study in 10 healthy fasted subjects showed that famotidine 40 mg reduced the bioavailability of cefpodoxime proxetil by about 40%. This confirms the findings of a previous study with ranitidine.

(e) Cefibuten
Ranitidine 150 mg every 12 hours for 3 days raised the maximum plasma levels and AUC of cefibuten by 23% and 16%, respectively, in 18 healthy subjects. However these values lie within the normal ranges seen in healthy subjects and no dosage adjustment is therefore thought to be needed.

(f) Cefuroxime axetil
Ranitidine 300 mg with sodium bicarbonate 4 g reduced the AUC of cefuroxime axetil 1 g by 43% when the combination was given to fasted subjects. However, when cefuroxime was given after food, its bioavailability was higher, and minimally affected by ranitidine plus sodium bicarbonate (10% reduction in AUC).

Mechanism
The reduction in the bioavailability of some of the cephalosporins is thought to be due to reduced dissolution at increased gastric pH values.

Importance and management
In most cases the interactions between the cephalosporins and H₂-receptor antagonists are not clinically significant. The clinical importance of the interaction with cefuroxime has not been studied, but the manufacturer recommends that cefuroxime is given at least 2 hours before H₂-receptor antagonists. As it is thought that a change in gastric pH is responsible for this interaction it would seem likely that proton pump inhibitors will interact similarly.

As long as cefuroxime is taken with food (as is recommended), any interaction is minimal. The bioavailability of cefetamet pivoxil, and cefpodoxime proxetil are also enhanced by food so it is probable that interaction of drugs which raise gastric pH may be similarly minimised.
Clinical evidence, mechanism, importance and management

Four patients developed acute renal failure, which appeared to be reversible, during treatment with colistin. Three were given ceftolaxin concurrently and the fourth had previously been taking this antibiotic. An increase in renal toxicity associated with concurrent use has been described in another report. The reason for this reaction is not known. What is known suggests that renal function should be closely monitored if these drugs are given concurrently or sequentially.

Cephalosporins; Ceftazidime + Penicillins

Azlocillin and mezlocillin may reduce the clearance of cefotaxime in subjects with normal or impaired renal function.

Clinical evidence, mechanism, importance and management

A patient with renal failure developed encephalopathy with focal motor status and generalised convulsions when given cefotaxime 2 g every 8 hours and azlocillin 5 g every 8 hours (high-dose). In a study in subjects with either normal or impaired renal function, the clearance of a single dose of cefotaxime was reduced by 40 to 50% regardless of renal function.

</table>

Cephalosporins; Cefpodoxime + Acetylcysteine

The pharmacokinetics of oral cefpodoxime proxetil are minimally affected by acetylcysteine and the interaction is unlikely to be of clinical importance.

Cephalosporins; Cefprozil + Metoclopramide or Propantheline

The pharmacokinetics of cefprozil are minimally affected by propantheline and metoclopramide, and an interaction of clinical importance is unlikely.

Cephalosporins; Ceftazidime + Indometacin

The clearance of ceftazidime is significantly reduced by indometacin in neonates, and dosage adjustments are likely to be necessary.

Clinical evidence, mechanism, importance and management

A study found the prenatal use of indometacin reduced the clearance of ceftazidime 25 mg/kg by 17.5% in 12 premature neonates (born at about 29 weeks) who were 10 days old. Further, in similar neonates who had not received indometacin, the clearance of ceftazidime increased over the first 10 days of life, but this was not seen when indometacin had been given.

1. A further study by the same authors intended to establish an appropriate

Table 10.2 Effect of probenecid on the pharmacokinetics of the cephalosporins (continued)

Cephalosporins; Cefotaxime + Phenobarbital

A 30-month study noted a very marked increase in drug-induced reactions in children in intensive care who were given high-dose phenobarbital and beta-lactam antibacterials (mainly cefotaxime). Twenty-four out of 49 children developed drug-induced reactions, which were mainly exanthematous skin reactions. The reasons are not known. It would seem prudent to consider this interaction in patients who develop skin reactions while taking both drugs.

Cephalosporins; Cefpodoxime + Acetylcysteine

The pharmacokinetics of oral cefpodoxime proxetil are minimally affected by acetylcysteine and the interaction is unlikely to be of clinical importance.

Cephalosporins; Ceftazidime + Indometacin

The clearance of ceftazidime is significantly reduced by indometacin in neonates, and dosage adjustments are likely to be necessary.

Clinical evidence, mechanism, importance and management

A study found the prenatal use of indometacin reduced the clearance of ceftazidime 25 mg/kg by 17.5% in 12 premature neonates (born at about 29 weeks) who were 10 days old. Further, in similar neonates who had not received indometacin, the clearance of ceftazidime increased over the first 10 days of life, but this was not seen when indometacin had been given.

1. A further study by the same authors intended to establish an appropriate
dose of ceftazidime for premature neonates. This study found that in 25 subjects who had received indometacin prenatally, the clearance of ceftazidime was reduced by 31% and therefore the authors suggest that additional dose reductions are required. However, note that the effect of indometacin was cancelled out in neonates who had also received betamethasone prenatally. Animal studies have shown that indometacin reduces ceftazidime excretion by decreasing its glomerular filtered load. Dosage of ceftazidime in preterm infants in the first week of life should be based on gestational age and glomerular filtration rate. Additional dosage adjustments are recommended in preterm infants who are also given indometacin.1,2

Chloramphenicol + Cimetidine

Isolated reports describe fatal aplastic anaemia in two patients given intravenous chloramphenicol and cimetidine.

Clinical evidence, mechanism, importance and management

Pancytopenia and aplastic anaemia developed in a man taking cimetidine 1.2 g daily, within 18 days of being given intravenous chloramphenicol 1 g every 6 hours. It proved to be fatal.1 Another patient, similarly treated, developed fatal aplastic anaemia after 19 days.2 A drug interaction with cimetidine was suspected because the onset of pancytopenia was more rapid than in previous cases where chloramphenicol alone induced aplastic anaemia. This effect may occur because the bone marrow depressant effects of the two drugs are additive. There are at least 8 other cases of aplastic anaemia following the use of parental chloramphenicol in the absence of cimetidine.4 The general importance of these observations is uncertain, but the authors of one of the reports suggest that these drugs should be used together with caution.

2. West BC, Devault GA, Clement JC, Williams DM. Aplastic anemia associated with parenteral chloramphenicol and cimetidine.1,2

Chloramphenicol + Dapsone

Dapsone does not significantly affect the pharmacokinetics of oral chloramphenicol.

Clinical evidence, mechanism, importance and management

A comparison of the pharmacokinetics of oral chloramphenicol in 8 healthy subjects and 8 patients with uncomplicated lepromatous leprosy found that the half-life of a single 500-mg dose of chloramphenicol was prolonged from 4.3 to 6.4 hours in patients with leprosy, possibly due to changes in liver function. The elimination half-life of chloramphenicol was further increased, to about 8 hours, when the subjects were also given dapsone 100 mg daily for 8 days. However, this latter increase was not statistically significant. Although there was no clinically significant interaction between dapsone and chloramphenicol, the disposition of chloramphenicol may be altered in leprosy.1

Chloramphenicol + Other antibacterials

An old report suggests that the use of chloramphenicol may antagonise the effects of ampicillin in bacterial meningitis. In contrast, no antagonism and even additive antibacterial effects have been described in other infections. Chloramphenicol levels have been markedly lowered by rifampicin (rifampin) in 4 children.

Clinical evidence

(a) Antibacterial antagonism

A study in 264 patients (adults, and children over two months old) with acute bacterial meningitis showed that when they were given ampicillin 150 mg/kg daily alone, the case-fatality ratio was 4.3% compared with 10.5% in comparable subjects given a combination of ampicillin, chloramphenicol 100 mg/kg daily up to 4 g and streptomycin 40 mg/kg daily up to 2 g. The neurological sequelae (hemiparesis, deafness, cranial nerve palsies) were also markedly increased by the combined use of these drugs.1 Antibacterial antagonism was clearly seen in a 10-week-old infant with Salmonella enteritidis meningitis, who was treated with chloramphenicol and ceftazidime.2

However, in contrast a report claims that antibacterial antagonism was not seen in 65 of 66 patients given chloramphenicol and benzylpenicillin for bronchitis or bronchopneumonia.3 Ampicillin with chloramphenicol is more effective than chloramphenicol alone in the treatment of typhoid,4 and in a study of 700 patients, procaine benzylpenicillin with chloramphenicol was shown to be more effective than chloramphenicol alone in the treatment of gonorrhoea (failure rates of 1.8% compared with 8.5%).5

(b) Pharmacokinetic interactions

In a study in premature and full-term neonates, infants and small children, it was found that the presence of penicillin markedly raised chloramphenicol levels.6 Two children, aged 2 and 5 years, with Haemophilus influenzae meningitis, were given chloramphenicol 100 mg/kg per day in four divided doses by infusion over 30 minutes. Within 3 days of starting rifampicin (rifampin) 20 mg/kg per day their peak serum chloramphenicol levels were reduced by 86 and 64%, respectively, and only returned to the therapeutic range when the chloramphenicol dosage was increased to 1.25 mg/kg per day.7

Two other children, of 5 and 18 months, with Haemophilus influenzae infections, are also reported to have shown reductions of 75% and 94%, respectively, in serum chloramphenicol levels when given rifampicin 20 mg/kg daily for 4 days. These reductions occurred despite 20 to 25% increases in the chloramphenicol dosage.8

Mechanism

By no means fully understood. Chloramphenicol inhibits bacterial protein synthesis and can change an actively growing bacterial colony into a static one. Thus the effects of a bactericide, such as penicillin, which interferes with cell wall synthesis, are blunted, and the death of the organism occurs more slowly. This would seem to explain the antagonism seen with some organisms.

It is thought that rifampicin, a potent enzyme inducer, markedly increases the metabolism of the chloramphenicol by the liver, thereby lowering its serum levels.7,8

Importance and management

Proven cases of antibacterial antagonism of chloramphenicol in patients seem to be few in number, and there is insufficient evidence to impose a general prohibition, because, depending on the organism, penicillins and chloramphenicol have been used together with clear advantage. So far only four cases of an interaction between rifampicin and chloramphenicol appear to have been reported. However, the evidence is of good quality and in line with the way rifampicin interacts with other drugs, so this interaction should be taken seriously. There is a risk that serum chloramphenicol levels may possibly expose the patient to a greater risk of bone marrow aplasia. They suggest delaying rifampicin prophylaxis in patients with invasive Haemophilus influenzae infections until the end of chloramphenicol treatment.1

### Chloramphenicol + Paracetamol (Acetaminophen)

Although there is limited evidence to suggest that paracetamol may affect chloramphenicol pharmacokinetics its validity has been criticised. Evidence of a clinically relevant interaction appears to be lacking.

**Clinical evidence, mechanism, importance and management**

Three studies report alterations in the pharmacokinetics of chloramphenicol by paracetamol. The first was conducted in 6 adults in intensive care after an observation that the half-life of chloramphenicol was prolonged by paracetamol in children with kwashiorkor. The addition of 100 mg of intravenous paracetamol increased the half-life of chloramphenicol in the adults from 3.25 to 15 hours. However, this study has been criticised because of potential errors in the method used to calculate the half-life, the unusual doses and routes of administration used, and because the pharmacokinetics of the chloramphenicol with and without paracetamol were calculated at different times after the administration of chloramphenicol. It has also been pointed out that malnutrition (e.g. kwashiorkor) can increase the elimination rate and AUC of chloramphenicol independently of paracetamol.

The second study demonstrated a different interaction, in that the clearance of chloramphenicol was increased and the half-life reduced. This study has also been criticised as it does not account for the fact that chloramphenicol clearance increases over the duration of a treatment course, which suggests that the changes seen in the pharmacokinetics of chloramphenicol may be independent of the paracetamol. The authors later admit this as a possibility. The third study found no differences in the pharmacokinetics of chloramphenicol after the first dose, but at steady state, the AUC and peak serum levels of chloramphenicol were lower in children who also received paracetamol.

Three other studies have failed to confirm the existence of a pharmacokinetic interaction between chloramphenicol and paracetamol.

The clinical significance of these reports is unclear, and clinical evidence of toxicity or treatment failure of chloramphenicol appears to be lacking. It would seem prudent to remain aware of the potential for interaction, especially in malnourished patients, but routine monitoring would appear unnecessary without further evidence.

### Chloramphenicol + Phenobarbital

Studies in children show that phenobarbital can markedly reduce serum chloramphenicol levels. There is a single report, in one adult, of markedly increased serum phenobarbital levels caused by chloramphenicol.

### Clinical evidence

**(a) Effects on chloramphenicol**

A study in a group of infants and children (aged 1 month to 12 years) given chloramphenicol 25 mg/kg every 6 hours found that 6 of them, also taking phenobarbital, had reduced serum chloramphenicol levels, when compared with 17 controls. The peak levels were lowered by 34%, from 25.3 to 16.6 micrograms/mL, and the trough levels were lowered by 44%, from 13.4 to 7.5 micrograms/mL. Two children aged 3 and 7 months were treated for *H. influenzae* meningitis with chloramphenicol 100 mg/kg daily, initially intravenously, and later orally. The chloramphenicol levels halved over the first 2 days of treatment, while the children were receiving phenobarbital 10 mg/kg/day to prevent convulsions. One child had serum chloramphenicol levels of only 5 micrograms/mL even though the initial doses used were expected to give levels of 15 to 25 micrograms/mL.

Another study confirmed that this interaction occurred in 20 neonates, but no statistically significant effect was found in 40 infants. Decreased chloramphenicol levels have been described in a single case report of a child who was also being treated with phenytoin and phenobarbital. The serum chloramphenicol levels were 35.1 micrograms/mL prior to the antiepileptics, 19.1 micrograms/mL after 2 days of phenytoin and 13.2 micrograms/mL a month after the addition of phenobarbital. For more information on the interaction of chloramphenicol with phenytoin see ‘Phenytoin + Chloramphenicol’, p.555.

**(b) Effects on phenobarbital**

A man admitted to hospital on numerous occasions for pulmonary complications associated with cystic fibrosis, had average serum phenobarbital levels of 33 micrograms/mL while taking phenobarbital 200 mg daily and oral chloramphenicol 600 mg every 6 hours. One week after the antibiotic was withdrawn, his serum phenobarbital levels were 24 micrograms/mL even though the phenobarbital dosage was increased from 200 to 300 mg daily.

### Mechanism

Phenobarbital is a potent liver enzyme inducer, which can increase the metabolism and clearance of chloramphenicol (clearly demonstrated in rats), so that its serum levels fall and its effects are reduced. Chloramphenicol inhibits the metabolism of the phenobarbital (also demonstrated in animals) so that the effects of the barbiturate are increased.

### Importance and management

This interaction appears to be established. The documentation is limited but what happened is consistent with the recognised enzyme-inducing actions of phenobarbital and the inhibitory actions of chloramphenicol. Concurrent use should be well monitored to ensure that chloramphenicol serum levels are adequate, and that phenobarbital levels do not become too high. Make appropriate dosage adjustments as necessary.

### Clindamycin or Lincomycin + Food or Drinks

The serum levels of lincomycin are markedly reduced (by up to two-thirds) if taken in the presence of food, but clindamycin is not significantly affected. Cyclamate sweeteners can also reduce the absorption of lincomycin.
Clinical evidence
In a study in 10 healthy subjects the mean peak serum levels of a single 500-mg oral dose of lincomycin were about 3 micrograms/mL when taken 4 hours before breakfast, 2 micrograms/mL when taken 1 hour before breakfast, and less than 1 microgram/mL when taken after breakfast. The mean total amounts of lincomycin recovered from the urine were 40.4, 23.8, and 8.9 mg, respectively. Reduced serum lincomycin levels due to the presence of food have been described in other reports, but the absorption of clindamycin is not affected.

Sodium cyclamate, an artificial sweetener found in diet foods, drinks, and some pharmaceuticals, can also markedly reduce the absorption of lincomycin. The AUC of lincomycin 500 mg was reduced by about 75% by 1 Molar equivalent of sodium cyclamate (said to be an amount equal to only a part of a bottle of diet drink, but exact quantity not stated).

Mechanism
Not understood.

Importance and management
The food interaction with lincomycin is well established and of clinical importance. Lincomycin should not be taken with food or within several hours of eating a meal if adequate serum levels are to be achieved. An alternative is clindamycin, a synthetic derivative of lincomycin, which has the same antibacterial spectrum but is not affected by food.

Clindamycin or Lincomycin + Kaolin
Kaolin-pectin can markedly reduce the absorption of lincomycin. This can be avoided by giving the lincomycin two hours after the kaolin. The rate but not the extent of clindamycin absorption is altered by kaolin-pectin. However, note that diarrhea is often an indication that these antibacterials should be withdrawn.

Clinical evidence
About 85 mL of Kaopectate (kaolin-pectin) reduced the absorption of lincomycin 500 mg by about 90% in 8 healthy subjects. Giving the Kaopectate 2 hours before the antibacterial had little or no effect on its absorption, whereas when Kaopectate was given 2 hours after lincomycin, the absorption was reduced by about 50%. The absorption rate of clindamycin is markedly prolonged by kaolin, but the extent of its absorption remains unaffected.

Mechanism
It seems probable that the lincomycin becomes adsorbed onto the kaolin, thereby reducing its bioavailability. The kaolin also coats the lining of the gut and acts as a physical barrier to absorption.

Importance and management
Information seems to be limited to this study, but the interaction between lincomycin and kaolin appears to be established and of clinical importance. For good absorption and a good antibacterial response separate their administration as much as possible, ideally giving the kaolin at least 2 hours before the antibacterial. Clindamycin appears to be a suitable alternative to lincomycin.

However, note that marked diarrhea is an indication that lincomycin or clindamycin should be stopped immediately. This is because it may be a sign of pseudomembranous colitis, which can be fatal.

Colistin + Sucralfate
An in vitro study with colistin sulfate found that it became markedly and irreversibly bound to sucralfate at the pH values found in the gut. This suggests that its efficacy for gut decontamination or gastrointestinal infections might be decreased by sucralfate.

Clinical evidence, mechanism, importance and management
To simulate what might happen in the gut, colistin sulfate 50 mg/L was mixed with sucralfate 500 mg in 40 mL of water at pH 3.5 and allowed to stand for 90 minutes at 25°C. Analysis of the solution showed that the colistin concentration fell rapidly and progressively over 90 minutes to about 40%. When the pH of the mixture was then raised to 6.5 to 7 for 90 minutes, there was no change in the concentration of colistin, suggesting that the interaction was irreversible. The reason for this change is not known, but the suggestion is that sucralfate forms insoluble chelates with colistin.

It is not known how important this interaction is likely to be in practice, but the efficacy of colistin in gut decontamination and gut infections may be decreased. Separating the dosages might not be effective in some postoperative patients because their gastric function may not return to normal for up to 5 days, and some sucralfate might still be present when the next dose is given.

Co-trimoxazole + Azithromycin
Azithromycin does not alter the pharmacokinetics of co-trimoxazole.

Clinical evidence, mechanism, importance and management
A study in 12 healthy subjects given co-trimoxazole (trimethoprim and sulfamethoxazole) 960 mg daily for 7 days found that a single 1.2-g dose of azithromycin given on day 7 did not alter the pharmacokinetics of either trimethoprim or sulfamethoxazole to a clinically relevant extent.

Co-trimoxazole + Cimetidine
Cimetidine has no significant effect on the pharmacokinetics of co-trimoxazole.

Clinical evidence, mechanism, importance and management
In a placebo-controlled study, 6 healthy subjects were given cimetidine 400 mg at 6 hours for 6 days, with a single 960-mg dose of co-trimoxazole (trimethoprim with sulfamethoxazole) on day 6. Although trimethoprim levels were consistently slightly higher in the presence of cimetidine, they were not significantly different. Cimetidine had no effect on the pharmacokinetics sulfamethoxazole.

Co-trimoxazole + Kaolin-pectin
Kaolin-pectin can cause a small but probably clinically unimportant reduction in serum trimethoprim levels, and has no effect on sulfamethoxazole pharmacokinetics.
Clinical evidence, mechanism, importance and management

Co-trimoxazole suspension (trimethoprim 160 mg with sulfamethoxazole 800 mg) was given to 8 healthy subjects, with and without 20 mL of kaolin-pectin suspension. The kaolin-pectin reduced the AUC and the maximum serum levels of the trimethoprim by about 12% and 20%, respectively. Changes in the sulfamethoxazole pharmacokinetics were not significant.1 The probable reason for this reduction in AUC is that trimethoprim is adsorbed onto the kaolin-pectin, which reduces the amount available for absorption. However, the reductions are small and unlikely to be clinically relevant.

---

Co-trimoxazole + Prilocaine/Lidocaine cream

Methaemoglobinemia developed in a baby treated with co-trimoxazole when Emla (prilocaine/lidocaine) cream was applied to his skin.

Clinical evidence, mechanism, importance and management

A 12-week-old child, given co-trimoxazole for 2 months for pyelitis, was treated with 5 g of Emla cream (prilocaine 25 mg and lidocaine 25 mg per gram) applied to the back of his hands and the cubital regions. Unfortunately his operation was delayed, and 5 hours later, just before the operation (a) Rifampin (Rifampin)

No significant pharmacokinetic interaction seems to occur when healthy subjects are given trimethoprim 240 mg daily with rifampicin 900 mg daily (both in standard doses). After 4 to 5 days, less trimethoprim is recovered in the urine, as more is metabolised prior to excretion due to the enzyme-inducing effects of rifampicin, but this does not appear to be of clinical importance.3,4 Another study also notes that no clinically significant pharmacokinetic interaction occurs between trimethoprim and rifampicin.5

However, a case-control study of the efficacy of co-trimoxazole in preventing toxoplasmosis in HIV-positive patients found a link between rifampicin use and co-trimoxazole failure,6 which prompted the authors to conduct a pharmacokinetic study. When rifampicin 600 mg daily was given to 10 HIV-positive patients with co-trimoxazole 960 mg daily, it was found that the AUCs of trimethoprim and sulfamethoxazole were reduced by 56% and 28%, respectively. These changes are sufficient to reduce the efficacy of co-trimoxazole treatment.1 It would therefore seem prudent to consider this interaction when giving rifampicin to HIV-positive patients taking co-trimoxazole prophylaxis.

In one study patients with tuberculosis, who had taken rifampicin 450 mg daily for at least 15 days, were given co-trimoxazole (trimethoprim 320 mg and sulfamethoxazole 800 mg 12-hourly) for 5 to 10 days. Rifampicin levels were measured at 5 time points over 6 hours before and during co-trimoxazole treatment.4 At 4 and 6 hours, rifampicin levels were significantly higher (27% and 56%, respectively) during co-trimoxazole treatment, but peak levels were only increased by about 18%. Concurrent use did not result in any increase in adverse effects over the study period.5

---

Co-trimoxazole or Trimethoprim + Rifamycins

The pharmacokinetics of trimethoprim are not significantly affected by rifabutin, and probably not by rifampicin (rifampin). Rifabutin does not affect the pharmacokinetics of sulfamethoxazole, but significantly increases exposure to its hydroxylamine metabolite and as a result may increase adverse reactions to sulfamethoxazole in HIV-positive patients. A significant reduction in co-trimoxazole levels and a decrease in prophylactic efficacy has been seen in HIV-positive patients taking rifampicin. Limited evidence suggests that co-trimoxazole can increase rifampicin serum levels. Trimethoprim does not affect the pharmacokinetics of rifampicin.

Clinical evidence, mechanism, importance and management

(a) Rifabutin

Twelve HIV-positive patients taking co-trimoxazole (sulfamethoxazole and trimethoprim; strength not stated) twice daily for 7 days were also given rifabutin 300 mg daily for a further 14 days. The sulfamethoxazole component remained unaffected by rifabutin but the trimethoprim AUC was decreased by 22%. This small reduction is not expected to be clinically significant.1 However, another study in HIV-positive patients given co-trimoxazole (sulfamethoxazole 800 mg with trimethoprim 160 mg daily) found that although rifabutin 300 mg daily had minimal effects on the disposition of sulfamethoxazole and its acetylated metabolite, it significantly increased the AUC, urinary recovery and formation clearance of its hydroxylamine metabolite by about 50%. As the hydroxylamine metabolite may be one of the factors associated with adverse reactions to sulfamethoxazole in HIV-positive patients, concurrent rifabutin may increase the rate of adverse reactions.2

(b) Rifampicin (Rifampin)

Salbutamol reduces the rate but increases the extent of sulfamethoxazole absorption.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects, oral salbutamol 4 mg four times daily for 2 weeks had no effect on the pharmacokinetics of a single 400-mg oral dose of sulfamethoxazole (co-trimoxazole), although the absorption rate constant was reduced by about 40% and the extent of absorption over 72 hours was increased by 22.6%.1 A possible reason for these effects is that salbutamol stimulates the beta receptors in the gut, causing relaxation, which allows an increased contact time, and therefore increased absorption of sulfamethoxazole.1 The clinical significance of this interaction is unknown, but it
seems unlikely to be of importance. No interaction would be expected with inhaled salbutamol.

### Cycloserine + Ethionamide

**Neurotoxic adverse effects may be potentiated by the concurrent use of cycloserine and ethionamide.**

**Clinical evidence, mechanism, importance and management**

Three cases of encephalopathy have been reported in patients taking antitubercular regimens which included ethionamide (and in 2 cases, isoniazid): in one case symptoms occurred during treatment with ethionamide and cycloserine. All 3 patients recovered after withdrawal of either ethionamide (and isoniazid) or cycloserine, and treatment with nicotinamide and other vitamin B compounds. The manufacturers note that the concurrent use of ethionamide can potentiate the neurotoxic adverse effects of cycloserine. The US manufacturer of ethionamide notes that convulsions have been reported in patients also taking cycloserine and they recommend special care when the treatment regimen includes both drugs.

### Cycloserine + Food or Antacids

Orange juice and an antacid (Mylanta) do not affect the pharmacokinetics of cycloserine, but a high-fat meal delays its absorption.

**Clinical evidence, mechanism, importance and management**

(a) **Antacids**

A study in 12 healthy subjects found that the bioavailability of a single 500-mg dose of cycloserine was not affected by 15 mL of Mylanta (aluminum hydroxide 400 mg, magnesium hydroxide 400 mg, simeticone 40 mg per 5 mL). Mylanta was given 9 hours before the cycloserine, at the same time as the cycloserine, immediately after meals, and at bedtime on the dosing day and following day.

(b) **Food**

A study in 12 healthy subjects found that the bioavailability of a single 500-mg dose of cycloserine was not significantly affected by 240 mL of orange juice. When cycloserine 500 mg was given 15 minutes after the start of a high-fat meal, which was completed within 30 minutes, the AUC was not affected, but the maximum serum levels were reduced by about 16% and the time to maximum levels was increased from 0.75 to 3.5 hours. It is possible that patients with relatively low plasma levels or patients receiving once rather than a twice daily dosage that the delay in absorption could result in increased periods of subinhibitory levels. However, there is no evidence to suggest that this is clinically significant.

### Cycloserine + Isoniazid

The adverse CNS effects of cycloserine are increased by isoniazid.

**Clinical evidence, mechanism, importance and management**

A report describes both an increase and a decrease in serum cycloserine levels in some subjects, which were apparently caused by isoniazid; however, the mean level of cycloserine was not significantly changed. Only one out of 11 patients taking cycloserine alone developed adverse effects (drowsiness, dizziness, unstable gait), but when isoniazid was added, 9 of the 11 developed these effects. The manufacturers recommend monitoring for these adverse effects and adjusting the doses as necessary to manage them. The adverse CNS effects of cycloserine are increased by isoniazid.

### Dapsone + Clarithromycin

Clarithromycin does not alter the metabolism of dapsone.

**Clinical evidence, mechanism, importance and management**

A study in 12 healthy subjects given single 100-mg doses of dapsone before and after taking clarithromycin 1 g twice daily for 10 days, found that the clearance of dapsone was unchanged. Of equal importance was finding that the AUC of the N-hydroxylation metabolite of dapsone, which appears to be responsible for the haematological toxicity (methaemoglobinemia), was also unchanged.

In another study, 11 HIV-positive patients were given dapsone 100 mg daily then clarithromycin 500 mg twice daily for 2 weeks. Clarithromycin had no effect on dapsone clearance or the production of the hydroxylamine metabolite of dapsone.

These results suggest that the cytochrome P450 isozyme CYP3A4, which is inhibited by clarithromycin, is not involved in dapsone metabolism. Clarithromycin would not be expected to alter the toxicity of dapsone, and no special precautions are required during concurrent use.

### Dapsone + Clofazimine

Dapsone can reduce the anti-inflammatory effects of clofazimine. Clofazimine does not affect the pharmacokinetics of dapsone.

**Clinical evidence, mechanism, importance and management**

Fourteen out of 16 patients with severe recurrent erythema nodosum leprosum (ENL) failed to respond adequately when given dapsone and...
clofazimine and needed additional treatment with corticosteroids. When the dapsone was stopped the patients responded to clofazimine alone, and in some instances the ENL was controlled by smaller doses. Further evidence of this interaction comes from a laboratory study, which suggests that the actions of clofazimine may be related to its ability to inhibit neutrophil migration (resulting in decreased numbers of neutrophils in areas of inflammation), whereas dapsone can have the opposite effect. Although the information is very limited, it would seem prudent to avoid the concurrent use of dapsone and clofazimine in the treatment of ENL. The authors of this report are at great pains to emphasise that what they describe only relates to the effects of dapsone on the anti-inflammatory effects of clofazimine, and not to the beneficial effects of combined use when treating drug-resistant Mycobacterium leprae.

A study in patients taking clofazimine and dapsone and four other studies in patients also taking isoniazid or rifampicin suggest that clofazimine does not affect the pharmacokinetics of dapsone. However, one earlier study found that clofazimine transiently increased the renal excretion of dapsone in 9 of 17 patients with leprosy who had recently discontinued dapsone. It would therefore seem that no additional precautions are needed if concurrent use of dapsone and clofazimine is avoided.

Dapsone + Drugs that affect gastric pH

Cimetidine raises serum dapsone levels, and may reduce methaemoglobinemia due to dapsone. Cimetidine, ranitidine and omeprazole do not appear to affect the outcome of dapsone prophylaxis against Pneumocystis pneumonia. The absorption of dapsone does not appear to be altered by nizatidine-induced increases in gastric pH.

Clinical evidence, mechanism, importance and management

The AUC of a single 100-mg dose of dapsone was increased by 40% in 7 healthy subjects after they took cimetidine 400 mg three times daily for 3 days. The probable reason is that the cimetidine (a known enzyme inhibitor) inhibits the metabolism of the dapsone by the liver. Although this might be expected to increase the risk of haematological adverse effects of dapsone by raising its serum levels, cimetidine also apparently markedly reduces the production of the hydroxylamine metabolite of dapsone (the AUC fell by more than half). Dapsone hydroxylamine appears to be responsible for the methaemoglobinemia and haemolysis that may occur with dapsone treatment. These findings were later confirmed in 6 patients taking long-term dapsone 75 to 350 mg daily who were given cimetidine 1.2 g daily for 2 weeks. Steady-state serum dapsone levels rose by about 47%, accompanied by a fall in serum methaemoglobin levels from 7.1 to 5.2% (reference range less than 2%), in the first week. Similar findings were reported in a further 3-month study in 8 patients. However, a sustained decrease in methaemoglobin was not seen, with levels returning to baseline at week 12, despite the continued use of cimetidine. Another report on a small number of patients, comparing those treated with cimetidine, ranitidine or omeprazole with those not taking acid suppression, found no difference in the outcome of dapsone prophylaxis for Pneumocystis pneumonia in HIV-positive patients. A study in healthy subjects found that the increase in pH produced by nizatidine did not result in any clinically significant changes in the rate or extent of dapsone absorption. It would therefore seem that no additional precautions are needed if H2-receptor antagonists or proton pump inhibitors are given to patients taking dapsone. Consider also ‘Dapsone + Antacids’, p.303.

Dapsone + Fluconazole

Fluconazole decreases the production of the toxic metabolite of dapsone, and might therefore reduce the incidence of adverse reactions to dapsone.

Clinical evidence, mechanism, importance and management

Twelve HIV-positive patients were given dapsone 100 mg daily for 2 weeks and then in random order either fluconazole 200 mg daily, rifabutin 300 mg daily or fluconazole with rifabutin, each for 2 weeks. Dapsone pharmacokinetics were unaffected by fluconazole. However, fluconazole inhibited the production of the N-hydroxylamine metabolite of dapsone (AUC, urinary recovery, and formation clearance reduced by about 50%). Hydroxylamine is assumed to be responsible for the haematological toxicity of dapsone (methaemoglobinemia). The findings of this study suggest that the production of this metabolite is mediated via the cytochrome P450 isoenzyme CYP2C9, which fluconazole inhibits.

The basis of these results, fluconazole would not be expected to alter the efficacy of dapsone, but might reduce its toxicity. Further study is needed to assess this potential.

Dapsone + Probencid

The serum levels of dapsone can be markedly raised by probenecid.

Clinical evidence

Twelve patients with quiescent tuberculous leprosy were given dapsone 300 mg with probenecid 500 mg, and 5 hours later another 300-mg dose of dapsone. At 4 hours, the dapsone serum levels were raised about 50%. The urinary excretion of dapsone and its metabolites were reduced.1

Mechanism

Not fully examined. It seems probable that the probenecid inhibits the renal excretion of dapsone by the kidney.

Importance and management

The documentation is very limited. It is likely that the probenecid will raise the serum levels of dapsone given long-term. The importance of this is uncertain, but the extent of the rise and the evidence that the haematological toxicity of dapsone may be related to dapsone levels suggests that it may well have some clinical importance. It would therefore seem prudent to monitor for dapsone adverse effects if probenecid is also given.

Dapsone + Proguanil

No pharmacokinetic interaction appears to occur between dapsone and proguanil, and they have been successfully used together for malaria prophylaxis.
Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects found that proguanil 200 mg daily had no effect on the pharmacokinetics of dapsone 10 mg daily, nor on its principal metabolite, monoacetyldapsone. However, the authors of this report are extremely cautious because, despite this lack of a pharmacokinetic interaction at these dosages, they say that increased dapsone toxicity cannot be ruled out.1 Dapsone 25 mg was successfully used with proguanil 200 mg daily for malarial prophylaxis in the Vietnam war,2 and the same regimen, but with the dapsone dosage every third day was successful as prophylaxis against proguanil-resistant falciparum malaria in Papua New Guinea. Moreover, a different dosage (dapsone 4 or 12.5 mg with proguanil 200 mg daily), was well tolerated over a period of 80 days when used as malaria prophylaxis in Thailand.3

Pyrimethamine does not significantly affect the pharmacokinetics of dapsone.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects given single doses of dapsone 100 mg, pyrimethamine 25 mg or both drugs together found that the peak plasma levels of dapsone fell by 17% and the half-life was unchanged, but the apparent volume of distribution was significantly increased from 1.53 to 1.93 L/kg. The pharmacokinetics of pyrimethamine were not affected by dapsone.1 In another study HIV-positive patients were given dapsone 200 mg weekly (the maximum tolerated dose) either alone or with pyrimethamine 25 mg weekly. In contrast to the earlier study, there was a decrease in volume of distribution of dapsone when it was given with pyrimethamine, although dapsone levels were not significantly altered.2 Furthermore, the tolerability of one-weekly dapsone plus pyrimethamine was found to be similar to that of once-weekly dapsone alone.2

Other studies in patients given both drugs for several days, similarly found reduced dapsone serum levels and an increased urinary excretion.2,7 Another study in 12 healthy subjects given a single 100-mg dose of dapsone before and after taking rifampicin 600 mg daily for 10 days, found that the clearance of the dapsone was considerably increased (from 2.01 to 7.17 litres/hour). Of equal importance was finding that the production of the hydroxylamine metabolite of dapsone, which appears to be responsible for the haematological toxicity (methaemoglobinaemia), was markedly increased. The 24-hour AUC of methaemoglobin was increased by more than 60%,8 suggesting that this interaction increases dapsone toxicity.

Mechanism

Rifampicin and rifabutin increase the metabolism and clearance of dapsone. Rifampicin also increases the blood levels of the toxic hydroxylamine metabolite of dapsone. Similarly, rifabutin increased the formation of this metabolite, although increases in the AUC were not seen.

Dapsone + Rifamycins

Rifampicin increases the urinary excretion of dapsone, lowers its serum levels and increases the risk of toxicity (methaemoglobinaemia). Similarly, rifabutin increases the clearance of dapsone, and may also increase its toxicity.

Clinical evidence

(a) Rifabutin

Twelve HIV-positive patients were given dapsone 100 mg daily for 2 weeks and then, in random order, either rifabutin 300 mg daily, fluconazole 200 mg daily, or fluconazole with rifabutin, each for 2 weeks. Rifabutin alone increased the clearance of dapsone by 67%. When combined with fluconazole, rifabutin increased the clearance of dapsone by 38%, which shows that fluconazole partially attenuated the enzyme-inducing effects of rifabutin. Rifabutin increased the formation clearance of dapsone by 92%, which was again attenuated by fluconazole. Rifabutin did not affect the AUC of the hydroxylamine metabolite of dapsone, which is thought to be associated with dapsone toxicity.1

(b) Rifampicin (Rifampin)

A study in 7 patients with leprosy given single doses of dapsone 100 mg and rifampicin 600 mg, alone or together, found that while the pharmacokinetics of rifampicin were not significantly changed, the half-life of the dapsone was roughly halved and the AUC was reduced by about 20%.2

Dapsone + Trimethoprim

The serum levels of both drugs are possibly raised by concurrent use. Both increased efficacy and dapsone toxicity have been seen.

Clinical evidence

Eighteen patients with AIDS, treated for Pneumocystis pneumonia and taking dapsone 100 mg daily, were compared with 30 other patients taking dapsone with trimethoprim 20 mg/kg daily. The trimethoprim raised dapsone levels by 40%, from 1.5 to 2.1 micrograms/mL, at 7 days (steady-state). Dapsone toxicity (methaemoglobinaemia) was also increased.1 Trimethoprim plasma levels were 48.4% higher in the 30 patients also taking dapsone when compared with another group of 30 patients given co-trimoxazole (trimethoprim with sulfamethoxazole), but the incidence of toxicity was higher in the co-trimoxazole group.1 However, a later study by the same authors in 8 asymptomatic HIV-positive patients given dapsone 100 mg daily and trimethoprim 200 mg every 12 hours found that the steady-state pharmacokinetics of each drug was unaffected by the other, although the single dose pharmacokinetics showed higher serum levels than at steady state for both drugs.2

Mechanism

Not understood. Dapsone and trimethoprim appear to have mutually inhibitory effects on clearance.
Importance and management

Information is limited. The difference between the results of the two studies may be because the first was in AIDS patients with Pneumocystis pneumonia and the second was in asymptomatic HIV-positive patients whose drug metabolism may possibly be different. Concurrent use appears to be an effective form of treatment, but be alert for evidence of increased dapsone toxicity (methaemoglobinemia).

Dapsone + Ursodeoxycholic acid (Ursodiol)

A single case suggests that the effectiveness of dapsone in the treatment of dermatitis herpetiformis may be reduced by ursodeoxycholic acid.

Clinical evidence, mechanism, importance and management

A 61-year-old man taking dapsone 50 mg daily for dermatitis herpeti-formis started taking ursodeoxycholic acid 450 mg twice daily for chole-cystitis. Two weeks later the dermatitis herpetiformis worsened and the dose of dapsone was increased to 150 mg daily. However, his condition did not improve, so ursodeoxycholic acid was stopped and, as his condition improved, the dapsone dose was reduced to 100 mg, and then 50 mg daily. Two months later ursodeoxycholic acid was restarted and there was again an exacerbation of the dermatitis herpetiformis.1 The general importance of this isolated report is unknown, but consider the possibility of reduced dapsone effects if ursodeoxycholic acid is also given.

Daptomycin + Miscellaneous

The use of statins and probably fibrates should be suspended during daptomycin use because of the possible increased risk of muscle toxicity. Daptomycin does not appear to interact with warfarin, but its use may result in falsely elevated prothrombin times. NSAIDs may reduce daptomycin excretion and concurrent use may increase the risks of renal impairment.

Clinical evidence, mechanism, importance and management

(a) Drugs causing myopathy

The US manufacturers describe a study in 20 healthy subjects taking sim-vastatin 40 mg daily, in which the addition of daptomycin 4 mg/kg per day for 14 days did not result in an increase in adverse effects, when compared to subjects given placebo. In contrast, in a phase III study of patients with tuberculosis, 5 out of 22 patients who were currently, or had recently, been taking a statin developed raised creatinine phosphokinase levels.2 Furthermore, a case report describes a patient who was given daptomycin 6.5 mg/kg daily, who developed muscle pain and a raised creatinine phosphokinase (20 771 units/L). He had been taking 6.5 mg/kg daily, who developed muscle pain and a raised creatinine phosphokinase.1

5. Cubicin (Daptomycin). Novartis Pharmaceuticals UK Ltd. UK Summary of product character-

(b) NSAIDs

The UK manufacturers note that NSAIDs (including coxibs) may reduce the renal excretion of daptomycin and have additive detrimental effects on renal function if used with daptomycin.3 They advise caution on concurrent use, which in practice probably means keeping a close eye on renal function and monitoring for possible daptomycin adverse effects.

(c) Warfarin

The US manufacturers describe a study in 16 healthy subjects in which daptomycin 6 mg/kg per day for 5 days did not affect either the pharmacokinetics or the INR in response to a single 25-mg dose of warfarin. The pharmacokinetics of daptomycin were also unchanged.1 However, as experience is limited the manufacturers advise monitoring the INR for the first few days of concurrent use. Note that daptomycin causes a concentration-dependent false prolongation of prothrombin time.1,2 This only appears to occur with recombinant thromboplastin reagents. Blood for INR testing should therefore be drawn during the daptomycin trough (i.e. immediately before the next dose). If a raised INR is found it is recommended that the INR should be re-tested, and alternative methods of monitoring should be considered.1

(d) Miscellaneous

The US manufacturers1 briefly mention small studies in which daptomy-cin was given with aztreonam or tobramycin without any significant change in the pharmacokinetics of either drug. They also mention a study in which probenecid did not alter the pharmacokinetics of daptomycin.

5. Cubicin (Daptomycin). Novartis Pharmaceuticals UK Ltd. UK Summary of product character-

Ethambutol + Antacids

Aluminium hydroxide and aluminium/magnesium hydroxide can cause a small but probably clinically unimportant reduction in the absorption of ethambutol in some patients.

Clinical evidence, mechanism, importance and management

A study in 13 patients with tuberculosis, given a single 50-mg/kg dose of ethambutol, found that when they were also given three 1.5-g doses of alu-minium hydroxide gel (at the same time and 15 and 30 minutes later) their peak serum ethambutol levels were delayed and reduced. The average urinary excretion of ethambutol over a 10-hour period was reduced by about 15%, but there were marked variations between individual patients. Some showed no interaction, and others showed increased absorption.1 No interaction was seen in 6 healthy subjects similarly treated.2 A further study in 1 healthy subjects found that 30 ml. of an aluminium/magnesium hydroxide antacid decreased the AUC and maximum serum levels of a 25-mg/kg dose of ethambutol by 10% and 29%, respectively.2 Just why this interaction occurs is not understood, but aluminium hydroxide can affect gastric emptying. The reduction in absorption is generally small and variable, and it seems doubtful if it will have a significant effect on the treatment of tuberculosis. However, the authors of the second study suggest avoiding giving antacid at the same time as ethambutol,2 and the US manufacturer states that aluminium hydroxide-containing antacids should not be taken until 4 hours after a dose of ethambutol.3

2. Pełoquin CA, Bulpitt AE, Jarekso GS, Jelliffe RW, Childs JM, Nix DE. Pharmacokinetics of ethambutol under fasting conditions, with food, and with antacids. Antimicrob Agents Chem-
Ethambutol + Food

The pharmacokinetics of ethambutol given with a high-fat breakfast were only slightly different to its pharmacokinetics when it is given in the fasting state. Therefore ethambutol may be given without regard to meals.

Ethambutol + Rifabutin

Rifabutin does not appear to affect the pharmacokinetics of ethambutol.

Clinical evidence, mechanism, importance and management

Ten healthy subjects were given a single 1.2-g dose of ethambutol before and after taking rifabutin 300 mg daily for a week. No clinically relevant changes in the pharmacokinetics of ethambutol were seen. Although 5 of the subjects experienced moderate to severe chills, and one had transient thrombocytopenia these reactions are unlikely to have been due to an interaction. No special precautions would appear to be necessary during concurrent use.

Ethionamide + Isoniazid

Isoniazid may contribute to acute psychotic reactions associated with ethionamide, but evidence for this is limited.

Clinical evidence, mechanism, importance and management

Acute psychiatric reactions occurring during treatment with either isoniazid or ethionamide are reported to be uncommon. Acute mania occurred in a patient treated with streptomycin, isoniazid and prednisolone for 4 months, and ethionamide and pyrazinamide for 27 days. It was thought that ethionamide was probably responsible for the psychotic reaction but that isoniazid and prednisolone may have potentiated the reaction. In another patient, ethionamide was considered to be responsible for psychological changes, which resolved when the drug was stopped. However, the contribution of alcohol and other concurrent drugs such as isoniazid was not ruled out. One study in patients found that ethionamide 750 mg increased serum levels of a single 10-mg/kg dose of isoniazid at 4 hours but not at 1 or 10 hours, but this was not considered to be of therapeutic significance and the toxic symptoms reported with the combination were considered not to be due to increased isoniazid levels.

A clinically significant interaction therefore seems unlikely, but as both drugs can, rarely, cause psychotic reactions these tentative reports cannot entirely be dismissed.

Ethionamide + Miscellaneous

A study in 12 healthy subjects found that the bioavailability of a single 500-mg dose of ethionamide was not significantly affected by food, orange juice or antacids, when compared with ethionamide bioavailability under fasting conditions. It was suggested that ethionamide may be given with food if tolerance is a problem.

Fosfomycin + Cimetidine

In a study in 9 healthy subjects the pharmacokinetics of a 50-mg dose of fosfomycin were not significantly altered by two 400 mg doses of cimetidine, given both the night before and 30 minutes before the fosfomycin.

Fosfomycin + Metoclopramide

Metoclopramide reduces fosfomycin bioavailability but the evidence suggests that this probably does not alter its efficacy in urinary tract infections.

Clinical evidence, mechanism, importance and management

Metoclopramide 20 mg given to 9 healthy subjects 30 minutes before fosfomycin 50 mg/kg reduced the peak serum levels of fosfomycin by 42% and reduced the AUC by 27%. These changes appear to occur because metoclopramide speeds the transit through the gut, so that less time is available for good absorption. However, despite these reductions, the urinary concentrations of fosfomycin remained above the minimum levels required for common urinary pathogens for at least 36 hours after the dose. This suggests that the interaction is unlikely to be clinically important.

Isoniazid + Aminosalicylic acid

Isoniazid serum levels are raised by aminosalicylic acid.

Clinical evidence, mechanism, importance and management

A study found that aminosalicylic acid significantly increased the plasma levels of isoniazid at 4 and 6 hours after administration by 32% and 114%, respectively in fast acetylators of isoniazid, and by 21% and 39%, respectively in slow acetylators. The half-life of isoniazid was increased from 1.32 to 2.89 hours in fast acetylators and from 3.05 to 4.27 hours in slow acetylators (see ‘Genetic factors’, (p.4), for more information about acetylator status). The effects were probably due to the inhibition of isoniazid metabolism by aminosalicylic acid. There seem to be no reports of isoniazid toxicity arising from this interaction, but the manufacturers of isoniazid warn that adverse effects are more likely in the presence of aminosalicylic acid.

Isoniazid + Antacids

The absorption of isoniazid from the gut is modestly reduced by aluminium hydroxide, less so by magaldrate, and not by affected by aluminium/magnesium hydroxide tablets or didanosine chewable tablets.
Clinical evidence

Aluminium hydroxide (Amphojel) 45 mL was given to 10 patients with tuberculosis at 6, 7 and 8 am, followed immediately by isoniazid and any other medication they were receiving. The plasma isoniazid levels at 1 hour were decreased, and peak plasma concentrations occurring between 1 and 2 hours after ingestion were reduced by about 25%, when adjusted for different dosages. The effect of magaldrate (hydrated magnesium aluminate) was less, and in another well-controlled study aluminium magnesium hydroxide (Mylanta) had no effect.

Didanosine chewable tablets contain antacids (aluminium/magnesium hydroxide) in the formulation, but it has been shown that they do not affect the bioavailability of isoniazid.

Mechanism

Aluminium hydroxide delays gastric emptying, causing retention of the isoniazid in the stomach. Since isoniazid is largely absorbed from the intestine, this explains the slight decrease in plasma isoniazid concentrations. Aluminium hydroxide also appears to inhibit the absorption of isoniazid.

Importance and management

Information on this interaction is limited, and it is not established. The clinical importance of the modest reductions in isoniazid levels with aluminium hydroxide in one study is uncertain, but likely to be small. However, aluminium/magnesium hydroxide did not interact, and neither did didanosine chewable tablets.

Ciprofloxacin may cause a modest increase in the bioavailability of isoniazid.

Clinical evidence, mechanism, importance and management

In a single-dose study ciprofloxacin 500 mg was found to increase the absorption of isoniazid 300 mg by about 15%. The time to reach maximum plasma levels was increased from 3 hours to 4 hours. The rate of elimination and plasma half-life of isoniazid were not significantly affected. The plasma levels was increased from 3 hours to 4 hours. The rate of elimination and plasma half-life of isoniazid were not significantly affected. The clinical importance of the modest reductions in isoniazid levels with aluminium hydroxide is uncertain, but likely to be small. However, aluminium/magnesium hydroxide did not interact, and neither did didanosine chewable tablets.

Isoniazid + Ciprofloxacin

Ciprofloxacin may cause a modest increase in the bioavailability of isoniazid.

Isoniazid + Disulfiram

In most patients, the concurrent use of isoniazid and disulfiram is uneventful, but difficulties in co-ordination, in changes in mental status, behaviour, and drowsiness have been reported in a small number of patients.

Clinical evidence

Seven patients with tuberculosis who had been taking isoniazid for at least 30 days, without problems, experienced adverse reactions within 2 to 8 days of starting to take disulfiram 500 mg daily. Among the symptoms were dizziness, disorientation, a staggering gait, insomnia, irritability and querulous behaviour, listlessness, and lethargy. One patient became hypomanic. Most of them were also taking chlor Diazepoxide, and other drugs included aminosalicylic acid, streptomycin and phenobarbital. The adverse reactions decreased or disappeared when the disulfiram was either reduced to 250 or 125 mg daily, or withdrawn. These 7 patients represented less than one-third of those who received both drugs. As disulfiram is known to inhibit the metabolism of chlor Diazepoxide, another 4 patients were given only isoniazid and disulfiram. Although their reaction was not as severe, all 4 developed drowsiness and depression.

In contrast, another report describes the concurrent use of both drugs, without problems, in 200 patients. A retrospective study in patients treated with isoniazid-containing regimens for tuberculosis found no difference in rates of toxicity in 13 patients taking disulfiram, when compared to a large group of patients not taking disulfiram. However, the small number of patients taking disulfiram in this study limits the strength of the negative finding. Another patient taking disulfiram with isoniazid and rifampicin (rifampin) also did not experience any problems.

Mechanism

Not understood. One idea is that some kind of synergy occurs between the two drugs because both can produce similar adverse effects if given in high doses. The authors of one report speculated that isoniazid and disulfiram together inhibit two of the three biochemical pathways concerned with the metabolism of dopamine. This leaves a third pathway open, catalysed by COMT (catechol-O-methyl transferase), which produces a number of methylated products of dopamine. These methylated products may possibly have been responsible for the mental and physical reactions seen.

Importance and management

Information about this interaction appears to be limited to the reports cited. Its incidence is uncertain but apparently quite small. Two-thirds of the patients in one study, and at least 200 other patients showed no interaction. It would therefore seem that concurrent use need not be avoided, but the response should be monitored. If marked changes in mental status occur, or there is unsteady gait, the manufacturers recommend that the disulfiram should be withdrawn.

Isoniazid + Ethambutol

Ethambutol does not appear to affect serum isoniazid levels. However, it seems that the optic neuropathy caused by ethambutol may be increased by isoniazid.

Clinical evidence, mechanism, importance and management

The mean serum levels of a 300-mg dose of isoniazid were not significantly changed in 10 patients with tuberculosis when they were given a single 20-mg/kg dose of ethambutol. The possible effects of concurrent use over a period of time were not studied. However, there is some evidence that the optic neuropathy caused by ethambutol may be increased by isoniazid, and any effects resolve more slowly after the use of isoniazid. One group of authors recommends that both ethambutol and isoniazid should be stopped immediately if severe optic neuritis occurs. They further recommend that isoniazid should be stopped if less severe optic neuritis does not improve within 6 weeks after stopping ethambutol.6
**Isoniazid + Fluconazole**

A double-blind, crossover study in 16 healthy subjects (8 ‘fast’ and 8 ‘slow’ acetylators of isoniazid) found that fluconazole 400 mg daily for a week had no clinically significant effect on the pharmacokinetics of isoniazid.¹ No special precautions would appear necessary during concurrent use.

**Isoniazid + Food**

The absorption of isoniazid is reduced by food. See also ‘Isoniazid + Food; Cheese or Fish’, below, for toxic reactions between isoniazid and specific foods.

**Clinical evidence**

In 9 healthy subjects the mean peak serum levels of isoniazid 10 mg/kg were delayed, and reduced by 79%, when isoniazid was given with breakfast rather than when fasting. The AUC was reduced by 43%.¹ In another study in 14 healthy subjects given isoniazid with a full fat breakfast, the maximum serum levels of isoniazid were decreased by 51%, the absorption was delayed, and the AUC was decreased by 12%.² Similar results have been found in another study.³

**Mechanism**

Uncertain. Food delays gastric emptying so that absorption further along the gut is also delayed, but the reduction in absorption is not understood.

**Importance and management**

Information is limited but the interaction seems to be established. For maximum absorption isoniazid should be taken without food, hence the manufacturer’s guidance to take it at least 30 minutes before or 2 hours after eating.¹

**Isoniazid + Food; Cheese or Fish**

Patients taking isoniazid who eat some foods, particularly fish from the scombroid family (tuna, mackerel, salmon, etc.) that are not fresh, may experience an exaggerated histamine poisoning reaction. Cheese has also been implicated in this reaction, but the adverse effects may be due to the weak MAOIs effects of isoniazid rather than histamine poisoning.

**Clinical evidence**

Three months after starting to take isoniazid 300 mg daily, a woman experienced a series of unpleasant reactions 10 to 30 minutes after eating cheese. These reactions included chills, headache (sometimes severe), itching of the face and scalp, slight diarrhoea, flushing of the face (and on one occasion the whole body), variable and mild tachycardia, and a burst-intolerance of the face and scalp, slight diarrhoea, flushing of the face (and on one occasion the whole body), variable and mild tachycardia, and a burst-

**Pharmacokinetic evidence** suggests that neither cimetidine nor ranitidine interact with isoniazid.

**Clinical evidence, mechanism, importance and management**

In 13 healthy subjects cimetidine 400 mg or ranitidine 300 mg, three times a day, for 3 days had no effect on the pharmacokinetics of a single 10-mg/kg dose of isoniazid. Neither the absorption nor the metabolism of...
Isoniazid were changed. Special precautions would appear to be necessary on concurrent use. Although data about other H2-receptor antagonists appears to be lacking, based on this study, they would not be expected to interact with isoniazid.

Isoniazid + Laxatives

Sodium sulfate and castor oil used as laxatives can cause a modest but probably clinically unimportant reduction in isoniazid absorption.

Clinical evidence, mechanism, importance and management

In an experimental study of the possible effects of laxatives on isoniazid absorption, healthy subjects were given 10 to 20 g of oral sodium sulfate or 20 g of castor oil (doses sufficient to provoke diarrhoea). Absorption, measured by the amount of isoniazid excreted in the urine, was decreased by 50% with castor oil and by 41% with sodium sulfate at 4 hours. However, serum levels of isoniazid were relatively unchanged. The overall picture was that while these laxatives can alter the pattern of absorption, they do not seriously impair the total amount of drug absorbed.1

Isoniazid + Pethidine (Meperidine)

An isolated case report describes hypotension and lethargy in a patient after he took isoniazid with pethidine.

Clinical evidence, mechanism, importance and management

A patient became lethargic and his blood pressure fell from 124/68 to 84/50 mmHg within 20 minutes of being given pethidine 75 mg intramuscularly. An hour before, he had been given isoniazid. There was no evidence of fever or cardiac arrhythmias, and his serum electrolytes, glucose levels and blood gases were normal. His blood pressure returned to normal over the next 3 hours. He had previously had both pethidine and isoniazid separately without incident. He was subsequently uneventfully given intravenous morphine sulfate, 4 mg every 2 to 4 hours.1 The authors of the report attribute this reaction to the MAO-inhibitory properties of the isoniazid and equate it with the severe and potentially fatal ‘MAOi-pethidine interaction’, (p.1140), but in reality this reaction was mild and lacked many of the characteristics of the more serious reaction. Moreover, isoniazid possesses only mild MAO-inhibitory properties and does not normally interact to the same extent as the potent antidepressant and antihypertensive MAOIs.

There is too little evidence to advise against concurrent use, but bear this interaction in mind in the case of an unexpected response to treatment.

Isoniazid + Prednisolone

Prednisolone can lower plasma isoniazid levels, but this may not be clinically important.

Clinical evidence, mechanism, importance and management

Isoniazid 10 mg/kg daily was given to 26 patients with tuberculosis. The 13 slow acetylators of isoniazid had a 23% fall in plasma isoniazid levels when they were given prednisolone 20 mg, while the 13 fast acetylators showed a 38% fall over 8.5 hours (see ‘Genetic factors’, (p.4), for an explanation of acetylator status). The reasons for these changes are not understood but changes in the metabolism, and/or the excretion of the isoniazid by the kidney, are possibilities. Despite these changes the response to treatment was excellent.1 In another group of 49 patients, both slow and fast acetylators of isoniazid, rifampicin 12 mg/kg largely counteracted the isoniazid-lowering effects of prednisolone.1

None of these interactions were of clinical importance, but the authors point out that if the dosage of isoniazid had been lower, its effects might have been reduced. Be aware of the possibility of a reduced response during concurrent use, and raise the isoniazid dosage if necessary. There seems to be no information about other corticosteroids.

Isoniazid + Propranolol

Propranolol causes a small reduction in the clearance of isoniazid, which seems unlikely to be of much practical importance.

Clinical evidence, mechanism, importance and management

The clearance of a single 600-mg intravenous dose of isoniazid was reduced by 21%, from 16.4 to 13 L/hour, in 6 healthy subjects after they took propranolol 40 mg three times daily for 3 days.1 It is suggested that propranolol reduces the clearance of isoniazid by inhibiting its metabolism (acetylation) by the liver.1 However, as the increase in isoniazid levels is likely to be only modest this interaction is probably of little clinical importance.

Isoniazid + Pyrimethamine

A study in 19 patients with tuberculosis found that pyrazinamide did not affect serum levels of isoniazid.1

Isoniazid + Rifamycins

The concurrent use of a rifamycin and isoniazid is common and therapeutically valuable, but there is evidence that the incidence of hepatotoxicity may be increased, particularly in slow acetylators of isoniazid. One study suggests the bioavailability of rifampicin may be reduced by isoniazid but other studies found no pharmacokinetic interaction. Rifabutin and rifampicin do not alter the pharmacokinetics of isoniazid.

Clinical evidence, mechanism, importance and management

(a) Rifabutin

Rifabutin 300 mg, given daily for 7 days to 6 healthy subjects, had no significant effect on the pharmacokinetics of a single 300-mg dose of isoniazid or its metabolite acetylisoniazid.1 Two of the 6 subjects were rapid acetylators of isoniazid (see ‘Genetic factors’, (p.4), for more information about acetylator status).

Although both drugs have been effectively used together in the treatment of tuberculosis, it is not clear whether concurrent use increases the incidence of hepatotoxicity, as occurs with isoniazid and rifampicin (see below). However, as regular monitoring of liver function is required for both isoniazid and rifabutin, no additional monitoring seems necessary on concurrent use. The manufacturer of rifabutin notes that haematological reactions of rifabutin could be increased by isoniazid, but, again, as regular monitoring of white blood cell and platelet counts is advised,2 no additional monitoring seems necessary.

(b) Rifampicin (Rifampin)

Most studies have shown that the serum levels and half-lives of both drugs are not significantly affected by concurrent use,3,4 even in those with hepatic impairment.6 There was also no difference7 between rapid and slow acetylators of isoniazid, (see ‘Genetic factors’, (p.4), for more information about acetylator status). One single-dose study in healthy subjects found that isoniazid 12 mg/kg reduced the AUC of rifampicin 10 mg/kg by about 25%.7 There is some evidence that the incidence and severity of hepatic toxicity rises if both drugs are given together.8 Reports from India suggest that the incidence can be as high as 8 to 10%, while much lower figures of
2 to 3% are reported in the US. There is certainly one case report that appears to prove that hepatotoxicity can arise rapidly from the use of both drugs. The patient tolerated both drugs individually, but hepatotoxicity reappeared on concurrent use. Increased isoniazid hepatotoxicity caused by rifampicin has been demonstrated in vitro.

The reasons for the hepatotoxicity are not fully understood but rifampicin or isoniazid alone can cause liver damage by their own toxic action. One suggestion is that the rifampicin alters the metabolism of isoniazid, resulting in the formation of hydrazine, which has been proven to be hepatotoxic. Higher plasma levels of hydrazine are said to occur in slow acetylators of isoniazid, but one study failed to confirm that this is so. There has certainly been at least one fatality caused by this combination. The manufacturers of rifampicin advise that caution is particularly needed in patients with impaired liver function, the elderly, malnourished patients, and children under two years of age. After baseline LFTs, further tests are only needed if fever, vomiting, or jaundice occur, or if the patient deteriorates. However, the manufacturers of isoniazid suggest that liver function tests should be reviewed regularly in patients on combined treatment.

A retrospective review of HIV-positive patients who were taking either an SSRI, isoniazid, or both, found that the rate of discontinuation of the SSRI was higher in those also taking isoniazid (7 of 10 patients) than in the group of patients taking an SSRI alone (2 of 14). It is unclear why this rate was increased; little mention is made of the influence of other drugs or medical conditions.

Mechanism, importance and management

Direct information about the concurrent use of isoniazid and SSRIs seems to be limited, but the case reports cited here would suggest that the combination of isoniazid and these SSRIs is normally without problems. However, also be aware that one report suggests the possibility of an increase in adverse effects with the combination of SSRIs and isoniazid. In theory isoniazid could interact with the SSRIs because it has some weak MAO inhibitory activity. However, isoniazid rarely interacts like the MAOIs. This is because isoniazid seems to lack activity on mitochondrial MAO even though it has activity on plasma MAO. Therefore no adverse MAOI/SSRI interaction would usually be expected.

Linezolid + Antacids

A study in healthy subjects found that Maalox 70mVal suspension 10 mL (aluminium/magnesium hydroxide) did not affect the pharmacokinetics of a single 600-mg dose of linezolid.

Linezolid + Antidepressants

The serotonin syndrome has been reported in patients taking linezolid with an SSRI or venlafaxine. The serotonin syndrome is also predicted to occur if linezolid is given with tricyclic antidepressants.

Clinical evidence

(a) SSRIs

In an analysis of phase III studies, changes in vital signs did not differ between patients given linezolid and comparator drugs (i.e. antibiotics) when either were used with drugs known to interact with MAOIs, including unnamed SSRIs. One patient taking fluoxetine had a transient episode of asymptomatic hypertension after one dose of linezolid, but this patient had no other symptoms of serotonin syndrome, it was not considered an interaction. However, a 4-year-old girl given fluoxetine 5 mg daily developed symptoms of the serotonin syndrome 2 days after starting linezolid 140 mg every 12 hours, and after a procedure for which she was given fentanyl 200 micrograms. Fentanyl may have been a contributing factor. Another case report describes an 85-year-old woman taking citalopram who developed tremor, confusion, dysarthria, hyperreflexia, agitation, and restlessness after linezolid was started. Citalopram was stopped and the symptoms resolved over 72 hours. There are several other case reports of this interaction between linezolid and SSRIs including citalopram, sertraline, paroxetine.

(b) Tricycles

In an analysis of phase III studies, changes in vital signs did not differ between patients given linezolid and comparator drugs (i.e. antibiotics) when either were used with drugs known to interact with MAOIs, including unnamed cyclic antidepressants. A case report describes the serotonin syndrome in an elderly patient treated with linezolid 600 mg every 12 hours, 21 days after amitriptyline 10 mg daily, paroxetine 20 mg daily and alprazolam 50 micrograms daily were started.

Isoniazid + SSRIs and related antidepressants

A few reports suggest that no important interaction occurs between isoniazid and the SSRIs or nefazodone. However, adverse reactions have been seen during concurrent use and one report found an increased discontinuation rate in patients taking an SSRI with isoniazid.

Clinical evidence

Two HIV-positive patients taking fluoxetine 20 mg daily were also given isoniazid. One patient tolerated the use of both drugs, but the other developed vomiting and diarrhoea, and after 10 days the fluoxetine was stopped. A woman who had been hospitalised for serious depression was given nefazodone 300 mg daily. A few days later she began to take isoniazid 300 mg daily, and was later discharged on an increased nefazodone dose of 400 mg daily. She was reported to have had no problems while taking both drugs for over 5 months. A woman with tuberculosis taking isoniazid 300 mg daily presented with depression and was given sertraline 50 mg daily, later raised to 150 mg daily, without problems. She responded well and was reported to have taken both drugs together for 8 months without problems.
The pharmacokinetics of intravenous atracon 1 g and intravenous linezolid 375 mg were not affected when they were given together in a single-dose study in healthy subjects. Therefore dose alterations are unlikely to be needed during concurrent use.1

### Linezolid + Dextromethorphan

There is no important pharmacokinetic interaction between linezolid and dextromethorphan, but one case of concurrent use resulted in the serotonin syndrome.

### Clinical evidence, mechanism, importance and management

In a study in 14 healthy subjects, two 20-mg doses of dextromethorphan given 4 hours apart, before and during the use of linezolid 600 mg every 12 hours, had no effect on linezolid pharmacokinetics. The AUC and maximum level of the dextromethorphan metabolite, dextrorphan was decreased by 30%, but this was not considered sufficient to warrant any dosing alterations. There was no evidence of the serotonin syndrome, as measured by changes in body temperature, alertness and mental performance.1 However, the manufacturers describe one case where the concurrent use of linezolid and dextromethorphan resulted in the serotonin syndrome.2 Linezolid has mild reversible MAOI activity, and the serotonin syndrome has been described when dextromethorphan was taken by patients also taking antidepressant MAOIs, see ‘MAOIs or RIMAs + Dextromethorphan’, p.1134. If the concurrent use of linezolid and dextromethorphan is considered necessary, it would seem prudent to monitor for symptoms of the serotonin syndrome’ (p.9).

### Linezolid + Food

Linezolid modestly increases the blood pressure response to oral tyramine, and as a consequence patients receiving linezolid should not consume excessive amounts of tyramine-rich foods and drinks. The bioavailability of linezolid is not affected by enteral feeds or food.

### Clinical evidence, mechanism, importance and management

#### (a) Enteral feeds

In a study a single 600-mg dose of linezolid was given as a suspension via a nasogastric tube or gastric tube to 9 patients receiving enteral feeds. The rate and extent of linezolid absorption was not significantly different to that found in another 6 patients not receiving enteral feeds. No dose adjustments are therefore thought to be required if linezolid is given with enteral feeds.1

#### (b) Food

A study in healthy subjects found that the plasma levels following a single 375-mg oral dose of linezolid as a tablet were 23% higher when given to fasted subjects than when it was taken immediately after a high-fat meal. However, the AUCs were not significantly different, indicating that the extent of absorption was not affected by food.2 Another study in healthy subjects found that food delayed the rate but not the extent of absorption and distribution of linezolid into tissues.3

#### (c) Tyramine-rich food

In a pharmacodynamic study in healthy subjects, the dose of oral tyramine required to raise the systolic blood pressure by 30 mmHg was decreased by a factor of about 3.5 (from a range of 300 to 600 mg without linezolid to 100 to 200 mg with linezolid) when the subjects were pretreated with linezolid 625 mg twice daily for 4 to 7 days. This increase in the pressor response to tyramine was similar to that seen with moclobemide 150 mg three times daily.4 Further, another placebo-controlled study in healthy subjects found that single doses of linezolid 600 mg and moclobemide 300 mg also caused similar increases in the pressor response to intravenous tyramine as measured by amount of tyramine required to raise the systolic blood pressure by 30 mmHg.5

### Linezolid + Atracon

The pharmacokinetics of intravenous atracon 1 g and intravenous linezolid 375 mg were not affected when they were given together in a single-dose study in healthy subjects. Therefore dose alterations are unlikely to be needed during concurrent use.6

---

Linezolid is a weak, non-selective inhibitor of MAO. As a consequence, it can inhibit the breakdown of the tyramine by MAO in the gut, and can also potentiate the effect of tyramine at nerve endings, therefore causing an increase in blood pressure (see Mechanism, under ‘MAOIs or RIMAs + Tyramine-rich foods’, p.1153). However, the extent of this rise was similar to that for moclobemide, which is much less than that seen with classical MAOIs.

The manufacturers of linezolid recommend that patients should avoid large amounts of tyramine-rich foods and drinks and should not consume more than 100 mg of tyramine per meal. For a list of the possible tyramine-content of various foods and drinks, see ‘Table 32.2’, (p.1152), ‘Table 32.3’, (p.1154) and ‘Table 32.4’, (p.1155). This is in line with the dietary restrictions recommended for RIMAs rather than the more stringent dietary recommendations required in patients taking non-selective MAOIs.

Clinical evidence, mechanism, importance and management

The manufacturer of linezolid contraindicates its use with the MAOIs, including the selective MAO-B inhibitor selegiline and the RIMA moclobemide.

Clinical evidence, mechanism, importance and management

The UK manufacturer contraindicates the concurrent use of linezolid or within 2 weeks of taking any other drug that inhibits MAO-A or MAO-B. They specifically name the non-selective MAOIs isocarboxazid and phenelzine, the RIMA, moclobemide, and the MAO-B inhibitor, selegiline. Linezolid has reversible non-selective MAO-inhibitory activity, and this warning is based on the sometimes serious reactions that have occurred when non-selective MAOIs are given sequentially (see ‘MAOIs + MAOIs or RIMAs’, p.1137) or MAOIs are given with MAO-B inhibitors, see ‘MAO-B inhibitors + MAOIs or RIMAs’, p.692.

Linezolid + Other drugs with MAOI activity

The UK manufacturer of linezolid1 (a drug with weak, reversible, non-selective MAO activity) contraindicates its use with pethidine, unless facilities are available for close observation and monitoring of blood pressure, because of the possibility of serious reactions, as have occurred with classical MAOIs and pethidine, see ‘MAOIs or RIMAs + Opioids; Pethidine (Meperidine)’, p.1140.

Linezolid + Pethidine (Meperidine)

The UK manufacturer of linezolid1 (a drug with weak, reversible, non-selective MAO activity) contraindicates its use with pethidine, unless facilities are available for close observation and monitoring of blood pressure, because of the possibility of serious reactions, as have occurred with classical MAOIs and pethidine, see ‘MAOIs or RIMAs + Opioids; Pethidine (Meperidine)’, p.1140.

Linezolid + Rifampicin (Rifampin)

Serum levels of intravenous linezolid are reduced by intravenous rifampicin.

Clinical evidence, mechanism, importance and management

A 31-year-old woman was given intravenous rifampicin 300 mg every 8 hours and linezolid 600 mg every 12 hours for an MRSA infection. During rifampicin treatment her linezolid peak and trough levels were 7.29 and 2.04 micrograms/mL, respectively. However, when the rifampicin was stopped the linezolid peak and trough levels were at 12.46 and 5.03 micrograms/mL, respectively.3

In an earlier study, healthy subjects were given a single 600-mg dose of intravenous linezolid either alone or with a single 600-mg dose of intravenous rifampicin. This study also found that rifampicin reduced the serum levels of linezolid by 10%, 20% and 35% at 6, 9 and 12 hours, respectively.

Linezolid is not metabolised by the cytochrome P450 enzyme system so the reduction in levels is unlikely to be due to increased metabolism associated with rifampicin enzyme induction. The reduction in linezolid serum levels may be attributable to the induction of P-glycoprotein by rifampicin, resulting in increased excretion of linezolid.12

The clinical significance of this interaction is unclear and the concurrent use of rifampicin and linezolid is not established. The available evidence suggests that, where possible, linezolid levels should be monitored if both drugs are given. If this is not possible it would seem prudent to monitor concurrent use closely to ensure that the antibacterial treatment is effective.

Linezolid + Sympathomimetics

Because of its weak MAO-inhibitory properties, the manufacturers of linezolid contraindicate its use with sympathomimetics (such as adrenergic bronchodilators, phenylpropanolamine, pseudoephedrine, adrenaline (epinephrine), noradrenaline (norepinephrine), dopamine and dobutamine) unless facilities for close observation and blood pressure monitoring are available. In one study the use of linezolid with phenylpropanolamine or pseudoephedrine resulted in additive hypertensive effects.

Clinical evidence

In a placebo-controlled study, 14 healthy patients were given two 60-mg doses of pseudoephedrine or two 25-mg doses of phenylpropanolamine 4 hours apart, with and without linezolid. The mean maximum blood pressure rise was 11 mmHg with placebo, 15 mmHg with linezolid, 18 mmHg with pseudoephedrine and 14 mmHg with phenylpropanolamine. When the subjects were given linezolid with pseudoephedrine the rise was 32 mmHg, which was similar to the 38 mmHg rise seen with linezolid plus phenylpropanolamine. However, these rises were transient, resolving in about 2 hours. No effects were seen on linezolid pharmacokinetics.1

Mechanism

Linezolid acts as a weak MAO-inhibitor, which allows the accumulation of some noradrenaline at adrenergic nerve endings associated with arterial blood vessels. Pseudoephedrine and phenylpropanolamine, both indirectly-acting sympathomimetics, can release these above-normal amounts of noradrenaline resulting in blood vessel constriction and a rise in blood pressure.

Importance and management

The manufacturers contraindicate the use of sympathomimetics (including adrenergic bronchodilators, phenylpropanolamine, adrenaline (epinephrine), noradrenaline (norepinephrine), dopamine, and dobutamine) with linezolid unless there are facilities available for close observation of the patient and monitoring of blood pressure.3 Some indirectly-acting sympathomimetics occur in cough and cold remedies, which can be bought without prescription. To keep in line with the manufacturers recommendations, patients should be told to avoid these preparations. However, it should be said that the evidence available indicates that blood pressure rises are unlikely to be of the proportions seen with the antidepressant MAOIs, which result in hypertensive crises. Consider also ‘MAOIs or RIMAs + Sympathomimetics; Indirectly-acting’, p.1147.
**Linezolid + Vitamins**

The pharmacokinetics of linezolid are not affected by either vitamin C or vitamin E.

**Clinical evidence, mechanism, importance and management**

Healthy subjects were given vitamin C 1 g daily or vitamin E 800 units daily for 8 days with a single 600-mg dose of linezolid on the sixth day. As in vitro studies have indicated that endogenous reactive oxygen species (ROS) may affect linezolid clearance, it was considered possible that antioxidant supplements may affect the balance of ROS and linezolid clearance. However, the study found that antioxidants (vitamins C and E) given in doses far higher than the recommended daily intake did not affect linezolid pharmacokinetics. Therefore no dosage adjustments are considered necessary during concurrent use.1

**Loracarbef + Acetylcysteine**

A study in healthy subjects found that acetylcysteine 200 mg had no effect on the absorption of loracarbef 400 mg.1

**Loracarbef + Food**

Food reduces the maximum plasma levels of loracarbef, but does not alter its bioavailability.

**Clinical evidence, mechanism, importance and management**

Loracarbef 400 mg was given to 12 healthy subjects either in a fasting state or following a standard breakfast. Food slowed the rate of absorption, but not the total bioavailability of loracarbef.1 In another study food was found to decrease the maximum plasma levels of a single 200-mg dose of loracarbef and increase the time to achieve maximum levels but the AUC of loracarbef was not significantly affected by food.2 Loracarbef should be taken 1 hour before or 2 hours after food.3

**Loracarbef + Probenecid**

Probenecid increases the half-life of loracarbef by about 50% but the clinical importance of this is unknown.1

**Macrolides + Antacids**

Aluminium/magnesium hydroxide antacids may reduce the peak levels of azithromycin. *Maalox* (aluminium/magnesium hydroxide) 30 mL had no significant effect on the AUC, peak serum concentration, or time to peak serum concentration of erythromycin stearate 500 mg, but the mean elimination rate constant was more than doubled. It was suggested that the effect on elimination may be due to a possible prolonging of absorption, although the reason for this effect is unclear. However, an in vitro study has suggested that the release and absorption of erythromycin stearate may be slowed in the presence of some antacids, including aluminium and magnesium hydroxides, aluminium and magnesium trisilicates, and simeticone because of adsorption of erythromycin by the antacids.2,3 The clinical relevance of this is uncertain, but likely to be small.

**Macrolides + Azoles**

Moderate pharmacokinetic interactions appear to occur between several of the azoles and macrolides but many of these are unlikely to be of clinical significance. However, clarithromycin may almost double itraconazole levels, and ketoconazole may almost double telithromycin levels.

**Clinical evidence, mechanism, importance and management**

**(a) Azithromycin**

Single doses of *fluconazole* 800 mg and azithromycin 1200 mg were given to 18 healthy subjects alone and together without any significant change in the pharmacokinetics of either drug.1

In healthy subjects, azithromycin 500 mg once daily for 3 days had no significant effect on the AUC and maximum plasma levels of *voriconazole* 200 mg twice daily.2

**(b) Clarithromycin**

Twenty healthy subjects were given clarithromycin 500 mg twice daily for 8 days. *Fluconazole* 400 mg daily was added on day 5, followed by 200 mg daily on days 6 to 8. The *fluconazole* increased the minimum plasma levels of the clarithromycin by 33% and the AUC_{0-12} by 18%.3 These relatively small changes in the pharmacokinetics of clarithromycin are almost certainly of little or no clinical importance.

A study in 8 AIDS patients taking *itraconazole* 200 mg daily found that when clarithromycin 500 mg twice daily was also given, for 14 days, the maximum serum levels and the AUC of the *itraconazole* were increased by 90% and 92%, respectively.4 Both clarithromycin and *itraconazole* are known to be metabolised by the hepatic cytochrome P450 isozyme CYP3A4 and it is therefore probable that competition for metabolism leads to a reduction in the clearance of *itraconazole*. This report does not comment on the outcome of this almost twofold increase in *itraconazole* levels, but it would seem prudent to be alert for the need to reduce its dosage. More study is needed.

**(c) Erythromycin**

The manufacturer notes that peak plasma levels and AUC of a single 200-mg dose of *itraconazole* were increased by 44% and 36%, respective-
ly, by a single 1-g dose of erythromycin ethyl succinate. However, no dosage adjustments are recommended.

In healthy subjects, erythromycin 1 g twice daily for 7 days had no significant effect on the AUC and maximum plasma levels of voriconazole 200 mg twice daily. 2

(d) Telithromycin

In a study in which healthy subjects were given either telithromycin 800 mg, ketoconazole 800 mg or both drugs once daily, it was found that the AUC and peak plasma levels of telithromycin were increased by 94.5% and 51.3%, respectively. It may be prudent to monitor for telithromycin adverse effects on concurrent use. In a further related study healthy subjects were given itraconazole 200 mg daily instead of ketoconazole. Itraconazole was found to increase the AUC and peak plasma levels of telithromycin by 53.8% and 21.7%, respectively. No serious adverse effects were reported in either study and telithromycin did not increase the QTc intervals observed with either ketoconazole or itraconazole alone. 6

Another study 7 by the same authors, in subjects aged 60 years or older and with a creatinine clearance of 30 mL/minute or more, found that, when ketoconazole was given, levels of telithromycin were increased but only slightly higher than those found in younger healthy subjects 8 in the earlier study.

Macrolides + H2-receptor antagonists

Cimetidine doubled the serum levels of erythromycin in one single-dose study, and a single case report describes reversible deafness, which was attributed to this interaction. No clinically significant interaction appears to occur when cimetidine is given with azithromycin or clarithromycin, or when ranitidine is given with clarithromycin, roxithromycin, or telithromycin.

Clinical evidence

(a) Cimetidine

A 64-year-old woman was admitted to hospital with cough, dyspnoea and pleuritic pain and was found to have an atypical pneumonia and renal impairment. All her antihypertensive treatment (methyldopa, propranolol, co-amilofruse) was stopped, due to hypotension, and her treatment for duodenal ulcer was changed from ranitidine 150 mg twice daily to cimetidine 400 mg at night. She was then started on amoxicillin 500 mg three times daily and erythromycin stearate 1 g four times daily. Two days later she complained of ‘fuzzy hearing’ and audiometry showed a bilateral hearing loss. The erythromycin was stopped and her hearing returned to normal after 5 days. 3 This prompted a study of this possible interaction in 8 healthy subjects, which found that cimetidine 400 mg twice daily increased the AUC of a single 250-mg dose of erythromycin by 73%. Maximum serum erythromycin levels were doubled.

The pharmacokinetics of azithromycin were not affected by a single 800-mg dose of cimetidine in one study, and although cimetidine prolongs the absorption of clarithromycin, this is unlikely to be of clinical significance. 3

(b) Ranitidine

The pharmacokinetics of clarithromycin, 4 roxithromycin 4 and telithromycin 5 are reported to be unaffected by ranitidine.

Mechanism

Cimetidine is known to inhibit the N-demethylation of erythromycin so that it is metabolised and cleared from the body more slowly and its serum levels rise. Deafness is known to be one of the adverse effects of erythromycin, which usually occurs with high-doses or intravenous therapy, and was probably exacerbated by renal impairment in the patient described above.

Importance and management

Clinical information about an interaction between cimetidine and erythromycin seems to be limited to this case and the associated single-dose study. The manufacturers 3 say that reversible hearing loss has been reported with erythromycin alone, usually in high doses (greater than 4 g daily), usually when given by the intravenous route, and in patients with renal impairment. Most UK manufacturers do not include this interaction in their product information, and evidence for an interaction seems limited.

Macrolides + Grapefruit juice

Grapefruit juice modestly increases the bioavailability of erythromycin, but does not affect the bioavailability of clarithromycin or telithromycin.

Clinical evidence

(a) Clarithromycin

In a study 12 healthy subjects were given a single 500-mg dose of clarithromycin and 240 mL of either water or freshly squeezed white grapefruit juice with and 2 hours after clarithromycin. Grapefruit juice increased the time to peak levels of both clarithromycin and its metabolite 14-hydroxy-clarithromycin from about 2 to 148 minutes and 84.5 to 172 minutes, respectively, but it did not affect the extent of clarithromycin absorption and had no significant effects on any other pharmacokinetic parameters. 1

(b) Erythromycin

A study in 6 healthy subjects given a single 400-mg dose of erythromycin with either water or grapefruit juice found that grapefruit juice increased the AUC and maximum plasma level of erythromycin by about 49% and 52%, respectively. The time to achieve maximum levels and the half-life of erythromycin were not affected. 2

(c) Telithromycin

A study in 16 healthy subjects given telithromycin 800 mg daily found that grapefruit juice did not affect telithromycin pharmacokinetics. 3

Mechanism

Some components of grapefruit juice, possibly flavonoids such as naringin, or a psoralen, dihydroxybergamottin, may inhibit the activity of the cytochrome P450 isozyme CYP3A4 in the gut. 3 The levels of drugs metabolised by CYP3A4, such as the macrolides, may therefore be raised by grapefruit juice. Erythromycin levels, but not those of clarithromycin or telithromycin appear to be affected by grapefruit juice. It has been suggested that a drug with low or variable bioavailability may be more likely to have its levels increased by grapefruit juice and it has been suggested that this may partly explain why the pharmacokinetics of clarithromycin (bioavailability of about 55%) and telithromycin (bioavailability of about 60%) are not significantly affected. 1

Importance and management

Information is very limited but is would appear that there is unlikely to be a clinically significant interaction between grapefruit juice and either clarithromycin or telithromycin. The increased bioavailability of erythromycin was found in a single-dose study and it has been suggested that more prolonged administration of erythromycin with grapefruit juice could increase levels and potentially increase the risk of adverse effects. 4 More study is needed.

If deafness were to occur, the management would seem to be similar (withdraw the erythromycin) regardless of whether or not cimetidine was present, so no additional precautions seem necessary.

There is evidence that azithromycin and clarithromycin do not interact, and ranitidine does not interact with clarithromycin, roxithromycin or telithromycin. No interaction would be expected between the macrolides and other non-enzyme inducing H2-receptor antagonists.

Clinical evidence
(a) Rifabutin
1. Neutropenia. A study in 12 healthy subjects was designed to investigate the safety and possible interactions between rifabutin 300 mg daily, and azithromycin 250 mg daily or clarithromycin 500 mg twice daily, for a course of 14 days. The subjects were matched against 18 healthy controls who received either of the macrolides or rifabutin alone. The study had to be abandoned after 10 days because 14 patients developed neutropenia; 2 taking rifabutin alone, and all 12 of those taking rifabutin with a macrolide. Eight subjects developed a fever, 5 required colony simulating factors, and 3 required hospitalisation.
2. Pharmacokinetics. In a study2 investigating a possible regimen for the prophylaxis of Mycobacterium avium complex (MAC) disease, 12 HIV-positive patients were treated with clarithromycin 500 mg daily, to which rifabutin 300 mg daily was added on day 15. By day 42 the clarithromycin AUC had fallen by 44%, and levels of the metabolite, 14-hydroxyclarithromycin, had risen by 57%. A related study2 in 14 patients given clarithromycin 500 mg every 12 hours and rifabutin 300 mg daily found that after 28 days the AUC of the rifabutin had increased by 99%, and the AUC of the active metabolite, 25-O-desacetyl-rifabutin, had increased by 375%. Another group of patients with lung disease due to MAC were treated with clarithromycin 500 mg twice daily. When rifabutin 600 mg was added the clarithromycin levels fell by 63% (from 5.4 to 2 micrograms/mL).3 Limited information from a randomised study in healthy subjects found similar results.1,4 Fluconazole appears to further increase the effects of clarithromycin on rifabutin.6 One study suggests that there is no pharmacokinetic interaction between azithromycin and rifabutin.1
3. Uveitis or arthralgias. Uveitis, and in some cases pseudojaundice, aphthous stomatitis and an arthralgia syndrome have been described in patients treated with both clarithromycin1 to 2 g daily and rifabutin 300 to 600 mg daily.5,8 The presence of fluconazole does not appear to affect the development of uveitis in patients taking clarithromycin with rifabutin,6,9 but it has been suggested that this was because only small doses (50 mg) were used.9 Reports suggest that uveitis develops between 27 to 370 days after taking the combination.6,9 The reaction appears to be dose-dependent. In patients taking rifabutin 600 mg with clarithromycin the incidence of uveitis was 14% in patients weighing more than 65 kg, 45% in those weighing between 55 and 65 kg and 64% in those weighing less than 55 kg. The risk of developing uveitis was reduced from a mean of 43% to 13% when the dose of rifabutin was reduced to 300 mg daily.9 Uveitis did not develop in 8 patients taking rifabutin and azithromycin500 mg daily,7 although cases of uveitis have been reported in patients taking rifabutin, fluconazole, and azithromycin1.2 g weekly but they have been attributed to an interaction between rifabutin and fluconazole.10 See ‘Azoles + Rifabutin’, p.219.

(b) Rifampicin (Rifampin)
Patients with lung disease due to MAC were treated with clarithromycin 500 mg twice daily. When rifampicin 600 mg daily was added, the mean serum levels of clarithromycin fell by almost 90% (from 5.4 to 0.7 micrograms/mL).3 Similar results are reported in another study.11 The manufacturer notes that rifampicin reduces the AUC and maximum serum levels of telithromycin by 86% and 79%, respectively.12 Two cases of cholestatic jaundice have been reported in patients taking rifampicin with troleandomycin.13,14

Mechanism
Both rifabutin and rifampicin are known enzyme inducers, which can increase the metabolism of other drugs by the liver, thereby reducing their serum levels. Rifampicin is recognised as being the more potent inducer. Rifabutin is also a substrate for cytochrome P450 isoenzyme CYP3A4. Both clarithromycin and fluconazole are inhibitors of CYP3A4 and it is probable that clarithromycin and fluconazole exert additive effects resulting in greater inhibition of rifabutin metabolism than occurs with either drug alone.4

The reason for the uveitis is not known, but based on animal studies it has been suggested that it is associated with effective treatment of MAC and is due to release of a mycobacterial protein, rather than a toxic effect of the drugs.1 It has been suggested that lower body weight and concurrent clarithromycin may result in toxic rifabutin serum levels, although concurrent fluconazole which increases levels does not appear to be a fac-

Macrolides + Penicillins

Some in vitro evidence suggests that antagonism may occur between erythromycin (a bacteriostatic drug) and penicillins (bactericidal drugs) when they are used against staphylococci and Streptococcus pneumoniae.2 However, another study has suggested that this in vitro antagonism against S. pneumoniae between ‘penicillin’ and erythromycin is minimal and dependent on the interpretative criteria applied.3 Clinical evidence for this interaction is apparently lacking, and the combination is generally used successfully for pneumonia.4 In the U.K., the combination of amoxicillin and erythromycin or another macrolide (e.g. azithromycin or clarithromycin) has been recommended by the British Thoracic Society (BTS) for adult patients with non-severe community-acquired pneumonia who require hospital admission.5 More recently the BTS has recommended an intravenous combination of a beta-lactamase stable antibiotic such as co-amoxiclav (amoxicillin with clavulanic acid) with a macrolide (erythromycin or clarithromycin) for severe community-acquired pneumonia in hospitalised patients.6

Macrolides + Rifamycins

Rifabutin and azithromycin seem not to affect the serum levels of each other, but a very high incidence of neutropenia was seen in one study of the combination. Both rifabutin and rifampicin markedly reduce the serum levels of clarithromycin. Clarithromycin increases the serum levels of rifabutin and the combination is associated with an increased risk of uveitis and neutropenia. Rifampicin (rifampin) greatly reduces telithromycin levels and concurrent use is not recommended.
The hepatotoxicity seen with rifampicin and troleandomycin is probably due to additive effects as both drugs are known to be hepatotoxic.

Importance and management

(a) Rifabutin and Rifampicin: Pharmacokinetics

Direct information appears to be limited to the reports cited but the interactions would appear to be established. What is not entirely clear is whether these interactions result in treatment failures because of the potentially subtherapeutic clarithromycin serum levels. Because of the lack of information, be alert for evidence of reduced efficacy if clarithromycin and rifampicin are used.

Although rifabutin can lower clarithromycin levels, the efficacy of this combination for MAC infection is established, although not without risk, see Uveitis, below. Clarithromycin raises rifabutin levels and therefore increases the risks of adverse effects. Concurrent use may therefore be desirable, but monitoring for adverse effects is necessary.

Due to a pharmacokinetic interaction the UK manufacturers recommend that telithromycin should not be given during and for 2 weeks after the use of rifampicin.

(b) Rifabutin: Neutropenia

Information regarding neutropenia with macrolides and rifamycins is very limited but what is known suggests that white cell counts should be monitored closely if rifabutin is given with azithromycin or clarithromycin. Rifabutin is known to cause polyarthritus on rare occasions, but in conjunction with clarithromycin it appears to happen at much lower doses. Careful monitoring is necessary.

(c) Rifabutin: Uveitis

The CSM in the UK has warned about the need to be aware of the increased risk of uveitis with clarithromycin and rifabutin and of the raised rifabutin levels. If uveitis occurs the CSM recommends that rifabutin should be stopped and the patient should be referred to an ophthalmologist. Because of the increased risk of uveitis they also say that consideration should be given to reducing the dosage of rifabutin to 300 mg daily in the presence of macrolides. Later review and a case-control study suggest that this dose is associated with a reduced risk of uveitis and maintains efficacy.\(^1^\,\,^1^\,\,^1^\)

A study in healthy subjects found that there did not appear to be a pharmacokinetic interaction between steady-state intravenous azithromycin and ceftriaxone and the combination was well-tolerated.\(^1^\)

Macrolides; Azithromycin + Chloroquine

A study in which healthy subjects were given azithromycin 1 g daily for 3 days either alone or with chloroquine base 600 mg daily on days 1 and 2, and 300 mg on day 3, found no pharmacokinetic interaction.\(^1^\)

Macrolides; Azithromycin + Food

Food appears to halve azithromycin absorption from the capsule formulation, but does not alter the AUC of tablets or suspension.

Clinical evidence, mechanism, importance and management

A review by the manufacturers briefly mentions that food reduced the absorption of azithromycin by about half.\(^1^\) It is suggested therefore that azithromycin capsules should not be given at the same time as food, but should be taken at least 1 hour before or 2 hours after a meal.\(^1\,\,^2\) However, the US prescribing information states that a high-fat meal increased the maximum levels of azithromycin and had no effect on the AUC.\(^3\) Similarly, food increased the maximum levels of azithromycin suspension by 56%, without altering the AUC.\(^3\) Azithromycin suspension and tablets could therefore be taken without regard to food.

Macrolides; Clarithromycin + Disulfiram

Fatal toxic epidermal necrolysis and fulminant hepatitis occurred in a patient taking disulfiram and clarithromycin.

Clinical evidence, mechanism, importance and management

A 47-year-old man who had taken disulfiram 250 mg daily for about a month, with clarithromycin 500 mg twice daily and paracetamol 500 mg three times daily for one week, developed fatal toxic epidermal necrolysis and fulminant hepatitis. He had not drunk alcohol for several weeks and although he was taking paracetamol, the dose was below the toxic range and therefore an interaction between disulfiram and clarithromycin was considered probable.\(^1\)

Disulfiram alone may cause hepatic toxicity, possibly as the result of hypersensitivity or toxic metabolites. It was suggested that inhibition of cytochrome P450 isozyme CYP3A4 by clarithromycin could have resulted in the accumulation of toxic metabolites of disulfiram. Hepatocellular damage is uncommon in patients receiving clarithromycin alone, but may occur in patients with underlying disease. Both clarithromycin and disulfiram alone may cause adverse skin reactions, but neither has been reported to cause toxic epidermal necrolysis. The reason why this should occur with concurrent use is not understood.\(^1\) Information seems to be limited to this single report, so no general conclusions can be drawn.

Macrolides; Erythromycin + Carbimazole

An isolated case describes torsade de pointes in an elderly patient taking carbimazole and oral erythromycin.

Clinical evidence

A 75-year-old woman with known mild mitral stenosis taking digoxin, furosemide, warfarin and carbimazole was given oral erythromycin 250 mg four times daily for a urinary tract infection. Three days later she experienced presyncopal episodes, and 4 days later she was admitted to hospital with syncope and self-terminating episodes of torsade de pointes. She completed the 7-day course of erythromycin on the day before admission. Five days after admission, when the QT interval was back to normal, she was inadvertently rechallenged with erythromycin, given as prophylaxis before permanent pacemaker insertion. After two doses of erythromycin 500 mg given at an interval of 6 hours, she developed torsade de pointes associated with a prolonged QT interval (QTc 612 milliseconds). The QT interval returned to normal 4 days after erythromycin was discontinued.

Mechanism

Intravenous erythromycin may cause QT prolongation and torsade de pointes. It is rare with oral erythromycin. Carbimazole is rapidly metabolised to thiamazole which is the active form of the drug. Thiamazole inhibits cytochrome P450 isoenzymes including CYP3A4 and it may therefore have inhibited the metabolism of erythromycin resulting in higher than normal levels. In addition, hypothyroidism can cause torsade de pointes, and therefore mild hypothyroidism induced by carbimazole could have contributed. Furthermore, bradycardia (heart rate less than 60 bpm) may also have contributed.

Importance and management

It was suggested that the combination of oral erythromycin and carbimazole could lead to torsade de pointes in susceptible individuals. In this case, female sex, presence of valvular heart disease, bradycardia, hypokalaemia, and hypothyroidism may all have been contributory factors. See also, 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.257.

Macrolides; Erythromycin + Sucralfate

Sucralfate does not appear to affect the pharmacokinetics of erythromycin.

Clinical evidence, mechanism, importance and management

The pharmacokinetics (elimination rate constant, half-life, AUC) of a single 400-mg dose of erythromycin ethylsuccinate were not significantly altered by a single 1-g dose of sucralfate in 6 healthy subjects. It was concluded that the therapeutic effects of erythromycin are unlikely to be affected by concurrent use.

Macrolides; Erythromycin + Urinary acidifiers or alkalinisers

In the treatment of urinary tract infections, the antibacterial activity of erythromycin is maximal in alkaline urine and minimal in acidic urine.

Clinical evidence

Urine taken from 7 subjects receiving erythromycin 1 g every 8 hours, was tested against 5 genera of Gram-negative bacilli (Escherichia coli, Klebsiella pneumoniae, P. mirabilis, Ps. aeruginosa and Serratia sp.) both before and after treatment with acetazolamide or sodium bicarbonate, given to alkalinise the urine. A direct correlation was found between the activity of the antibacterial and the pH of the urine. In general, acidic urine had little or no antibacterial activity, whereas alkalinised urine had activity.

Clinical studies have confirmed the increased antibacterial effectiveness of erythromycin in the treatment of bacteriuria when the urine is made alkaline.

Mechanism

The pH of the urine does not apparently affect the way the kidney handles the antibacterial (most of it is excreted actively rather than passively) but it does have a direct influence on the way the antibacterial affects the micro-organisms. Mechanisms suggested include effects on bacterial cell walls, and changes in ionisation of the antibacterial, which enables it to enter the bacterial cell more effectively.

Importance and management

An established interaction, which can be exploited. Should erythromycin be used to treat urinary tract infections its efficacy can be maximised by making the urine alkaline (for example with acetazolamide or sodium bicarbonate). Treatment with urinary acidifiers will minimise the activity of the erythromycin for urinary tract infections and should be avoided. There is no evidence that the efficacy of erythromycin in other infections is affected by urinary acidifiers or alkalinisers.

Methenamine + Urinary acidifiers or alkalinisers

Urinary alkalinisers (e.g. potassium or sodium citrate) and those antacids that can raise the urinary pH above 5.5 should not be used during treatment with methenamine because they inhibit its activation.

Clinical evidence, mechanism, importance and management

Methenamine and methenamine mandelate are only effective as urinary antiseptics if the pH is about 5.5 or lower, when formaldehyde is released. This is normally achieved by giving urinary acidifiers such as ammonium chloride, ascorbic acid, or sodium acid phosphate. In the case of methenamine hippurate, the acidification of the urine is achieved by the presence of hippuric acid. The concurrent use of substances that raise the urinary pH such as acetazolamide, sodium bicarbonate, potassium or sodium citrate is clearly contraindicated. Potassium citrate mixture BPC has been shown to raise the pH by more than 1 at normal therapeutic doses, thereby making the urine sufficiently alkaline to interfere with the activation of methenamine to formaldehyde. Some antacids (containing magnesium, aluminium or calcium as well as sodium bicarbonate mentioned above) can also cause a significant rise in the pH of the urine.

Metronidazole + Antacids, Colestyramine or Kaolin-pectin

The absorption of metronidazole is unaffected by kaolin-pectin, but it is slightly reduced by an aluminium hydroxide antacid and colestyramine, although not to a clinically relevant extent.
Clinical evidence, mechanism, importance and management

The bioavailability of a single 500-mg dose of metronidazole in 5 healthy subjects was not significantly changed by 30 mL of a kaolin-pectin anti-diarrhoeal mixture. However, a 14.5% reduction in metronidazole bioavailability occurred with 30 mL of an aluminium hydroxide/simeticone suspension, and a 21.3% reduction occurred with a single 4-g dose of colestyramine.1 The clinical importance of these reductions is probably small, and no special precautions seem necessary.

Metronidazole + Barbiturates

Phenobarbital markedly increases the metabolism of metronidazole and treatment failure has been reported in both adults and children.

Clinical evidence

A woman with vaginal trichomoniais was given metronidazole on several occasions over the course of a year, but the infection flared up again as soon as it was stopped. When it was realised that she was also taking phenobarbital 100 mg daily, the metronidazole dosage was doubled to 500 mg three times daily, and she was cured after a 7-day course.1 A pharmacokinetic study found that the clearance of metronidazole was increased (half-life 3.5 hours compared with the normal half-life of 8 to 9 hours).3

A retrospective study in children who had not responded to metronidazole for giardiasis or amoebiasis found that 80% of them had been taking long-term phenobarbital. In a prospective study in 36 children the normal recommended metronidazole dosage had to be increased approximately threefold to 60 mg/kg to achieve a cure. The half-life of metronidazole in 15 other children taking phenobarbital was found to be 3.5 hours compared with the normal half-life of 8 to 9 hours.2

Other studies in patients with Crohn’s disease and healthy subjects have shown that phenobarbital reduces the AUC of metronidazole by about one-third,3 and increases the clearance of metronidazole 1.5-fold.4

Mechanism

Phenobarbital is a known, potent liver enzyme inducer, which increases the metabolism and clearance of metronidazole from the body.

Importance and management

An established and clinically important interaction. Monitor the effects of concurrent use and anticipate the need to increase the metronidazole dosage to threefold if phenobarbital is given. All of the barbiturates are known, potent liver enzyme inducers, which increase the metabolism of metronidazole and treatment failure has been reported in both adults and children.

Metronidazole + Chloroquine

An isolated report describes acute dystonia in one patient, which was attributed to an interaction between metronidazole and chloroquine.

Clinical evidence, mechanism, importance and management

A patient was given a 7-day course of metronidazole and ampicillin, following a laparoscopic investigation. She developed acute dystonic reactions (facial grimacing, coarse tremors, and an inability to maintain posture) on day 6, within 10 minutes of being given chloroquine phosphate (equivalent to 200 mg of base) and intramuscular promethazine 25 mg. The dystonic symptoms started to subside within 15 minutes of being given diazepam 5 mg intravenously, and had completely resolved within 2 hours.3

The authors of the report attribute the dystonia to an interaction between metronidazole and chloroquine as she had taken both drugs alone without adverse effect. However, they do not fully assess the possible contribution of promethazine, which is known to cause dystonias. It is therefore possible that the reaction seen was an adverse effect of the promethazine, or perhaps even an interaction between promethazine and chloroquine. No general recommendations can therefore be made from this single report.

Metronidazole + Cimetidine

Cimetidine reduces the metabolism of tinidazole, and possibly also metronidazole, but this is probably not clinically important.

Clinical evidence

(a) Metronidazole

The half-life of a 400-mg intravenous dose of metronidazole was increased from 6.2 to 7.9 hours in 6 healthy subjects after they took cimetidine 400 mg twice daily for 6 days. The total plasma clearance was reduced by almost 30%.1 However, in another study in 6 patients with Crohn’s disease, cimetidine 600 mg twice daily for 7 days was found not to affect either the AUC or the half-life of metronidazole,2 and no evidence of an interaction was found in a further study in 6 healthy subjects.3

(b) Tinidazole

In a study in 6 healthy subjects cimetidine 400 mg twice daily for 7 days raised the peak serum levels of a single 600-mg dose of tinidazole by 21%, increased the 24-hour AUC by 40% and increased the half-life by 47%, from 7.66 to 11.23 hours.4

Mechanism

Cimetidine is a well known enzyme inhibitor, which probably inhibits the metabolism of the metronidazole and tinidazole by the liver.

Importance and management

The modest changes in the pharmacokinetics of tinidazole with cimetidine seem unlikely to be clinically significant, but bear them in mind in the case of an unexpected response to treatment. The interaction between metronidazole and cimetidine is not established, but any changes in metronidazole pharmacokinetics seem to be modest and unlikely to be important.

Metronidazole + Diosmin

Diosmin reduces the metabolism of metronidazole to some extent, but the clinical importance of this is probably small.

Clinical evidence, mechanism, importance and management

A single 800-mg dose of metronidazole was given to 12 healthy subjects following 9 days of treatment with diosmin 500 mg daily. The metronidazole AUC and maximum plasma concentrations were raised by 27% and 25%, respectively.1 This interaction is thought to occur because of an inhibitory effect of diosmin on metronidazole metabolism by hepatic enzymes, and inhibition of P-glycoprotein. The increase in metronidazole levels is similar to that seen with other drugs (e.g. ’cimetidine’ (above)) that are not considered to be clinically significant. Therefore no clinically
significant interaction is likely to occur if metronidazole is given with diosmin.

<tr>
<th>Metronidazole + Disulfiram</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Acute psychoses and confusion can be caused by the concurrent use of metronidazole and disulfiram.</strong></td>
</tr>
</tbody>
</table>

**Clinical evidence, mechanism, importance and management**

In a double-blind study in 58 hospitalised chronic alcoholics taking disulfiram, 29 patients were also given metronidazole 750 mg daily for a month, then 250 mg daily thereafter. Six of the 29 subjects in the group receiving metronidazole developed acute psychoses or confusion. Five of the 6 had paranoid delusions and in 3 visual and auditory hallucinations were also seen. The symptoms persisted for 2 to 3 days after the drugs were withdrawn, but disappeared at the end of a fortnight and did not reappear when disulfiram alone was restarted.1 Similar reactions have been described in two other reports.2,3

The reason for this interaction is not understood, but it appears to be established. Concurrent use should be avoided or very well monitored.

<table>
<thead>
<tr>
<th>Metronidazole + Mebendazole</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>A case-control study identified the concurrent use of metronidazole and mebendazole as a risk factor in an outbreak of Stevens-Johnson syndrome/toxic epidermal necrolysis.</strong></td>
</tr>
</tbody>
</table>

**Clinical evidence, mechanism, importance and management**

A case control study was conducted in an attempt to identify risk factors associated with an outbreak of Stevens-Johnson syndrome/toxic epidermal necrolysis that occurred amongst Filipino workers in Taiwan. The risk of developing this serious condition was significantly higher in workers who had taken both metronidazole and mebendazole sometime in the preceding 6 weeks (odds ratio of 9.5). In addition, there was an increase in risk with higher doses of metronidazole.1

The information is limited to this report, which does not establish an interaction. However, Stevens-Johnson syndrome/toxic epidermal necrolysis is a serious condition, and therefore, the manufacturer of mebendazole states that the concurrent use of mebendazole and metronidazole should be avoided.2 Caution would certainly seem appropriate if both drugs are considered essential.

<table>
<thead>
<tr>
<th>Metronidazole + Prednisone</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Prednisone modestly decreases the AUC of metronidazole.</strong></td>
</tr>
</tbody>
</table>

**Clinical evidence, mechanism, importance and management**

In 6 patients with Crohn’s disease the AUC of metronidazole 250 mg twice daily was reduced by 31% by prednisone 10 mg twice daily for 6 days, probably because prednisone induces the metabolism of metronidazole by liver enzymes.1

Information appears to be limited to this report and the interaction is probably of only limited clinical importance. Information about other corticosteroids is lacking.

<table>
<thead>
<tr>
<th>Metronidazole or Tinidazole + Rifampicin (Rifampin)</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Rifampicin modestly increases the clearance of metronidazole and tinidazole but the clinical importance of this is uncertain.</strong></td>
</tr>
</tbody>
</table>

**Clinical evidence**

**(a) Metronidazole**

Intravenous metronidazole 500 mg or 1 g was given to 10 healthy subjects before and after taking rifampicin 450 mg daily for 7 days. Rifampicin reduced the AUC of metronidazole by 33% and increased its clearance by 44%. Results were the same with both metronidazole doses.1

**(b) Tinidazole**

After 6 healthy subjects took rifampicin 600 mg daily for 7 days the peak serum levels of a single 600-mg dose of tinidazole were reduced by 22%, the AUC0–24 was reduced by 30% and the half-life was reduced by 27% (from 7.66 to 5.6 hours).2

**Mechanism**

This interaction almost certainly occurs because rifampicin (a well-recognised and potent enzyme inducer) increases the metabolism of metronidazole and tinidazole by the liver.

**Importance and management**

The clinical significance of these interactions appear not to have been studied. A 30% reduction in metronidazole levels would not be expected to be of much clinical significance and there do not appear to be any reports of an interaction in practice. Rifampicin is known to act synergistically with metronidazole,3 so it may be that any reduction in levels is offset by enhanced antimicrobial activity. Tinidazole acts very much like metronidazole, and therefore a clinically significant interaction between rifampicin and either of these drugs seems unlikely.

<table>
<thead>
<tr>
<th>Metronidazole + Silymarin</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Silymarin (the active constituent of milk thistle) modestly reduces metronidazole levels, but the clinical significance of this is unclear.</strong></td>
</tr>
</tbody>
</table>

**Clinical evidence, mechanism, importance and management**

Silymarin 140 mg daily was given to 12 healthy subjects for 9 days, with metronidazole 400 mg three times daily on days 7 to 10. Silymarin reduced the AUC of metronidazole and hydroxymetronidazole (a major active metabolite) by 28% and the maximum serum levels by 29% and 20%, respectively. The authors suggest that silymarin causes these pharmacokinetic changes by inducing P-glycoprotein and the cytochrome P450 isoenzyme CYP3A4, which are involved in the transport and metabolism of metronidazole.1 The clinical significance of this interaction is unclear, but a 28% reduction in the AUC of metronidazole would not be expected to be of much clinical significance.

<table>
<thead>
<tr>
<th>Metronidazole + Sucralfate</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Sucralfate does not alter the pharmacokinetics of metronidazole.</strong></td>
</tr>
</tbody>
</table>
Clinical evidence, mechanism, importance and management

Because oral triple therapy to eradicate *H. pylori* using sucralfate instead of bismuth has yielded inconsistent results, a 5-day study was undertaken in 14 healthy subjects to investigate whether sucralfate interacts with metronidazole. It was found that sucralfate 2 g twice daily had no effect on the pharmacokinetics of a single 400-mg dose of metronidazole. Sucralfate would therefore not be expected to alter the effects of metronidazole.

**Nitrofurantoin + Antacids**

Magnesium trisilicate reduces the absorption of nitrofurantoin, but the clinical significance of this is unknown. Aluminium hydroxide is reported not to interact with nitrofurantoin. Whether other antacids interact adversely is uncertain.

**Clinical evidence**

Magnesium trisilicate 5 g in 150 mL of water reduced the absorption of a single 100-mg oral dose of nitrofurantoin in 6 healthy subjects by more than 50%. The time during which the concentration of nitrofurantoin in the urine was at, or above 32 micrograms/mL (a level stated to be the minimum inhibitory concentration) was also reduced. The amounts of nitrofurantoin adsorbed by other antacids in *in vitro* tests were as follows: magnesium trisilicate and charcoal 99%, bismuth subcarbonate and t alc 50 to 53%, kaolin 31%, magnesium oxide 27%, aluminium hydroxide 2.5% and calcium carbonate 0%. A crossover study in 6 healthy subjects confirmed that aluminium hydroxide gel does not affect the absorption of nitrofurantoin from the gut (as measured by its excretion into the urine). Another study in 10 healthy subjects found that an antacid containing aluminium hydroxide, magnesium carbonate and magnesium hydroxide reduced the absorption of nitrofurantoin by 22%.

**Mechanism**

Antacids can, to a greater or lesser extent, adsorb nitrofurantoin onto their surfaces, as a result less is available for absorption by the gut and for excretion into the urine.

**Importance and management**

Information appears to be limited to these reports. There seems to be nothing in the literature confirming that a clinically important interaction occurs between nitrofurantoin and antacids. One reviewer offers the opinion that common antacid preparations are unlikely to interact with nitrofurantoin.

It is not yet known whether magnesium trisilicate significantly reduces the antibacterial effectiveness of nitrofurantoin but the response should be monitored. While it is known that the antibacterial action of nitrofurantoin is increased by drugs that acidify the urine (so that reduced actions would be expected if the urine were made more alkaline by antacids) this again does not seem to have been confirmed. The results of the *in vitro* studies suggest that the possible effects of the other antacids are quite small, and aluminium hydroxide is reported not to interact.

**Nitrofurantoin + Antigout drugs**

On theoretical grounds the efficacy and toxicity of nitrofurantoin may possibly be increased by probenecid and sulfinpyrazone.

**Clinical evidence, mechanism, importance and management**

A study of the way the kidneys handle nitrofurantoin found that intravenous sulfinpyrazone 2.5 mg/kg reduced the secretion of nitrofurantoin by the kidney tubules by about 50%. This reduction would be expected to reduce its urinary antibacterial efficacy, and the higher serum levels might lead to increased systemic toxicity, but there do not seem to be any reports suggesting that this represents a real problem in practice. The same situation would also seem likely with probenecid, but there do not appear to be any reports confirming this interaction.

The clinical importance of both these interactions is therefore uncertain, but it would seem prudent to be alert for any evidence of reduced antibacterial efficacy and increased systemic toxicity if either sulfinpyrazone or probenecid is used with nitrofurantoin.

**Nitrofurantoin + Antimuscarnicines or Diphenoxylate**

Diphenoxylate and anticholinergic drugs such as propantheline can double the absorption of nitrofurantoin in some patients, but the clinical importance of this is uncertain.

**Clinical evidence, mechanism, importance and management**

In 6 healthy subjects propantheline 30 mg given 45 minutes before nitrofurantoin approximately doubled the absorption of nitrofurantoin 100 mg (as measured by the urinary excretion). In another study, diphenoxylate 200 mg daily for 3 days nearly doubled nitrofurantoin absorption in 2 out of 6 men. Atropine 500 micrograms given subcutaneously 30 minutes before a single 100-mg dose of nitrofurantoin had little effect on the bioavailability of nitrofurantoin, but the absorption and excretion into the urine was delayed.

It was suggested that the reduced gut motility caused by these drugs allows the nitrofurantoin to dissolve more completely so that it is absorbed by the gut more easily. Whether this is of any clinical importance is uncertain but it could possibly increase the incidence of dose-related adverse reactions. So far there appear to be no reports of any problems arising from concurrent use.

**Nitrofurantoin + Azoles**

In an isolated case hepatic and pulmonary toxicity occurred when nitrofurantoin was given with fluconazole, but not with itracona zole.

**Clinical evidence, mechanism, importance and management**

A 73-year-old man who had taken nitrofurantoin 50 mg daily for 5 years was given fluconazole 150 mg weekly for onychomycosis. At the start of treatment with fluconazole his hepatic enzyme levels were slightly raised, and 3 weeks later they were increased more than twofold. Two months after starting fluconazole the patient’s hepatic enzyme levels had increased fivefold and he had fatigue, dyspnoea on exertion, pleuritic pain, burning tracheal pain, and a cough. Bilateral pulmonary disease was confirmed by chest X-rays, and pulmonary function tests suggested nitrofurantoin toxicity. Both fluconazole and nitrofurantoin were discontinued, and hepatic and lung function gradually improved.

Either fluconazole or nitrofurantoin could have caused the liver toxicity. However, it was considered that both the lung and liver toxicity may have been due to an interaction between nitrofurantoin and fluconazole, possibly due to increased nitrofurantoin concentrations resulting from competition with fluconazole for renal tubular secretion.

Some 2 years earlier the patient had received pulse itraconazole (less
than 1% excreted in the urine as active drug) with nitrofurantoin without raised liver enzymes or any other adverse effects.1

Information appears to be limited to this report, but bear it in mind in the event of increased nitrofurantoin adverse effects. More study is needed.

### Nitrofurantoin + Metoclopramide

The antibacterial effects of nitrofurantoin have been found to be reduced in vitro by magnesium and calcium ions because they form chelates with the nitroxine.1 In the absence of any direct clinical information it would seem prudent to monitor concurrent use for any evidence that its antibacterial effects are reduced.

### Nitroxine + Antacids

The absorption of amoxicillin may be significantly reduced when given with or 2 hours after acacia. Guar gum causes a small reduction in the absorption of phenoxymethylpenicillin (penicillin V).

Clinical evidence, mechanism, importance and management

When 10 healthy subjects were given nitrofurantoin 1 g daily for 13 days with rifampicin 600 mg daily, the nitrofurantoin half-life was reduced from 5.85 to 2.66 hours and the AUC was reduced by almost 50%. There were no significant changes to the half-life or AUC of rifampicin. The serum levels is only small. It would clearly only be important if the reduced amount of penicillin absorbed was inadequate to control infection. The effect of guar gum on other penicillins seems not to have been studied.

### Novobiocin + Rifampicin (Rifampin)

The absorption of amoxicillin may be significantly reduced when given with or 2 hours after acacia. Guar gum causes a small reduction in the absorption of phenoxymethylpenicillin (penicillin V).

Clinical evidence, mechanism, importance and management

When 10 healthy subjects were given nitrofurantoin 1 g daily for 13 days with rifampicin 600 mg daily, the nitrofurantoin half-life was reduced from 5.85 to 2.66 hours and the AUC was reduced by almost 50%. There were no significant changes to the half-life or AUC of rifampicin. The serum levels is only small. It would clearly only be important if the reduced amount of penicillin absorbed was inadequate to control infection. The effect of guar gum on other penicillins seems not to have been studied.

### Penicillins + Acacia or Guar gum

The absorption of amoxicillin may be significantly reduced when given with or 2 hours after acacia. Guar gum causes a small reduction in the absorption of phenoxymethylpenicillin (penicillin V).

Clinical evidence, mechanism, importance and management

(a) Acacia

In healthy subjects the maximum serum levels and AUC of a single 500-mg dose of amoxicillin were reduced by 73% and 79%, respectively, when given with acacia (gum arabic: amount not stated) and by 56% and 49%, respectively, when given 2 hours after ingestion of acacia. The pharmacokinetics of amoxicillin were not significantly affected when it was given 4 hours after acacia. Acacia is used in pharmaceutical preparations as a suspending, demulcent and emulsifying agent. Concurrent administration with amoxicillin could result in subtherapeutic levels of the antibacterial, but whether or not this would occur with the amount of acacia in a dose of a preparation containing it as an excipient is not known. In some countries acacia is given to patients with chronic renal failure. The authors suggest that if amoxicillin is used to treat urinary-tract infections in patients also treated with acacia, it should be given 4 hours before or after the acacia.1

(b) Guar gum

Guar gum 5 g (Guareem, 95% guar gum) reduced the absorption of a single 100-mg dose of phenoxymethylpenicillin (penicillin V) in 10 healthy subjects. Peak serum penicillin levels were reduced by 25% and the AUC was reduced by 28%.2 The reasons are not understood. The clinical significance of this interaction is uncertain, but the reduction in serum levels is only small. It would clearly only be important if the reduced amount of penicillin absorbed was inadequate to control infection. The effect of guar gum on other penicillins seems not to have been studied.

### Penicillins + Allopurinol

The incidence of skin rashes in patients taking either ampicillin or amoxicillin is increased by allopurinol.

Clinical evidence

A retrospective search through the records of 1324 patients, 67 of whom were taking allopurinol and ampicillin, found that 15 of them (22%) developed a skin rash compared with 94 (7.5%) of the patients not taking allopurinol.1 The types of rash were not defined. Another study found that 35 out of 252 patients (13.9%) taking allopurinol and ampicillin developed a rash, compared with 251 out of 4434 (5.9%) taking ampicillin alone.2 A parallel study revealed that 8 out of 36 patients (22%) taking amoxicillin and allopurinol developed a rash, whereas only 52 out of 887 (5.9%) did so when taking amoxicillin alone.3

A case report describes a patient who developed erythema multiforme shortly after starting amoxicillin and allopurinol and who was found to have both allopurinol hypersensitivity and type IV amoxicillin hypersensitivity.3

In contrast, one study did not find that the incidence of penicillin-related rashes was increased by allopurinol, and the authors suggested that this contrasting finding may be because exposure to penicillins was shorter in their study.4

Mechanism

Not understood. One suggestion is that the hyperuricaemia was responsible.1 Another is that hyperuricaemic individuals may possibly have an altered immunological reactivity.5

Importance and management

An established interaction of limited importance. There would seem to be no strong reason for avoiding concurrent use, but prescribers should recognise that the development of a rash is by no means unusual. Whether this also occurs with penicillins other than ampicillin or amoxicillin is uncertain, and does not seem to have been reported.

Penicillins + Antacids

Aluminium/magnesium hydroxide and aluminium hydroxide do not significantly affect the bioavailability of amoxicillin or amoxicillin with clavulanic acid (co-amoxiclav). Antacids may reduce the absorption of the hydrochloride salt of pivampicillin.

Clinical evidence, mechanism, importance and management

(a) Amoxicillin or Co-amoxiclav

The pharmacokinetics of amoxicillin 1 g, and both amoxicillin and clavulanic acid (given as co-amoxiclav 625 mg), were not significantly altered by 10 doses of aluminium/magnesium hydroxide (Maalox) 10 mL, with the last dose given 30 minutes before amoxicillin. Another study found that four 40-mg doses of aluminium hydroxide (Aluhydrax) given at 20 minute intervals had no effect on the pharmacokinetics of either amoxicillin or clavulanic acid (given as co-amoxiclav 750 mg with the second dose of antacid).

There would seem to be no reason for avoiding the concurrent use of antacids and amoxicillin or co-amoxiclav.

(b) Pivampicillin

The UK manufacturers used to recommend that, because antacids may decrease pivampicillin absorption, concurrent use should be avoided. This warning relates to a hydrochloride salt formulation, which needs acidic conditions for optimal absorption, whereas the basic salt formulation should not be affected by any pH change.

Penicillins + Catha (Khat)

Chewing khat reduces the absorption of ampicillin and, to a lesser extent, amoxicillin, but the effects are minimal 2 hours after khat chewing stops.

Clinical evidence, mechanism, importance and management

A study in 8 healthy Yemeni male subjects found that chewing khat reduced the absorption of oral ampicillin from the gut. When ampicillin 500 mg was taken with 250 mL water 2 hours before or just before khat chewing started, or midway through a 4-hour chewing session, the amounts of unchanged ampicillin in the urine fell by 46%, 41% and 49%, respectively. Even when ampicillin was taken 2 hours after a chewing session had stopped, the amount of drug excreted unchanged in the urine fell by 12%. A parallel series of studies with amoxicillin 500 mg found much smaller reductions. The equivalent reductions were 14%, 9%, 22% and 13%. A similar study found that chewing khat resulted in variable reduction in the bioavailability of amoxicillin 500 mg, which was maximal (22%) when it was given midway during the 4-hour chewing period.

The reasons for this interaction are not known, but the authors of the reports suggest that tannins from the khat might form insoluble and non-absorbable complexes with these penicillins, and possibly also directly reduce the way the gut absorbs them.

Khat (the leaves and stem tips of Catha edulis) is chewed in some African and Arabian countries for its stimulatory properties. The authors of one of the studies concluded that both ampicillin and amoxicillin should be taken 2 hours after khat chewing to ensure that maximum absorption occurs.

Penicillins + Chloroquine

Chloroquine reduces the absorption of ampicillin, but bacampicillin is unaffected.

Clinical evidence

Chloroquine 1 g reduced the absorption (as measured by excretion in the urine) of a single 1-g dose of oral ampicillin by about one-third (from 29 to 19%) in 7 healthy subjects. Another study by the same author demonstrated that the absorption of ampicillin from bacampicillin tablets was unaffected by chloroquine.

Mechanism

A possible reason for the reduction in absorption is that the chloroquine irritates the gut so that the ampicillin is moved through more quickly, thereby reducing the time for absorption.

Importance and management

Information appears to be limited to the studies cited, which used large doses of chloroquine (1 g) when compared with those usually used for malarial prophylaxis (300 mg base weekly) or for rheumatic diseases (150 mg daily). The reduction in the ampicillin absorption is also only moderate. The general clinical importance of this interaction is therefore uncertain. However, one report suggests separating the dosing by not less than 2 hours. An alternative would be to use bacampicillin (an ampicillin pro-drug), which does not appear to interact with chloroquine. More study is needed to confirm and evaluate the importance of this interaction.

Penicillins + Food

The absorption of many penicillins is not significantly affected by food. The exceptions are ampicillin (food may reduce its levels by up to 50%), cloxacillin, and possibly pivampicillin and phe-noxyethylpenicillin.

Clinical evidence, mechanism, importance and management

(a) Dietary fibre

The AUC of a single 500-mg oral dose of amoxicillin was found to be 12.17 micrograms/mL per hour in 10 healthy subjects on a low fibre diet (7.8 g of insoluble fibre daily) but only 9.65 micrograms/mL per hour when they ate a high fibre diet (36.2 g of insoluble fibre daily); a difference of about 20%. Peak serum levels were the same and occurred at 3 hours. The clinical relevance of these changes is likely to be minimal.

(b) Enteral and parenteral feeds

A single 250-mg intravenous dose of ampicillin was given to 7 healthy subjects 2 hours into a 12-hour infusion of parenteral nutrition or 4 hours after an enteral meal. The parenteral nutrition was of two types, one with and one without amino acids, calcium and phosphorus, both without lipids, and of similar calorific content and volume to the enteral feed. None of the three regimens altered the pharmacokinetics of intravenous ampicillin. Note that the ampicillin was given in a separate limb to the parenteral nutrition.

(c) Food

1. Amoxicillin and co-amoxiclav. Food eaten immediately before amoxicillin reduced its serum levels by about 50% and reduced urinary excretion, when compared with the fasted state. However, in another study, a standard breakfast had no effect on the AUC of a single 500-mg dose of amoxicillin in 16 healthy subjects. Similarly, a crossover study in 18 healthy subjects given co-amoxiclav (amoxicillin 500 mg with clavulanic acid 250 mg), either 2 hours before or with a fried breakfast, found that the breakfast had no significant effect on the pharmacokinetics of amoxicillin or clavulanic acid. Moreover, a further study in 43 healthy subjects found that taking co-amoxiclav with food tended to minimise the incidence (but
not the severity) of gastrointestinal adverse effects (watery stools, nausea and vomiting). It would therefore be beneficial to take co-amoxiclav with a meal.

2. Ampicillin. Food eaten immediately before a single 500-mg dose of ampicillin reduced its serum levels by about 50% and reduced urinary excretion.

A standard breakfast reduced the AUC of a single 500-mg dose of ampicillin by 31% in 16 healthy subjects. Another study found ampicillin absorption was delayed and the total absorption reduced when it was taken with food. Urinary excretion of ampicillin was about 30% of a dose when given on an empty stomach and about 20% when given with food. It is recommended that ampicillin is taken one hour before food or on an empty stomach to optimise absorption.

3. Bacampicillin. The AUC of ampicillin was assessed when 6 healthy subjects took a 1.6-g dose of bacampicillin either 35 minutes after breakfast or 2 hours before breakfast. The AUC was 26% lower with the post-breakfast dose, but this difference was not statistically significant. On the basis of other work that also suggests that no important interaction occurs with food, the manufacturers say that bacampicillin can be given without regard to time of food intake.

4. Flucloxacillin. A study in children given flucloxacillin 12.5 mg/kg as either tablets or mixture found that while the absorption depended on both the formulation and age of the child, there was no difference in levels achieved when given to a subject when fasting or with a breakfast. However, it is recommended that flucloxacillin is taken one hour before food or on an empty stomach to optimise absorption. The presence of food is reported to reduce the rate and extent of absorption of the related drug cloxacillin, and therefore it may be prudent to follow the advice given for flucloxacillin.

5. Pivampicillin. A study in healthy subjects found the absorption of pivampicillin was delayed when it was given with food, but the amount absorbed was not affected. The urinary excretion of amoxicillin following pivampicillin was about 60% of the dose when taken with or without food. However, another study which pivampicillin 350 mg was given in the fasting state or with a standardised cooked breakfast found that food both delayed and reduced the absorption of pivampicillin by almost 50%.

6. Pivmecillinam. The manufacturers of pivmecillinam note that its absorption is practically unaffected when the tablets are taken with food.

(d) Milk

The peak levels and the AUCs of oral phenoxymethylpenicillin and oral benzylpenicillin were reduced by 40 to 60% in infants and children when they were given with milk. It is recommended that phenoxymethylpenicillin is taken one hour before food or on an empty stomach to optimise absorption.

Co-amoxiclav (amoxicillin 500 mg with clavulanic acid 250 mg) was given to 16 healthy subjects at the same time as the second of four 200-mL glasses of milk (taken at 20 minute intervals). Although the bioavailability of the amoxicillin and clavulanic acid tended to be decreased, and the time to peak levels delayed, the changes did not reach statistical significance. No special precautions would seem to be necessary.

Penicillins + H₂-receptor antagonists

Cimetidine does not adversely affect the bioavailability of ampicillin or co-amoxiclav, but the bioavailability of oral benzylpenicillin may be increased in some subjects. Ranitidine does not affect the pharmacokinetics of amoxicillin, but may possibly reduce the bioavailability of bacampicillin.

Clinical evidence, mechanism, importance and management

(a) Amoxicillin and Co-amoxiclav

Cimetidine 200 mg, given three times daily the day before and with a single 200-mg dose of co-amoxiclav (amoxicillin with clavulanic acid), had no significant effect on the bioavailability of amoxicillin or clavulanic acid. Another study found that given 300 mg given the day before and 150 mg given with the antibacterial) had no effect on the pharmacokinetics of a single 1-g dose of amoxicillin.

(b) Ampicillin

The pharmacokinetics of ampicillin were unchanged in a placebo controlled study in which 6 healthy subjects were given cimetidine 400 mg every 6 hours for 6 days, with a single 500-mg dose of ampicillin on day 6.

(c) Bacampicillin

One small study suggested that when bacampicillin was given with ranitidine 300 mg and sodium bicarbonate 4 g, the AUC was reduced by 78% when the drugs were given with breakfast and by 55% when the drugs were given without food. However, these results have been criticised because the study only included 6 subjects and because of differences in methodology between compared groups. The findings remain unconfirmed, and their clinical significance is uncertain.

(d) Benzylpenicillin

A study using a 600-mg oral dose of benzylpenicillin found that cimetidine raised the benzylpenicillin serum levels by about 3-fold in one subject, but did not significantly affect benzylpenicillin levels in another 4 subjects. The clinical significance of these findings is unclear, especially as benzylpenicillin is more usually given parenterally.

Penicillins + Miscellaneous

Aspirin, indometacin, phenylbutazone, sulfaphenazole and sulfinpyrazone prolong the half-life of benzylpenicillin whereas chlorothiazide, sulfamethizole and sulfamethoxypyridazine do not. Some sulfonamides reduce oxacillin blood levels. Pirenzepine does not affect the pharmacokinetics of amoxicillin.

Clinical evidence, mechanism, importance and management

Studies in patients given different drugs for 5 to 7 days showed the following increases in the half-life of benzylpenicillin: aspirin 63%, indometacin 22%, phenylbutazone 139%, sulfaphenazole 44% and sulfinpyrazone 65%. It seems likely that competition between these drugs and benzylpenicillin for excretion by the kidney tubules caused these increases. Changes in the half-life with chlorothiazide, sulfamethizole and sulfamethoxypyridazine were not significant.
In healthy subjects, sulfamethoxypyridazine 3 g given 8 hours before a 1-g dose of oral oxacillin reduced the 6-hour urinary recovery by 55%. Sulfadiazine 3.9 g given 3 hours before the oxacillin reduced the 6-hour urinary recovery by 42%.2

Pirenzipine 50 mg given three times daily on the day before and with a single 1-g dose of amoxicillin had no significant effect on the pharmacokinetics of the antidepressant.3

None of the interactions listed appears to be adverse, and no particular precautions would seem necessary during concurrent use of these drugs and the penicillins. The importance of the interaction between oxacillin and the sulfonamides is uncertain, but it can easily be avoided by choosing alternative drugs.

---

**Penicillins + Nifedipine**

Nifedipine increases the absorption of amoxicillin from the gut but this is unlikely to be clinically important. Nafcillin increases the clearance of nifedipine, but the clinical significance of this is unclear.

**Clinical evidence, mechanism, importance and management**

(a) Amoxicillin

In 8 healthy subjects when amoxicillin 1 g was given 30 minutes after a 20-mg nifedipine capsule, the peak serum amoxicillin levels were raised by 33%, the bioavailability was raised by 21% and the absorption rate was raised by 70%.1 The authors speculate that the uptake of amoxicillin through the gut wall is increased by nifedipine in some way.1 There would seem to be no good reason for avoiding concurrent use as overall the bioavailability was not significantly altered.

(b) Nafcillin

In a randomised, placebo-controlled study, 9 healthy subjects were given a single 10-mg nifedipine capsule after a 5-day course of nafcillin 500 mg four times daily. The nifedipine AUC was decreased by 63% and the clearance was increased by 145%, but the effect of these changes on nifedipine pharmacodynamics was not assessed. It was suggested that nafcillin is an inducer of cytochrome P450 isoenzymes, and increased the metabolism of nifedipine.2 The clinical significance of these changes is unclear.

---

**Penicillins + Probendecid**

Probendecid reduces the excretion of the penicillins.

**Clinical evidence**

(a) Amoxicillin

In 10 healthy subjects a single 3-g dose of amoxicillin was given with or without probendecid 1 g. Two hours after administration, the serum levels of amoxicillin taken with probendecid were 55% higher than those with amoxicillin alone, and they remained higher for up to 18 hours.1 Similar results were found in another study.2 Amoxicillin 3 g twice daily plus placebo, amoxicillin 1 g twice daily plus probendecid 1 g twice daily, and amoxicillin 1 g twice daily plus probendecid 500 mg four times daily were given to 6 patients to treat bronchiectasis. The maximum serum concentration and half-life of both high- and low-dose amoxicillin were similar, but in the regimens containing probendecid the clearance of amoxicillin was reduced by two-thirds, when compared with amoxicillin given alone.3

(b) Benzylpenicillin

Four healthy subjects were given infusions of benzylpenicillin at three different rates, either alone or with probendecid given as a separate infusion, at rates to provide low and high plasma levels. An infusion rate of probendecid 83 mg/hour, corresponding to a daily dose of 2 g was found to produce about 90% inhibition of the tubular excretion of benzylpenicillin (at plasma levels of 25 mg/L). Doses of probendecid above 2 g daily did not have a significantly greater effect.4

(c) Mezlocillin

A study in healthy subjects found that probendecid 1 g, given one hour before an intramuscular injection of mezlocillin, increased the peak serum levels and AUC of mezlocillin by 65% and decreased the total clearance, renal clearance and apparent volume of distribution by 38%, 52%, and 35%, respectively.3

(d) Nafcillin

A study in 5 healthy subjects given 500 mg of intravenous nafcillin sodium with probendecid, 1 g given orally the previous night and 1 g given 2 hours prior to the antibiotic, showed that the urinary recovery of nafcillin was reduced from 30% to 17%, and its AUC was approximately doubled.3

(e) Piperacillin/Tazobactam

In 10 healthy subjects probenecid 1 g given 1 hour before a single infusion of piperacillin 3 g/tazobactam 375 mg caused a decrease of about 25% in the clearance of both components. The half-life of tazobactam was increased by 72%.7 A study in 8 healthy subjects found that oral probenecid 1 g, given one hour before an intramuscular injection of piperacillin 1 g, increased both the peak plasma level and terminal half-life of piperacillin by 30% and the AUC by 60%. The apparent volume of distribution of piperacillin was reduced by 20% and renal clearance was reduced by 40%.8

(f) Pivampicillin

In a crossover study healthy subjects were given either pivampicillin 350 mg every 8 hours or a tablet of MK-356 (approximately, pivampicillin 350 mg with probenecid 200 mg). Peak ampicillin levels of 4 to 5 micrograms/mL were found about 1 hour after administration of the first and last dose of both treatments suggesting that probenecid did not affect the ampicillin elimination. Administration of MK-356 (pivampicillin 700 mg with probenecid 400 mg) twice daily indicated that peak serum levels of ampicillin were increased and elimination rate slowed following successive doses.9

(g) Procaine benzylpenicillin

A study in patients given intramuscular procaine benzylpenicillin 2.4 or 4.8 million units with or without probenecid 2 g found the peak serum levels were higher in patients given probenecid, but because of wide interpatient variation, possibly associated with differences in the release of penicillin from the injection sites, the exact potentiating effect of probenecid could not be determined.10 However, another study in men and women given procaine benzylpenicillin 2.4 million units and 4.8 million units, respectively (for uncomplicated gonorrhoea), found treatment failure after 1 week in 15.4% of men and 10.4% of women. Failure rates were reduced to 1.8% and 3.7%, respectively, when oral probenecid 1 g was given with the penicillin.11

(h) Ticarcillin

Probendecid, either 500 mg twice daily, 1 g daily, or 2 g daily was added to ticarcillin 3 g every 4 hours, which was being given to treat infections in adult cystic fibrosis patients. In all cases the clearance of ticarcillin was reduced: by about 27% with the 500-mg-dose regimen, by about 32% with the 1-g-dose regimen and by about 43% with the 2-g-dose regimen.12

**Mechanism**

In each case the penicillin competes with the probenecid for excretion by the kidney tubules, although with nafcillin, non-renal clearance may also play a part.

**Importance and management**

In the case of amoxicillin, benzylpenicillin, nafcillin and ticarcillin the effects are of clinical significance. In the case of the ticarcillin study the authors suggest that a 12-hourly dosing regimen could be used if probenecid is given concurrently, which has implications for home treatment. With piperacillin/tazobactam the changes were not thought to provide any benefit in terms of dose reduction or alteration of the dosage interval. Note that this is generally considered to be a beneficial interaction, but bear in mind that this is unlikely to be clinically important.
mind that, in some cases, such as in renal impairment, the increase in penicillin levels may be undesirably large.

Penicillins + Tetracyclines

Data from the 1950s suggested that the tetracyclines can reduce the effectiveness of penicillins in the treatment of pneumococcal meningitis and probably scarlet fever. It is uncertain whether a similar interaction occurs with other infections. This interaction may possibly be important only with those infections where a rapid kill is essential.

Clinical evidence

When chlortetracycline originally became available it was tested as a potential treatment for meningitis. In patients with pneumococcal meningitis it was shown that benzylpenicillin one million units, intramuscularly every 2 hours was more effective than the same regimen of penicillin with chlortetracycline 500 mg intravenously every 6 hours. Out of 43 patients given penicillin alone, 70% recovered, compared with only 20% in another group of 14 essentially similar patients who had received both antibiotics.1

Another report about the treatment of pneumococcal meningitis with intramuscular or intravenous penicillin and intravenous tetracyclines (chlortetracycline, oxytetracycline, tetracycline) confirmed that the mortality was much lower in those given only penicillin, rather than the combination of penicillin and a tetracycline.2 In the treatment of scarlet fever (Group A beta-haemolytic streptococci), no difference was seen in the initial response to treatment with penicillin (oral procaine benzylpenicillin) and chlortetracycline or the penicillin alone, but spontaneous re-infection occurred more frequently in those who had received both antibiotics.3

Mechanism

The generally accepted explanation is that bactericides such as the penicillins, which inhibit bacterial cell wall synthesis, require cells to be actively growing and dividing to be maximally effective, a situation that will not occur in the presence of bacteriostatic antibiotics, such as the tetracyclines.

Importance and management

Documentation is limited, but this is an apparently important interaction when treating pneumococcal meningitis and probably scarlet fever as well. However, the use of these antibiotics for such severe infections has largely been superseded. It has not been shown to occur when treating pneumococcal pneumonia.4 It has been suggested that antagonism, if it occurs, may only be significant when it is essential to kill bacteria rapidly, i.e. in serious infections such as meningitis. Any penicillin and any tetracycline would be expected to behave in this way.

Note that, the macrolides, which are also bacteriostatic would be expected to attenuate the action of penicillins, but this does not seem to occur in practice. See ‘Macrolides + Penicillins’, p.316.

Penicillins; Amoxicillin + Amiloride

Amiloride can cause a small but probably clinically unimportant reduction in the absorption of amoxicillin.

Clinical evidence, mechanism, importance and management

When 8 healthy subjects were given amiloride 10 mg followed 2 hours later by a single 1-g oral dose of amoxicillin, the bioavailability and maximum serum levels of amoxicillin were reduced by 27% and 25%, respectively, and the time to reach maximum levels was delayed from 1 hour to 1.56 hours. When amoxicillin was given intravenously its bioavailability was unchanged by amiloride.1 It is thought that the absorption of beta lactams like amoxicillin depends on a dipeptide carrier system in the cells lining the intestine (brush border membrane). This system depends on the existence of a peptide gradient between the inside and outside of the cells, which is maintained by a Na-H exchanger. As this exchange is inhibited by amiloride the reduced absorption would seem to be explained. This reported reduction in the absorption of the amoxicillin is only small and unlikely to have very much clinical relevance. There seems to be no information about other penicillins.

Penicillins; Cloxacillin + Proguanil

Proguanil may reduce the bioavailability of cloxacillin.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in healthy subjects given cloxacillin 500 mg with or without proguanil 200 mg found the total amount of cloxacillin excreted in the urine in 12 hours was reduced by up to 48% by proguanil. The time to maximum excretion and the half-life were increased by 23% and 34%, respectively. The reasons why cloxacillin absorption is reduced by proguanil are not known, but it has been suggested that it may be due to adsorption of cloxacillin on to proguanil in the gut, formation of a drug complex, increased gastric motility or increased beta-lactam ring hydrolysis leading to reduced cloxacillin bioavailability.3 The clinical implications of the interaction are unknown.

Penicillins; Dicloxacillin + Rifampicin

Rifampicin increases the oral clearance of dicloxacillin and reduces its plasma levels.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects found that rifampicin 600 mg daily for 10 days decreased the maximum plasma level of a single 1-g dose of dicloxacillin by 27% and increased the mean oral clearance by 26%. The mean absorption time increased from 0.71 to 1.34 hours. Rifampicin increased the formation clearance, maximum level and AUC of the 5-hydroxymetabolite of dicloxacillin by 135%, 119%, and 59%, respectively. Dicloxacillin is a substrate of P-glycoprotein and it was suggested that the
effects of rifampicin on dicloxacillin were due to induction of both intestinal P-glycoprotein and dicloxacillin metabolism.\(^1\)

**Penicillins; Piperacillin/tazobactam + Vancomycin**

Vancomycin does not interact to a clinically relevant extent with piperacillin/tazobactam.

**Clinical evidence, mechanism, importance and management**

A randomised, crossover study in 9 healthy subjects found that infusions of vancomycin 500 mg and piperacillin 3 g with tazobactam 375 mg had little or no effect on the pharmacokinetics of any of the antibacterials, except that the piperacillin C\(_\text{max}\) was raised by 7%. It was concluded that no dosage adjustments are needed if these drugs are given together.\(^1\)

**Penicillins; Pivampicillin or Pivmecillinam + Valproate**

An isolated report describes hyperammonaemic encephalopathy in an elderly patient during treatment with valproate and pivmecillinam. The manufacturers of both pivmecillinam and pivampicillin advise the avoidance of concurrent valproate because of the increased risk of carnitine deficiency.

**Clinical evidence, mechanism, importance and management**

There is a report of hyperammonaemic encephalopathy which developed in a 72-year-old woman taking valproate monotherapy for partial epilepsy after she started treatment with pivmecillinam 600 mg daily. She recovered after discontinuation of valproate and use of cefuroxime instead of pivmecillinam.\(^1\) Valproate may reduce serum carnitine,\(^1\) for reasons that are not well understood.\(^2\) Valproate-induced hyperammonaemic encephalopathy may be due to reduced carnitine levels.\(^1\)

Pivmecillinam and pivampicillin are hydrolysed to release mecillinam or ampicillin respectively, pivalic acid and formaldehyde. One of the potential problems of these drugs is that the pivalic acid can react with carnitine to form pivaloyl-carnitine, which is excreted in the urine, and so the body can become depleted of carnitine. Carnitine deficiency also manifests as muscle weakness and cardiomyopathy. The risks of carnitine deficiency due to pivmecillinam or pivampicillin seem to be small in healthy adults, but the manufacturers of pivmecillinam and pivampicillin advise a warning about long-term or frequently repeated treatment.\(^3,4\)

The authors of the report advise caution if pivmecillinam is added to treatment with valproate.\(^1\) Although this appears to be the only report of an adverse effect due to the combined effects of pivmecillinam and valproate on carnitine levels, the manufacturers advise the avoidance of both pivampicillin or pivmecillinam with valproic acid or valproate or other medication liberating pivalic acid.\(^3,4\)

**Penicillins; Pivampicillin or Pivmecillinam + Valproate**

An isolated report describes hyperammonaemic encephalopathy in an elderly patient during treatment with valproate and pivmecillinam. The manufacturers of both pivmecillinam and pivampicillin advise the avoidance of concurrent valproate because of the increased risk of carnitine deficiency.

**Clinical evidence, mechanism, importance and management**

There is a report of hyperammonaemic encephalopathy which developed in a 72-year-old woman taking valproate monotherapy for partial epilepsy after she started treatment with pivmecillinam 600 mg daily. She recovered after discontinuation of valproate and use of cefuroxime instead of pivmecillinam.\(^1\) Valproate may reduce serum carnitine,\(^1\) for reasons that are not well understood.\(^2\) Valproate-induced hyperammonaemic encephalopathy may be due to reduced carnitine levels.\(^1\)

Pivmecillinam and pivampicillin are hydrolysed to release mecillinam or ampicillin respectively, pivalic acid and formaldehyde. One of the potential problems of these drugs is that the pivalic acid can react with carnitine to form pivaloyl-carnitine, which is excreted in the urine, and so the body can become depleted of carnitine. Carnitine deficiency also manifests as muscle weakness and cardiomyopathy. The risks of carnitine deficiency due to pivmecillinam or pivampicillin seem to be small in healthy adults, but the manufacturers of pivmecillinam and pivampicillin advise a warning about long-term or frequently repeated treatment.\(^3,4\)

The authors of the report advise caution if pivmecillinam is added to treatment with valproate.\(^1\) Although this appears to be the only report of an adverse effect due to the combined effects of pivmecillinam and valproate on carnitine levels, the manufacturers advise the avoidance of both pivampicillin or pivmecillinam with valproic acid or valproate or other medication liberating pivalic acid.\(^3,4\)

**Pyrazinamide + Antacids**

In 14 healthy subjects 30 mL of *Mylanta* (aluminium/magnesium hydroxide) given 9 hours before, with, and after a single 30 mg/kg dose of pyrazinamide decreased the time to peak absorption by 17%, but had no effect on other pharmacokinetic parameters.\(^3\) This change is not clinically important.

**Pyrazinamide + Antigout drugs**

Pyrazinamide commonly causes hyperuricaemia and may therefore reduce the uricosuric effect of benzbromarone and probenecid. Allopurinol is unlikely to be effective against pyrazinamide-induced hyperuricaemia, and may exacerbate the situation, whereas benzbromarone may have modest efficacy in reducing hyperuricaemia caused by pyrazinamide.

**Clinical evidence, mechanism, importance and management**

The manufacturers of pyrazinamide warn that hyperuricaemia is a contraindication for its use, and that if hyperuricaemia accompanied by acute gouty arthritis occurs during treatment, the pyrazinamide should be

**Protonamide + Other antimiycobacterials**

Protonamide appears to be very hepatotoxic and this is possibly increased by the concurrent use of rifampicin or rifabutin. Protonamide does not affect the pharmacokinetics of either dapsone or rifampicin.

**Clinical evidence**

In a study of 39 patients with leprosy, 39% became jaundiced after treatment for 24 to 120 days with *dapsone* 100 mg daily, protonamide 300 mg daily and *rifabutin* [isopropenzylrifamycin SV] 300 to 600 mg monthly. Laboratory evidence of liver damage occurred in a total of 56% of patients and despite the withdrawal of the drugs from all the patients, 2 of them died.\(^1\) All the patients except two had taken *dapsone* before, alone, for 3 to 227 months without reported problems.\(^1\) In another group of leprosy patients, 22% (11 of 50) had liver damage after treatment with *dapsone* 100 mg and protonamide 300 mg given daily, and *rifampicin* 900 mg, protonamide 500 mg and *clofazimine* 300 mg given monthly over a period of 30 to 50 days. One patient died.\(^1\) Most of the patients recovered within 30 to 60 days after withdrawing the treatment.

Jaundice, liver damage and deaths have occurred in other leprosy patients given *rifampicin* and protonamide or *ethionamide*.\(^2,4\) Protonamide does not affect the pharmacokinetics of either *dapsone* or *rifampicin*.\(^2\)

**Mechanism**

Although not certain, it seems probable that the liver damage was primarily caused by the protonamide, and possibly exacerbated by the rifampicin or the rifabutin.

**Importance and management**

This serious and potentially life-threatening hepatotoxic reaction to protonamide is established, but the part played by the other drugs, particularly the rifampicin, is uncertain. Strictly speaking this may not be an interaction. If protonamide is given the liver function should be very closely monitored in order to detect toxicity as soon as possible.

stopped and not restarted. They also say that pyrazinamide should not be given unless regular uric acid determinations can be made.\(^1\)

\((a)\) Allopurinol

It is thought that pyrazinamide is hydrolysed in the body to pyrazinoic acid, which appears to be responsible for the hyperuricaemic effect of pyrazinamide. Pyrazinoic acid is oxidised by the enzyme xanthine oxidase to 5-hydroxy-2-pyrazinoic acid.\(^2\) Since allopurinol is an inhibitor of xanthine oxidase, its presence increases pyrazinoic acid concentrations\(^3\) thereby probably worsening the pyrazinamide-induced hyperuricaemia.\(^4\) Allopurinol would therefore appear to be unsuitable for treating pyrazinamide-induced hyperuricaemia.

\((b)\) Benzbromarone

A single dose of pyrazinamide completely abolished the uricosuric effect of a single 160-mg dose of benzbromarone in 5 subjects with hyperuricaemia and gout.\(^5\) Other authors also briefly mention the same finding.\(^6\) However in another study, when benzbromarone 50 mg daily for 8 to 10 days was given to 10 patients taking pyrazinamide 35 mg/kg daily for tuberculosis, uric acid levels were reduced by an average of 24.3%, and returned to normal in four of them.\(^7\) It is unclear from these studies whether or not pyrazinamide abolishes the uricosuric effects of benzbromarone. However, pyrazinamide commonly causes hyperuricaemia, and would be expected to antagonise the effects of uricosuric drugs such as benzbromarone. Benzbromarone may have modest efficacy in reducing hyperuricaemia caused by pyrazinamide, but further study is necessary. However, see above, for advice relating to hyperuricaemia caused by pyrazinamide.

\((c)\) Probenecid

The interactions of probenecid and pyrazinamide and their effects on the excretion of uric acid are complex and intertwined. Probenecid increases the secretion of uric acid into the urine, apparently by inhibiting its resorption from the kidney tubules.\(^8\) Pyrazinamide on the other hand decreases the secretion of uric acid into the urine by one-third to one-half,\(^9\) resulting in a rise in the serum levels of urate in the blood, thereby causing hyperuricaemia.\(^10\) The result of using probenecid and pyrazinamide together is not however merely the simple sum of these two effects. This is because pyrazinamide additionally decreases the metabolism of the probenecid and prolongs its uricosuric effects, and the effect of pyrazinamide is reduced. Also, probenecid inhibits the secretion of pyrazinamide, increasing its effects.\(^11\)

The likely overall effect is that if probenecid were to be used to treat the hyperuricaemia caused by pyrazinamide, the normal uricosuric effects of probenecid would be diminished, and larger doses would be required. However, see above, for advice relating to hyperuricaemia caused by pyrazinamide.

Continued
nolones that have yet to be studied, but in the absence of direct information a 2-hour separation errs on the side of caution.

(d) Sodium antacids

Sodium bicarbonate does not interact significantly with norfloxacin but information about other quinolones appears to be lacking. However, bear in mind that in the case of ciprofloxacin an excessive rise in urinary pH (which can be caused by antacids like sodium bicarbonate) may possibly result in urinary crystalluria and kidney damage.20

Possible alternatives to the antacids, which do not appear to interact with the quinolones, include the ‘H₂-receptor antagonists’, (p.335) and ‘omeprazole’, (p.338).

13. Lomaestro BM, Bailie GR. Effect of multiple staggered doses of calcium on the bioavailabil-
17. Ciprifox Tablets (Ciprofloxacin hydrochloride). Bayer plc. UK Summary of product character-
18. Clinical evidence

(a) Ciprofloxacin

Six patients with newly diagnosed haematological malignancies (5 with acute myeloid leukaemia and one with non-Hodgkin’s lymphoma) were given ciprofloxacin 500 mg twice daily to control possible neutropenic in-
fections. It was found that, after 13 days of chemotherapy, their mean maximum serum ciprofloxacin levels had fallen by 46%, from 3.7 to 2 mg/L and the AUC₀₋₄ was reduced by 47%. There were large individual differences between the patients. The antineoplastics used were cyclo-
phosphamide, cytarabine, daunorubicin, doxorubicin, mitoxantrone and vincristine. Methotrexate toxicity has occurred in 2 patients during treatment with ciprofloxacin, see ‘Methotrexate + Antibacterials; Cipro-
floxicin’, p.643.

(b) Ofloxacin

Ten patients with non-Hodgkin’s lymphoma, hairy cell leukaemia or acute myeloid leukaemia were given ofloxacin 400 mg at breakfast time for antibacterial prophylaxis during neutropenia. Blood samples were taken 3 days before chemotherapy began and then at 2 to 3, 5 to 7, and 8 to 10 days. The maximum serum ofloxacin levels were reduced by 18% two to three days after the chemotherapy but none of the other pharmacokinetic-
measurements were changed by the antineoplastic treatment. The serum levels had returned to normal by days 5 to 7. At all times serum levels exceeded the expected MICs of the gram-negative potential pathogens. The antineoplastics used were cyclophosphamide, cytarabine, doxorubicin, etoposide, ifosfamide (with mesna), vincristine.2

Mechanism

Uncertain. The interaction seems to result from a reduction in the absorp-
tion of the quinolones by the small intestine, possibly related to the dam-
egging effect cytotoxic antineoplastics have on the rapidly dividing cells of the intestinal mucosa.

Importance and management

Direct information is limited, but these reports are consistent with the way cytoxic antineoplastics can reduce the absorption of some other drugs. The authors of both reports suggest that these changes are probably clini-
cally unimportant, because the serum levels of achieved are likely to be suf-
cient to treat most infections. If the suggested mechanism of interac-
tion is correct, no interaction should occur if quinolones are given parenterally. Nothing appears to be documented about any of the other quinolones.

2. Brown NM, White LO, Blundell EL, Chowen SR, Slade RR, MacGowan AP, Reeves DS. Ab-

Quinolones + Chinese herbal medicines

Sho-saiko-to, Rikkunshi-to and Sairei-to do not interact with ofloxacin, and Hotyu-ekki-to, Rikkunshi-to and Juzen-taiho-to do not interact with levofloxacin.

Clinical evidence, mechanism, importance and management

The bioavailability and urinary recovery of a single 200-mg oral dose of levofloxacin were not significantly altered in 7 healthy subjects by three Chi-
ense herbal medicines (Sho-saiko-to, Rikkunshi-to or Sairei-to).1 The bioavailability and renal excretion of a single 200-mg oral dose of lev-
ofloxacin was not affected in 8 healthy subjects given single 2.5-g doses of Hotyu-ekki-to, Rikkunshi-to or Juzen-taiho-to.2 There would therefore seem to be no reason for avoiding concurrent use. Information about other quinolones is lacking. The ingredients of these herbal medicines are detailed in ‘Table 10.4’, (p.333).

Quinolones + Dairy products

Dairy products reduce the bioavailability of ciprofloxacin and norfloxacin, and to a minor extent, gatifloxacin, but not enoxacin, lomefloxacin, moxifloxacin, ofloxacin and probably not flerox-
axin.

Clinical evidence

(a) Ciprofloxacin

A study in 7 healthy subjects given a single 500-mg dose of ciprofloxacin found that 300 mL of milk or yoghurt reduced the peak plasma levels by 36% and 47%, respectively, and the AUC by 33% and 36%, respectively.1 In another study 300 mL of milk reduced the AUC of ciprofloxacin 500 mg by about 30%2.
(b) Enoxacin
A study found that milk and a standard breakfast had no effect on enoxacin absorption.3

(c) Fleroxacin
In a study, a fat and liquid calcium meal had no clinically significant effect on the pharmacokinetics of fleroxacin.4 In another study, milk had no effect on fleroxacin pharmacokinetics.2

(d) Gatifloxacin
In one study 200 mL of milk reduced the AUC of gatifloxacin 200 mg by about 15%.5

(e) Lomefloxacin
Milk had no effect on the pharmacokinetics of lomefloxacin.6

(f) Moxifloxacin
A study found that the rate of absorption of a single 400-mg dose of moxifloxacin was slightly delayed by 250 g of yoghurt. The maximum plasma level of moxifloxacin was reduced by about 15%, but the bioavailability was unaffected.7

(g) Norfloxacin
A study found that 300 mL of milk or yoghurt reduced the absorption and the peak plasma levels of a single 200-mg dose of norfloxacin by roughly 50%.8

(h) Ofloxacin
A study in 21 healthy subjects found that 8 oz (about 250 mL) of milk had no clinically significant effects on the absorption of 300 mg of ofloxacin.9 Another study confirmed the lack of a significant interaction between ofloxacin and both milk and yoghurt.10

Mechanism
The proposed reason for these changes is that the calcium in milk and yoghurt or other dairy products combines with the ciprofloxacin and norfloxacin to produce insoluble chelates. Compare also ‘Quinolones + Antacids or Calcium compounds’, p.328.

Importance and management
The effect of these changes to ciprofloxacin and norfloxacin pharmacokinetics on the control of infection is uncertain but until the situation is clear patients should be advised not to take these dairy products within 1 to 2 hours of either ciprofloxacin or norfloxacin to prevent admixture in the gut. The slight reduction in gatifloxacin levels is probably not clinically relevant.

The quinolones that do not interact significantly would appear to be enoxacin, lomefloxacin, moxifloxacin, ofloxacin and probably fleroxacin. They may provide a useful alternative to the interacting quinolones.

Quinolones + Didanosine

An extremely marked reduction in the serum levels of ciprofloxacin occurs if it is given at the same time as didanosine tablets, because of an interaction with the antacid buffers in the didanosine formulation. Taking the ciprofloxacin 2 hours before or 6 hours after didanosine tablets minimises this interaction. Other quinolones are expected to interact similarly. Didanosine enteric-coated capsules do not interact with ciprofloxacin.

Clinical evidence

When 12 healthy subjects were given ciprofloxacin 750 mg with two didanosine placebo tablets (i.e. all of the antacid additives but no didanosine), the ciprofloxacin AUC and maximum serum levels were reduced by 98% and 93%, respectively.1 The antacids in this formulation were dihydroxyaluminium sodium carbonate and magnesium hydroxide. Other studies have looked at whether separating the administration times affects this interaction. When 16 HIV-positive patients were given ciprofloxacin 1.5 g daily 2 hours before didanosine tablets, the ciprofloxacin AUC was reduced by only 26%.2 Another study in just one subject found that when ciprofloxacin 500 mg was given 2 hours after taking two didanosine placebo tablets the ciprofloxacin serum levels were reduced below minimal inhibitory concentrations, but giving the ciprofloxacin 2 hours before the didanosine placebo tablets resulted in normal blood levels.3

The enteric-coated capsule formulation of didanosine (which does not contain antacids) does not interact with ciprofloxacin.4

Mechanism

Didanosine is extremely acid labile at pH values below 3, so one of the formulations contains buffering agents (dihydroxyaluminium sodium carbonate and magnesium hydroxide) to keep the pH as high as possible to minimise the acid-induced hydrolysis. Ciprofloxacin forms insoluble non-absorbable chelates with these metallic ions in the buffer so that its bioavailability is markedly reduced. See also ‘Quinolones + Antacids or Calcium compounds’, p.328.

Importance and management

Direct information is limited to these reports but the interaction between buffered didanosine and ciprofloxacin appears to be clinically important. Such drastic reductions in serum ciprofloxacin levels mean that minimal inhibitory concentrations are unlikely to be achieved. Ciprofloxacin should be given at least 2 hours before or 6 hours after didanosine tablets (see ‘Quinolones + Antacids or Calcium compounds’, p.328). Other quinolone antibacterials that interact with antacids are also expected to interact with didanosine tablets, but so far reports are lacking. Didanosine enteric-coated capsules do not interact.

Apart from ‘dairy products’ (p.332), most foods delay but do not reduce the absorption of ciprofloxacin, enoxacin, gemifloxacin, lomefloxacin, ofloxacin or sparfloxacin. A high-fat/high-calcium breakfast did not reduce ciprofloxacin levels. Calcium-fortified orange juice significantly reduces the absorption of ciprofloxacin, but not gatifloxacin or levofloxacin.

Clinical evidence

A. Enteral feeds

(a) Ciprofloxacin

The oral bioavailability of ciprofloxacin 750 mg was reduced by 28% and the mean maximum serum ciprofloxacin levels were reduced by 48% when it was given to 13 fasted subjects with Ensure. In this study the subjects were given 120 mL of the study liquid (Ensure or water) and this was repeated at 30-minute intervals for 5 doses. The ciprofloxacin was crushed and mixed with the second dose of the study liquid and the cup rinsed with another 60 mL of the study liquid.1

Other enteral feeds given orally (Osmolite, Pulmocare, and Resource) similarly reduced the bioavailability and maximum serum levels of ciprofloxacin by about one-quarter to one-third in two other studies.2,3 One comparative study found that Ensure reduced the AUC of ciprofloxacin by 40.2% in men but by only 14.5% in women.4

Ciprofloxacin bioavailability was reduced by 53% and 67% by Jevity or Sustacal, respectively, when given via gastrostomy or jejunostomy tubes in a study of 26 hospitalised patients. Despite this, the serum levels achieved with gastrostomy tubes were roughly equivalent to those seen in subjects taking tablets orally.5 In another study in patients given Jevity or Osmolite, the 4 patients with a nasoduodenal tube achieved a ciprofloxacin AUC that was about double that seen in the 3 patients with a nasogastric tube or a gastrostomy.6 In contrast, in another study in healthy subjects, there was no difference in the bioavailability of ciprofloxacin when it was given alone or when it was given with Osmolite via a nasogastric tube.7

The bioavailability of ciprofloxacin 750 mg every 12 hours in 5 patients with severe gram-negative intra-abdominal infections was reduced by 47% when it was added to enteral feeding with Nutrition or Nutrition E+ and given via nasogastric or nasoduodenal tubes. The serum levels were similar to those found in another 7 patients given ciprofloxacin with these enteral feeds and also to those found when the 5 original patients were given intravenous ciprofloxacin 400 mg every 12 hours.8 In another study in 12 intensive care patients the AUC of ciprofloxacin 400 mg given by intravenous infusion was similar to that found after a dose of 750 mg given via nasogastric tube during enteral feeding with Normo-Réal fibres.9

An in vitro study found an 83% decrease in the concentration of ciprofloxacin when a 500-mg ciprofloxacin tablet was crushed and mixed with Ensure. Mixing with solutions of calcium chloride and/or magnesium chloride did not significantly reduce ciprofloxacin concentrations.10

(b) Levofloxacin

An in vitro study found a 61% decrease in the concentration of levofloxacin when a 500-mg levofloxacin tablet was crushed and mixed with Ensure. Mixing with solutions of calcium chloride and/or magnesium chloride did not significantly reduce levofloxacin concentrations.10

(c) Moxifloxacin

Compared to oral administration of an uncushred tablet with water, the oral bioavailability of a single 400-mg dose of moxifloxacin was slightly decreased (by 9%) when given to 12 healthy subjects as a suspension of a crushed tablet via a nasogastric tube with either water or Isosource Energy. Maximum plasma levels were decreased by 5% and 12% after nasogastric administration with water and Isosource Energy, respectively.11

(d) Ofloxacin

The oral bioavailability of ofloxacin 400 mg was reduced by 10% when given to 13 healthy subjects with Ensure. The mean maximum serum ofloxacin levels were reduced by 36%. The same procedure as described in (a) was followed.1 Only small reductions in the AUCs of ofloxacin were seen in another study (10.5% in men, 13.2% in women) with Ensure.4 However, an in vitro study found a 46% decrease in the concentration of ofloxacin when a 300-mg tablet of ofloxacin was crushed and mixed with Ensure. Mixing with solutions of calcium chloride and/or magnesium chloride did not significantly reduce ofloxacin concentrations.10

Quinolones + Enteral feeds or Food

The absorption of ciprofloxacin can be reduced by enteral feeds such as Ensure, Jevity, Osmolite, Pulmocare and Sustacal. An in vitro study found a significant reduction in the concentration of ciprofloxacin, levofloxacin and ofloxacin with Ensure but other studies suggest the interaction with moxifloxacin or ofloxacin is much smaller than that with ciprofloxacin and probably of little clinical importance.

References

7. 98% and 93%, respectively.
Cimetidine can increase the serum levels of some quinolones (intravenous enoxacin or fleroxacin and oral clinafloxacin or pefloxacin). Famotidine can reduce the serum levels of norfloxacin, and ranitidine can reduce the absorption of enoxacin. None of these interactions appear to be clinically important.

**Clinical evidence and mechanism**

**Quinolones + H2-receptor antagonists**

**Cimetidine**

Neither cimetidine nor ranitidine appear to have a clinically important effect on the pharmacokinetics of ciprofloxacin.

**Clinical evidence and mechanism**

(a) *Ciprofloxacin*

- **Neither cimetidine nor ranitidine appear to have a clinically important effect on the pharmacokinetics of ciprofloxacin.**

(b) *Clinafloxacin*

- **Cimetidine 300 mg four times daily for 4 days increased the maximum serum levels of clinafloxacin by 15% and increased its AUC by 44%.**

(c) *Enoxacin*

- The plasma levels of a 400-mg intravenous dose of enoxacin were higher when cimetidine 300 mg four times daily was given concurrently. Renal clearance and systemic clearance were reduced by 26% and 20%, respectively, and the elimination half-life was increased by 30%.

- In one study ranitidine 150 mg twice daily did not affect the pharmacokinetics of a single 400-mg intravenous dose of enoxacin. However, in another, ranitidine 50 mg given intravenously 2 hours before a single 400-mg oral dose of enoxacin reduced the absorption by 26 to 40% which seemed to be related to changes in gastric pH caused by the ranitidine.
Cimetidine decreased the total clearance of fleroxacin by about 25%, without much effect on renal clearance, and increased its elimination half-life by 32%.9

Gatifloxacin
does not alter the pharmacokinetics of gatifloxacin.10

Grepafloxacin
does not alter the pharmacokinetics of grepafloxacin.11 Similarly, intravenous famotidine in a dose of up to 40 mg had no effect on the pharmacokinetics of a 400-mg dose of grepafloxacin.12

Levofloxacin
does not alter the pharmacokinetics of levofloxacin.14

Lomefloxacin
does not alter the pharmacokinetics of lomefloxacin.15,16

Maxifloxacin
does not affect the pharmacokinetics of moxifloxacin.17

Norfloxacin
does not affect the pharmacokinetics of norfloxacin.18

Famotidine
given 8 hours before norfloxacin significantly reduced its maximum serum concentrations in 6 healthy subjects, but the AUC and urinary recovery rate were unchanged.18

Ofoxacin
does not alter the pharmacokinetics of ofloxacin.19

Pefloxacin
increased the AUC of intravenous pefloxacin by about 40%. It increased the half-life from 10.3 to 15.3 hours and the clearance was reduced by almost by 30%.20

Sparfloxacin
does not alter the pharmacokinetics of sparfloxacin.21

Trofloxacin
does not alter the pharmacokinetics of trofloxacin.22

Importance and management
Although the pharmacokinetic changes seen in some of these studies are moderate, none has been shown to affect the outcome of treatment and they are probably only of minor clinical relevance.

Ferrous fumarate, gluconate, sulfate and other iron compounds can reduce the absorption of ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, norfloxacin, ofloxacin and sparfloxacin from the gut. Serum levels of the antibacterial may become subtherapeutic as a result. Limited evidence suggests that fleroxacin is not affected and lomefloxacin is only minimally affected. Gemi- noxacin does not affect the pharmacokinetics of grepafloxacin.13 Simi- larly, intravenous famotidine in a dose of up to 40 mg had no effect on the pharmacokinetics of grepafloxacin.12

Quinolones + Iron or Zinc compounds

Ferrous fumarate, gluconate, sulfate and other iron compounds can reduce the absorption of ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, norfloxacin, ofloxacin and sparfloxacin from the gut. Serum levels of the antibacterial may become subtherapeutic as a result. Limited evidence suggests that fleroxacin is not affected and lomefloxacin is only minimally affected. Gemi- noxacin does not affect the pharmacokinetics of grepafloxacin.13

Clinical evidence
(a) Ciprofloxacin
The absorption of ciprofloxacin is markedly reduced by iron and zinc compounds. Several studies have clearly demonstrated reductions in the AUC and maximum serum levels of 30 to 90% with ferrous fumarate,1 ferrous gluconate,2 ferrous sulfate,2,5 iron-glycine sulfate,6 Centrum Forte7 (a multi-mineral preparation containing iron, magnesium, zinc, calcium, copper and manganese) and with Stresstabs 600-with-zinc8 (a multivitamin-with-zinc preparation). However iron-ovotransferrin has been found to have no significant effect on the absorption of ciprofloxacin.2

(b) Fleroxacin
A study in 12 subjects found that ferrous sulfate (equivalent to 100 mg of elemental iron) had no significant effect on the pharmacokinetics of fleroxacin.8

(c) Gatifloxacin
A study in 6 healthy subjects found that ferrous sulfate 160 mg given with gatifloxacin 200 mg decreased the maximum serum levels and AUC of gatifloxacin by 49% and 29%, respectively.9

(d) Gemifloxacin
Gemifloxacin 320 mg was given either 3 hours before or 2 hours after ferrous sulfate 325 mg in a study in 27 healthy subjects. The pharmacokinetics of gemifloxacin were not significantly altered in either case.10

(e) Levofloxacin
Ferrous sulfate has been found to reduce the bioavailability of levofloxacin by 79%.11

(f) Lomefloxacin
When lomefloxacin 400 mg was given with ferrous sulfate (equivalent to 100 mg of elemental iron), the lomefloxacin maximum serum levels were reduced by about 28% and the AUC by about 14%.12

(g) Maxifloxacin
In 12 healthy subjects ferrous sulfate (equivalent to 100 mg of elemental iron) reduced the AUC and maximum plasma levels of a single 400-mg dose of moxifloxacin by 39% and 59%, respectively. Ferrous sulfate caused a 51% reduction in the norfloxacin AUC in another study,14,15 and a 97% reduction in bioavailability in a further single dose study.16 The same authors also found that both...
sulfate and zinc sulfate reduced the urinary recovery of norfloxacin by 55% and 56%, respectively. 17

(j) Ofloxacin

In 8 healthy subjects ferrous sulfate (equivalent to 100 mg of elemental iron) reduced the AUC and maximum serum levels of a single 400-mg dose of ofloxacin by 25% and 36%, respectively. 5 In 9 healthy subjects ferrous sulfate 1050 mg decreased the absorption of ofloxacin 200 mg by 11%. 18 In 12 healthy subjects elemental iron 200 mg (in the form of an iron-glycine-sulfate complex) reduced the bioavailability of ofloxacin 400 mg by 36%. 6

(j) Sparfloxacin

In a single dose study in 6 subjects, 525 mg of ferrous sulfate (equivalent to 170 mg of elemental iron) reduced the AUC of sparfloxacin 200 mg by 27%. 14, 15

Mechanism

It is believed that the quinolones form a complex with iron and zinc (by chelation between the metal ion and the 4-oxo and adjacent carboxyl groups), which is less easily absorbed by the gut. However, a study in rats using oral iron and intravenous ciprofloxacin suggested that the interaction may not be entirely confined to the gut. 19 This needs further study. Iron-ovotransferrin differs from other iron preparations in being able to combine directly with the transferrin receptors of intestinal cells, and appears to release little iron into the gut to interact with the quinolones.

Importance and management

The interactions between the quinolones and iron compounds are established and would appear to be of clinical importance because the serum antibacterial levels can become subtherapeutic. In descending order the extent of the interaction appears to be: norfloxacin, levofloxacin, ciprofloxacin, moxifloxacin, gatifloxacin, ofloxacin/sparfloxacin, then least affected, lomefloxacin.

None of these quinolones should be taken at the same time as any iron preparation that contains substantial amounts of iron (e.g. ferrous sulfate, ferrous gluconate, ferrous fumarate, iron-glycine-sulfate). Since the quinolones are rapidly absorbed, taking them 2 hours before the iron should minimise the risk of admixture in the gut and largely avoid this interaction. Information about other quinolones seems to be lacking but the same precautions should be taken with all of them except fleroxacin, which appears not to interact, and lomefloxacin, which seems to interact only minimally.

Iron-ovotransferrin does not interact with ciprofloxacin and is not expected to interact with any of the quinolones (see ‘Mechanism’) but this awaits confirmation.

There seems to be very little data about the interactions between zinc compounds and quinolones, but zinc appears to interact like iron and therefore the same precautions suggested for iron should be followed.

Clinical evidence

A number of cases of convulsions have been seen in Japanese patients given fenbufen with enoxacin, and there is also one possible case involving ofloxacin. Use of these particular drugs together should be avoided. Normally no interaction seems to occur with most quinolones and NSAIDs, except where there is a predisposition to convulsive episodes. Isolated cases of convulsions, other neurological toxicity or skin eruptions have been seen when ciprofloxacin was given with indometacin, mefenamic acid or naproxen. These appear to be very rare events.

Quinolones + NSAIDs

A study in 8 healthy subjects found that the pharmacokinetics of ciprofloxacin were unaffected by treatment with fenbufen for 3 days. Another study found that combined single doses of ciprofloxacin and fenbufen in 12 healthy subjects produced no evidence, using EEG recordings, of increased CNS excitatory effects.

(b) Enoxacin

A total of 17 Japanese patients have been identified, with apparently no previous history of seizures, who in the 1986 to 1987 period developed convulsions when given fenbufen 400 mg to 1.2 g daily with enoxacin 200 to 800 mg. 5 Two case reports of this interaction have been published. 6, 7 An 87-year-old Japanese woman taking enoxacin 200 mg also had convulsions after receiving a single 50-mg intravenous dose of flurbiprofen. 8

(c) Levofloxacin

A study in 24 healthy subjects found plasma levels of single 125-mg and 500-mg doses of levofloxacin were increased by about 13%, 6.5 hours after they were given fenbufen 600 mg. No changes in CNS activity were found. 9

(d) Ofloxacin

One patient taking fenbufen 800 mg had involuntary movements of the neck and upper extremities after taking ofloxacin 600 mg. 5 The pharmacokinetics of ofloxacin 200 mg twice daily were unchanged by ketoprofen 100 mg daily for 3 days in 10 healthy subjects. 10 The incidence of psychotic adverse effects (euphoria, hysteria, psychosis) in 151 patients on ofloxacin were not increased by the concurrent use of NSAIDs (aspirin, diclofenac, indometacin, dipryone). 11

(e) Pefloxacin

The pharmacokinetics of pefloxacin 400 mg twice daily were not affected by ketoprofen 100 mg daily for 3 days in 10 healthy subjects. 10

5. Lode H, Stuhlert P, Deppermann KH, Mainz D, Borner K, Kotvas K, Koeppe P. Pharmacokinetics of pefloxacin 400 mg decreased the absorption of ofloxacin 200 mg by 27%.
A 62-year-old woman developed drug eruptions (erythematous papules), which were attributed to sparfloxacin hypersensitivity induced by mefenamic acid.12

**Mechanism**

Not fully understood. Convolusions have occurred in a few patients taking quinolones alone, some of whom were epileptics and some of whom were not (see ‘Antiepileptics + Quinolones’, p.522). Experiments in mice have shown that quinolones competitively inhibit the binding of gamma-amo-nobutyric acid (GABA) to its receptors.13 GABA is an inhibitory transmitter in the CNS, which is believed to be involved in the control of convulsive activity. Enoxacin and fenbufen are known to affect the GABA receptor site in the hippocampus and frontal cortex of mice, which is associated with convulsive activity.14 It could be that, if and when an interaction occurs, the NSAID simply lowers the amount of quinolone needed to precipitate convulsions in already susceptible individuals.

**Importance and management**

The interaction between enoxacin and fenbufen is established, but it seems to be an extrapolation from the interaction between enoxacin and fenbufen, and from some animal experiments. In addition to the data cited above, an epidemiological study of 856 users of quinolones (ciprofloxacin, enoxacin, nalidixic acid) and a range of NSAIDs found no cases of convulsions.16 The overall picture would therefore seem to be that although a potential for interaction exists, the risk is very small indeed and normally there would seem to be little reason for most patients taking quinolones to avoid NSAIDs. Epileptic patients are a possible exception (see ‘Antiepileptics + Quinolones’, p.522) and it would seem prudent to avoid quinolones and NSAIDs wherever possible in these patients.

Reports of adverse interactions between other quinolones and NSAIDs are extremely rare. The general warning about convulsions with quinolones and enoxacin. There are very many alternatives.

Clinical evidence, mechanism, importance and management

A single-dose study found that omeprazole 20 or 80 mg had no significant effect on the pharmacokinetics of single doses of ofloxacin 400 mg, ciprofloxacin 500 mg or lomefloxacin 250 or 400 mg.1 Another study in 27 subjects found that omeprazole 40 mg daily for 3 days did not affect the pharmacokinetics of a single 1-g dose of an extended-release formulation of ciprofloxacin (Depomed).2 Omeprazole 40 mg caused an 18% reduction in the AUC of a single 300-mg dose of trovafloxacin and a 32% reduction in the maximum serum levels, but this was considered not to be of clinical significance.3 A double-blind, randomised, crossover study in 12 healthy subjects found that the maximum serum levels and the AUC of a single 320-mg dose of gemifloxacin were increased by 11% and 10%, respectively, after taking omeprazole 40 mg daily for 4 days. The confidence intervals indicated that the respective increases were unlikely to exceed 36% and 43%, and it was concluded that these two drugs could be given together without any need for dosage adjustments.4

**Quinolones + Opioids**

Morphine modestly reduces the AUC of trovafloxacin, but this is not considered to be clinically significant. Trovafloxacin did not alter the effects or pharmacokinetics of morphine. Oxycodone does not appear to significantly affect the pharmacokinetics of either levofloxacin or gatifloxacin. It has been suggested that opiates decrease oral ciprofloxacin levels, but good evidence for this appears to be lacking.

Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

In one non-randomised study1 the levels of oral ciprofloxacin were only 1.3 mg/L in the presence of intramuscular papaveretum, compared to 3.22 mg/L in a control group not receiving papaveretum. The authors say that this means the peak ciprofloxacin levels in the papaveretum group were not reached because of the use of a number of gut pathogens. They name *Bacteroides fragilis* (but it should be noted that the levels of the control group also did not reach the MIC of this organism), and *Enterococcus faecalis*, many strains of which are only moderately susceptible to ciprofloxacin. Further, the papaveretum group in this study had only 4 patients, and, as the authors note, the control group was not matched.1 Based on this rather slim evidence, the manufacturers of ciprofloxacin state that the use of ciprofloxacin tablets is not recommended with the use of opiate premedicants due to the risks of inadequate ciprofloxacin levels.2,3 This advice is also given by the manufacturers of *morphine* sulfate,4 and was added at the request of the UK Medicines and Healthcare Regulatory Agency.5

(b) Gatifloxacin

In 12 healthy subjects, the pharmacokinetics of gatifloxacin 400 mg were not significantly altered by oxycodone 5 mg every 4 hours.6

(c) Levofloxacin

In 8 healthy subjects, the pharmacokinetics of oral levofloxacin 500 mg were not significantly altered by oxycodone 5 mg every 4 hours.7

(d) Trovafloxacin

An intravenous infusion of morphine 150 micrograms/kg given with oral trovafloxacin 200 mg to 18 healthy subjects caused a 36% reduction in the trovafloxacin AUC and a 46% reduction in the maximum serum levels. These levels were considered sufficient for prophylaxis of infection, and remained above the MICs of the most likely organisms to cause post-surgical infections. The bioavailability and effects of morphine were not significantly changed by trovafloxacin.8

4. Allen A, Youden M, Lewis A. Effect of omeprazole on the pharmacokinetics of oral gimi-

**Quinolones + Omeprazole**

Omeprazole has no clinically important effect on the pharmacokinetics of ciprofloxacin, gemifloxacin, lomefloxacin, ofloxacin or trovafloxacin.
There appear to be few documented cases of clinically relevant interactions between the quinolones and other antibiotics. However, note that clindamycin may antagonise the effects of ciprofloxacin on *S. aureus*. Further, in vitro studies have demonstrated antagonistic antibacterial effects when nitrofurantoin and nalidixic acid are used together, and other quinolones are also said to antagonise the effects of nitrofurantoin.

**Clinical evidence, mechanism, importance and management**

(a) Aminoglycosides

A study found that a single 100-mg intravenous dose of tobramycin had no effect on the pharmacokinetics of pefloxacin, and pefloxacin did not affect the pharmacokinetics of tobramycin. Similarly no pharmacokinetic interaction was found between pefloxacin and amikacin.

(b) Cephalosporins

A study found that a single 2-g intravenous dose of ceftazidime had no effect on the pharmacokinetics of pefloxacin, and pefloxacin did not affect the pharmacokinetics of ceftazidime.

In a study of 11 healthy subjects, the pharmacokinetics of cefotaxime and ofloxacin were similar, whether given alone or in combination, and the antimicrobial effect of the combination was additive for *S. aureus, S. pneumoniae, E. cloacae* and *K. pneumoniae*, but not for *P. aeruginosa*.

(c) Clindamycin

One study found that the pharmacokinetics of intravenous ciprofloxacin 200 mg were not affected by intravenous clindamycin 600 mg and there is evidence that combined use may possibly enhance the antibacterial activity, particularly against *S. aureus* and *S. pneumoniae*. However, another study found that the serum bactericidal activity of ciprofloxacin against *S. aureus* was completely antagonised by clindamycin, if the strains were susceptible to the latter.

(d) Macrolides

A study designed to assess the potential interaction between trovafloxacin and azithromycin found no significant alteration in the pharmacokinetics of either drug.

(e) Metronidazole

A study found that a single 400-mg oral dose of metronidazole had no effect on the pharmacokinetics of pefloxacin, and similarly pefloxacin did not affect the pharmacokinetics of metronidazole. Another study investigating the use of metronidazole 500 mg intravenously and metronidazole 200 mg intravenously, and metronidazole with ciprofloxacin orally.

A further study, investigating the use of metronidazole 500 mg intravenously and ciprofloxacin 200 mg intravenously, also did not find any significant pharmacokinetic changes, although metronidazole reduced the ciprofloxacin volume of distribution by 20%. This is not expected to be clinically significant.

(f) Nitrofurantoin

The antibacterial activity of *nalidixic acid* can be attenuated by sub-inhibitory concentrations of nitrofurantoin. In 44 out of 53 strains of *Escherichia coli*, *Salmonella* and *Proteus*, antagonism was shown. Another study confirmed these findings. Whether this similarly occurs if both antibacterials are given to patients is uncertain, but the advice that concurrent use should be avoided when treating urinary tract infections seems sound. Active division of bacteria is required for the bactericidal activity of quinolones such as nalidixic acid, and the presence of a bacteriostatic drug such as nitrofurantoin may inhibit its action. Other quinolone antibacterials (not named) and nitrofurantoin have been found to be antagonistic in vitro and although the clinical significance of this is unknown.

A single-dose study in 6 healthy subjects found that intravenous azlocillin 60 mg/kg reduced the clearance of intravenous ciprofloxacin 4 mg/kg by 35%. The pharmacokinetics of azlocillin were not affected.

Another study found that when a single 4-g intravenous dose of piperacillin was given with pefloxacin 400 mg the pharmacokinetics of both drugs were unchanged.

The absorption of ofloxacin 400 mg was not altered by amoxicillin 3 g in 6 healthy subjects.

In another study in 12 healthy subjects, the serum bacterial activity of ciprofloxacin plus piperacillin against a variety of organisms was found to be additive, rather than antagonistic or synergistic despite the fact that the clearance of ciprofloxacin was reduced by 24%.

A single-dose study in 5 healthy subjects found that ciprofloxacin 500 mg decreased the peak serum levels of rifampicin 600 mg by 12%, and prolonged its half-life from 3.5 to 3.8 hours. In a further study, ciprofloxacin did not affect the percentage of rifampicin recovered in the urine, but it did increase its initial rate of excretion.

A single-dose study in 8 healthy subjects found that rifampicin 900 mg daily for 10 days decreased the half-life and AUC(0-12) of pefloxacin 400 mg twice daily by about 30%, due to a 35% increase in total plasma clearance. Despite these changes the serum pefloxacin levels still remained well above the minimal inhibitory concentrations (0.5 mg/L) for 90% of strains of methicillin-sensitive *S. aureus* and *S. epidermidis*. A single-dose study in 5 healthy subjects found that pefloxacin 500 mg increased the AUC of a single 600-mg dose of rifampicin by about twofold. In further study the urinary recovery of rifampicin was increased from 15.6% of the dose to 20.1% by pefloxacin.

Another study in 13 healthy subjects found that rifampicin 600 mg daily for a week increased the clearance of ofloxacin 400 mg daily by 15%. However, the ofloxacin levels remained above the MIC(90) of methicillin-sensitive strains of *S. aureus* and *S. epidermidis* for at least 24 hours. No special precautions would seem necessary if rifampicin is given with any of these quinolones.

Quinolones + Pirenzepine

Four doses of pirenzepine 50 mg delayed the absorption of ciprofloxacin and ofloxacin in 10 healthy subjects, but their bioavailabilities remained unchanged.1 The delayed absorption is unlikely to be of clinical significance.

Quinolones + Probenecid

Probenecid increases the serum levels and/or decreases the urinary excretion of cinoxacin, ciprofloxacin, clinafloxacin, enoxacin, fleroxacin, levofloxaacin, nalidixic acid and norfloxacin. The clinical importance of these changes is uncertain, but it seems likely they will only be important in the presence of other drugs that also affect renal excretion. Grepafloxacin, moxifloxacin, sparfloxacin, and probably ofloxacin, appear not to interact with probenecid.

Clinical evidence

(a) Cinoxacin
A study in 6 healthy subjects found that probenecid 500 mg three times daily roughly doubled the serum levels of a 3-hour intravenous infusion of cinoxacin. The renal clearance of cinoxacin was also reduced from 68 to 46% during and for the 4 hours after the infusion.1

(b) Ciprofloxacin
In one study, probenecid 1 g, given 30 minutes before ciprofloxacin 500 mg, was found to reduce the renal clearance of ciprofloxacin by up to 50%. Other pharmacokinetic parameters (maximum serum levels, AUC) were unchanged and no accumulation of ciprofloxacin appeared to occur, probably due to an increase in extra-renal elimination.2

Another study found that the renal clearance of ciprofloxacin was reduced by 64% by probenecid. However, in contrast to the other study cited, the AUC of ciprofloxacin was increased by 74% and the AUC of its 2-aminoethylamino metabolite was increased by 234%. As a consequence, levels of ciprofloxacin in tears, sweat and saliva were also increased, but probenecid had no direct effect on ciprofloxacin distribution into these fluids.3

(c) Clinafloxacin
Probenecid 1 g, given 1 hour before a single 400-mg dose of clinafloxacin, reduced the total and renal clearance of clinafloxacin by 24% and 36%, respectively, raised the AUC by 32% and increased the elimination half-life from 6.3 to 7 hours.4

(d) Enoxacin
In one subject, the renal clearance of enoxacin 600 mg was approximately halved, and the half-life increased from 3.5 to 4.5 hours by a single 2.5-g dose of probenecid.5

(e) Fleroxacin
A study in 6 healthy subjects given a single 200-mg dose of fleroxacin, followed by 500 mg of probenecid AUC was increased by 37%, and the fleroxacin urinary excretion was decreased by 22%.6 Another study found that probenecid increased the AUC of fleroxacin 400 mg by 26% (not statistically significant), and had no effect on fleroxacin urinary excretion.7

(f) Grepafloxacin
A study in 32 healthy subjects found that probenecid had no effect on the pharmacokinetics of a single 200-mg dose of grepafloxacin.8 In another 6 healthy subjects probenecid similarly had no significant effect on grepafloxacin pharmacokinetics.9

(g) Levofloxaacin
A study in 12 healthy subjects found that although probenecid reduced the renal clearance of a single 500-mg oral dose of levofloxaacin by about one-third and increased its AUC and half-life by similar amounts, the 72-hour urinary levofloxaacin excretion was unaltered.10

(h) Moxifloxaacin
A study in 12 healthy subjects found that probenecid had no clinically significant effects on the pharmacokinetics of a single 400-mg dose of moxifloxaacin.11

(i) Nalidixic acid
Two volunteers, acting as their own controls, took nalidixic acid 500 mg with and without probenecid 500 mg. The peak serum levels of nalidixic acid were unaffected at 2 hours, but at 8 hours the levels were increased threefold by the probenecid.12

Another study in 5 women with urinary tract infections treated with nalidixic acid showed that probenecid increased the maximum serum nalidixic acid levels and AUC by 43% and 74%, respectively.13

(j) Norfloxacin
The mean 12-hour urinary recovery of norfloxacin 200 mg was reduced by about half in 5 subjects when they were given probenecid 1 g. Norfloxacin serum concentrations were unaffected.14

(k) Ofloxacin
A study in 8 healthy subjects found that probenecid 500 mg increased the AUC of a single 200-mg dose of ofloxacin by 16% and decreased the total body clearance by 14%. Other pharmacokinetic parameters were not significantly affected.15

(l) Sparfloxacin
Probenecid 1.5 g did not significantly affect the clearance, the AUC or the half-life of sparfloxacin 200 mg in 6 healthy subjects.16

Mechanism
The likely explanation for this interaction is that probenecid successfully competes with some quinolones for tubular excretion, so that their renal elimination is reduced. Some quinolones are more dependent on glomerular filtration (e.g. grepafloxacin) than tubular excretion for elimination, and thus are unaffected by competition for tubular excretion.1

Importance and management
Established interactions, but their clinical importance seems not to have been assessed. There appears to be no reason for avoiding concurrent use. The increased levels and decreased renal excretion of clinafloxacin caused by probenecid are not considered large enough to warrant dosage adjustment,8 and most of the changes seen with the other quinolones were of a similar magnitude. However, caution has been advised in the presence of other drugs that may also compete for renal excretion (such as some penicillins or cephalosporins).3,4 Grepafloxacin, moxifloxacin, sparfloxaacin, and probably ofloxacin, appear not to interact.
In a study in 8 healthy subjects, sucralfate 1 g four times daily reduced the AUC and maximum serum concentration of cilofloxacin 500 mg by 88% and 90%, respectively. A patient given sucralfate 1 g four times daily had serum cilofloxacin levels which were 85 to 90% lower than 5 other patients who were not taking sucralfate. A single dose study found a 96% reduction in the AUC of cilofloxacin following a 2-g dose of sucralfate. A study in 12 healthy subjects found that a 1-g dose of sucralfate given 6 and 2 hours before a single 750-mg dose of cilofloxacin, reduced the cilofloxacin AUC by about 30%. Three of the subjects showed little or no changes in AUC but a decrease of more than 50% was seen in 4 others. A related study in 12 healthy subjects found that the bioavailability of cilofloxacin 750 mg was reduced by 7%, 20%, and 95%, respectively, when sucralfate was given 6 hours before, 2 hours before, or at the same time as, the cilofloxacin. Oral sucralfate does not alter the effects of cilofloxacin on aerobic bacteria in the gut.

In 8 healthy subjects, the bioavailability of enoxacin 400 mg was reduced by 54% and 88%, respectively, when sucralfate 1 g was given 2 hours before or with the enoxacin. When sucralfate was given 2 hours after the enoxacin, the bioavailability was not affected.

The bioavailability of fleroxacin 400 mg was reduced by 24% in 20 healthy subjects taking sucralfate 1 g every 6 hours.

In a study in 27 healthy subjects, gemifloxacin 320 mg was given either 3 hours before or 2 hours after sucralfate 2 g. The pharmacokinetics of gemifloxacin were not significantly altered when sucralfate was given after the gemifloxacin, probably due to its rapid absorption. However, when sucralfate was given 3 hours before gemifloxacin, the AUC and maximum plasma levels were decreased by 53% and 69%, respectively.

The pharmacokinetics of levofloxacin are unaffected by sucralfate taken 2 hours after the quinolone.
Clinical evidence, mechanism, importance and management

In a crossover study in 15 healthy subjects the AUC of ciprofloxacin was reduced by 39% and the relative oral bioavailability was reduced by 48% when a single 750-mg dose of ciprofloxacin was taken with sevelamer 2.8 g. The reduction was variable. The mechanism of the interaction is unknown. Based on the results of this study, sevelamer should not be given at the same time as ciprofloxacin because the efficacy of ciprofloxacin might be reduced in some patients. Further study is needed to establish whether or not the interaction could be avoided by separation of the doses.

Quinolones; Ciprofloxacin + Ursodeoxycholic acid (Ursodiol)

An isolated report describes a reduction in serum ciprofloxacin levels in a patient taking ursodeoxycholic acid.

Clinical evidence, mechanism, importance and management

A man with metastatic colon cancer had unusually low serum levels of ciprofloxacin following oral dosing; his only other medication was ursodeoxycholic acid 300 mg twice daily for gallstones. Despite the low antibacterial serum levels the bacteremia cleared. Several months later when he was readmitted to hospital, both drugs were again given, initially staggered, and then later together. When taken together the AUC of the ciprofloxacin was reduced by 50% by ursodeoxycholic acid. The reason for this interaction is not understood. This seems to be the first and only report of an interaction between a quinolone and ursodeoxycholic acid and its importance is uncertain. More study is needed to establish this interaction, its importance, and its mechanism.

Quinolones; Levofloxacin + Antiretrovirals

There appears to be no clinically important pharmacokinetic interaction between levofloxacin and efavirenz or nelfinavir.

Clinical evidence, mechanism, importance and management

A study in HIV-positive patients who were taking antiretroviral therapy consisting of zidovudine and lamivudine with either efavirenz or nelfinavir, found that levofloxacin 500 mg daily for 4 days did not affect the steady-state pharmacokinetics of either efavirenz 600 mg daily or nelfinavir 750 mg three times daily. The pharmacokinetics of levofloxacin during concurrent treatment with efavirenz or nelfinavir were unaffected, except for the time to maximum levels, which was increased from 0.9 to 1.7 hours in control subjects, to 3.3 hours with efavirenz. This may have occurred as a result of delayed gastric emptying caused by the efavirenz. A clinically important interaction between levofloxacin and either efavirenz or nelfinavir is unlikely.

Quinolones; Lomefloxacin + Furosemide

Furosemide causes a small, almost certainly unimportant, rise in the serum levels of lomefloxacin. The pharmacokinetics and diuretic effects of the furosemide are not changed.

Clinical evidence, mechanism, importance and management

A study in 8 healthy subjects found that when a single 200-mg dose of lomefloxacin was taken with furosemide 40 mg, the AUC of lomefloxacin was increased by 12%. The maximum serum levels and the half-life were

Quinolones; Ciprofloxacin + Pancreatic enzymes

The pharmacokinetics of ciprofloxacin are not affected by pancreatic enzyme supplements.

Clinical evidence, mechanism, importance and management

Six patients with cystic fibrosis, chronically infected with Ps. aeruginosa and treated with a range of drugs including cefazidime, tobramycin, ticarcillin and salbutamol, demonstrated no significant changes in the pharmacokinetics of a single 250-mg dose of ciprofloxacin when it was given with standard doses of pancreatic enzymes (seven Pancrease capsules).

Another study in 12 patients with cystic fibrosis found that administration of pancreatic enzyme supplements 30 minutes before a single 750-mg dose of ciprofloxacin did not alter the pharmacokinetics of ciprofloxacin.

No special precautions would seem to be necessary during concurrent use.

Quinolones; Ciprofloxacin + Phenazopyridine

Phenazopyridine appears to increase the bioavailability of ciprofloxacin.

Clinical evidence, mechanism, importance and management

A study in 23 healthy subjects given a single 500-mg dose of ciprofloxacin either alone or with phenazopyridine 200 mg found that phenazopyridine increased the AUC and mean residence time of ciprofloxacin by about 30%. The time to achieve maximum plasma levels was increased from 1 to 1.5 hours. If anything, this seems likely to be a beneficial, rather than adverse, interaction.

Quinolones; Ciprofloxacin + Sevelamer

Sevelamer reduced the bioavailability of ciprofloxacin by 48% in one study.
also increased, but not to a statistically significant extent. The suggested reason for the interaction is that there is some competition between the two drugs for excretion by the kidney tubules. No significant changes were seen in the pharmacokinetics of the furosemide nor in its diuretic effects. The small rise in the serum levels of lomefloxacin is almost certainly too small to be important and there would seem to be no reason for avoiding concurrent use. Information about other quinolone antibacterials appears to be lacking.

Quinolones; Moxifloxacin + Itraconazole

A study in healthy subjects found that itraconazole 200 mg daily for 9 days did not affect the pharmacokinetics of a single 200-mg dose of moxifloxacin given on day 7. No clinically relevant changes were found in the pharmacokinetics of itraconazole. No special precautions would seem to be necessary during concurrent use.

Quinolones; Ofloxacin + Cetramate

A single-dose study found that cetraxate (dose not stated) did not affect the pharmacokinetics of a single 200-mg dose of ofloxacin. No special precautions would seem to be necessary on concurrent use.

Quinupristin/Dalfopristin + Miscellaneous

In vitro studies have found that quinupristin/dalfopristin inhibits the CYP3A4-mediated metabolism of docetaxel, tamoxifen and terfenadine and is predicted to inhibit the metabolism of other drugs by this enzyme system.

Clinical evidence, mechanism, importance and management

In vitro studies found quinupristin/dalfopristin inhibited the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of docetaxel, tamoxifen, and terfenadine. Quinupristin/dalfopristin is predicted to raise the levels of other drugs including antiarrhythmics (disopyramide, lidocaine, quinidine), antiretrovirals (such as delavirdine, indinavir, nevirapine, ritonavir), astemizole, carbamazepine, cисapride, methylprednisolone, paclitaxel, statins (but see ‘Lipid regulating drugs’, (p.1086)), and vinca alkaloids. More study is needed.

Rifampicin (Rifampin) + Antacids

The absorption of rifampicin can be reduced up to about one-third by antacids, but the clinical importance of this is uncertain.

Clinical evidence

When 5 healthy subjects took a single 600-mg dose of rifampicin with various antacids the absorption of rifampicin was reduced. The antacids caused a fall in the urinary excretion of rifampicin as follows: 15 or 30 mL of aluminium hydroxide gel 29 to 31%; 2 or 4 g of magnesium trisilicate 31 to 36%; and 2 g of sodium bicarbonate 21%. Three groups of 15 patients with tuberculosis were given a single oral dose of rifampicin 10 to 12 mg/kg, isoniazid 300 mg and ethambutol 20 mg/kg either alone or with about 20 mL of antacid. A ‘significant number’ of patients had peak rifampicin concentrations below 6.5 micrograms/mL (serum level quoted as necessary to achieve adequate lung concentrations) in the group receiving Aludrox (aluminium hydroxide), but no significant effect was noted in the group receiving Gelusil (aluminium hydroxide plus magnesium trisilicate). However, in a further study in 14 healthy subjects, 30 mL of Mylanta (aluminium/magnesium hydroxide) given 9 hours before, with and after rifampicin had no effect on rifampicin pharmacokinetics.

Mechanism

It has been suggested that the rise in stomach pH caused by these antacids reduces the dissolution of the rifampicin and thereby inhibits its absorption. In addition, aluminium ions may form less soluble chelates with rifampicin, and magnesium trisilicate can adsorb rifampicin, both of which would also be expected to reduce bioavailability.

Importance and management

Direct information seems to be limited to these reports. The effects of 20 to 35% reductions in rifampicin absorption do not appear to have been assessed, but if antacids are given it would be prudent to be alert for any evidence that treatment is less effective than expected. The US manufacturers of rifampicin advise giving rifampicin 1 hour before antacids.

Rifampicin (Rifampin) + Clofazimine

There is no pharmacokinetic interaction between rifampicin and clofazimine.

Clinical evidence, mechanism, importance and management

Clofazimine 100 mg daily, given to 15 patients with leprosy taking rifampicin 600 mg daily and dapsone 100 mg daily, had no effect on the pharmacokinetics of rifampicin.1 A single-dose study similarly found that the bioavailability of clofazimine remained unaltered when rifampicin was given, although a reduction in the rate of absorption was seen.2 No special precautions would seem to be necessary on concurrent use.

Rifampicin (Rifampin) + Food

Food delays and reduces the absorption of rifampicin from the gut.

Clinical evidence

The absorption of a single 10-mg/kg dose of rifampicin was reduced when it was given to 6 healthy subjects with a standard Indian breakfast (125 g wheat, 10 g visible fat, 350 g vegetables). The AUC after 8 hours was reduced by 26% and the peak plasma levels were prolonged (from 11.84 micrograms/mL at 2 hours to 8.35 micrograms/mL at 4 hours) and reduced by about 30%.1 In another study, a high-fat breakfast reduced the maximum serum level of rifampicin 600 mg by 36% and delayed the absorption, but the AUC was not significantly altered.2

Mechanism

Not understood.

Importance and management

An established interaction. Rifampicin should be taken on an empty stomach (at least 30 minutes before a meal, or 2 hours after a meal) to ensure rapid and complete absorption.

Rifampicin (Rifampin) + Probenecid antagonists

No clinically significant interaction appears to occur between rifampicin and cimetidine or ranitidine.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

In a study, 12 patients given daily doses of rifampicin 8 mg/kg, isoniazid 8 mg/kg and ethambutol 25 mg/kg, and 13 untreated control subjects were given intravenous cimetidine 300 mg. In the patients receiving antimycobacterials, the non-renal clearance of cimetidine was increased by 52% but the total clearance and volume of distribution were unchanged. The reduction in renal clearance in the patients may have been associated with age-related impairment of renal function, but it was suggested that the increased non-renal clearance may have been due to enzyme induction of cimetidine metabolism.1 As total clearance was unchanged this interaction seems unlikely to be clinically significant.

(b) Ranitidine

In a controlled study, 112 patients with pulmonary tuberculosis were treated in 2 groups, one with a daily regimen of rifampicin 10 mg/kg, isoniazid 300 mg and ethambutol 20 mg/kg and ranitidine 150 mg twice daily, and the other with the same antimycobacterials but without ranitidine. The pharmacokinetics of rifampicin (as measured by the total and unchanged urinary excretion) were not affected by ranitidine. No changes occurred in the incidence of adverse hepatic reactions, while gastrointestinal reactions were reduced.2 There would seem to be no reason for avoiding the use of ranitidine, or any other H₂-receptor antagonists, in patients taking rifampicin.

Rifampicin (Rifampin) + Phenobarbital

Phenobarbital possibly modestly increases the clearance of rifampicin. The effect of rifampicin on phenobarbital levels is unknown, but note that rifampicin markedly increased the clearance of another barbiturate hexobarbital, used as a marker of drug metabolism.

Clinical evidence

In one study, the serum levels of rifampicin were reduced by 20 to 40% in 12 of 15 patients taking phenobarbital 100 mg daily.1 In another study, although phenobarbital 100 mg daily for 7 days reduced the mean half-life of a single 600-mg dose of rifampicin by 15%, this was not statistically significant. However, in a further 5 patients with cirrhosis of the liver, phenobarbital did reduce the half-life of rifampicin by a mean of 2.2 hours.2 The effect of rifampicin on phenobarbital levels does not appear to have been studied, but rifampicin markedly increased the clearance of another barbiturate hexobarbital, used as a marker of drug metabolism.3,6

Mechanism

Both rifampicin and phenobarbital are potent liver enzyme inducers. The outcome of their effects when combined is not clear.

Importance and management

The documentation for this interaction is very limited, and the outcome of concurrent use is unclear. Concurrent use need not be avoided, but be alert for a reduced response to both drugs.

Rifampicin (Rifampin) + Probenecid

Probenecid increased rifampicin levels in one study, but not in another.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects given probenecid 2 g before and after a single 300-mg dose of rifampicin found that probenecid increased the mean peak serum rifampicin levels by 86%. At 4, 6, and 9 hours after the dose the increases were 118%, 90%, and 102%, respectively.1 However, subsequent studies in patients taking either rifampicin 600 mg daily, or rifampicin 300 mg daily 30 minutes after a 2-g dose of probenecid found that the probenecid group achieved serum rifampicin levels that were only about half those achieved by those taking rifampicin 600 mg alone, suggesting that no interaction occurred.2 The reasons for these discordant results are not understood, although it has been suggested that erratic
rifampicin absorption may have played a part. The interaction is not proven, but it seems possible that some patients will experience a rise in rifampicin levels. Consider this interaction as a possible cause if rifampicin adverse effects are troublesome.

**Sodium fusidate + Colestyramine**

*In vitro* studies have shown that colestyramine can bind with sodium fusidate in the gut, thereby reducing its activity, and *in vivo* animal studies have shown peak fusidate levels are decreased by 33 to 77% by colestyramine, but whether this also occurs clinically has not been confirmed. It is generally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine.

---

**Sulfonamides; Sulfafurazole (Sulfisoxazole) + Laxatives**

Sodium sulfate and castor oil used as laxatives can cause a modest but probably clinically unimportant reduction in sulfafurazole absorption.

**Clinical evidence, mechanism, importance and management**

In an experimental study of the possible effects of laxatives on the absorption of sulfafurazole, healthy subjects were given 10 to 20 g of oral sodium sulfate or 20 g of castor oil (doses sufficient to provoke diarrhoea). Absorption, measured by the amount of sulfafurazole excreted in the urine, was decreased by 50% with castor oil, and by 33% with sodium sulfate at 4 hours. However, serum levels of the drugs were relatively unchanged. The overall picture was that while these laxatives can alter the pattern of absorption, they do not seriously impair the total amount of drug absorbed.

---

**Tetracyclines + Antacids**

The serum levels and therefore the therapeutic effectiveness of the tetracyclines can be markedly reduced or even abolished by antacids containing aluminium, bismuth, calcium or magnesium. Other antacids, such as sodium bicarbonate, may also reduce the bioavailability of some tetracyclines. Even intravenous doxycycline levels can be reduced by antacids.

**Clinical evidence**

(a) Aluminium-containing antacids

A study in 5 patients and 6 healthy subjects found that within 48 hours of starting to take about 10 mL of aluminium hydroxide gel (*Amphogel*) every 6 hours with *chlortetracycline* 500 mg the serum levels of the antibiotic were reduced by 80 to 90%. One patient had a recurrence of her urinary tract infection, which only subsided when the antacid was withdrawn, and one patient maintained *chlortetracycline* levels despite antacid treatment.

Further studies have shown similar interactions with other tetracyclines:

- 30 mL of aluminium hydroxide reduced *oxytetracycline* serum levels by more than 50%.
- 20 mL of aluminium hydroxide caused a 75% reduction in *demeclocycline* serum levels.
- 15 mL of aluminium hydroxide caused a 100% reduction in serum *doxycycline* levels.
- 30 mL of aluminium/magnesium hydroxide (*Maalox*) caused a 90% reduction in *tetracycline* serum levels.

Intravenous doxycycline also appears to be affected. The mean serum levels of an intravenous dose of *doxycycline* were found to be reduced by
36% when 30 mL of aluminum hydroxide was taken four times daily, for 2 days before and after the antibacterial. 

(b) Bismuth-containing antacids

Bismuth subsalicylate reduces the absorption of tetracycline by 34% and reduces the maximum serum levels of doxycycline by 50%. It has been suggested that the excipient Feogum (magnesium aluminum silicate) in some bismuth subsalicylate formulations enhances this effect. Bismuth carbonate similarly interacts with the tetracyclines in vitro. 

(c) Calcium-containing antacids

There seem to be no direct clinical studies with calcium-containing antacids, but a clinically important interaction seems almost a certainty, based on in vitro studies with calcium carbonate, and calcium in milk, (see ‘Tetracyclines + Food or Drinks’, p.347), dicalcium phosphate, and calcium as an excipient in tetracycline capsules. 

(d) Magnesium-containing antacids

Magnesium sulfate certainly interacts with tetracycline, but in the only clinical study available the amount of magnesium was much higher than would normally be found in the usual dose of antacid.

(e) Sodium-containing antacids

Sodium bicarbonate 2 g reduced the absorption of a 250-mg capsule of tetracycline by 50% in 8 subjects. If however tetracycline was dissolved before administration, the absorption was unaffected by the sodium bicarbonate. Another study stated that sodium bicarbonate 2 g had an insignificant effect on tetracycline absorption. 

Mechanism

The tetracyclines bind with aluminum, bismuth, calcium, magnesium and other metallic ions to form compounds (chelates), which are much less soluble and therefore much less readily absorbed by the gut. Because doxycycline undergoes enterohepatic recirculation, even intravenous doxycycline is affected, although less so than oral. It has also been suggested that the antacids reduce gastric acidity and thereby decrease the absorption of tetracyclines, but studies demonstrating the lack of a significant interaction with H2-receptor antagonists, (p.348) suggest that this is not the case. The reduced absorption with bismuth compounds may be because they adsorb tetracyclines. The interaction of some tetracycline preparations with sodium bicarbonate is unexplained.

Importance and management

Extremely well-documented, and well-established interactions. Their clinical importance depends on how much the serum tetracycline levels are lowered, but with normal antacid dosages the reductions cited above (50 to 100%) are large enough to mean that many organisms will not be exposed to minimum inhibitory concentrations (MIC) of antibiotic. As a general rule none of the aluminium, bismuth, calcium or magnesium-containing antacids should be given at the same time as the tetracycline antibacterials. If they must be used, separate the dosages by 2 to 3 hours and it seems probable that they increase the metabolism of the doxycycline. 

Patients should be warned about taking any antacids and indigestion preparations. Instead of using antacids to minimise the gastric irritant effects of the tetracyclines it is usually recommended that tetracyclines are taken after food, however it is not entirely clear how much this affects their absorption (see ‘Tetracyclines + Food or Drinks’, p.347). H2-receptor antagonists may be suitable non-interacting alternatives to antacids in some situations, see ‘Tetracyclines + H2-receptor antagonists’, p.348.

Tetracyclines + Antiepileptics

The serum levels of doxycycline are reduced and may fall below the accepted minimum inhibitory concentration in patients receiving long-term treatment with barbiturates, phenytoin or carbamazepine. Other tetracyclines do not appear to be affected.

Clinical evidence

A study in 14 patients taking phenytoin 200 to 500 mg daily, carbamazepine 300 mg to 1 g daily, or both, found that the half-life of doxycycline was approximately halved from 15.1 hours in patients not taking antiepileptics, to 7.2 hours in patients taking phenytoin, 8.4 hours in patients taking carbamazepine, and 7.4 hours in patients taking both drugs. Similar results were found in 16 other patients taking various combinations of phenytoin, carbamazepine, primidone or phenobarbital. The serum doxycycline levels of almost all of them fell below 0.5 micrograms/mL during the 12 to 24 hour period following their last dose of doxycycline 100 mg. Tetracycline, methacycline, oxytetracycline, demeclocycline and chlorotetacycline levels were not significantly affected by these antiepileptics. Other studies confirm this interaction between some barbiturates (amobarbital, pentobarbital, phenobarbital) and doxycycline.

Mechanism

Uncertain. These antiepileptics and barbiturates are known enzyme inducers and it seems probable that they increase the metabolism of the doxy-cycline by the liver, thereby increasing its clearance from the body.

Importance and management

The interactions between doxycycline and the enzyme-inducing antiepileptics are established, but the clinical significance of the reduction in levels does not seem to have been studied. Serum doxycycline levels below 0.5 micrograms/mL are less than the minimum inhibitory concentration (MIC) quoted by the authors, however, so that it seems likely that the antibacterial will be less effective. To accommodate this potential problem it has been suggested that the doxycycline dosage could be doubled. Alternatively any of the tetracyclines that are reported not to be affected by these antiepileptics (tetracycline, methacycline, oxytetracycline, demeclocycline and chlorotetacycline) may provide a suitable alternative.

Colestipol can reduce the absorption of tetracycline by about a half. Information about other tetracyclines is lacking but it seems likely that they will interact similarly.

Clinical evidence
Colestipol 30 g taken either in 180 mL of water or orange juice reduced the absorption of a single 500-mg dose of oral tetracycline in 9 healthy subjects by 54 to 56%, as measured by recovery in the urine.1

Mechanism
Colestipol binds to bile acids in the gut and can also bind with some drugs, thereby reducing their availability for absorption. An in vitro study found a 30% binding with tetracycline.2 The presence of citrate ions in the orange juice, which can also bind to colestipol, appears not to have a marked effect on the binding of the tetracycline.

Importance and management
An established interaction. Direct information seems to be limited to the report cited, but it is consistent with the way colestipol interacts with other drugs. In practice up to 30 g of colestipol is given daily in single or two divided doses, and tetracycline 250 to 500 mg is given every 6 hours. As other drugs need to be given 1 hour before or 4 hours after colestipol it may be difficult to avoid some mixing in the gut. It seems very probable that a clinically important interaction will occur, but by how much the efficacy of tetracycline is affected seems not to have been determined. Tell patients to separate the dosages as much as possible. Monitor the outcome well. Information about other tetracyclines is lacking but it also seems likely that they will interact similarly, but those that can be given less often may prove easier to administer, although note that doxycycline undergoes enterohepatic recirculation and therefore separating dosages may not be completely effective.

Tetracyclines + Diuretics

It has been recommended by some that the concurrent use of tetracyclines and diuretics should be avoided because of their association with rises in blood urea nitrogen levels.

Clinical evidence, mechanism, importance and management
A retrospective study of patient records as part of the Boston Collaborative Drug Surveillance Program showed that an association existed between tetracycline use with diuretics (not named) and rises in blood urea nitrogen (BUN) levels.1 Both diuretics and tetracyclines are known to cause rises in BUN levels.2 It was suggested that tetracyclines should be avoided in patients taking diuretics when alternative antibacterials could be substituted.1 However, the results of this study have been much criticised as the authors could not exclude physician bias,1,2 they did not define what was meant by ‘clinically significant rise in BUN’,2 they did not state whether or not this rise affected patient outcomes,2 they did not measure creatinine levels2 and they did not specify which diuretics were involved.2 The patients most affected also had the highest levels of BUN before starting tetra-

cyclines. Tetracyclines alone are known to cause rises in BUN, especially where a degree of renal impairment exists, although it has been suggested that doxycycline is less prone to this effect.3 It would seem that tetracyclines and diuretics may be used together safely, although it would be wise to give thought to the patient’s renal function.

2. Tannenberg AM. Tetracyclines and rises in urea nitrogen. JAMA (1972) 221, 713.

The calcium in food can complex with tetracycline to reduce its absorption. This is particularly notable with dairy products, which can reduce the absorption of the tetracyclines by up to 80%, thereby reducing or even abolishing their therapeutic effects. Doxycycline and minocycline are less affected by dairy products (25 to 30% reduction). Orange juice and coffee do not interact with tetracycline.

Clinical evidence, mechanism, importance and management
(a) Dairy products
1. Demeclocycline. The serum levels of a 300-mg dose of demeclocycline were 70 to 80% lower in 4 subjects given dairy products, when compared with those who took it with a meal containing no dairy products. The dairy products used were either 8 oz (about 250 mL) of fresh pasteurized milk, 8 oz of buttermilk or 4 oz of cottage cheese.1
2. Doxycycline. The plasma doxycycline levels were reduced by 20%, from 1.79 to 1.45 micrograms/mL, 2 hours after a single 100-mg oral dose was taken with 240 mL of milk.2 Another study in healthy subjects found a 30% reduction in the absorption, and a 24% reduction in the peak serum levels of doxycycline 200 mg when it was taken with 300 mL of fresh milk.3 However, two other studies suggest that the absorption of 200 mg of doxycycline is unaffected by milk,4,5 although in one the half-life was almost halved and the clearance increased.6
3. Methacycline. In one study 300 mL of milk reduced the absorption of methacycline 300 mg by about 63%.4
4. Minocycline. About 180 mL (6 oz) of homogenised milk reduced the absorption of minocycline 100 mg by 27% in one study.6
5. Oxytetracycline. In one study 300 mL of milk reduced the absorption of oxytetracycline 500 mg by about 64%.6
6. Tetracycline. About 180 mL (6 oz) of homogenised milk reduced the absorption of tetracycline hydrochloride 250 mg by 65% in one study.6 In another study the absorption of tetracycline 500 mg was reduced by about 50% by 300 mL of milk.4
(b) Other calcium-containing foods or drinks
A study in 9 healthy subjects found that 200 mL of orange juice or coffee (milk content, if any, unstated) did not significantly affect the bioavailability of a single 250-mg dose of tetracycline. This is despite the fact that orange juice contains 35 to 70 mg calcium per 100 mL.7 Tetracycline 250 mg was given to 9 healthy subjects with 200 mL of water on an empty stomach. The tetracycline bioavailability was compared with its administration after a standard meal (two slices of bread, ham, tomato, and water, containing 145 mg calcium) and a Mexican meal (two tortillas, beans, two eggs, tomato and water, containing 235 mg calcium). The cumulative amounts of tetracycline excreted in the urine at 72 hours were about 151 mg (fasting), 90 mg (standard meal) and 68 mg (Mexican meal).8 The absorption of a 300-mg dose of demeclocycline was not affected when it was given with a meal not containing dairy products,1 and doxycycline seems to be minimally affected by food not containing dairy products.6

Mechanism
The tetracyclines have a strong affinity for the calcium ions that are found in abundance in dairy products and some foodstuffs. The tetracycline/calcium chelates formed are much less readily absorbed from the gastrointestinal tract and as a result the serum tetracycline levels achieved are much lower. Some tetracyclines have a lesser tendency to form chelates, which explains why their serum levels are reduced to a smaller extent.9

Orange juice appears not to interact, despite its calcium content, because at the relevant pH values in the gut, the calcium is bound to components within the orange juice (citric, tartaric and ascorbic acids) and is not free to combine with the tetracycline.7

Importance and management
Well documented and very well established interactions of clinical impor-
tance. Reductions in serum tetracycline levels of 50 to 80% caused by calcium-rich foods are sufficiently large to reduce or even abolish their

antibacterial effects. For this reason tetracyclines should not be taken with milk or dairy products such as yoghurt or cheese. Separate the ingestion of these foods and tetracycline as much as possible. In the case of iron, which interacts by the same mechanism, 2 to 3 hours is enough. Doxycycline1,10 and minocycline2 are not affected as much by dairy products (reductions of about 25 to 30%) and in this respect have some advantages over other tetracyclines.

It is usual to recommend that tetracyclines are taken 1 hour before or 2 hours after food (which would be expected to contain at least some calcium), to minimise admixture in the gut and thereby reduce the effects of the interaction. The separation is something of a compromise, because food can help to minimise the gastric irritant effects of the tetracyclines.

Clinical evidence

(a) Effect on tetracyclines

An investigation in 10 healthy subjects given single oral doses of tetracyclines showed that ferrous sulfate 200 mg decreased the serum antibacterial levels as follows: doxycycline 200 mg, 80 to 90%; methacycline 300 mg, 80 to 85%; oxytetracycline 500 mg, 50 to 60% and tetracycline 500 mg, 40 to 50%. Another study in 2 groups of 8 healthy subjects found that ferrous sulfate 300 mg reduced the absorption of tetracycline and minocycline by 81% and 77%, respectively.2

Other studies found that in some instances iron caused the tetracycline serum levels to fall below minimum bacterial inhibitory concentrations.3,4 If the iron was given 3 hours before or 2 hours after most tetracyclines the serum levels were not significantly reduced.3,5 However, even when the iron was given up to 11 hours after doxycycline, serum concentrations were lowered by 20 to 45%.5 In contrast to this, another study found that four doses of ferrous sulfate (each equivalent to 80 mg of elemental iron) starting 11.5 hours after doxycycline did not affect the absorption of a 200-mg dose of doxycycline, and only reduced the AUC of a 100-mg dose of doxycycline by 17%.6

(b) Effect on iron

When ferrous sulfate 250 mg (equivalent to 50 mg of elemental iron) was given with tetracycline 500 mg, the absorption of iron was reduced by up to 78% in healthy subjects, and up to 65% in those with depleted iron stores.7,8

Mechanism

The tetracyclines have a strong affinity for iron and form poorly soluble tetracycline-iron chelates, which are much less readily absorbed by the gut, and as a result the serum tetracycline levels achieved are much lower.9,10 There is also less free iron available for absorption. Separating the administration of the two prevents their admixture.3,4 However, doxycycline undergoes enterohepatic recycling, which could affect any attempt to keep the iron and antibacterial apart, although the significance of the enterohepatic recycling has been said to be minimal.6 Even when given intravenously the half-life of doxycycline is reduced.3 The different extent to which iron compounds interact with the tetracyclines appears to be a reflection of their ability to liberate ferrous and ferric ions, which are free to combine with the tetracycline.11

Importance and management

The interactions between the tetracyclines and iron compounds are well-documented, well-established, and of clinical importance. The 30 to 90% reductions in serum tetracycline levels that are caused by iron are so large that tetracycline levels may fall below the MIC.4 However, the extent of the reductions depends on a number of factors.

- the particular tetracycline used: tetracycline and oxytetracycline in the study cited above were the least affected.
- the time-interval between the administration of the two drugs: giving the iron 3 hours before or 2 to 3 hours after the antibacterial is satisfactory with tetracycline itself, but one study found that even 11 hours was inadequate for doxycycline.
- the particular iron preparation used: with tetracycline the reduction in serum levels with ferrous sulfate was 80 to 90%, with ferrous fumarate, succinate and gluconate, 70 to 80%; with ferrous tartrate, 50%; and with ferrous sodium edetate, 30%. This was with doses containing equivalent amounts of elemental iron.11

The interaction can therefore be accommodated by separating the dosages as much as possible. It would also seem logical to choose one of the iron preparations causing minimal interference, but it seems unlikely that there will be a clinically significant difference between those that are commonly available (i.e. sulfate, fumarate and gluconate).

Only tetracycline, oxytetracycline, methacycline, minocycline and doxycycline have been shown to interact with iron, but it seems reasonable to expect that the other tetracyclines will behave in a similar way.

Tetracyclines + Iron compounds

The absorption of both the tetracyclines and iron compounds is markedly reduced by concurrent use, leading to reduced serum levels of the tetracyclines. Their therapeutic effectiveness may be reduced or even abolished.

Kaolin-pectin reduces the absorption of tetracycline by about 50%.

Clinical evidence, mechanism, importance and management

Healthy subjects were given tetracycline 250 mg as a solution or as a capsule, with and without 30 mL of kaolin-pectin (Kaopectate). The absorption of both formulations was reduced by about 50% by the kaolin-pectin. Even when the kaolin-pectin was given 2 hours before or after the tetracycline, the drug absorption was still reduced by about 20%. The likely reason for this interaction is that tetracycline becomes adsorbed onto the kaolin-pectin so that less is available for absorption.

If these two drugs are given together, consider separating the dosages by at least 2 hours to minimise admixture in the gut. It may even then be necessary to increase the tetracycline dosage. Information about other tetracyclines is lacking, but be aware that they may interact similarly.

Tetracyclines + Kaolin-pectin

Metoclopramide 20 mg was found to double the rate of absorption and slightly reduce the maximum serum levels of a single 500-mg dose of tetracycline in 4 patients. This appears to be of little clinical importance.

Tetracyclines + Metoclopramide

The absorption of oral tetracycline is reduced by the magnesium carbonate excipient in some quinapril formulations.

Clinical evidence

Quinapril, formulated as Accupro also contains magnesium carbonate (250 mg in a 40 mg quinapril capsule, 47 mg in a 5 mg capsule). A pharmacokinetic study in 12 healthy subjects investigating the potential interaction between the magnesium carbonate in these capsules and tetracycline found that single doses of both of these formulations of quinapril markedly reduced the tetracycline absorption. The 5 mg and 40 mg quinapril capsules reduced the tetracycline AUC by 28% and 37%, respectively, and the maximum serum levels were reduced by 25% and 34%, respectively.

Mechanism

The reason for these reductions in tetracycline levels is that the magnesium carbonate and the tetracycline form a less soluble chelate in the gut which is less well absorbed (see ‘Tetracyclines + Antacids’, p.345).

Importance and management

An established interaction but the extent of the reduction is only moderate and its clinical importance is uncertain. However, the authors of the study recommend that the concurrent use of this formulation of quinapril and tetracycline should be avoided. This is repeated by the manufacturers. Other tetracyclines would be expected to behave similarly. One possible way to accommodate this interaction (as with the antacid interaction) is to separate the dosages as much as possible (by about 2 to 3 hours) to minimise admixture in the gut.

Tetracyclines + Quinapril

On theoretical grounds the absorption of tetracycline may possibly be reduced by sucralfate, but clinical confirmation of this appears to be lacking.

Clinical evidence, mechanism, importance and management

The manufacturers of sucralfate, point out that it may reduce the bioavailability of tetracycline, probably because the two become bound together in the gut, thereby reducing absorption. It is suggested that they should be given 2 hours apart to minimise their admixture in the gut. There do not appear to be any clinical reports in the literature confirming this potential interaction so it has yet to be shown to be clinically relevant.

However, the in vitro formation of a tetracycline-sucralfate acid complex has been investigated in animal studies and indicates that the interaction may be clinically useful for Helicobacter pylori eradication because of direct delivery of tetracycline to the gastric mucosa for extended periods of time. The absorption of tetracycline may possibly be reduced by sucralfate, but clinical confirmation of this appears to be lacking.

Tetracyclines + Thiomersal

Patients being treated with tetracyclines who use contact lens solutions containing thiomersal may experience an inflammatory ocular reaction.

Clinical evidence, mechanism, importance and management

The observation that 2 patients had ocular reactions (red eye, irritation, blepharitis) when they used a 0.004% thimersal-containing contact lens solution while taking a tetracycline, prompted further study of this interaction. A questionnaire revealed another 9 similar cases that suddenly began after patients who had used thimersal containing solutions for 6 months without problem started to take a tetracycline. In each case the reaction cleared when the thimersal or the tetracycline was stopped. The same reaction was also clearly demonstrated in rabbits. The reasons are not understood. It would seem prudent to avoid the concurrent use of these compounds.

Tetracyclines + Zinc compounds

The absorption of tetracycline can be reduced by as much as 50% by zinc sulphate. Separating their administration as much as possible minimises the effects of this interaction. Doxycycline interacts minimally with zinc.

Clinical evidence

When tetracycline 500 mg was given to 7 subjects either alone or with zinc sulphate 200 mg (equivalent to 45 mg of elemental zinc) the tetracycline serum concentrations and AUC were reduced by about 30 to 40%.

This study was repeated with doxycycline 200 mg and zinc, but doxycycline absorption was not affected. A reduction in tetracycline absorption of more than 50% has been seen in other studies when zinc was given concurrently.2,3

Tetracycline appears to cause minimal reductions in zinc concentrations.4

Mechanism
Zinc (like iron, calcium, magnesium and aluminium) forms a relatively stable and poorly absorbed chelate with tetracycline in the gut, which results in a reduction in the amount of antibacterial available for absorption.5

Importance and management
An established and moderately well documented interaction of clinical importance. Separate the administration of tetracycline and zinc compounds as much as possible to minimise admixture in the gut. In the case of ‘iron’, (p.348), which interacts by the same mechanism, 2 to 3 hours is usually enough. Alternatively it would seem that doxycycline is less affected, so it may be a useful alternative.6 Other tetracyclines would be expected to interact like tetracycline itself, but this needs confirmation. The small reduction in serum zinc concentrations is likely to be of little practical importance.7

Tetracyclines; Doxycycline + Dimeticon

A study in 8 healthy subjects found that dimeticone 2.25 g did not alter the bioavailability of a single 200-mg dose of doxycycline.1

Tetracyclines; Doxycycline + Rifampicin (Rifampin)

Rifampicin may cause a marked reduction in doxycycline levels, which has led to treatment failures in some cases.

Clinical evidence
Rifampicin 10 mg/kg daily caused a considerable reduction in the serum levels of doxycycline 200 mg daily in 7 patients. The reduction was very marked in 4 patients but not significant in the other 3 patients. The AUC of doxycycline was reduced by 54%, its clearance was approximately doubled, and its half-life was reduced from about 14 hours to 9 hours.2

Five patients with brucellosis taking doxycycline 200 mg daily had a reduction in the doxycycline half-life from 14.52 to 7.99 hours when they took rifampicin 200 mg daily.3 Another study of 20 patients treated for brucellosis found that the mean AUC of doxycycline was nearly 60% lower in the presence of rifampicin as opposed to streptomycin. There were no treatment failures in the patients taking doxycycline and streptomycin, but 2 treatment failures occurred in the 10 patients taking doxycycline and rifampicin.4

A meta-analysis of 6 studies involving 544 patients with brucellosis found a significantly higher numbers of relapses and lower numbers of initial cures if doxycycline was given with rifampicin rather than streptomycin.5

Mechanism
Not established, but it seems almost certain that the rifampicin (a known potent enzyme inducer) increases the metabolism of the doxycycline thereby reducing its levels.

Importance and management
The interaction between doxycycline and rifampicin is established and of clinical importance. Monitor the effects of concurrent use and increase the doxycycline dosage as necessary. No clinically important adverse interaction appears to occur between doxycycline and streptomycin.

Tetracyclines; Minocycline + Ethinylestradiol

There is some evidence that ethinylestradiol may accentuate the facial pigmentation that can be caused by minocycline.

Clinical evidence
Two teenage sisters with severe acne vulgaris, taking minocycline 50 mg four times daily for 14 days then 50 mg twice daily thereafter, developed dark-brown pigmentation in their acne scars when they took Diane (cyproterone acetate and ethinylestradiol) for about 15 months.1 The type of pigmentation was not identified because they both declined to have a biopsy, but in other cases it has been found to consist of haemosiderin, iron, melanin and a metabolic degradation product of minocycline.2 Other reports describe facial pigmentation in patients taking minocycline, two of whom were taking oral contraceptives containing ethinylestradiol.3 Other young women who have developed minocycline pigmentation may also have been taking oral contraceptives because they fall into the right age group, but this is not specifically stated in any of the reports.

Mechanism
Not understood. It seems possible that the facial pigmentation (melasma, chloasma) that can occur with oral contraceptives may have been additive with the effects of the minocycline.1

Importance and management
Evidence is very limited but it has been suggested that all patients given long-term minocycline treatment should be well screened for the development of pigmentation, particularly if they are taking other drugs such as the oral contraceptives that are known to induce hyperpigmentation.1 Remember also that very rarely contraceptive failure has been associated with the use of minocycline and other tetracyclines, see ‘Hormonal contraceptives + Antibacterials; Tetracyclines’, p.983.

Tetracyclines; Minocycline + Phenothiazines

An isolated report describes black galactorrhoea, which was attributed to an interaction between minocycline and perphenazine.

Clinical evidence, mechanism, importance and management
A woman taking minocycline 100 mg twice daily for 4 years to control pustulocystic acne, and also taking perphenazine, amitriptyline and diphenhydramine, developed irregular darkly pigmented macules in the areas of acne scarring and later began to produce droplets of darkly coloured milk. The milk was found to contain macrophages filled with positive iron-staining particles, assumed to be haemosiderin. The situation resolved when the drugs were withdrawn: the galactorrhoea within a week
and the skin staining over 6 months. \(^1\) Galactorrhoea is a known adverse effect of the phenothiazines and is due to an elevation of serum prolactin levels caused by the blockade of dopamine receptors in the hypothalamus. The dark colour appeared to be an adverse effect of the minocycline, which can cause haemosiderin to be deposited in cells, and in this instance to be scavenged by the macrophages that were then secreted in the milk. The general significance of this isolated case is unknown, but it seems likely to be small.

---

**Trimethoprim + Food or Guar gum**

Guar gum and food can modestly reduce the absorption of trimethoprim suspension.

**Clinical evidence, mechanism, importance and management**

In a study over a 24-hour period, 12 healthy subjects were given a single 3-mg/kg oral dose of a trimethoprim suspension with food, with or without guar gum. The mean peak serum levels were reduced by food and by food given with 5 g of guar gum by 21% and 15%, respectively. Food, both with guar gum and alone, reduced the AUC of trimethoprim by about 22%. \(^1\) The greatest individual reductions in peak serum levels and AUC were 44% and 36%, respectively with food, and 48% and 38%, respectively, with food and guar gum. \(^1\) The reasons are not understood but it may be due to adsorption of the trimethoprim onto the food and guar gum.

The clinical importance of this interaction is uncertain but a marked reduction in absorption can occur in some individuals. However, trimethoprim is generally taken without regard to food, so this interaction would not appear to be significant in most patients.

---

**Vancomycin + Colestyramine**

Colestyramine may bind with vancomycin in the gut.

**Clinical evidence, mechanism, importance and management**

Colestyramine binds with vancomycin within the gut, thereby reducing its biological activity (about tenfold according to in vitro studies). The combination of vancomycin and colestyramine used to be used in antibacterial-associated colitis (now no longer recommended) and to overcome this interaction it was suggested that a vancomycin dosage of 2 g daily should be used, and that administration of the vancomycin and colestyramine should be separated as much as possible to minimise their admixture in the gut. \(^1\) It is usually recommended that other drugs should be taken 1 hour before or 4 to 6 hours after colestyramine.

---

**Vancomycin + Dobutamine, Dopamine and Furosemide**

There is some evidence to suggest that dobutamine, dopamine and furosemide can markedly reduce vancomycin serum levels following cardiac surgery.

**Clinical evidence, mechanism, importance and management**

A retrospective evaluation of the records of 18 critically ill patients in intensive care units following cardiac surgery, suggested that drugs with important haemodynamic effects (dobutamine, dopamine, furosemide) may lower the serum levels of vancomycin. It was noted that withdrawal of the interacting drugs was followed by an increase of in the minimum steady-state serum levels of vancomycin, from 8.79 mg/L to 13.3 mg/L, despite no major changes in body weight or estimated renal clearance. This resulted in a mean dose reduction of 4.26 mg/kg per day. It is suggested that this interaction occurs because these drugs increase cardiac output, which increases the renal clearance of vancomycin, and therefore reduces its serum levels. \(^1\) The clinical implication is that in this particular situation creatinine clearance is a less good predictor of vancomycin clearance and consequently dose. Good therapeutic drug monitoring is needed to ensure that serum vancomycin levels are optimal. More confirmatory study is needed.

---

**Vancomycin + Indomethacin**

Indomethacin reduces the renal clearance of vancomycin in premature neonates. This interaction does not appear to have been studied in adults.

**Clinical evidence, mechanism, importance and management**

In 6 premature neonates with patent ductus arteriosus given indomethacin, the half-life of vancomycin 15 to 20 mg/kg given intravenously over 1 hour was found to be 24.6 hours, compared with only 7 hours in 5 other premature neonates without patent ductus arteriosus who were not given indomethacin. \(^1\) The reason for this effect is uncertain but it seems possible that the indomethacin reduces the renal clearance of vancomycin. The authors of this report suggest that the usual vancomycin maintenance dosage should be halved if indomethacin is also being used. If vancomycin therapeutic drug monitoring is possible it would be advisable to take levels and adjust the vancomycin dose accordingly. It is not known whether indomethacin has the same effect on vancomycin in adults.

---

**Vancomycin + Nephrotoxic or Ototoxic drugs**

The risk of nephrotoxicity and otoxicity with vancomycin may possibly be increased if it is given with other drugs with similar toxic effects.

**Clinical evidence, mechanism, importance and management**

Vancomycin is both potentially nephrotoxic and ototoxic, and its manufacturers therefore suggest that it should be used with particular care, or avoided in patients with renal impairment or deafness. \(^1\) They also advise the avoidance of other drugs that have nephrotoxic potential, because the effects could be additive. They list amphotericin B, aminoglycosides, bacitracin, colistin, polymyxin B, viomycin and cisplatin. They also list etacrynic acid and furosemide as potentially aggravating ototoxicity.

The monograph ‘Aminoglycosides + Vancomycin’, p.291 outlines some of the evidence that additive nephrotoxicity can occur with the aminoglycosides, but there seems to be no direct evidence about the other drugs. Even so, the general warning issued by the manufacturers to monitor carefully is a reasonable precaution.

---

**Vancomycin + Theophylline**

Theophylline appears not to interact with vancomycin in premature infants.

**Clinical evidence, mechanism, importance and management**

Five premature infants (mean gestational age of 25 weeks and weighing 1.1 kg) were given theophylline (serum levels of 6.6 mg/L) for apnoea of prematurity. It was found that the pharmacokinetics of vancomycin 20 mg/kg given every 12 to 18 hours for suspected sepsis were unchanged by the presence of the theophylline, when compared with previously published data on the pharmacokinetics of vancomycin in neonates. \(^1\) There seems to be no other clinical reports about vancomycin with theophylline, and nothing to suggest that vancomycin has any effect on the serum levels of theophylline.

---

The anticholinesterase drugs (or cholinesterase inhibitors) can be classified as **centrally-acting**, **reversible** inhibitors such as donepezil (used in the treatment of Alzheimer’s disease), **reversible** inhibitors with poor **CNS penetration**, such as neostigmine (used in the treatment of myasthenia gravis), or **irreversible** inhibitors, such as ephedrine and metrifonate. The centrally-acting anticholinesterases and the reversible anticholinesterases form the basis of this section, and these are listed in ‘Table 11.1’, (see below). Interactions where the anticholinesterases are affecting other drugs are covered elsewhere in the publication.

Due to their differing pharmacokinetic characteristics, the centrally-acting anticholinesterases have slightly different interaction profiles, although they share a number of common pharmacodynamic interactions. Tacrine is metabolised by the cytochrome P450 isoenzyme CYP1A2, and so interacts with ‘fluvoxamine’, (p.356), a potent inhibitor of this isoenzyme, whereas there is no evidence to suggest the other centrally acting anticholinesterases do. On the other hand, donepezil and galantamine are metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP2D6, and so they may interact with ‘ketoconazole’, (p.353) and ‘quinidine’, (p.356), respectively, whereas tacrine would not be expected to do so. Rivastigmine, which is metabolised by conjugation, seems relatively free of pharmacokinetic interactions. Consideration of concurrent drug use would therefore seem to be an important factor in the choice of centrally-acting anticholinesterase.

Note that, organophosphorus compounds such as insecticides are also anticholinesterases.

No pharmacokinetic interaction appears to occur between risperidone and donepezil or galantamine, but extrapyramidal symptoms occurred in one patient given donepezil with risperidone. The pharmacokinetics of thioridazine are not affected by donepezil. Two isolated reports describe severe parkinsonism when haloperidol was given with tacrine.

Clinical evidence, mechanism, importance and management

(a) Donepezil

1. Risperidone. In a randomised, crossover study 24 healthy subjects were given risperidone 500 micrograms twice daily with donepezil 5 mg daily. Although donepezil caused slight changes in the levels of risperidone and 9-hydroxyrisperidone they did not exceed the limits for bioequivalence. Concurrent use did not increase adverse effects. In one study 16 schizophrenic patients taking risperidone were given donepezil 5 mg daily for 7 days without any alteration in their risperidone and 9-hydroxyrisperidone levels. The pharmacokinetics of donepezil were similar in the risperidone-treated patients and healthy controls taking donepezil alone. However, a case report describes the emergence of parkinsonian symptoms in an 80-year-old woman after she was given donepezil 5 mg daily, with risperidone 1 mg daily added 12 days later. Risperidone was discontinued and she recovered without treatment. This appears to be an isolated report and its general significance is therefore unknown.

2. Thioridazine. In a crossover study 11 healthy subjects were given donepezil 5 mg daily for 16 days, with a single 50-mg dose of thioridazine on the final day. Although donepezil did not affect the pharmacokinetics of thioridazine or its effects on the QT interval, thioridazine, either alone or in combination with donepezil, was poorly tolerated and resulted in postural hypotension and increases in heart rate. It would therefore seem prudent to use an alternative antipsychotic wherever possible.

(b) Galantamine

In a randomised, crossover study 16 patients over 60-years-old were given galantamine 12 mg twice daily with risperidone 500 micrograms twice daily, both for 13 doses. Although galantamine caused slight changes in the levels of risperidone and 9-hydroxyrisperidone, their combined level (the active moiety) was unchanged. The combination was well-tolerated so no additional precautions would seem to be necessary on concurrent use.

(c) Tacrine

An isolated report describes an 87-year-old man with dementia, who started taking haloperidol 5 mg daily for symptoms of agitation and paranoia. Doses of greater than 5 mg were noted to cause extrapyramidal symptoms. After 10 days, tacrine 10 mg four times daily was added. Within 72 hours he developed severe parkinsonian symptoms, which resolved within 8 hours of stopping both drugs. Another isolated report describes a woman taking haloperidol 10 mg daily who similarly developed a disabling parkinsonian syndrome within one week of starting tacrine 10 mg four times daily. One possible reason is that the haloperidol blocked the dopamine receptors in striatum, thereby increasing striatal acetylcholine activity, which was further increased by the tacrine. It is not clear whether patients given other dopamine receptor blocking drugs and tacrine would similarly show this reaction.

Anticholinesterases; Centrally acting + H₂-receptor antagonists

Cimetidine possibly increases the effects of tacrine. Cimetidine does not appear to significantly affect the pharmacokinetics of donepezil or galantamine, and ranimidine does not affect the bioavailability of galantamine.

Clinical evidence, mechanism, importance and management

(a) Donepezil

In one study, donepezil 5 mg daily was given to 18 healthy subjects with cimetidine 800 mg daily. It was found that after one week of concurrent use the maximum serum levels and AUC of donepezil were increased by 13% and 10%, respectively. Donepezil had no effect on the pharmacokinetics of cimetidine. None of the increases in donepezil levels were considered to be clinically significant.1

(b) Galantamine

The US manufacturer notes that when a single 40-mg dose of galantamine was given on day 2 of a 3-day course of cimetidine 800 mg daily the bioavailability of galantamine was increased by 16%, which would not be expected to be clinically significant. Ranitidine 300 mg daily had no effect on galantamine bioavailability.2 No interaction would therefore be expected with any H₂-receptor antagonist.

(c) Tacrine

Cimetidine 300 mg four times daily for 2 days decreased the clearance of a single 40-mg dose of tacrine by 30%, and increased the AUC and maximum level by about 35% in 11 healthy subjects.3 The manufacturers of tacrine also say that cimetidine increases the AUC and the maximum plasma level of tacrine by 64% and 54%, respectively.4 The reason is not known, but it seems probable that cimetidine (a well-recognised liver enzyme inhibitor) reduces the metabolism of tacrine by the cytochrome P450 isoenzyme CYP1A2 (see also ‘fluvoxamine’, (p.356)).3 An increase in the effects and possibly adverse effects of tacrine (nausea, vomiting, diarrhoea) seems possible. One patient in the study mentioned3 had to be withdrawn due to nausea and vomiting, but none of the other 11 subjects particularly suffered from adverse effects. More study is needed to find out whether this interaction is generally clinically important. If the suggested mechanism of interaction is correct, the other H₂-receptor antagonists would not be expected to interact. Tacrine also increases the secretion of gastric acid but it is not clear whether this would oppose the actions of the H₂-receptor antagonists.

Anticholinesterases; Centrally acting + HRT

A small study suggests that HRT treatment can almost double the serum levels of tacrine. Limited evidence suggests that oestrogens do not affect rivastigmine pharmacokinetics.

Clinical evidence, mechanism, importance and management

Following the observation that HRT appeared to increase the response of postmenopausal Alzheimer’s patients to tacrine, a randomised, crossover, placebo-controlled study was undertaken in 10 healthy women who were given HRT (estradiol 2 mg with levonorgestrel 250 micrograms daily) with a single 40-mg dose of tacrine on day 10. The HRT increased the mean tacrine AUC by 60%, increased the mean peak serum level of tacrine by 46% and reduced the tacrine clearance by 31%. The AUC of one individual was increased threefold. These pharmacokinetic changes are thought to occur because HRT reduces the metabolism of the tacrine to its main metabolite (1-hydroxytacrine) by the cytochrome P450 isoenzyme CYP1A2. The importance of this interaction is still uncertain, but increased tacrine levels would be expected to increase its adverse effects. Be alert therefore for the need to use a smaller tacrine dose in patients given HRT. More study of this interaction is needed.

In contrast, analysis of population data from 70 subjects found that oestrogens did not affect rivastigmine pharmacokinetics.2

Anticholinesterases; Centrally acting + Memantine

Memantine does not appear to attenuate the anticholinesterase effects of donepezil, galantamine, or tacrine, nor affect the pharmacokinetics of galantamine or donepezil.

Clinical evidence, mechanism, importance and management

(a) Donepezil

An in vitro study in rats suggested that memantine does not attenuate the anticholinesterase effects of donepezil at therapeutic concentrations.1 In a later study 19 healthy subjects were given memantine 10 mg before and on the last day of taking donepezil (5 mg daily for 7 days then 10 mg daily for 22 days). The pharmacokinetics of both drugs were not significantly affected by concurrent use, and the effects of donepezil on anticholinesterase were also unaffected.2 Furthermore, an efficacy and safety study of one year’s duration has reported that the combination is well tolerated and beneficial.3

(b) Galantamine

An in vitro study in rats suggested that memantine does not attenuate the anticholinesterase effects of galantamine at therapeutic concentrations.1 A study in 15 healthy subjects found that the concurrent use of extended-release galantamine 16 mg daily with memantine 10 mg twice daily for 12 days did not affect the pharmacokinetics of galantamine and generally did not increase the incidence of adverse effects, although dizziness may have been more common.4 Furthermore, a review of efficacy studies suggested that the effects of galantamine on anticholinesterase are unaffected, that the combination is safe and generally well tolerated.5

(c) Tacrine

An in vitro study in rats suggested that memantine does not attenuate the anticholinesterase effects of tacrine at therapeutic concentrations.1

Anticholinesterases + Miscellaneous

A number of drugs can affect myasthenia gravis, often by increasing muscular weakness. This is, strictly speaking, a drug–disease interaction, but such effects may be expected to oppose the actions of the drugs used to treat myasthenia gravis. A number of drugs (e.g. chlorpromazine, methocarbamol, and propafenone) are clearly contraindicated in patients with myasthenia, and, as this is not strictly a drug interaction, they
Effect seen
Precipitation of a myasthenic crisis in an undiagnosed 15-year-old girl.
Aggravation of muscular weakness in patients with myasthenia gravis taking unnamed anticholinesterases.
Persisting myasthenic symptoms, including muscular weakness, attributed to prior chloroquine use. Development of myasthenic symptoms in 3 patients, one who took chloroquine in overdose.
Aggravation of myasthenic symptoms in a patient taking pyridostigmine, and unmasking of myasthenia in one patient.
Aggravation of myasthenic symptoms in a patient taking pyridostigmine.
Aggravation of myasthenic symptoms in one patient taking pyridostigmine and another taking neostigmine.
Persisting myasthenic symptoms, including muscular weakness, attributed to prior chloroquine use. Development of myasthenic symptoms in 3 patients, one who took chloroquine in overdose.
Aggravation of myasthenic symptoms in a patient taking pyridostigmine.
Aggravation of myasthenic symptoms in a patient taking pyridostigmine.
Aggravation of myasthenic symptoms in a patient taking pyridostigmine.
Aggravation of myasthenic symptoms in a patient taking pyridostigmine and another taking neostigmine.
Aggravation of myasthenic symptoms in numerous patients taking anticholinesterases. Amitriptyline and imipramine also implicated in 2 cases.
Aggravation of myasthenic symptoms in an untreated patient.
Aggravation of myasthenic symptoms in a patient taking pyridostigmine.
Serious aggravation of myasthenic symptoms in a patient taking pyridostigmine. Two other less severe cases also reported.
Aggravation of myasthenic symptoms in 3 patients, one who took chloroquine in overdose.

Drugs that should be used with caution in myasthenia gravis.

</tr>
</tbody>
</table>

are not dealt with here. A number of case reports (see ‘Table 11.2’, (above)) describe the worsening or unmasking of myasthenia gravis with a range of different drugs. The evidence for many of these interactions is very sparse indeed, and in some instances they are simply rare and isolated cases. It would therefore be wrong to exaggerate their importance, but it would nevertheless be prudent to be alert for any evidence of worsening myasthenia if any of the drugs listed are added to established treatment.

### Anticholinesterases + Other drugs that affect acetylcholine

The effects of centrally-acting anticholinesterases (e.g. donepezil) are expected to be additive with those of other anticholinesterases (e.g. neostigmine) and cholinergics (e.g. pilocarpine). The effects of centrally-acting anticholinesterases and drugs with antimuscarinic effects are expected to be antagonistic.
Clinical evidence, mechanism, importance and management

Anticholinesterases raise acetylcholine levels: some are more selective for raising acetylcholine levels in the brain (e.g. donepezil), whereas others (e.g. neostigmine) have a more generalised effect. Therefore if both drugs are given together their effects may be expected to be additive. Similarly, additive effects may be expected if anticholinesterases are given with cholinergic drugs, such as bethanechol, carbachol, and pilocarpine, which mimic the effects of acetylcholine,1-6 and depolarising neuromuscular blockers, which act like acetylcholine to cause depolarisation (see ‘Neuromuscular blockers + Anticholinesterases’, p.114, for reports of this interaction).

In contrast, drugs with antimuscarinic (anticholinergic) effects (see ‘Table 18.2’, (p.674)), which block the actions of acetylcholine, would be expected to oppose the actions of the anticholinesterases.

A number of case reports describe an interaction between centrally-acting anticholinesterases and other antimuscarinics. Two patients taking donepezil and one taking rivastigmine were given tolterodine (an antimuscarinic). One patient (taking donepezil) developed confusion, while the other two developed delusional states. This is the opposite effect to the predicted interaction (where the anticholinesterase inhibitor may be expected to oppose the antimuscarinic effects of tolterodine). The authors suggest that the combination causes ‘cholinergic neurogenic hypersensitivity’ similar to that seen as a withdrawal reaction to anticholinesterases.7

In contrast, a case report describes the successful use of tolterodine 6 mg daily in a patient taking donepezil 10 mg daily. The authors of this report suggest that, despite the predictions of an interaction, a trial of an antimuscarinic for urinary incontinence may be worthwhile in patients taking centrally-acting anticholinesterases.3

All of these interactions, additive or antagonistic, are in theory possible, but whether most of them are of real practical importance awaits confirmation. It would certainly be prudent to monitor the concurrent use of any of these potentially interacting groups of drugs.

Anticholinesterases; Centrally acting + SSRIs

Fluoxetine markedly increases the levels of tacrine, and increases its cholinergic adverse effects, whereas fluoxetine, paroxetine, and sertraline are not expected to interact. Paroxetine and fluoxetine may increase donepezil and galantamine levels. Sertraline does not appear to have a pharmacokinetic interaction with donepezil, and concurrent use seems generally well tolerated; however, one report describes hepatotoxicity, possibly as a result of their concurrent use. Rivastigmine and fluoxetine appear not to interact.

Clinical evidence, mechanism, importance and management

(a) Donepezil

Two case reports suggest that donepezil and paroxetine may interact, in one case with an increase in gastrointestinal adverse effects, and the other with increased CNS effects. These adverse effects were thought to occur because paroxetine may inhibit donepezil metabolism by the cytochrome P450 isoenzyme CYP2D6.1 The manufacturer logically predicts that fluoxetine could also inhibit the metabolism of donepezil, and until more information is available, they suggest caution with concurrent use of donepezil and CYP2D6 inhibitors.8

In a crossover study 16 healthy subjects were given sertraline (50 mg daily increasing after 5 days to 100 mg daily) with donepezil 5 mg daily for 15 days. The pharmacokinetics of both drugs were not significantly altered by concurrent use, and, although there was some indication that digestive adverse effects may have been increased, overall adverse effects were not changed.3 Another study has similarly found that the concurrent use of donepezil and sertraline is well tolerated.6 A case report describes an 83-year-old woman taking sertraline 200 mg daily, who developed drug-induced cholestatic jaundice within 10 days of starting donepezil 5 mg daily. The authors suggest that although this reaction could have been in response to either drug, it may also have been precipitated by their concurrent use. The general significance of this report is unclear.5

(b) Galantamine

The manufacturers6,7 note that interaction studies have shown that paroxetine 20 mg daily for 16 days increased the bioavailability of galantamine by about 40%, by inhibiting galantamine metabolism by the cytochrome P450 isoenzyme CYP2D6. They therefore warn about the increased risk of galantamine adverse effects (in particular nausea and vomiting) if paroxetine is added. If such adverse effects develop or worsen, the manufacturers suggest a reduction in the galantamine dosage.6 They also predict that other SSRIs that are potent inhibitors of CYP2D6 may interact similarly, and they list fluoxetine and fluvoxamine,8 although it should be noted that fluvoxamine is only a weak inhibitor of CYP2D6. Thus far there appear to be no reports of adverse reactions with any of these drugs.

(c) Rivastigmine

The manufacturers of rivastigmine report that in studies in healthy subjects no pharmacokinetic interactions were seen between rivastigmine and fluoxetine.8,9 No special precautions appear necessary.

(d) Tacrine

Fluvoxamine is an inhibitor of cytochrome P450 isoenzyme CYP1A2, the main isoenzyme involved in the metabolism of tacrine. In vitro study showed that fluvoxamine is a potent inhibitor of tacrine metabolism, and it was therefore predicted that fluvoxamine may dramatically increase tacrine plasma levels in patients.10 This prediction was confirmed in a placebo-controlled study in 13 healthy subjects who had an eightfold increase in the mean AUC of a single 40-mg dose of tacrine after taking fluvoxamine 100 mg for 6 days. A very large increase in the AUC of the hydroxylated metabolites of tacrine, and an eightfold fall in the clearance of tacrine

Anticholinesterases; Centrally acting + Quinidine

Quinidine does not affect the metabolism of tacrine, but is predicted to inhibit the metabolism of donepezil and galantamine.

Clinical evidence, mechanism, importance and management

(a) Donepezil

In vitro study has shown that quinidine inhibits donepezil metabolism, and, as no clinical information is available, the manufacturer suggests care with the combination,1 as an increase in donepezil levels and adverse effects is theoretically possible.

(b) Galantamine

Quinidine, like paroxetine, is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, an enzyme involved in the metabolism of galantamine.2 Paroxetine, (below) has been shown to increase galantamine levels and therefore quinidine is predicted to do the same. Consequently the manufacturers of galantamine suggest that concurrent treatment with quinidine may result in increased adverse effects (mainly nausea and vomiting), and, if this occurs, a reduction in the maintenance dose of galantamine should be considered.2

(c) Tacrine

Quinidine 83 mg every 8 hours did not affect the clearance of a single 40-mg dose of tacrine in 11 healthy subjects.3 Since quinidine inhibits the cytochrome P450 isoenzyme CYP2D6 in the liver, it may be concluded that CYP2D6 does not have an important role to play in the metabolism of tacrine and therefore that other drugs that inhibit this enzyme are unlikely to interact with tacrine by this means.

was also seen. No subjects had any adverse effects when they took tacrine after placebo, but 5 had adverse effects (nausea, vomiting, sweating, and diarrhoea) when they took tacrine after fluvoxamine.11 Another pilot study in one individual found that the total clearance of tacrine was reduced about tenfold and its half-life increased tenfold by fluvoxamine 100 mg daily.12 A further study by the same authors found that the clearance of tacrine was reduced by about 85% in 18 healthy subjects taking fluvoxamine 50 or 100 mg.13 It is likely that standard tacrine doses will be poorly tolerated in the presence of fluvoxamine because of cholinergic adverse effects, and a decrease in tacrine dose is probably necessary.13 Alternatively, other SSRIs such as fluoxetine, paroxetine, or sertraline may be suitable alternatives, since these are unlikely to inhibit tacrine metabolism (they are only weak inhibitors of CYP1A2).

5. Exelon (Rivastigmine tartrate). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, October 2006.

Finished the anticholinesterases

Anticholinesterases; Centrally acting + Tobacco

Smoking tobacco reduces the serum levels of tacrine and increases the clearance of rivastigmine.

Clinical evidence, mechanism, importance and management

A comparative study in 7 tobacco smokers and 4 non-smokers found that the AUC of a single 40-mg dose of tacrine in the smokers was about 10% of that in the non-smokers. The elimination half-life in the smokers was also reduced, to about two-thirds of that in non-smokers. The increase in tacrine metabolism in smokers is thought to occur because some of the components of tobacco smoke increase the activity of the cytochrome P450 isozyme CYP1A2 in the liver, by which tacrine is metabolised.1 In practical terms this means that smokers who are likely to need larger doses of tacrine than non-smokers, although this needs confirmation in multiple dose studies. Other centrally acting anticholinesterases (donepezil, galantamine, rivastigmine) would not be expected to interact in this way, as they are not metabolised by CYP1A2. However, the US manufacturers note that nicotine use increases rivastigmine clearance by 23%, so other mechanisms may have a part to play. One observational study has suggested that patients with Alzheimer’s disease who are smokers are more likely to improve if they are given centrally-acting anticholinesterases than non-smokers.2 Whether this counteracts the effects of any pharmacokinetic interaction is unclear.

Donepezil + Ginkgo biloba

Ginkgo biloba does not appear to affect the pharmacokinetics or pharmacodynamics of donepezil.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study 14 elderly patients with Alzheimer’s disease were given donepezil 5 mg daily for at least 20 weeks, after which Ginkgo biloba extract 90 mg daily was also given for a further 30 days. Concurrent use did not affect the pharmacokinetics or cholinesterase activity of donepezil, and cognitive function appeared to be unchanged.1 Therefore, over the course of 30 days, concurrent use appears neither beneficial nor detrimental.

Tacrine + Ibuprofen

An isolated report describes a woman taking tacrine who became delirious when she also started to take ibuprofen.

Clinical evidence, mechanism, importance and management

A 71-year-old diabetic woman with probable Alzheimer’s disease developed delirium while taking tacrine 40 mg four times daily. The symptoms included delusions, hallucinations, and fluctuating awareness. She was also bradycardic, diaphoretic and dizzy.1 She was eventually stabilised with tacrine 20 mg four times daily, and continued this for 8 months without problems, but became delirious again 2 weeks after starting to take ibuprofen 600 mg daily. The delirium resolved when both drugs were withdrawn. The reasons for this reaction are unknown. This is the first and only report of this apparent interaction and its general importance is probably small, especially as the patient had previously experienced delirium with tacrine alone.

Tacrine + Quinolones

Enoxacin possibly increases the effects of tacrine.

Clinical evidence, mechanism, importance and management

_In vitro_ studies with human and rat liver microsomes found that enoxacin, a specific inhibitor of the cytochrome P450 isozyme CYP1A2, significantly inhibited all known routes by which tacrine is metabolised.1 A reasonable conclusion to be drawn from this is that the effects of tacrine (both beneficial and adverse) would be increased by enoxacin, but this interaction does not appear to have been studied in patients or healthy subjects. The same study also suggested that enoxacin possibly inhibits the production of the hepatotoxic metabolites of tacrine.1 Other quinolones vary in the extent to which they inhibit CYP1A2 (see ‘Theophylline + Quinolones’, p.1192), so that any interaction with other quinolones would be expected to reflect this variation.

Anticoagulants

The blood clotting process

When blood is lost or clotting is initiated in some other way, a complex cascade of biochemical reactions is set in motion, which ends in the formation of a network or clot of insoluble protein threads enmeshing the blood cells. These threads are produced by the polymerisation of the molecules of fibrinogen (a soluble protein present in the plasma) into threads of insoluble fibrin. The penultimate step in the chain of reactions requires the presence of an enzyme, thrombin, which is produced from its precursor prothrombin, already present in the plasma. This is initiated by factor III (tissue thromboplastin), and subsequently involves various factors including activated factor VII, IX, X, XI and XII, and is inhibited by antithrombin III. Platelets are also involved in the coagulation process. Fibrinolysis is the mechanism of dissolution of fibrin clots, which can be promoted with thrombolytics. For further information on platelet aggregation and clot dissolution, see ‘Antiplatelet drugs and thrombolitics’, (p.697).

Mode of action of the anticoagulants

Anticoagulants may be divided into direct anticoagulants, which have an immediate effect, and the indirect anticoagulants, which inhibit the formation of coagulation factors, so have a delayed effect as they do not activate coagulation factors already formed. See ‘Table 12.1’, (p.359), for a list.

(a) Direct anticoagulants

The direct anticoagulants include heparin, which principally enhances the effect of antithrombin III, thereby inhibiting the effect of thrombin (factor IIa) and activated factor X (factor Xa). Low-molecular-weight heparins are salts of fragments of heparin and act similarly, except that they have a greater effect on factor Xa than factor IIa. They have a longer duration of action than heparin and usually require less monitoring. The heparinoids (such as danaparoid) are similar. A more recent introduction is the synthetic polysaccharide fondaparinux, which is an inhibitor of factor Xa. The other group of direct anticoagulants are the thrombin inhibitors, which bind to the active thrombin site. These include recombinant forms or synthetic analogues of hirudin such as bivalirudin and lepirudin. Meglatran and its oral prodrug ximelagatran act similarly, but have been withdrawn because of liver toxicity.

(b) Indirect anticoagulants

The indirect anticoagulants inhibit the vitamin K-dependent synthesis of factors VII, IX, X and II (prothrombin) in the liver, and may also be referred to as vitamin K antagonists. The most commonly used are the coumarins, principally warfarin, but alsoacenocoumarol and phenprocoumon. The indanediones such as phenindione are now less frequently used. The indirect anticoagulants have the advantage over currently available direct anticoagulants in that they are orally active. They are often therefore referred to as oral anticoagulants, but this term may become misleading with the development of direct-acting oral anticoagulants, such as ximelagatran, which have different monitoring requirements and interactions.

Coagulation tests

During anticoagulant therapy the aim is to give protection against intravascular clotting, without running the risk of bleeding. To achieve this, doses of heparin and oral anticoagulants should be individually titrated until the desired response is attained. With the coumarin and indanedione oral anticoagulants, this procedure normally takes several days because they do not act directly on the blood clotting factors already in circulation, but on the rate of synthesis of new factors by the liver. The successful titration is determined by one of a number of different but closely related laboratory tests, see ‘Table 12.2’, (p.360) and below. Note that routine monitoring of anticoagulant effect is not required for low-molecular weight heparins or heparinoids, except in patients at increased risk of bleeding, such as those with renal impairment or who are overweight. Also, note that these tests cannot be used to monitor the anticoagulant effect of fondaparinux or the direct thrombin inhibitors, and these require no routine monitoring.

(a) Prothrombin time

The prothrombin time test (PT, Pro-Time, tissue factor induced coagulation time) is the most common method employed in clinical situations. It measures the time taken for a fibrin clot to form in a citrated plasma sample containing calcium ions and tissue thromboplastin. The PT is usually reported as the International Normalised Ratio (INR).

1. International normalised ratio (INR). The INR was adopted by the WHO in 1982 to standardise (using the International Sensitivity Index) oral anticoagulant therapy to take into account the sensitivities of the different thromboplastins used in laboratories across the world. The formula for calculating the INR is as follows:

\[ \text{INR} = \text{(patient’s prothrombin time in seconds/mean normal prothrombin time in seconds)} \]

The PT values obtained from the patient’s sample are compared to a control, and this gives the INR. The higher the INR, the higher the PT value so if the patient’s ratio is 2, this means the PT (and therefore clotting) is twice as long as the normal plasma. The British Corrected Ratio is essentially the same, but was calculated to a standard British thromboplastin.

2. Quick Value. The Quick Value is expressed as a percentage; the lower the value, the longer the blood takes to coagulate. Therefore as the Quick Value increases, the corresponding INR value gets smaller and vice versa.

(b) Activated partial thromboplastin time

The activated partial thromboplastin time (aPTT) is the second most common method for monitoring anticoagulant therapy, measuring all the clotting factors in the intrinsic pathway as opposed to the PT test, which measures the extrinsic pathway.

(c) Other methods of assessing clotting

Other tests used, which in some instances offer more sensitivity to specific aspects of therapy, include the prothrombin-proconvertin ratio (PP), the thrombotest, the thrombin clotting time test (TCT, activated clotting time), the platelet count and the bleeding time test. The use of the most appropriate test will depend on the situation and the desired result.

Anticoagulant interactions

Stable oral anticoagulant therapy is difficult to achieve even during close monitoring. For example, in one controlled study in patients with atrial fibrillation, only 61% of INR values were within the target range of 2 to 3, despite monitoring the INR monthly and adjusting the warfarin dose appropriately. A large number of factors can influence levels of coagulation, including diet, disease (fever, diarrhoea, heart failure, thyroid dysfunction), and the use of other drugs. It must therefore be remembered that it is particularly difficult to ascribe a change in INR specifically to a drug interaction in a single case report, and single case reports or a few isolated reports for widely used drugs do not prove that an interaction occurs. Nevertheless, either the addition or the withdrawal of drugs may upset the
(a) Metabolism of the coumarins

The coumarins, warfarin, phenprocoumon and acenocoumarol, are racemic mixtures of S- and R-enantiomers. The S-enantiomers of these coumarins have several times more anticoagulant activity than the R-enantiomers. Reports suggest for example, that S-warfarin is three to five times more potent a vitamin K antagonist than R-warfarin. The S-enantiomer of warfarin is metabolised primarily by the cytochrome P450 isozyme CYP2C9, and to a much lesser extent, by CYP3A4. The metabolism of R-warfarin is more complex, but this enantiomer is primarily metabolised by CYP1A2, CYP3A4, and CYP2C19. S-warfarin is eliminated in the bile and R-warfarin is excreted in the urine as inactive metabolites. There is much more known about the metabolism of warfarin compared with other anticoagulants, but it is established that S-phenprocoumon and S-acenocoumarol are also substrates for CYP2C9 and that they differ from warfarin in their hepatic metabolism, and stereospecific potency.2

It makes sense to assume therefore, that an inhibitor of CYP2C9 (e.g. ‘fluconazole’, (p.387)) is likely to increase the concentration of the coumarin and enhance the anticoagulant effect. Drugs that induce CYP2C9 (e.g. ‘rifampicin’, (p.375)) reduce plasma levels of the coumarins by increasing the clearance.

‘Genetic differences’, (p.4), in the genes for these cytochrome P450 isoenzymes may have an important influence on drug metabolism of the coumarins. For example, different versions of the gene encoding CYP2C9 exist and the enzymatic activity of the most clinically important CYP2C9 variants, CYP2C9*2 and CYP2C9*3, is significantly reduced. Studies have suggested an association between patients possessing one or more of these variants and a low-dose requirement of warfarin. Similar observations have been seen with the CYP2C9*3 variant and acenocoumarol.

While the metabolism of the coumarins, especially warfarin, are well known, the numerous interaction pathways and the variability in patient responses, makes the clinical consequences difficult to predict.

(b) Other mechanisms for anticoagulant interactions

Some drugs, such as ‘colestyramine’, (p.393), may also prevent the absorption of the coumarins and reduce their bioavailability. See also ‘Drug absorption interactions’, (p.3). Additive anticoagulant effects can occur if anticoagulants are given with other drugs that also impair coagulation by other mechanisms such as ‘antiplatelets’, (p.700). Coumarins and indanediones act as vitamin K antagonists, and so dietary intake of ‘vitamin K’, (p.409) can also ‘reduce or abolish’, (p.9) their effects. ‘Protein-binding displacement’, (p.3) is another possible drug interaction mechanism but this usually plays a minor role compared with other mechanisms.3

Bleeding and its treatment

When prothrombin times become excessive, bleeding can occur. In order of decreasing frequency the bleeding shows itself as ecchymoses, blood in the urine, uterine bleeding, black faeces, bruising, nose-bleeding, haematoma, gum bleeding, coughing and vomiting blood.

Vitamin K is an antagonist of the coumarin and indanedione oral anticoagulants. The British Society for Haematology has given advice on the appropriate course of action if bleeding occurs in patients taking warfarin, and this is readily available in summarised form in the British National Formulary.

If the effects of heparin are excessive it is usually sufficient just to stop the heparin, but protamine sulfate is a specific antidote if a rapid effect is required. Protamine sulfate only partially reverses the effect of low molecular weight heparins.

There is currently no known specific antidote for fondaparinux, or for the direct thrombin inhibitors.

</table>
There is a single, isolated and unexplained case of melaena attributed to an interaction between acenocoumarol and fosinopril. No other ACE inhibitor studied has so far been shown to interact to a clinically relevant extent with the coumarins.

Clinical evidence

(a) Benazepril

Benazepril 20 mg daily for 7 days did not affect the steady-state plasma levels of either warfarin or acenocoumarol in healthy subjects. The anticoagulant activity of acenocoumarol was not altered. The effects of warfarin were slightly reduced, as demonstrated by a mean reduction in PT of about 4%, but this is not enough to be clinically important.1

(b) Cilazapril

Cilazapril 2.5 mg daily for 3 weeks had no effect on the thrombotest times or coagulation factors II, VII and X in 26 patients taking long-term acenocoumarol or phenprocoumon.2

(c) Enalapril

Enalapril 20 mg for 5 days did not affect the anticoagulant effects of warfarin 2.5 to 7.5 mg daily, according to a brief summary of unpublished data cited in a review.3

(d) Fosinopril

A 74-year-old patient stabilised on acenocoumarol, enalapril, piiretamine, and digoxin had the piiretamine and enalapril switched to furosemide and fosinopril. Eleven days later, he presented with dark faeces (melaena) and had a low haemoglobin. Fosinopril and acenocoumarol were stopped, and then enalapril and acenocoumarol were restarted. On gastrointestinal endoscopy, no explanation for the melaena was found, and his haemoglobin level had returned to normal 15 days later. This case was attributed to posdoscopy, no explanation for the melaena was found, and his haemoglobin had a low haemoglobin. Fosinopril and acenocoumarol were stopped, and stabilised on these anticoagulants, when compared with placebo.7

(e) Moexipril

In 10 healthy subjects, the pharmacokinetics and pharmacodynamics of a single 50-mg dose of warfarin were not altered when it was given with the first dose of moexipril 15 mg daily for 6 days.5

(f) Ramipril

In 8 healthy subjects, ramipril 5 mg daily for 7 days had no effect on the steady-state pharmacokinetics or anticoagulant effects of phenprocoumon.6 Similarly, ramipril 5 mg daily for 3 weeks did not alter the anticoagulant effects of acenocoumarol or phenprocoumon in patients stabilised on these anticoagulants, when compared with placebo.7

(g) Temocapril

In 24 healthy subjects, temocapril 20 mg daily for 2 weeks had no effect on the steady-state pharmacokinetics or pharmacodynamics of warfarin.8 The absence of an interaction between warfarin and temocapril was also shown in another study.9

(h) Trandolapril

In a study in 19 healthy subjects,10 trandolapril 2 mg daily for 13 days did not affect the pharmacodynamics of a single 25-mg dose of warfarin given on day 8.

Mechanism, importance and management

No important pharmacokinetic or pharmacodynamic interaction has been demonstrated for any ACE inhibitor and coumarin anticoagulant. Contrasting with all this evidence, there is a single, unexplained and isolated case of melaena attributed to an interaction between acenocoumarol and fosinopril. There seems to be no other evidence that fosinopril normally interacts with the oral anticoagulants and so this interaction is unlikely to be of general significance.

No special precautions would therefore seem necessary if any of these coumarin anticoagulants and ACE inhibitors are used concurrently.

Importance and management

The absence of an interaction between warfarin or phenprocoumon and alcohol in those free from liver disease is well documented and well established. It appears to be quite safe for patients taking oral anticoagulants to drink small or moderate amounts of wine or spirits. Even much less conservative amounts (up to 8 oz/250 mL of spirits4 or a pint of wine) do not create problems with the anticoagulant control, so that there appears to be a good margin of safety even for the less than abstemious. Only warfarin and phenprocoumon have been investigated but other coumarin anticoagulants would be expected to behave similarly. The single case of increased INR in a patient who started to drink beer is unexplained. Further study specifically with beer is needed to throw light on this possible interaction.

On the other hand, those who drink heavily may possibly need above-average dosages of the anticoagulant, while limited evidence suggests that those with liver damage who binge drink may experience marked fluctuations in their prothrombin times. It might be prudent to avoid anticoagulation in this type of patient unless they can abstain from drinking. Nevertheless, although one cohort study in patients taking warfarin found a slight trend towards serious bleeding events in patients with a history of binge drinking, this was not significant, and other risk factors were more important (highly variable prothrombin time ratio, or prothrombin time ratio greater than 2).2

Clinical evidence

(a) Dicoumarol

In 6 healthy subjects, allopurinol 2.5 mg/kg twice daily for 14 days increased the mean half-life of a single 4-mg/kg dose of dicoumarol from 51 to 153 hours, with large inter-individual variation.1 In another similar study, only 1 of 3 healthy subjects showed an increase in dicoumarol half-life (from 13 to 17 hours) when they were also given allopurinol.2

(b) Phenprocoumon

Two patients stabilised for a few weeks taking phenprocoumon developed prolonged bleeding times, with haematuria in one of them, within 4 to 5 weeks of starting to take allopurinol 300 mg daily.3

(c) Warfarin

In a study in 8 healthy subjects, the half-life of a single 25-mg dose of warfarin was not altered by pretreatment with allopurinol 100 mg twice daily for 10 days.5 Similarly, in 6 subjects, the elimination of a single 50-mg dose of warfarin was not altered by 2 or 4 weeks treatment with allopurinol 100 mg three times daily, although one subject had a 30% reduction in the elimination of warfarin after 4 weeks.4 No change was seen in the prothrombin ratios of 2 patients taking warfarin who took allopurinol 100 mg three times daily for 3 weeks.4 In contrast, one patient stabilised on warfarin had a 42% increase in his prothrombin ratio after taking allopurinol 100 mg daily for 2 days.7

Mechanism

It has been suggested that, as in rats, allopurinol inhibits the metabolism of the anticoagulants by the liver, thereby prolonging their effects and half-lives.1,2,5 There is a wide individual variability in the effects of allopurinol on drug metabolism,4 so that only a few individuals are affected.

Importance and management

Documentation is poor, and a pharmacokinetic interaction is not established. There appear to be few case reports of any important interaction. Nevertheless, consider increased monitoring of the anticoagulant effect in any patient taking a coumarin with allopurinol.

Counmarins + Aliskiren

Aliskiren did not alter the pharmacodynamics or pharmacokinetics of a single dose of warfarin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study in 15 healthy subjects, aliskiren 150 mg daily for 11 days did not alter the pharmacodynamics of a single dose of warfarin given on day 8. In addition, there was no change in the AUC or half-life of R- and S-warfarin.1 This study suggests that no warfarin dose adjustments would be expected to be needed if aliskiren is used in patients taking warfarin.1

Counmarins + Allopurinol

A number of studies and case reports suggest that allopurinol does not alter the pharmacokinetics or pharmacodynamics of warfarin. Nevertheless, a few case reports suggest that allopurinol might have increased the effect of warfarin. Two cases have also been reported with phenprocoumon. Allopurinol increased the half-life of dicoumarol in some healthy subjects, but there do not appear to be any reports of a clinically significant interaction.

Counmarins + Alpha blockers

Studies suggest that tamsulosin does not alter the pharmacokinetics or anticoagulant effect of acenocoumarol, and alfuzosin does not interact with warfarin. Doxazosin is said not to interact with anticoagulants.

Clinical evidence, mechanism, importance and management

In a double-blind, placebo-controlled, crossover study in 12 healthy subjects, tamsulosin 400 micrograms daily for 9 days had no effect on the pharmacokinetics or anticoagulant effects of a single 10-mg dose of acenocoumarol given on day five.1 The UK manufacturers of alfuzosin report that no pharmacodynamic or pharmacokinetic interaction was observed in healthy subjects given alfuzosin with warfarin,2 and the US manufacturers report that in 6 healthy
subjects alfuzosin 5 mg twice daily for 6 days did not affect the pharmacological response to a single 25-mg dose of warfarin. 3

One UK manufacturer of doxazosin says that no adverse drug interaction has been observed with anticoagulants (unspecified). 4

No coumarin dose adjustment would therefore be expected to be needed with concurrent use of these alpha blockers.

**Coumarins and related drugs + Amiodarone**

The anticoagulant effects of warfarin, phenprocoumon and acenocoumarol are increased by amiodarone and bleeding may occur. The interaction may be maximal in 2 to 7 weeks, and may persist long after the amiodarone has been withdrawn.

**Clinical evidence**

A. Inhibition of coumarin metabolism

**(a) Warfarin**

In the one of the first reports of an interaction between amiodarone and warfarin, 5 out of 9 patients who were stabilised on warfarin showed signs of bleeding (4 had microscopic haematuria and one had diffuse ecchymoses) within 3 to 4 weeks of starting amiodarone (dosage not stated). All 9 had increases in their prothrombin times averaging 21 seconds. It was necessary to decrease the warfarin dosage by an average of a third (range 16 to 45%) to return their prothrombin times to the therapeutic range. The effects of amiodarone persisted for 6 to 16 weeks in 4 of the patients from whom it was withdrawn. 7

Since then numerous other case reports have described a prolongation in prothrombin times and/or bleeding in patients taking warfarin and amiodarone. 4

Increased anticoagulant effects and bleeding has been seen in patients taking a coumarin anticoagulant or the indandione, phenindione and an anabolic steroid or testosterone.

Clinical evidence

(a) Anabolic steroids

Six patients stabilised on warfarin or phenindione were given oxymetho-

olone 15 mg daily. One patient developed extensive subcutaneous bleed-
ing and another had haematuria. After 15 to 30 days all 6 patients had

thrombostetes of less than 5%, which returned to the therapeutic range

within a few days of oxymetholone being withdrawn.1 Other similar cases

have been reported with oxymetholone and warfarin,2,3 or acenocou-

marol.2 In 3 of the reports2,3 the interaction was severe enough to discon-

tinue the oxymetholone. In one patient1 the warfarin dose was reduced by

59%, and in another2 the acenocoumarol dose was reduced by 66 to

75%.

Similarly increased anticoagulant effects and bleeding have been de-

scribed in studies and case reports involving:

- dicumarol with norethandrone,6
- dicumarol with stanozolol,7
- phenindione with methandienone,8
- phenindione with ethylestradiol9
- warfarin with methandienone,2,8,10,11 (62% to 73% decrease in dose re-

quired in 3 cases2 and 38% in 7 others8)
- warfarin with stanozolol,12-15 (40% and 64% decrease in dose required

in 2 patients and about a 70% increase required after stopping stanozolol12).

In a pharmacokinetic study in 15 healthy subjects, the manufacturer noted

that the concurrent use of warfarin and oxandrolone 5 or 10 mg twice
daily increased the S-warfarin AUC by 2.65-fold and doubled its half-life,

and had similar effects on R-warfarin.16 Microscopic haematuria occurred

in 5 subjects and gingival bleeding in one. A 5.5-fold decrease in warfarin
dose (about 80 to 85%) was necessary to maintain a target INR of 1.5.

(b) Androgens

A 58-year-old man receiving methyltestosterone replacement therapy

37.5 mg daily required a maintenance dose of phenprocoumon of just

0.94 mg daily: control subjects required 2.62 mg daily.17

One report notes that 3 patients receiving warfarin and Sustanon (con-

taining four combined esters of testosterone) had no changes in their an-

ticoagulant requirements,5 whereas another report describes a woman who

showed a 78% and a 65% increase in prothrombin times on two occasions

when using a 2% testosterone propionate vaginal ointment twice daily.

She needed a 25% reduction in warfarin dosage.18

Mechanism

Not understood. One study showed that norethandrolone did not alter the

metabolism of dicumarol, and did not alter the plasma levels of vitamin-

K dependent clotting factors. However, a more recent study of oxandrolo-

ne and warfarin shows a pharmacokinetic basis for this interaction.16

Importance and management

Well documented, well established and clinically important interactions that
develop rapidly, possibly within 2 to 3 days. Most, if not all, patients are

affected.1,6 If concurrent use cannot be avoided, the dosage of the an-
ticoagulant should be appropriately reduced. In a few cases, where pa-

tients have been able to stabilised on the combination, up to 75% reduc-
tions in anticoagulant dose have been required, and the study16 with

oxandrolone suggests an 85% reduction in dose of warfarin might be

necessary. After withdrawal of the interacting drug the anticoagulant dosage

will need to be increased.

It seems probable that all the coumarin and indandione anticoagulants will

interact with any 17-alkyl substituted anabolic steroid. The situation with

testosterone and other non 17-alkylated steroids is not clear as there are

only case reports, which are conflicting. Until more is known it would

seem prudent to increase the frequency of INR monitoring if these drugs are

given with coumarins or indanediones.

Coumarins + Antacids

There is some evidence that the absorption of dicoumarol may be increased by magnesium hydroxide, but there is no direct evidence that this is clinically important. Aluminium hydroxide does not interact with either warfarin or dicoumarol, and magnesium hydroxide does not interact with warfarin.

Clinical evidence

(a) Dicoumarol

Magnesium hydroxide (Milk of Magnesia) 15 mL taken with and 3 hours after a single dose of dicoumarol was found to raise the peak plasma levels and AUC of dicoumarol by 75% and 50%, respectively, in 6 healthy subjects. Conversely, aluminium hydroxide (Amphogel) 30 mL did not alter dicoumarol levels.1

(b) Warfarin

Aluminium/magnesium hydroxide (Maalox) 30 mL given with and for four 2-hourly doses after warfarin had no effect on the plasma warfarin levels or on the anticoagulant response in 6 subjects.2 Similarly, neither aluminium hydroxide (Amphogel) 30 mL nor magnesium hydroxide (Milk of Magnesia) 15 mL taken with and 3 hours after a single 75-mg dose of warfarin had any effect on warfarin peak levels or AUC.1

Mechanism

It is suggested that dicoumarol forms a more readily absorbed chelate with magnesium so that its effects are increased.3 An in vitro study suggested that the absorption of warfarin may be decreased by magnesium trisilicate,4 where as another in vitro study found no effect.5

Importance and management

No special precautions need be taken if aluminium or magnesium hydroxide antacids are given to patients taking warfarin, or if aluminium hydroxide is given to those taking dicoumarol. Choosing these antacids avoids the possibility of an adverse interaction. Despite the evidence of increased absorption of dicoumarol with magnesium hydroxide, there seems to be no direct clinical evidence of any important adverse interaction for this combination, or indeed between any coumarin and an antacid.

Coumarins + Antibacterials

Altered (usually enhanced) coumarin response has been reported with virtually every class of antibacterial. While some such as sul-famethoxazole, clearly have a pharmacokinetic interaction, for others there is no clear explanation for why an interaction might be expected. Theoretical mechanisms include reduced intestinal bacterial production of vitamin K \(_1\) substances, or reduced enterohepatic recycling. Possible confounding mechanisms include a reduction in dietary vitamin K \(_1\) intake because of illness, or the effect of fever or infection on coagulation or drug metabolism.

Clinical evidence and mechanism

Various studies have implicated antibacterials in general as being a risk factor for overanticoagulation. For example, in a large prospective cohort study, INR levels of greater than 7 were recorded in 31 patients. When compared with 100 patients with stable INRs, these 31 patients were more likely to have been treated with an antibacterial (not specified) in the previous 4 weeks (odds ratio 6.2), and more likely to have an intercurrent illness (odds ratio 4.48).1 Various mechanisms may be responsible for these findings, and these are discussed below.

(a) Confounding effects relating to the infection

1. Dietary factors. Patients taking coumarins and related drugs are advised to maintain a constant dietary intake of ‘vitamin K \(_1\)’, (p.409), since sustained changes in intake of vitamin K \(_1\)-rich foods, such as green leafy vegetables, causes clinically relevant changes in anticoagulation. It is therefore possible that patients who stop eating for a more than a day or so could develop over-anticoagulation. The same could happen with a reduced appetite leading to a sustained reduction in intake of vitamin K \(_1\)-rich foods.

2. Fever. Fever might possibly be a confounding factor in reports of antibacterial warfarin interactions, because it might increase the catabolism of vitamin K \(_1\)-dependent coagulation factors by producing a hypermetabolic state. However, in one cohort study, there was no difference in the frequency of fever between patients who developed over-anticoagulation (INR greater than 6) while taking antibacterials and those who did not develop over-anticoagulation while taking antibacterials.2

3. Reduced metabolism. There is some evidence from animal studies that infection can down regulate cytochrome P450 isoenzymes, which might result in reduced drug metabolism.3 Whether the metabolism of warfarin is different during an acute infection does not appear to have been studied.

(b) Effects relating to the antibacterial

1. Direct anticoagulant effects. Cephalexin and related beta lactams with an N-methylthiotetrazole or similar side-chain can occasionally cause enough hypoprothrombinemia for bleeding to occur when they are used
alone, and this effect might therefore be additive with coumarins, although there is not that much evidence to support this, see ‘Coumarins + Antibacterials; Cephalosporins and related beta lactams’, p.367.

2. Intestinal production of vitamin K₂ substances by bacteria. The activity of intestinal microflora produces menaquinones (vitamin K₂ substances). Suppression of the microflora might therefore result in reduced vitamin K₂, and hence reduced synthesis of vitamin-K dependent clotting factors. There is some evidence from studies in healthy subjects receiving vitamin K₁ restricted diets and taking warfarin that giving menaquinones (an extract of bacterially synthesised material) decreases the response to warfarin. In addition, ‘Natto’, (p.408), which is a rich source of bacterially-derived menaquinones markedly inhibits the effect of warfarin. It is therefore possible that antibacterials that decimate gut microflora might increase the effect of warfarin by reducing vitamin K₂ levels. However, this effect might be important only if vitamin-K₁ intake from dietary sources is also reduced.

3. Protein-binding displacement. Many drugs can displace warfarin from protein-binding sites leading to an increase in unbound (active) concentrations. However, any effect is transient, as the unbound warfarin is quickly metabolised. The exception to this is if the metabolism of warfarin is markedly inhibited at the same time. The only drug that is known to interact via both these mechanisms is ‘phenytoin’, (p.434). Consider also ‘Protein-binding interactions’, (p.3). Altered protein binding has not clearly been shown to be an important mechanism in any interaction between warfarin and an antibacterial, but it is often suggested as one.

4. Reduced or increased metabolism. Sulfamethoxazole clearly inhibits the metabolism of warfarin by the cytochrome P450 isoenzyme CYP2C9, so enhancing its effect. Some macrolides such as erythromycin inhibit CYP3A4, and therefore have a minor inhibitory effect on warfarin, which would, on its own, be unlikely to be of any clinical relevance. Conversely, ‘rifamycins’, (p.375) are well established inducers of drug metabolism, and clearly reduce the effect of warfarin. Most other antibacterial classes have no effect on warfarin pharmacokinetics.

Importance and management

All these factors in their own right might affect the intensity of anticoagulation. Therefore, a few case reports of an enhanced response to warfarin on starting a specific antibacterial do not necessarily imply that the antibacterial has a direct interaction with warfarin. Conversely, demonstration of a lack of a specific interaction between an antibacterial and warfarin does not mean that a patient prescribed that drug for an infection will not have a change in coagulation status. Therefore, if a patient is unwell enough to require an antibacterial, it may be prudent to increase monitoring of coagulation status even if no interaction is expected. In some circumstances the effects of the oral antibacterials (coumarins and indaneindones) would be expected to be significantly increased and appropriate precautions should be taken. There is nothing to suggest that an adverse interaction occurs between the oral antibacterials and other parenteral aminoglycosides.

A sparsely documented interaction but common experience seems to confirm that normally no interaction of any significance occurs. Concurrent use need not be avoided. Occasionally vitamin K deficiency and/or spontaneous bleeding is seen after the prolonged use of broad-spectrum antibacterials combined with a totally inadequate diet, starvation or some other condition in which the intake of vitamin K is very limited. Under these circumstances the effects of the oral antibacterials (coumarins and indanediones) would be expected to be significantly increased and appropriate precautions should be taken. There is nothing to suggest that an adverse interaction occurs between the oral antibacterials and other parenteral aminoglycosides.

Coumarins + Antibacterials; Aminosalicylic acid and/or Isoniazid

A report attributes bleeding in a patient taking warfarin to the concurrent use of isoniazid. Another report describes a markedly increased anticoagulant response in a patient taking warfarin when the dose was doubled and aminosalicylic acid and isoniazid were started. In one study, isoniazid inhibited warfarin metabolism in vitro.

Clinical evidence

A man who had recently started to take warfarin 10 mg daily and isoniazid 300 mg daily began to bleed (haematuria, bleeding gums) within 10 days of accidentally doubling his dosage of isoniazid. His prothrombin time had increased from about 26 to 53 seconds.

Another patient taking digoxin, potassium chloride, docusate, diazepam and warfarin 2.5 mg daily, was also given aminosalicylic acid 12 g, isoniazid 300 mg and pyridoxine 100 mg daily, and at the same time the warfarin dose was doubled to 5 mg daily. His prothrombin time increased from 18 to 130 seconds over 20 days but no signs of haemorrhage were seen.

Limited data suggest that no clinically significant interaction occurs between dicoumarol or warfarin and oral neomycin or paromomycin in most patients. However, individual patients have shown some alteration in anticoagulant effect (usually increases) when given oral neomycin and parenteral streptomyacin.

Clinical evidence

Six out of 10 patients taking warfarin who were given oral neomycin (2 g daily or 4 g daily) over a 3-week period had a gradual increase in their prothrombin times averaging 5.6 seconds.
Mechanism
Not understood. It seems possible that isoniazid may inhibit the metabolic process of the coumarin anticoagulants, since in vitro studies have shown that in human liver microsomes there has been shown a decrease in the activity of the CYP2C9 isoenzyme. Isoniazid increased the anticoagulant actions of dicumarol in dogs but not of warfarin in rabbits. Two patients taking isoniazid, aminosalicylic acid and streptomycin (but not taking anticoagulants) developed haemorrhage attributed to the anticoagulant effects of isoniazid.

Importance and management
These two isolated cases of possible interactions are far from conclusive, and the interactions of warfarin with isoniazid and aminosalicylic acid are not established. Nevertheless, given that the in vitro data suggest that isoniazid might inhibit warfarin metabolism, some caution might be appropriate. Further study is needed.

Coumarins + Antibacterials; Cephalosporins and related beta lactams
Cephalosporins and related beta lactams with an N-methylthiotetrazole or similar side-chain can occasionally cause enough hypoprothrombinemia for bleeding to occur when they are used alone. These effects could therefore be additive with those of the coumarins; and this appears to have been shown in a study with cefamandole or cefazolin and warfarin. Similarly, a few cases of over-anticoagulation have been reported with cephalosporins and related beta lactams that have caused increases in prothrombin times when used alone, and might therefore be predicted to interact, include aztreonam, cefalotin, cefoperazone, ceftriaxone, and latamoxef. Other cephalosporins with a related side-chain include cefmenoxime, ceftazamide, cefminox, ceforanide, cefotetan, and cefpiramide.

Clinical evidence
(a) Cephalosporins with N-methylthiotetrazole or similar side-chains
1. Cefamandole or cefazolin. Two patients who had received prophylactic cefamandole before cardiac valve replacement developed unusually high prothrombin times, with bleeding in one case, within 48 hours of an initial dose of warfarin 10 mg. Because of this, the records of a total of 60 other patients who had undergone heart valve replacement surgery were reviewed. They had been given antibacterials prophylactically before the first chest incision was made, and every 6 hours thereafter for about 72 hours. The 44 patients given cefamandole 2 g showed a much greater anticoagulant response than the 16 patients given vancomycin 500 mg. Fourteen of the cefamandole group had a prothrombin time greater than 32 seconds after the initial warfarin dose, compared with only one of the vancomycin group. In a later randomised study by the same workers, the prothrombin times as a percentage of activity after 3 days of concurrent use with warfarin were as follows: cefamandole 29%, cefazolin 38%, and vancomycin 51%, suggesting that cefamandole had a much greater effect on anticoagulant response than vancomycin.
2. Cefonicid. In a study in 9 patients stabilised on warfarin, there was no change in prothrombin times when they were given intravenous cefonicid 2 g daily for 7 days. In contrast, a later study identified 9 patients taking acenocoumarol who had increased INRs within 3 to 8 days of being given cefonicid. They needed a reduction in the anticoagulant dosage of about one-third to one-half. Another patient stabilised on acenocoumarol, with a prothrombin index of 28% bled 2 days after starting cefonicid 1 g daily and had a prothrombin index of less than 5%.3
3. Cefotiam. Severe haemorrhage has been reported in 3 patients taking acenocoumarol with cefotiam. One developed an abdominal haematoma and an INR of 10.4 within 2 days. Another had gastrointestinal bleeding and melena after one day of concurrent use. The third died from intracranial haemorrhage on the day she started cefotiam.

(b) Cephalosporins without N-methylthiotetrazole or similar side-chains
1. Cefaclor. Over the period 1979 to 1997, there had been 3 cases of raised INRs with or without clinical bleeding in patients taking acenocoumarol, warfarin or an unknown anticoagulant and cefaclor reported to the CSM in the UK. No cases seem to have been published.
2. Cefixime. Cefixime has also been implicated in a handful of cases of bleeding and/or increased INRs in patients taking warfarin or phenindione, but the evidence is inconclusive. No cases seem to have been published.
3. Cefotiam. Cefotiam, cefoperazone and ceftriaxone have on record a few cases of over-anticoagulation. None of 36 patients taking warfarin and prescribed an oral cephalosporin (not named) experienced a change in their INR in a prospective study of the effect of antibacterials on anticoagulation.

Mechanism
Cephalosporins with an N-methylthiotetrazole side-chain can, like the oral anticoagulants, act as vitamin K antagonists to reduce the production of some blood clotting factors. They can therefore cause bleeding on their own. For example, serious bleeding following the use of cefamandole (in the absence of an anticoagulant) has been described in 3 out of 37 patients in one report, and a further report highlights a further 16 cases. Other similar cephalosporins and related beta lactams that have been reported to cause hypoprothrombinemia when used alone include cefoperazone,12-16 cefotetan,17 ceftriaxone,18 cefalotin,19 cefazolin,20-22 and latamoxef.23,24 The incidence is very variable: in some instances only isolated cases have been reported whereas a 15% bleeding rate was found in one study24 with latamoxef alone, 22% in another25, but only 8% with cefoxitin alone.26 These cephalosporins might therefore worsen the risk of bleeding by simple addition if given with coumarin or indanedione anticoagulants. In addition, some of them may also inhibit platelet function. Ceftriaxone seems to act similarly although it has an N-methylthiotriazine ring instead, as does cefazolin, which has an N-methylhidazolide side chain. Aztreonam can also increase the prothrombin time.26-28 See also ‘antibacterials’, (p.365).

Importance and management
Most cephalosporins and related beta lactams do not normally cause bleeding so would not be expected to have an additive interaction with the oral anticoagulants. In contrast, cephalosporins with the N-methylthiotetrazole side-chain appear to increase the risk of bleeding, and might therefore interact. Both cefamandole and to a lesser extent cefazolin have been shown to increase the response to warfarin, and cases of over-anticoagulation have been reported for cefonicid and cefotiam. All other cephalosporins and related beta-lactams with the N-methylthiotetrazole or similar side-chain might be expected to behave similarly, but have not so far been reported to do so. These include cefotolin, cefmenoxime, ceftazamide, cefminox, cefoperazone, ceforanide, cefotetan, and cefpiramide. Aztreonam has also been predicted to interact similarly, although, again there are no reports. Although not having an N-methylthiotetrazole side-chain, the manufacturers of cefixime and cefaclor have on record a few cases of over-anticoagulation.
Patients most at risk seem to be those whose intake of vitamin K is restricted (poor diet, malabsorption syndromes, etc.) and those with renal failure. The use of an anticoagulant represents just another factor that may precipitate bleeding.
A possible solution to the problem is to use a non-interacting cephalosporin. Alternatively you should monitor the outcome closely, particularly in the early stages of treatment, adjusting the anticoagulant dosage if necessary. Excessive hypoprothrombinemia can be controlled with vitamin K.

Coumarins + Antibacterials; Chloramphenicol

There is some limited evidence to suggest that the anticoagulant effects of acenocoumarol and dicoumarol can be increased by oral chloramphenicol. An isolated report attributes a marked INR rise from 3 to 13 in a patient taking warfarin to the use of chloramphenicol eye drops. An isolated report describes bleeding and a markedly increased INR rise in a patient taking warfarin to the use of chloramphenicol eye drops.

Clinical evidence
A study in 4 patients showed that the half-life of dicoumarol was increased on average from 8 to 25 hours when they were given oral chloramphenicol. A study in 4 patients showed that the half-life of dicoumarol was increased on average from 8 to 25 hours when they were given oral chloramphenicol. An isolated report describes bleeding and a markedly increased INR rise in a patient taking warfarin to the use of chloramphenicol eye drops.

Coumarins + Antibacterials; Clindamycin

An isolated report describes bleeding and a markedly increased INR in a woman stabilised on warfarin, which was tentatively attributed to an interaction with clindamycin. Another report found no cases of a serious increase in INR in patients taking acenocoumarol or phenprocoumon with clindamycin.

Clinical evidence, mechanism, importance and management
A 47-year-old woman with multiple medical problems stabilised on warfarin (and also taking azathioprine, captopril, furosemide, insulin, captopril, prednisone, levothyroxine, valproic acid and zolpidem) had all her tests removed under general anaesthetic. Sixteen days later she needed a dental abscess drained and was given oral clindamycin 300 mg four times daily with ibuprofen 600 mg for any discomfort. On day 17 she needed a suture to stop some bleeding and her INR was found to be 3.5. By day 20 she had developed more severe oral bleeding, which needed emergency room treatment. Her INR was found to have risen to 13 and her haematocrit decreased to 18%. She was treated successfully with a blood transfusion and vitamin K.

This appears to be an isolated case, from which no general conclusions should be drawn (see also ‘antibacterials’, (p.365)) because the whole picture is so uncertain. Note that in a cohort study, none of 37 patients stabilised on acenocoumarol or phenprocoumon developed over-
antiocoagulation (an INR greater than 6) when they were given clindamycin. ²

### Coumarins + Antibacterials; Linezolid

Linezolid had only minor effects on the pharmacokinetics and anticoagulant activity of single-dose warfarin, which were not considered to be clinically significant.

**Clinical evidence, mechanism, importance and management**

Linezolid 600 mg twice daily was given to 13 healthy subjects for 5 days followed by a single 25-mg dose of warfarin. The pharmacokinetics of warfarin with linezolid were within 20% of those seen with warfarin alone, and the INR was minimally affected (about a 10% increase in maximal INR). These effects were not considered to be clinically relevant. See also ‘antibacterials’, (p.365).

### Coumarins + Antibacterials; Macrolides

Most studies suggest that macrolides do not significantly alter the pharmacokinetics or anticoagulant effects of warfarin. There is less information about other anticoagulants but studies similarly suggest that acenocoumarol and phenprocoumon do not usually interact with the macrolides; however one study has suggested that clarithromycin increases the risk of bleeding in patients taking these coumarins. Furthermore, a number of case reports describe bleeding in patients taking coumarins and macrolides.

**Clinical evidence**

(a) Azithromycin

There are no studies of the effect of azithromycin on the pharmacokinetics of coumarins. One pharmacodynamic study and two case series suggest no interaction occurs with warfarin. However, at least 7 published case reports suggest an interaction might occur. These are discussed below.

The manufacturer notes that a 5-day course of azithromycin (500 mg on day one then 250 mg daily for 4 days) did not affect the prothrombin time response to a single 15-mg dose of warfarin in healthy subjects. ¹,² A retrospective study of 26 patients stabilised on warfarin found no evidence that treatment with azithromycin had any effect on their INRs. The patients had stable INRs for at least 2 consecutive periods before receiving azithromycin, and an INR taken within 14 days (9 patients) or 30 days (17 patients) of starting the azithromycin. ³ The same finding was reported in another similar smaller study in 17 patients. ⁴ A major disadvantage of these 2 retrospective studies is the small numbers of patients who had an INR value within 7 days of starting azithromycin.

In contrast, there are now a number of published case reports suggesting that azithromycin might potentiate the activity of warfarin. ⁵⁻¹¹ In one of these cases, a 57-year-old woman stabilised on warfarin with an INR ranging from 1.75 to 3.03 in the previous 3 months was prescribed a 5-day course of azithromycin (500 mg on day one, then 250 mg daily for 4 days) for a possible upper respiratory tract infection. Two days after completing the azithromycin, a routine INR was found to be 8.32. She had no signs or symptoms of bleeding. During the infection she had a fever on the second day, and she reduced her ‘smoking’, (p.456) from 1 pack of cigarettes daily to 1 pack over 3 days. ⁶ In other cases, a rise in INR of 1.4-fold to sixfold occurred within 1 to 7 days of starting azithromycin. ⁵,⁸,¹⁰,¹¹ Three patients had bleeding complications, ⁶,⁷,¹⁰ and 4 required vitamin K administration. ⁵,⁸,¹⁰ Most of these patients had possible confounding factors such as recent increases in warfarin dose, ⁷,⁸ other concurrent antibacterials, ⁸,¹¹ fever and decreased appetite, ⁵,¹⁰ or complex disease states and heart failure. ⁶,¹⁰

The manufacturers ¹² say that as of December 1998, they had received 47 reports (40 in the US, 7 elsewhere in the world, including 2 in the UK) of possible interactions between azithromycin and warfarin. A 2004 report from the Australian Adverse Drug Reactions Advisory Committee said they had received 3 reports of interactions between warfarin and azithromycin, ₁³ which presumably includes the 2 published cases. ⁵

(b) Clarithromycin

There are no studies of the effect of clarithromycin on the pharmacokinetics or anticoagulant activity of coumarins. However, there are at least 13 cases of increased INRs in published reports, and one cohort study suggesting that the use of clarithromycin is associated with an increased risk of bleeding in patients taking coumarins. These are discussed below.

1. Acenocoumarol. The INR of a 75-year-old woman stabilised on acenocoumarol rose from 2.1 to 9 within a week of starting to take clarithromycin 250 mg twice daily. ¹⁴ Five patients stabilised on acenocoumarol had a mean increase in their INRs from about 2.5 to 5.5 when they took clarithromycin. ¹⁵ The largest increase was from 1.95 to 7.01. In one cohort study in patients taking acenocoumarol, clarithromycin significantly increased the risk of overanticoagulation (INR greater than 6; relative risk of 11.7 range 3.6 to 37.8). The risk was highest during the first 3 days of combined use. ¹⁶
